Five adult female cats had electrodes surgically implanted under halothane-nitrous anesthesia. Teflon-coated, stainless-steel stranded wires were placed in the diaphragm and posterior cricoarytenoid (PCA) muscle for recording diaphragmatic and laryngeal abductor EMG. Polyethylene tubing was placed in the abdominal aorta via the femoral artery for recording blood pressure, and in the right atrium via the internal jugular vein for administering pressor agents. Electrodes for monitoring sleep-waking state were also implanted. EMG activity was amplified, band-pass filtered, rectified, and integrated. Data were recorded onto polygraph paper and were digitized by a PDP-11 minicomputer. Transient hypertension was induced with phenylephrine hydrochloride (10 ug/kg) in a 0.2 mL bolus of 0.9% NaCl during waking, quiet sleep, and REM sleep states. Sections of the record starting four breaths before pressor administration were extracted for analysis. Respiratory statistics were calculated by a computer using the integrated diaphragmatic and PCA traces, and were correlated with blood pressure on a breath-by-breath basis.

Following pressor administration, blood pressure rose 60-80 mm Hg. The respiratory rate fell during the first three breaths from the beginning of the pressor response, and expiratory duration increased. In both the diaphragm and PCA, peak integrated EMG decreased during the first three breaths in all three states. However, peak integrated EMG in PCA decreased much more from control values than in diaphragm, as did the total integrated EMG amplitude. Occasionally, PCA phasic EMG activity disappeared for several breaths following hypertension onset in the absence of diaphragmatic silence. When the diaphragm did become silent during transient hypertension, phasic PCA activity disappeared as well.

These results provide evidence that neural mechanisms underlying laryngeal abductor activity are more affected by inhibitory baroreceptor responses to transient hypertension than diaphragmatic control mechanisms.

334.7 RATE DISCHARGE PATTERNS OF NEURONS IN THE CENTRAL NUCLEUS OF THE AMYGDALA: RELATIONSHIP WITH STATE AND RESPIRATORY ACTIVITY. J.X. Zhang, R.C. Frysinger, and R.M. Harper. Brain Research Institute and Department of Anatomy, UCLA, Los Angeles, CA 90024.

Neurons of the central nucleus of the amygdala (ACE) discharge phasically with the cardiac and respiratory cycle, and these relationships are state dependent (Zhang et al., Soc. Neurosci. Abs. 9: 1163, 1983). Moreover, cryoprobe blockade of the ACE decreases the amplitude of spontaneous diaphragmatic inspiratory efforts in the awake state, but this effect is greatly reduced by state. The state-dependent nature of these neuronal discharge characteristics led us to partition these cells by rate and location within the ACE, and to describe spontaneous discharge rates of neurons within this nucleus.

Bundles of fine wire microelectrodes, together with electrodes to record sleep-state and cardiorespiratory parameters, were placed in the ACE of four cats under halothane anesthesia. After surgical recovery, we recorded neuronal discharge, diaphragmatic EMG activity, ECG, and EEG from the intact, unrestrained, drug-free cat during waking (AW), quiet sleep (QS), and active sleep (REM) states.

Cell discharge rates in the ACE were low (n=207, range: <1/s to 90/s), with the greatest proportion (68%) discharging less than 10 spikes/s and 15% discharging less than 2 spikes/s. Cell discharge rate differed, depending on location within the ACE. The fastest firing cells (30-90 Hz) were located in the posterior dorsomedial region of the ACE. Most cells (n=71, 34%) discharged fastest in AW, slowest in QS, and faster in REM. The next most common pattern (16%) was rates slightly faster in QS than AW and faster in REM than QS. No consistent relationship between rate of discharge or change in rate of discharge across states and phasic discharge to the respiratory cycle was observed.

334.8 PERIPHERAL AND CENTRAL CONTROL MECHANISMS DURING RESPIRATORY SUSPENSIONS IN TRANSCENDENTAL MEDITATION AS EVIDENCED BY LATENCY, HYPOXIA AND RQ CHANGE. J. Kesterson*, N. Clinch*(SPON:K. Walton). Dept. of Neuroscience, Maharishi International University, Fairfield, Iowa 52556.

Previous studies have reported the occurence of respiratory suspensions (RS) during Transcendental Meditation (TM) (Farrow, J., Psychosom. Med.,(44)2:133,1982). The current research attempts to explain the control mechanisms involved and their relationship to the previously reported decrease in metabolic rate associated with TM. Current findings include:

1) Six practitioners of TM (4 male) with consistent patterns of RS during TM were tested repeatedly (2 to 8 times) in a rest, TM, rest protocol. Metabolic rates and frequency of breathing were measured with Beckman gas analyzers. Metabolic rates dropped 5% to 25%. Sixteen suspensions from 10 to 45 seconds began within 5 seconds of the cue to begin TM, before metabolic rates began to drop.

2) A single male subject with consistent RS patterns during TM was tested for hypoxic and hypercapnic drives using a Stead-Wells spirometer and Beckman gas analyzers. The protocol was 10 minutes rest, 10 minutes TM. During TM,suspensions of up to 20 seconds persisted even with an end tidal CO2 as high as 57mmHg, an unusual condition considering the increase in frequency and tidal volume that results from such a high value of CO2. During rest, an end tidal O2 of 49 mmHg had no effect on frequency or tidal volume, but during TM, following suspensions, an end tidal O2 of only 73 mmHg produced a change from 4 breaths per minute to 18 breaths per minute.

3) Repeated testing of 6 meditators showing consistent RS using Beckman gas analyzers in a rest, TM, rest protocol showed drops from .03 to .20 in RQ with TM and an overshoot above pre-TM rest levels of .05 to .15 during post-TM rest. One subject was tested by collecting expired air in collection bags. RQ for 10 minutes rest was .84; for 20 minutes TM: .60; for 10 minutes post-TM rest: .95. Metabolic rates, and thus O2 consumption declined for the TM period. The drop in RQ was due to a decrease in CO2 exhaled.

Conclusions: 1) Initiation of the RS during TM is neurogenic and centrally controlled. 2) Cessation of the RS is a consequence of blood gas levels, with an increased contribution of hypoxic drive. 3) Drop of metabolic rate does not initiate the RS but may contribute to its duration.

335.1 EFFECT OF NEWBORN RAT DENERVATION ON THE SKELETAL MUSCLE CREATINE KINASE ACTIVITY. O.C. Ramírez, L.A. Baiza* and M.A. Ibañez*. Dept. Biochemistry, C.I.E.A. and Natl. Sch. Biol. Sci., Polytech. Inst. México, D.F. 07000

The effect of muscle disuse after denervation on the levels and rates of synthesis of several glycolyic enzymes in mature chicken breast-"white" muscle resulted in a 50% reduction in the concentration of these enzymes 2 weeks after severing the nerves. Denervation for 6 weeks did not have a significant effect on the levels of creatine kinase (CK) activity from non-contractile breast muscle (J. Biol. Chem. 256:6423, 1981). Results from mammalian and amphibian skeletal muscle, in vivo and in vitro, indicate that continued contractile activity resulted in an increased activity of CK, 5' adenylic deaminase and adenylic kinase (Biochem. J. 103:207, 1967). To try to solve the discrepancy between authors who observe changes in activity of muscle CK and those who do not, we studied the effect that denervation at birth of rat fast and slow twitch muscles had on muscle growth and on the levels of CK activity. A fragment of thigh sciatic nerve was removed and, as a control, the contralateral extremity was kept intact. After 30 and 70 days, significant differences in weight values and in CK specific activity were found among experimental and control fast-extensor digitorum longus (EDL) and slow-soleus muscles. Denervation caused a larger decrease on the weight of soleus as compared with EDL. The weight of denervated slow and fast muscles were 15.4 ± 5.4% and 20.8 ± 3.8% of their respective unoperated controls at 30 days; denervated EDL was 18.4 ± 2.1% of its normal control at 70 days. Denervated soleus was extremely atrophied at 70 days.

Regarding CK specific activities, denervated soleus and EDL contained 13.6 ± 4.2% and 32.9 ± 7.6% of their respective controls at 30 days; denervated EDL showed 37.6 ± 2.7% of its control at 70 days. No CK activity increase was shown from 30 to 70 days in control soleus (41.9 ± 7.9 to 41.1 ± 5.8 units per mg protein). Whereas, in contrast to chick mature fast muscle, control and denervated EDL showed a similar proportional activity increase from 30 to 70 days post-denervation (CK 70/30 days ratios were 1.3 and 1.5 respectively).

It is concluded that species-and muscle-type specificity, as well as distinct levels of muscular maturation are responsible for the observed nerve-dependent or nerve-independent changes in CK activity and muscle growth or atrophy.

335.2 DIFFERENTIAL EFFECTS OF TENOTOMY ON THE MOLECULAR FORMS OF ACETYLCHOLINESTERASE IN FAST- AND SLOW-TWITCH SKELETAL MUSCLES OF YOUNG RATS. M.R. Emmerling* and E. Schultz* (Spon: G.J. Royce) Dept. of Anatomy, UW-Madison, Madison, WI 53706

The fast-twitch extensor digitorum longus (EDL) and gastrocnemius (GAS) and slow-twitch soleus (SOL) of 30-day old rats were tenotomized in order to study the effects of disuse on the expression of acetylcholinesterase (AChE) and its molecular forms. Animals were sacrificed on days 0, 3, 7 and 14 of tenotomy. Unoperated muscles of the contralateral hindlimbs were used as controls. On day 3, the cut ends of the tendons remain separate but began to reattach by day 7 and were completely attached and functional by day 14. AChE activity was 15-45% greater in tenotomized EDL and GAS than control until day 14 when it became slightly less. In contrast, SOL AChE activity was less than control on all days studied. Analysis of AChE forms showed that increases in AChE activity in tenotomized EDL and GAS were due primarily to 10S AChE. Reductions in 16S, 12S and 6/4S AChE accounted for the loss of activity in tenotomized SOL. Tenotomy appeared not to affect 10S AChE in SOL or 16S AChE in GAS or EDL. To determine whether or not the effects of tenotomy can occur in the absence of neural influences, the EDL and SOL were tenotomized and/or denervated for 3 days. Denervation of the EDL affected the 16S and 6/4S AChE forms but not 10S AChE. Tenotomy of the EDL increased 10S but produced no change in 16S and 6/4S. In the SOL, denervation decreased 16S and 12S AChE, but not 10S AChE or 6/4S AChE which was markedly reduced by tenotomy along with the 16S and 12S AChE forms. In the SOL the combined effects caused a greater loss of both AChE activity and 16S, 12S and 6/4S forms than either of the treatments alone. It also caused the loss of 10S AChE not previously seen. In contrast, denervation/tenotomy of the EDL increased AChE activity and, specifically, 10S AChE, but not to the level in tenotomized only EDL. The above results reveal that tenotomy produces changes in AChE and its forms unique to muscle type and unlike those caused by muscle denervation. The fact that tenotomy has an effect on AChE even after denervation suggests that the mechanism by which tenotomy affects AChE expression is separable from neural influences. A major effect of muscle tenotomy is the elimination of passive stretch. It is likely that the elimination or stretch is partly, if not principally, responsible for the effects of muscle tenotomy on AChE. It is particularly intriguing that 10S AChE in EDL and 6/4S AChE in SOL remain after both denervation and tenotomy because it suggests that influences beyond those examined help determine whether or not a muscle type possesses a particular form of AChE. (Funded by NSF grant PCM 8302348).

335.3 NERVE BLOCK WITH TETRODOTOXIN MIMICS AXOTOMY OF CAT MG MOTONEURONS. J.B. Munson, R.C. Foehring and G.W. Sypert. Depts. of Neuroscience and Neurosurgery, University of Florida College of Medicine, Gainesville, FL 32610.

This work tested whether conduction block of the intact MG nerve of cats would result in changes in MG motoneuron electrical properties similar to those which occur following axotomy. Conduction block of 17 days duration was produced by perfusion of the MG nerve with TTX (.25 µg/hour) using an osmotic pump implanted subcutaneously (Betz et al. J. Physiol. 303). To date only one animal has fulfilled our requirements of (i) MG muscle contraction in response to electrical stimulation of the MG nerve distal to but not proximal to the perfusion cuff and (ii) absence of fibrillations of the MG muscle at the time of the terminal experiment. Motoneuron electrical properties measured were rheobase ($I_{Rh}$), input resistance ($R_N$), conduction velocity (CV) and afterhyperpolarization half-decay time (AHP). Measurements were made of MG motoneurons in normal (MG-NML), 2-3 weeks-axotomized (MG-AXT) and TTX-perfused (MG-TTX) cats. As an internal control, properties of LG motoneurons not TTX-perfused were also measured in the MG-TTX experiments (LG-EXP) and compared with normal LG (LG-NML). The following data were obtained (values are means; number in parentheses is n):

| | $I_{Rh}$ (nA) | $R_N$ (Mohm) | CV (m/s) | AHP (ms) |
|---|---|---|---|---|
| MG-NML | 14 (147) | 1.0 (117) | 94 (111) | 28 (118) |
| MG-AXT | 4 (67) | 2.6 (60) | 70 (72) | 30 (65) |
| MG-TTX | 5 (21) | 2.1 (21) | 74 (28) | 26 (21) |
| LG-NML | 17 (102) | 1.0 (97) | 96 (99) | 23 (101) |
| LG-EXP | 16 (6) | 1.1 (6) | 88 (9) | 20 (6) |

These limited preliminary data from one successful experiment support the hypothesis that the electrical signs of motoneuron axotomy may also be produced by TTX-perfusion of the intact MG muscle nerve. Activation of the neuromuscular synapse may be one requirement for expression of normal, mature MG motoneuron properties (Czeh et al. J. Physiol. 281). (Supported by NS 15913 (NIH) and the MRS (VA).

335.4 DENERVATED FAST-TWITCH MUSCLES OF MICE: MYOTROPHIC EFFECTS OF NERVE EXTRACT. H.L. Davis, B.H. Bressler*, L.G. Jasch*, and E.A. Heinicke*. Departments of Anatomy; McGill University, Montreal, Canada; University of British Columbia, Vancouver, Canada; University of Western Ontario, London, Canada.

Changes in a denervated skeletal muscle result from the disuse caused by paralysis of the muscle, and from the loss of special myotrophic substances. Proteins extracted from rats' or sheep's sciatic nerves have been shown to ameliorate the atrophy of hindlimb muscles denervated for 7 days in adult rats or mice when administered by daily intramuscular or intraperitoneal injections respectively. The present investigation was undertaken to examine the effects of denervation and myotrophic effects of nerve extract on several physiological, biochemical and morphological parameters during the postnatal period of growth in mice.

The right hindlimbs of male C57BL mice were denervated at 2 weeks and redenervated at 4 weeks of age. During a 4-week period of denervation the mice either were untreated (UnRx) or received daily intraperitoneal injections of sheep nerve extract (500 mg protein/kg body weight/day) (Rx). Fast-twitch muscles from both denervated (DN) and contralateral normally innervated (NOR) hindlimbs were examined for one or more of the following parameters: wet weight, cross-sectional areas of fibers (CSA), content of total, soluble, myofibrillar and sarcoplasmic proteins, content of parvalbumin, twitch and tetanus tensions (Po, Pt), time to peak twitch tension (TTP), half-relaxation time (½RT) and post-tetanic potentiation (PTP). The muscles studied were extensor digitorum longus (EDL), tibialis anterior (TA) and gastrocnemius (G). Injections of extract had only a small effect on the atrophy of the denervated muscles. DN-Rx muscles exhibited 30% larger CSA of type II fibres (EDL) and 26% stronger tetanus tension (EDL) than DN-UnRx muscles. There was no significant effect on quantities or proportions of general muscle proteins (TA, G). However, injections of nerve extract prevented completely the decrease of parvalbumin (EDL, TA, G) and over 50% of the increases of TTP and ½RT (EDL) in denervated muscles. Thus the ameliorative effects of nerve extract on denervated muscles in young mice are greater on time- than strength-related changes in contractile function. The nerve extract also affected NOR muscles. The wet weights (TA, G) and content of sarcoplasmic protein (G) were smaller in NOR-Rx than NOR-UnRx muscles.

335.5 MOTOR NERVE TERMINAL OUTGROWTH INDUCES RAPID MODIFICATION OF JUNCTIONAL ACETYLCHOLINE RECEPTOR CLUSTERS IN ADULT MAMMALIAN SKELETAL MUSCLE. W-C Yee* and A. Pestronk. Neuromuscular Division, Johns Hopkins Sch. of Med., Baltimore, MD 21205.

Outgrowth of motor nerve terminals at neuromuscular junctions (NMJs) occurs rapidly in response to denervation changes in muscle. Using a combined cholinesterase-silver stain to visualize NMJs, nerve terminal outgrowth (NTO) is manifest as an elongation of the NMJ (cholinesterase-staining area) with an increase in the number of nerve terminal branches within this area. In the present experiments we have begun to study whether NTO can induce changes in the stable cluster of acetylcholine receptors (AChRs) at the adult mammalian NMJ.

We first examined whether the NTO-induced increase in NMJ size results in elongation of the postsynaptic AChR cluster. NTO was evoked by using botulinum toxin to block neuromuscular transmission and cause denervation changes in the rat soleus muscle. Seven days later, a time when significant NMJ elongation could be demonstrated using the cholinesterase stain, junctional AChRs were visualized using an α-bungarotoxin-peroxidase-antiperoxidase technique. Our results showed that the length of the junctional AChR cluster increased from 40 ± 1 μm to 51 ± 1 μm over the 7 day period of NTO. This change was similar to the elongation in the cholinesterase staining area which increased from 39 ± 3 μm to 50 ± 2 μm over the same period. The similarity in the changes in cholinesterase staining and AChR clusters was also evident at the level of individual NMJs. Using a double staining technique, we found that the distributions of cholinesterase and AChRs were virtually identical at each normal or elongated NMJ. In contrast to these findings, no change in the length of junctional AChR clusters was seen after surgical denervation of muscle. This suggests that elongation of the AChR cluster is induced by NTO and is not a result of denervation changes in muscle per se.

We next studied whether the elongation of the junctional AChR cluster was accompanied by an increase in the number of AChRs at the NMJ. Using an $^{125}$I-α-bungarotoxin binding technique, we found that the number of junctional AChRs was significantly increased in soleus muscles with NMJ elongation. After NTO there were 5.5 ± 0.3 x $10^7$ AChRs/NMJ, a figure 62% higher than the 3.4 ± 0.4 x $10^7$ AChRs/NMJ found in controls.

Our data show that NTO results in elongation of the junctional AChR cluster and an increase in the number of AChRs within the cluster. Thus, NTO is capable of producing rapid and significant modifications in the previously stable postsynaptic AChR cluster at the mammalian NMJ.

335.6 COMPARISON OF THE EFFECTS OF DENERVATION AND NEUROMUSCULAR BLOCKADE ON ACETYLCHOLINE (ACh) RECEPTOR NUMBERS IN ADULT RAT SKELETAL MUSCLE. L. Bambrick* and T. Gordon (sponsored by Dr. S. Malhotra), Department of Pharmacology, University of Alberta, Edmonton, Alberta, Canada, T6G 2H7.

The synthesis, incorporation and distribution of ACh receptors in skeletal muscle membranes is one of the most striking examples of muscle plasticity to neural influence and to levels of muscle activity. We have examined whether the increase in extrajunctional ACh receptor following denervation can be accounted for by loss of neuromuscular transmission. We have compared the binding of [$^{125}$I]-iodo-α-bungarotoxin [$^{125}$I-BTX] to muscle homogenates prepared from denervated or botulinum toxin (BOTX) poisoned triceps surae muscles (excluding soleus). As BOTX acts presynaptically to block ACh release this blockade provides a chemically silent but otherwise intact neuromuscular junction. Increased $^{125}$I-BTX binding was first observed after 3 days and the numbers rose exponentially ($\tau$=2.8 days) in denervated and BOTX blocked muscles, attaining maximum values, shown in the table for 7-8 muscles each, after 9 days.

| Triceps surae muscles | $^{125}$I-BTX sites (X±S.E.) | |
|---|---|---|
| | fmoles/mg muscle protein | fmoles/mg muscle weight |
| Denervated | 25.9±3 | 2.6±0.2 |
| BOTX treated | 24.5±3 | 2.9±0.5 |

It is clear that the effects of BOTX treatment and denervation were equivalent. This was also true for muscle atrophy as seen by a decrease of 28% in muscle weight with respect to untreated controls. These results, together with previous data (Berg and Hall, J. Physiol. 244: 659, 1975; Brown et al., J. Physiol. 327: 29, 1983; Lavoie et al., Exp. Neurol. 54: 148, 1977) are consistent with the idea that blockade of ACh receptors or of the release of ACh is equivalent to denervation in promoting skeletal muscle hypersensitivity. (Supported by the AHF and the AHFMR).

335.7 CHRONIC ELECTRICAL STIMULATION OF AXOTOMIZED NEURONS IN THE RABBIT. R. Orozco*, T. Gordon, L.A. Davis* and G. Goldsand*. Department of Pharmacology and Surgery, University of Alberta, Edmonton, Alberta, Canada, T6H 2H7.

When a mammalian peripheral nerve is severed, there is an initial decline, then stabilization in the diameter of the fibers which remain in continuity with the cell bodies (Davis et al. J. Physiol. 285: 543, 1978). This atrophy can be reversed if functional connections are remade with denervated end-organs, as a result of either re-establishing neural activity or by allowing the flow of trophic factors. Two observations, namely that the most rapid atrophy coincided with a fall in neuronal activity in the injured neurons, and that the silenced sensory axons atrophied relatively more than active motor axons (Hoffer et al. Brain Research, 178, 347-361, 1979) suggested to us that superimposing neural activity might reverse atrophy in axotomized neurones.

Extracellular cuff electrodes were bilaterally implanted around the sciatic nerve and the common peroneal or tibial nerve in 12 rabbit hindlimbs for chronic stimulation and monitoring of the compound action potential (CAP). Evoked CAP amplitude and latency were measured and used as a reference for nerve diameter. In a second operation common peroneal or tibial nerves were cut bilaterally and ligated distal to their cuff electrodes. Electrical stimulation of the proximal segment of the nerve was carried out at a frequency of 10 Hz, 8 hours a day for up to 200 days in one limb while the other served as control. CAP and latency were again recorded at 5 days intervals to monitor changes in axon diameter. Evoked CAP amplitude declined to about 25% of preoperative values with a similar time course irrespective of whether the axotomized neurons were chronically stimulated or not. An increase in CAP latency was also similar in stimulated and nonstimulated nerves.

The present study shows that chronic electrical stimulation neither prevents atrophy in axotomized neurons nor stimulates recovery of atrophic neurons. Thus, the most likely explanation for the recovery of axotomized neurons after reinnervation is the reinstitution of trophic factors.

Supported by Canadian MRC & AHFMR.

335.8 ACTIVITY-DEPENDENT REGULATION OF ACH SYNTHESIS IN CULTURED CILIARY GANGLION J.B. Tuttle and D.B. Gray, Department of Physiology and Neurobiology, University of Connecticut, Storrs, CT 06268.

Recent work from this laboratory has demonstrated that co-culture of striated muscle cells with ciliary ganglion neurons can not only increase basal acetylcholine (ACh) synthesis and choline acetyltransferase (ChAT) in neurons, but allow an acceleration of ACh synthesis following stimulation-induced transmitter release. This latter characteristic is considered to be a measure of synaptic maturity. In addition, muscle co-culture with E9 ciliary ganglion neurons removes the dependence of these neurons upon the presence of chick embryo extract for survival past 3 days in vitro.

In order to test if synaptic transmission or electrical activity is responsible for these effects, co-cultures were chronically exposed to tetrodotoxin (TTX) at concentrations of 1 nM to 1 uM which have been shown to completely block spike propagation in the ciliary ganglion. Even at 1 uM, there was no significant effect of TTX on survival in co-cultures, and less than a 10% decrease in survival of cultures of neurons alone.

In cultures of neurons alone, ACh synthesis rates in basal conditions and in stimulus-induced accelerations were not affected by chronic exposure to TTX. However, in muscle co-culture, 30-50% of the stimulus-induced acceleration of ACh synthesis was sensitive to TTX at concentrations of at least 1 nM. Acute exposure of neurons to TTX during synthesis measurements had no effect. These experiments were also repeated on cultures of neurons plated upon membrane fragments of lysed myotubes. This substrate also supports the development in vitro, of a compensatory ACh synthetic capacity following stimulation, although not as great as in co-culture with live muscle. Chronic exposure to TTX had no significant effect upon synthesis rates in these cultures.

Thus, TTX-sensitive electrical activity may be responsible for a portion of the compensatory increase in ACh synthesis trophically induced in ciliary ganglion neurons by co-culture with live muscle. Although it is tempting to conclude that this trophic interaction may be mediated by both activity dependent factors and membrane contact factors (as represented by membrane fragments), electrical activity not sensitive to TTX, such as calcium spikes, cannot be ruled out. However, chronic exposure of cultures to high K+ medium (28mM KCl) which depolarizes cells and might be expected to increase inward calcium currents, increases ACh synthesis rates overall, but lowers the amount of compensatory ACh synthesis following stimulation when expressed as a percentage of basal rates. Supported by the U.S. Army Res. Offices and BSN 8410581.

335.9 FOREBRAIN CHOLINERGIC NEURONS SURVIVE AND DIFFERENTIATE IN CULTURE IN THE ABSENCE OF ASTROCYTES. J. Hartikka* and F. Hefti. (SPON: A. Dravid). Dept. of Neurology, University of Miami School of Medicine, Miami, FL 33101.

Forebrain cholinergic neurons degenerate selectively in senile dementia. Knowing the factors which are needed for the development and survival of these neurons might help to find the reason for their degeneration. In vivo, neurons are surrounded by glia cells, astrocytes being a major population of them. Astrocytes seem to be important for maintenance of function of neurons in the mature brain. Furthermore, it has been proposed that they guide neuronal growth and promote differentiation during development. We have therefore studied the effects of astrocytes on the development of forebrain cholinergic neurons in primary cell cultures.

Cultures of dissociated cells were prepared from fetal (E17) rat septum. They were grown in a modified L-15 medium. After ten days in vitro the amount of protein and the activity of choline acetyltransferase (ChAT) were determined. The activity of ChAT, the specific enzyme marker for cholinergic neurons, provived an index for differentiation. Another set of cultures was taken for cell counting. Total number of cells was counted by staining the nuclei with bisbenzimide (Hoechst 33258). Astrocytes were identified by their content of glial fibrillary acidic protein which was visualized immunocytochemically. Cholinergic neurons were identified using ChAT immunocytochemistry and acetylcholinesterase cytochemistry. The proliferation of non-neuronal cells was suppressed by using two different compounds: cytosine arabinoside (Ara-C) and aphidicolin. Ara-C is a nucleotide analogue which terminates DNA replication. Aphidicolin is a specific inhibitor of DNA polymerase alpha, which is the enzyme needed for DNA replication in dividing eucaryotic cells. Using either of these compounds three types of cultures were prepared: 1) control cultures in which non-neuronal cells were allowed to proliferate freely. After ten days about 50% of the cells in these cultures were identified as astrocytes; 2) mixed cultures containing 5-10% astrocytes; 3) pure neuronal cultures containing less than 2.5% astrocytes.

The results showed that the survival of cholinergic neurons was independent of the presence of astrocytes. The ChAT activity per cholinergic neuron was significantly higher in, both, mixed cultures and pure neuronal cultures, than in control cultures. As compared to the control cultures ChAT activity was increased in mixed cultures and in pure neuronal cultures by 80% and by 130%, respectively.

The results suggest that forebrain cholinergic neurons survive and grow in culture for ten days in the absence of astrocytes. No beneficial effect from astrocytes on neuronal differentiation was observed. Astrocytes even seem to attenuate the expression of cholinergic properties in these cultures.

335.10 THE INFLUENCE OF TARGET AND NON-TARGET CELLS ON THE DEVELOPMENT OF SEPTAL CHOLINERGIC NEURONS: A HISTOCHEMICAL STUDY OF REAGGREGATING CELL CULTURES. J. Hsiang,* B.H. Wainer, A. Heller and P.C. Hoffmann (SPON: A. Levey). Dept. of Pharmacological and Physiological Sciences, University of Chicago, Chicago, IL 60637.

Cholinergic neurons of the septohippocampal pathway are known to have an important role in cognitive function. To better understand the factors responsible for the development and maintenance of this system, we have studied these cells in rotation-mediated reaggregating cell cultures. Brain cells were obtained by dissociation with 0.1% trypsin from the following areas of 15 day fetal mouse brain: (i) septum containing the cholinergic projection cells, (ii) hippocampus containing their target cells, (iii) and cerebellum containing non-target cells. The following combinations were aggregated in 10% serum supplemented medium in a rotatory incubator: (a) septal cells alone; (b) hippocampal cells alone; (c) cerebellar cells alone ($10 \times 10^6$ cells for each case), (d) septal-hippocampal cells, together and (e) septal-cerebellar cells, together ($5 \times 10^6$ cells from each area). After 6 days, the aggregates were transfered to serum-free defined medium for 2 weeks. Serial sections (60 $\mu$m) prepared from paraformaldehyde-fixed aggregates were studied using acetyl-cholinesterase (AChE) histochemistry. In all aggregates containing septal cells large AChE-positive neurons were present with prominent proximal dendrites. Sections from aggregates containing either hippocampal or cerebellar cells alone contained only a few weakly positive cells in which proximal processes were rarely seen. However, septohippocampal coaggregates displayed abundant fine-caliber varicose fibers suggestive of axonal arborizations. This fiber pattern was found much less often in aggregates of either septum alone, or septal-cerebellum and in many of these sections both coarse and fine fibers appeared to have degenerated. In aggregates with hippocampal and cerebellar cells alone, no fine varicose fibers were seen. AChE-positive cells with proximal dendrites (counted in randomly selected sections) were significantly more numerous in septal-hippocampal coaggregates (5104 cells) than in septal aggregates (1969 cells) or septal-cerebellar coaggregates (710) ($p < 0.001$ in both cases). These results, taken together, suggest that hippocampal target cells influence the development of cholinergic neurons. Supported by NS-17661, HD-04583, MH 28942, and the Brain Research Foundation (The University of Chicago).

335.11 CONTROL OF MYELINATION IN THE FISH OPTIC NERVE. R.Karam*, A. Maggs*and J. Scholes* MRC Cell Biophysics Unit, King's College London, 26-29 Drury Lane, London WC 2. UK.

The optic nerve in fish is comprehensively myelinated. The only exception is a discrete bundle of immature fibres along the ventral edge of the nerve. This persists throughout growth during adult life and usually contains around 25,000 unmyelinated axons. New fibres are continually added to this bundle, just as older ones become myelinated, at a rate that accumulates about 250,000 myelinated fibres in the optic nerve by 6 months age. The number of axons in the unmyelinated bundle thus reflects some balance achieved between the rate of new fibre production and the rate at which oligodendrocytes proliferate and myelinate them. It came as a surprise to find we could change this number by changing the growth rate of the fish.

Growth in 6 month-old Tilapia nilotica brood-mates was either slowed by crowding and restricted feeding, or accelerated by free-range conditions and more food, for a period of 1 month before sacrifice when the optic nerves were prepared for electron microscopy. Normal brood-mate controls were sacrificed at the beginning of the experiments. Compared with a rough estimate of around 250,000 myelinated fibres, representative unmyelinated fibre counts in these fish were: NORMAL, 25,000; SLOW, 15,000 and FAST, 45,000.

These figures show that some rate limiting step prevents myelination keeping up with new fibre production. The fibre diameter profile among the unmyelinated axons agrees with this interpretation: the increase in numbers with rapid growth comes from proliferation of the very smallest, uniformly sized (ca. 0.15$\mu$m)new axons, rather than from the minority of fibres that begin to increase their diameter (upto 0.25$\mu$m) just before they myelinate.

We wondered if the rate limiting step could be the time taken by new fibres to colonise the optic tectum and form synapses there. We investigated this idea using two approaches, (1) by removing the tectum to see if preventing or delaying synapse formation increases the number of unmyelinated fibres seen in the growing optic nerve and (2) by examining retrograde transport of labelled precursors and markers for signs of a correlation between myelination and synapse formation.

335.12 MYELIN BASIC PROTEIN EXPRESSION IS ENHANCED BY NEURONS. L. Bologa, Y. Aizenman*, and J. deVellis, Beckman Research Institute of the City of Hope, Duarte, CA 91010 and UCLA School of Medicine, Los Angeles, CA 90024.

Myelin basic protein (MBP) is a marker for differentiated oligodendrocytes. Though previous results suggested that the expression of MBP is enhanced by neurons, this has not been positively proven. We present now direct evidence that the expression of MBP by cultured oligodendrocytes is enhanced by neurons. Cell cultures from total brain of neonatal rats and pure neuronal cultures from embryonic rat brain were prepared. At 7 days in vitro, the total brain cell cultures were divided into 3 groups. Group (a) received pure neurons; group (b) received neuronal conditioned medium; group (c) served as control. Three days later the cultures were fixed and immunostained. Results showed that in groups (a) and (b) the expression of MBP was enhanced. This indicates that neurons and soluble factors released by them enhance the expression of MBP.

335.13 EXTRACELLULAR PROTEOLYSIS IN CNS HISTOGENESIS: EXPRESSION OF PLASMINOGEN ACTIVATOR ACTIVITY BY THE DIFFERENTIATING ASTROCYTES. Nurit Kalderon. The Rockefeller Univ., New York, NY 10021

The role of extracellular proteolysis as a modulator of the cytoarchitecture of the developing and regenerating nervous system is being studied; specifically, of the serum proteolytic system, the plasmin-generating system. This system is composed of plasminogen and plasminogen activator (PA), and their product is the protease plasmin. It has been established by studies performed in this laboratory that the plasmin-generating system is expressed as well as modulated at certain developmental stages by the differentiating nervous system. Results show that this system is active at those stages when glia proliferate: (A) in embryonic spinal cord both in vivo (1985, submitted) and in vitro (J.Neurosci.Res. 1982 8:509); and (B) in purified Schwann cell populations, where PA activity is expressed predominantly in the proliferating cell populations (PNAS 1984 81:7216).

The following study is focused on the identification of the glial cell types which produce PA during CNS histogenesis and the characterization of the mode of expression of PA activity as a function of cell differentiation. Purified astrocytes and oligodendrocytes in cell culture were obtained following the procedure of McCarthy & de Vellis (J. Cell Biol. 1980 85:890). These glial cells were dissociated from cerebral tissue of rat pups at age P2-P3 (postnatal days) and the two cell types were separated 8-9 days later, i.e., corresponding to the age of P10-P12. The extracellular and cellular PA activities were determined on the purified cell populations. Extracellular PA activity was detected in the growth medium of the astrocytes but not of the oligodendrocytes. Astrocytes expressed PA cellular activity, whereas no cellular PA activity was detected in the oligodendrocytes (P11 or P15) which seemed to exhibit some protease inhibitory activity. Astrocytic cellular PA specific activity was determined as a function of their age during the period corresponding to P11-P24. The highest specific activity, 0.2 Ploug U/mg protein, was monitored at P15; this activity gradually declined with age (P18, P22, P24) and vanished on day P24. These results correlate with reported data that PA specific activity in postnatal rat cerebrum declines as function of tissue development and levels off at the age of P25 (Brain Res. 1981 216:361).

Results so far suggest that the Schwann cell and the premature astrocyte are the "suppliers" of PA activity in the developing nervous tissues. Proteolytic activity was detected in regenerating injured sciatic nerve but not in the injured optic nerve (Acta Neuropathol. 1982 58:224). It is speculated that whereas the Schwann cell retains the capacity to express PA activity in regenerating PNS, the astrocyte upon maturation loses this capacity, hence, the deficiency in extracellular proteolysis in mature or injured CNS.

335.14 INTERCELLULAR TRANSFER OF HRP LABEL IN CRAYFISH GIANT AXONS. R.A. Sheller*, K.R. Seshan*, T.A. Viancour, and G.D. Bittner (SPON: M.A. Olivo) Zool., U. Texas Austin, TX 78712 and Biol. Sci., U. Maryland, Baltimore Cty, Catonsville, MD 21228.

Intercellular transfer of the protein markers HRP and wheat germ agglutin (WGA)-HRP has been observed among crayfish giant axons and glial cells. The crayfish ventral nerve cord has two lateral giant axons (LGAs) and two medial giant axons (MGAs). The LGA is a functional unit composed of a chain of electrically coupled homologous single lateral giant axons (SLGAs). Each SLGA arises from a cell body located in a caudal ganglion and extends rostrally to form electrotonic gap junctions with the next-most anterior SLGA. Each MGA arises from a cell body in the supraesophageal ganglion and extends the length of the nerve cord.

When HRP is intracellularly iontophoresed in vitro (physiological saline containing 13.5 mM Ca++) into an SLGA in a nerve cord ligated anterior to the first abdominal ganglion, HRP injected posterior to the second abdominal ganglion transfers to an adjacent SLGA about 50% of the time. HRP transfers to the caudal SLGA (30%) significantly more often ($p<.01$) than it transfers to the rostral SLGA (20%). When HRP injections were performed in a reduced Ca++ (1.5 mM) saline with added Ca++ antagonists (5mM Mn++ and 5mM Co++), then only one cell in 44 transferred in either direction.

It is difficult to detect HRP transfer from giant axons to adaxonal glia, if HRP is iontophoresed into a giant axon and then maintained at 20°C before developing with DAB. However if the axon is incubated at 30°C for 2 hours after injecting the HRP at 20°C, HRP is seen in adaxonal glia, in some cases obviously in vesicles. It is also difficult to see evidence of HRP uptake in giant axons if the HRP is placed extracellularly to the axon at 20°C. However WGA-HRP placed extracellularly at 20°C for 1-3 hours, is readily taken up into the axons, where it is clearly seen in vesicles.

These data show that crayfish giant axons transfer protein markers between adjacent SLGAs and between giant axons and glia, possibly by an active process involving endocytosis/exocytosis. Previous studies (Bittner, G.D., Comp. Biochem. Physiol. 68A. :299-306, 1981) have shown that severed MGAs appear to depend upon glial sheath cells for long term survival (90-300 days) whereas severed LGAs depend primarily upon adjacent SLGAs for long term survival (>700 days) of enucleated axonal processes. Since both SLGAs have many 250-500 Å vesicles where they are closely apposed and MGAs have many 250-500 Å vesicles facing glial cells, this intercellular transfer may be the basis for long term survival of these axons when the axons are severed from their cell bodies.

335.15 IS THE INCORPORATION OF EXOGENOUS GM1 INTO NEUROBLASTOMA MEMBRANES MEDIATED BY A MEMBRANE PROTEIN? K.C. Leskawa*, R.E. Erwin* and E.L. Hogan (SPON: N.L. Banik). The Medical University of South Carolina, Charleston, SC 29425

To better understand the mechanisms by which exogenous gangliosides promote the sprouting and extension of neurites from nerve cells, the association of exogenous ganglioside GM1 with membranes of neuroblastoma cells in culture was studied. Previously we have reported that the presence of calcium ion inhibits three forms of GM1-membrane association, including incorporation into the membrane lipid bilayer (Leskawa et al., Soc. Neurosci., 1984 Anaheim, CA). Since divalent cations are known to render gangliosides more hydrophobic in a biphasic partitioning system (Quarles and Folch-Pi, 1967, J. Neurochem., 12: 543), incorporation into the membrane lipid bilayer was expected to increase in the presence of Ca++, rather than decrease, as was found.

Neuro-2A cells were grown in culture and synchronized in the G1/GO phase of the cell cycle by serum deprivation for 48 hr. Cells were removed from the substratum and incubated in HEPES-buffered saline containing 3H-GM1 at 0.1 mM. GM1 incorporated into the plasma membrane was defined as the radioactivity remaining in a cell pellet after (1) washing the cells with a serum-containing medium, (2) trypsin treatment and (3) washing in buffered saline (see Facci et al., 1984, J. Neurochem., 42: 299). Cells in suspension were pretreated with EDTA before incubation with 3H-GM1. One group was 'reloaded' with Ca++, another with Ca++, Mg++ and Mn++, and a third washed with saline only. After incubation, incorporation was determined as described above and no significant differences between the three groups were observed. These results suggest that inhibition of GM1 incorporation is due to Ca++ interactions with ganglioside micelles or oligomers in solution, rather than with Ca++ sensitive sites on the membrane.

These data suggest that incorporation of exogenous GM1 cannot be explained by considerations of lipophilicity alone, but rather that incorporation may be mediated by a membrane protein. This view is supported by the following: treatment of N2A cells with purified trypsin or chymotrypsin prior to incubation with 3H-GM1 resulted in decreased incorporation (6.2 and 3.8% of control values), whereas pretreatment with collagenase, neuraminidase and hyaluronidase resulted in little change. A preliminary analysis of varying pH upon membrane incorporation is also supportive of incorporation being protein-mediated, since pH optima were found. If incorporation was solely due to hydrophobic forces, one would expect altering pH to have an effect only at the pKa of sialic acid (pH 2.6-2.75). Thus, these studies suggest membrane transfer protein(s) being involved in an initial GM1 recognition event, which may then bring the ganglioside in close proximity to the lipid bilayer for incorporation to occur.

335.16 NON-NEURONAL CELLS MEDIATE VIP STIMULATION OF NEURONAL SURVIVAL DURING DEVELOPMENT. D.E. Brenneman, S.W. d'Autremont* and E.A. Neale. Lab. of Dev. Neurobiol., NICHD, NIH, Bethesda, Md 20205

The regulation of neuronal development by neuropeptides was explored with various cell cultures. Vasoactive intestinal peptide (VIP) has been shown to influence neuronal survival in dissociated spinal cord cultures. The purpose of the present study was to examine the cellular mechanism of such a trophic effect. Previous studies have shown that blockade of electrical activity with tetrodotoxin (TTX) decreased the survival of cultured spinal cord neurons during a critical period in development. This effect was dependent on removal of endogenous conditioning substances. Tetrodotoxin blocks the spontaneous release of VIP-like immunoreactivity in dissociated spinal cord cultures. Addition of 0.1nM VIP to these cultures prevented the TTX-mediated neuronal cell death and neuronal death which occurred naturally during this period in development (days 7-21). In the present study, we investigated if this trophic action of VIP was due to a direct effect on neurons or if VIP was acting indirectly as a releasing agent for trophic substances derived from non-neuronal cells.

Three types of cultures were prepared from dissociated spinal cord tissue: non-neuronal background (BG) cultures, grown in MEM with 10% fetal calf serum; neuronal plus background (N+BG) cultures, grown in defined medium supplemented with 5% horse serum; and neuronal (N) cultures, grown in defined medium without serum. Control N cultures contained fewer neurons and substantially fewer background (GFAP positive) cells than N+BG cultures. A comparison was made of N versus N+BG cultures after TTX and/or VIP treatment. After 5 days treatment with TTX, both types of cultures exhibited a 35% decrease from neuronal cell counts of controls. Addition of 0.1 nM VIP plus TTX to N+BG cultures prevented neuronal cell death; whereas the same treatment in N cultures did not prevent TTX-mediated decreases in neuronal survival. VIP treatment alone had no significant effect on either N or N+BG cultures.

To further test the hypothesis that non-neuronal cells mediate the survival effects, 0.1 nM VIP was added to BG cultures for 3 days and then the conditioned medium (CM) was collected and tested on N cultures, which were previously shown not to respond to VIP treatment alone. This conditioned medium from VIP-stimulated BG cultures prevented neuronal cell death when added to the medium of N cultures treated with TTX. CM comprised 20% of the volume of the test cultures. Conditioned medium from BG cultures which were not treated with VIP had no protective action on N cultures. These data suggest that VIP stimulates the release of a survival promoting substance from non-neuronal cells, which is then competed for by a subpopulation of neurons whose survival is affected by changes in electrical activity.

335.17 TEMPORAL SEQUENCE OF ANGIOGENESIS IN NEURAL TRANSPLANT MODELS. J.M. Krum and J.M. Rosenstein. Dept. of Anatomy, George Washington Univ. Sch. of Med., Wash. D.C. 20037.

The survival of a neural transplant is ultimately dependent on the formation of functional vascular connections between it and host CNS. The temporal sequence with which renewal of transplant blood circulation occurs is related to the type of neural tissue grafted, the graft site, trauma incurred during surgery, or the mechanism of transplant revascularization.

Our studies have focused on the time course of transplant revascularization, utilizing both adult superior cervical ganglia (SCG) and fetal (E17-20) cortex cerebri allografted in the fourth ventricle of perinatal Wistar rats. Tritiated thymidine was administered one hour prior to sacrifice at postoperative time periods ranging from 4 hours to 4 weeks. The tissue was processed for light microscopic autoradiography and labelling indices (L.I.) of host parenchymal and pial endothelial cells within a 150 um area of the transplant were determined for each postoperative time period. The L.I. of transplant endothelial cells was also calculated.

In the atraumatic intraventricular operative procedure, cerebellar and medullary pial vessels subjacent to the graft site are only rarely damaged. After 4 hours, SCG transplants were firmly attached to the pial surfaces, and their intrinsic vessels collapsed and barely discernable. Labelling of pial vessels was not observed until 16 hours, with the highest endothelial L.I. occurring between 20 and 24 hours postoperatively. At these times, most SCG vessels were patent but unlabelled, although static pooling of red blood cells was present in many vascular profiles. This suggests a reperfusion of the original SCG vessels had occurred via inosculation with host pial vessels.

Fetal cortical transplants contained relatively few patent vessels which had a low endothelial L.I. at 24 hours postoperatively. The pliant fetal tissue was insinuated around pial vessels, in which the highest endothelial L.I. occurs at 48-72 hours postoperatively. At this time vessel profiles and L.I. increased within the developing transplants. At one week, pial, but not transplant, endothelial L.I. was significantly decreased. It appears the primary mechanism for supplying blood to both autonomic and CNS transplants is inosculation between host pial and intrinsic transplant vessels.

335.18 THE PRESENCE OF A BLOOD VESSEL OR PERIPHERAL NERVE IMPLANT INDUCES TROPHIC RESPONSES IN LESIONED RAT RETINA. E. Thomas Chappell* and James E. Turner (SPON: T. Troost). Department of Anatomy, Bowman Gray School of Medicine of Wake Forest University, Winston-Salem, NC 27103.

Unlike the embryonic vertebrate retina and the adult retina of many lower vertebrate species, the adult mammalian retina cannot regenerate at the histological level. However, under appropriate lesion conditions the adult retinal ganglion cell axons exhibit some capacity for collateral and/or regenerative sprouting. Moreover, it is clear that trophic substances are instrumental in the development, maintenance, and regeneration of neuronal populations. Presented here is evidence that the presence of a portion of mesenteric artery or sciatic nerve can affect the survival of retinal cell populations and contribute to the closure of a retinal incision. This evidence is obtained in a new in vivo model involving an incision in the dorsal surface of the eye in Sprague-Dawley rats, implantation of an arterial graft or peripheral nerve segment, and closure by microsuture. The histologic and morphometric data show the rescue of retinal cells (which normally die in the lesion area), close apposition of the wound margins (while there is a "die back" zone in the absence of an implant), and maintenance of retinal layer organization with a thickening of some layers (where disorganization is usually the case in lesions without implants). A double lesion paradigm indicates that the peripheral nerve implant can exert its influence over a distance of at least 1 mm. These results implicate the potential for trophic induction of plasticity in the adult mammalian retina. Supported by grant EY 04377 from the National Eye Institute awarded to James E. Turner.

## OPIATES, ENDORPHINS AND ENKEPHALINS: ANATOMICAL LOCALIZATION

336.1 SEPTAL LESIONS CAUSE A REVERSIBLE INCREASE IN ENKEPHALIN-LIKE BUT NOT DYNORPHIN A-LIKE IMMUNOREACTIVITY IN THE HIPPOCAMPUS. J.F. McGinty, J-S Hong, M. Blockus* and C.J. Frederickson*. Dept. Anatomy, East Carolina Univ. Sch. Med. Greenville, NC 27834, Lab Behav. Neurol. Toxicol. NIEHS/NIH Research Triangle Park, NC 27709 and Dept. Psychology, Univ. Texas at Dallas, Richardson, TX 75080.

Hippocampal dentate granule cells receive afferent input through the fornix from medial septal-diagnonal band (MS-DBB) nuclei and through the perforant pathway from entorhinal cortex. The MS-DBB projection is largely cholinergic whereas the lateral perforant and dentate granule-mossy fiber pathways contain proenkephalin-A and prodynorphin derived peptides, respectively. Four days after a unilateral transection of the fornix, the met-enkephalin content of the ipsilateral hippocampus was demonstrated to be significantly increased (Hong and Schmid, Brain Res. 205:415, 1981). In this study, we deafferented the hippocampus of its MS-DBB projection and examined enkephalin and dynorphin A immunoreactivity in the hippocampal formation at 3, 10, 16, 21, and 30 days post lesion. Bilateral electrolytic lesions (1mA for 30 sec) of the MS-DBB area were performed on male Sprague-Dawley rats. On the appropriate post lesion day, lesioned and control rats were perfused with formaldehyde for leu-enkephalin and dynorphin A (1-17) immunostaining of adjacent sections through the hippocampal formation and entorhinal cortex. MS-DBB lesions, verified by Nissl stained sections through the extent of the electrode site, caused a transient increase in enkephalin immunostaining in the lateral perforant pathway which was especially prominent in the outer molecular layer of the ventral dentate fascia. This increase in enkephalin immunostaining was maximal at 3 and 10 days and was not reliably different from control brains by day 21 post lesion. Dynorphin immunostaining in the dentate granule cell-mossy fiber pathway of lesioned rats did not appear to differ from control rats at any time point examined. Radioimmunoassays for enkephalin and dynorphin on similarly treated rats at the same time points are underway. The time course of the observed changes in perforant path enkephalin immunostaining parallels the transient increase in zinc dithizonate density in mossy fibers (Stewart, G. et al., Brain Research 290:43, 1984) as well as the time course of sympathetic fiber ingrowth (Loy and Moore, Exper. Neurol. 57:645, 1977) into the hippocampus after septal lesions.

Supported by NS20451.

336.2 ENKEPHALIN FIBERS IN SYMPATHETIC NUCLEAR REGIONS: SEGMENTAL VS CENTRAL ORIGIN. M.A. Romagnano and R.W. Hamill. Dept of Neurology, Monroe Community Hosp. U of Roch Med Ctr., Rochester, NY 14603

Previous studies have demonstrated a ladder-like network of enkephalin (Enk) fibers in thoracolumbar spinal cord coinciding with the distribution of preganglionic sympathetic nuclear regions. The present studies in the rat employ transections, hemisections, dorsal and/or ventral rhizotomies to determine whether Enk fibers in sympathetic nuclei are of central or intraspinal origin.

Spinal cord transections and hemisections are performed at T5/6 or C8-T1. Dorsal and/or ventral roots are severed at levels T5-T10 or C7-T5. Animals are perfused with Zamboni's fixative one week or one month following surgery. Spinal cords are removed and 40µ horizontal serial vibratome sections are stained for Enk by the unlabeled antibody method of immunocytochemistry. Sections are incubated for 48-72 hrs at 4°C in the primary antiserum used at a dilution of 1/500-1/2000 (D.S.Sundberg).

Enk immunoreactivity is not altered in those segments with severed dorsal and/or ventral roots when compared to control sections. Likewise, spinal cord hemisections at T5/6 or C8-T1 resulted in no apparent changes in the distribution of Enk on the ipsilateral or contralateral side below the lesion.

One week following C8-T1 spinal transection there is a large decrease in Enk fibers in the intermediolateralis nucleus,pars principalis (ILp), intermediolateralis nucleus,pars funicularis (ILf) and dorsal commissural nucleus. Moderate decreases in Enk immunoreactivity is found in the intercalatus spinalis nucleus (IC) and the intercalatus nucleus, pars paraependylmalis (ICpe). One month following the C8-T1 spinal transection there is a greater decrease in Enk immunoreactivity in the ILp, ILf and dorsal commissural nuclei when compared to one week survival times. The ILp cell clusters appear completely devoid of immunoreactivity while a moderate decrease in immunoreactivity is still evident in the IC and ICpe nuclei compared to control sections.

The resulting changes in the distribution of Enk in the sympathetic nuclei is similar at both one week and one month following T5/6 spinal transection. Below the lesion there is a moderate decrease in Enk staining in ILp, ILf and dorsal commissural nuclei while there is a moderate-slight loss of fibers seen in the IC and ICpe nuclei. Above the lesion the Enk distribution pattern appears similar to that found in control sections.

These results indicate that: 1. Enk fibers found in thoracolumbar sympathetic nuclei are of both central and intraspinal origin; 2. descending (suprasegmental) central Enk pathways primarily project to the ILp, ILf and dorsal commissural nuclei; 3. intraspinal (segmental) Enk pathways appear to primarily exist in IC and ICpe nuclear areas. These new observations suggest that specific patterns exist for supraspinal and intraspinal Enk pathways.

336.3 CO-DISTRIBUTION OF DYNORPHIN B AND OXYTOCIN IN CERTAIN HYPOTHALAMIC NEURONS IN THE RAT. B. Quinn and E. Weber, Institute for Advanced Biomedical Research, Oregon Health Sciences University, Portland, OR 97201.

Immunohistochemical studies from a number of laboratories have demonstrated that several hypothalamic hormones (including oxytocin, vasopressin, and CRF) may be organized into different neuronal subpopulations, in which different opioid neuropeptides are expressed in each subpopulation. The differential co-storage of these neuropeptides may be important in determining the roles of different components of the hypothalamo-pituitary axis.

This study was undertaken to examine the distribution of peptides derived from the pro-dynorphin precursor throughout the magnocellular system. Male rats were treated with 50 ug of colchicine icv 48 hours prior to perfusion with buffered 4% paraformaldehyde/5% sucrose, and the brains were immersed overnight in 12% sucrose/2% polyethylene glycol (MW 400). The tissue was then frozen in dichlorodifluromethane in a liquid nitrogen bath. Serial 2-micron frozen sections were stained with antisera directed against oxytocin, vasopressin, met-enkephalin-arg-gly-leu, and several pro-dynorphin products: dynorphin A(1-17), dynorphin A(1-8), dynorphin B, and alpha-neo endorphin. Immunoreactivity was visualized using fluorescein-labeled second antibodies.

In the rostral hypothalamus, in the nucleus of the anterior commisure, all or nearly all oxytocin perikarya were also immunoreactive, in adjacent sections, for dynorphin B. These cells also showed some staining for alpha-neo-endorphin, but not for dynorphin A or dynorphin(1-8), or met-enkephalin-arg-gly-leu. In contrast, moving caudally, in the paraventricular and supraoptic nuclei very few oxytocin cells showed dynorphin B immunoreactivity. However, in these areas most of the vasopressin perikarya stained with each pro-dynorphin antiserum.

These results demonstrate the first immunohistochemical evidence for the same opioid peptide colocalized in both the oxytocin and vasopressin systems. Further, they suggest a potential neuropharmacological distinction in the release of oxytocin by rostral vs. caudal hypothalamic neurons, which could support potentially distinct physiological roles for these different oxytocinergic groups.

336.4 IMMUNOCYTOCHEMISTRY OF LEUCINE-ENKEPHALIN AND DYNORPHIN B IN SPINAL CORD AND DORSAL ROOT GANGLION NEURONS GROWN IN CULTURE. D. Durand*, M.A. Werz and R.L. Macdonald, (SPON: L.T. Rutledge), Dept. of Neurology, Univ. of Michigan, Ann Arbor, MI, 48109.

Opioid receptors in the spinal cord are localized at least in part on primary afferent fibers. In addition, opioid receptors are present also on dorsal root ganglion (DRG) neuron somatic membranes. We have investigated the actions of opioids using intracellular techniques and have determined that mu-, delta-, and kappa- receptors are present on the somata of mouse DRG neurons grown in primary dissociated cell culture where binding of opioids to receptors results in a decrease of calcium influx (Werz and Macdonald, JPET, 227:394-402, 1983). It is likely that opioid receptors on primary afferent terminals are coupled to similar ion channels since opioids decrease neurotransmitter release from such fibers (Macdonald & Nelson, Science, 199:1449-51, 1978). It would be of interest to observe decreases of calcium influx following release of opioids from neurons. As a prelude to such investigation, we have studied the distribution of opioid peptides within primary dissociated cell cultures of spinal cord and dorsal root ganglia using the peroxidase-antiperoxidase technique of Sternberger. Two antisera have been emloyed, one directed against dynorphin B and one directed against leucine-enkephalin, to allow differentiation of the two opioid systems within spinal cord. Specificity of the immunohistochemical reactions was tested by carrying out primary incubations in the presence of a saturating concentration of the respective synthetic peptide and by crossblocking experiments distinguishing leucine-enkephalin immunoreactivity from dynorphin B immunoreactivity.

We observed small (<20 μm), multipolar spinal cord neurons that were immunoreactive for leucine-enkephalin. Spinal cord neurons positive for dynorphin B were not observed. In contrast, a small number of large DRG neuron somata were positively stained for dynorphin B but not for leucine-enkephalin. The differential localization of leucine-enkephalin and dynorphin B suggests different roles for these opioid systems in processing information within the spinal cord. Since opioid receptors are present on a subpopulation of DRG neuron somata, it would be of interest to determine if these same neurons are immunoreactive for dynorphin. Such a finding might suggest that opioid receptors on DRG neurons are autoreceptors.

We thank Dr. Stanley J. Watson for his kind gift of antisera. Supported by grant BNS-8118762.

336.5 PRO-DYNORPHIN IN THE ANTERIOR LOBE: ANATOMICAL, BIOCHEMICAL AND MOLECULAR BIOLOGICAL STUDIES. H. Khachaturian, T.G. Sherman, R.M. Dores, S.J. Watson and H. Akil. Mental Health Research Institute, University of Michigan, Ann Arbor, MI 48109, U.S.A.

The existence of dynorphin in the pituitary anterior lobe (AL) has been previously described (Seizinger et al., BBRC, 103: 256-263, 1981). However, little is known about the anatomical or biosynthetic origin of this opioid in AL. What is established is that the dynorphin-like immunoreactivity in AL tends to be of higher molecular weight forms. Others (Civelli, Douglass and Herbert, personal communication), however, have had difficulty detecting pro-dynorphin mRNA in AL, bringing into question the anatomical origin of AL dynorphin. This problem is also underscored by the difficulty in visualizing pro-dynorphin peptides in AL using classical immunohistochemical tools. We now report our efforts in further characterizing this opioid family in AL.

Dynorphin immunoreactive cells can be visualized in the AL of colchicine-treated male Sprague-Dawley rats following chronic footshock stress. In these animals, both dynorphin A and dynorphin B immunoreactivities are present in a subpopulation of AL cells, which are distinct from the POMC containing corticotrophs. Dynorphin-like material can also be visualized in some AL cells in developing rats beginning at E17. To further characterize the precursor and its product, we have studied pro-dynorphin mRNA using a rat genomic probe from Civelli et al. (PNAS, in press, 1985). Anterior lobe dynorphin mRNA exhibits an apparent MW similar to that in hypothalamus and striatum (2400 nucleotides). Finally, we have been successful in showing pro-dynorphin biosynthesis in AL short-term cell cultures using a classical pulse-labelling approach with [$^3$H]leucine. Three immunoaffinity columns were used for the purification: anti-dynorphin A (1-17), anti dynorphin A (1-8) and anti-pro-dynorphin Bridge Peptide. All 3 columns captured a common and unique 24K molecular species. Taken together, our results show the existence of pro-dynorphin mRNA and the translation of that message in AL. The system appears to become induced by repeated stress since dynorphin concentrations increase to an immunohistochemically detectable level. The exact type of AL cells which express the pro-dynorphin gene is currently under investigation.

This work was supported by NIMH Grant # MH39717 (SJW).

336.6 DYNORPHIN CELLS IN THE LATERAL HYPOTHALAMUS INNERVATE THE AMYGDALA, CENTRAL GRAY, PARABRACHIAL NUCLEUS AND DORSAL VAGAL COMPLEX. A.M. Zardetto-Smith, M. Moga, D. Magnuson, S. J. Watson and T.S. Gray, Dept. Anat., Loyola Stritch School of Medicine, Maywood, IL 60153 and Mental Health Res. Inst., Univ. Mich., Ann Arbor, MI 48109.

Previous studies have localized dynorphin(DYN)-immunoreactivity within the paraventricular, supraoptic, arcuate and lateral hypothalamic nuclei. The median eminence has been demonstrated to be a major recipient of projections from the magnocellular DYN-immunoreactive neurons. In the present study, evidence is presented that DYN-immunoreactive neurons in the lateral hypothalamus have extensive extrahypothalmic projections.

Male Long-Evans rats (150-250 gm) were anesthetized and unilateral 50-100 nl injections of the retrograde tracer fast blue were stereotaxically placed into the central nucleus of the amygdala (CNA), central gray (CG), parabrachial nucleus (PBN) or dorsal vagal complex (DVC). Intracerebroventricular injections of colchicine were administered 24-72 h prior to sacrifice. Postoperative survival after fast blue injections ranged from 7-12 days. Animals were perfused transcardially with 4% paraformaldehyde and brains were cut at 20 um using a vibratome. Sections were incubated overnight with primary antibody generated against dynorphin A or an adrenal enkephalin precursor fragment, BAM-22-P. The sections were then rinsed and incubated in a rhodamine-conjugated goat anti-rabbit immunogammaglobulin. After mounting, sections were examined for cells that contained both fast blue and rhodamine immunofluorescence.

DYN-immunoreactive retrogradely labeled neurons were observed in the posterolateral hypothalamus and perifornical area after injections into the CNA, CG, PBN and DVC. Occasionally retrogradely labeled DYN-immunoreactive neurons were seen in the paraventricular nucleus. In contrast, cells labeled for both fast blue and BAM-22-P were rarely observed.

The present study provides evidence for lateral hypothalamic dynorphinergic innervation of a number of brain nuclei that are thought to control autonomic outflow. This projection parallels, but is separate from, the pro-opiomelanocortin projections originating from the medial basal hypothalamus and arcuate nucleus. In addition, evidence was lacking for a strong, similarly projecting enkephalinergic pathway. A possible function of this DYN peptidergic projection may be to mediate the integration of autonomic responses that occurs during emotional and/or stress related behaviors. (Supported by NIH grant NS 20041).

336.7 **COMPARATIVE IMMUNOCYTOCHEMICAL DEMONSTRATION OF PEPTIDE F-, MET$^5$-ENKEPHALIN- AND MET$^5$-ENKEPHALIN-ARG$^6$-GLY$^7$-LEU$^8$-CONTAINING NEURONS IN THE RAT GASTROINTESTINAL TRACT.** Y.N. Wang, A.C. Church and R.J. Wyatt. Neuropsychiatry Branch, NIMH, Saint Elizabeths Hospital, Washington, D.C. 20032.

Peptide F, a thirty-four amino acid fragment derived from the proenkephalin A molecule has been found in the brain and adrenal medulla of several species by radioimmunoassay. In the present study we report that Peptide F is present in the neuronal elements of the rat gastrointestinal (GI) tract and that the distribution appears to be similar to that of the proenkephalin derivatives, Met$^5$-enkephalin (Met-enk) and Met$^5$-enkephalin-Arg$^6$-Gly$^7$-Leu$^8$ (Met-enk-Arg-Gly-Leu). Esophagus, stomach, duodenum, jejunum, ileum and colon were fixed in periodate-lysine-paraformaldehyde (PLP) and sectioned with a cryostat (8-10 $\mu$m). Tissue sections were incubated first in antisera to either Peptide F, Met-enk or Met-enk-Arg-Gly-Leu, and then in fluorescein conjugated goat anti-rabbit IgG. Specificity of the Peptide F antiserum was established by incubating control tissues (adjacent slices) in antiserum previously absorbed with 10 $\mu$M synthetic Peptide F. Peptide F-containing neurons were found in all parts of the GI tract while the greatest number of immunoreactive neurons was observed in the duodenum. Peptide F-containing nerve cell bodies were mainly located in the myenteric plexus. Peptide F-containing nerve fibers were primarily present in the myenteric plexus, and the circular muscle layer while a few immunoreactive fibers were seen in the longitudinal muscle and the muscularis mucosa layers, the submucous plexus, and the mucosa. By comparing the distributions between Peptide F and the other related enkephalins we found that these three peptides have a similar distribution in the GI tract, and that they are most likely located in the same neurons. The results suggest that Peptide F, an intermediate of proenkephalin A, may play a physiological role within certain functional neurons of the enteric nervous system.

336.8 AUTORADIOGRAPHIC DIFFERENTIATION OF MULTIPLE OPIOID RECEPTOR SUBTYPES WITH SELECTIVE LIGANDS. Alfred Mansour, Michael E. Lewis, Henry Khachaturian, and Stanley J. Watson. Mental Health Research Institute, University of Michigan, Ann Arbor, MI 48109, U.S.A.

Previous opioid receptor autoradiographic studies used ligands which are less selective than those available now. The present experiments were therefore designed to characterize the opioid receptor subtypes in the rat forebrain using [$^3$H]DAGO (Tyr-D-Ala-Gly-NMe-Phe-Gly-ol), a selective mu ligand, [$^3$H]DPDPE (D-Pen$^2$, D-Pen$^5$-enkephalin), a selective delta ligand, and [$^3$H]bremazocine, a kappa opiate (in the presence of 100 nM DAGO and DPDPE). Thaw-mounted coronal sections were incubated with either 4.85 nM DAGO, 36 nM DPDPE, or 0.89 nM bremazocine in 50 mM Tris HCl (pH 7.4) for 60 min at 25°C. These concentrations were determined to be 3 times the $K_d$ value of each of the ligands and therefore represented 76-78% receptor occupancy. Incubations were terminated by four consecutive Tris washes (30 sec for DAGO and DPDPE, 4 min for bremazocine at 4°C), followed by a 2 sec water (4°C) rinse. The sections were dried, apposed to tritium-sensitive LKB Ultrofilm with 14 step tritium standards (American Radiolabeled Chemicals, 0.0-489.1 uCi/g), stored at 25°C, developed, and analyzed densitometrically. In agreement with previous studies, the mu ligand labelled sites in a patchy distribution in the caudate-putamen, while the delta ligand labelled sites diffusely. Unlike previous reports, the striatal distribution of delta sites was not uniformly diffuse, but exhibited an increased density in cytoarchitecturally distinct subareas. The mu-delta differentiation was also evident in substantia nigra, where [$^3$H]DAGO and [$^3$H]DPDPE binding sites were concentrated in the pars compacta and pars reticulata, respectively. These findings illustrate the importance of using selective ligands to facilitate the autoradiographic discrimination of opioid receptor subtypes. [$^3$H]Bremazocine autoradiograms are not presently available, but will be presented at the meeting.

336.9 ALFENTANIL-INDUCED RIGIDITY IN THE RAT: THE ROLE OF THE NUCLEUS RAPHE PONTIS AND THE CAUDATE NUCLEUS. T.A. Blasco*, D. Lee, M. Amalric, N.R. Swerdlow, N. Ty Smith*, and G.F. Koob. Dept. of Basic and Clinical Research, Div. of Preclin. Neuroscience and Endocrinology, Scripps Clinic and Research Foundation, La Jolla, CA., Dept. of Anesthesiology, Univ. of Cal., San Diego.* (SPON: Rita Valentino)

Previous attempts to eliminate the rigidity associated with high-dose narcotic anesthesia in the operating room have proven only partially successful. Past laboratory work investigating the neuroanatomical sites of this rigidity have implicated both the nucleus raphe pontis (NRP) within the reticular formation (Broekkamp et al., Neurosci. Letters, 50:313-318, 1984) and the caudate nucleus (CN) within the basal ganglia (Havemann et al., Arc. of Pharmacol., 313:139-144, 1980). The present study, using systematically administered alfentanil (ALF), a new powerful, short-acting narcotic, and intracerebrally applied methylnaloxonium (MN), attempted to further elucidate the functional role of the NRP and the CN in rigidity.

Wistar rats were used in developing a dependable model of ALF-induced rigidity (ALF 0.5 mg/kg s.c.) as documented by a gastrocnemius electromyogram (EMG). The duration of this rigidity lasted approximately 30 minutes. The general ability of MN to antagonize rigidity was studied with intraventricular injections 15 minutes prior to the ALF treatment. The 2.0 ug and 4.0 ug doses prevented rigidity ($P < 0.005$), while a 0.5 ug dose demonstrated borderline antagonism ($P < 0.10$). In the NRP 0.125 ug and 0.5 ug of MN were able to significantly antagonize rigidity ($P < 0.005$) compared with a saline control. In the CN neither 1.0 ug or 4.0 ug antagonized rigidity. These observations demonstrate the NRP to be at least 10 times more sensitive to antagonism of rigidity by MN than the ventricular injections. The NRP was at least 32 times more sensitive to antagonism of rigidity by MN than the CN. Results suggest that the NRP may be an important site for the muscular rigidity associated with high dose narcotic administration. This work was supported in part by Janssen Pharmaceutical Company.

336.10 QUANTITATION OF LOCAL CEREBRAL GLUCOSE UTILIZATION DURING OPIOID DEPENDENCE AND NALOXONE-PRECIPITATED WITHDRAWAL. A.S. Kimes, R.C. Walovitch and E.D. London. Neuropharmacology Lab., NIDA Addiction Research Center, Baltimore, MD 21224.

Localization of the cerebral areas which may be activated or inhibited during opioid dependence and naloxone-precipitated morphine withdrawal have been studied using 2-deoxy-D-[1-$^{14}$C]glucose ([$^{14}$C]DG) mapping (Wooten, G. F. et al., Proc. Natl. Acad. Sci., 79:3360, 1982; Geary, W.A. and Wooten, G.F., Brain Res., 275:117, 1983). We have extended this work by measuring local cerebral glucose utilization (LCGU) in morphine-dependent or naloxone-precipitated abstinent rats. LCGU of both groups was compared to values in drug-naive controls. LCGU was measured by quantitative autoradiography using the [$^{14}$C]DG method of Sokoloff, L. et al. (J. Neurochem., 28:897, 1977). Fischer-344 male rats were made morphine-dependent by implantation of 75 mg morphine pellets (one on day 1 and 2 on day 4). Control rats were implanted with placebo pellets according to the same schedule. On day 8, each rat was prepared for the [$^{14}$C]DG procedure by implantation of femoral venous and arterial catheters, and was partially restrained by a lower body plaster cast. Injections of naloxone (0.5 mg/kg, s.c.) or saline were given 2 min before [$^{14}$C]DG (125 $\mu$ Ci/kg, i.v.). Naloxone produced prominent signs of withdrawal which included vocalization, teeth chattering, hyperactivity and nosebleeds. Concentrations of [$^{14}$C]DG and glucose were measured in 14 timed blood samples which were taken during the experimental period. The rats were overdosed with Na pentobarbital 45 min after the [$^{14}$C]DG injection. The brains were removed and frozen for cryostatic sectioning.

Although LCGU was relatively unchanged in morphine-dependent rats, there were significant increases in naloxone-precipitated abstinent rats. Many of the affected areas are rich in opioid receptors and/or have been related electrophysiologically to the withdrawal syndrome (Geary, W.A. and Wooten, G. F., J. Pharmacol. Exp. Therap., 225:234, 1983; Aghajanian, G., Nature, 276:186, 1978). These areas include the central gray, locus ceruleus, central and medial amygdaloid nuclei and anteroventral thalamic nucleus. In contrast to findings by Wooten et al., (Proc. Natl. Acad. Sci., 79:3360, 1982), increases in LCGU in the hippocampus during morphine dependence were not detected in our study. Possible reasons for this discrepancy include the following: 1) Using grey matter/white matter optical density ratios may have overestimated relative hippocampal LCGU in the morphine-treated rats studied by Wooten, G.F., et al.; 2) The morphine pellets were not removed from our rats prior to LCGU measurement, but Wooten, F. et al. did remove the pellets 2 hr before [$^{14}$C]DG injection; 3) Wooten, G. F., et al. used naloxone-injected morphine naive rats as controls.

337.1 INCREASED GROWTH OF MYELINATED PERIPHERAL NERVE INTO AGANGLIONIC SEGMENTS OF THE LS/LS MUTANT MOUSE. V.M. Tennyson, T.D. Pham*, T.P. Rothman, and M.D. Gershon. Dept. of Anatomy and Cell Biology, Columbia University, College of P & S, New York, N.Y., 10032.

The enteric nervous system is colonized by cells that migrate to the gut from the neural crest. In the ls/ls mutant mouse, the terminal hindgut fails to be colonized by neural crest-derived precursors of intrinsic neurons; thus, the terminal segment lacks myenteric and submucosal plexuses and the mouse develops congenital megacolon. We have postulated that the defect occurs because the microenvironment of the terminal hindgut is segmentally abnormal and does not permit migration and/or survival of the enteric neuronal precursors in the affected zone. There are nerve fibers in the aganglionic region. These fibers are supported by Schwann cells that express the high intensity of glial fibrillary acid protein (GFAP) that is normally characteristic of enteric glia. In order to determine whether neural supporting cells in the aganglionic ls/ls bowel are Schwann cells or enteric glia we have examined the ultrastructure of the nerves in the abnormal tissue in detail. We now report that in the absence of the intrinsic enteric innervation, the microenvironment of the gut permits or induces the ingrowth into both the presumptive myenteric region and the submucosa of large peripheral nerve bundles. We found that these bundles even contain myelinated axons. In a few cases, we observed neurons on the external surface of the aganglionic bowel within peripheral nerve bundles in regions where the external longitudinal muscle was absent. The supporting cells of the unmyelinated and myelinated nerves in the aganglionic ls/ls bowel all had the typical morphology of peripheral Schwann cells (individual ensheathment of axons, a basal lamina, no astrocytic contour). Large bundles of peripheral nerve containing neurons and myelinated axons were absent in the enteric plexuses of the terminal bowel of control mice, but they were found in the adventitia 50 to 100 um external to the longitudinal muscle. We suggest that the extracellular matrix of the terminal bowel of the control ls/ls mouse may prevent the ingrowth of the normal precursors of the glia as well as neurons of the enteric nervous system, but permit or encourage the ingrowth of abnormal numbers of extrinsic axons. These nerves may carry supporting cells into the gut where they express high levels of GFAP but are otherwise typical Schwann cells. 337.2 DEVELOPMENTAL POTENTIAL OF INNERVATED EMBRYONIC QUAIL GUT BACK TRANSPLANTED TO A NEURAL CREST MIGRATION PATHWAY OF CHICK EMBRYOS: INTERACTION WITH THE HOST'S CNS. T.P. Rothman, N.M. LeDouarin* and M.D. Gershon. Dept. Anat. & Cell Biol., Columbia Univ. P&S, NY and l'Inst. d'Embryol., CNRS, Nogent-sur-Marne, France.

The enteric nervous system (ENS) has a structure that resembles the brain and is different from that of other regions of the PNS. The neural crest-derived precursor cells that colonize the bowel and form the ENS proliferate extensively even after definitive enteric neurons can be recognized. It has been shown that precursor cells that co-exist with neurons in other developing peripheral ganglia will travel along neural crest migration pathways when grafted (back-transplanted) into younger embryos. The destinations and fate of the migrating cells reflect the extent of their determination at the time of grafting. In order to gain insight into the developmental capability of the primordial ENS and the enteric mesenchyme with which it interacts, embryonic quail duodenum (4 day) was grafted into neural crest migration pathways of chick embryos through which precursor cells normally migrate to the sympathetic ganglia and adrenal medulla (somites 20-21 of embryos of 20-24 somites). Grafts were placed between the somite and the neural tube and the embryos were killed at stage 35 (9 days). Donor cells in the chimeric embryos displayed the quail nuclear marker. Cells migrated from the gut into the dermis and dorsal mesenchyme of the host entering forming muscle and feather germs; however, no enteric cells participated in the formation of cartilage. In fact, the development of vertebrae was impeded unilaterally at the site of the graft. Quail cells also invaded the proximate dorsal root and sympathetic ganglia, the meninges, peripheral nerves, dorsal and ventral roots, and the adrenal medulla but not the gut. Moreover, there was migration of donor cells into the spinal cord where they entered the gray matter of the anterior horn. The host CNS reacted to the grafts. Large bundles of nerve fibers connected the spinal cord and the adjoining donor tissue. These fibers mixed with and became enveloped by whirls of elongate quail cells. There was also a unilateral hypertrophy of the spinal cord. These results are consistent with the hypothesis that the primordial ENS contains precursor cells that can leave the bowel and follow neural crest migratory pathways. Unlike other grafts involving peripheral ganglia, however, the back-transplantated bowel interacts with the developing CNS. This interaction, and especially the apparent local stimulation of host CNS growth by the grafts of bowel suggest that the CNS may respond to growth factors produced by the enteric mesenchyme. Supported by grants BNS-8204904, INT8413816, and NS15547.

337.3 POSTNATAL GENERATION OF NEURONS IN THE DEVELOPING ENTERIC NERVOUS SYSTEM. S. Benjamin*, T.P. Rothman and M.D. Gershon. Dept. Anatomy and Cell Biol., Columbia Univ. P&S, New York, NY.

During ontogeny of the mammalian enteric nervous system (ENS) peptide-containing neurons appear later than those containing small molecule neurotransmitters. It is possible that late-appearing neurons may be derived from a reservoir of proliferating neuroblasts that co-exists with neurons in the immature ENS. Experiments were thus done to determine for how long proliferating neural precursors persist following the first appearance of neurons in the developing bowel. $^{3}$H-Thymidine ($^{3}$H-TdR; 5 uc/g) was injected (i.p.) at 1 day, 7 days, 2 weeks and 29 days of postnatal life. For each developmental age, groups of animals were divided into several subsets. One group of animals received only 1 injection of the isotope. These animals were killed 90 min later in order to identify properties of proliferating cells without allowing them time to complete a cell cycle. A second group of animals received 4 injections over a 12 hour period in order to be sure all cells that might pass through the S phase of the cell cycle during the 12 hours would be labeled. Animals in this subset were killed 24 hours after the initial injection. For "birth date" studies, at each developmental age some animals that were labeled for a 12 hour period were allowed to survive for an additional 1-2 weeks while the bowel of others was not studied until the 33rd postnatal day. For each experiment the duodenum was removed, fixed appropriately and prepared for radioautography. Some tissues were embedded in Epon and cut at 1 um so that the morphology of dividing cells could be recognized. Additional experiments were done with frozen sections to simultaneously demonstrate $^{3}$H-TdR labeling and serotonin (5-HT) or vasoactive intestinal polypeptide (VIP) immunoreactivity in the same sections. Results indicate that: (1) On the first postnatal day the precursors of some cells that express VIP are still dividing; however, no cells with 5-HT were found to be labeled even by a 12 hour exposure to $^{3}$H-TdR. (2) The murine gut does retain a pool of proliferating neuroblasts, at least until the 2nd week of postnatal life. Neurons continue to be labeled by $^{3}$H-TdR injected up to this time. By one month of age only glia became labeled by $^{3}$H-TdR. Thus proliferation of precursor cells continues throughout or beyond the period when neuronal phenotypic expression occurs. VIP-containing neurons could be derived from the pool of proliferating neuroblasts. Since serotonergic neurons are probably all postmitotic while VIP-containing neurons are still being born, it is unlikely that this peptidergic neuron arises from earlier-developing serotonergic neurons that change their transmitter. Supported by NIH grants NS15547, AM07030 and NSF BNS83-04904.

337.4 ONTOGENY OF SEROTONIN RECEPTORS IN THE MURINE GUT. T. Branchek and M.D. Gershon. Anatomy and Cell Biology, Columbia University, Coll. of P&S, New York, NY 10032.

The enteric nervous system (ENS) is critical in regulating intestinal absorption and motility. In order to gain insight into the factors involved in expression of receptors in the ENS, we investigated the development of a receptor for a transmitter the ontogeny of which is already known, the enteric type of serotonin (5-HT) receptor (5-HTR). 5-HT is a transmitter that acts in both myenteric and submucosal plexuses. The enteric 5-HTR has recently been characterized by radioligand binding studies and shown to be different from either of the major classes of 5-HT receptor that have been found in the CNS. 5-HTR are located on myenteric and submucosal neurons and they are probably also present on primary afferent nerve fibers in the intestinal mucosa. We followed the time course of the elaboration of enteric 5-HTR by radioautographically localizing high affinity $^{3}$H-5-HT binding sites in embryonic and early postnatal mice. Specific binding was defined as that displaced by a 1000-fold excess of 5-HT. Embryos were obtained on gestational days E11-18. Neonatal mice and animals at postnatal days 2,6, 14, and 22 were also examined. Stomach, small and large intestines were dissected in oxygenated Krebs solution, divided into segments, keeping the oral-anal sequence intact, and frozen in OCT embedding compound with liquid nitrogen. Unfixed cryostat sections were cut at 15um, incubated with $^{3}$H-5-HT (in the presence or absence of excess 5-HT), dried, and apposed to $^{3}$H-sensitive film for 2 weeks at room temperature. The developed images were examined for specific binding of $^{3}$H-5-HT. 5-HTR could first be detected on day E14. At this time they were evident in the stomach and the proximal small intestine. One day later, the entire small bowel was found to contain 5-HTR. The proximal colon began to elaborate these receptors by day E16. At day E18, 5-HT receptors extended from the stomach through the proximal colon. Expression of 5-HTR in the distal colon was quite delayed and was not detectable until day P14; the terminal 2-5mm of bowel (measured from the anus) were devoid of detectable 5-HTR until day P22. Serotonergic neurons in the ENS develop very early in relation to other types of enteric neuron and make their appearance in proximodistal sequence from stomach to anus over the course of two days (E12-E14). In contrast, 5-HTR, which also appear in a proximodistal sequence, are elaborated over a later and much longer time course, nearly 4 weeks. The role of 5-HT in regions of the ENS in which the mature type of 5-HTR has not yet appeared is unclear. The appearance of 5-HTR after serotonergic neurons is consistent with the hypothesis that these neurons play a role in inducing the formation of 5-HTR. This hypothesis remains to be tested. Supported by Grants NS12969, NS15547 and the PMAF.

337.5 SYMPATHETIC NERVOUS SYSTEM CONTROL OF PLASMA RENIN ACTIVITY IN DEVELOPING RATS. R. F. Kirby and A. K. Johnson. Dept of Psychology and the Cardiovascular Center, Univ. of Iowa, Iowa City, IA 52242.

Sympathetic nervous system innervation to the heart and adrenal medulla becomes functional during the first postnatal week in the rat. However, the development of sympathetic control of renin release from the kidney has not been examined.

In previous work, doses of tyramine and insulin were found which produced comparable increases in plasma renin activity (PRA) at 30 min post-injection in 20 day old Sprague-Dawley rats. Tyramine was used to directly stimulate norepinephrine release from sympathetic terminals, while insulin was selected because it produces a centrally-mediated activation of the sympathetic nervous system, causing the release of both epinephrine and norepinephrine. In the present study, PRA was measured as an index of functional sympathetic innervation to the juxtaglomerular cells of the kidney in 10 and 15 day old rat pups.

Pups 10 and 15 postnatal days of age received subcutaneous administration of vehicle (distilled $H_2O$), the direct beta-adrenoceptor agonist isoproterenol (0.1 mg/kg), or insulin (20 IU/kg). Pups were decapitated 30 min post-injection and trunk blood was collected into chilled, EDTA treated tubes. Blood samples were then centrifuged and plasma was removed for determining PRA by measuring the formation of angiotensin I in the presence of endogenous angiotensinogen.

Isoproterenol led to large increases in PRA at both ages, indicating that direct beta-adrenoceptor activation is effective in stimulating PRA by 10 days of age. However, tyramine treatment did not produce a significant increase in PRA until day 15. The development of a functional response to tyramine between postnatal days 10 and 15 may indicate that sympathetic terminal mechanisms involved in the uptake and release of norepinephrine mature during this period. Insulin treatment did not stimulate PRA in either 10 or 15 day old pups. Therefore the PRA response to sympathetic nervous system activation with insulin must mature sometime between postnatal days 15 and 20, the age at which our previous dose-response studies had been done.

These results suggest that functional innervation to the juxtaglomerular cells of the kidney matures very late in development when compared to the onset of functional sympathetic nervous system innervation to other target organs, such as the heart and the adrenal medulla.

337.6 PARASYMPATHETIC REGULATION OF THE HEART IN DIABETES. G.O. Carrier and R.S. Aronstam. Department of Pharmacology and Toxicology, Medical College of Georgia, Augusta, GA 30912.

Atria isolated from rat rendered diabetic by exposure to streptozotocin (STZ) are supersensitive to muscarinic agonists (J.Mol. Cell.Cardiol. 16:963, 1984). To further define the nature of this change, the following measurements were made in spontaneously-beating right atria and electrically-stimulated left atria isolated from short-term (10-12 weeks) STZ-diabetic and age-matched control rats: 1) The influence of agonists on chronotropic and inotropic properties, 2) muscarinic receptor number and binding properties, 3) acetylcholinesterase activity, and 4) high affinity [$^3$H]choline uptake.

Atria from STZ-diabetic rats were supersensitive to the negative chronotropic actions of acetylcholine, carbamylcholine and bethanechol. There was no difference, however, in the sensitivity of electrically-stimulated left atria to the negative inotropic actions of the three agonists (Table).

Physiological Responses to Muscarinic Agonists, EC50 Values in uM

| | Chronotropic | | Inotropic | |
|---|---|---|---|---|
| Agonist | Control | Diabetic | Control | Diabetic |
| Acetylcholine | 210 | 15 | 0.41 | 0.28 |
| Carbamylcholine | 0.62 | 0.16 | 0.18 | 0.10 |
| Bethanechol | 10 | 4.6 | 3.0 | 3.2 |

Acetylcholinesterase levels in the right atria from STZ-diabetic rats were lower than in controls (3.59±0.28 vs 5.73±0.83 nmoles/mg protein/min; $p<.05$, N=12). This reduction was accompanied by a 30% decrease in the number of [$^3$H]QNB binding sites. In contrast, there was no change in acetylcholinesterase levels in left atria from STZ-diabetic and age-matched control rats (3.2±0.3 vs 3.8±0.5 nmoles/mg protein/min, respectively).

Uptake of [$^3$H]choline was measured in strips of freshly dissected left and right atria. Neuronal uptake of choline in both right and left atria was not changed in diabetes. Hemicholinium-3 inhibited 39±6% of the uptake in control right atria compared to 41±4% in STZ-diabetic rats. Similarly, in left atria 46±3% and 46±5% of choline uptake could be inhibited by hemicholinium-3 with tissues from control and STZ-diabetic rats, respectively.

These results indicate that cholinergic regulation of heart rate, but not contractility, is altered in the early stages of diabetes. The postganglionic parasympathetic system appears to be intact at this stage of the disease process insofar as choline uptake is not altered. The enhanced sensitivity of right atrium to cholinergic agonists may be related to changes in postsynaptic receptor transduction mechanisms.

Supported by the Georgia Heart Association and HL-31518.

337.7 DEVELOPMENT OF LOW-FREQUENCY VARIATION IN HEART RATE OVER THE FIRST 6 MONTHS OF LIFE DURING SLEEP STATES. V.L. Schechtman, Z. Frostig*, and R.M. Harper. Neuroscience Program, Department of Anatomy, and the Brain Research Institute, UCLA, Los Angeles, CA 90024.

A prominent feature of infant heart rate is rhythmic variation at frequencies of .07 to .12 cycles/sec (periods of approximately 8 to 14 seconds). A variety of mechanisms have been suggested to underlie the source of this low-frequency variation, including circulation time and alterations in blood pressure. Sleep states, particularly REM sleep, dramatically alter blood pressure and peripheral and visceral blood flow. We thus studied state-related influences on low-frequency heart rate variation. Because cardiovascular dynamics change markedly with age, particularly over the first 3 months, we examined developmental characteristics of low-frequency variation in cardiac R-R intervals over the first 6 months of life.

Twenty-five normal infants were polygraphically recorded for determining sleep and cardiac parameters at 1 week and at 1, 2, 3, 4, and 6 months of age. Variations in heart rate were extracted from R-R intervals by a peak/trough detection algorithm (Frostig, Z., et al., Soc. Neurosci. Abs., 1985) and variations with periods ranging from 8.3 to 14.3 seconds were examined. The median amplitude of this variation was determined for each minute, and the median of these values was calculated for quiet sleep (QS) and REM sleep for each age.

The amplitude of low-frequency heart rate variation showed a pronounced drop at 1 month in both QS and REM. That decline, however, was largely dependent on the concomitant rise in heart rate. Overall heart rate greatly affected the amplitude of variation, especially after 1 week. After partitioning heart rate contributions, covariance analysis revealed that the amplitude of variation was higher in REM than in QS at every age, and gradually declined with age during REM.

The extent of low-frequency heart rate variation is altered by many factors, including development, sleep state, and heart rate.

337.8 TYROSINE HYDROXYLASE ACTIVITY IN ADRENAL AND HEART: EFFECTS OF PARTIAL DAMAGE AND STRESS. G.L. Snyder*, S.J. Fluharty*, L.E. Rabow*, E.M. Stricker, and M.J. Zigmond. Psychobiology Program and Center for Neuroscience, Univ. of Pittsburgh, Pittsburgh, PA 15260. (Spon: David C. Wood)

Adrenal tyrosine hydroxylase (TH) activity is elevated by stress and by partial damage to sympathetic nerves. Increased TH activity probably functions to couple catecholamine (CA) synthesis with increased demands for adrenal CA secretion under both conditions. In the present experiments, we studied the impact of unilateral adrenalectomy (UAX) on TH activity in the remaining adrenal medulla and cardiac sympathetic nerves during stress.

Four days after UAX in adult male Sprague-Dawley rats, adrenal TH activity was found to be significantly elevated (by 44%). 6-Hydroxydopamine (6-HDA) treatment (100 mg/kg, s.c.), which by itself increased TH activity by 68%, raised it by 112% in rats with UAX. As indicated in the Table below, there was a further increase in TH activity when rats either were exposed to cold (4 days at 4°C) or were given 20 U/kg insulin and killed 1 hr later.

The TH activity of cardiac sympathetic nerves also was elevated by UAX (by 43%), and it was further increased by cold and insulin treatments (see Table). Denervation of the contralateral adrenal gland abolished the effect of UAX on adrenal TH activity but had little additional effect on basal cardiac TH activity, although it did have an additive effect on cardiac TH activity when UAX rats were exposed to chronic cold stress. These results illustrate that CA synthesis is elevated both in adrenal medulla and sympathetic nerves after UAX, as after subtotal damage to the sympathetic nerves, presumably in response to some functional consequence of the loss of circulating CA. Nevertheless, the capacity for CA synthesis can be raised still further by stress.

TH Activity (% basal control)

| | ADRENAL | | CARDIAC | |
|---|---|---|---|---|
| | Cold | Insulin | Cold | Insulin |
| Control | 193 ± 10 | 135 ± 11 | 170 ± 17 | 132 ± 7 |
| UAX | 250 ± 5 | 198 ± 5 | 173 ± 10 | 176 ± 14 |
| 6-HDA | 267 ± 11 | 202 ± 6 | | |
| UAX + 6-HDA | 434 ± 5 | 293 ± 12 | | |

337.9 THE EFFECTS OF NEONATAL GUANETHIDINE TREATMENT ON THE ADRENAL MEDULLA OF THE RAT. L.L. Ross, A. Pylypiw*, L. McCarthy* and L. Cosio*. Dept. of Anatomy, The Medical College of Pennsylvania, Philadelphia, PA 19129.

Chronic administration of guanethidine to some strains of developing rats during the first 3 weeks of life has been reported to produce a total and irreversible destruction of sympathetic postganglionic neurons. Both parasympathetic postganglionic neurons and adrenal chromaffin cells are apparently unaffected by this treatment. We have previously shown that accompanying this peripheral loss is a parallel loss of preganglionic neurons in the thoracolumbar spinal cord. Since the same pool of spinal cord neurons provides preganglionic innervation to sympathetic neurons and to the adrenal medulla, we examined the effects of chronic guanethidine treatment on the adrenal medulla and its preganglionic innervation.

Guanethidine (50mg/kg/day) was administered to neonatal Sprague-Dawley rats 5 days/week for 3 weeks starting at 3 days of age. The degree of sympathectomy at 25 days of age was shown by the absence of norepinephrine (NE) in the spleen and in the heart while gut levels of NE were reduced to 15% of control values. On the other hand, adrenal levels of NE and epinephrine (E) were 50% and 25% greater than controls, respectively. The degree of hyperactivity of the adrenal medulla was further demonstrated by the observation that plasma NE levels were down by only 15%. Normally, the adrenal medulla provides only 10% of the circulating NE. Although adrenal choline acetyltransferase (CAT) was elevated by 40% in the sympathectomized animals, there was no increase in the numbers of preganglionic neurons projecting to the adrenal medulla as determined by true blue retrograde labeling. The most striking response to neonatal guanethidine treatment is by the adrenal chromaffin cell itself, whose mitotic activity was 5x that of controls, resulting in a 75% increase in the number of chromaffin cells at 25 days of age. This increase is not accompanied by a significant increase in the size of the adrenal medulla. Thus, the adrenal medulla compensates for the guanethidine destruction of sympathetic neurons by cell proliferation and increased synthesis of NE and E. This is accomplished without any enhancement of central innervation, an indication of the great degree of plasticity of the developing chromaffin cell and its ability to compensate for decreased circulating levels of NE.

337.10 LOSS OF $Ca^{2+}$ SENSITIVE $K^+$ CONDUCTANCE MAY INCREASE $Ca^{2+}$ INFLUX INTO AXOTOMIZED SYMPATHETIC NEURONES. M.E.M. Kelly*, J. Shapiro*, T. Gordon & P.A. Smith. Department of Pharmacology, University of Alberta, Edmonton, Alberta, Canada, T6G 2H7.

Neuronal cell bodies undergo various physiological changes following section of their axons. These changes may be related to the neurones ability to regenerate and re-innervate its target organ. Transection of the axons of soleus motoneurones results in shortening of the action potential after-hyperpolarization (AHP, Kuno et al. J. Physiol 240, 725, 1974). We used standard intracellular recording techniques to test whether axotomy produced similar changes in another neuronal type; B cells in bullfrog sympathetic ganglia. As in slow motoneurones, the duration of the antidromically evoked action potential AHP was reduced from 147.6±15.1 msec (n=27) to 47.2±2.4 msec (n=47), 14-47 days after section of the post-ganglionic nerve. The amplitude of the response was reduced from 29.5±0.7 mV (n=27) to 18.2± 0.8mV (n=47). In addition, the duration of the action potential was increased from 3.4±0.1 msec (n=24) to 4.4±0.2 msec (n=47). All changes were significant ($P<0.001$). The $Ca^{2+}$ channel blockers $Cd^{2+}$ (200 μM) or $Mn^{2+}$ (10 mM) produced similar effects by blocking the $Ca^{2+}$ sensitive $K^+$ conductance(s) ($g_{K,Ca}$) which underlie part of the AHP and which may also contribute to the repolarization of the action potential (Adams et al. Nature 296, 746, 1982, MacDemott & Weight, Nature 300, 185, 1982). $Cd^{2+}$ or $Mn^{2+}$ did not shorten the AHP of axotomized cells. Despite this, $Ca^{2+}$ spikes could be evoked in these cells in the presence of 10 mM TEA/2 μM TTX. This implies that $Ca^{2+}$ channel function was preserved after axotomy but the $g_{K,Ca}$ which underlies part of the AHP may be lost. Such a response to axotomy might be expected to enhance $Ca^{2+}$ influx as a result of spike broadening (cf MacDermott & Weight, Nature 300, 185, 1982). Increased intracellular $Ca^{2+}$ could then activate further processes which may be related to regeneration.

337.11 DEVELOPMENTAL REGULATION OF NEURON NUMBER IN A PARASYMPATHETIC GANGLION. R. David Heathcote and Peter B. Sargent. Department of Cell Biology, Stanford University School of Medicine, Stanford, CA. 94305.

The regulation of neuronal number is presumed to play a role in the matching of populations of neurons with their targets. Little is known about the mechanisms which regulate the proliferation and death of neurons and thus control their number. We have studied the regulation of neuronal number in an autonomic ganglion whose neurons are generated over an extended period of time and do not undergo detectable cell death. The cardiac ganglion of the frog Xenopus laevis is derived from the embryonic neural crest. Differentiated neurons can be selectively stained for acetylcholinesterase and begin to appear in the heart during embryogenesis. Approximately 30 neurons are present at the end of the first week of development and approximately 1300 are present in the adult. The prolonged period of neuron addition has allowed the use of various manipulations designed to examine the regulation of neuronal number.

One possible regulative mechanism is that the increase in neuron number is controlled by an internal clock such that a defined number of neurons is added at regular intervals. However, by raising animals of the same chronological age under different conditions, it is possible to introduce as much as a three-fold difference in neuronal number. Those animals with more neurons are developmentally more advanced and larger than their siblings. To distinguish between developmental stage and size, animals were arrested at a particular developmental stage by blocking thyroxine production with propylthiouracil. These animals continue to increase in size, and the number of neurons in their cardiac ganglia increase many-fold until the approximate number of adult neurons is attained. Thus neither a chronological or developmental clock times the addition of neurons to the ganglion. However the above results are consistent with animal and target size playing a role in the regulation of neuronal number.

During development the size of cardiac neurons changes as well as their number. Between one week of development and the end of metamorphosis, the average size actually decreases due to the addition of many small neurons. As postmetamorphic adults increase in size, their neurons also get larger. Animal size increases by over four orders of magnitude and is highly correlated with the product of neuronal size and neuronal number. The relationship is a power function of the form $y=bx^m$ and allows one to predict the total neuronal volume of a ganglion if the size of the animal is known.

The growth of the cardiac ganglion can be divided into three overlapping segments. First, a dowry of neurons is provided by the neural crest. Second, neurons are added to the ganglion. This addition is correlated with the size of the animal and its target and does not occur at specific times or developmental stages. Third, once the adult number of neurons is reached, neurons increase in size. In all three phases, the relationship between total neuronal volume and the size of both the target tissue and the animal is maintained.

337.12 CATECHOLAMINERGIC INNERVATION OF THE PANCREAS IN THE AGED MOUSE: PRELIMINARY OBSERVATIONS. B.J. Davis, J.A. Orsini* and T.H. McNeill. Department of Neurology, University of Rochester School of Medicine and Dentistry, Rochester, NY 14642.

Pancreatic islets are innervated by autonomic nerve fibers that may play a role in maintaining islet function and growth. The purpose of the present study was to determine whether normal islet innervation patterns are maintained during senescence using the C57BL/NNia mouse as an animal model.

Pancreata were obtained from five 6-month-old (young adult) and six 30-month-old (senescent) male mice. Samples of the head, body and tail of the pancreas were fixed in Bouin's fluid then dehydrated and embedded in a single paraffin block. Serial 4 um sections obtained at 200 um intervals through the tissue block were stained for immunocytochemical localization of insulin (B), glucagon (A), somatostatin (D) and pancreatic polypeptide (PP) cells using the avidin-biotin (Vectastain) method. Additional samples of pancreas from each animal were processed for catecholamine histofluorescence using the sucrose-phosphate-glyoxylic acid (SPG) technique. Tissues from young and senescent animals were processed concurrently to minimize variability due to differences in handling.

Morphometric analysis revealed that when compared with young adult mice, the senescent mice showed an increase in the total amount (volume density) of islet tissue in the pancreas. While the quantitative relationships of the A, B, D and PP cells were similar between the two age groups, senescent mice tended to show an increase in the relative proportion of B cells within the islets. Fluorescence histochemical analysis revealed a striking increase in autofluorescent lipofuscin-like material associated with the cytoplasm of exocrine and endocrine cells in the pancreas of senescent mice. Lipofuscin-containing neuronal perikarya also were seen in the senescent, but not in the young pancreas. Catecholamine-containing nerve fibers appeared coarser and more intensely fluorescent and were more densely distributed in some areas of the senescent pancreas.

These preliminary results suggest that catecholaminergic innervation of the pancreas shows considerable plasticity, but is well maintained during aging.

338.1 MOTOR INNERVATION OF CAT'S DIAPHRAGM: RELATION TO VOMITING. L.K. Tan and A.D. Miller. Rockefeller University, NY, NY 10021.

Vomiting is primarily produced by co-ordinated action of the respiratory muscles. Most of the diaphragm contracts during both retching and expulsion; however, the region around the esophagus is virtually inactive during expulsion, thereby facilitating rostral movement of gastric contents (2). We report our studies of (i) localization of motoneurons supplying these different regions of the diaphragm, including an extra-phrenic innervation, and (ii) the functional significance of this extra-phrenic motor innervation.

Horseradish peroxidase was injected into the diaphragm within 0.7 cm of the esophagus in 2 cats (35-50 µl of 30% HRP), using Nembutal anesthesia and aseptic procedures. Four days later, the animals were sacrificed and tissue reacted with TMB. Labeled motoneurons were found bilaterally over a widespread region from caudal C4-rostral C7 and from T5-L1. Injections (65 µl) into the region of the diaphragm that is active during expulsion (> 1 cm from the cat's esophagus) in a third animal resulted in labeled motoneurons from caudal C4-rostral C7 and from T2-L1. More labeled neurons were observed in the thoracic cord than in the phrenic pool. Control injections were made in the thoracic (10 µl) and abdominal cavities (20-55 µl) in 2 cats to ensure that thoracic labeling was not due to spread of HRP.

In a separate series of experiments involving decerebrate cats, EMG electrodes were sewn into different regions of the diaphragm, and nerve activity was recorded from the contralateral C5 phrenic nerve and upper lumbar abdominal nerves. Vomiting was produced by electrical stimulation of the sub-diaphragmatic vagus nerve (1). Latencies to expulsion averaged somewhat less than 1 min. After cutting all phrenic nerves at the cervical level in 2 cats, respiratory-related diaphragmatic EMG activity was abolished or greatly reduced; remaining EMG activity could be either inspiratory, expiratory, or phase-spanning (cf.3). In contrast, latencies to expulsion were virtually unchanged, and the diaphragm continued to be phasically activated during vomiting, at 20-80% of its amplitude prior to phrenic nerve section.

These studies reveal a large motor innervation of the diaphragm from thoracic levels and show that these thoracic motoneurons can participate in the control of the diaphragm during vomiting.

338.2 ELECTRICAL STIMULATION IN THE EXTERNAL CUNEATE NUCLEUS: EFFECTS ON RESPIRATION. C. Dean* and D.R. Kostreva (SPON: J.P. Kampine) Dept. Anesth., Med. Col. Wis. and VAMC, Wood, WI 53193

[$^{14}$C]2-deoxyglucose studies have suggested that the external cuneate nucleus is involved in cardiovascular control (Kostreva Physiologist 26:333-350,1983). Recent experiments in anesthetized cats in our laboratory have shown that electrical stimulation within the external cuneate nucleus can evoke profound changes in arterial blood pressure, heart rate, efferent renal and cardiopulmonary sympathetic nerve activity (Dean & Kostreva Fed. Proc. 44: 1029 (3616), 1985). Such stimulation can also elicit changes in respiration. Experiments were carried out on spontaneously breathing cats anesthetized with sodium pentobarbital (Nembutal 35 mg/kg i.v.) in which arterial blood pressure, heart rate and the electromyography of the diaphragm were recorded. Electrical stimulation was effected using indium/ Woods metal filled glass microelectrodes, with a tip diameter of 10-20 um. The stimulus parameters were 50 uA, 0.1 ms duration, 5-100 Hz. Stimulation of localized sites within, and immediately adjacent to the external cuneate nucleus could increase the duration of inspiration, the duration of expiration and the depth of inspiration. These effects were observed simultaneously with the pressor or depressor responses, in addition to the bradycardia or tachycardia previously identified during external cuneate nucleus stimulation. At some sites respiratory responses lasted three times longer than did the cardiovascular responses. The evoked responses were frequency dependent as decreasing this stimulus parameter could change the response elicited, for example, from an increased expiratory period and diminished depth of inspiration to an inspiratory apnea. Stimulus sites were subsequently identified histologically. These results indicate that in addition to an involvement in cardiovascular control, the external cuneate nucleus may also be involved in the control of respiration. Considering the generally accepted view that the external cuneate nucleus is a system for transmission of information from the forelimbs and trunk to the cerebellum, perhaps a further role for this nucleus is in the mediation of somato-autonomic and somato-respiratory reflex responses in such circumstances as exercise. (Supported by NIH Grants HL27968, NS18037, RCDA HL00959, and the VA).

338.3 MEDULLARY BULBOSPINAL EXPIRATORY NEURON RESPONSE TO INTERCOSTAL MUSCLE TENDON ORGANS. R. Shannon, D.C. Bolser* and B.G. Lindsey. Dept. Physiology, Col. Med., Univ. So. Florida, Tampa, FL 33612.

Previous studies from this laboratory provided evidence that external and internal intercostal muscle tendon organs have (a) a generalized inhibitory effect on medullary dorsal and ventral respiratory group inspiratory neurons driving the inspiratory muscles (diaphragm, intercostals and laryngeals), and (b) an augmenting effect on medullary expiratory laryngeal motoneurons. The objective of this study was to determine the effects of intercostal tendon organs on ventral respiratory group expiratory neurons which control expiratory intercostal and abdominal muscle activity.

Studies were conducted on decerebrate, vagal intact and vagotomized, mechanically ventilated cats (six). Tendon organs in the T6 intercostal muscles were stimulated by impeded muscle twitches, elicited by electrical stimulation of the peripheral end of cut T6 ventral roots (VRS). The T6 space was surgically separated from adjoining spaces and all muscles other than those being studied were denervated. Medullary expiratory neurons were extracellularly recorded from the caudal ventral respiratory group (below obex) and identified as bulbospinal by antidromic stimulation (positive collision test) of the cord at T1. Phrenic efferent activity was also monitored. The strength of the impeded twitches was adjusted by VRS to produce the maximum change in phrenic activity (transient reduction or complete termination), and then the response of expiratory neurons was determined. Impeded twitches during the expiratory phase caused a transient reduction in firing rate in 17 of 33 E-neurons (8/17 were identified as bulbospinal).

Combining these results with previous studies on expiratory neurons, in which electrical stimulation of intercostal nerve Group I and II afferent fibers showed similar effects and muscle spindle ending stimulation by vibration had no effect on medullary respiratory activity, we conclude the following about external and internal intercostal tendon organs: (1) They can reduce the activity of some medullary bulbospinal expiratory neurons, and at the same time extend the duration of the expiratory phase. (2) They have different effects on the medullary control of expiratory laryngeal muscles and expiratory bulbospinal neurons. (Supported by NIH Grant HL-17715).

338.4 EFFECTS OF LESIONS OF NUCL. PARABRACHIALIS MEDIALIS AND OF BARBITURATE ON PHRENIC AUGMENTATION RATE AND PHRENIC FACILITATION BY LUNG INFLATION. W.R. See*, M.I. Cohen and A.L. Sica*. Dept. of Physiology, Albert Einstein College of Medicine, Bronx, NY 10461.

Phrenic augmentation rate and the degree to which it is facilitated by lung inflation is dependent on central nervous system state. We have recently demonstrated that elevation of $CO_2$ tends to increase the excitatory effect of lung inflation on phrenic discharge (Fed. Proc. 44(5): 1586, 1985). In the present series we investigated the influence of unilateral lesions of the Nucl. parabrachialis medialis (NPBM) and of small i.v. doses of pentobarbital (1.8-2.6 mg/kg) on the phrenic response to lung inflation. Experiments were performed in unanesthetized, paralyzed, decerebrate cats ventilated by a cycle triggered pump. The effects of lung inflation on the magnitude and augmentation rate (slope) of phrenic activity were ascertained by comparison of activity during equivalent time periods in inflation (control) vs. no-inflation (test) inspiratory phases under different conditions (low and high $CO_2$, pre- and post- pontine lesion, and pre- and post- barbiturate). The effects of lung inflation were classified as facilitatory (+), depressant (-), or not significant (0), using the ratios of phrenic activity and slope between test and control cycles. Barbiturate or unilateral lesions of the NPBM reduced the slope of phrenic activity in both inflation and no-inflation cycles but to a lesser extent in no-inflation cycles, which resulted in a reduction or complete disappearance of the (+) response and in some cases the conversion of a (0) response into a (-) response. In conclusion, in contrast to the effect of $CO_2$, which increases the excitability of the inspiratory ramp generator to lung receptor inputs, barbiturate or lesions of the NPBM reduce this excitability.

338.5 EVIDENCE FOR MECHANISMS OF ACTIVATION AND ANALAGOUS ACTIONS OF DECREMENTING VENTRAL RESPIRATORY GROUP NEURONS AT INSPIRATORY AND EXPIRATORY PHASE TRANSITIONS. L.S. Segers*, R. Shannon, and B.G. Lindsey (SPON: S. Saporta). Dept. Physiol., Univ. South Florida Med. Ctr., Tampa, FL 33612

Data from this laboratory (1) are consistent with the idea that E/IE cells with decrementing activity in the E phase play a role in I-E phase switching and in control of augmenting E neuron activity. Here we report additional observations in support of this hypothesis, data consistent with the hypothesis that decrementing early I cells serve analagous functions at the E-I phase transition and in control of augmenting I activity, and additional data relevant to the mechanisms contributing to the activation of these cell types. Methods were as described elsewhere (1); responses of cells to vagal or internal intercostal ($T_7$) nerve stimulation were noted in some cases. The stimulation studies support the idea that E/IE cells help to control the ramp of augmenting E activity via inhibitory effects on augmenting E cells (1): both an increase in E/IE and a decrease in augmenting E cell activities have been observed following vagal stimulation late in the I phase. Cycle triggered histograms (CTHs) show that the average time course of the decline in rate of a decrementing early I cell is the reciprocal of that of the average rate increase of simultaneous phrenic efferent activity. Cross-correlograms (CCHs) and CTHs generated for simultaneously recorded augmenting E and decrementing early I cells show that activities of these two cell types may overlap, a finding consistent with the hypothesis that decrementing early I cells may contribute to the termination of the E phase by inhibiting augmenting E cells. CCHs consistent with inhibition of augmenting I cells by decrementing early I cells and with excitation of decrementing early I cells by EI cells were also obtained. CTHs generated for sequentially recorded neurons in apneustic animals indicate that the durations of the E phase and decrementing early I cell activity can be independent of the duration of the I phase and support the idea that E/IE cells receive inhibitory inputs throughout the I phase (1). E/IE cells are silent during the first part of the I phase, corresponding to decrementing early I cell activity, after which they are active at a low rate until the I-E phase transition. Furthermore, vagal stimulation during the I phase can inhibit phrenic activity before E/IE cell activity increases. Finally, cycle triggered scatter diagrams generated for simultaneously recorded decrementing E cells show that the cells are most strongly synchronized at the start of the E phase. This is consistent with coincident disinhibition. In summary, our data support the hypothesis that decrementing I and decrementing E cells each contribute to the termination of the preceding phase of the cycle and are involved in the development of augmenting respiratory neuron activity in their respective phases. Reference: 1. Lindsey, B.G., et al., these proceedings. Support: NIH Grant NS19814.

338.6 FUNCTIONAL ASSOCIATIONS AMONG VENTRAL RESPIRATORY GROUP (VRG) NEURONS IN THE CAT. IMPLICATIONS FOR CENTRAL PATTERN GENERATION. B.G. Lindsey, L.S. Segers*, and R. Shannon. Dept. Physiol., Univ. South Florida Med. Ctr., Tampa, FL 33612

Interactions among brainstem respiratory neurons are believed to be necessary for respiratory rhythmogenesis. However, these associations are not well understood. We have reported (1) evidence for functional interactions among various types of VRG (region of n. ambiguus, n. retroambigualis, retrofacial n.) neurons based on spike train correlation methods. Proposed interactions included: 1. excitation of bulbospinal (b.s.) $I^{\dagger}$ neurons by propriobulbar (p.b.) I cells, 2. inhibition of p.b.E/IE cells by decrementing p.b.I cells, 3. inhibition of I/EI cells by some E/IE cells, and 4. excitation of augmenting E cells by other E/IE cells. Here we report further associations among ipsilateral VRG cells. Cats (n=31) were anesthetized, paralyzed, vagotomized and artifically ventilated. VRG neurons were recorded with 4-6 tungsten electrodes. Phrenic efferent activity was monitored. Cycle triggered histograms were generated; most neurons were tested for spinal and vagal projections by antidromic stimulation methods. 467 pairs of neurons were analyzed; 16% were correlated in a manner indicative of cross-connections or shared inputs. Cross-correlograms suggesting the following additional associations were obtained: 1. excitation of p.b.I cells by p.b.I/EI cells, 2. inhibition of p.b. augmenting E cells by p.b.E/IE cells and 3. inhibition of E cells by tonic cells. These and other data from this laboratory (1,2,3) provide evidence for network interactions which could play a role in central pattern generation. Working hypotheses include: 1. E/IE cells inhibit inspiratory drive late in the I-phase as their activity increases due to reduced decrementing I cell activity, (i.e., disinhibition), which in turn may be due to central and afferent mechanisms operating in parallel. 2. E/IE cells also inhibit augmenting E cells. 3. The inhibitory actions of E/IE cells decline during the E-phase, promoting augmenting E cell activity and eventually releasing EI and I cells from inhibition. 4. P.b.I/EI cells drive p.b. I cells, some of which may drive b.s. pre-motor neurons.

$^{\dagger}$Phase of maximum firing rate: I=inspiratory, E=expiratory. Phasic cells active during more than one phase have second descriptor, e.g., E/IE denoting phase transition during discharge.

338.7 CHARACTERISTICS OF VAGAL AFFERENT CONTROL OF THE DISCHARGE PATTERNS OF MEDULLARY RESPIRATORY NEURONS. E.J. Zuperku* and F.A. Hopp*. (SPON: J. Seagard). Dept. of Anesth., Med. Col. Wisc. and the VAMC, Wood, WI 53193.

The central processing of vagal afferent input patterns which play a role in the control of breathing was studied by analyzing the responses of individual respiratory neurons to these inputs. Unit recordings were obtained from both inspiratory (I) and expiratory (E) neurons in the medulla of halothane anesthetized, paralyzed, artifically ventilated, bivagotomized dogs. Phrenic nerve activity was used as a timing reference and to measure I and E phase durations($T_I$ & $T_E$). Electrical activation of the largest vagal A fibers was used to alter $T_I$ and $T_E$ and present various temporal input patterns to I and E neurons. Discharge patterns were quantitated using cycle triggered histograms (CTHs). The net neuronal response to vagal input patterns was measured as the difference between input ($H_s$) and no input (control, $H_c$) CTHs or $H_d=H_s-H_c$. In the majority of neurons, the following observations, which are independent of type (I or E) and pattern (augmenting or decrementing), were made: 1) the difference histogram ($H_d$) is zero at the onset of the input and is either a monotonically increasing or decreasing function of time; 2) for I-neurons, the step response time from onset of stimulus to 90% of max response was greater than 300 msec; for E-neurons, this response time was greater than 1 sec.; 3) the vagal pulse-to- spike interval histograms show no or a small, broad, delayed increase in the probability of neuronal firing; 4) among neurons the shape of the $H_d$ time-course appears not to be consistent, varying from convex-to-linear-to-concave. In a given neuron the shape varies with step frequency; 5) plots of $H_d$ vs $H_c$ or $H_s$ appear to be linear with r>.8; this implies that: $H_s=\beta \cdot H_c+\alpha$ (where $\beta$ is slope, $\alpha$ is intercept); 6) for a given step input, the time course of $H_c$ and $H_s$ can be predicted from that of $H_d$ with a mean error of less than 10%; and 7) for graded shortening of $T_I$ by step vagal inputs, the plots of $(1/\beta)$ vs $T_I$ are linear. A similar relationship appears to exist for $T_E$. In conclusion, the vagal modulation of respiratory neuronal discharge patterns appears to be directly related (proportional) to the time-course of the control (no input) discharge pattern. This modulation appears to be mediated via the phase timing mechanisms. In addition, these results suggest a possible multiplicative interaction involved with the vagal control of phase timing. (Supported by the VA Medical Ctr.)

338.8 POSSIBLE SITES FOR TACHYPNEIC ACTION OF THYROTROPIN RELEASING HORMONE (TRH)

Hedner*, J.A., McCown, T.J., Mueller, R.A., Breese, G.R. Departments of Anesthesiology, Pharmacology and Biological Science Research Center, University of North Carolina, Chapel Hill, N.C., 27514 and Department of Clinical Pharmacology, Sahlgrens Hospital, Göteborg, Sweden.

Thyrotropin releasing hormone (TRH) has previously been shown to possess potent respiratory stimulating properties (1,2). The tachypnea following intracerebroventricular (i.c.v.) TRH administration produces both a shortening of the inspiratory time and an increase in respiratory frequency. Recently we have shown that the raphe obscurus in the rat medulla is a very sensitive locus for TRH-induced shortening of inspiratory time. The tachypneic response can be blunted by decerebration at the collicular level of unanesthetized rabbit pups (3). We have now attempted to localize sites rostal to the collicular level which are associated with the tachypneic response to TRH in halothane anesthetized rats.

Cannulae guides were implanted at least 48 hours prior to the experiments. Arterial blood gas tensions, blood pressure, heart rate and ventilatory parameters were continuously determined during the experiment. TRH was administered i.c.v. (0.5-5µg/15µl) or locally (100ng/0.5µl). Local injection of TRH (100ng) did not reduce Ttot after injection into the raphe nuclei, the septal region, cerebral cortical areas, cerebellum, amygdala, n. accumbens, or lateral ventricle. However, injection of TRH (100ng) into the posterior hypothalamus, the interpeduncular nucleus and to a lesser extent the habenula nuclei resulted in a tachypneic response similar to that seen somewhat later after i.c.v. administration of higher doses of TRH (1µg). Blood pressure and heart rate changes were small and slight with decreases as well as increases seen.

The present results indicate that the tachypneic response seen after i.c.v. TRH administration to rats involves diencephalic sites. Increased ventilation following activation of these sites might be closely related to the well known arousal effects of TRH. The respiratory stimulating effect after excitation of the ventricular activating system by hypothalamic electrical stimulation (see e.g.[4]) might be of a similar nature.

338.9 SEROTONIN-MEDIATED EXCITATION OF RECURRENT LARYNGEAL NERVE MOTONEURONS ELICITED BY STIMULATION OF THE RAPHE OBSCURUS. J.R. Holtman, Jr., T.E. Dick, and A.J. Berger. Dept. of Physiology and Biophysics, Univ. of Washington Sch. of Med., Seattle, WA 98195.

Evidence is available suggesting that serotonin and the raphe nuclei may be involved in central respiratory control. Serotonin is present within nuclei known to be involved in respiratory control (Steinbusch, Neuroscience 6: 557, 1981; Maley and Elde, Neuroscience 7: 2469, 1982; Holtman et al., J. Neuroscience 4: 1064, 1984) and stimulation of the raphe nuclei affects overall ventilation (Sessle et al., Brain Res. 216: 145, 1981; Holtman et al., Soc. Neurosci. Abstr. 10: 708, 1984). We have previously investigated the effects of electrical stimulation of the raphe obscurus (RO) and raphe pallidus (RP) on short-latency averaged responses in the phrenic nerves. Stimulation within the RO produced a delayed excitatory response that was reduced by methysergide, a serotonin receptor antagonist (Fed. Proc. 44: 1585, 1985). In the present study, we have extended this work to examine the effects of stimulation of the RO and RP on short-latency averaged responses in the recurrent laryngeal nerve (RLN) and determined if the elicited responses involved serotonin.

Recurrent laryngeal nerve activity was recorded in nine chloralose-urethane (30 and 150 mg/kg) anesthetized, paralyzed (gallamine, 5 mg/kg/hr) and artifically ventilated cats (2-4 kg). Electrical stimulation (2.5-80 μA, 5-80 Hz, 150 μs pulse duration) of the RO and RP was performed using monopolar electrodes. The short-latency responses in the RLN were processed using signal averaging techniques (40 μs/bin, 1024 bins, 200 sweeps).

Analysis of the post-stimulus triggered averages revealed a maximal excitatory response in the RLN produced by stimulation within the RO. The latency to onset for this response was 6.0±0.3 ms. The latency to the peak of this response occurred at 7.8±0.4 ms. This excitatory response was present when the stimulation of the RO was performed during inspiration as well as during expiration. The magnitude of the excitatory response was directly related to current intensity and was also dependent upon stimulus frequency. The threshold stimulus current was 5 μA. Intravenous administration of methysergide (0.1-1.2 mg/kg) resulted in a dose-dependent reduction in the magnitude of the excitatory response.

These results demonstrate that stimulation within the RO produces an excitatory response in the RLN, which is mediated in part by the activation of a serotonergic pathway. The characteristics of the excitatory response in the RLN and the delayed excitatory response in the phrenic nerves are similar. Both responses were: 1) dependent upon stimulus current and frequency, 2) elicited by stimulation during inspiration and expiration and 3) reduced in magnitude by methysergide. 338.10 ACUTE NERVE AGENT TOXICITY: TIME-COURSE OF RESPIRATORY AND CARDIOVASCULAR EFFECTS. E.T. Beers*, J.F. Glenn, B.L. Perrone*, C. Opalka*, and D.L. Rickett (SPON: R. Ray) Neurotoxicology Branch, US Army Medical Research Institute of Chemical Defense, APG, MD 21010-5425.

While respiratory failure is the common end-point of acute poisoning by organophosphate compounds, the respiratory and cardiovascular systems experience a variety of toxic symptoms prior to respiratory arrest. In the present study, four organophosphate nerve agents (soman, sarin, tabun, and VX) were compared to identify the relative significance of their toxic effects on the central and peripheral nervous system components of the respiratory system and on selected cardiovascular variables. Using DIAL (70 mg/kg, IP) anesthetized cats, recordings were made of i) medullary respiratory-related unit activity, ii) phrenic nerve activity, iii) diaphragm electromyographic activity (EMG), iv) diaphragm contractions, v) airflow, vi) femoral arterial pressure, and vii) electrocardiographic activity; also blood gases and expired $CO_2$ were monitored. The agents were infused at the rate of 1 $LD_{50}$ per 15 minutes until cessation of spontaneous respiration, at which time the phrenic nerve was stimulated supramaximally to test diaphragmatic contraction. Agent infusion then was resumed at 3 times the initial rate, while diaphragm contraction was tested periodically. Of the variables recorded, respiratory-related unit activity is the most sensitive indicator of agent-induced respiratory distress. Unit activity consistently becomes disrupted prior to changes in the other variables. This is followed by changes in phrenic nerve activity, diaphragm EMG, respiratory rate, airflow and heart rate. In addition, blood pressure frequently exhibits a biphasic response, with an increase in pressure followed by a decrease to below control values just prior to respiratory arrest. Moreover, cessation of spontaneous respiration precedes cardiovascular collapse, even though the animal's cardiovascular system becomes increasingly compromised. At the time of respiratory arrest, arterial blood pressure is 82% of control for soman, 74% for tabun, 55% for sarin, and 48% for VX. Similar effects are seen for heart rate. However, the diaphragm muscle still contracts tetanically when challenged with a 100 Hz train of 2 msec pulses for 500 msec at the time of respiratory arrest. Therefore, loss of central respiratory drive results in respiratory failure. Our findings support previous studies in barbiturate-anesthetized animals showing that the central nervous system is most sensitive to nerve agent intoxication and that agent-induced respiratory arrest results from loss of central respiratory drive (de Candole et al., 1953).

338.11 PHARMACOLOGY OF FICTIVE BREATHING IN THE ISOLATED LAMPREY BRAIN. C.M. Rovainen and D.F. Russell. Dept. of Cell Biology & Physiology, Washington University Medical School, St. Louis, MO 63110.

The pharmacological modulation of respiratory bursting was tested in isolated preparations of the lamprey brain or medulla. The experimental advantages include a neuropharmacology similar to that of higher vertebrates, penetration of the nervous tissue by most bath-applied drugs, and spontaneous respiratory bursts in cranial IX-X motoneurons. Adult lampreys of 4 species were used: Ichthyomyzon unicuspis, Lampetra fluviatilis, Lampetra lamottenii, and Petromyzon marinus.

Inhibitory amino acids: 0.2-0.5 mM glycine or GABA reduced the amplitudes and frequencies of respiratory bursts. Strychnine and picrotoxin blocked these effects but did not prevent fictive breathing (Neurosci. 10: 875-882).

Excitatory amino acids: 0.1-1 mM N-methyl-aspartate (NMA), 50 μM kainate, or 2 mM D-glutamate disrupted breathing and produced steady firing of respiratory motoneurons. Lower concentrations produced spontaneous EPSPs and tonic firing in motorneurons, with superimposed respiratory bursts and subsequent pauses. Alpha-aminoadipate at 1-2 mM or 2-amino-5-phosphonovalerate at 100 μM blocked excitation by NMA but not by kainate. Neither antagonist blocked fictive breathing in adult I.u.. However, the less specific antagonist cis-2,3-piperidine dicarboxylate at 2 mM did block fictive breathing as well as the excitation by NMA or kainate.

Substance P: In adult L.f., 1 μM had little effect, 10 μM increased the frequency and burst amplitude of respiration, and 100 μM disrupted breathing and produced sporadic intense 1 s discharges of n.X motorneurons.

Amines: Serotonin at 1-10 μM reversibly depressed the frequency of respiration. Norepinephrine at 1-10 μM dramatically increased the frequency and burst amplitude of fictive breathing in all the species tested.

338.12 CONNECTIVITY OF SLOWLY ADAPTING PULMONARY STRETCH RECEPTORS (PSRs) TO DORSAL RESPIRATORY GROUP (DRG) NEURONS REVEALED BY INTRACELLULAR SPIKE-TRIGGERED AVERAGING (STA). A.J. Berger and T.E. Dick. Department of Physiology & Biophysics, University of Washington School of Medicine, Seattle, WA 98195.

Lung inflation influences the behavior of DRG inspiratory (I) neurons. It reduces the excitability of DRG Iα cells and facilitates both Iβ and P-cells; the latter are not driven by central I activity. Previous work from this laboratory (Averill et al., J. Neurophysiol. 52:771-785, 1984) has shown, using single unit cross-correlation analysis, that Iβ and P-cells are monosynaptically excited by PSRs. Further, connectivity from any one PSR was seen in 20% of cases for Iβ neurons and 26% of cases for P-cells. But cross-correlation analysis may not be able to detect PSR-evoked unitary EPSPs of small amplitudes (Cope et al., Soc. Neurosci. Abstr. 8: 448, 1982). In contrast, Backman et al. (Pflügers Arch. 402:129-136, 1984), using intracellular STA, observed PSR-derived monosynaptic EPSPs in all cells they classified as Iβ (N=11 cells), that is, a 100% connectivity. This connectivity is surprisingly high and may be a consequence of their classifying a neuron as Iβ if it received an observable volley of EPSPs in response to lung inflation.

To investigate PSR connectivity, we used intracellular STA on a large population of DRG neurons in anesthetized, paralyzed, artificially ventilated cats. Single-unit PSR activity was recorded in the nodose ganglion and intracellular membrane potentials were recorded from neurons in the ipsilateral DRG. We classified DRG neurons based on a comparison of cycle-triggered histograms (CTH) of intracellularly recorded membrane potentials and action potentials, using an inflate and no-inflate paradigm (Cohen and Feldman 36:2367-2374, 1977). We studied the connectivity of only those PSRs exhibiting extracellularly recorded terminal potentials in the DRG (Berger and Averill, J. Neurophysiol. 49:819-830, 1983).

Fifty intracellularly recorded DRG neurons were classified as either Iα, Iβ or P-cells. Twelve of 25 Iβ neurons showed evidence of a PSR-derived unitary monosynaptic EPSP (mean amplitude 70 μV, range 15-254 μV). Two of four P-cells exhibited EPSPs (amplitudes of 120 and 239 μV). No unitary EPSPs were observed in the 21 Iα neurons investigated. We estimate that a minimal detectable EPSP was 5-10 μV in amplitude. We conclude that the percentage connectivity of a single PSR to an Iβ neuron is approximately 50% for neurons classified on the basis of CTH analysis of their responses to lung inflation. In a large sample of Iα neurons, we observed no evidence for PSR-derived EPSPs. The absence of this connectivity is consistent with a lung-volume-derived reduced excitability of Iα activity. (Supported by USPHS grant NS 14857, and a Parker B. Francis Fellowship to T.E.D.)

339.1 THE INFLUENCE OF AGE ON AUGUST LEVELS OF PINEAL IMMUNOREACTIVE ARGININE VASOTOCIN (iAVT) IN RATS. M.M. Prechel*, T.K. Audhya* and W.H. Simmons* (SPON: F.W. Lavelle). Dept. of Biochemistry and Biophysics. Loyola Univ. Med. Ctr., Maywood, IL 60153.

The level of iAVT in rat pineal glands varies with a circannual rhythm; it is barely detectable during most of the year but increases several hundred-fold in August (Prechel et al., Endocrinology 112: 1474, (1983)). It has been reported that AVT bioactivity in pineal diminishes rapidly with age (Pavel et al., J. Endocrinol. 66: 283, (1978)). However, we have observed that the August iAVT peak is qualitatively and quantitatively similar in both weanling and adult rats (Prechel et al. , Endocrinology 112: 1474, (1983)); J. Pineal Res. 1: 175 (1984)). The purpose of this study was to systematically evaluate the influence of age on pineal iAVT levels during August when the hormone is readily measurable.

Pineal glands were collected from separate groups (n=4) of either male or female rats (Sasco-King, Oregon WI) at 14, 34, 54, and 74 days of age on August 4, 12 and 19, 1984. The glands, obtained after decapitation, were immediately frozen on dry ice and then stored at -80°C. Glands were later homogenized in 0.1N acetic acid containing $10^{-6}$M pepstatin and subsequently heat denatured to precipitate large proteins. The supernatants from individual glands were assayed for iAVT by RIA (Fernstrom et al., Endocrinology 106: 243, (1980)). The data were subjected to a three-way ANOVA to determine the influence of age, gender and sampling date on iAVT.

The results of this study confirm that the level of pineal iAVT varies in a highly significant way with date of sampling during August. However, all groups of rats reached the same peak-level of pineal iAVT during August (700-750 pg/gland) regardless of age or gender. Minor, but significant, interactions were observed between age and sampling date, as well as between gender and sampling date, suggesting that age and gender may influence slightly the phasing of the annual peak of iAVT.

339.2 ISOLATION OF cDNA CLONES FOR RETINAL S-ANTIGEN. Cheryl M. Craft[1], Paul Stein[2], David C. Klein[1], Igal Gery [2] and Toshimichi Shinohara[3]
[1] Laboratory of Developmental Neurobiology, National Institute of Child Health and Human Development, and [2] Laboratory of Vision Research and [3] Laboratory of Molecular and Developmental Biology, National Eye Institute, NIH, Bethesda, Maryland.

S-antigen is a soluble protein (50 KD) which is originally isolated from bovine retinal photoreceptor cells. Recent immunological studies indicate it is present in all animal photoreceptor cells and pineal glands. This protein is of special interest because it is capable of inducing experimental uveitis in animals and is thought to be involved in the process of visual transduction. Complementary DNA (cDNA) clones for bovine retinal S-antigen were isolated from a λgtll recombinant DNA expression library by polyclonal S-antigen antiserum. These clones were further verified by monoclonal antibodies. Subsequent cDNA clones from a λgtl0 retinal library were also screened using the 500 base pair cDNA from the λgtll library as a probe. Several S-antigen cDNA clones with approximately 250 to 900 base pair inserts were analyzed using restriction enzymes. Polypeptide synthesized with these cDNA clones greater than 400 base pairs has at least 2 different epitopes recognized by 2 different monoclonal antibodies. In contrast, smaller than 400 base pairs have at least one epitope. These polypeptides were unable to induce uveitis in the experimental animals indicating that these cDNA clones may not encode the uveitogenic determinant. A 500 base pair S-antigen cDNA was found to hybridize specifically to mRNA (approximately 1700 ± 200 nt) prepared from bovine retina and pineal gland but not to mRNA from liver, cerebral cortex or cerebellum. This is consistent with SDS-PAGE immunological analysis, which indicates that the retina and pineal gland contain the S-antigen. These S-antigen cDNA clones will be a useful tool in future studies of the S-antigen gene.

339.3 MODIFICATIONS OF SECRETORY PATTERNS OF PINEAL MELATONIN IN THE RABBIT. Y.M. Cheung*, Y.S. Chan and S.F. Pang*. Department of Physiology, Faculty of Medicine, University of Hong Kong, Sassoon Road, Hong Kong.

In rodents, pineal melatonin is secreted into the confluens sinuum before entering the general circulation. Investigation on blood levels of melatonin in the confluens sinuum provides direct measurements on the secretory patterns of pineal melatonin in these animals. In our laboratory the sinus sagittalis superior of the anaesthetized rabbit (Sagatal, May & Baker, 35 mg/kg i.v.) was cannulated and blood samples from the confluens sinuum were collected at 2- or 4-minute intervals. Plasma melatonin were extracted by dichloromethane and quantified by radioimmunoassay. It was found that the confluens sinuum had melatonin levels 4-20 times higher than those in the peripheral circulation. In addition, melatonin levels in the sinus blood exhibited episodal release pattern and diurnal variation with high levels in the dark period. When the sympathetic trunk innervating the pineal gland was stimulated unilaterally by electrical pulses (0.5 ms pulses, 300 Hz, continuous pulse trains usually lasting 8 s repeated once every 20-25 s), melatonin levels in the confluens sinuum increased to over 130% of the prestimulated values. However, unilateral electrical stimulation of the sympathetic nerve by pulse trains of shorter duration (0.5 ms pulses, 300 Hz, pulse trains of 60 ms duration repeated once every 500 ms) had no apparent effect. Injection of norepinephrine which caused a transient increase in blood pressure also enhanced concentrations of plasma melatonin in the confluens sinuum by over 50%. Our data suggest that the secretion of pineal melatonin in the rabbit has: 1) a pulsatile release pattern superimposed on a basal level of secretion, 2) a diel rhythm, and 3) a regulatory system that is stimulated by circulating norepinephrine and activation of its sympathetic innervation.

339.4 REPRODUCTIVE EFFECT OF O-ACETYL-5-METHOXYTRYPTOPHOL (aML) IN MALE SYRIAN HAMSTERS. M.K. Vaughan, B.N. Joshi*, M.E. Troiani*, G.M. Vaughan*, I. Smith* and R.J.Reiter. Dept. Cellular & Structural Biology, Univ. Texas Health Science Center, San Antonio, TX 78284; U.S. Army Institute of Surgical Research, Fort Sam Houston,TX 78234 and Courtauld Institute of Biochemistry, London, U.K.

O-acetyl-5-methoxytryptophol (aML), an indole with only an O substituted for the sidechain N of melatonin (aMT), has been identified in the pineal gland (Smith et al., Biochem. J. 185: 537, 1980). This new pineal indole was tested for its ability to: 1) cause gonadal regression like aMT when aML is injected each afternoon into hamsters exposed to a 14:10 light:dark (LD) cycle and 2) prevent gonadal regression like aMT when implanted as a chronically releasing subcutaneous pellet in hamsters exposed to short photoperiod (SP, 10:14 LD) or injected each evening with aMT. In Exp. 1, hamsters received either saline injections (controls) or 2.5, 12.5, 25 or 50 µg/day at 1700 h of synthetic aML. Testes weights were not significantly depressed by any dose of aML although accessory organ weights were depressed by the 50 µg dose. In Exp. 2, hamsters in SP or receiving afternoon injections of aMT were implanted every 2 weeks for 12 weeks with a beeswax pellet containing 1 mg aML. Subcutaneous pellets of aML did not prevent the testicular or accessory organ weight regression induced by exposure of hamsters to SP or daily afternoon injections of aMT. The results indicate that aML does not have the same antigonadotrophic properties that aMT has in the Syrian hamster (Supported by NSF grant No. PCM8410592).

339.5 STRESS DEPRESSES N-ACETYLTRANSFERASE ACTIVITY (NAT) AND MELATONIN LEVELS IN THE PINEAL GLAND OF THE RAT. M.E. Troiani*, B.N. Joshi*, J. Milin*, F. Nürnburger*, and R.J. Reiter. Dept. Cellular and Structural Biology, Univ. Texas Hlth. Sci. Ctr. at San Antonio, TX 78284.

It was recently shown that a 1.5 cc injection of physiological saline into the back leg of rats caused morphological changes in the pineal gland which were interpreted as evidence that the secretory activity of the pineal gland was increased (Milin, J., et al., Arch. d'Anat. Micro., 73: 159, 1984). This observation prompted the present series of studies which examined pineal NAT activity and melatonin content after animals were stressed in the manner described. In the initial study, young adult male rats were kept under light:dark cycles of 14:10 (lights on from 0600-2000 h) and given a saline injection into the back leg during the light phase at 18:30 h. Ten minutes later the already low daytime levels of melatonin were significantly depressed. Because of this unexpected finding a time course study was conducted during darkness when pineal NAT activity and melatonin levels were increasing. At 0200 h the experimental rats received a subcutaneous saline injection as described above; these were killed at either 10, 20, 30, 40, 60 or 90 min after the injection. Control animals remained untreated and were killed at either 0 or 30 min. Pineal NAT activity roughly doubled in the control rats between 0200-0230 h. In contrast, pineal NAT values dropped precipitously to roughly 1/5 the initial control values within 20 mins; NAT levels remained significantly depressed until 60 min after the saline injections. By 90 min the NAT values were returned to those in the controls. Melatonin levels responded similarly. In control rats, pineal melatonin levels rose from 1712 at 0200 h to 3322 pg/gland at 0230. In contrast pineal saline-injected rats contained only 1332 pg/gland at 0230 h; however, as with the NAT, melatonin levels had returned to control values at 90 min after the saline injection. In the next study, the nighttime response of the pineal to the stress was compared in intact and adrenalectomized rats. Adrenalectomy totally prevented the changes in NAT activity associated with the saline injection. In the case of melatonin, the absence of the adrenals not only prevented the drop in melatonin but these animals had higher melatonin values, compared to those in controls, at 20 min after the injection. It is presumed that the observed alterations are due to changes in adrenomedullary catecholamines rather than to adrenocortical gluco- or mineralocorticoids. These findings seem to be opposed to the general dogma that increased circulating catecholamines normally would exaggerate pineal melatonin production. Supported by NSF grant # PCM 8410592.

339.6 SIMILAR EFFECTS OF SHORT PHOTOPERIOD AND MELATONIN TREATMENT ON GONADOTROPINS IN OVARIECTOMIZED INBRED LSH/SsLak HAMSTERS. U. E. Hauser* and B. Benson. Dept. of Anatomy, Univ. of Arizona, Tucson, AZ 85724.

Previous experiments carried out in inbred LSH/SsLak female hamsters showed that these animals become acyclic after 20 to 30 days of short photoperiod (SP) exposure, and have reduced postcastration gonadotropin rises compared with long photoperiod (LP) exposed animals. Since melatonin (MEL) is synthesized in the pineal gland and is postulated to be the hormone mediating SP effects on the reproductive system, the following experiment was designed to compare directly gonadotropin levels in SP and MEL treated animals.

Forty 4-5 month old, regularly cycling LSH/SsLak female hamsters were maintained in LP (14L:10D cycle; lights on at 6.00 h). On the day following bilateral ovariectomy, the animals were divided into five groups, two of which were transferred to SP (8L:16D cycle; lights on at 6.00 h). One group in each photoperiod received daily subcutaneous injections of either 25 µg MEL or the vehicle; one LP-exposed group remained untreated. Daily injections were given between 15.30 and 16.00 h in LP animals and 13.30 and 14.00 h in SP animals. After 20 days of treatment all animals were sacrificed during morning hours and sera and pituitaries saved for hormonal determinations. NIADDK kits with LH-RP-2 and FSH-RP-2 standards were used for hormonal determinations by RIA.

| | LH | | FSH | |
|---|---|---|---|---|
| Treatment | Serum(ng/ml) | Pit.(µg) | Serum(ng/ml) | Pit.(µg) |
| LP-Control | 0.90±0.20 | 1.80±0.13 | 40.3±4.5 | 0.91±0.06 |
| LP-MEL | $^{b}$0.34±0.02 | 1.51±0.12 | $^{c}$14.0±1.1 | $^{c}$0.65±0.05 |
| SP-Vehicle | $^{b}$0.37±0.03 | $^{b}$1.30±0.38 | $^{c}$20.8±2.4 | $^{a}$0.69±0.07 |
| SP-MEL | $^{b}$0.38±0.07 | 1.55±0.13 | $^{a}$14.9±1.4 | $^{b}$0.68±0.06 |

$^{a}p < 0.05$; $^{b}p < 0.025$; $^{c}p < 0.005$. All vs. LP-Control.

The results are summarized above. Since values in LP vehicle-treated and untreated groups were not significantly different, they were pooled. Serum and pituitary FSH levels were depressed by either SP or MEL treatment. MEL given to SP animals did not produce an additive effect. In response to SP or MEL, LH levels showed similar trends. These results indicate that SP and MEL treatments have comparable suppressive effects on gonadotropin levels in the absence of gonadal steroids, and also provide further support for the hypothesis that MEL may mediate the antigonadal effects of SP.

This work was partially supported by N.I.H. grant no. HD18570.

339.7 THE EFFECT OF ELECTRICAL STIMULATION OF THE PARAVENTRICULAR NUCLEUS AREA OF THE HYPOTHALAMUS ON THE MELATONIN RHYTHM GENERATING SYSTEM OF THE RAT. J. Yanovski*, J. Witcher*, N. Adler, S. Markey* and D. Klein*. Univ. of Penn. Dept. of Psychology, Phila., PA and National Institutes of Health, Bethesda, MA.

The circadian rhythm in mammalian pineal melatonin production appears to be controlled by the Suprachiasmatic Nuclei via a polysynaptic pathway. Previous studies have suggested that the Paraventricular Nuclei (PVNs) may be intermediate in this pathway; the PVNs receive efferents from the Suprachiasmatic Nuclei and send efferents to the spinal cord (and thus to the Superior Cervical Ganglion, the final common pathway for pineal neural input). Additionally, lesions of the PVNs have been shown to eliminate the circadian rhythm in pineal melatonin production as measured in a variety of ways (Klein et al, 1983).

The present study seeks a role for the PVNs in the melatonin rhythm generating system by examining the effects of electrical stimulation of the PVNs on levels of urinary 6-OH-Melatonin, the major metabolite of Melatonin. Female Sprague Dawley CD rats, implanted with unipolar electrodes, were placed in metabolic cages under a 14:10 light/dark cycle and their urine collected over dry ice. Each animal's urine was collected as day time and night time specimens for three day periods consisting of: 1) a 24 hour control period; 2) a 24 hour period in which 3 hours of electrical stimulation of the Paraventricular Nucleus area began either one hour after lights-on or one hour after lights-off; and 3) a second 24 hour control period following the stimulation period. The urine of all animals was collected under both types of electrical stimulation conditions, with a minimum of two weeks between stimulations.

Histological verification of electrode placement was obtained. All urine samples were evaluated for 6-OH-Melatonin content by Gas Chromatography-Negative Chemical Ionization Mass Spectroscopy (Tetsuo et al, 1980).

In animals with electrode placements in the PVNs, electrical stimulation during the early light induced a three to four fold rise in the lights-on urinary 6-OH-Melatonin concentration as compared to that produced on control days. Stimulation during the early dark in these same animals did not uniformly induce a significant rise in urinary 6-OH-Melatonin levels.

These results are consistent with a role for the PVNs in the polysynaptic circuit controlling the melatonin circadian rhythm generating apparatus. A more fine-grained examination of the effects of electrical stimulation at differing times of day and night is currently under way.

339.8 DAILY ISOPROTERONOL INJECTIONS INDUCE GONADAL REGRESSION IN ADULT MALE DJUNGARIAN HAMSTERS. T.H. Champney and M.H. Stetson. School of Life and Health Sciences, University of Delaware, Newark, DE 19716.

When exposed to short photoperiods (less than 14 hours of light per day), male Djungarian hamsters (Phodopus sungorus sungorus) exhibit marked gonadal regression and increased duration of pineal melatonin production during the dark period. Likewise, daily melatonin injections during the late afternoon can also elicit gonadal regression in this species; ostensibly by adding to the endogenous melatonin produced and thereby simulating a long night (increased duration of melatonin exposure). Isoproterenol, a potent beta adrenergic agonist, stimulates pineal melatonin production in Djungarian hamsters. Therefore, the purpose of this study was to determine if endogenous melatonin release, induced by isoproterenol injection, could produce the same alterations in the reproductive state as those observed in animals which are exposed to short photoperiods or injected with melatonin.

Male Djungarian hamsters exposed to LD 16:8 (lights on at 0500) were divided into three groups and received daily subcutaneous isoproterenol injections (0.75 mg/kg) at either 1000, 1600, or 1800 hours. After eight weeks of injections, the hamsters were killed and their body and testes weights were recorded. No significant differences were observed in body weight between any of the groups. However, testes weights were significantly depressed in the groups injected at 1600 ($p < 0.05$, $n = 9$) and 1800 ($p < 0.001$, $n = 7$) hours, while the testes weights of the animals injected at 1000 ($n = 12$) hours were unchanged by the isoproterenol treatment. All of the hamsters injected at 1800 hours had completely regressed testes, while only 2 of 9 animals at 1600 hours showed complete regression after eight weeks of injections. These results are very similar to those in hamsters which receive melatonin injections at these same times.

These findings demonstrate that stimulating production of pineal melatonin, at a specific time of day, causes gonadal regression in male Djungarian hamsters. Supported by NSF Research Grant DCB 84-12587.

340.1 BIOCHEMICAL AND BEHAVIORAL CORRECTION OF MPTP PARKINSON-LIKE SYNDROME BY FETAL CELL TRANSPLANTATION, R.A.E. Bakay,* D.L. Barrow,* A. Schiff* and M. Fiandaca* (SPON:J.W. Manning) Emory University, Atlanta, Ga. 30322.

We have successfully produced a Parkinsonism-like syndrome using MPTP in non-human primates and have reversed the syndrome through transplantation of fetal mesencephalic brain tissue. Movement was both qualitatively and quantitatively assessed through videotape recordings which were scored by a blinded observer. Following the administration of MPTP the overall quality of the movements decreased, the movement repertoire decreased and the time spent in certain types of movements significantly stastistically diminished as much as 50%. Sedimentary behavior appeared to increase and there was a stastistically significant increase in the time spent in one particular type of movement without change to a different type of movement pattern. Corresponding with these movement changes, there was a decrease in CSF L-Dopa representing as much as an 80% reduction.

Two Macaca Mulattas received fetal mesencephalon cell preparations stereotactically implanted in multiple sites of the caudate nucleus bilaterally. These animals demonstrated qualitative improvements in their movements and stastistically significant quantitative increases in the amount of active behavior observed over a two month period. Despite these improvements the repertoire remained somewhat limited. CSF L-Dopa increased to baseline concentrations.

Neuropathological studies have been performed which demonstrate the successful integration of fetal tissue cells in the caudate. Catecholamine-fluorescent cells were observed in the transplant. No evidence of rejection was present. We therefore feel that fetal tissue transplantation in primates can effectively reverse behavioral abnormalities and biochemical abnormalities induced by MPTP. Long term studies are being preformed to determine whether or not the transplant can survive and function chronically.

340.2 BEHAVIORAL, BIOCHEMICAL AND PATHOLOGICAL CHARACTERISTICS OF AN MPTP MODEL OF PARKINSON'S DISEASE IN THE CAT. J.S. Schneider, A. Yuwiler and C.H. Markham. Department of Neurology, UCLA School of Medicine and Neurobiochemistry Lab; Brentwood V.A. Hospital, Los Angeles, CA 90024.

Systemic injections of MPTP (N-methyl-4-phenyl-1,2,3,6-tetrahydropyridine) cause a parkinsonian syndrome in humans and non-human primates. Severe loss of pigmented substantia nigra (SN) compacta cells has been documented in both cases. While transient dopamine depletions have been observed in other species exposed to MPTP (rat, guinea pig) structural changes in the SN have not been well documented. We presently report that MPTP administered to cats can produce severe SN compacta cell damage, long-lasting striatal dopamine (DA) depletions and a behavioral syndrome with many similarities to that observed in both humans and non-human primates.

Following administration of MPTP (5-10 mg/kg, i.p., 5-7 days) cats quickly exhibit drooling, shaking, pupil dilation, apparent hallucinations (cats adopt attack postures, hiss violently, track imaginary objects, pinnae in constant motion), and become hypersensitive to sensory stimulation.

Subacutely, pronounced motor deficits are observed. Cats exhibit hypo- and bradykinesia, loss of or severe impairment of postural reflexes, drooling, reduced response to sensory stimuli, decreased vocalization, flexed, abnormal postures, and "freezing" episodes during attempted movement. Abnormal postures and hypo- and bradykinesia are reversed with L-dopa treatment. The degree of motor impairment following a given dose of MPTP is somewhat variable (from very mild to very severe) and dependent to some extent upon the age of the animal. To date, all cats (both those mildly and severely affected) have recovered gross motor functions 3-4 weeks after MPTP administration.

Severely affected animals had at least an 85-90% striatal DA depletion and severe SN compacta cell loss and associated glial proliferation. A few remaining SN cells looked relatively normal but many more appeared pyknotic. Mildly affected animals had 30% decrease in striatal DA and many normal-looking SN compacta cells. Behavioral recovery (at one month) did not coincide with recovery of striatal DA content.

The recovery of function observed in these animals may be due to functional recovery of noradrenergic and serotonergic neurons, compensatory increases in surviving SN cell DA synthesis,increased transmitter release from DA terminals, DA receptor proliferation, or some combination of these factors. Studies in the cat should provide a good means for assessing the biochemical and physiological consequences of MPTP exposure.

340.3 GLOBUS PALLIDUS UNIT ACTIVITY IN THE MONKEY DURING THE INDUCTION OF PARKINSONISM BY 1-METHYL-4-PHENYL-1,2,3,6,-TETRAHYDROPYRIDINE (MPTP). M. Filion, R. Boucher and P. Bédard, Lab. Neurobiol., Enfant-Jesus Hosp. and Laval Univ., Quebec, Canada G1K 7P4.

We have already described abnormal neuronal activities in the globus pallidus of monkeys made parkinsonian by electrolytic midbrain lesions (Brain Res., 178 (1979) 425-441). These anomalies were related to the amount of cell loss in the pars compacta of the substantia nigra. Recently, the neurotoxin MPTP was shown to destroy these nigral neurons much more specifically and to produce permanent parkinsonism in primates. The present work was undertaken to determine whether MPTP also induces alterations of pallidal activities similar to those reported above.

We recorded the spontaneous activity of over 150 neurons in the internal (GPi) and external (GPe) segments of the globus pallidus. Recordings were made daily during one week before and 5 weeks after the i.v. injection of MPTP (0.6 mg/kg). The animal gradually developed severe bradykinesia, apraxia, and tremor. These signs remained present until he was sacrificed. However, some recuperation occurred. Thus, on day 14 the animal started to regain the ability to feed himself, lost completely on day 4.

During the first 2 weeks after MPTP, the tonic firing pattern characteristic of GPi neurons, and the long bursts and long periods of silence, typical of GPe, both became more and more disorganized. Rates of firing were measured over periods of minutes. Unexpectedly in GPi, they were on average about 50% higher than those recorded nearby in the same segment of the nucleus before MPTP. Inversely in GPe, during the same period, firing rates were about 50% lower.

After the second week the abnormal activities were clearly similar to those observed in parkinsonism due to electrolytic lesions. Short irregular bursts were present in both GPe and GPi. Rhythmic bursting at 15 Hz, often observed in monkeys with electrolytic lesions, was first recorded on day 14, and then appeared intermittently in more and more neurons. After day 14, firing rates were close to normal in GPi, as in monkeys with electrolytic lesions; they remained somewhat slower in GPe.

In conclusion, MPTP induces alterations of pallidal activities similar to those observed in parkinsonism due to electrolytic lesions. This becomes obvious, however, only several days after the injection of the neurotoxin. Early effects of MPTP, such as changes in firing rates, were probably present in the animals with electrolytic lesions but were overlooked since most of these animals were studied several weeks after making the lesions. Nevertheless, the fact that the early effects of MPTP appear to be somehow compensated suggests a functional reorganization that warrants further studies. [Supported by the MRC of Canada].

340.4 Persistent Alterations in locomotor activity of Mice following treatment with MPTP. J.L. Carlson*, M.E. Melnick and L.L. Vacca. Department of Anatomy and Department of Physical Therapy Education, University of Kansas Medical Center, Kansas City, Kansas 66103.

One of the criteria for a rodent model of Parkinson's Disease utilizing MPTP is that the motoric effects of the drug persist beyond the injection period. Previous results in this laboratory (Shellenberger & Melnick, Neurosci Abstr 1984) have shown that alterations in activity levels and locomotion persist at least 10 days after injection with MPTP in one year-old rats. This study investigated long term changes in activity and locomotion in $C_{57}$ mice. The mice were injected for 3 days, 5 days or 10 days with either MPTP at 30 mg/kg or a control solution. Activity levels were investigated immediately after the first injection and then at 5 day intervals up to 33 days after injections had ceased by measuring movement in a continuous maze. Locomotion was assessed on the same schedule by gait analysis measuring stride length, stride width and the ratio of width to length. Activity was severely depressed one hour after injection; was increased in the three-day injection group and slightly depressed in the five-day and ten-day injected group at 5, 10, and 15 days when compared to controls. Activity levels were then within normal limits. Gait analysis showed that the treated animals took shorter, wider steps within one hour of injection. These gait alterations persisted for thirty days for all treatment paradigms. We conclude that there is long-term impairment in motoric activity of $C_{57}$ mice after injections with MPTP. The brain of these animals are now being analyzed to see if there are accompanying changes in immunohistochemical staining for tyrosine hydroxylase and/or changes in the number of perikarya in the Substantia Nigra.

340.5 EFFECTS OF MPTP ON BASAL GANGLIA PHYSIOLOGY IN MONKEYS. E.B. Montgomery, Jr., S.R. Buchholz*, A. Delitto*, and R.C. Collins. Dept. of Neurol. and Neurol. Surg. (Neurology) and Program in Phys. Ther., Washington Uni. Sch. of Med., St. Louis, MO 63110

Effects of MPTP on the physiology of the basal ganglia (BG) in two macaca nemestrina monkeys were studied combining extracellular neural recording of single unit activity and 14-C-2-deoxyglucose autoradiography. Mean resting discharge frequencies in spikes/sec (MRDF) for 41 units in the putamen and 56 units in the globus pallidus compared to 40 units in the putamen and 53 units in the globus pallidus following total cumulative MPTP doses of 2.7 mg/kg for monkey A and 1.4 mg/kg for monkey B. Prior to sacrifice each monkey was given 14-C-2-deoxyglucose (2-DG) under conditions similar to those during single unit recording.

Values for MRDF for putamen (median MRDF 3.7, range 0.35-40) and for globus pallidus (median 31, range 1.7-122.2) before MPTP were similar to those reported by Crutcher and DeLong (Exp. Brain Res. 53:244-258, 1984). Values for MRDF following MPTP were not significantly changed (Kolmogorov-Smirnov test). 2-DG results were: (micromoles of glucose per 100 gms of tissue per minute)

| | normal | | | parkinsonian | |
|---|---|---|---|---|---|
| | A | B | C | A | B |
| caudate nucleus | 72 | 52 | 70 | 77 | 88 |
| putamen | 68 | 53 | 70 | 83 | 95 |
| globus pallidus external segment | 22 | 26 | 38 | 60.5 | 69 |
| globus pallidus internal segment | 24 | -- | -- | 56.5 | 68 |

Normal values reported in the literature: A.) Caveness, Ann. Neurol. 7:230-237, 1980; B.) Kennedy, Ann. Neurol. 12:333-340, 1982; and C.) Deuel and Collins, Ann. Neurol. 15:521-529; 1984.

Our findings of mildly increased glucose utilization in the putamen and a 2-fold increase in the globus pallidus are in agreement with changes in rats following unilateral 6-hydroxydopamine lesions of the substantia nigra (J. Neurosci. 1:285-291, 1981) and in PET scans of human parkinsonians (Canad. J. Neurol. Sci. 11:169-173, 1984). Yet, single unit activity in "parkinsonian" monkeys at rest was normal. However, the experimental conditions for the single unit recording and 2-DG were not strictly the same. In single unit recording any sample collection contaminated by movement was rejected. This is not feasible in 2-DG experiments because of the 50 minute sampling period during which the monkeys invariably move. Transient increases in glucose utilization associated with occasional movements are additive because phosphorylated 2-DG is essentially trapped intracellularly. It is possible that the increased BG 2-DG uptake following MPTP reflects changes from normal glucose utilization associated with movements occurring during the 2-DG experiment. If so, then the pathophysiology of parkinsonism is related to abnormal dynamic changes in neuronal activity associated with movement production and not in the resting activity.

340.6 INTRACELLULAR RESPONSES IN THE CAUDATE NUCLEUS OF A PARKINSONIAN DOG. J.S. Wilson & J.A. Wilson. Department of Anatomy, Howard University, Washington, D.C. 20059 & Lab. of Preclinical Studies, Nat. Inst. on Alcohol Abuse & Alcoholism, Rockville, M.D. 20852.

Systemic injections of MPTP (methyl-4-phenyl-1,2,3,6-tetrahydropyridine) induce a selective degeneration of the pars compacta of the substantia nigra, depletion of striatal dopamine levels and a Parkinsonian-like syndrome in man, monkey, dog and mouse. Because degeneration of the nigrostriatal pathway is often associated with Parkinson's disease, it is thought that the substantia nigra may modulate inputs to the striatum which are directly related to motor control such as cortical area 4. The purpose of this research is to study the changes which occur in the physiology of the caudate (Cd) nucleus in dogs which have developed a Parkinsonian-like syndrome because of systemic injections of MPTP.

Recordings were made in the head of the Cd nucleus of normal beagle puppies and puppies which were injected with MPTP (2.5-3.0 mg/kg; i.v.) 12-18 days before the recording experiments. Stimulating electrodes were placed in the primary motor cortex, supplementary motor cortex and premotor cortex. Preliminary results are based on 21 and 15 neurons recorded intracellularly in the normal and MPTP treated dog, respectively. In the normal dog, 16 of the neurons responded to at least one of the 3 cortical stimulation sites. The most frequently recorded response was an initial excitation followed by a longer duration inhibition, ie. an E-I response complex. Usually, one of the three stimulation sites was more effective in producing an E-I response. In the MPTP treated dog, cortical stimulation produced a response in 13 neurons. E-I responses were observed in 5 of the responding cells. In the remaining 8 neurons, the responses were unusual in that the initial excitatory response often had a larger amplitude and longer duration than was observed in control conditions. In addition, the inhibitory component of the response was greatly attenuated or absent. Our preliminary data also suggest that Cd neurons can follow repetitive stimuli at higher frequencies in the MPTP treated dog. We are continuing this study to further document the changes in the response of Cd neurons to cortical inputs in the Parkinsonian dog. (Supported by MBRS 2S06-RR08016-13).

340.7 ACUTE EFFECTS OF MPTP ON THE FIRING RATE OF NIGRAL PARS COMPACTA CELLS IN RATS AND MICE. H. Klemfuss*, R.F. Gariano, and P.M. Groves.* Department of Psychiatry, School of Medicine, University of California, San Diego, La Jolla, CA 92093.

Neurons in the pars compacta of the substantia nigra were recorded extracellularly in male Sprague-Dawley rats and C57 Black mice anesthetized with urethane. Based on waveform, spontaneous firing rate, and antidromic activation from the striatum, the cells were considered to be dopaminergic nigrostriatal projection neurons. MPTP (1-methyl-4-phenyl-1,2,3,6 tetrahydropyridine) base was dissolved in either 1% ethanol or normal saline and administered subcutaneously.

In the rat 10 mg/kg MPTP resulted in a 10-20% decrease in the spontaneous firing rate of pars compacta cells which developed within five minutes and lasted at least thirty minutes ($p<.05$ at ten minutes post-injection, n=5). Mice were somewhat more sensitive to the rate-depressant effects, with a decrease to 49% of pre-injection firing rate at ten minutes ($p<.01$, n=5). At a dose of 30 mg/kg MPTP there was a similar decrease in the firing rate of mouse pars compacta cells to 50% at ten minutes post-injection ($p<.01$, n=6), although this dose was ultimately lethal. Injection of vehicle alone resulted in no significant effect on the firing rate of these cells ($p>.10$, n=9).

Our results show that after acute administration, MPTP has a rate-depressant effect on nigrostriatal dopamine cells in rodents. This evidence argues that the action of MPTP can be distinguished from neurotoxic agents which cause a hyperexcitation of neuronal activity immediately after acute administration. Preliminary work using the method of terminal excitability testing indicates that the acute effects of MPTP can also be discriminated from dopamine-releasing agents such as amphetamine. We are studying the actions of MPTP on terminal excitability in the rat and mouse.

340.8 MPTP AND MPDP+ CAUSE A NON-REVERSIBLE DEPRESSION OF SYNAPTIC TRANSMISSION IN MOUSE NEO-STRIATAL BRAIN SLICE. J.A. Wilson, F.F. Weight, & J.S. Wilson Lab. of Preclinical Studies, Nat. Inst. on Alcohol Abuse & Alcoholism, Rockville, MD 20852. & Dept. of Anatomy, Sch. of Med., Howard Univ., Washington, DC 20059.

MPTP (1-methyl, 4-phenyl, 1,2,3,6,tetrahydropyridine) causes a Parkinson's disease-like syndrome in man, monkeys, dogs and mice (Lewin, Science 225: 1460, 1984). The mechanism of MPTP's neurotoxicity is not known; however, it has been found that the toxic effects are prevented by either dopamine uptake blockers or by monoamine oxidase inhibitors (MAO) (Heikkila et. al., Nature 311: 467, 1984). Two compounds, MPDP+ and MPP+, have been identified as products of MPTP's oxidation. We studied the effects of these compounds, as well as MPTP, on synaptic transmission in neo-striatum using a brain slice from C57 black mice. The preparation, stimulation, and recording parameters were similar to those reported by Cordingley & Weight (Soc. Neurosci. Abs. 8: 373, 1982) for the rat neo-striatal slice. The neo-striatum was stimulated using bipolar electrodes and a two component field was recorded extracellularly; the first component, N-1, is a negative going fiber volley, and the second component, N-2, is a synaptic response. MPTP caused a decrease in the amplitude of N-2 (62 $\pm$ 1.4% of control, n=9) that was not reversed with up to 4 hours of wash. This non-reversible change was blocked by the addition of either pargyline, a MAO inhibitor or GBR-32, a selective dopamine uptake blocker, to the slice prior to and during MPTP application. Thus compounds which block the effects of MPTP in vivo also block the non-reversible decrease in N-2. MPP+ also caused a change in N-2; however, the change in amplitude was reversible and returned to the control value within a 2 hour wash period (107 $\pm$ 1.3% of control, n=8). Thus, the presence of MPP+ in the slice does not appear to be responsible for the non-reversible actions of MPTP. MPDP+, like MPTP, caused a non-reversible decrease in the amplitude of N-2 (46 $\pm$ 5.8% of control, n=4). Castagnoli et. al. (Life Sci. 36: 225, 1985) have proposed that MPDP+ may oxidize dopamine to toxic quinones while being reduced to MPTP. MAO would then reoxidize MPTP to MPDP+ and the cycle could continue. If this proposed cycle is responsible for forming toxic compounds, pargyline should decrease or prevent MPDP+'s toxicity. Application of pargyline prior to and simultaneously with MPDP+ produced a reversible decrease in N-2 amplitude which returned to control amplitude in less than 1 hr. of wash (110 $\pm$ 7.4% of control, n=3). These results suggest that the cyclical reduction of MPDP+ and oxidation of MPTP are crucial for the non-reversible depression of synaptic transmission we have observed in the mouse neo-striatum.

We thank Dr. W. Gessner for the gift of the MPDP+. J.A.W.'s current address: Dept. of Physiology, School of Medicine, Creighton Univ. Omaha, NE 68178.

340.9 NEURONAL ACTIVITY IN AREA 4 RECORDED IN TRAINED MONKEY AFTER I.V. ADMINISTRATION OF 1-METHYL-4-PHENYL, 1,2,3,6-TETRAHYDROPYRIDINE (MPTP). D. Doudet*, Ch. Gross*, Ph. Lebrun-Grandié* and B. Bioulac, Lab. of Neurophysiology, Groupe Motricité, Univ. of Bordeaux II, 33076 BORDEAUX CEDEX (FRANCE).

Numerous reports (Burns et al., Proc. Natl. Sci. USA, 80 : 4546, 1983 ; Langston et al., Brain Res. 292 : 390, 1984 ; Doudet et al., Brain Res., sous presse, 1985). Showed that the systemic administration of 1-Methyl-4-Phenyl, 1,2,3,6, tetrahydropyridine (MPTP) in monkeys induces (1) hypertonia, hypokinesia and similar perturbations in movement parameters and EMG activity as observed in Parkinson's disease and (2) a selective degeneration of the dopaminergic neurons located in the pars compacta of the substantia nigra. Although it exists many data concerning the modulatory influence exerted by the sensory feed back loop (Bioulac and Lamarre, Brain Res., 172 : 427, 1979) and the cerebellum (Lamarre et al., J. Physiol. (Paris) ; 74 : 253, 1978) on the neuronal activity of the motor cortex (area 4), there is very little data concerning the role of the SN in this modulation (Gross et al., Exp. Brain Res., Suppl. 7, 181 : 1983). By using the MPTP primate model for the lesionning of the SN, the aim of the present work was to appreciate its possible influence on the unit activity of area 4. **Methods**. Extracellular unit activity of motor cortex was recorded in two monkeys (Macaca Mulatta) trained to perform a rapid movement of flexion or extension of the contralateral forearm in response to an auditory cue. Bilateral degeneration of the SN was obtained by the systemic administration of MPTP. MPTP (0.35 mg/kg, i.v.) was injected daily for 4 consecutive days. Three series of injection were administered at 2 weeks intervals. Unit recordings were performed after complete recovery of the acute effect of the drug. **Results**. In normal animals, the majority of neurons in area 4 modified their discharge frequency before the onset of arm displacement (80 to 160 msec before) and returned to baseline level just after this onset (0 to 200 msec after). In MPTP-treated monkeys, the main observation was that numerous motor cortex neurons still modified their discharge before the onset of movement but did not stop with it and lasted well beyond the arm displacement (200 to 400 msec after). The behavioral reaction time is increased and the maximal velocity of the movement is drastically decreased. **Conclusion** These preliminary data are consistent with previous results reported in area 4 after a stereotaxic unilateral lesion of the SN in monkeys (Gross et al., Exp. Brain Res., Suppl. 7, : 181, 1983). It may be suggested that the disturbed discharge of area 4 may result in the long lasting movements in MPTP-treated animals and stereotaxic lesioned animals and would correspond, at the clinical level, to bradykinesia, one of the most invalidant trait of Parkinson's disease.

This study was supported by CNRS ERA 493, the INSERM N° 15 and the EPR Aquitaine.

340.10 IMPAIRMENT OF FASTEST VOLUNTARY MOTOR ACTIVITY IN BASAL-GANGLIA DISEASES V.Hömberg*,H.Hefter* and H.J.Freund Dept. of Clinical Neurology,Univ. of Düsseldorf, W.Germany (SPON: European Neuroscience Association)

Whereas bradykinesia is the most prominent clinical feature in Parkinson's disease (PD) it is only rarely mentioned in another degenerative basal ganglia disorder,Huntington's disease (HD),which is rather characterised clinically by the release of irregular rapid involuntary movements.Little research has been done on the impairment of voluntary motor activity in HD and how it relates to the abnormalities in PD. We therefore analysed fastest voluntary index finger activity in patient groups with PD (subdivided into tremulous (PDTR,N=10) and akineto - rigid (PDAR,N=15) subgroups), HD (N=22) and their offspring at risk to develop the disease later in life (HDRI,N=30), compared to matched controls (N=45).
Fastest alternating flexion/extension movements were recorded by an accelerometer taped to the tip of the index finger and the fastest alternation frequency (ALT) was determined from power spectra. Reaction times (RT) and contraction times (CT) for fastest possible non-targeted isometric contractions were determined in a simple reaction time paradigm.

ALT,RT and CT were slowed to about half the normal values in all disease groups.Adopting a criterion of 2 standard deviations around the age-related regression lines over the controls revealed abnormalities of these parameters also in 20-30 % of the clinically normal HDRIs.
In both PD and HD the normal increase of the rate of rise of tension with increasing amplitude of isometric contraction ,which keeps contraction time invariant over a wide range of contraction amplitudes , was disturbed to a similar degree.

PD and HD, however ,showed considerable differences in the shape of force trajectories : Wherea in HD force and EMG build-up were smoothly prolonged, in both PDTR and PDAR the prolongation of contraction time was caused by superimposed action-tremor-like oscillations at a frequency of 8-10 Hz,which disrupted the force development.

It is concluded,that impairment of fastest voluntary motor activity is a common feature in basal-ganglia disorders.It may be detected already in very early "subclinical" stages. Pathophysiological mechanisms causing this common bradykinesia however are different in disorders affecting primarily the dopaminergic input compared to those affecting intrinsic basal ganglia neurons.

340.11 SUBSTANTIA NIGRA: A SITE OF ACTION OF MUSCLE RELAXANT DRUGS. L. Turski*, M. Schwarz*, T. Klockgether* and K.-H. Sontag* (SPON: P.L. Herrling). Max-Planck-Inst. Exp. Med., D-3400 Göttingen, F.R.G.

The reticular part of the substantia nigra (SNR) constitutes an output station of the basal ganglia which interconnects striatum with ventromedial thalamus, superior colliculus and reticular formation. γ-Aminobutyric acid (GABA) is considered to subserve the transmitter role of these pathways. The substantia nigra receives also an excitatory cortical input. Within subcortical structures of the brain, the substantia nigra has been identified as one principal region that is involved in the propagation and generalization of seizures, and regulation of the muscle tone. In rats, functional inhibition of the SNR by GABA agonists leads to suppression of the tonic component of generalized convulsions and motor expression of kindled seizures. An activation of neurons of the SNR with GABA antagonists leads to catalepsy and to increase in the muscle tone of the hind limbs. The present studies were undertaken to explore the role of the substantia nigra in the mechanism of action of well established muscle relaxants, baclofen (BAC) and midazolam (MID), and drugs acting via GABA or excitatory amino acid receptors, muscimol (MSC), γ-vinyl-GABA (GVG) and (-)2-amino-7-phosphonoheptanoic acid (AP7). In the following we will describe the changes in the pathologically increased muscle tone in genetically spastic Wistar rats (Han:WIST; spa/spa), which exhibit tonic activity in the electromyogram (EMG) of the gastrocnemius (GS) muscle.

The activity in the EMG was recorded from the GS muscle of genetically spastic rats of either sex, at the age of 12 weeks, 100-140 g in weight, with pairs of teflon-insulated wire electrodes. The electrical signals were amplified, band-pass filtered, full-wave rectified and fed into an integrator. The microinjections into the SNR were performed through chronically implanted guide cannulae. The drugs were delivered in a volume of 0.5 µl at a rate of 0.1 µl/min.

Intranigral injection of saline, 0.5 µl, bilaterally, did not alter the spontaneous tonic activity in the EMG recorded from the GS muscle of mutant rats. Microinjections of BAC (0.0001-0.001 µmol), MID (0.001-0.015 µmol), MSC (0.00025-0.001 µmol) and AP7 (0.001-0.01 µmol), into the SNR, bilaterally, reduced the tonic activity in the EMG in a dose- and time-dependent manner. Microinjection of GVG, 0.04 µmol, into the SNR, bilaterally, decreased the tonic activity in the EMG of GS-muscle in a time-dependent way. The effect of GVG reached its maximum 10-20 h after intranigral injection and abated during 48-72 h. The depressant action of MSC and AP7 on the tonic activity in the EMG was antagonized by co-administration of bicuculline and N-methyl-D-aspartic acid into the SNR, respectively.

These results identify the SNR as a site of action of muscle relaxant drugs and convincingly demonstrate that a profound myorelaxant effect may be achieved from the supraspinal motor center.

340.12 EFFECT OF UNILATERAL KAINIC ACID LESIONS OF THE ENTOPEDUNCULAR NUCLEUS AND SUBSTANTIA NIGRA RETICULATA IN POSTURE AND MOVEMENT IN THE CAT. A.G.Russell, C.G.Kukulka, K.Kultas-Ilinsky. Physical Therapy Research Labs, and the Department of Anatomy, University of Iowa College of Medicine, Iowa City, IA 52240.

The cortical-striatal-pallidal/nigral-thalamic-cortical loop has been implicated in movement initiation and in the modulation of ongoing activity. The output of the entopeduncular nucleus (EPN) and the substantia nigra reticularis (SNr) represents the sum of the sensory-motor integration in the neostriatum. The loss of this inhibitory influence on the thalamus should be reflected in movement changes.

The purpose of the study was to investigate postural and movement disturbances induced by unilateral chemical lesioning of the SNr and the EPN. Cats were trained to perform a self-initiated forelimb task which involves pushing a bar press while assuming the quadrupedal position on the force table. Postural and movement vertical reaction forces under each paw were measured prior to and following the unilateral chemical lesions. Electrical activity of selected postural and movement muscles were monitored by chronically implanted fine wire electrodes. It was possible to measure the force changes which occurred in preparation for and during the movement.

Onset of force increases, sequencing of initial force changes, and peak force developments in the support limbs prior to and during the movement appeared unchanged for pre- and post-lesioned animals. Further analysis of movement time, movement velocities and EMG parameters are ongoing and changes in these values may be revealed. Correlation of the results of histological verification of the sites and extent of lesions with behavioral parameters will be presented.

The preliminary results suggest minimal postural and movement disturbances following unilateral lesions of the feline EPN and SNr nuclei.

Supported by American Parkinson Disease Association.

340.13 DEVELOPMENT OF THE STRIATONIGRAL PATHWAY REVEALS A POSSIBLE MECHANISM OF STRIATAL COMPARTMENTALIZATION. G. Fishell* and D. van der Kooy (Spon: L. Grupp). Department of Anatomy, University of Toronto, Toronto, Canada M5S 1A8

Recently we have shown that the perinatal distribution of cell bodies giving rise to the striatonigral pathway is clustered. These clusters closely match the distribution of dopamine islands present perinatally. Dopamine islands are an early marker for the patch/matrix compartmentalization seen in the adult striatum. In order to assess the developmental importance of the early striatonigral cell clusters we investigated the time course over which this pathway is established. Using the retrograde fluorescent tracer true blue, nigral injections were made in various pre or postnatal rats (embryonic day 16 to postnatal day 7). Rats were sacrificed 16 to 24 hours after injection. After E16 injections the few striatal cells having nigral projections were restricted to the ventro-lateral striatum. By E17 most neurons that had been generated in the neostriatum projected to the nigra and thus labeled cells were diffusely distributed throughout the striatum; although dense labeling in the ventro-lateral part of the subcallosal streak is already present. At E19 well defined clusters of labeled cells (in a large adjacent matrix of non-nigral projecting striatal cells) were seen throughout the striatum. A clear subcallosal streak (of cells) was visualized. Clusters of labeled cells were best delineated at birth and were clearly visible until postnatal day 4. The clustered striatonigral pattern became diffuse as the majority of striatal cells acquired nigral projections over postnatal days 5 and 6. By postnatal day 7 striatonigral projection cells were diffusely distributed throughout the striatum.

Two important observations emerge. First, the perinatal changes in the distribution of the striatonigral projection cells (from diffuse to patchy to diffuse) parallels the modifications occurring in the striatal dopamine islands. This suggests that a tight developmental relationship exists between the striatonigral cells and the reciprocal dopaminergic pathway. Second, the embryonic appearance of clustering in the striatonigral projections coincides with or precedes the earliest patch/matrix marker known previously. Moreover, the diffuse retrograde labeling of most striatal cells at E17 suggests that the patch component of the neostriatum is born first. Thus neuronal birthdate is likely an important mechanism in organizing striatal compartmentalization.

340.14 ELECTROPHYSIOLOGICAL AND BEHAVIORAL ACTIONS OF DYNORPHIN IN THE SUBSTANTIA NIGRA J.M. Walker and M.W. Friederich, Department of Psychology, Brown University, Providence, Rhode Island 02912.

The cloning and sequence analysis of prodynorphin, established the third gene family of opioid peptides. These neurons apparently secrete several opioid products (α-Neo-endorphin, dynorphin, rimorphin) and possibly some non-opioid peptides as well (bridge peptide, C-peptide). The presence of dynorphin immunoreactivity in the substantia nigra (SN) pars reticulata, and its disappearance following ibotenic acid lesions to the caudate nucleus, strongly suggests the existence of a prodynorphin striato-nigral pathway.

Indeed, striato-nigral projections have been investigated for over forty years, and are widely believed to secrete substance P (and related products from the substance P precursor) as well as GABA. It has been hypothesized that striato-nigral projections provide feedback to the SN pars compacta. It has also been suggested that striato-nigral fibers serve as output cells from the basal ganglia, forming connections in the SN pars reticulata in route to lower motor structures.

The roles of the products of prodynorphin in the SN pars reticulata have been under investigation in our laboratory. We found that dynorphin and any number of opiate and non-opiate fragments of dynorphin induce contralateral rotation in rats after microinjection in the SN pars reticulata. This effect is markedly reduced by haloperiodol, and the effects of 6-hydroxydopamine lesions are under investigation.

Electrophysiological studies have also been carried out using extracellular recording with administration of prodynorphin products locally using micropressure-ejection methodology. Dynorphin-17 and Dynorphin-8 fail to have direct effects on substantia nigra pars compacta dopamine (DA) cells. ZR-DA interneurons described by Grace and Bunney were identified just ventral to the pars compacta by an increase in firing rate in response to foot pinch. These cells respond to dynorphin with a decrease in firing rate. The effects of dynorphin on these cells resemble the effects of several other opiates in this area. In the deeper zona reticulata mainly excitatory effects are seen. The nature of these excitatory actions are under investigation.

The data suggest that dynorphin disinhibits DA cells by way of an interneuron in the zona reticulata. An apparently non-opiate action in the deeper areas of the zona reticulata is consistent with opiate insensitive actions on rotational behavior, but the physiological relevance of this action remains to be determined.

340.15 ASYMMETRIC DOPAMINE RELEASE IN THE SUBSTANTIA NIGRA OF RATS RUNNING ON A CURVED TURNTABLE TREADMILL. B.K. Yamamoto and C.R. Freed Univ. of Colo. Med. Ctr., Denver, CO 80262.

We have shown that rats trained to circle have increased dopamine (DA) turnover in substantia nigra ipsilateral to the circling direction. In a reciprocal manner, DA release and turnover in caudate was increased in the contralateral side. Furthermore, rats forced to run on a curved turntable treadmill show a contralateral increase in caudate DA that is proportional to both running speed and body arc. We now have studied DA release in the substantia nigra pars compacta (SNc) of rats forced to run in place on a curved turntable treadmill. Male Sprague Dawley rats weighing 250-300 g were bilaterally implanted with 200 μm in vivo electrochemical carbon paste electrodes into the SNc. One day following implantation, signals were measured by linear sweep voltammetry at a rate of 10mV/sec every 5 min using a DCV 5 voltammetry amplifier with semi-derivative signal processing. Following a one hour baseline stabilization period, rats were placed on the treadmill and forced to run for one hour.

Contralateral and ipsilateral refer to the side relative to the postured running direction. Electrochemical signals are represented as percent of baseline. N=6

| | BASELINE | RUNNING (minutes) | | POST-RUNNING BASELINE |
|---|---|---|---|---|
| | 0 | 30 | 60 | 180 |
| Contralateral | 100 ± 1 | 85 ± 5* | 90 ± 2 | 96 ± 3 |
| Ipsilateral | 100 ± 1 | 104 ± 3 | 111 ± 3* | 101 ± 2 |

*p<0.05

In separate groups of animals, changes in the signal during running were abolished by pre-treatment with 300 mg/kg αmethyl-p-tyrosine (αMPT). Further experiments showed that the MAO inhibitor, pargyline (75 mg/kg) decreased the signal by 15%. Subsequent administration of αMPT decreased the signal by an additional 25%. The combination thus produced a total decrease of 40% (p<.01). αMPT alone produced a comparable decrease of 35% (p<.01). Therefore, the catecholamine signal in the SNc represents both DA and DOPAC.

In conclusion, these results are in agreement with electrophysiological studies showing that DA is inhibitory on SNc cell firing resulting in decreases in caudate DA release. Therefore, during curved treadmill running, an increase in DA release in ipsilateral SNc may represent inhibition of nigral cell firing with a reciprocal decrease in release of caudate DA. Conversely, a decrease in release in contralateral SNc increases nigral firing and increases DA release in the caudate on that same side.

340.16 TRANSPLANTATION OF CULTURED FETAL HUMAN ADRENAL CHROMAFFIN AND SPINAL CORD CELLS TO RAT BRAIN, H. Kamo[1]*, S. U. Kim[2]*, P. L. McGeer[1] and D.H. Shin[2]* (SPON. John G. Sinclair). [1]Kinsmen Laboratory of Neurological Research and [2]Division of Neurology, Depts. of Psychiatry and Medicine, University of British Columbia Vancouver, B.C. V6T 1W5, Canada.

The loss of specific neuronal groups has been reported in Parkinson's disease, Huntington's disease and Alzheimer's disease. Drug therapy either does not exist or only provides symptomatic relief. One approach to compensate for these neuronal losses might be the transplantation of a critical mass of neurons, capable of producing appropriate neurotransmitters, into the involved anatomical sites. For this to be feasible in human disease, it would appear best to use cultured human cell lines. This abstract reports preliminary studies in which such cultured human cell lines were transplanted into lesioned adult rat brains.

Adrenal chromaffin cells, obtained from a therapeutically aborted human fetus of about 11 weeks gestation, were cultured for three weeks in vitro with exposure to NGF to transform them into catecholaminergic neurons. They were transplanted to the left striatum of rats which had been subjected 1-2 weeks previously to a unilateral 6-hydroxydopamine lesion of the left nigro-striatal tract. Transplanted cells became established through strands of tissue growing into the host striatum. No signs of inflammation or rejection were observed up to the time of sacrifice one month post-tranplantation. Histofluorescence examination of the implanted areas showed many clusters of cells having an intensely positive catecholamine fluorescence with some of the cells developing conspicuous processes.

In similar studies the septal-hippocampal pathways in rats was surgically lesioned in the hippocampal fimbria. Cultured spinal cord neurons from a therapeutically aborted human fetus were subsequently implanted just posterior to the lesion. Possible cholinergic reinnervation of the hippocampus is being studied by acetylcholinesterase histochemistry, choline acetyltransferase immunohistochemistry and biochemical assays for choline acetyltransferase. This study employs the techniques of Bjorklung and Sveni (Cell Tissue Res. 185: 289-302, 1977) but is the first to report transplantation of cultured human cell lines.

This study, showing survival of such cultured human cells transplanted into rat brain tissue, might indicate the feasibility of using cultured human material for future human neuronal transplantation studies as a therapeutic measure.

340.17 SINGLE UNIT ANALYSIS OF THE VENTRAL TIER OF LATERAL THALAMIC NUCLEI IN PATIENTS WITH PARKINSONIAN TREMOR. F.A. Lenz*, R.R. Tasker*, H.C. Kwan, S. Schnider*, R. Kwong* and J.T. Murphy. Departments of Neurosurgery, Physiology and Electrical Engineering, University of Toronto, Toronto, Canada.

Cells which fire in bursts of frequency similar to that of tremor ('tremor cells') have been described at the thalamic lesion site for relief of parkinsonian tremor. In this study, the functional properties of these cells were defined by single unit analysis at the time of stereotactic surgery in an attempt to understand the mechanism of parkinsonian tremor.

In the ventral tier of lateral thalamic nuclei, sensory cells were found which reproducibly responded to specific modalities of sensory stimulation in well defined receptive fields. Anterior to these cells, at the optimal lesion site in parkinsonian tremor, three cell types were encountered: 1) voluntary cells which significantly increased their activity in advance of specific voluntary movements, 2) combined cells with voluntary and sensory properties linked so that sensory stimulation produced movement in the direction opposite to the voluntary movement related to cellular activity, and 3) no response cells with neither voluntary nor sensory activity.

Many of these cells had a large amount of activity at tremor frequency and were significantly correlated with tremor as tested by spectral cross-correlation analysis, with evaluation of the coherence function. Therefore, on the basis of location at the lesion site and correlation with tremor, these cells were identified as potentially driving tremor. During tremor, the latency between thalamic and EMG activity was measured from spike triggered averages (STA) of EMG activity. Conduction delays for transmission from thalamus to muscle via motor cortex were estimated to be 20-30 ms or, if experimental errors in the STA technique are included, 0-50 ms. Only in the case of combined cells did a majority of the cells have latencies in the 0-50 ms range. These results suggest that combined cells drive tremor by involvement in an unstable long loop reflex arc traversing movement receptors, thalamus, motor cortex and spinal motor neurons.

340.18 ARE POSTURAL AND AGONIST MUSCLES AFFECTED SIMILARLY IN PARKINSON'S DISEASE? M.W. Rogers* (Spon: D.W. Baxter). Physical Therapy Res. Labs., College of Medicine, Univ. of Iowa, Iowa City, IA 52242, and School of Physical and Occupational Therapy, McGill University, Montreal, Quebec, Canada H3G 1Y5

Single unit recordings have indicated that activity of the basal ganglia precedes and accompanies both ballistic and slow movements of the limb. In addition, the earliest task related EMG changes have been observed in the postural (paraspinal) musculature in advance of the limb muscles over a range of movement velocities (DeLong and Strick, Brain Res. 71: 327, 1974). Given the abnormalities in movement speed and postural stabilization manifested by Parkinson's patients, this study investigated whether the control of postural (biceps femoris=BF, erector spinae=ES) and agonist (anterior deltoid=AD) muscles might be affected similarly in patients with Parkinson's disease in association with arm movements performed at different speeds.

Nine idiopathic Parkinsonians and age-matched controls performed standing unilateral shoulder flexion movements in response to a light flash which followed a warning signal, at each of 3 different speeds (S=40±8 deg./s., I=80±16 deg./s., F='as fast as possible'). Movements made at F velocities were executed under a simple reaction time (SRT) paradigm. Movement onset (MO), movement time (MT), EMGs, and segmental body sway were recorded simultaneously.

Analysis revealed that for both subject groups: (1) The postural muscles were usually activated before the agonist during F speed movements, but were recruited fewer times and later with respect to AD as MT became slower; (2) Pre-movement EMG duration decreased for ES but not BF as a function of increasing MT; (3) The mean EMG onset times for postural muscles relative to agonist activation and MO were comparable between groups.

In contrast to controls, EMG patterns of the postural muscles in Parkinsonians were characterized by intermittent activity, and shorter pre-movement durations for ES ($p<.01$) and BF ($p<.05$) across all speeds. A similar discontinuity of EMG activity was observed for the agonist during shoulder flexion at S and I velocities, while that of F speed was often accompanied by segmented bursts of normal duration.

Under the simple reaction time condition, akinetic Parkinsonians (n=4) with prolonged SRT ($p<.05$) demonstrated delays in EMG onset latencies for AD ($p<.05$), ES ($P<.05$), and BF ($p<.10$).

These results suggested that the normal control of both postural and agonist muscles may be altered similarly in Parkinson's disease. In particular, parallel changes in postural and agonist muscle activation patterns may indicate a disruption of a common drive to functionally linked muscle synergists over a range of movement speeds.

## DISORDERS OF MOTOR SYSTEMS AND NEURAL PROSTHESES

341.1 MICTURITION INDUCED IN PARAPLEGIC CATS BY REFLEX INHIBITION OF THE EXTERNAL URETHRAL SPHINCTER. P.W. Ruenzel,* F.A. Jolesz,* and E. Henneman. (SPON: M. Moore-Ede). Dept. of Physiology and Biophysics (Harvard Medical School) and Dept. of Radiology (Brigham & Women's Hosp.) Boston, Mass. 02115.

It was previously reported (Jolesz et al., Science 216: 1243, 1982) that in paraplegic cats by recording motor nerve electrical activity in the pudendal nerve branch which supplies the external urethral sphincter (EUS) all the reflex responses characteristic of a flexor reflex could be demonstrated. We also found that in paraplegic rats single motor unit EMG activity in the external anal sphincter was similar and roughly parallel to that in the hindlimb flexor muscles. This suggested that limb muscle reflexes might be evoked to inhibit EUS overactivity (which occurs in paraplegia and many spinal injuries) if the pudendal nerve on one side had previously been severed, leaving the EUS under unilateral reflex control. We now report that we have induced micturition in paraplegic cats by performing limb maneuvers that evoke reflexes inhibitory to the motoneurons supplying the EUS on the innervated side.

Under ether anesthesia the spinal cords of cats of either sex were transected at the mid-thoracic level by extra-dural ligation. A 3-5 mm segment of the right pudendal nerve was extirpated, leaving the EUS innervated only on the left. 50 ml of Renografin-60 radio-opaque contrast material was infused I.V. On the following day the animals were continent, and they had not voided. Fluoroscopic examination revealed an overfull bladder and a closed EUS. Manual pressure on the bladder did not overcome EUS resistance to urine flow.

The following maneuvers, all inhibitory to motoneurons supplying flexor muscles in the left hindlimb, were performed: (1) left hindlimb was placed in full flexion, stretching the extensors and reflexly causing inhibition of the motoneurons supplying the left side of the EUS, (2) right hindlimb was placed in full extension, stretching the flexors and causing crossed inhibition of the motoneurons supplying the left side of the EUS, (3) footpad of right hindlimb was pinched, evoking a crossed extension reflex of the left hindlimb and crossed inhibition of the motoneurons supplying the left side of the EUS. On fluoroscopic examination these maneuvers caused relaxation of the bladder neck, and when the bladder was squeezed, urine was seen to pass freely down the urethra. Although this approach solves the problems caused by spasm of the external sphincter, active contraction of the bladder (induced at the same time) would be of further advantage in obtaining complete emptying of the bladder.

341.2 INFORMATION TRANSFER RATES IN ELECTROCUTANEOUS SPATIAL POSITION FEEDBACK CODES. R.R. RISO AND A.R. IGNAGNI*. Rehabilitation Eng. Program, Case Western Reserve Univ., Cleveland, OH, 44109

Electrocutaneous communication techniques are being developed to provide substitute and augmentative sensory feedback for users of Functional Neuromuscular Stimulation (FNS) systems that restore movement to otherwise paralyzed and asensory extremities. As the basis for this feedback technique, coded electrical stimuli are applied to the user's skin in an area where sensation is normal. One specific application is to give feedback information about shoulder protraction-retraction movements which spinal injury patients currently use to control FNS orthoses that provide functional grasp. A linear array of electrodes is used to form a display in which the relative position of the shoulder is signaled by activating a corresponding electrode site within the array. A sternum mounted joy stick controller that is connected to the shoulder via a telescoping wand is used to track the user's shoulder movements. An important issue with regard to the design of the electrocutaneous display is the number of electrode elements to use: Theoretically, the amount of information transferred by a code increases as the number of possible code words is increased. Thus, a spatial position code which utilizes eight electrodes would transfer more information per stimulus presentation than, for example, four electrodes. The number of electrode sites dictates the absolute resolution that could be provided about the position of the shoulder, however, subjects require increased decision time in order to "track" or interpret codes as the number of possible code words increases. This restriction serves to diminish the information transfer rate (ITR). We computed the rates of information transfer from specially designed psychomotor tasks. Experiments were performed on 4 normal adults and results compared for electrode displays consisting of 4,5,6,7 and 8 stimulation sites. Electrodes 1-4 were located axially on the upper arm and 5-8 were placed horizontally on the upper back. Electrodes were spaced 40 mm apart on both the arm and back skin, and S's were pretrained to correctly identify any randomly activated electrode with 90% surety. S's identified each randomly activated electrode by releasing a reaction time response key and then depressing one of N numbered keys to register their choice. S's were told in advance of each portion of the experiment whether the display set would consist of the elements 1-4,1-5,1-6 or 1-8. The mean reaction times (MRT) for recognition of N electrode sites averaged across all subjects are given below. Also presented are the associated mean computed information transfer rates. Data are corrected for increases in reaction time engendered by S's having to choose among the N response keys. Supported by NIHR Grant #G008300118.

| | N=4 | N=5 | N=6 | N=7 | N=8 |
|---|---|---|---|---|---|
| MRT (msec + SE) | 626 + 4 | 623 + 4 | 751 + 5 | 902 + 8 | 930 + 8 |
| ITR (bits/sec + SE) | 3.01+.01 | 3.57+.01 | 3.30+.01 | 3.01+.01 | 3.12+.01 |

341.3 REACTION TIME AND MOVEMENT TIME DEFICITS IN PARKINSONIAN PATIENTS. C.J. Hunker* and J.H. Abbs* (SPON: R. Netsell). Boys Town National Institute, Omaha, NE 68131 and Speech Motor Control Labs, University of Wisconsin, Madison, WI 53705.

Even though a number of investigators have shown that the temporal aspects of voluntary limb movements in patients with Parkinson's disease were impaired, there appears to be considerable individual variation in these performance deficits. Some parkinsonian subjects have been found to be quite slow in movement initiation (akinesia) and execution (bradykinesia) whereas others have shown normal response initiation and/or movement times. In an effort to further understand these phenomena, the initiation and duration of orofacial and index finger movements were examined relative to characteristic symptoms. Reaction time movements and agonist EMG from the lips, tongue, jaw and index finger were recorded from two groups of parkinsonian subjects (with and without resting tremor), as well as from a normal control group.

Subjects identified clinically as predominately tremorous exhibited more impaired reaction times (RT) than their rigid counterparts. In examining movement times (MT) of the specific subject groups, it was found that the rigid subjects were more impaired in movement durations than the tremorous group. When RT and MT were examined as a function of the clinically defined groups, they were inversely related. In the tremorous group, prolonged RTs were present in conjunction with near normal MTs while in the rigid group normal RTs were present in conjunction with prolonged MTs.

These data support the hypothesis of Evarts et al. (Brain, 104: 167, 1981) that impairments in voluntary movement initiation and execution may be mutually exclusive. The results presented here suggest that the pathological mechanisms involved in tremor and muscle rigidity may account, in part, for the movement aberrations of akinesia and bradykinesia, respectively. Research supported by a grant from NIH (NS 22318).

341.4 CONTROL OF SPEECH TIMING FOLLOWING BASAL GANGLIA AND WHITE MATTER LESIONS. C.L. Ludlow, N.P. Connor*, and J. Rosenberg*. Human Motor Control Section, MNB, NINCDS, Bethesda, MD 20205.

Neurological diseases involving the basal ganglia have been found to impair control of syllable execution time (Huntington's Disease) and sentence execution time (Parkinson's Disease) (Ludlow, Connor & Bassich, Neurosci. Abstr.10:906, 1984). Our purpose was to study speech timing when lesions involve both the basal ganglia and white matter tracts. Patients with penetrating missile wounds involving both the basal ganglia and white matter tracts on the right or left side were studied 15 years post-lesion. In conversation, all patients presented with a speech rhythm and rate disorder; speech dysprosody (SD). Experimental tasks were administered to determine: 1) whether simple reaction time, syllable repetition rate and control of execution time were impaired in the SD patients; 2) whether speech timing task performance differed between SD patients and patients without white matter tract involvement; and, 3) whether the normal inter-relationships between different aspects of speech timing were found in SD patients. Measures made from sound spectrograms of speech during experimental tasks included: reaction time following a click; syllable repetition rate; syllable, word, phrase, pause, and sentence execution time; and changes in syllable, word, pause, phrase and sentence execution times with alterations in speech rate and syllable stress. The SD patients were significantly impaired ($p \leq .05$) on: reaction time, syllable repetition rate and control of syllable initiation time during stress contrasts. This group was not impaired on any of the execution time measures or measures of change in execution time. The normal relationships between syllable repetition rate and change in syllable initiation time for stress were not found in the SD patients. Change in syllable initiation time for stress was related to sentence execution time and execution time change only in the SD patients. In basal ganglia disease, these deficits were not found, and reaction time did not relate to other aspects of speech timing. In conclusion, difficulties with syllable initiation were characteristic of SD patients with basal ganglia and white matter damage, but were not found in patients without white matter involvement.

341.5 THE GENERATION OF A RHYTHMICAL 3-4 HZ CEREBELLAR TREMOR REQUIRES MUSCLE STRETCH. J. Hore and D. Flament. Dept. of Physiology, Univ. of Western Ontario, London, Ont., Canada N6A 5C1.

One classic sign of a lesion of the lateral cerebellar nuclei is a rhythmical oscillation of the limb at about 3-4 Hz (cerebellar intention tremor). This tremor can occur when moving a limb or when attempting to hold it stationary. Two theories exist which could explain this tremor. The first is that tremor results from a central neural network behaving as an oscillator (eg. tremor still occurs after dorsal rhizotomy[2,3]). The second is that tremor results from unstable long loop stretch reflexes (eg. tremor is strongly influenced by proprioceptive feedback[1]).

To provide further information about cerebellar tremor 3 Cebus monkeys were trained to perform a step-tracking task under isotonic and isometric conditions. In the isotonic situation monkeys moved a handle against different torques between 2 targets displayed on an oscilloscope and separated by about 40°. In the isometric situation the handle was clamped and the 2 targets represented different levels of force. These tasks were performed during normal conditions and during cerebellar dysfunction produced by reversibly cooling through 2 probes implanted on either side of the dentate nucleus.

Under normal conditions monkeys performed both isotonic and isometric tasks smoothly and without tremor. In the isotonic situation during cerebellar cooling a marked 3-4 Hz rhythmical oscillation occurred when attempting to hold the arm stationary following movements in all 3 monkeys. In the isometric task during cerebellar cooling records of force became irregular as the monkeys were unable to hold force steady at the new level. Oscillations occurred in some trials when attempting to hold force steady, but they were more irregular and at a lower frequency (2-3 Hz) than the oscillations in the isotonic situation. Furthermore, tremor following isotonic movements was synchronized to end of movement as previously reported[1] while oscillations following isometric contractions were not synchronized to the end of the contraction.

The results indicate that peripheral feedback resulting from muscle stretch is necessary for the generation of a rhythmical 3-4 Hz cerebellar tremor.

341.6 THE INFLUENCE OF CONDITIONING STIMULATION OF THE COMMON AND SUPERFICIAL PERONEAL NERVES ON THE SOLEUS H-REFLEX IN NORMALS AND IN SUBJECTS WITH SPASTICITY. M. Levin*, A.B. Arsenault* and C.E. Chapman. Ecole de réadaptation, Univ. de Montréal and Institut de réadaptation de Montréal, Montréal, Québec, Canada, H3C 3J7.

In patients with spinal spasticity the soleus Hoffmann (H) reflex recovery curve conditioned by tibial nerve stimulation shows characteristic changes from the normal situation. Changes have also been reported in the soleus H-reflex conditioned by common peroneal nerve (CPN) stimulation although only delays of up to 30ms have been investigated in detail. This study has looked at longer delays (10-2000ms), comparing soleus H-reflex recovery curves conditioned by stimulation of the CPN and its cutaneous branch, the superficial peroneal (SPN), in 10 normal subjects and in 11 subjects with spasticity due to a clinically complete traumatic lesion of the spinal cord. The results were correlated with a clinical evaluation of spasticity. The conditioning stimulus was a train of 3 pulses (pulse duration 0.2ms) at 100Hz, repeated every 10s. The intensity was 1.4 X motor threshold (CPN) and 1.5 X threshold for a compound sensory action potential (SPN). The test stimulus (1ms pulse) was adjusted to produce an H-reflex, 75% of maximum.

In normal subjects, H-reflex recovery curves conditioned by the CPN showed (1) a large decrease at delays of 10-100ms, (2) a rapid recovery peaking at 140-160ms, (3) a slight decrease at 400ms and (4) a gradual recovery towards control levels which was still incomplete at 2s. Stimulation of the SPN had only facilitatory effects, two peaks occurring at about 40 and 140ms. In spastic subjects, the effects of CPN stimulation varied. In 6 subjects with moderate/severe spasticity, there was an early decrease and rapid recovery as in normals but the recovery was usually faster and earlier. There was little evidence of the late peak (at 140ms) and subsequent depression as in normals. In 4 subjects with mild spasticity, the H-reflex showed a gradual and modest decline (onset: 20ms, end: 600ms), followed by a slow recovery to control values. SPN stimulation caused, if anything, a slight decrease of the soleus H-reflex in the spastic subjects.

The results suggest that muscular, but not cutaneous, afferents are responsible for the inhibitory effects of CPN stimulation on the soleus H-reflex. Cutaneous afferents may contribute to the late peak at 140ms, perhaps through a supraspinal loop since these facilitatory effects were absent in the spinal subjects. The results also suggest that the shape of the soleus H-reflex recovery curve conditioned by CPN stimulation may give an indication of the severity of the spasticity. Supported by the FRSQ and FCAC.

341.7 SPASTIC LOCOMOTION:A DYNAMIC ANALYSIS OF STROKE PATIENTS BEFORE AND AFTER THERAPY. C.J. Winstein* and A. Garfinkel* (SPON: J.L.Smith). Dept. of Kinesiology, University of California, Los Angeles, CA 90024.

Following therapy, stroke patients demonstrated improvements in specific gait measures (Winstein, C.J. and Perry, J., Phys Ther., submitted, 1985). It was suggested that a possible source of this improvement was a reduction of interfering spasticity. Typically, spasticity is evaluated clinically with passive limb movement. This method is clearly not appropriate for assessing spasticity in motion. Qualitative dynamics offers a possible approach to describing spastic limb motion (Garfinkel, A., Am. J. Physiol. 245: R455-R466, 1983). The following knee and ankle motion analyses examined spastic locomotion and the changes which occurred following therapy. Qualitative dynamics and associated quantitative indices were compared.

Stroke patients walked on a 15 meter walkway at a self-chosen comfortable velocity before and after a three week therapy program**. Signals from two electrogoniometers (double-parallelogram design) and two footswitches were recorded. The footswitch signals were used to define the gait cycle variables (gait cycle time, stride length, single limb stance time, etc.). Electrogoniometric signals were digitized (625 samples /sec). These digitized data were sampled every 20 msec, smoothed and then processed by a PDP 11/34 computer. Intersegmental knee-ankle coordination plots and phase plane plots of joint position as a function of an estimate of the first order derivative were generated.

Preliminary results indicate that while several subjects showed large improvements in linear velocity, they demonstrated quite divergent changes in qualitative dynamics. In particular, of two subjects who showed similar quantitative changes, one developed a totally different intersegmental coordination pattern, while the other displayed an intersegmental coordination pattern that was similar to the pre-treatment pattern, but scaled up in size. The phase plane plots revealed a dominant velocity oscillation which had a relatively smaller amplitude post-treatment. This finding suggests that dynamic spasticity was not itself reduced, but that its relative interference to joint motion was reduced due to a concomitant increase in angular joint velocity.

341.8 INHIBITION OF PROSTAGLANDIN SYNTHETASE PRODUCES A MUSCULAR DYSTROPHY-LIKE MYOPATHY. I.S. McLennan* (SPON: R. Mark). Dept. of Behavioural Biology, Research School of Biological Sciences, Australian National University, Canberra, ACT, 2601, Australia

The function of striated muscle is dependent upon the highly organised nature of its myofibrils. Disruption of myofibrillar structure is part of the aetiology of many muscle pathologies, including various forms of muscular dystrophy. The regulation of myofibrillar assembly is therefore of interest. I report here that administration of inhibitors of prostaglandin synthetase to chicken embryos disrupts the development of their myofibrils and creates a pathology similar to that of muscular dysgenesis and muscular dystrophy.

Chicken embryos were treated with either aspirin (2.7mg) or indomethacin (0.17mg) when 4 days old and sacrificed when either 10 or 19 days old. Their hindlimbs were skinned, fixed in a solution containing 2.5% glutaraldehyde, 4% formaldehyde and 0.1M sodium cadodylate, pH 7.4. Their Iliofibularis were then dissected from their thighs, postfixed with osmium tetroxide, stained en block with uranyl acetate and embedded in araldite. Light microscope sections were stained with toluidine blue and electron microscope sections with lead citrate.

The myofibrillar structure of the treated muscles was grossly and variably distorted. In the extreme, the myofibrils had totally dissociated. More frequently, the myofibrils had formed but were malaligned and had a variety of distorted structures, including disruption of the Z band, lack of electron density in the H zone, depletion of thick or thick and thin filaments and inappropriate splitting.

These results indicate that prostaglandin E1 is an important regulator of myofibrillogenesis and that abnormal prostaglandin function may directly or indirectly be involved in the pathogenesis of diseases such as muscular dystrophy and muscular dysgenesis. Prostaglandin E1 may therefore have therapeutic value in ameliorating the loss of function associated with many muscle pathologies.

341.9 VALIDATION OF AN ANIMAL MODEL OF IMPAIRED MUSCLE GLYCOLYSIS: IODOACETATE DOES NOT DIRECTLY ALTER EXCITATION-CONTRACTION COUPLING. R.L.RUFF. Dept. of Neurology, Cleveland VAMC and Case Western Reserve University, Cleveland, Ohio 44106.

There are several inherited disorders of muscle glycolysis and glycogenolysis. In these diseases ischemic exercise results in severe muscle cramping and sometimes rhabdomyolysis. The muscle cramping is electically silent, suggesting that ischemic contraction produces either excessive release of calcium from the sarcoplasmic reticulum (SR) or blocks the ability of the SR to uptake calcium. An understanding of the molecular basis of the contracture could suggest specific treatments and might also provide additional insights into the common problem of muscle cramping. Because these diseases are rare and human tissue is difficult to obtain, an animal model would be useful. Brumback et al. (Muscle and Nerve 6:52,1983) showed that intra-aortic injection of iodoacetate, which blocks the glycolytic enzyme glyceraldehyde-3-phosphate dehydrogenase, produced exercise-induced, electrically silent muscle contraction and rhabdomyolysis. There were no systemic complications from the injections so that muscle changes could be studied in vivo. However, for this model to be valid, iodoacetate must not directly affect excitation-contraction coupling.

The actions of iodoacetate were studied in intact and chemically skinned muscle fibers from the extensor digitorum longus (EDL) muscle in adult (300g) Sprague Dawley rats. Membrane potential, input resistance, and electrical excitability of muscle fibers studied in vivo were not altered by arterial injection of iodoacetate followed by ischemic stimulation resulting in prolonged muscle contracture. The strength-duration relationship of individual fibers studied in vitro were not changed by treatment with iodoacetate. Iodoacetate did not cause spontaneous contraction, change the pCa-tension relationship, or alter the normalized tension of skinned muscle fibers. It did not cause calcium release from the SR, or prevent calcium accumulation by the SR. Therefore, iodoacetate did not appear to have any direct effects on the sarcolemma, the myofibrillar proteins, or the SR. Thus it appears that iodoacetate produces exercise-induced contracture by blocking muscle glycolysis which results in depletion of high energy stores

341.PO DYSFUNCTION OF VOLUNTARY MOVEMENT IN SCHIZOPHRENIA. P.B. Vrtunski, D.M. Simpson*, K.M. Weiss* and G.C. Davis*. Cleveland VA Medical Center (Research Service), Brecksville, OH 44141.

A number of disturbances of motor function have been observed in schizophrenia. The most extensive work was done on the eye tracking dysfunction (ETD) by Holzman and his collaborators. Voluntary movement involving skeletal musculature was not systematically investigated, however. The present study involves the use of reaction time paradigm to generate a button-press response which is then subjected to microbehavioral analysis. The analysis is carried out by recording the force analogs which make up the actual response, dividing it into premotor and motor segments, and observing whether the tasks of varied difficulty differentially modify movement performance.

The control group (N=20) with mean age of 30.6 years, and the schizophrenic group (N=19) who met DSM-III criteria with mean age of 33.0 years, were compared. Four types of stimuli were used, varying in modality of presentation (visual or auditory), and type of material (verbal or nonverbal). Thus, the task involved a standard choice reaction time procedure in which the subject made a forced choice discrimination with lines, pictures, sounds and spoken words (Vrtunski, P.B. et al. Brain, 106:929, 1983).

Schizophrenics had significantly longer premotor segments, 1020 msec overall, than the control subjects, 659 msec overall ($F=22.03$, $p<.0001$). The four stimulus conditions differentially affected this variable ($F=138.96$, $p<.0001$), with line discriminations being accompanied by the shortest premotor segments and word disciminations, by the longest. The group by stimulus condition interaction term was not significant. Schizophrenics exhibited significantly longer motor segments (353 msec overall) than controls (207 msec overall) ($F=16.38$, $p<.001$). Duration of motor segment also increased significantly with task difficulty ($F=11.64$, $p<.0001$). Most importantly, there was a significant group by stimulus condition interaction ($F=3.58$, $p<.02$) with schizophrenics showing longer motor segments after verbal discriminations with either visual or auditory stimuli.

Although increased duration of movement performance in the isometric button-press may, like disordered visual tracking, not prove specific for schizophrenia (Holzman, P.S. Schizoph. Bull., 9:33, 1983), our results provide a method for examining questions of the cognitive deficits in schizophrenia and their interaction with psychomotor organization. The large deterioration produced in motor response with verbal discrimination tasks in schizophrenics suggests the impairment of specifically verbal information processing.

342.1 EFFECT OF FAR ULTRAVIOLET RADIATION (EXCIMER LASER) ON THE ADULT SPINAL CORD OF RAT. H. O. Nornes, R. Srinivasan*+, R. Solanki*, and E. Johnson*. Departments of Anatomy and Electrical Engineering, Colorado State University, Fort Collins, CO 80523, +IBM Watson Research Center, Yorktown Heights, N.Y. 10958

Transplantation methods have possibilites for reconstruction of the injured central nervous system (CNS), and we are investigating the possibility of using an excimer laser as an ideal surgical tool which causes minimal damage to the surrounding CNS tissue and does not coagulate and seal the surgical surface. This laser emits ultraviolet radiation at 193 nm which interacts photochemically with organic polymers and breaks the molecules into smaller volatile fragments (photoablation) without heating the surrounding material (B. G. Garrison, R. Srinivasan, J. of Applied Physics, 55: 1985).

A laminectomy was performed on 8-10 week old Sprague/Dawley female rats at $T_{10}$, and the spinal cord was exposed to 193 nm radiation generated from argon-flouride laser. A cavity was made in the middorsal region about 1-3 mm deep and 1-2 mm in diameter. Five weeks post-surgery, the animals were analyzed with the light microscope (Bodian silver and hematoxylin, eosin, phyloxine stains.

The cavities in the spinal cord became filled with loose fibrous connective tissue, while the edges had sharp boundaries along both white and grey matter. In some cases there was no evidence of necrotic tissue or hyperplasia of glia cells in either the white and grey matter. The cuts with little or no visible tissue damage had extensive regeneration of nerve fibers across the boundary and into the loose fibrous scar. This regeneration occurred in both the grey and white matter and was in sharp contrast to the response in cavities made with knife-cuts or suction lesions. Those edges were irregular and exhibited necrosis and hyperplasia, and there was little or no regeneration of host fibers across the host-scar boundary.

The unique finding of this study was the extensive regeneration of spinal cord axons across the host-scar boundary into the loose fibrous scar in the tissue cut with the laser. These results raise the possibility that the excimer laser may be an ideal tool for reconstructive surgery in the central nervous system.

342.2 THE MODIFIED VASCULAR CLAMP TECHNIQUE: A NEW EXPERIMENTAL MODEL FOR SPINAL CORD INJURY. E. C. Benzel and M. M. Thomas. Louisiana State University School of Medicine, Shreveport, LA, 71130.

The evaluation of therapeutic modalities for the treatment of spinal cord injury (SCI) has been heavily influenced by animal models involving the application of a dorsally applied injury. Although these models are both easily performed and quantitable they do not offer an accurate reproduction of the mechanisms of injury in most SCI clinical situations. Most patients who incur a traumatic SCI do so by way of a ventrally located force (mass) impinging upon the spinal cord. This force (mass) persists following the initial impact. The standard weight-drop technique of SCI fails in mimicking the clinico-pathological situation in several ways: First the force is placed dorsally, not ventrally. Second, the injury is incurred following a decompressive laminectomy. Third, the force (mass) does not persist following the initial impact.

A new SCI model in the rat has been devised in which a DeBakey aortic aneurysm vascular clamp has been modified to produce a ventral persisting mass (bone and/or soft tissue) without first performing a decompressive operation (i. e. laminectomy performed as part of the weight-drop technique). This model is capable of producing a wide spectrum of neurologic injury ranging from a minimal injury to a complete myelopathy.

The Tilt Board Technique was utilized for neurologic evaluation following the injury. The utilization of the above mentioned standardized vascular clamp technique in 24 surviving animals to date has resulted in 9 apparent complete myelopathies 13 apparent incomplete myelopathies and 2 animals without apparent injury. The percent loss of neurologic function (change in degrees of tilt via the Tilt Board Technique) lost in each group was 48%, 38%, and 12% respectively. Sagital post-morteum sections confirm a mass lesion located ventral to the spinal cord.

This experimental model appears to accurately reproduce the clinico-pathological situation seen in human SCI in which an apparent similar bony/soft tissue injury results in a variety of clinical manisfestations ranging from a complete myelopathy to no apparent injury with approximately a 20% mortality.

342.3 A PHYSIOLOGICAL ANALYSIS OF A HYBRID COMPUTER-CONTROLLED SPINAL CORD INJURY DEVICE. S.K. Somerson* and B.T. Stokes, Dept. Physiology, Ohio State Univ. Coll. of Med., Columbus, OH 43210

The time course of extracellular hypocalcia was studied in the rat spinal cord following the production of a mechanically predictable spinal cord injury. Animals were rigidly held by spinous process clamps and needles through the interspinous ligaments. The displacement (magnitude and duration) of the spinal cord during injury was regulated by a hybrid computer which used negative feedback circuitry to compare the preset displacement function to the actual displacement parameters. By allowing the delivered force to vary, a reproducible displacement profile could be achieved. The entire impact injury was over in app. 20 msec and the impactor withdrawn (< 4.0 msec) to a position (4.0 mm above the dural surface) that prevented subsequent contact of the animal with the device. The necessary force adjustments during injury also allowed an assessment of the variance in mechanical characteristics of the spinal compartment. Based on previous studies involving behavioral and histopathological assessments, three levels (light, intermediate and heavy) of displacement injury were produced. Impact duration for these levels were 14, 19 and 24 msec respectively; magnitudes ranged from 1.5-1.8 mm.

Calcium activities in the spinal cord of control animals showed little variation to electrode position or time of placement (mean +/- SEM = 1.08 +/- 0.01 mM). After injury, calcium activities at the injury site decreased to values below 0.1 mM and then recovered towards normal values over the next three hours. Incomplete recoveries occurred in the intermediate and heavy injury groups (0.72 +/-0.01 mM and 0.58 +/-0.01 mM respectively). Calcium activity in the light injury group recovered to normal levels by 3 hrs. Specific injury protocols therefore result in reproducible responses in the cellular microenvironment. In addition, since we have previously shown all animals in the light injury group have transient neurological and pathological defects, it is probable that acute hypocalcia transients are predictive of the subsequent outcome of acute spinal cord injury. (Supported by USPHS-10165 to The Ohio State University).

342.4 A BEHAVIORAL AND ANATOMICAL ANALYSIS OF SPINAL CORD INJURY PRODUCED BY A FEEDBACK CONTROLLED COMPUTERIZED IMPACTION DEVICE. Bresnahan, J.C., Todd, F.D.*, Noyes, D.H.*, and Beattie, M.S., Depts. of Anat., Physiol., Surgery (Div. Neurosurg.), and Neurosci. Res. Lab., The Ohio State University, Columbus, Ohio 43210.

The weight-drop method of Allen is still the most widely used experimental technique for spinal cord injury. In order to provide a reproducible experimental injury with immediate information on the actual mechanical impact properties, we have developed a feedback-controlled, electromagnetically-driven impactor. The device is sensitive to the characteristics of the injured tissue and allows continuous manipulation of force and displacement. The physical descriptors of each impact include cord surface displacement (cm) and force (kdyne), which yield impulse momentum (kdynes-sec), velocity (cm/sec), power (Mdyne-cm/sec), and work (kdyne/sec).

We have tested the device by delivering a wide range of impact intensities to the mid-thoracic spinal cord of rats. Impact descriptors were correlated with motor performance and lesion volume. Motor performance tests were administered preoperatively and over a 3 week post-injury period, and included open field walking (rated on a modified Tarlov scale), inclined plane test, and an agility test (grid-walking). The results showed significant correlations ($p < 0.01$) between lesion volume and all impact descriptors (rho = 0.81 to 0.93). Early in the recovery period, open-field walking and inclined plane performance correlated significantly ($p < 0.05$) with lesion volume and all impact descriptors. Later, performance on the agility test correlated ($p < 0.05$) with lesion volume and all impact parameters indicating that this test was most sensitive to residual neurological deficits.

We also tested the reliability of the device by setting it to produce a uniform time-displacement pulse, chosen from the prior experiment to yield a significant but partially reecoverable deficit. The results suggest that the descriptors of the actual impact are highly predictive of subsequent behavioral and histopathologic findings. Infrequent deviations from intended impact parameters are immediately noted.

Thus, the system provides three distinct advantages over previous methods: 1) a wide range of impact parameters; 2) a consistent and controllable lesion; and 33) immediate recognition of mechanical variability. (Supported by NIH Grant #NS 10165)

342.5 **A MOTOR EVOKED POTENTIAL AS AN INDICATOR OF RECOVERY IN CHRONIC SPINAL CORD INJURED CATS.** M. McCaffrey, W. J. Levy, and D. H. York. University of Missouri Health Sciences Center, Columbia, Missouri 65212

We have evaluated the predictive value for motor function of an evoked potential created by stimulating the motor cortex in spinal cord injured cats, both acute and chronic animals. This signal is derived from either direct or transcranial stimulation of the motor cortex, producing a descending activation of the pyramidal tracts which can be recorded in the peripheral nerves and produces EMG and movement responses. We have previously reported on the characteristics of this signal which is largely abolished by pyramidotomy and unaffected by red nucleus lesions. Its conduction velocity is approximately 100 meters per second and it travels in both dorsolateral and ventral cord. In a series of acute spinal cord injury cats, using a weight drop model, we determined the relative sensitivity of the motor evoked potential and the somatosensory evoked potential to cord injury. Adult conditioned cats were anesthetized under ketamine with arterial and venous lines placed and ventilated on a Harvard animal ventilator via a tracheostomy. Evoked potential monitoring was done with a Cadwell 7400. While the somatosensory evoked potential is frequently abolished by 200 gm cm of force, the motor evoked potential in the spinal cord is abolished at 100-150 gm cm of force. The motor evoked potential recorded in the peripheral nerve is much more sensitive to injury and is abolished by as little as 50 gm cm of force in some animals. In most cats, 75 to 100 gm cm of force will abolish the motor evoked potential in the peripheral nerve. It was observed at injury levels below those required to cause a temporary loss of the signal, the lesion produces an instability in the response. This results in a lessening of the frequency rate at which the signal will follow. At frequency rates below this, the signal fatigues, observed by sequential runs without pause recorded on the signal averager with both a progressive increase in latency and a decrease in amplitude evident. It was also observed that in some animals metabolic abnormalities, such as a metabolic acidosis, produce an instability in the signal from trial to trial with varying amplitudes and latencies. A series of chronic spinal cord injury to animals is now underway and we have observed that weight drop lesions in the 100-150 gm cm range abolish the motor evoked potential for an hour of post injury follow-up recording. They do not abolish the SEP, consistent with acute studies. However, these animals are paraplegic for a period of time ranging from days to weeks after injury. As they recover, the motor evoked potential recovers strength and consistently is stronger in the leg which is stronger in the ambulating cat. In some cases, the recovery of the motor evoked potential preceeds the recovery of function in the leg and can be used to predict the stronger leg. This suggests that the test is of clinical value in man since in humans recovery from spinal cord injury is much less effective than in the cat and lighter weight drop injuries would likely result in permanent damage. Therefore, the MEP is a better indicator of motor function than the SEP.

342.6 MECHANICAL PARAMETERS OF IMPACT CORRELATE WELL WITH OVERALL LOSS OF MYELINATED AXONS IN SPINAL CORD INJURY BUT NOT WITH DEMYELINATION, CALIBER SPECTRUM, OR RECOVERY OF FUNCTION. A.R. Blight, Depts. Neurosurgery and Physiology & Biophysics, New York Univ. Medical Center, 550 First Avenue, New York, NY 10016.

Contusion injury forms the most realistic controlled model of spinal trauma for studying pathophysiological mechanisms or potential treatment. Its usefulness has been limited, however, largely because of variability in the functional deficits that result from apparently 'standardized' mechanical impact, and because of the difficulty of measuring deficits or variability at sufficiently high resolution.

The characteristic pattern of axonal destruction and demyelination that follows contusion injury of the cat thoracic spinal cord was studied quantitatively by line-sampling in 1 µm plastic sections with the light microscope (see Neuroscience, 10: 521). Injuries were produced by a weight-drop with the vertebra below the impact (T9) stabilized by supports under the transverse processes. Using 2 groups of 10 animals, the effects of 2 levels of injury were examined: 10 or 13 g dropped 20 cm. The impact was delivered through a 5 mm dia teflon piston. Animals were kept for 3 months after injury, then fixed by perfusion.

The overall extent of axonal loss correlated well with the kinetic energy of the weight at impact, but only when expressed per unit cross sectional area of cord. Above 0.002 J $mm^{-2}$ there was practically no survival of axons at the lesion site. Between 0.0008 and 0.002 J $mm^{-2}$ the number of surviving axons varied between 100,000 and 2,000 with a linear correlation coefficient of -0.85.

Both caliber spectrum and myelin index distribution varied widely between animals, but neither variable correlated significantly with axon number or mechanical parameters. No recovery of hindlimb postural function was seen with less than 50,000 myelinated axons at the lesion center, but recovery of function in animals with more than 50,000 axons did not correlate well with axon number or injury mechanics.

Several precautions are necessary in interpreting data from contusion injuries: a) the size of the spinal cord must be taken into account; b) not all tissue pathology relates directly to the initial impact; c) tissue destruction is not distributed evenly and its extent is reflected poorly by testing the function of small subsets of axons. Given such precautions, contusion injury may provide the best possible combination of simplicity, realism and repeatability, but the phenomena themselves remain complex, intrinsically variable, and difficult to interpret without searching analysis. Supported by NS10164 and NS15590 from NINCDS and by the American Paralysis Association.

342.7 DEVELOPMENT OF CHANGES IN THE SPINAL CORD OF THE RAT AFTER CONTUSIVE INJURY. L.J. Noble and J.R. Wrathall. Dept. of Anatomy, Georgetown Univ. Sch. of Med., Washington, D.C. 20007.

We have previously described an experimental model of contusive injury in which groups of rats with mild, moderate, or severe functional deficit may be produced by a weight drop (WD) technique (EXP. NEUROL. 88,108-149,1985). Morphometric analyses of the epicenter (region of maximal disruption) at 4 weeks post-injury indicated significant correlations between the degree of functional deficit and areas of both the lesion and residual tissue. In particular residual white matter was highly correlated to functional deficit (r= -0.91) as measured by a combined behavioral score. We have now examined the development of these lesions with time after injury.

Rats were sacrificed at 15 min, 24 hrs, 1 wk, 4 wks, or 8 wks after injury. Spinal cord tissue was embedded in paraffin and transverse, serial sections were cut and stained for visualization at the light microscopic level. Sections representing the epicenter were measured using a digitizing pad and interfaced with an Apple IIe computer. The total cross-sectional area of the cord, the cavity, and the remaining gray and white matter were determined.

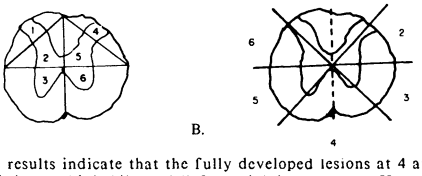
The time course of lesion development was generally similar for the different injury groups. 15 MIN AFTER INJURY. The gray matter was generally replaced by hemorrhage with the exception of the peripheral rims of the dorsal and (with lesser injuries) ventral horns. 24 HRS AFTER INJURY. A central cavity, containing cords of nonneuronal cells, typically replaced the ventral horn and most if not all the dorsal horn. The white matter contained variable numbers (depending on injury level) of axons and microcysts. Many of the axons appeared to be swollen. Demyelination was observed primarily in the dorsal columns and the paracentral white matter. 1 WK AFTER INJURY. The epicenter was characterized by a central cavity or core of granular, amorphous material. The residual white matter consisted of a complete or partial rim of tissue, exhibited regions of demyelination (most notably in the dorsal and dorsolateral white matter), and contained numerous microcysts and swollen axon cylinders. 4 AND 8 WKS AFTER INJURY. The epicenter consisted of a central cavity which contained primarily macrophages and was surrounded by a glial limitans. The remaining white matter exhibited areas of demyelination, and contained empty myelin sheathes, and microcysts. Many axon profiles were swollen and appeared granular and acidophilic. In a limited number of cases the epicenter was composed of only a meningeal framework enclosing a cavity.

Several significant trends were apparent from the quantitative analysis. First, the formation of a cavity was apparent between 15 min and 24 hrs and reached a maximum area at 1 wk after injury. Secondly, the total cross-sectional area of the cord became significantly less between 1 and 4 wks after injury. This was largely accounted for by a reduction in the area of the cavity. Third, the significant reduction in gray and white matter occurred between 24 hrs and 1 wk after injury. Thereafter, the areas of gray and white matter for each injury group remained constant. (Supported by NIH NINCDS contract NO1-NS-2-2310.)

342.8 SECTOR ANALYSIS OF SPINAL CORD LESIONS PRODUCED BY CONTUSIVE INJURY IN THE RAT. J.R. Wrathall and L.J. Noble, Dept. of Anatomy, Georgetown Univ., Washington, D.C. 20007

We have previously described a rat model of experimental spinal cord injury in which groups of animals with mild, moderate or severe functional deficits can be produced by dropping a 10 g weight 2.5, 5.0 or 17.5 cm respectively onto the exposed dura at the T8 level (EXP. NEUROL. 88:108-122, 1985). Morphometric analyses showed significant correlations between measures of the lesion epicenter (area of maximal damage) at 4 weeks after injury and the functional deficit as measured by behavioral tests (EXP. NEUROL. 88:135-149, 1985). Such analyses provide an overall view of the lesion but do not reflect important regional differences in the response of the spinal cord to experimental contusive injury. We have now examined different sectors of the spinal cord to investigate the loss of gray and white matter of the cord with time after injury.

Groups of rats were subjected to a 2.5, 5.0 and 17.5 cm weight drop injury and perfused with fixative at 15 min, 24 hr, 1 week, 4 weeks and 8 weeks after injury. Spinal cord tissue centering on the injury site was embedded in paraffin and serial transverse sections prepared. Sections representing the lesion epicenter were traced and subjected to quantitative analysis in terms of the total area, areas of recognizable gray and white matter, areas of hemorrhage and of cavitation in each sector of the cord. Sectors were defined by transparent overlays that divided the cord into 6 regions. For analysis of residual gray matter the 6 sectors included left and right dorsal peripheral (laminae I-IV), dorsal central (IV, V, VII, X) and ventral (VII-X) regions of the cord as shown in Fig 1A. For analysis of residual white matter radial sectors divided the cord into dorsal, left and right dorsal lateral and ventral lateral, and ventral regions as shown in Fig. 1B. Areas were traced on a digitizing pad and calculated using a computerized morphometry system (Bioquant).



The results indicate that the fully developed lesions at 4 and 8 weeks after injury exhibit bilateral (left vs right) symmetry. However, in all three injury groups more central than peripheral and more dorsal than ventral spinal cord tissue is lost. The time course studies indicate that not only is more central and dorsal tissue eventually lost but also that overt necrosis in these areas appears to occur at earlier times after injury. (Supported by NIH NINCDS contract NO1-NS-2-2310)

342.9 EFFECT OF SPINAL CORD INJURY ON THE "PARAVASCULAR" INFLUX OF HORSERADISH PEROXIDASE (HRP) FROM THE SUBARACHNOID SPACE. C.P. Barrett*, S.H. Deschner*, M.L. Rennels, J.P. Petrali*, E.J. Donati*, and L. Guth* Dept. of Anatomy, University of Maryland School of Medicine, Baltimore, MD 21201

After injection into the ventricles or subarachnoid space, HRP is rapidly distributed throughout the neuraxis via the perivascular spaces of large intraparenchymal blood vessels and the sleeve-like basal laminae around capillaries. This rapid "paravascular" distribution of tracer and its accumulation within the extracellular spaces defines a circulatory pathway by which the CSF equilibrates with the interstitial fluid compartment of the brain and spinal cord (Rennels et al., 326: 47, 1985). We examined the effect of localized spinal cord injury on this fluid pathway with the goal of determining whether the intrathecal route is useful for administering agents designed to promote healing of spinal cord lesions. Twelve adult female Wistar rats were anesthetized and, after laminectomy at T5, their spinal cords were crushed by extradural compression with a fine Dumont forceps. Six control rats were anesthetized and subjected to laminectomy without spinal crush. At selected intervals from 5 min to 3 days postoperatively, 4ul of a 6% solution of type VI HRP (Sigma) was injected into the lumbar cistern and 5 minutes later the animals were perfused intracardially with 1.5% glutaraldehyde-1.0% paraformaldehyde (in 0.1 M phosphate buffer, pH 7.4). Frozen sections were prepared and reacted for HRP activity using tetramethylbenzidine as chromogen. In both experimental and control rats, the tracer spread rapidly from lumbar to cervical levels and was distributed throughout undamaged regions of spinal parenchyma via the perivascular route. In regions of spinal cord crush, however, the tracer failed to enter the lesion via this route and, as a result, there was a zone of 2-3 segments in length that was free of HRP reactivity. These results indicate that access of CSF to the interstitium is diminished at sites of spinal injury. Such a decreased circulation of interstitial fluid could result not only in changes in extracellular pH, osmolarity, and ionic composition but might also produce secondary metabolic derangements that contribute to the extensive necrosis that accompanies spinal cord injury.

342.10 EFFECTS OF DORSAL BILATERAL RHIZOTOMY ON THE HIGH AFFINITY UPTAKE OF ($^3$H)-GLUTAMATE, -GABA AND -5-HT BY MYELIN-FREE SYNAPTOSOMAL PREPARATIONS FROM THE SPINAL CORD OF SPASTIC AND NONSPASTIC DOGS. P.V. Hall*, E. Chernet*, S. Shapiro*, C. Sartorius* and W.J. McBride. Depts. of Surgery & Psychiatry, Indiana Univ. School of Medicine, Indianapolis, IN 46223.

Previous studies from our laboratory (McBride et al., J. Neurochem. 42: 1625, 1984) indicated that the high affinity uptake of ($^3$H)-glutamate was greater in the spinal cord of spastic dogs than in the control group. One interpretation of the data is that the increase in uptake in the spastic group is due to axonal sprouting of the primary afferents and/or interneurons following degeneration of descending pathways. Using the high affinity uptake of glutamate as a marker, the present study was undertaken to test the hypothesis that (a) glutamate is the transmitter from some primary afferents, and (b) sprouting of glutamatergic primary afferents has occurred in the spastic animals. The myelin-free synaptosomal fraction, obtained by centrifugation procedures of the spinal cord of mongrel dogs, was used for the uptake studies. There were 4 groups of experimental animals: (a) sham-operated; (b) dorsal bilateral rhizotomy ($L_2$-$L_6$) for 1 week (DBR); (c) mid-thoracic crush for 4 or more weeks (spastic group); and (d) mid-thoracic crush for 4 or more weeks and DBR for one week (spastic + DBR). In addition to the high affinity uptake of 1 µM ($^3$H)-glutamate, the uptake of 1 µM ($^3$H)-GABA (an interneuronal marker) and 30 nM ($^3$H)-5-HT were also determined. The uptake of glutamate was 20% lower ($P < 0.05$) in the DBR group (245 + 35 pmol/min/mg protein, N=7) relative to the control group (299 + 33, N=7). The uptake of GABA was not different between the two groups (188 + 15 pmol/min/mg protein for sham vs. 178 + 21 for DBR). Surprisingly, there was a 45% decrease in the uptake of 5-HT in the DBR group (0.57 + 0.10 pmol/min/mg protein, N=6) compared to the control values (1.04 + 0.23, N=6). As expected, midthoracic crush of the spinal cord produced a 97% decrease in the uptake of 5-HT, indicating a loss of descending serotonergic fibers. One week after DBR treatment of the spastic dogs, there was a significant ($P < 0.005$) 25% reduction in the uptake of both glutamate and GABA. The 20% lower uptake of glutamate in the DBR group relative to sham operated is consistent with the idea that a portion of the primary afferents may use glutamate as a transmitter. Furthermore, the finding that DBR treatment of spastic dogs reduced the elevated glutamate uptake by 25% may indicate some sprouting of the primary afferents has occurred in the spastic dogs. However, the reduction in the uptake of GABA with DBR treatment of the spastic group and of 5-HT with DBR treatment of normal dogs is difficult to explain.

## MOTIVATION AND EMOTIONS

343.1 PROPOSED ANXIOGENIC ENDOCOID: MODULATION BY GABA AND BENZODIAZEPINE SYSTEMS. C.M. Harris and H. Lal. Dept. of Pharmacol., Tex. Coll. Osteopath. Med., Fort Worth, TX 76107

Chloride (Cl) conductance is mediated by an ionophore located in a supramolecular complex with receptors for GABA, benzodiazepines (BZ), pentobarbital (PB), picrotoxin, and other still unidentified ligands. BZ, PB and GABAergic agents increase Cl conductance and reduce anxiety (Lal et al., Neuropharmacol. 19:785, 1980). If there is an endogenous substance (endocoid) which produces anxiety by inhibiting Cl conductance, its action should be unmasked by removal of the endogenous influences which stimulate the GABA and BZ systems. Towards testing this hypothesis, anxiogenic properties of antagonists for GABA and for BZ were tested singly and in combination in an animal model for anxiety. This model provides a rate-independent assay for anxiogenic drugs (Lal and Emmett-Oglesby, Neuropharmacol. 22:1423, 1983). Rats were trained in a food-reinforced operant task to select 1 of 2 levers after injection of the anxiogenic drug pentylenetetrazol (PTZ), and the other lever after saline. These rats selected the PTZ-lever after PTZ and the other lever after saline, diazepam (DZ) or PB. PTZ-lever selection was blocked by pretreatment with DZ or PB. Subconvulsant doses of GABA antagonists (bicuculline, 2.5 mg/kg, or picrotoxinin, 0.32 - 0.64 mg/kg) and of a GABA synthesis inhibitor (isoniazid, INH, 100 - 200 mg/kg) failed to mimic PTZ. Similarly, BZ-receptor blockers (RO15-1788, 2.5 - 40 mg/kg, and CGS 8216, 10 - 40 mg/kg) also failed to mimic PTZ. However a marked PTZ-like effect was observed after combinations of a subconvulsant dose of INH (200 mg/kg) with low doses of the BZ antagonists (RO15-1788, 0.64 - 10 mg/kg, or CGS 8216, 2.5 mg/kg). The PTZ-like stimulus produced by the combination of RO15-1788 and isoniazid was blocked by PB, 5 mg/kg. These data support the hypothesis that there is an anxiogenic endocoid, and that its anxiogenic effect is antagonized by ligands for the BZ, PB and GABA receptors. The BZ and GABA systems appear to act in a concerted manner such that, if the function of one system is compromised, the other system compensates for and/or facillitates the function of the compromised system. It is unlikely that the site of action of this endocoid is the BZ receptor because an anxiogenic effect was detected when the BZ receptors were blocked. The site of action for this anxiogenic endocoid may be the same as that for PB because PB blocked the anxiogenic effect. Both PB and the endocoid may act directly at the Cl ionophore, with the endocoid blocking, and the PB increasing Cl conductance. However, another site cannot be ruled out.

343.2 EFFECTS OF THE BETA-CARBOLINE, FG 7142, ON THE SOCIAL BEHAVIOR OF MALE RATS IN A LIVING CAGE. C.H.M. Beck[1] and S.J. Cooper[2], [1]Dept. of Psychology, University of Alberta, Edmonton, Alberta, Canada T6G 2E1, [2]Dept. of Psychology, University of Birmingham, Birmingham B15 2TT, U.K.

The benzodiazepine inverse agonist FG 7142 (N'methyl-ß-carboline-3-carboxamide) decreased the time during which a pair of male rats interacted with each other in an arena (File, S.E. & Pellow, S., Arch. Internat. Pharm. Ther., 271:198, 1984). The purpose of the present study was to describe the effects, and their time-courses, of FG 7142 on social behavior in more detail. Four 6-min dyadic social encounters in a familiar living cage were observed in a paradigm in which one member of a pair of rats was injected. The behavior of the injected animal was coded on a microprocessor into exhaustive and mutually exclusive behavior categories including approaching, avoiding, and fighting with the other rat, locomoting, sniffing the cage, self-grooming and immobility. The four treatments were i.p. injections of vehicle (distilled water + Tween 80), and FG 7142 at 2.5, 5.0 and 10.0 mg/kg, respectively. N = 8 pairs of adult male hooded rats per group (body weight range: 178-262 g). All injections were administered 2 min before the start of the first observation trial; the observer was blind to injection conditions.

Compared to the effects of vehicle injection alone, FG 7142 decreased aggressive behavior but did not alter the total level of social interaction. This was because FG 7142 induced compensating increases in approaching and avoiding the other animal. The FG 7142 effects on these social behaviors were most apparent in the first two trials. All were dose dependent. Locomotion declined marginally and immobility increased in FG 7142-injected rats. Twitches and convulsions were seen in 3 of the 10 rats given 10 mg/kg FG 7142.

The rats in the foregoing study had been housed in pairs prior to testing. In a second experiment in which rats housed in isolation were used, vehicle-injected animals spent twice as much time in aggression as did the control animals in the pair-housed study. In spite of the increase in level of aggression, FG 7142 at 5.0 mg/kg again significantly decreased aggression. Thus our studies demonstrate that the inhibitory effect of FG 7142 on social behavior in male rats may be specifically related to aggression in situations which permit the expression of agonistic displays.

FG 7142 was generously supplied courtesy of Dr. E.N. Petersen, A/S Ferrosan, Copenhagen.

343.3 HYPOTHALAMIC TEMPERATURES OF RATS BEHAVIORALLY THERMOREGULATING IN 2450-MHz MICROWAVE FIELDS. D.M. Levinson (Univ. Missouri-K.C., 64110; & VA Med Ctr, K.C., MO), D.W. Riffle and D.R. Justesen (VA Med Ctr, Kansas City, MO 64128).

Four female Long-Evans rats, each with a chronic cannula implanted in the brain (target area: preoptic hypothalamus), were observed for performance of a lever-depression task in which they controlled either a 2450-MHz multipath microwave field at various dose rates (30, 60, or 90 mW/g) and at a constant ambient temperature (25.3°C); or the 2450-MHz field at a constant dose rate (60 mW/g) and at various ambient temperatures (17, 25, and 33°C). During daily 30-min. sessions (2 under each condition), each depression of the lever extinguished the field; which remained extinguished while the lever was depressed. A photic cue was presented in temporal synchrony with the field. Hypothalamic temperature was measured continuously by a Vitek thermometer with a field non-perturbing probe, which was acutely inserted into the cannula during each 30-min. session. Pre- and post-session colonic temperatures were measured by a Bailey thermometer.

Final means of hypothalamic and colonic temperature did not differ reliably, and under most conditions they ranged between 38.5°C and 39.5°C. (Under 17°C conditions, final temperatures ranged between 37.7°C and 40.1°C.) Means of hypothalamic temperatures typically rose 0.5 - 1.5°C above pre-exposure baselines within the initial 5 min. of a session, after which they gradually and reliably fell during the remainder of the session, for both varying dose rates [$F$ (9,27) = 13.01, $p$ <.001] and ambient temperatures [$F$ (9,27) = 5.50, $p$ <.001]. Hypothalamic temperatures did not reliably differ as a function of either dose rate or ambient temperature [both $F$s(2,6)<1.00]; however, there was a reliable interaction between minutes of sessions and ambient temperatures [$F$ (18,54) = 2.74, $p$ <.01]. This interaction is reflective of gradually declining temperatures following the initial rise for the 17°C and 25°C conditions, as opposed to no decline in temperatures following the initial rise for the 33°C condition. Times in the field were highly and negatively correlated with dose rates and ambient temperatures ($r$s (1) = -.94 and -.99 respectively], decreasing as these increased; further, times in the field differed reliably both as a function of dose rate [$F$ (2,6) = 82.22, $p$ <.001] and ambient temperature [$F$ (2,6) = 7.91, $p$ <.05]. These data indicate that rats exposed to fairly intense microwave fields will behave in a manner which enables them to maintain relatively consistant hypothalamic temperatures; the data also indicate that at higher ambient temperatures the animals' ability to thermoregulate behaviorally may become impaired, possibly because of thermal overload.

343.4 INVOLVEMENT OF THE DOPAMINERGIC PROJECTION FROM VENTRAL TEGMENTAL AREA TO NUCLEUS ACCUMBENS IN THE MOTIVATION UNDERLYING TWO-WAY AVOIDANCE IN THE RAT. W. J. Wilson and E. G. Baeske*. Department of Psychological Sciences, Indiana University - Purdue University at Fort Wayne, Fort Wayne, IN 46805.

Lesions of the nucleus accumbens (1,2) or the ventral tegmental area (VTA) (3) enhance two-way avoidance responding in rats. Izquierdo and his colleagues (4) have identified three independent factors that motivate shuttle responding in the signalled two-way avoidance paradigm. They are a "drive" state (D), resulting from nonassociative effects of the shock, a "pairing" factor (P) due to the temporal contiguity between signal and shock, and a "contingency" factor (C) that arises because a response during the signal effectively avoids the shock. Schutz and Izquierdo (2) have shown that the enhancement of avoidance by accumbens lesions is due to an increase in D. We are examining VTA lesioned rats to determine whether the enhancement of avoidance behavior is mediated by a similar increase in D, or instead by a change in P or C. If both lesions increase D, then the VTA-accumbens system must normally inhibit generalized drive.

Rats receive either bilateral electrolytic lesions of the VTA or sham lesions. They are then placed in a shuttle box and exposed to one of four behavioral paradigms in which 5 sec tones and 1.5 mA scrambled ac shocks are presented either with or without temporal contiguity, and with or without a contingency between responding during the tone and shock avoidance. The paradigms are:

D) no contiguity, no contingency; tones and shocks occur randomly, shuttle does not avoid shock.

DP) contiguity, but no contingency; tones always precede shock, but a shuttle is ineffective.

DC) contingency, but no contiguity; tones and shocks presented pseudo-randomly, shuttle during tone avoids the next shock.

DPC) contiguity and contingency; tones always precede shock, shuttle during tone avoids the next shock.

According to Izquierdo's analysis, a comparison of the shuttle responses to the tone in each of the four conditions by the VTA and sham lesioned rats will allow the determination of any differences in D, P, or C between the two groups. Such an analysis will indicate any similarities in the motivational involvement of the accumbens and the VTA.

343.5 **AUGMENTING/REDUCING OF CAT VISUAL EVOKED POTENTIALS AND INDIVIDUAL DIFFERENCES IN BEHAVIOR.** P. M. Saxton, J. Siegel and J. H. Lukas*[1]. Inst. for Neuroscience, Univ. of Delaware, Newark, DE, 19716.

The change in amplitude of the visual evoked potential (VEP) to an intensity series of light flashes varies between cats. Individuals showing increasing amplitudes to increasing intensities are termed augmenters; reducers show decreasing amplitudes at the highest intensities. A/R slopes correlate with ratings of cat behavior to novel or frightening stimuli. This experiment examines if cortical A/R is predictive also of an inhibitory capacity to control behavior under conditions of stress.

Eight cats were implanted with electrodes over primary visual cortex and VEPs were collected. Behavioral ratings were correlated with slopes of components NI and PI-NI to medium and high flash intensity ranges. Responses to novel stimuli indicated that augmenting cats were more active (r=0.55 to 0.72 for NI and PI-NI averaged slope at medium intensity range) and explorative (.52). Reducers vocalized more, were difficult to handle and aggressive toward other cats. Cats were trained to bar press for food reward in a cued two bar situation at a fixed interval (FI) and then in a differential reinforcement of low rate of response (DRL) paradigm. The disruptive effects of loud noise bursts during the FI and DRL performance and increasing task difficulty in the two bar DRL were tested. Latency to learn, rate of bar pressing, number and type of errors and efficiency were recorded for each 30 minute session.

When correlated with bar press learning PI-NI slopes at the high intensity range were more predictive. Reducers took longer to habituate to the situation (-.81) and to learn to bar press (-.4), and more days to reach FI criterion (-.49). Overall bar pressing ability correlated significantly (.71) with the high range PI-NI slope, indicating that augmenters, being more active and explorative, learned to bar press quickly and were better at it. A/R slope also correlated (.78) with extra presses in the two bar situation which is consistent with augmenter's exploratory behavior and faster learning.

In contrast to the FI task, in the DRL correlations were stronger with the NI slopes at the medium intensity range. In this inhibitory task augmenters took longer to learn (.76) and had less change in efficiency with noise. Augmenters did so poorly on this inhibitory task that they consequently showed less change when the task was made more difficult or stressful. In ranking the cat's overall control in the DRL task augmenters showed least control (.72).

The slope of PI-NI at high intensities correlates with spontaneous behaviors and learning of a FI task, while the A/R slope of the NI component at a medium intensity range is more predictive of inhibitory control required on a DRL task. Augmenters are active and responsive, learn the FI task faster, bar press vigorously and hence work with maximum efficiency. Reducers, on the other hand, show not only cortical inhibition but an enhanced capacity for learning and performing on an inhibitory task.

343.6 MULTIPLE UNIT ACTIVITY IN RESPONSE TO MOTIVATIONAL AND VISUAL STIMULATION. M. Morales* and J.J. Keene* (SPON: C. Zuazaga). Dept. of Physiology, Lab. of Neurobiology, Univ. Puerto Rico, San Juan, 00901.

Neural responses to motivational and sensory stimuli were analyzed using the multiple unit activity recording technique. Data was collected from 6 cat cerveau isole preparations. The data contained samples from cortex, thalamus, internal capsule and caudate. Motivational stimuli were applied to the medial forebrain bundle (M) and the mesencephalic reticular formation (R), which were rewarding and aversive inputs respectively. The sensory stimulus was visual and consisted of a pair of incandescent bulbs placed in front of the cat's eyes. The motivational and sensory stimuli were delivered separately and in combination in random order. Extracellular recordings were taken for an initial period of a 0.5 second, (during the intervals between the stimulus train of pulses), and during a prolonged period for 4.5 seconds.

Specific interactions between the motivational and sensory stimuli were found in response to particular stimulus combinations. In the cingulate cortex the M stimulus elicited an inhibitory response while the R stimulus was excitatory. When both stimuli were delivered together there was a cancellation of these effects. These opposite responses reflect the opposite motivational significance of the stimuli. In the presence of light, however, the M-elicited inhibition and the R- elicited excitation were abolished. On the other hand, in the ventral anterior- ventral lateral nuclei (VA-VL) of the thalamus the R stimuli elicited pronounced inhibition while M stimulation alone elicited no effect. However, when the M and R stimuli were delivered together the R-elicited inhibition was abolished. This gating effect persisted in the presence of the light stimulus.

While the opposite responses observed in the cingulate cortex and M gating of R-elicited inhibition observed in the VA-VL nuclei may both be neural representations of the rewarding and aversive properties of the intracranial stimuli, it is interesting that only the differential responses in VA-VL persist in the presence of the light stimulus. These effects were localized in these two structures. In addition to these differential responses to M and R stimuli, similar responses were found in the somatosensory cortex, visual cortex, posterior lateral thalamus and caudate. Thus the interactions observed were highly localized in specific anatomical structures. (Partially supported by NIH Grant RR-08102).

343.7 INHIBITION OF CRICKET KILLING BY LATERAL HABENULAR LESIONS.
L.M. Brandeberry* and J.L. Gibbons, Dept. of Psychology, Saint Louis University, St. Louis, MO. 63103.

Electrolytic lesions were used to study the role of the lateral habenula in cricket and mouse killing by rats. Long-Evans hooded rats which spontaneously killed crickets but not mice were used as subjects. Behavioral tests included cricket killing, mouse killing, reactivity, activity, locomotion, food and water intake, food spillage, and weight. The experiment consisted of a mixed within and between subject design. The between subject variable was treatment condition: bilateral habenular lesion (.8 ma, 30 sec.) (N=10), sham lesion (N=16), or unoperated control (N=10). The within subject variable was repeated tests with one pretest and two posttests for each of the measures, with the exception of food and water intake, food spillage, and weight which were measured daily. Cricket killing was tested during the sixth hour of the light cycle and mouse-killing during the sixth hour of the dark cycle one day prior to surgery and on days 4 and 8 postoperatively. Reactivity testing occurred 3 days prior to surgery and on days 3 and 7 postoperatively. Activity and locomotor ability testing occurred 2 days prior to surgery and on days 5 and nine post-operatively. A multivariate repeated measures analysis of variance was performed on all data. A significant treatment by time interaction ($p = .007$) was found for cricket killing. Cricket killing was significantly inhibited for the lesioned group of both posttests. A significant treatment by time interaction ($p = .002$) for food intake was also found for the lesioned group with food intake significantly decreased immediately following surgery but returning to baseline by nine days postoperatively. No other measure was significantly affected by the lesions. This inhibition of cricket killing by habenular lesions is hypothesized to result from the release of the mesencephalic raphe from inhibition resulting in elevated activity of serotonergic neurons.

343.8 INTRASPECIFIC AGGRESSION IN CATS AFTER DUAL ELECTRICAL STIMULATION OF SEPTUM AND HYPOTHALAMUS.
J.M. Ramirez. Department of Psychobiology, University of Seville, 41003 Sevilla, Spain.

The working hypothesis that intraspecific aggressive behavior is related to different neural fields in functional interdependence was analyzed by single and dual brain stimulation in free cats. It is now well known that septum selectively suppresses interspecific aggression elicited by lateral hypothalamical stimulation (Siegel, A. and Skog, D., Brain Research,23: 371-380, 1970). The present study analyzes whether the concurrently electrical stimulation of both structures might also influence intraspecific aggression. It is an extension of previous observation that simultaneous stimulation of other brain areas also modulates agonistic or intraspecific aggression (Ramirez, J.M. et al. Aggressive Behavior,9:104, 1983).

For this purpose cats were prepared with 30 to 50 stereotaxically implanted needle guides in the skull through which roving electrodes were lowered at 0.5 mm steps. After repeated functional testing, permanent electrodes were implanted in those sites whitin the ventromedial hypothalamus capable of eliciting some fragments of agonistic behavior and in those others within the septum capable of significantly modulating the mentioned behavioral fragments.

Single VMHT stimulation elicited many different behavioral effects: overt autonomic components, such as pupillary dilation, deep breathing, piloerection and salivating, and visible motor signs, such as arching of the back, baring of teeth and hissing. Among the different components observed, hissing was selected for the dual stimulation analysis. Concurrent stimulation of VMHT and septum showed their modulation of intraspecific aggression through a functional interrelation of both structures. Stimulation of much of septal areas -both, ipsilateral and contralateral to VMHT stimulating points- resulted in significantly facilitation of hypothalamically-elicited behavior.

Results suggest that these both brain structures, as many others, are functionally interrelated and coordinate spatial and temporal appearance of many agonistic components. Next step should be to determine which are the structures and pathways involved into the regulation of intraspecific aggression and to clarify their mechanisms of action.

343.9 14C-DEOXYGLUCOSE IDENTIFICATION OF EFFERENT PATHWAYS OF ATTACK INDUCED BY STIMULATION OF RAT HYPOTHALAMUS. W.W. Roberts. Department of Psychology, University of Minnesota, Minneapolis, MN 55455.

Electrodes were chronically implanted in the anterior ventral region of the lateral hypothalamus of male rats, where electrical stimulation induces vigorous biting/jumping attack on mice and rats. After tests for attack, male sexual behavior, eating, drinking and gnawing, rats were selected for an attack group that displayed strong attack during stimulation and for a stimulated control group that evidenced no attack but displayed other behaviors similar to those accompanying attack in the first group (exploratory behavior, upward escape jumping, turning, etc.). 14C-deoxyglucose was administered via a chronic caval catheter while the rats were anesthetized, and intermittent stimulation was administered for 45 minutes. After perfusion with 3.3% formalin, the brains were removed and sectioned in a cryostat, and the dried sections on coverslips were exposed to x-ray film. A diagrammatic analysis was made of areas darkened unilaterally in the attack group, followed by a quantitative densitometric comparison of the attack and stimulated control groups.

Although a considerable number of ascending, lateral, dorsal, and descending projections were evident in the autoradiographs, one descending system was most strongly associated with attack: the bilateral ventral supraoptic commissural path that follows the optic tract to the midbrain peripeduncular area and thence 1) medially through the posterior ventral thalamus to the periventricular gray, and 2) posteriorly to the vicinity of the cuneiform nucleus. A considerably weaker attack-related projection was located in the periventricular and central gray.

A separate correlational analysis of upward escape-like jumping, which was similarly represented in both groups and therefore orthogonal to the attack response, disclosed a close association in the combined groups with a number of ipsilateral medial structures, including an anterior projection through the medial preoptic area to the lateral septal area, a dorsal extension to the thalamic periventricular/parataenial region, and a posterior projection through the posterior hypothalamus to the dorsal premamillary nucleus and dorsal periventricular gray.

343.10 ANATOMY OF AFFECTIVE VOCALIZATIONS IN CHICKS.
L. Normansell* P. Bishop* & J. Panksepp. (SPON: F. DeEskinazi). Department of Psychology, Bowling Green State University,Bowling Green, OH 43403.

Areas associated with the production of social separation-induced distress vocalizations (DVs) have been extensively studied in the domestic chick. Distinguishing systems directly controlling DV output from neural circuits which act indirectly by modulating emotional response to social isolation is more difficult. We attempted such a discrimination using brain lesioning techniques aimed for circuits from which DVs can be elicited with electrical stimulation.

Three day old domestic chicks received bilateral lesions of either the ventral archistriatum (Av), the medial intercollicular area (MICo), dorsomedial thalamus (DMT), or Area C. Number of DVs emitted during 10 min of social isolation was assessed 2 days after surgery. MICo lesions reduced DVs by 95.4%, DMT lesions by 68.8%, and Area C and Av by 51.7 and 31.2, respectively. Immediately after isolation testing, like-lesioned birds were paired in an open field for 3 min. Both Av and MICo lesioned groups showed a complete cessation of DVs, while DMT and Area C lesioned animals showed a 73.8 and 60.9% reduction, respectively. The following day vocalization rates were assessed in a cold stress condition. Animals with DMT lesions increased 122.6% from their pre-cold baseline, suggesting this area, as well as the Av, participates in the emotional modulation of DVs. Lesions in both ICo and Area C produced reductions in DVs in all experimental conditions, indicative of a probable disruption of the CNS areas controlling the more generalized expression of DVs.

In a follow-up study, animals lesioned in the MICo were injected intracerebroventricularly with 1 ug curare, reported earlier to activate vocalization circuitry (Panksepp, et al, Soc Neurosci Abstr 9: 979, 1983). Animals whose rates of DVs were reduced 53% following surgery, returned to control levels following injection. Animals in which lesions totally eliminated DVs were apparently unresponsive to the vocalization promoting effects of curare, although flight behaviors remained intact.

343.11 2-DEOXYGLUCOSE STUDIES OF DEPRESSED BEHAVIOR IN RATS.
S. Caldecott-Hazard, D. Slabaugh*, R. Ackermann, J. Mazziotta, M. Phelps.
Nuclear Medicine and Biophysics, UCLA Medical School, L.A., CA. 90024

Human studies using positron emission tomography (PET) are limited by an inability to use some invasive techniques and experimental drugs. Therefore we are developing 3 rat models to study mechanisms underlying changes in local cerebral glucose utilization, identified by PET in depressive disorders. Our models were induced by multiple injections of alpha-methyl-para-tyrosine over a 12 hour period (AMPT) (Rech et al, J PET, 153:412 1966), withdrawal from amphetamine administered by subcutaneous pellets for 4 days (AmpWD) (Ellison et al, Science, 201:276, 1978), or 3 weeks of physical and psychological stressors (Katz et al, Neurosci & Biobehav. Rev, 5:259, 1981). Two symptoms of depression in humans, motoric retardation and weight loss, were measured in rats. Locomotor retardation was studied using an open-field apparatus. The number of squares crossed per minute was significantly reduced in each of the 3 models compared to controls. The antidepressant, tranylcypromine reversed this depression under AMPT and AmpWD conditions but by itself did not affect behavior. Weight loss during the period of model induction was also significant in each of the 3 models as compared to controls.

Glucose metabolism was studied using 14-C-2-deoxy-glucose (2DG) quantitative autoradiography. Metabolism was decreased globally by 26% in the stress model (N=6, $p<.05$), 40% in the AMPT model (N=4), and 22% in the AmpWD model (N=3). Also, the medial prefrontal cortex, anterior ventral thalamic nucleus, ventral hippocampus, and dorsal tegmental nucleus of Gudden showed bilateral reductions in metabolism in each of the 3 models. The lateral habenula showed bilaterally increased metabolism in all models. Tranylcypromine, which by itself had no effect on metabolism in controls, reversed the habenula's increased metabolism under AMPT, concommitant with reversal of depressive behavior.

These results indicate that both global changes and specific limbic structures may mediate depressed behavior in rats. These data parallel findings in bipolar depressed patients of 29% reductions in supratentorial global metabolism, compared to normals, with specific decreases in frontal cortex and thalamus (Baxter et al in press).

343.12 TAIL PINCH-INDUCED BEHAVIORS IN DORSAL RHIZOTOMIZED RATS.
T.R. Gallub*, D. Berman & E. Schneider*. Dept. of Psychology, Queens College, CUNY, Flushing, NY 11367.

Animals with section of the dorsal roots innervating a limb tend to self-mutilate the deafferented extremity. This phenomenon has been interpreted as a response either to putative dysesthesias or to the animal's perception of the limb as a foreign object. In an effort to clarify this issue, dorsal rhizotomized (DR) rats were subjected to intermittent tail pinch. Tail pinch in intact rats results in chewing and gnawing, typically directed at food or other chewable objects (Antelman & Szechtman, Science, 189: 731, 1975). It was reasoned that, if an insensate limb were perceived as an extra-personal inanimate object, it would become a target for tail pinch-induced chewing.

Male Long-Evans rats were subjected to dorsal rhizotomy of the left forelimb (C6-T1, n=5) or hindlimb (L1-L6, n=4; T13-L6, n=1). Two and a half to twelve months later, food-sated operated and unoperated control animals (n=5) were tested with tail pinch with and without food, but with no other chewable stimuli available. In the presence of food, but without tail pinch, no animal showed chewing behavior. During tail pinch in the absence of food, intact animals showed increased restlessness and irritability, but no chewing or licking directed to any body part; in the presence of food, they showed energetic licking and chewing of food pellets.

Four of the five forelimb DR animals and all of the five hindlimb DR animals subjected to tail pinch showed licking of the deafferented limb when no food was present, sometimes actually drawing blood. Even when food was present, they responded to tail pinch with licking of the affected limb, as well as licking and chewing of the food.

In a preliminary attempt to address the issue of whether a dysesthesic state underlies post-dorsal rhizotomy self-mutilation, intact and DR rats were injected with formalin subcu. This procedure elicited licking of injected intact limbs, but not of injected deafferented limbs. When tail pinch was applied to intact animals 20 and 40 min after injection, all licking ceased and was replaced by agitated behaviors, such as backing up, licking the bowl, and attempts at escape.

These results are not incompatible with the hypothesis that DR rats perceive their insensate limbs as foreign objects. However, the extremely short latency in some animals from the onset of tail pinch to the start of vigorous licking of the affected limb, even in the presence of food, suggests a more active process. It is improbable that tail pinch-induced licking of the DR limb is related to nociception as tail pinch reduced, rather than increased, limb licking after formalin injection.

## MOTIVATION AND EMOTION: REWARD SYSTEMS

344.1 KAPPA RECEPTORS MEDIATE THE AVERSIVE MOTIVATIONAL EFFECTS OF OPIATES. A. BECHARA* and D. van der Kooy. Neurobiology Research Group. Dept. of Anatomy, University of Toronto, Tornto, Canada M5S 1A8

Endogenous and exogenous opioids produce positive reinforcing effects through an action on central nervous system opiate receptors and aversive effects through an action on peripheral opiate receptors. We now report that in addition to the anatomical specificity of the motivational effects of opiates, there may be a pharmacological specificity as well. Employing a place conditioning paradigm, separate groups of drug naive rats were administered various subcutaneous or intraperitoneal doses of the specific Kappa receptor agonist U50,488 (.005-16 mg/kg) or of morphine (.005-1.25 mg/kg). Regardless of the route of administration, increasing doses of morphine produced conditioned place preferences, whereas a wide range of doses of U50,488 produced conditioned place aversions. Only a low dose of morphine (.05 mg/kg) i.p. but not s.c., produced significant place aversions, suggesting a local gut effect, possibly on Kappa receptors in the gut. Although morphine is about 8 times more potent than U50,488 in producing analgesia, the lowest dose of U50,488 that produced aversions was 5 times lower than the low dose of morphine that produced aversions. Even at very high doses, U50,488 never produced the conditioned place preferences seen with morphine. Vagotomy blocked the aversive properties of both U50,488 and morphine. The results suggest that peripheral Kappa receptors mediate the aversive effects of opiates, whereas central mu receptors mediate the positive reinforcing effects. The motivational effects produced by selective stimulation of central Kappa receptors remain to be investigated.

344.2 NALOXONE SUPPRESSES SELF-STIMULATION BY CENTRAL BLOCKADE OF REINFORCEMENT. J. D. Belluzzi, K. A. Trujillo, C. D. Sun*, and L. Stein. Department of Pharmacology, College of Medicine, University of California at Irvine, Irvine, CA 92717.

Opiate receptor antagonists, such as naloxone (NAL) and naltrexone (NTX), suppress self-stimulation (SS) of enkephalin-rich brain regions following peripheral administration. According to the endorphin theory of reinforcement, these antagonists suppress SS by blocking central opiate receptors, thereby preventing the reinforcing action of stimulation-released endogenous opioids (Belluzzi and Stein, 1977). However, since SS can be suppressed by effects unrelated to reinforcement, others have suggested that these drugs may produce nonspecific performance deficits. The present studies tested whether opiate antagonists interfere with reinforcement or performance in SS. Since the reinforcing effects of brain stimulation are centrally mediated, one would expect that the suppressant effects of opiate antagonists would also involve central processes. Rats were trained to lever-press for nucleus accumbens brain stimulation in 1-hr daily sessions. When stable baseline rates were obtained, NAL and NTX were compared to their quaternary derivatives, naloxone methobromide (BrNAL) and naltrexone methobromide (BrNTX), for potency to suppress SS. BrNAL and BrNTX do not cross the blood-brain barrier and therefore block only peripheral opiate receptors. NAL (0.2, 2.0, and 20 mg/kg s.c.) caused significant suppression of SS (83.0, 61.7, and 35.0 mean % of saline control, respectively), whereas even the highest dose of BrNAL examined (20 mg/kg s.c.) had no effect on this behavior (95.4 % of control). Similarly, NTX (20 mg/kg s.c.) produced a strong suppression (42.6 % of control) while BrNTX showed no effects (95.7 % of control). These findings suggest that opiate antagonists suppress SS by blocking opiate receptors in the brain. To determine if opiate antagonists suppress SS by interfering with the ability of the animals to respond, the effects of NAL were compared on lever-pressing and nose-poking for nucleus accumbens SS. Nose-poking is a simple response requiring little motor output, whereas lever-pressing is more difficult. If opiate antagonists act by interfering with motor capacity, then nose-poking should be relatively unaffected by NAL. On the other hand, if these drugs act by blocking reinforcement, then nose-poking and lever-pressing should be equally suppressed (Leibman, 1983). NAL (0.2, 2.0, and 20 mg/kg s.c.) suppressed nose-poking and lever-pressing for SS equally (65.3 vs. 66.3; 38.6 vs. 35.8; 29.5 vs. 21.2 mean % of saline control, respectively). These results suggest that opiate antagonists suppress SS by interfering with reinforcement rather than motor output. Our findings support previous work demonstrating that NAL and NTX produce an extinction-like response decrement pattern in SS (Trujillo, Belluzzi and Stein, 1984) and are consistent with the suggestion that endogenous opioids mediate brain stimulation reward. (Supported by AFOSR grant 84-0325)

344.3 NALOXONE BLOCKADE OF AMPHETAMINE REWARD IN PLACE PREFERENCE CONDITIONING. K. A. Trujillo, J. D. Belluzzi, P. R. Tabrizi*, and L. Stein. Department of Pharmacology, University of California, Irvine, CA 92717.

The conditioned place preference (CPP) paradigm was used to study possible interactions between endogenous opioids and catecholamines in reinforcement. These neurotransmitters have been suggested to serve as putative "reinforcement transmitters" in the brain. In addition, studies suggest that the endogenous opioids and catecholamines may interact in reinforcement. In the present studies amphetamine (AMPH), which potentiates the release of catecholamines, and naloxone (NAL), a potent and selective opiate receptor antagonist, were examined alone and in combination in CPP. Two identical shuttle boxes were used in which two compartments are distinguished by color, odor, and texture. Initial compartment preferences were determined by measuring the time spent in each compartment for three baseline days. Rats were then conditioned by pairing one compartment with drug and the other with saline over eight 30 minute sessions. The reinforcing or aversive properties of a drug were determined in post-conditioning tests by measuring the change in compartment preference from baseline. Reinforcing effects were assessed by pairing drug injections with the initially non-preferred compartment, while aversive effects were assessed by pairing drug with the initially preferred compartment. As observed in previous studies, AMPH (1.0 mg/kg, sc) shifted place preference to the compartment associated with drug, demonstrating AMPH's reinforcing properties (Fig. 1A). NAL (2.0, 0.2, and 0.02mg/kg, sc) administered with AMPH blocked the preference for the compartment paired with AMPH. The higher doses of NAL appeared to be aversive, in that rats avoided the compartment paired with this drug. The low dose, while having no aversive effects alone, still blocked place conditioning by AMPH (Fig. 1B). These data suggest that 1) AMPH is indeed reinforcing, 2) moderate doses of NAL are aversive, and 3) opiate receptor blockade can prevent the reinforcing properties of AMPH. Furthermore, these results suggest that endogenous opioids may be important in the reinforcing effects of AMPH, and support the possibility of interactions between endogenous opioids and catecholamines in reinforcement. 344.4 MORPHINE AFFECTS THE SUMMATION PROCESSES UNDERLYING THE PRODUCTION OF BRAIN STIMULATION REWARD. T.H.Hand and A.Laferrière*. Dept. of Psychology, McGill University, Montréal, Qué. Canada H3A 1B1

The effect of chronic morphine (5 mg/kg) on the sensitivity of the substrate for lateral hypothalamic self-stimulation (ICS) was determined by evaluating the effect of the drug on the current-frequency tradeoff function. The rationale for the use of this function is as follows: pulse frequency determines the firing rate of stimulated fibres passing through the effective area of stimulation, while current level determines the size of the stimulated area, and hence the number of fibres recruited. As one of these two variables is increased, the other can be decreased proportionally to maintain a predetermined level of ICS. If the rewarding efficacy of a train of pulses depends on the total number of firings of behaviourally relevant fibres, the reciprocal relation between current and frequency exists because as the firing rate of individual neurons is elevated, the number of neurons necessary to maintain ICS diminishes correspondingly. The tradeoff of current and frequency is thought to manipulate spatial and temporal summation processes (respectively) underlying ICS (Gallistel et al., Psychol. Rev. 88: 228, 1981).

Chronic morphine treatment is known to facilitate ICS, and although this facilitation is usually reported as increased ICS rate or decreased ICS threshold, neither of these drug-induced changes is very useful in determining what morphine actually does to the ICS substrate. On the other hand, morphine's effect (or lack thereof) on the current-frequency tradeoff function would be of considerable value in better understanding morphine-induced facilitation of ICS. Accordingly, the function was determined in 6 rats, and was redetermined after several days of chronic morphine treatment (1h post-injection). Each rat served as its own control. In all subjects, morphine reduced the current necessary to maintain half-maximal responding across a wide range of frequencies (28 - 200 Hz), with a maximal reduction at the lowest frequencies tested. This shift in the tradeoff function shows that morphine increases the sensitivity of the ICS substrate, especially when it is activated at low frequencies. It further shows that the drug enhances the spatiotemporal summation processes underlying ICS behaviour. The ability of morphine to increase ICS rate and decrease ICS threshold may be related to this enhancement.

We are currently evaluating the effect of morphine on the strength-duration curve and on other psychophysiological curves, and these results will also be presented.

344.5 EFFECTS OF FOREBRAIN KNIFE CUT TRANSECTIONS ON MEDIAL FOREBRAIN BUNDLE SELF-STIMULATION IN THE RAT. Meg A. Waraczynski*(SPON: J.R. Stellar). Department of Psychology and Soc. Rel., Harvard University, Cambridge, MA 02138.

Data from psychophysical, autoradiographic, and electrophysiological experiments suggest that descending projections from the forebrain to the ventral tegmentum form an important part of the directly stimulated substrate for the rewarding effects of medial forebrain bundle (MFB) stimulation. Specifically, nuclei ventral and slightly caudal to the genu of the corpus callosum are promising candidates for the site(s) of origin of fibers carrying the reward signal (Shizgal, Bielajew, and Kiss, Neurosci. Abst., 6:422, 1980; Yadin, Guarini, and Gallistel, Brain Res., 266:39-50, 1983; Shizgal and Rompre, Neurosci. Abst., 10:310, 1984). This study investigates the effects of knife cut transections which disrupt efferents from these sites on MFB self-stimulation.

Rats are implanted with an MFB stimulating electrode, and an ipsilateral guide shaft cannula through which the knife cut is later made. Self-stimulation responding is evaluated using the reward summation function technique (Edmonds and Gallistel, JCPP,87: 876-883, 1974). The rat presses a lever for stimulation of various pulse frequencies. The resulting rate-frequency curve is then analyzed into two statistics: the maximum response rate (an index of performance capacity) and the frequency required to sustain half that rate. The latter statistic is called the "locus of rise" of the curve, and is interpreted as an index of the reward effectiveness of stimulation. Rats are tested until baseline responding stabilizes; they are then given the knife cut. Changes in maximum rate and locus of rise are observed on a daily basis for up to two weeks. Following testing, brains are sectioned in the sagittal plane, and the extent of knife cut damage is reconstructed on a single coronal section. Knife cut transections were chosen over electrolytic lesioning for this study, because this method allows one to produce selective damage in a small cross-sectional area while avoiding attendant rostrocaudal damage characteristic of lesions.

To date, 12 subjects have completed the experiment, with knife cuts at the level of the lateral preoptic area. Results from these rats show that lateral, ventral cuts in this area are more effective than medial cuts in attenuating MFB stimulation reward. The more medial, ineffective cuts completely transect the medial preoptic area and damage the medial portion of the lateral preoptic area, suggesting that these regions are probably not critical sources of descending fibers of the directly driven substrate. Implications of these results will be presented for the role of efferents from more anterior nuclei, which pass through the area of transection on their way to the medial forebrain bundle.

344.6 THE EFFECTS OF DIAZEPAM ON SELF-STIMULATION, ESCAPE FROM CONTINUOUS LATERAL HYPOTHALAMIC EXCITATION AND STIMULATION-BOUND FEEDING DISCRIMINATE BETWEEN PURE REWARD AND REWARD-ESCAPE RATS. S. E. Carden* and E. E. Coons (SPON: S. M. Feldman). Psychology Dept., New York Univ., New York, N.Y. 10003.

Pure reward and reward-escape rats, chronically implanted with lateral hypothalamic (LH) electrodes, were assessed for effects of Diazepam (DZ) on stimulation-bound feeding (SBF), barpressing rates for the onset of long and short trains of LH stimulation and for escape from continuous LH excitation. By testing across a range of behaviors, the question was raised whether pure reward and reward-escape rats display two discrete behavioral patterns or represent endpoints in a continuum of behavior which vary more in degree than in kind.

Sixteen combinations of currents and frequencies were used for all self-stimulation and escape conditions. Following the collection of baseline data and a period of drug acclimation, animals were retested with DZ (5 mg/kg, i.p.). Although pure reward rats barpressed at higher rates than reward-escape animals, the pattern of response magnitude showed the same configuration for both groups on baseline and drug trials, for long and short trains, whether plotted by current or frequency. After an initial sharp rise, responses plateaued and then decreased. In every condition, the combination of high current and high frequency reduced barpressing rates. These high stimulation levels either could be activating an aversive element within the LH reward system, or be providing positive reinforcement so powerful that it persists beyond the offset of stimulation. The similarity of response patterns in the two groups of animals would suggest that the neural substrate for reward is functioning in like manner for both groups and is comparably drug sensitive, but that there exists an additional aversive component in the reward-escape animals. This concept is supported by DZ trials demonstrating augmented reward for both groups but not displaying diminished escape in reward-escape rats.

The data in this study was confirmatory of previous research in this laboratory (Simson and Coons, Soc.Neurosci. Abstr., Vol. 9, Part 2, p.980, 1983) showing pure reward animals to be feeders and reward-escape animals to be non-feeders.

344.7 SELF-STIMULATION TRAIN DURATION RESPONSE FUNCTIONS MAINTAIN A STEP-LIKE APPEARANCE DESPITE 2.0 MSEC DURATION SPACING. R. A. Frank. Department of Psychology, University of Cincinnati, Cincinnati, OH 45221.

Self-stimulation train duration response functions typically show a dramatic, step-like increase from no responding to near maximal response rates as one increases train durations from sub-threshold to suprathreshold levels. This finding suggests that animals respond to the stimulation in an "all or none" fashion rather than titrating their response rates to the gradations in train duration. However, previous research has spaced the test durations by 10 msec, and it could be argued that if the spacing was reduced in the perithreshold region, a more gradual change in response rate would emerge. This hypothesis was tested by generating train duration response functions with test durations spaced at 2.0 msec intervals. Six male Sprague-Dawley rats implanted with bipolar stimulating electrodes in the ventral tegmental area (VTA) were trained to lever press for brain stimulation using a procedure that alternated 1.5 min test periods with 30 sec time-outs. Train durations ranging from 20 to 44 msec (in 2 msec increments) were presented in a descending order, along with a 0 msec (i.e., no stimulation) trial. Stimulation frequency and current intensity remained constant at 60 Hz and 50 $\mu$A, respectively. Two 28.0 min test sessions were run consecutively each day for three days. The data were analyzed by examining the response rates generated for each train duration during the final 30 sec of each trial. It was found that all six subjects produced the step-like functions that had been observed with the more widely spaced train durations. In fact, 93% of the trials produced response rates of either below 5 responses/30 sec or above 50 responses/30 sec. Additional work with these animals demonstrated that d-amphetamine shifted the train duration response functions to the left, but did not alter the shape of the curves. With amphetamine, 91% of the trials produced less than 5 or more than 50 responses/30 sec. The results clearly show that self-stimulating rats are extremely sensitive to variations in train duration. They also suggest that a critical train duration exists below which the rats are unwilling to respond and above which very vigorous responding is observed. Finally, it would appear that a 2.0 msec change in train duration is sufficient to cross over the critical duration value.

This research was supported by a University of Cincinnati URC grant to R. Frank.

344.8 INDIVIDUAL DIFFERENCES IN THE EFFECT OF MORPHINE ON TRAIN DURATION THRESHOLDS AND RESPONSE RATES IN SELF-STIMULATING RATS. A. Markou and R. A. Frank. Department of Psychology, University of Cincinnati, Cincinnati, OH 45221

In a previous study conducted in our laboratory, an effort was made to assess the effects of chronic morphine administration on train duration thresholds and response rates in self-stimulating rats. It was found that the magnitude and direction of morphine-induced changes in rates and thresholds varied substantially from animal to animal. This situation was further complicated by the failure of many animals to return to their pre-drug thresholds and response rates. The present experiment used higher doses of morphine (15 mg/kg) and a longer testing regimen in an attempt to clarify the results of the previous study. Eleven male Sprague Dawley rats implanted with bipolar stimulating electrodes in the ventral tegmental area or substantia nigra were trained to lever-press for brain stimulation using a procedure that alternated 1.5 min test with 0.5 min time-out periods. The brain stimulation train duration that was available during each testing period was varied from 20 to 140 msec in 10 msec increments. The train durations were presented in a random order during each testing session. Two 28 min testing sessions were run each day; the first 2 hr and the second 4 hr post-injection. During pre- and post-drug baseline periods normal saline was administered whereas 15 mg/kg morphine was injected (SC) on each of 15 consecutive drug testing days. Examination of the data, averaged across all animals, revealed that train duration thresholds were elevated during the initial days of morphine administration, the effect being more prominent during the 2.0 hr post-injection session. This depressive effect of morphine tended to tolerate over days. During the post-drug testing days, thresholds returned to the pre-baseline levels. Average response rates were markedly depressed during the first days of morphine administration. This depressive effect also tolerated over days and finally a facilitation in rate of responding became evident. Although the depressive effect was observed in both daily sessions, the facilitative effect was observed only during the second daily session. Response rates failed to return to pre-drug baseline levels despite extensive testing. Inspection of individual subject data revealed that the averaged data were not representative of the performance of all animals. The time course of facilitation and depression for both rates and thresholds was remarkably different from animal to animal. For example, several animals demonstrated decreases in thresholds after the administration of morphine while others exhibited marked threshold elevation during the same period. These results emphasize the importance of examing individual subject data when assessing the influence of morphine on self-stimulation behavior.

344.9 SELF-STIMULATION TRAIN DURATION THRESHOLDS PREDICT DEGREE OF SELF-DEPRIVATION. L. L. Wiggins & R. A. Frank. Department of Psychology, University of Cincinnati, Cincinnati, OH 45221.

It has often been assumed that self-stimulation thresholds provide an index of the attractiveness of brain stimulation. However, relatively few experiments have sought an explicit validation of this assumption. The present study assessed the relationship between self-stimulation train duration thresholds and the degree of self-deprivation observed during food/brain stimulation competition. Sixteen male Sprague-Dawley rats implanted with bipolar stimulating electrodes in the ventral tegmental area (VTA) were trained to lever press and nose poke for brain stimulation using a procedure that alternated 1.5 min stimulation periods with 30 sec time-outs. The animals were then reduced to 85% of their free-feeding body weights and tested with brain stimulation train durations that ranged from 30 to 150 msec in 10 msec increments. The order of train duration presentation was random, and an additional 0 msec (i.e. no stimulation) trial was included to measure free operant response rates. Each testing session lasted 28 min. Lever pressing and nose poking were used on alternate days. Once five sessions had been run with each operant, the rats were habituated to feeding in the testing chambers for three days. During this time, no brain stimulation was available. Subsequently, food and brain stimulation were available simultaneously during six food/brain stimulation competition sessions. Lever pressing and nose poking were alternated across test days and train durations were set at 250 msec for these sessions. It was found that train duration thresholds (defined as the train duration that supported 50% of maximal response rate) were significantly correlated with the degree of self-deprivation (defined as the mean amount of food consumed/session) for both lever pressing ($r = -.65$, $p < .01$) and nose poking ($r = -.80$, $p < .01$). These results support the claim that self-stimulation thresholds measure variations in the attractiveness of brain stimulation. They also suggest that the relationship between thresholds and self-deprivation does not depend on the operant that one chooses.

344.10 SHORT- AND LONG-TERM SUMMATION CHARACTERISTICS OF ELECTRICAL SELF-STIMULATION REWARD. P.A. Mason and P.M. Milner (SPON: N.M. White). Dept. of Psychology, McGill University, Montreal, Quebec, H3A 1B1, Canada.

Using a Y-maze preference test paradigm, we examined the characteristics of the neural networks that integrate trains of rewarding stimulation pulses. Rats with mid-posterior lateral hypothalamic electrodes compared the rewarding effectiveness of various durations of a test reinforcement (0.15, 0.35, 0.55, 0.75, 1.05, 2.52, 4.52, 9.52, or 19.0 sec) to those of three durations of a standard reinforcement (0.50, 1.0, or 2.0 sec). At each duration of the test reinforcement its pulse frequency was adjusted so that the test reinforcement was chosen on approximately 50% of the trials when compared to the standard reinforcement. This procedure was repeated for each duration of the standard reinforcement. The standard reinforcement was delivered with a 100 Hz pulse frequency. The pulses were always 0.1 msec duration.

By changing the duration of the standard reinforcement while keeping the pulse frequency constant, we varied the stimulation magnitude to which the test reinforcement was being compared. This enabled us to examine the relationships between stimulation parameters both within a constant stimulation magnitude and across different stimulation magnitudes.

The data were inconsistent with a simple integrating system with a single decay time-constant, such as has sometimes been proposed (Gallistel, J. Comp. Physiol. Psychol., 92: 977-998, 1978). They can most parsimoniously be accounted for by two systems having quite widely differing time constants. The first integrator has a time-constant of approximately 450 msec and summates all activity produced by the stimulation. The second integrator has a time-constant of approximately 6.5 sec and preferentially summates stimulaton delived at low pulse frequencies. The reason this integrator responds poorly to high pulse frequencies may not have anything to do with the characteristics of the integrator itself, but rather to the long refractory periods of the fibers that provide input to this integrator. (Supported by NSERC Canda grant A66 to P.M. Milner).

344.11 COMPARISON OF NEUROBEHAVIORAL PARAMETERS OF BSR BETWEEN LATERAL HYPOTHALAMIC AND VENTRAL TEGMENTAL BRAIN SITES. M.J. Lewis and R.W. Phelps*, Dept. of Psychology, Howard Univerisity, Washington D.C. 20059, and Cortex Incorporated, Wellesley, MA., 02181.

Recent investigations of drug effects on brain stimulation reward (BSR) at lateral hypothalamic (LH) and ventral tegmental projection of the ventral noradrenergic bundle (VNB) brain sites have indicated differential effects at these sites. Data from the author's laboratory show that at VNB sites naloxone increases BSR threshold and decreases response rate; however, at LH sites the same doses have no effect on responding. Conversely, low doses of ethanol have no facilitatory effects on responding for VNB stimulation; however, such doses reduce BSR threshold for stimulation at LH sites. We report here a systematic investigation of BSR at both brain sites employing a sophisticated multifunctional brain stimulation system (Phelps and Lewis, Beh. Res. Meth. & Instr. 1982, 14(3), 323-328).

Male albino rats were implanted with platinum (PL) or stainless steel (SS) bi-polar electrodes using standard stereotaxic procedures. Electrodes were directed at lateral hypothalamic (LH) sites within the medial forebrain bundle or the ventral tegmentum (VT) posterior to the substantia nigra. Animals were shaped to lever-press for BSR at each site. Animals were trained initially under continuous reinforcement and then under a fixed ratio schedule of reinforcement.

BSR threshold rates were found to be lower and response rates higher for animals with LH electrodes in comparison to those with VNB electrodes irrespective of electrode type. Brain impedance measures were found to be lower at the LH sites with both PL and SS than at the VNB sites.

Electrode type seemed to affect stability in BSR. Animals that were implanted with PL electrodes and tested over a 9 month period showed unchanged BSR threshold. Animals with SS electrodes in the LH showed progressive increase in threshold over this period.

Brain impedance and BSR response rates showed no change with PL electrodes, whereas impedance increased and response rates became more variable over the 9 month period.

Examination of BSR threshold determination by descending current schedules and both ascending and descending schedules showed correlations of .92 for PL electrodes and .87 for SS electrodes between the two methods.

These data show site specific differences in BSR performance at LH and VNB brain sites which may explain previously reported differences in drug effects at these sites. Moreover, they indicate the importance of the type of electrode and the measurement of multiple parameters of BSR.

344.12 **PHARMACOLOGICAL EVIDENCE FOR CHOLINERGIC MODULATION OF THE SENSORY CUES ELICITED BY ELECTRICAL STIMULATION OF THE VTA.** **J.P. Druhan, M.T. Martin-Iverson, D. Wilkie*, H.C. Fibiger and A.G.Phillips.** Dept. Psychol.; Div. Neurol. Sci., Univ. of British Columbia, Vancouver, B.C., Canada, V6T 1W5.

**Recent studies have shown that drugs which affect the functioning of dopamine neurons do not alter discriminated responding when discrete pulses of rewarding lateral hypothalamic (LH) or ventral tegmental area (VTA) brain stimulation are used as the discriminative stimuli. These results suggest that the discrete sensory events associated with delivery of brain stimulation to these areas are not related to the activation of dopamine neurons. The present study was designed to investigate whether cues produced by VTA stimulation involve a cholinergic substrate. Rats with VTA electrodes were trained to make a discriminated operant response (for a food pellet) on one of two levers following pulses of high intensity brain stimulation, or on the alternate lever after low intensity pulses. Each daily session included 90 trials, delivered at variable 20 sec intervals, with 4 pulses of either high or low intensity sine-wave stimulation being delivered randomly on different trials. Following training, the rats were given generalization tests in which intermediate current intensities wee administered on 20% of the trails. Stimulus generalization gradients were obtained for each animal after separate injections of physostigmine (.25 mg/kg and .5 mg/kg) and saline. Methyl-scopolamine (.5 mg/kg) was injected in conjunction with both doses of physostigmine to block the enhancement of peripheral cholinergic activity, thus each rat was also tested after administration of methyl-scopolamine plus saline to control for possible effects of this drug. The high dose of physostigmine (.5 mg/kg) produced a shift to the left in the generalization function as compared to that obtained under the saline condition. In the presence of the drug, lower intensity stimuli elicited responding on the lever appropriate for the high current intensity, indicating a possible augmentation of the stimulus property of a fixed intensity of brain stimulation. In contrast, neither the low dose of physostigmine nor methyl-scopolamine plus saline resulted in comparable changes in discriminated responding. Modulation of the discriminative stimulus properties of VTA stimulation by physostigmine may indicate a cholinergic involvement in the sensory properties of electrical stimulation in this region of the brain.**

**Supported by a grant (PG-23) from the Medical Research Council of Canada.**

344.13 **INCREASED DA RELEASE FOLLOWING FR10 ICSS WHEN COMPARED TO CRF ICSS AND CONTROLS.** **H. M. Fenton, D.B. Neill*, and J.B. Justice Jr. (SPON: C. K. Erickson) Department of Psychology, Emory University, Atlanta, GA 30322.**

**The dopamine (DA) theory of intracranial self-stimulation (ICSS) remains a parsimonious explanation for much experimental data. The theory states that each electrical stimulation activates a reward pathway, in which DA serves as a critical link. According to this theory, more stimulations should elicit greater DA release. However, analysis of tissue levels of the DA metabolite DOPAC after ICSS sessions have not supported this theory (Mitchell, et al., Life Sci. 30:1081-1085, 1982). Seiden and colleagues (Brain Res. 183: 403-419, 1980) have found that responding for water on partial reinforcement schedules (e.g. fixed ratio 5: FR5) increases DA release. ICSS studies predominately use continuous reinforcement schedules (CRF). Extending Seiden's results to ICSS, one could predict that responding on an FR10 schedule would elicit more DA release than responding on a CRF schedule. Our objective was to assess DA release in rats after ICSS responding on a CRF schedule or FR10 schedule vs. a home cage control condition. DA and DOPAC levels were measured regionally.**

**All rats were initially trained to bar press for lateral hypothalamic ICSS on a FR-10 schedule. Stimulation parameters were 0.5 msec biphasic square waves, 100 pps, 150 msec trains. Current intensities were adjusted to maintain low levels of responding (1500 per 22 min session), and this current was used throughout the experiment. When responding stabilized on the FR10 schedule, animals were put into one of three treatment conditions for 5 days: FR10-ICSS, CRF-ICSS or home cage controls. Thirty min after the session (to allow for DOPAC accumulation (Michael, Justice, and Neill, in press)) on the fifth day brains were rapidly removed, 1 mm slices were cut, and tissue punches taken ipsilateral and contralateral to the electrode. The following DA terminal regions were examined: olfactory tubercule, n. accumbens, anterior striatum, and central striatum. DA and DOPAC were measured using ion-pair reverse-phase HPLC-EC, and protein was assessed by the Lowry method.**

**T-test analysis of DOPAC/DA ratios per brain area revealed no differences when the two sides of the brain were compared (i.e., no assymetric release). No significant differences were found between home cage controls and CRF-ICSS for any brain site assayed. The FR10 animals had significantly higher DOPAC/DA ratios in the n. accumbens and anterior striatum, when compared to the CRF animals and the home cage controls. This was due to increased DOPAC levels. Our results do not support the DA theory of hypothalamic ICSS. However, these results are consistent with the idea of DA release during partial reinforcement.**

344.14 AVERSION-GATING SITES IN LATERAL HYPOTHALAMUS: AN ANATOMIC AND PHARMACOLOGIC STUDY. K.D. Carr and S. Uysal*. Dept. of Psychiatry, NYU Med. Ctr., New York, N.Y. 10016.

Lateral hypothalamic (LH) electrical stimulation may diminish the aversive dimension of pain through operation of a supraspinal mechanism ('aversion-gating'). For example, LH stimulation inhibits a post-stimulus vocalization response (PSV) elicited by brief tail shock (Carr and Uysal, 1985). PSV is organized in forebrain structures and is considered an "affective" response to pain. Simpler vocalization and motor responses, organized in hindbrain and spinal cord respectively, are unaffected. LH stimulation also diminishes aversion that is induced supraspinally by stimulation in pain-related nucleus gigantocellularis (NGC) (Carr and Coons, 1982). In the present study, the relationship between electrode placement and potency of the aversion-gating effect was evaluated. In the tail-shock paradigm (N=19), LH stimulation intensities were at threshold for ICSS and therefore equated across rats with regard to positive reinforcement. However, the % elevation in PSV threshold varied greatly among rats (25-200%). Electrodes associated with the greatest effects were localized to the dorsolateral quadrant of the MFB. In the NGC paradigm (N=19), LH electrodes in which low stimulation intensities reduced NGC-escape rate by a criterion 50% were also localized to the dorsolateral MFB. Sites in which ICSS could be elicited at low intensities were localized to a central region that extended across the width of the MFB. The dorsolateral region associated with strong aversion-gating effects is distinguished by proximity to dopamine-containing (Ungerstedt, 1971) and dynorphin-containing (Weber et al., 1982) neurons. In the NGC paradigm, pimozide, the dopamine antagonist, had no effect on aversion-gating at 0.125 mg/kg (i.p.) but reduced the effect by about 10% at 0.25 mg/kg (N=4). Both doses are reported to effect substantial decreases in LH ICSS (Fouriezos et al., 1978). In the tail-shock paradigm, the opioid antagonist naltrexone (10 mg/kg, s.c.) substantially reduced (50-100%) the effect of LH stimulation (N=6). Naltrexone did not alter thresholds for ICSS in these LH electrodes. In the NGC paradigm, naltrexone produced a small decrease in aversion-gating in 3 rats (15-20%) and a larger decrease in 3 others (40-80%). Electrodes for the latter 3 were localized to the dorsolateral MFB while the others were scattered and distant from the dorsolateral locus.

These results suggest that 1) the population of LH neurons which mediates inhibition of NGC-induced aversion may be the same as that which mediates inhibition of PSV, 2) the population which mediates aversion-gating effects is not identical to the population which mediates ICSS, 3) unlike ICSS, dopaminergic activity may not play a key role in aversion-gating, and 4) unlike ICSS, opioid activity is involved in the aversion-gating effect and is preferentially stimulated by electrodes in the dorsolateral MFB focus of the aversion-gating system.

344.15 REFRACTORY PERIODS AND CONNECTIVITY OF THE SUBSTRATE FOR BRAIN STIMULATION REWARD AND STIMULATION INDUCED FEEDING. A. Gratton* and R.A. Wise (SPON: P. Shizgal). Center for Studies in Behavioral Neurobiology, Concordia University, Montreal, Canada H3G 1M8.

The refractory periods (RPs) of the directly activated medial forebrain bundle (MFB) substrates for brain stimulation reward (BSR) and stimulation induced feeding (SIF) were compared at the same site of stimulation. The RPs were inferred behaviorally using a paired-pulse technique, where the animal's response to a train of pulse pairs was compared to its response to a train of single pulses. Systematically varying the delay (C-T interval) between the two constitutent pulses (C and T pulses) of the paired-pulse condition yielded a distribution of RPs of the BSR and SIF-relevant fibers. The data show that BSR and SIF are subserved by fibers having essentially the same distribution of RPs. Furthermore, as was the case for BSR, a flat portion in the SIF RP curve was found between 0.6 and 0.7 msec. Similar RP estimates for SIF and BSR were obtained at a variety of MFB sites which extended from the ventral tegmental area (VTA) to the anterior lateral hypothalamus (LH). This last finding is consistent with the idea that SIF, like BSR, is subserved by MFB fibers extending between LH and VTA.

To determine if SIF in LH and VTA is subserved by a common set of fibers, a variation of the paired-pulse technique was used in rats feeding in response to unilateral stimulation of both VTA and LH. In this preparation a train of C-pulses was applied to one electrode while a train of T-pulses was applied to the other electrode at a variety of C-T intervals. Connectivity between the two stimulation sites was inferred from an abrupt rise in T-pulse effectiveness which occurred at C-T intervals longer than 1.5 msec. This C-T interval is assumed to reflect the sum of the refractory period and the collision time between the two electrodes. Estimates of refractory periods (0.4 to 2.0 msec) and conduction velocity (approx. 2.45 m/sec) were consistent with those associated with BSR. Our data suggest that SIF-relevant fibers do extend without synaptic interruption between LH and VTA. The fact that T-pulse effectiveness increased at the same critical C-T interval when the T-pulse was applied to either the LH or VTA electrode strengthens this conclusion.

344.16 BOUNDARIES AND HOMOGENEITY OF BRAIN STIMULATION REWARD SITES IN THE ANTERIOR MEDIAL FOREBRAIN BUNDLE. Adina Blander* and Roy A. Wise. (SPON: Robert B. Malmo) Center for Studies in Behavioral Neurobiology, Department of Psychology, Concordia University, Montreal, Quebec.

Recent studies have suggested that the directly activated mechanism of medial forebrain bundle brain stimulation reward involves fibers projecting in a rostro-caudal direction with the cell bodies located somewhere anterior to the lateral hypothalamus. The present study was a detailed mapping of brain stimulation reward sites in the anterior hypothalamic medial forebrain bundle. Forty adult male Long-Evans rats were tested using moveable electrodes that allowed testing at .25mm intervals over a 2.5mm dorsal-ventral range. Reward thresholds, response rates at various stimulation intensities, and stimulation side effects (including locomotion and seizures) were noted for each of the 350 sites tested. Positive sites were found at most levels of the MFB from the lateral hypothalamus to the preoptic-area. Many sites in the lateral pre-optic area were negative. Within the range of anterior-posterior coordinates tested, sites at .05mm from the midline were negative. Positive sites ranged from 1.0mm to as far as 3.0mm lateral. Dorsal-ventral boundaries varied substantially with medial-lateral and anterior-posterior coordinates. No evidence was found to support the view that the reward fibers arise from a single, anatomically restricted group of cell bodies at the head of the medial forebrain bundle.

344.PO SEROTONERGIC CONTROL OF AGGRESSIVE "STATE" BY THE ACCUMBENS/PREOPTIC AREA (APOA) 3. STATE-ASSOCIATED CHANGES IN $5HT_2$ RECEPTORS M. Potegal and H.R. Wagner. N.Y. State Psychiatric Institute and the Columbia University College of Physicians and Surgeons, N.Y., N.Y.

"Priming" a female hamster by allowing it one biting attack on a drug-treated target hamster reduces the latency of the subsequent attack. "Satiating" a hamster with a series of targets until it meets a criterion of 3 successive target presentations without attack increases the latency and decreases the number of subsequent attacks. The half life of the priming effect is approximately 12 hr; that of the satiation effect is 24 hr (Potegal and Popken, Behav. Processes, In press).

We have previously found bidirectional priming/satiation-related changes in APOA 5HT uptake that were neuroanatomically, neurochemically, and behaviorally specific (Barkai, et al, Neurosci Abst., 10: 1170, 1984). We now report similar priming/satiation-associated changes in $5HT_2$ receptors as indicated by ketanserin binding.

Ketanserin binding was characterized in pooled hamster APOA. Following homogenization and centrifugation (40,000g x 10 min), membranes were suspended in 250 volumes (W/V) of iced 50 mM Tris-HCl (pH 7.6 at 25°C). Twelve $^3$H-ketanserin concentrations between 0.1-8.0 nM were added to aliquots containing approximately 200 µg protein, with or without $10^{-5}$M methysergide, to a final assay volume of 1 ml. Samples were incubated to equilibrium (30 min at 23°C) in a shaker. The assay was terminated by vacuum filtration. The Whatman (GF/B) filters were washed, dried, suspended in Aquasol (NEN) and counted by liquid scintillation spectrometry. Scatchard analysis of specific binding, defined as the difference in total binding in the presence and absence of methysergide, yielded a $B_{max}$= 48.2 fmol/mg protein and a $K_d$=1.11 nM.

Eighteen hamsters were subsequently matched into triplets by aggression screening score. Members of each triplet were sacrificed at the same point in the light cycle after being either attack-primed, attack-satiated or given a control manipulation. There was an 8% increase in specific APOA binding of 0.5 nM $^3$H-ketanserin in primed animals (21.6 fmol/mg protein) and an 18% decrease in satiated animals (16.3 fmol/mg protein) relative to control levels. The difference between matched pairs of the primed and satiated animals was significant [$t(5)=3.3$, $p<.05$]. There were no significant differences in APOA $^3$H-5HT binding.

It is noteworthy that for both ketanserin binding and 5HT uptake, the difference between the primed and satiated groups was approximately 20% and the change from control levels in the satiated group was slightly more than twice that in the primed group. The larger satiation-associated changes are consistent with the longer half life of the satiation effect. The regulation of aggressive state apparently involves a complex series of changes in serotonergic function.

345.1 DESCENDING PAIN INHIBITION: OPIATE RECEPTOR SUB-TYPES IN THE PAG. D.J.Smith, J.M. Perrotti*, A.L. Mansell*, J.M. Scalzitti* and J.T. Long*. Dept. of Anesth., WVU Med. Cent., Morgantown, WV 26506.

An important neuronal pathway involved in the analgesic response to morphine-like narcotics (mu, μ, opiate receptor agonists) is the pain inhibitory system originating in the periaqueductal gray (PAG) region of the midbrain and descending into the spinal cord dorsal horn (Yaksh & Rudy, Pain 4: 299, 1978). However, little is known of the contribution of the PAG in the antinociceptive action of narcotics with preferences for other opiate receptors. Thus, prototypic agents for these subtypes were examined for their ability to activate this spinopetal system. These included: 1) d-alanine, d-leucine enkephalin (DADL), Delta (δ) receptor: 2) ethylketocyclazocine (EKC), Kappa (K) receptor; 3) n-allyl normetazocine (NAM), Sigma (σ) receptor and 4) ketamine, an anesthetic with opiate receptor properties similar to those of the benzomorphan (i.e., K and σ) narcotics (Smith, et al.: Neuropharmacol. 21:604, 1982, Pain 21: 353, 1985). The drugs were either 1) microinjected directly into the PAG and their analgesic effect evaluated using the tail-flick reflex or 2) were given systemically and the sensitivity of their action to the microinjection of naloxone was determined.

The microinjection of morphine caused a dose-dependent increase in tail-flick latency (TFL was twice the pre-drug value with 3 nmoles and reached "cut-off", 15 sec, with 24 nmoles). Naloxone administered either systemically or by sequential microinjection (1 hour after the agonist) antagonized morphine's action. In contrast to morphine, EKC (10-100 nmoles), NAM (4-40 nmoles) and ketamine (0.4 - 420 nmoles) failed to produce analgesia. However, DADL was slightly effective at the highest dose (40 nmoles) tested. This suggested that its action may be related to higher and less specific doses interacting with μ receptors through which morphine acts.

Systemic administration of the agonists, with naloxone being given by microinjection, confirmed results obtained with some of the drugs. However, analgesia from systemic EKC (10 mg/kg,s.c.) was transiently attenuated by the antagonist, suggesting that an activation of intrinsic (PAG) opiate nerves may have occurred via an action of the agonist on convergent neuronal processes.

In conclusion, only drugs that interact functionally as μ (morphine-like) or partial μ agonists (e.g., potentially DADL in high doses) will be effective in inducing activation of the descending inhibitory nerves originating in the PAG.

Supported by NIH grant GM 30002 and the WV Med. Corp.

345.2 MONOAMINE AND OPIATE INVOLVEMENT IN MIDBRAIN INHIBITION OF SPINAL NOCICEPTIVE NEURONS IN THE RAT. E. S. Culhane*, R. Banisadr* and E. Carstens (SPON: J. D. Miller). Dept. Animal Physiology, Univ. Calif., Davis, CA 95616.

Electrical stimulation of the midbrain periaqueductal gray (PAG) and more lateral reticular formation (LRF) inhibits spinal dorsal horn neuronal discharges to noxious skin heating and produces analgesia. To determine if inhibition from these two areas is pharmacologically distinct, we tested whether antagonists of three putative neurotransmitters-endogenous opiates, serotonin, and noradrenaline-block or reduce inhibition from PAG or LRF.

Responses of 38 single dorsal horn units to noxious skin heating (50-54°C, 10 s) of the hind footpad were recorded in the lumbosacral enlargement of rats continuously infused with sodium pentobarbital. Responses with or without PAG or LRF stimulation (100 msec trains at 100 Hz, 3/s, 25-400 μA) were recorded alternately at 2 min intervals. Inhibition was expressed as the ratio of the unit's response to heat during midbrain stimulation/unit's response to heat in the absence of stimulation. Once a stable degree of inhibition was obtained from PAG and/or LRF, either the opiate antagonist naloxone (5-10 mg/kg), the serotonin antagonist methysergide (2-6 mg/kg) or the adrenergic antagonist phentolamine (2-4 mg/kg) was injected via the femoral vein. Inhibition was said to be reduced post-drug (+) if it was > 20% below the pre-drug level of inhibition; a change of < 20% was called no effect (o).

Results for each unit tested to date are tabulated below. Methysergide reduced PAG inhibition in 2 additional units in which LRF was not tested, and phentolamine reduced LRF inhibition in 2 units in which PAG was not tested.

| DRUG | PAG↓/LRFO | PAG↓/LRF↓ | PAGO/LRF↓ | PAGO/LRFO |
|---|---|---|---|---|
| naloxone: | 1 | 3 | 1 | 7 |
| methysergide: | 5 | 1 | 0 | 8 |
| phentolamine: | 0 | 1 | 2 | 4 |

Reduction in inhibition by naloxone was apparently independent of the stimulation site within PAG or LRF. The inconsistent effects of naloxone indicate that endogenous opiates are not primarily involved in mediating inhibition from these areas.

The ability of methysergide to frequently reduce inhibition from PAG, but not LRF, suggests a role for serotonin in mediating inhibition from the PAG, although methysergide's lack of effect in other units indicates that other transmitters may also be involved. Likewise, while the data with phentolamine suggest a partial adrenergic involvement in inhibition from LRF, noradrenaline is certainly not the sole mediator. We are currently studying possible cholinergic involvement in descending inhibition, as well as a possible spinal site of action of monoamine antagonists (via intrathecal administration) to affect midbrain inhibition.

345.3 CHOLINERGIC AND TRH INTERACTIONS UPON OPIATE AND NONOPIATE ANALGESIC MECHANISMS. R.J. Bodnar, P.D. Butler, E.S. Sperber, E. Kramer, P.E. Mann, M.T. Romero* and L.S. Truesdell. Dept. of Psychology, Queens College, CUNY, Flushing, NY 11367.

Both acetylcholine and thyrotropin-releasing hormone (TRH) modulate various forms of analgesic responses. For instance, while cholinergic muscarinic receptor blockade with scopolamine reduces the analgesic responses following either inescapable foot shock or cold-water swims (CWS), intracerebroventricular (ICV) TRH potentiates these responses. The present experiments extend these findings, and also demonstrate that cholinergic and TRH analgesic mechanisms interact. The first experiment compared the abilities of non-analgesic doses (50 ug, ICV) of TRH, its analog (RX 77368) and its metabolite (diketopiperazine: DKP) to potentiate CWS (21 C for 3.5 min) analgesia on the tail-flick and jump tests. TRH and DKP significantly potentiated CWS analgesia on both tests 30 min following the swim, while the longer-lasting analog (RX 77368) potentiated CWS analgesia across the entire 2 h time course. These effects could not be attributed to hypothermic changes. The second experiment examined the effects of a non-analgesic TRH dose (50 ug, ICV) upon pilocarpine (10 mg/kg, IP) analgesia on the tail-flick and jump tests. TRH significantly potentiated analgesia on the tail-flick, but not the jump test 30 and 60 min after injection of the muscarinic receptor agonist. Finally, given the inconsistent reports of mucarinic receptor involvement in opiate analgesia, the third experiment examined whether scopolamine (10 mg/kg, IP) pretreatment altered analgesia induced by the delta receptor agonist, d-ala,d-leu-enkephalin (DADL: 40 ug, ICV), the epsilon receptor agonist, beta-endorphin (BEND: 1 ug, ICV) and the mu receptor agonist, morphine (MOR: 5 mg/kg, SC). While scopolamine failed to alter BEND analgesia on the jump test, it significantly potentiated both DADL and MOR analgesia. Therefore, while acetylcholine and TRH each modulate both opiate and nonopiate forms of analgesia, they also interact with each other in these processes. (Supported by PSC/CUNY Grant 6-64187.)

345.4 RESPONSES OF SPINOTHALAMIC TRACT CELLS TO OPIATES AFFECTING DIFFERENT RECEPTOR SUBCLASSES. W.S. Willcockson*, J. Kim*, H.K. Shin*, J.M. Chung and W.D. Willis. Marine Biomedical Institute, Univ. Texas Medical Branch, Galveston, TX 77550.

Characterization of opiate actions on nociceptive cells of the spinal cord is important for identifying analgesic mechanisms and more selective drugs for pain relief. Opiates can produce analgesia at the spinal cord level (review Yaksh 1981) and have also been shown generally to inhibit nociceptive neurons in the dorsal horn when given systemically or applied iontophoretically (reviews North 1979, Duggan and North, 1984, Zieglgansberger 1984). Evidence now exists for multiple opiate receptors (reviews Kosterlitz 1983, Martin 1984). The relationship of these different receptors to nociceptive mechanisms is unclear although it is believed that opiates of the mu (μ) and delta (δ) subtypes cause analgesia. In the present study, we have iontophoretically applied representative agonists of 4 different subclasses onto cells of the spinothalamic tract (STT). Morphine (MOR) was the prototypic μ agonist. Dynorphin 1-13 fragment (DYN) was used as a kappa (k) drug (Chavkin et al. 1982). [D-Ala$^2$] met-enkephalinamide (MKN) was the δ agonist. The sigma (σ) agonist N-allylnormetazocine (NAM) was also compared, as was phencyclidine (PCP) which binds σ sites and has actions similar to NAM on dorsal horn interneurons (Zukin and Zukin 1979, Quirion et al. 1981, Lodge and Anis 1982).

Experiments were performed in anesthetized monkeys (Macaca fascicularis). The opiates were usually tested against activity evoked by pulsed release of GLU although effects on responses evoked by noxious mechanical or electrical stimuli were included.

While MOR was found to have predominantly inhibitory actions on STT cells, excitatory and mixed inhibitory and excitatory effects were seen. More intriguing was the ability of MOR to cause multiple single or biphasic responses on single STT cells, depending upon either current strength or change in position of the electrode relative to the cell body. DYN also produced inhibitory or excitant actions on the GLU activity of STT cells including multiple actions on single cells depending on dose or position. MKN, PCP and NAM, on the other hand, inhibited all cells studied, although some biphasic actions were also noted. Iontophoretic naloxone (NLX) at times antagonized the MOR effects but had little effect on the action of the other drugs.

The multiple effects of the opiates on STT neurons may be due to actions at multiple receptors. The selectivity, however, of most of these agents for their corresponding receptors is incomplete. Future assessment of opiate action on nociceptive cells will be aided by studies with more selective receptor agents.

345.5 DISCOVERY OF A NON-OPIOID ANALGESIC WITH ANTIDEPRESSANT PROPERTIES, TAZADOLENE SUCCINATE. J.Szmuszkovicz*, P.F.VonVoigtlander*, R.A.Lewis*, M.C.Ochoa*, and H.J.Triezenberg* (SPON: E.D.Hall). CNS Research, The Upjohn Company, Kalamazoo, MI 49001.

Tazadolene succinate, 1-(2-(phenylmethylene)cyclohexyl)azetidine butanedioate, was synthesized as part of a program aimed at the discovery of non-opioid, centrally acting analgesics. Preliminary evaluation in mice revealed that tazadolene (T) has analgesic (HCl-induced writhing antagonism), but also antidepressant-like (yohimbine and apomorphine potentiation and oxotremorine antagonism) activity. Further evaluation in rats and mice confirmed and extended these observations. For example, in the hot plate test, T was effective against both a low (49.5°C) and a high (54.5°C) intensity stimulus. Subcutaneously, potency of T on these tests exceeds that of pentazocine (P) and approaches that of morphine (M); orally T was more potent than either P or M. This activity was confirmed in a writhing assay in rats, but T was inactive, or only weakly active, in analgesic tests (mouse tail flick and rat tail immersion) involving a spinal reflex response. In the hot plate and writhing assays, the antinociceptive activity of T was not altered by pretreatment with opioid antagonists. Repeated dosing with T did not lead to a diminished analgesic response or to hyperalgesia upon cessation of treatment. This is in contrast to M and P. Moreover, animals tolerant of M displayed no cross-tolerance to T, and T decreased withdrawal hyperexcitability in mice made physically dependent on M. These properties suggest that T may be particularly useful in the treatment of chronic pain. Chronic pain is often associated with depression, thus the antidepressant properties of T may be of added importance. T is more than twice as potent as imipramine in a behavioral despair test, and is an effective blocker of the uptake systems for serotonin, dopamine, and norepinephrine both in vitro and in vivo. Thus T is an analgesic as well as an antidepressant-like agent in animals, and may have special utility in the treatment of chronic pain in man.

345.6 CENTRAL ANTINOCICEPTIVE EFFECT OF ACETYLSALICYLIC ACID AND PARACETAMOL. K. Hole*, S. Hunskaar* and O.B. Fasmer* (SPON: A. Njå). Dept. Physiol., Univ. i Bergen, N-5000 Bergen, Norway.

The analgesic effects of non-steroid anti-inflammatory agents are thought to be peripheral, however, experiments using central application of aspirin-like drugs indicate that a central action may also exist.

Intrathecally administered substance P (2.5 ng in 5 µl), or capsaicin (10 ng), a compound that releases substance P from primary sensory afferent terminals, elicited a pain-related behavioral response consisting of vigorous biting, licking and scratching of the caudal part of the body in mice (Fasmer, O.B. et al., Neuropharmacol., 22:485, 1983). This response is assumed to be nociceptive and similar to behavior induced by a clearly noxious stimulus (Hylden, J.L.K. and Wilcox, G.L., Brain Res., 217:212, 1981). Pretreatment of the mice with intraperitoneally injected acetylsalicylic acid (300 and 400 mg/kg), paracetamol (300 and 400 mg/kg) and morphine (2.5 and 5 mg/kg) reduced the responses in a dose dependent manner. The highest doses of the drugs reduced the number of bites, licks and scratches to approximately one third of the control values elicited by substance P, and to approximately one half when this behavior was elicited by capsaicin.

These results show that acetylsalicylic acid and paracetamol as well as morphine may act in the spinal cord or supraspinally to inhibit behavioral responses that probably are pain-related, suggesting a central site of action for at least part of the antinociceptive effects of all these drugs. This analgesia is probably mediated by a postsynaptic substance P sensitive mechanism both for the mild analgesics and for morphine.

345.7 ACTIVITY OF NEURONS IN THE PERIAQUEDUCTAL GRAY DURING WITHDRAWAL FROM NOXIOUS HEAT. M.M. Heinricher, Z.-F. Cheng* and H.L. Fields. Depts. of Physiology and Neurology, Univ. of California, San Francisco, CA 94143.

The midbrain periaqueductal gray (PAG) and the rostral ventromedial medulla (RVM) are important links in a neuronal network which modulates nociceptive transmission. In the RVM, two classes of neurons have been identified which show changes in activity at the time of the tail flick response (TF) elicited by noxious heat (Fields, et al., J. Neurosci., 1983, 3, 2545). We now report that a significant number of neurons in the PAG region also show changes in activity which are related to the TF.

Male Sprague-Dawley rats (275-325g) were anesthetized with pentobarbital (60 mg/kg, i.p.) and a microelectrode was stereotactically placed at the dorsal border of the PAG. Following surgery, the animals were maintained in a lightly-anesthetized state by continuous infusion of methohexital at a rate (15-30 mg/kg/hr, i.v.) which prevented signs of discomfort and allowed a stable TF latency of 4-5 sec. The electrode was then lowered until TF suppression (10 sec cut-off) was obtained at stimulation currents of 10 µA or less (400 µsec pulses, 50 Hz continuous trains). Midbrain units were isolated and responses to noxious and non-noxious cutaneous stimulation determined. The units were then characterized according to the classification system used in the RVM. Cell activity, time of TF occurrence and tail temperature were stored during 5 repetitions of the heat stimulus. Peri-response and peri-stimulus histograms were plotted with respect to the TF and tail temperature, respectively.

A significant number of neurons in the PAG region showed changes in activity related to the TF. Two classes of TF-related neurons, similar to those described in the RVM, were identified in the PAG region. "On-cells," which displayed an abrupt increase in firing just prior to the TF, comprised approximately 20% of the cells recorded to date. "Off-cells," which showed an abrupt pause just prior to the TF, made up approximately 3% of the cells recorded. The remaining PAG neurons usually had no cutaneous receptive field and showed no change in discharge correlated with the TF.

Thus, cells with changes in activity related to the TF are present in the PAG region as well as in the RVM. The PAG has a large projection to the RVM, and microinjection of morphine in the PAG increases activity of RVM off-cells and decreases that of RVM on-cells. Thus, it is likely that on- and off-cells in the PAG participate in the well-documented modulation of nociceptive reflexes by the PAG and that this action is mediated by TF-related neurons in the RVM.

345.8 THE EFFECT OF STIMULUS PARAMETERS AND ATTENTION ON THE MONKEY'S ABILITY TO DETECT SMALL INCREASES IN TEMPERATURE IN THE NOXIOUS RANGE. D.R. Kenshalo, Jr., R. Bates* and R. Dubner. Neurobiology and Anesthesiology Branch, NIDR, NIH, Bethesda, MD 20205.

In monkeys, detection latencies to small incremental temperature shifts in the noxious range provide an indirect measure of the perceived intensity of sensation (Bushnell et al., J. Neurosci., 1985, in press). The present study systematically examined the relationship between the intensity of noxious thermal stimulation and the monkey's ability to detect subsequent small temperature changes.

Four monkeys were trained in a psychophysical task to detect small temperature changes in the noxious range. A trial was initiated when the monkey pressed an illuminated panel button. Subsequently, a contact thermode, positioned on either the upper lip or on the volar surface of the wrist, increased in temperature from a baseline of 38°C to temperatures of 44°, 45°, 46° or 47°C (T1). After a variable time period of 3 to 9 sec, the thermode increased an additional 0.1°, 0.2°, 0.4°, or 0.6°C (T2). The monkey received 0.3 cc of fruit juice for releasing the button within 2.4 sec of the onset of T2. The detection latency was defined as the amount of time elapsing between the onset of T2 and the release of the button.

For all monkeys, as the first temperature shift (T1) increased, the T2 detection threshold systematically decreased from 0.6°C at a T1 of 44° to approximately 0.1°C at a T1 of 47°C. The median detection latencies were also inversely related to the intensity of T2 for suprathreshold temperature shifts. In addition, the detection latency following the onset of T2 was dependent on the T1 level. The results were similar for the face and the arm.

The influence of attentional factors on the detection of noxious thermal stimuli was studied by signaling the detection difficulty of the T2 stimulus. Near threshold stimuli (T2 = 0.2°-0.4°C) were signaled by a red light, while suprathreshold stimuli (T2 = 0.8°-1.2°C) were signaled by a blue light. Signaling the monkey that a difficult detection was about to occur resulted in a consistent decrease in the median detection latency and increase in the probability of detection for near threshold T2 stimuli. The median detection latency did not change for suprathreshold T2 stimuli.

These data suggest that monkeys are exquisitely sensitive to small temperature changes in the noxious range and that sensitivity improves in the noxious range of 45° to 47°C. Furthermore, detection latencies, which provide a measure of the perceived intensity of noxious stimuli, are systematically altered by attentional factors.

345.9 EFFECTS ON NOCICEPTIVE THRESHOLD OF THIP AND BICUCULLINE MICROINJECTED IN THE NUCLEUS RAPHE MAGNUS. E.J. Drower and D.L. Hammond. Dept. of Biological Research, G.D. Searle & Co., Skokie, IL 60077.

4,5,6,7-tetrahydroisoxazolo-[5,4-c]-pyridin-3-ol (THIP) is a GABA agonist reported to produce analgesia in the rodent and primate. A previous study from this laboratory determined that THIP did not act at the spinal level to produce analgesia. However, a supraspinal site of action was not excluded. The present study sought to determine whether the analgesic action of THIP was mediated supraspinally by neurons of the nucleus raphe magnus (NRM) and nucleus reticularis paragigantocellularis (NRPG), two medullary nuclei implicated in the regulation of nociceptive threshold.

Male Sprague-Dawley rats were implanted with a microinjection guide sheath aimed at the NRM or NRPG. One week later, either saline, the GABA agonist THIP (0.3-1.0 µg), or the GABA antagonist bicuculline (0.1-1.0 µg) was injected in a volume of 0.5 µl at sites in the NRM or NRPG. Alterations in nociceptive threshold were determined by measurements of tail flick latency (TFL), hot plate latency (HPL) and responsiveness to noxious pinch prior to and at fixed intervals after microinjection. Microinjection of saline did not significantly alter TFL, HPL or responsiveness to pinch. Microinjection of THIP in the NRM and NRPG decreased TFL and increased responsiveness to noxious pinch, but did not significantly alter HPL. In contrast, microinjection of bicuculline in the NRM and NRPG increased TFL and reduced responsiveness to noxious pinch; HPL was unaffected. These data suggest that neurons of the NRM and NRPG that regulate nociceptive threshold are subject to a tonic, GABA-ergic input. Removal of this input, by microinjection of bicuculline, produced analgesia, suggesting that the GABA-ergic input to the NRM and NPRG is inhibitory. These data further indicate that the analgesic activity of THIP is not mediated by neurons of the NRM and NRPG as microinjection of THIP at these sites produced hyperalgesia, rather than analgesia. Supported by G.D. Searle & Co.

345.10 ENDOGENOUS ANALGESIA IN THE PREGNANT RAT: AN ARTIFACT OF WEIGHT-DEPENDENT MEASURES? J.L. Dahl, B.W. Silva*, T.B. Baker*†, and S.T. Tiffany*†. Departments of Pharmacology and Psychology†, University of Wisconsin-Madison, Madison, WI 53706.

It has been reported that pain thresholds increase during pregnancy and parturition in the rat and that these increases can be prevented by administration of the opioid antagonist, naltrexone [Science 210, 193 (1980)]. These observations merit careful examination because they suggest that pregnancy activates a unique form of endogenous analgesia: one which is tonic, opioid-mediated, yet not associated with the development of tolerance. We used five different measures of nociceptive response across multiple experiments to compare the responsiveness of pregnant and nonpregnant female rats to painful stimuli. Pregnant and nonpregnant animals did not differ in response when assessed by tail-flick, tail-shock vocalization, and hot-plate tests. When nociception was assessed with a computerized flinch/jump procedure or with a jump-threshold test, there were significant differences between the responses of pregnant and nonpregnant control animals. However, a close inspection of the data showed that body weight differences could account for the apparent differences in the pain responsivity of pregnant and nonpregnant rats observed with these measures. Body weight accounted for a greater portion of variance in jump-response data than did pregnancy status. Furthermore, neither acute naloxone or chronic naltrexone administration blocked the increase in jump thresholds observed in pregnant rats, nor would we expect them to if the jump-threshold changes are determined wholly or partially by weight changes. In summary, we can find no evidence of an endogenous analgesia of pregnancy; instead, our results suggest that findings of a diminished response to painful stimuli in pregnant rats may be an artifact related to the greater body mass/weight of pregnant animals. Supported by funds provided by the Research Committee of the University of Wisconsin Graduate School to JLD.

345.11 EX VIVO INHIBITION OF MOUSE BRAIN PROSTAGLANDIN E2 FORMATION BY NON-OPIOID ANALGESICS. Richard A. Ferrari, Concetta Zobre*, Mary J. Connell* and Susan J. Ward*. Department of Pharmacology, Sterling-Winthrop Research Institute, Rensselaer, New York 12144

Prostaglandin E2 (PGE2) is known to be hyperalgesic. Reduction in PGE2 levels locally at the site of injury and/or in the brain is thought to be the mechanism of action of non-steroidal analgesics. A new animal model was developed to assay the effect of selected analgesics on post mortem PGE2 increases in mouse brain in a test system which closely approximates in vivo conditions.

The ex vivo synthesis of PGE2 from endogenous arachidonic acid in post mortem mouse brain was determined after incubating the brain at room temperature. The reaction was stopped by freezing on Dry Ice or by immersion in liquid nitrogen. Brains were homogenized in the frozen state in pH 3.5 citrate containing EDTA and indomethacin. Prostaglandins were adsorbed onto and then eluted from C18 Bond Elut columns (recoveries were 93 to 100%) prior to radioimmunoassay (sensitivity = 0.25 pg/assay tube).

The ex vivo PGE2 synthesis increased with time and plateaued at 2 min post mortem during which time zero control levels of PGE2 rose 20-fold from an average of 0.16 to 3.3 pg/mg brain. The ability of selected analgesics to prevent this post mortem formation of PGE2 after oral drug intubation was tested. Time course experiments demonstrated that a post drug treatment time of 30 min was optimal. The $ED_{50}$ values, in mg/kg as free acids, were: indomethacin 0.13, zomepirac 0.32, naproxen 1.7, ibuprofen 2.4, aspirin 35 and acetaminophen 113.

Minimal changes in time zero PGE2 levels were found at 30 min post-treatment p.o. with aspirin (1 to 300 mg/kg), indomethacin (0.1 to 3 mg/kg),. zomepirac (3 to 300 mg/kg) or acetaminophen (30 to 1000 mg/kg) when compared to vehicle treated controls.

The $ED_{50}$ values for preventing PGE2 formation ex vivo correlated well with antinociceptive activity in mice (0.98) and with in vitro inhibition of brain microsomal cyclooxygenase (0.94). Therefore, this model appears to be predictive of analgesic potency and suggests a central component within this class of drugs.

345.12 EVIDENCE THAT ACUPUNCTURE-LIKE ELECTRICAL STIMULATION OF MOTOR POINTS MODIFIES FUSIMOTOR TONE IN CONTRALATERAL LIMB MUSCLES R.J. Milne, N.J. Dawson*, M.J. Butler* and O.C.J. Lippold, Department of Physiology, University of Auckland, New Zealand.

Electro-acupuncture is one of many physical therapies used to relieve muscle spasm and associated musculo-skeletal pain. Our experiments were designed to determine whether electro-acupuncture is capable of modifying the excitability of spinal reflex pathways, either directly through α motoneurons or indirectly through γ (fusimotor) outflow.

Surface electromyographic (EMG) recordings were made from human extensor digitorum communis (EDC) or first digital interosseous (FDI) muscles. Subjects were instructed to contract the muscle and to maintain a constant level of rectified, integrated EMG. Reflex responses to brief stretch of the muscle, or electrical stimulation of its nerve supply, were extracted from noise by averaging the rectified signal (64 sweeps at 1 second intervals). Reflexes were recorded at 5 minute intervals before, during and after a 25 minute period of acupuncture-like low frequency electrical stimulation of points LI4 (Hoku) and LI11 in the contralateral arm. The cathode was placed proximal.

In one series of experiments, monosynaptic responses to brief stretch of EDC muscle were inhibited by 23% when electro-acupuncture began ($p<0.001$). The effect faded gradually during stimulation. In control experiments, when acupuncture needles were inserted subcutaneously and stimulated with the same current parameters, the reflexes were not affected.

In a second series of experiments, monosynaptic reflexes were elicited alternately in the same subjects by stretch of the FDI muscle or by transdermal electrical stimulation of the ulnar nerve at the wrist. Electro-acupuncture to the contralateral arm depressed the mechanically evoked monosynaptic reflex by 28%, the effect persisting beyond the period of stimulation ($p<0.001$). In contrast, the electrically evoked reflex remained unchanged. Since mechanical stimulation activates muscle spindles whereas electrical stimulation bypasses these structures, we conclude that electro-acupuncture alters somatic reflexes by modifying the sensitivity of muscle spindles to stretch, presumably by depressing fusimotor tone. Such a mechanism could in principle relieve musculo-skeletal pain associated with muscle spasm.

345.13 AFFERENT PROJECTIONS TO THE MEDIAL THALAMUS Eve Andersen, Dept Anatomy, Univ. Mass Med School, Worcester, Mass

In order to determine the afferent projections to the medial and intralaminar thalamic nuclei (MTh), injections of wheat germ lectin bound horseradish peroxidase (HRP) (2%, 0.1 ul) were made into the following thalamic nuclei: central medial, parafascicularis, central lateral, medialdorsal, centre median and paraventricularis. Rats survived 24-48 hours, and the brains were processed by the tetramethylbenzidine method. Very little, if any injection material was found in the ventral medial, ventral basal, anterior, reuniens, rhomboid, or gelatinous thalamic nuclei, or the habenula.

Retrogradely labeled cell bodies and fibers were found in the brainstem and forebrain. Cell bodies were found in brainstem nuclei associated with the production of neurotransmitters, including the pontine raphe nuclei, midbrain raphe nuclei, ventral PAG, nucleus cuneiformis, locus coeruleus, and substantia nigra. Labeled cell bodies were also found in the somatosensory and reticular activating system, namely in the pontine and midbrain reticular formation, reticular thalamus, zona incerta, and somatosensory cortex. Labeled cells were found in areas associated with motor and posturing functions, including deep layers of the superior colliculus, globus pallidus, ventral pallidum, and entopeduncular nucleus. Labeled fibers, but no cell bodies were found in the caudate nucleus. Finally, cell bodies and fibers were found in areas which process visceral and taste information, the parabrachial nucleus and the deep agranular insular cortex.

There was no apparent labeling in areas of the limbic system, including the septum, hippocampus, hypothalamus, amygdala, entorhinal cortex, or mammillary bodies. There was also no labeling in the motor cortex, medial or lateral geniculate, red nucleus, interpeduncluar nucleus, or trigeminal nuclei. There was no apparent uptake by the fiber pathways which traverse the medial thalamus including the fornix, stria medullaris, mammillothalamic tract, fascicularis retroflexus, or medial lemniscus.

Thus, the MTh receives input from brain areas known to produce modulatory neurotransmitters, and from somatosensory, reticular, visceral, taste, and extrapyramidal motor areas. By far the most heavily labeled areas were the parabrachial nucleus, zona incerta and reticular thalamus. It is very possible that the MTh receives information about visceral and somatosensory pain from these regions. It can also receive modulatory influences from brainstem nuclei which produce neurotransmitters. For example, we have previously shown that the MTh in the rat responds to noxious peripheral stimuli and that this response can be modulated by an ascending serotonergic pain modulation pathway from the dorsal raphe. This evidence suggests that the medial thalamus may have an important role in the modulation of visceral or somatic pain.

345.14 **SUBCOERULEUS-PARABRACHIAL INHIBITION OF CARDIAC INPUT TO SPINOTHALAMIC TRACT NEURONS IN THE MONKEY.** R.D. Foreman, T.J. Brennan*, N.M. Girardot and W.S. Ammons. Dept. of Physiol., Univ. of Okla. HSC, Oklahoma City, OK 73190.

Anatomical studies in the primate have demonstrated that neurons of the subcoeruleus-parabrachial (SC-PB) region project to the dorsal horn of the thoracic spinal cord (Westlund and Coulter, Brain Res. Rev. 2:235, 1980). The purpose of the present study was to examine the effects of electrical stimulation of the SC-PB region on spinothalamic tract (STT) neurons with input from cardiopulmonary (CP) sympathetic afferent fibers of the heart.

Left $T_2$-$T_5$ spinal segments were searched for cells antidromically activated from ventral posterior lateral nucleus and intralaminar nuclei of the contralateral thalamus in α-chloralose anesthetized monkeys. All STT cells received convergent excitatory input from the left chest or arm and the CP sympathetic afferent fibers. Electrical stimulation of the SC-PB region (20-350 μA, 100 Hz, 100 μs) inhibited the background cell activity and the increased discharge rate elicited by noxious pinch of 22 neurons studied. Intracardiac injection of the algesic substance bradykinin excited 8 of 12 cells tested; the responding cells increased their activity from 12 ± 3 to 31 ± 8 spikes/s. Stimulation of the SC-PB region (200 μA, 100 Hz, 100 μs) reduced the peak activity caused by bradykinin to 6 ± 2 spikes/s. The conditioning-test technique revealed that a conditioning stimulus (4 pulses within 10 ms) from the SC-PB region reduced the burst discharge of STT cells (n=5) by 50% about 10 ms after the stimulus was applied to the CP sympathetic fibers. The responses of cells were inhibited for up to 150 ms. Effects of both $A\delta$- and C-fibers were reduced by SC-PB stimulation. Histologic examination showed that effective sites for inhibition were located in the lateral PB, medial PB and SC regions.

In conclusion, electrical stimulation of the SC-PB region produces descending inhibition of visceral input from the heart. In addition, we have shown in earlier studies that stimulation of CP vagal afferent fibers also produces supraspinally mediated inhibition of excitatory input from the heart. In light of anatomical studies in the primate demonstrating that the caudal nucleus of the tractus solitarius receives the vagal afferent input (Beckstead and Norgren, J. Comp. Neurol. 184:455, 1979) and in turn projects directly to the SC-PB region (Beckstead et al., J. Comp. Neurol. 190:259, 1980), the present studies suggest that inhibition of STT neurons by CP vagal afferent stimulation may, in part, be mediated through the SC-PB region. (Supported by NIH grant HL22732, HL27260, and HL07430).

345.15 RECIPROCAL ACTIVITY IN ON- AND OFF-CELLS IN THE ROSTRAL VENTROMEDIAL MEDULLA OF THE RAT. N.M. Barbaro*, H.L. Fields, and M.M. Heinricher. Depts. of Neurosurgery and Physiology and Neurology, University of California, San Francisco, CA 94143.

On- and off-cells are putative pain modulating neurons in the rat rostral ventromedial medulla (RVM). On-cell activity abruptly increases while off-cells pause just prior to the tail-flick response(TF) elicited by noxious heat. In the unstimulated, lightly-anesthetized rat, both on- and off-cells periodically alternate between silent and active periods which last from several seconds to a few minutes. Opiates, whether administered systemically or microinjected into the PAG, produce analgesia and concomitantly abolish the periodic fluctuation in firing: all off-cells become continuously active while all on-cells become silent. Thus, it is possible that the analgesia produced by morphine depends on the synchronization of RVM cells whose periodicity is ordinarily out of phase. The present experiments investigate whether or not the spontaneous activity of all cells within a given class is synchronized in the absence of morphine.

Rats were maintained in a lightly anesthetized state by a continuous infusion of methohexital. The simultaneous activity of pairs of RVM neurons was recorded using two stainless steel microelectrodes placed on opposite sides of the midline near the rostral and caudal poles of the nucleus raphe magnus. A TF-related neuron was found with each electrode, and the spontaneous activity of the pair was recorded.

Twenty-five pairs of neurons were examined in this manner. In every case, two cells of the same class showed synchronous changes in spontaneous activity. In contrast, when the pair consisted of an on- and an off-cell, the two cells showed alternating active periods.

Thus, in lightly-anesthetized rats, all neurons of a given class not only respond in the same way to noxious stimulation and to opiates, but also show tightly coupled fluctuations in spontaneous firing. This phenomenon implies the existence of synaptic connections which synchronize each class of TF-related RVM neurons. These connections could include common external inputs and/or extensive excitatory interconnections among cells of a given class. We have also demonstrated a striking reciprocity of firing between the two cell classes. This could occur if there were a reciprocal input to the two classes, if one class inhibited the other, or if the two classes were mutually inhibitory. Thus, the entire range of opiate effects on RVM neurons could be accounted for by an action on the preexisting synaptic relations between on- and off-cells.

346.1 FATTY ACIDS EXPAND THE CELL SURFACE AREA OF TISSUE CULTURED NEURONS. H.Horie, Y.Kawasaki* & Takenaka,T. Dept. of Physiol. Sch. of Med. Yokohama City Univ.,Yokohama,232 Japan and Mitsubishi-Kasei Institute of Life Sciences, Tokyo, 194 Japan.

2-Decenoic acid, a fatty acid having 10 carbon atoms, reversibly inhibit the Na-channels of squid giant axons on internal and external application. This fatty acid also increased lateral motion of membrane lipids. This indicates that the fatty acid might be packed in the membrane . Since the axonal surface moves during action potential,it is important for the analysis of the Na-channel inhibition mechanism by the fatty acid to clarify that 2-Decenoic acid changes cell surface area. In this work we have studied effets of 2-Decenoic acid on two aspects of tissue cultured dorsal root ganglion neurons dissected from adult mice. (1) the intensity in a round area, dia 4μm, of fluorescent probe F18, 5(octadecylthiocarbamoylamino)fluorescein, labeled to the neurons (2) size of the neurons measured under Nomarski optics equipped with a computerized video system.

After DRG neurons were incubated in F18 containing medium, only the cell membranes were homogeneously labeled with F18 and the intensity was not affected by changing external solution. It is thought that the intensity is proportional to the concentration of F18 in a unit area of the membrane. When 2.1mM 2-Decenoic acid was externally applied to the labeled neurons, the relative value of the intensity of F18 decreased 0.82 and after washing out the fatty acid the intensity recovered to the same level as before the treatment. It is thought that the intensity might decrease as a result of cell surface expansion caused by the fatty acid and a relative value of the cell surface area might increase about 1.22. From the analysis of the video picture a relative value of the diameter of the neurons increased 1.07 and that of the height of neurons increase 1.12 when 2.1mM 2-Decenoic acid was applied to the neurons. After washing it out this value recovered to the same level as before the treatment. From calculation with these two values, a relative value of the cell surface area increased about 1.20. This value is almost equal to that calculated from the change of the fluorescent intensity. It is thought that the surface membrane expansion might accompany with increase of pressure in the membrane and this pressure might reduce the opening ability of the Na- channels.

346.2 **INITIAL CHARACTERIZATION OF THE INFLUENCE OF SKELETAL MUSCLE (SK) ON THE ELECTRICAL EXCITABILITY OF DORSAL ROOT GANGLION (DRG) NEURONS IN CULTURE.** **G.G. Chen*, A.E. Cole, A.B. MacDermott and J.L. Barker** (SPON: T.G. Smith,Jr.) Lab. of Neurophysiology, NINCDS, NIH, Bethesda, MD 20205.

Mouse DRG neurons maintained in medium conditioned with dissociated cultured SK frequently show repetitive action potential activity (repetitive firing, RF) when injected with sustained depolarizing current. This is in contrast to DRG neurons grown in normal medium which exhibit such behavior far less often (Cole et al., NSA 10:1056, see also for methods). We have examined this action of the muscle-conditioned medium (CM) as well as changes in the excitability of DRG neurons grown in co-culture with SK. Both control and CM-treated cells showed an increased tendency to display RF with increasing age of culture. For example, using whole-cell recording, 16% of control cells and 45% of CM cells at 6-13 days in culture (DIC) show RF while 52% control and 84% CM cells show RF at 22-34 DIC. The increase in frequency of RF occurred when CM was added after as few as 2 or as many as 22 DIC. Young cells were used to test the effect of short duration exposure to CM, since young control DRG neurons showed the lowest level of RF. In experiments with 1.5 to 7 hours of incubation in CM, 15 of 18 cells showed RF while matched control cells had only 1 of 15 cells with RF. Preliminary results suggest that a minimum time of exposure of 30 min is required to elicit RF during continuous application of CM to cells being monitored with repeated depolarizing current pulses. The appearance of RF was not dependent on plating density ($150\text{-}400 \times 10^3$ cells/dish) and was not induced by varying the concentration of NGF (10-200ng/ml). However, the effect on RF could be eliminated by heating the CM at 56° C for 30 min.

We observed that the incidence of RF following DRG neurons co-cultured with muscle was nearly 100%, resulting in a reliable source of cells showing RF. These were used to study the ionic mechanisms driving the action potentials (APs) and ultimately the mechanisms regulating RF. In mouse DRG neurons single APs include both $Na^+$ and $Ca^{2+}$ currents (Ransom & Holz, Brain Res., 136:445, 1977). In our experiments, pressure-applied 1 uM TTX did not block all of the single APs in control cells or first spikes in RF cells, but did block all of the second and subsequent APs in RF cells. These subsequent APs were also more readily blocked by pressure-applied $Na^+$-free medium. Neither the first nor subsequent APs were blocked in the presence of 200 uM $Cd^{2+}$, 2 mM $Co^{2+}$, or 4 mM $Mn^{2+}$. These results indicate that SK releases some factor(s) that is heat labile, not NGF, and requires many minutes (30 min) to induce RF of $Na^+$-dependent APs in DRG neurons.

346.3 **COMPARISON OF THE EFFECTS OF 4-AMINOPYRIDINE (4-AP) AND SKELETAL MUSCLE ON THE EXCITABILITY OF DORSAL ROOT GANGLION (DRG) NEURONS IN CULTURE.** A.E. Cole, G.G. Chen*, A.B. MacDermott and J.L. Barker, Lab. of Neurophysiology, NINCDS, NIH, Bethesda, MD.20205.

We have shown that exposure to conditioned medium (CM) from skeletal muscle (SK) or co-culturing with dissociated SK increases the incidence of repetitive firing in DRG neurons grown in tissue culture (see preceding abstract). In addition, co-culture of DRG neurons with SK nearly doubles the action potential duration of the DRG cells with little change in spike amplitude (n=33). The convulsant 4-AP has been shown to increase cell excitability and prolong the action potential duration in several mammalian neuronal types, perhaps by blocking a transient potassium conductance, the A-current. In the present study, we applied 4-AP (0.5-5mM) to cultured mouse DRG neurons recorded with the whole cell patch technique. In 10/11 control cells, which fired only 1 or 2 action potentials in response to a 100 ms depolarizing pulse, 4-AP produced a rapid increase in the number of action potentials. In addition, the action potential duration was increased in all cells (n=11). In response to long depolarizations (1-2 sec) 4-AP increased cell firing from 1 Hz to 14-20 Hz and showed little adaptation throughout the stimulus. Although there is no evidence at this time for an A-current in DRG neurons, we found that 4-AP blocked a sustained outward current activated by a depolarizing voltage step under voltage-clamp conditions.

It has been suggested that some actions of 4-AP are mediated by an increase in $Ca^{2+}$ conductance (Rogawski and Barker, Br.Res.280:180,1983). To see if these actions of 4-AP on DRG neurons were mediated by an effect on $Ca^{2+}$, we applied 4-AP in the presence of the $Ca^{2+}$ blocker, $Cd^{2+}$ (100-200 uM). Even with $Cd^{2+}$ present, 4-AP still increased cell excitability and prolonged the action potential duration, although the increase in spike duration was not as dramatic. When 4-AP was applied to co-cultured DRG neurons (n=6) that already fired multiple spikes, the number of spikes was decreased, although the action potential duration was prolonged. Neither of these effects was blocked by $Cd^{2+}$.

In the present study, we found that the actions of 4-AP on cultured DRG neurons were similar to the effects of CM or co-culturing DRG cells with SK, including: 1) increased incidence of repetitive firing, 2) prolonged action potential duration and 3) resistance of these actions to blockade by $Cd^{2+}$. Voltage-clamp experiments are in progress to elucidate the mechanism of action of 4-AP and CM on DRG neurons. It may prove useful to compare and contrast the results from these two treatment conditions.

346.4 **WHOLE CELL PATCH AND OPTICAL RECORDINGS OF CALCIUM TRANSIENTS IN SINGLE CLONAL PITUITARY CELLS.** A.B. MacDermott, S.J. Smith*, B. Dufy, J.L. Barker. Lab of Neurophysiology, NINCDS, NIH Bethesda MD 20205.

The present work was undertaken to directly monitor changes in the internal free $Ca^{2+}$ concentration measured by the absorbance of the metallochromic indicator, arsenazo III (Ar III) and the associated electrophysiological events, on single pituitary cells. ArIII (98%, Na salt, Sigma) was dissolved in the recording solution at a concentration of 1-2mM and allowed to diffuse passively into GH3/B6 cells. Patch pipettes contained (in mM): 140 K-gluconate or CsCl, 2 $MgCl_2$, and 5 Hepes. Three photodiodes were used for measurement of transmitted light intensity of GH3 cells at wavelengths centered at 570, 660 and 700 (all ± 15 nm). Large electrical (current steps) and ionic (KCl, 50 mM) depolarizations of the cell membrane evoked peaks in the ArIII signal indicating, as expected, increases in $Ca^{2+}$ cytoplasmic concentration. Currents steps accompanied by multiple action potential firing were also associated with $Ca^{2+}$ signals and at the highest dye concentration, individual spikes evoked individual peaks in ArIII signal (Fig. 1). However, under these conditions, the kinetics of $Ca^{2+}$ removal was slowed. Voltage clamp experiments using CsCl filled electrodes showed that ArIII signals corresponded closely to $Ca^{2+}$ current amplitudes (Fig. 2). Preliminary evidence indicates that under certain conditions (see adjacent abstract), thyrotrophin releasing hormone (TRH) causes an increase in intracellular $Ca^{2+}$ due to $Ca^{2+}$ buffering by the dye.

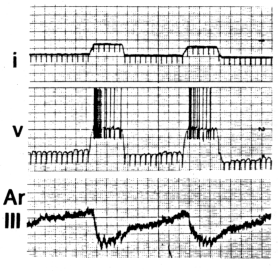

Fig. 2

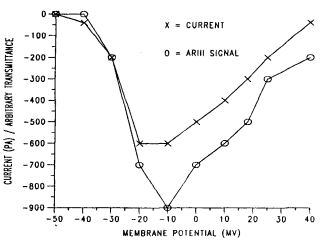


346.5 A BIOCHEMICAL STUDY OF SINGLE GH3 PITUITARY CELLS USING WHOLE-CELL PATCH RECORDINGS. B.Dufy, A.B.MacDermott, J.L.Barker. Lab of Neurophysiology, NINCDS, Bethesda MD 20205

The stimulus-secretion coupling process by which a secretagogue controls the hormonal release from pituitary cells involves a series of electrical and biochemical events that are not yet completely understood. Electrophysiological events are analysed at the level of the single cell, whereas biochemical processes are normally studied in cell populations. Biochemical studies may be performed on single cells using whole-cell recordings (WCR). WCR technique permits replacing intracellular medium with solutions in the recording pipette while monitoring electrophysiological parameters. We used GH3/B6, a subclone of the GH3 pituitary cell line. The bathing solution consisted of Hanks balanced and buffered salt solution with (in mM) 10 $CaCl_2$ and 2 $MgCl_2$. WRC pipettes had resistances of 3-7 MOhm when filled with the following solution (in mM) 140 K-Gluconate, 2 $MgCl_2$, 5 HEPES, 1.1 EGTA (pH 7.3). Under these conditions the resting potential was -52±9 mV (n=8) and the input resistance was around 3 GOhm. In GH3 cells using conventional intracellular recording techniques with sharp,high resistance microelectrodes, it has been repeatedly reported that thyrotropin releasing hormone (TRH), which stimulates the release of prolactin, induces a transient hyperpolarization of the cell membrane thought to be due to a rapid rise in $Ca_i$ and increase in $K^+$ conductance, followed by generation of action potentials. In the WCR configuration, the effect of TRH (50 nM) vanished very quickly (<5 min) or completely failed to appear in most of the cells recorded (n=35). Restoration of electrical response to TRH was accomplished by filling the WCR pipettes with a cytoplasmic extract of GH3 cells. This was made as follows: $1.5x10^6$ cells were allowed to lyse in the presence of 1 ml distilled water; the supernatant was collected, filtered through a .45 micron millipore filter and then used to prepare the K-Gluconate recording solution. In order to identify the cytoplasmic factor(s) involved in the TRH-induced electrophysiological response, we undertook pharmacological manipulations of the WCR recording solution, including addition of ATP, GTP, and inositol triphosphate (IP3). Only IP3 (5uM) partially substituted for the cytoplasmic extract. At higher concentrations (10-20 uM), IP3 hyperpolarized the cell and decreased input resistance as well as decreasing the amplitude of action potentials. These effects are consistent with persistent high levels of intracellular $Ca^{2+}$. IP3 intracellular concentration may be critical in TRH-induced activation of $K^+$ conductance in GH3 cells but it does not appear to be able to restore the peptide signal to full intensity.

346.6 D-TUBOCURARINE SUPPRESSES SPIKE AFTER-HYPERPOLARIZATION IN GUINEA PIG PREVERTEBRAL NEURONS. N. Mo*, Z.G. JIANG*, N.J. Dun and A.G. Karczmar. Dept. of Pharmacol. Loyola Univ. Med. Ctr., Maywood,IL 60153

Intracellular recordings were made from neurons of the guinea pig celiac-superior mesenteric and inferior mesenteric ganglia in vitro. An action potential evoked by either brief depolarizing current pulse injected through the recording microelectrode or by presynaptic nerve stimulation was followed by an after-hyperpolarization (AH) with an amplitude and duration ranging from 5-25 mV and 30-500 ms, respectively. The AH in most of the neurons clearly exhibited two components; a fast decaying component ($AH_F$) with a time constant ($\tau$) of about 22 ms was followed by a slowly decaying component ($AH_S$) which has a mean $\tau$ of about 85 ms. The $AH_F$ was linearly dependent on membrane potentials and nullified between -90 and -100 mV; the equilibrium potential shifted to a less negative level in solutions of elevated K as predicted by Nernst Equation. $AH_F$ therefore seems to be largely due to an increase of a voltage sensitive K conductance ($G_K$). $AH_S$ appeared to be dependent on extracellular Ca for its generation as it was enhanced by caffeine (5 mM) and eliminated by removing Ca from the bathing solution. $AH_S$ was also membrane potential dependent and nullified at the same potential level as $AH_F$. Hence, $AH_S$ appears to be mediated principally by a Ca activated $G_K$ ($G_{Ca-K}$) as has been suggested for other vertebrate and invertebrate neurons. D-Tubocurarine (d-Tc, 10-100 µM) reversibly suppressed the $AH_S$ in a concentration dependent manner; the half decay time of AH was shortened by 40,55 and 61% in neurons exposed to 10,50 and 100 µM of d-Tc, respectively. The $AH_F$ on the other hand was only slightly depressed by d-Tc. A second type of Ca dependent after-hyperpolarization, namely the post-tetanic (20-30 Hz, 1-2 sec) spike after-hyperpolarization, was also reversibly depressed by d-Tc in a concentration dependent manner. When Na content was replaced with isotonic Ca plus 10 mM tetraethylammonium in the bathing solution, strong depolarizing current pulse evoked in ganglion cells a slowly rising and falling spike potential that appeared to be largely generated by Ca current. Superfusion of d-Tc onto the ganglion cells did not significantly change the amplitude and configuration of the Ca spike potentials. The lack of effect of d-Tc on Ca spike potentials indicates that d-Tc reduced $AH_S$ by interfering with the activation of $G_{Ca-K}$ rather than Ca influx. Collectively, these findings suggest that d-Tc reduced $G_{Ca-K}$, thereby shortening interspike intervals and favoring repetitive cell discharges. Moreover, our results suggest that a shortening of spike AH by d-Tc may contribute to its well known effect as a seizure producing agent in cortical neurons. (Supported by USAMRDC contract DAMD 17-83-C-3133).

346.7 CONTROL OF REPETITIVE FIRING IN RABBIT PARASYMPATHETIC TRACHEAL GANGLION CELLS IN VITRO. J. C. Fowler and D. Weinreich. Dept. of Pharmacology and Experimental Therapeutics, University of Maryland School of Medicine, Baltimore, Maryland 21201.

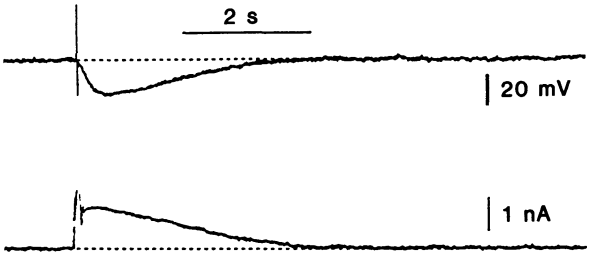
The electrophysiology of rabbit parasympathetic tracheal ganglia was investigated with conventional intracellular recording techniques. Isolated tracheal segments (2-3 cm) were incubated in a .01% neutral red solution for 30 min to visualize ganglia and individual neurons (Skoogh et al., J. Neurosci. Meth. 8:33-39, 1983). The stained ganglia were then undercut and pinned to the floor of a recording chamber maintained at room temperature. Neurons were impaled under visual control at 350 X with glass micropipettes (40-90 MΩ, 1 M KAC). Cells were included in this study only if they showed a stable membrane potential and generated an action potential of greater than 50 mV in response to a depolarizing current step. Values are mean ± S.E.M. These neurons possessed a resting membrane potential of 46.1 ± 2.5 mV (n = 14), an input resistance of 74.0 ± 10.5 MΩ (n = 19) and a time constant of 8.4 ± 1.3 msec (n = 15). Spike height averaged 59.6 ± 3.6 mV (n = 17) with threshold at a membrane potential of 31.7 ± 1.3 mV (n = 17). The fast spike afterhyperpolarization amplitude averaged 14.3 ± 1.2 mV (n = 17) and persisted for 75.5 ± 8.9 msec (n = 11). Slow (several sec) afterhyperpolarizations similar to those observed under comparable conditions in rabbit vagal sensory neurons were not seen (Fowler et al., J. Physiol., in press; Higashi et al., J. Physiol. 355:479-492, 1984).

Neurons could be classified into several types by their response to depolarizing current steps (<1 nA). Some cells fired one (n = 2) or, at most, 4 spikes (n = 6) during a sustained (>600 msec) current step. The remaining cells fired repetitively throughout the depolarizing current pulse (n = 10).

Repetitively firing cells showed a decline in instantaneous firing frequency during a current pulse. Two $K^+$ currents have been shown to modulate firing frequency in peripheral ganglia: a $Ca^{++}$-activated $K^+$ current (Hirst and Spence, Nature 243:54-56, 1973), and an M-current which is reduced by muscarinic agonists and barium ions (Brown et al., J. Aut. Nerv. Sys. 6:23-35, 1982). A substantial role for a $Ca^{++}$-activated $K^+$ current can be excluded: $Cd^{++}$ (100 µM - 1 mM; n = 6), a $Ca^{++}$ current antagonist, and $Ca^{++}$-free (10 mM $Mg^{++}$) Locke solution (n = 1) produced only minimal effects on spike frequency. Carbachol (1-10 µM; n = 2), muscarine (10 µM; n = 1) and acetylcholine (10 µM; n = 1) did not affect spike frequency. However, $Ba^{++}$ (1 mM, n = 2) produced a robust and reversible increase in spike frequency discharge during a depolarizing current step. These results suggest that a $Ba^{++}$-sensitive current which is not affected by muscarinic agonists plays a dominant role in the control of spike frequency in these cells. (Supported by N.I.H. Grant NS 22069 to D.W.)

346.8 HYPERPOLARIZING AFTER-CURRENT IN MYENTERIC NEURONS OF THE GUINEA-PIG ILEUM. T. Tokimasa*, H. Hasuo*, T. Akasu* and R. A. North. *Dept. of Physiol., Kurume Univ. Sch. of Med., Kurume 830, Japan and Neuropharmacology Laboratory, M.I.T., 56-245, Cambridge, MA 02139, USA.

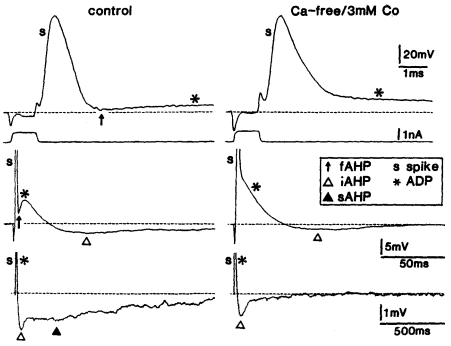
AH (type 2) cells in myenteric plexus of the guinea-pig ileum were voltage-clamped using a single micro-electrode in tetrodotoxin (300 nM) containing Krebs solution (∿ 3 kHz switching frequency with a 50-50 duty cycle). The cells were held at the resting membrane potential of -60 mV and subjected to brief (20-100 ms) depolarizing commands to beyond -25 mV, which evoked a transient inward Ca-current. The inward Ca-current was followed by an outward current during commands. This inward/outward-current was followed by a long-lasting (up to 20 s at -60 mV) outward tail current (see Fig.). The tail current was associated with an increase in membrane conductance. Reversal of the tail current occurred at more negative potential than -90 mV. The tail current became smaller in K-rich (10-20 mM) solution and the reversal potential shifted by about 50 mV for one decade change in extracellular K-concentration. The tail current was markedly augmented in K-free solution and was completely eliminated in Ca-free and Co (1 mM) containing solution. It was therefore concluded that the long-lasting outward tail current arose from an activation of Ca-activated K-current, which corresponds to the spike after-hyperpolarization. The tail current was not blocked by TEA (1-3 mM) or Cs (2 mM) but was markedly depressed by Ba (0.3-10 mM) in a dose dependent fashion. Ba itself mimicked the muscarinic slow synaptic current (North and Tokimasa, J. Physiol., 333: 151, 1982), which was insensitive to TEA (5 mM).



346.9 CALSIUM-DEPENDENT SPIKE REPOLARIZATION, AND THREE KINDS OF AFTER-HYPERPOLARIZATION (AHP) IN HIPPOCAMPAL PYRAMIDAL CELLS. J. Storm*. (SPON: P. R. Adams) Inst. of Neurophysiology, University of Oslo, Norway. Present address: Dept. of Neurobiology & Behavior, SUNY at Stony Brook, Stony Brook NY 11794.

Hippocampal cells are known to have two types of AHP: (1) a slow Ca-dependent AHP (sAHP) lasting 1-5 s, and (2) a shorter (50-100ms) Ca-independent AHP (iAHP). Here I report a third, fast AHP (fAHP, 2-5ms) which follows as a direct continuation of the spike repolarization. Both fAHP and spike repolarization show Ca-dependence and (unlike iAHP and sAHP) are sensitive to low doses of 4-aminopyridine (4-AP) and tetraethylammonium (TEA).

CA1 cells (n=38) were studied in rat hippocampal slices (28-38°C 1-3 mM Ca). Spikes elicited by short (1-2ms) current pulses were each followed by a sequence of afterpotentials: fAHP, an afterdepolarization (ADP), iAHP and sAHP. The same sequence followed each spike during slow repetitive firing (steady current), whereas high-frequency trains of 2-10 spikes were followed by an iAHP and a much enhanced sAHP. Perfusion with Ca-free medium (with 3mM Co, or 10mM Mg/0.5mM EGTA) reversibly slowed the spike repolarization and abolished the fAHP. The sAHP was also blocked, whereas the iAHP and the spike upstroke were essentially unaffected (the spike amplitude increased slightly in some cells). 5mM Mn or 0.2-0.4mM Cd had the same effects. During partial blockade of fAHP, the ADP was often enhanced, and sometimes (n=7) triggered an extra spike. 4-AP (20-100μM) and TEA (1mM) also reversibly slowed spike repolarization and blocked fAHP, but not iAHP or sAHP. These results suggest that a fast Ca-dependent outward current contribute to the spike repolarization in mammalian central neurons, as previously shown in frog ganglion cells.



Ca-dependence of the spike and after-potentials (following a single spike in the same cell) shown at different gains and time-bases. Bottom 4 traces averaged.

346.10 SINGLE CHANNEL CURRENTS RECORDED FROM DENDRITIC MEMBRANES OF CULTURED DISSOCIATED NEURONS FROM THE RAT HIPPOCAMPUS. Leona Masukawa, Anker Hansen* and Gordon Shepherd Section of Neuroanatomy, Yale University School of Medicine, New Haven, CT. 06510.

Previous intracellular studies from isolated apical dendrites of pyramidal neurons from hippocampal brain slices demonstrated that calcium conductances are present principally in dendrites rather than cell bodies (Benardo, Masukawa and Prince, 1982, J. Neurosci 2:1614). These conductances have been postulated to underlie burst potentials during epileptic states.

In order to characterize further the conductances of dendrites, cell attached patch recordings were obtained from apical dendrites (1-3 um in diameter) at sites up to 100 microns from the cell body of cultured hippocampal neurons from 1-2 day old rats. Cells were incubated in DMEM, 10% fetal bovine serum and 2.5% chick embryo extract on collagen coated coverslips for 3-14 days before recordings were made. Single channel current recordings from dendrites during command ramps from rest to 100mV depolarized from rest showed outward currents in control medium. These currents were sensitive to cesium and TEA. The single channel currents increased in amplitude and frequency with depolarizing command voltage steps. These channels were classified as the delayed rectifier ( ~0.6pA and ~12pS) and the Ca-dependent K channel ( ~ 2 pA and ~40 pS) at 60 mV depolarized from rest. Inward currents that were sensitive to cesium and TEA were activated at 40 mV hyperpolarized from rest. These channels were classified as the anomalous rectifier ( ~3 pA and ~150 pS).

In addition, inward single channel currents were present in dendritic cell attached patch recordings during steps from rest to 60mV depolarized from rest. The single channel current amplitudes were ~1pA with a conductance of ~17pS, and were non-inactivating and had short open times, 1-25 msec during 150 msec command steps. These inward currents were classified as Ca-dependent by their insensitivity to TTX (2uM) in the patch pipette. It is hypothesized that these inward single channel currents may underlie the burst response of the dendrite during depolarizing steps and during epileptic states, and that a variety of single channel conductances underlie the regulation of electrical responses in hippocampal neurons.

346.11 CALCIUM CURRENT IN VOLTAGE-CLAMPED ISOLATED GROWTH CONES. S. Marom* and D. Dagan. Rappaport Family Institute for Research in the Medical Sciences and Department of Physiology and Biophysics, Faculty of Medicine, Technion-Israel Institute of Technology, Haifa 31096, Israel.

Severance of a growth cone from its neurite in primary cultures of Helix aspersa induces rapid withdrawal of filopodia. The isolated growth cone often rolls up spontaneously into a sphere which remains attached to the substrate at one point. The smooth surface of these growth balls and their spherical shape make them ideal geometric bodies for good spatial clamps and, at the same time, enable accurate measurements of the total surface area of any growth cone. Growth cones were obtained from 3- to 6-day-old cultures plated on polylysine- or Helix lectin-treated coverslips. Cells were grown in Leibovitch-15 medium with appropriate salt concentrations at 27°C. Utilizing single-electrode voltage clamping in the whole-cell patch electrode configuration, we measured the ionic currents of isolated growth balls, typically 10-20 μm in diameter.

Membrane current induced by a voltage step from -70 to +20 mV shows an early activating inward current and a delayed outward current when the growth ball is in a medium containing 80 mM NaCl, 4 mM KCl, 7 mM $CaCl_2$, 5 mM $MgCl_2$, 10 mM Tris-HCl, pH 7.4, 10 g/l glucose, and the intracellular solution is dialyzed by the 135 mM KCl electrode solution. Peak inward current is reached in 2-6 ms and inactivates to 50% in 10 ms. Peak outward current is reached in 25-30 ms.

Changing the extracellular solution to one with 10 mM CaCl and 35 mM Tris-HCl, 50 mM TEA, 5 mM CsCl, 5 mM 4-AP, 15 MgCl , and 5 g/l glucose shows an inward current carried by calcium ions. The inward calcium current peaks at +10 mV and reverses at +58 mV. Time to peak of the calcium current in a voltage step from -70 to +20 mV was 3 ms. Mean peak current was found to be 0.3-1.2 pA/μm . This methodology enables us to measure calcium current densities at various conditions during neuronal regeneration.

346.12 PATCH CLAMP STUDIES OF ISOLATED PEPTIDERGIC NERVE TERMINALS. E. Stuenkel*, J. Lemos[1], J. Nordmann* and I. Cooke. Bekesy Laboratory of Neurobiology, University of Hawaii, Honolulu, HI 96822.

The sinus gland (SG), a crustacean neurohemal structure, is a dense aggregation of peptidergic axon terminals. In the crab, Cardisoma carnifex, terminals (5-30 μm dia.) can be isolated by trituration of the SG following collagenase treatment. In EM sections, the isolated terminals appear as circular, membrane-bounded profiles, devoid of adhering material, completely filled with neurosecretory granules (80-210 nm). Each of the terminal types distinguishable morphologically in sections of intact SG are found after isolation. The isolated terminals form 10-40 Gohm seals with electrodes thus permitting patch clamp recording. "Whole terminal" recordings under voltage clamp show both inward and outward currents on step depolarizations from $V_p$ = -55 mV. Inward currents have been resolved into (a) a TTX-insensitive component, rapidly activating, slowly inactivating, that "runs down" after ca. 30 min; and (b) an inward current, activated at steps to $V_p$ = -15 mV or more depolarized that is blocked by TTX and does not run down during recordings lasting 2 hrs. Intracellular recordings from terminals in situ of overshooting action potentials that have both Na- and Ca-dependence permits attributing the currents to Ca (a) and Na (b). Outward current is also activated by steps to $V_p$ = -20 mV or more depol. It shows little inactivation (depol. for >0.5 s), partial block by $[TEA]_o$ = 50 mM, and complete block by internal Cs (from the pipette).

Recordings from inside-out excised patches have been made under conditions favoring K-conductance channels (symmetrical KCl solutions). Two channel types have been observed. One has a slope conductance of ca. 70 pS over a range of $V_m$ = ±55 mV; events occur in bursts at pos. and neg. potentials. Distributions of closed lifetimes are biexponential with bursts and brief (0.1-2 ms) transitions to the open state within the burst; interburst intervals are 0.1-2 s. This type is a K channel, exhibiting rectification on perfusion (internal face) with CsCl or $Na_2SO_4$, but not with $K_2SO_4$ or KCl. A second channel type has a slope conductance of ca. 150 pS. It shows events at both ± $V_m$ having an open state lasting several seconds, with numerous flickers. With $[K^+]_{in}$ high and normal saline in the pipette (high $[Na^+]$ outside), transitions to open state show inward current with steps to negative $V_m$ values, suggesting this channel type is permeable to $Na^+$ as well as $K^+$. Events occur more frequently when $[Ca^{++}]_{in}$ is increased; it is partially blocked by TEA. It thus resembles in ionic characteristics a Ca-activated cation channel. The two channel types are occasionally found in the same patch.

346.13 EFFECT OF PENTOBARBITAL ON THE TRIPHASIC, PROLONGED CURRENT RESPONSE INDUCED BY CALCIUM INJECTION IN APLYSIA GIANT NEURONS. Jones, L.S., Lewis, D.V., and Wilson, W.A. Duke Univ. Med. Center and Veterans Administration Hospital, Durham, NC 27710.

Following early reports of a monophasic current response to intracellular $Ca^{++}$ injection (Meech, R.W., Comp.Biochem.Physiol. 42A 493, '72), and later reports of a biphasic response (Hofmeier, G. and Lux, H.D., Pflugers Arch. 391:242, '81), the effect of $Ca^{++}$ injections in Aplysia neurons was studied in this laboratory and found to produce a complex, triphasic response (Lewis, D.V. et al., Soc.Neur.Abs. 10:242, '84). When the usually silent R2 or LP1 was held in voltage clamp at resting potential, an iontophoretic injection of $Ca^{++}$ induced a response comprised of an early outward current (phase I) initiated by the injection, followed by an inward current (phase II) that peaked 10-20 seconds after the termination of the injection, then followed by a very slow, prolonged outward current (phase III) that was maximally present 50-100 seconds after the end of the injection. This report examines the results of preliminary studies on the effects of pentobarbital (P) on all three phases of the $Ca^{++}$ induced currents observed.

The triphasic response was most easily seen in cells that were voltage clamped at slightly depolarized potential (-30 to -40 mV) during the iontophoretic injection. The triphasic response induced by $Ca^{++}$ injection was found to be markedly effected by the bath application of 100 uM P. The most obvious effect was a striking, reversible enhancement of the inward current (phase II). Phase II was so enhanced in some cells that it encroached upon the outward phase I, shifting the entire phase I current in a net inward direction. The peak for the phase II current also tended to occur sooner (<15 seconds after the end of the $Ca^{++}$ injection) in P. Where the effect on phase II was very strong, phase III would appear reduced or unchanged, but in cells where the effect on the inward current was less striking, there was evidence that the outward current of phase III also might be enhanced by P. It is possible that the P is routinely enhancing this current but that the effect is being masked by the intensity of the effect on the inward current response. If the outward current of phase III represents the same conductance system as the slow outward current seen in Aplysia giant neurons with depolarization (Zbicz, K.L. and Wilson, W.A., J.Pharm.Exp.Ther., 217:222, '81), then one might expect the P to have the same enhancing effect on phase III that it does on the latter slow outward current.This may be the case.

Preliminary work also shows that removing calcium from the bath doesn't interfere with the triphasic response, and that the P effect on the response is similarly unaffected.

346.14 **CONTROL OF LIGHT EMISSION FROM COELENTERATE CELLS CONTAINING ENDOGENOUS CALCIUM-ACTIVATED PHOTOPROTEIN.** K. Dunlap and P. Brehm. Dept. of Physiology, Tufts Univ. School of Medicine, Boston, MA., 02111.

In the hydrozoan coelenterate Obelia geniculata, bioluminescence is normally triggered by an action potential which propagates through the non-neuronal endoderm. Although light emission requires the presence of extracellular $Ca^{++}$, the nature of coupling between the action potential and the resultant rise in intracellular calcium within the luminescent cells (photocytes) is poorly understood. We studied this interaction by voltage-clamping dissociated endodermal tissue. Following dissociation the photocytes, either in small cell clusters or in isolation, were distinguished from non-luminescent cells on the basis of intense green fluorescence which is characteristic of endogenous calcium-activated photoprotein. Macroscopic membrane currents were recorded by whole cell recording technique from photocytes in artificial sea water (ASW). The electrode contained (in mM) 140 KCL, 11 EGTA, 696 Glucose, 1 $CaCl_2$, and 10 HEPES. All photocytes examined (greater than 60 cells) exhibited a transient outward current which was carried primarily by $K^+$. The reversal potential of the tail current shifted 61 mV per decade shift in external $K^+$ and the current was effectively blocked by inclusion of 1 mM 4-aminopyridine in the external solution. This K channel activated at potentials more positive than -10 mV and inactivated within 150 ms at 20 mV. Both the rate of activation and inactivation increased with depolarization while recovery from inactivation was slowed with depolarization . All of these characteristics were qualitatively similar to those previously described for coelenterate egg (Hagiwara, Yoshida, & Yoshii, J. Physiol.,318:123). Unexpectedly, we never observed a voltage-activated inward Ca or Na current even after block of the transient K current by 4-AP. Moreover, both early and late current-voltage relations were linear both after block of the K current by 4-AP and following inactivation of the K current by depolarization, suggesting that the transient K current is the only voltage dependent current measurable by this technique in photocytes. The lack of voltage-activated Ca current in photocytes was corroborated by the finding that rapid application of ASW containing 360 mM KCl (n=8) or direct electrical stimulation (n=5) did not elicit light in any of the cells examined. On the other hand, small clusters of cells containing one photocyte did elicit light when depolarized with high K (7 out of 8) or when a neighboring non-luminescent cell was electrically stimulated under whole cell clamp (8 out of 8). Light emission was blocked in Ca-free ASW. These data suggest that activation of photoprotein through elevation of internal calcium concentration requires interaction with adjacent non-luminescent cells and that this signal occurs by a mechanism other than direct depolarization. Further experiments are necessary to determine whether synaptic interactions are responsible for control of luminescence from photocytes.

346.15 Ouabain inhibits the depolarization of frog skeletal muscle induced by palytoxin. Sonia Ortiz* and Gladys Escalona de Motta, Laboratory of Neurobiology and College of Pharmacy, U. of Puerto Rico Med. Sc. Campus, San Juan P.R. 00936.

Palytoxin (PTX) isolated from corals of the genus Palythoa is the most potent marine toxine known. It exerts a $Na^+$- sensitive and tetrodotoxin (TTX)- insensitive depolarizing action on nerves and skeletal muscle cells. It also induces contraction of smooth muscle and cardiac tissues. The toxin purified from P. Caribaeorum (C-PTX) also exhibits a potent hemolytic effect which may be inhibited by ouabain and potentiated by $Ca^{+2}$ (Naunyn-Schmiedeberg's Arch. Pharmacol. 323: 261, 1983). C-PTX fractions were obtained through ethanol (95%) extraction and chromatographic (Amberlite XAD-2) separation monitoring continuosly the toxicity by survival of i.p. injected mice. These fractions depolarized frog sartorius muscle fibers (average $\Delta Vm=80mV$) and caused irreversible contractures of frog rectus abdominus muscles. Both effects were potentiated increasing $[Ca^{+2}]_o$ and were inhibited lowering $[Na^+]_o$. Neither inorganic Ca channel blockers or TTX blocked these C-PTX effects. Ouabain, however, inhibited the muscle responses to C-PTX in a dose and time dependent manner. Ouabain itself exerted a delayed depolarizing action but shorter exposure times (1 hr or less) or lower concentrations (between $10^{-6}$ and $10^{-5}$M) inhibited from 20 to 80% of the depolarizing and contractile actions of C-PTX. These results suggest that the site where C-PTX acts to increase the membrane cation permeability leading to frog muscle depolarization and contraction is related to the $Na^+$-$K^+$ ATPase as it has been proposed to occur in red blood cell and smooth muscles. 346.16 ASSOCIATION BETWEEN THE DEPOLARIZING AFTERPOTENTIAL AND THE SUPERNORMAL PERIOD IN MYELINATED FIBERS. C.M. Bowe, J.D. Kocsis,and S.G Waxman. Palo Alto VA Medical Center and Stanford University, Palo Alto, CA 94304

Activity-dependent variations in axonal excitability and conduction velocity have been described for a number of axon systems. Following the relative refractory period, a period of increased excitability, the supernormal period (SNP), is often present. Although the mechanism of the SNP is not well established, early electrophysiologists noted a correspondence of the SNP with the depolarizing afterpotential (DAP) in myelinated axons. Barrett and Barrett (J.Physiol.323:117,1982) have suggested that DAP results from the passive electrical properties of the myelinated axons. However, the direct association of the DAP with threshold changes during the SNP has not been reported. The present experiments were designed to examine the relationship of the SNP to passive membrane depolarization in myelinated fibers.

Sciatic nerves from Wistar rats and frogs were excised and studied in vitro. The nerves were stimulated proximally and compound action potentials were recorded at the distal end. Intra-axonal impalements were obtained with glass microelectrodes (60-120 megohms) filled with 2 M KCl. Eighty-four rat and 67 frog axons having resting potentials >60 mV and spike amplitudes >70 mV were used in this study. Double shock experiments were carried out to evaluate threshold changes following a conditioning stimulus. Eleven per cent of the rat fibers studied at resting potential had an SNP. However, when continuous hyperpolarization was applied to the axon, the DAP increased and 54% of the axons developed an SNP. The SNP began 5-7 msec after the conditioning spike, peaked betweer 10-20 msec, and thresholds gradually returned to control values over 60-120 msec. In addition to whole nerve stimulation, individual axons were stimulated with brief depolarizing pulses applied through the recording microelectrode. Whereas long duration depolarizing pulses produced a period of increased threshold following the pulse, brief depolarizing pulses, even at subthreshold intensities, were capable of eliciting a slowly decaying depolarization after the pulse that resembled a DAP. Furthermore, threshold was reduced during this slow depolarization indicating that the action potential is not a prerequisite for induction of the SNP.

These results support previous observations of the association of DAP with an SNP in myelinated axons. More importantly, the ability of a subthreshold depolarizing pulse to produce both a slowly decaying depolarization similar to the DAP and a concomitant period of reduced threshold similar to the SNP strongly supports the proposal that these phenomena are associated with passive membrane properties in large myelinated fibers.

346.17 CHANGES IN MEMBRANE DEPOLARIZATION AND EXTRACELLULAR POTASSIUM CONCENTRATION DURING THE SUPERNORMAL PERIOD OF TURTLE OLFACTORY NERVE. D.L. Eng*and J.D. Kocsis (SPON: M. Miller). Dept of Neurology, Stanford University Medical School and Palo Alto Veterans Administration Medical Center, Palo Alto, California 94304.

The turtle olfactory nerve is a relatively long bundle of homogenous fine caliber nonmyelinated axons. These axons exhibit a pronounced supernormal period (SNP) following a single conditioning volley(Bliss and Rosenberg,Pflügers Arch. 381:209,1979). The SNP is characterized by a period of increased excitability following the relative refractory period. The mechanism of the SNP for nonmyelinated axons is uncertain, but it has been suggested that depolarization associated with accumulation of extracellular potassium, $[K^+]_o$,may account for the SNP(Kocsis et al.,J.Physiol.334,225,1983). To test this proposal we used a combination of the sucrose gap technique with $K^+$-selective microelectrodes to simultaneously monitor membrane potential, $[K^+]_o$, and axonal excitability during the SNP. Adult redear turtles were decapitated and the olfactory nerve was exposed. The nerve was either used in situ or dissected free and placed in a sucrose gap chamber. The nerve was stimulated with stainless steel bipolar electrodes and recordings were made across the sucrose gap chamber and with double barrelled $K^+$-selective microelectrodes. The field potential recorded with a microelectrode following a single stimulus was a triphasic positive-negative-positive wave with a duration of 3.0 msec. However, when recorded across the sucrose gap chamber the return to baseline of the negativity was delayed and occurred with a time course greater than 500 msec. In paired stimulation experiments the excitability of the conditioned response was enhanced as evidenced by latency reduction and increased field potential amplitude. These activity dependent increases in excitability which are indicative of the SNP occurred with a similar time course as the delayed depolarization recorded in the sucrose gap chamber. Additionally an increase in $[K^+]_o$ of about 0.5 mM following a single stimulus occurred with a similar time course as the SNP and the membrane depolarization. Repetitive stimulation led to increases in $[K^+]_o$ to $>$ 7.0 mM, simultaneous to the development of a prolonged membrane depolarization. The excitability of the axons increased during the first several responses of the stimulus train as $[K^+]_o$ began to rise, but was decreased during further stimulation. In order to directly study the effects of $[K^+]_o$ on axonal excitability, the $K^+$ concentration of the superfusate was varied and excitability was tested at the new $[K^+]_o$. As $[K^+]_o$ was increased the resting excitability increased and the SNP was obliterated. Further increases in $[K^+]_o$ led to a reduction in excitability and at $[K^+]_o > 12$ mM the fiber volleys were blocked. These results support the proposal that the SNP in the nonmyelinated axons of the turtle olfactory nerve is the result of activity dependent increases in $[K^+]_o$ that leads to membrane depolarization and a reduction in threshold. Supported by NIH and Med.Res.Ser.ofVA

346.18 POSTSYNAPTICALLY-MEDIATED INCREASES IN EXTRACELLULAR POTASSIUM MODULATE PRESYNAPTIC EXCITABILITY IN HIPPOCAMPUS. N.P. Poolos*, D.L. Eng*, M.D. Mauk, and J.D. Kocsis. Dept. of Neurology, Stanford Univ. Medical School, and Veterans Administration Medical Center, Palo Alto, CA 94306.

Recent studies have indicated that ionic changes in the extracellular space associated with postsynaptic activity, such as accumulation of potassium, can influence the excitability of presynaptic elements (Kocsis et al., J. Physiol 334:225, 1983). We have investigated this effect at the synapse between Schaffer collaterals onto CA1 pyramidal cells in rat hippocampus. Slices of hippocampus (400 um) were stimulated in the stratum radiatum of CA1 with a tungsten electrode. Glass microelectrodes filled with 3 M NaCl were placed 200-400 um away along the longitudinal extent of the Schaffer collaterals to record "on-beam" fiber activation and pyramidal postsynaptic activity. The characteristic field potential following a single stimulus consisted of a short latency negativity of up to 6 mV (N1) corresponding to the presynaptic fiber volley, followed by a smaller negative potential of longer time course (N2), which was abolished in the absence of calcium and thus represented postsynaptic activity. The Schaffer collaterals also showed a supernormal period (SNP), with a submaximal test stimulus evoking a potentiated fiber volley following a single conditioning stimulus. With repetitive stimulation (e.g. 50 hz; 1 sec), the fiber volley and ensuing postsynaptic potential showed a progressive and nearly complete attenuation. This effect is correlated with a rise in $[K^+]_o$: monitoring with K-sensitive electrodes showed that stimulation at 50 hz produced a $[K^+]_o$ rise from a resting value of 3 mM to over 7 mM, which returned to a baseline value with a time course of 2 sec. However, when synaptic transmission was blocked (N2 abolished) by the superfusion of calcium-free Kreb's solution, the presynaptic volley showed little attenuation during repetitive stimulation, and the rise in $[K^+]_o$ was reduced by approx. two-thirds. Similarly, when N2 was abolished by application of adenosine (a putative presynaptic neuromodulator) in normal Kreb's solution at concentrations of 10-100 uM, the fiber volley remained substantially unattenuated and the rise in $[K^+]_o$ was reduced.

These results suggest that activity-dependent rises in $[K^+]_o$ at the Schaffer collateral-CA1 pyramidal cell synapse largely derive from postsynaptic activity, and that these fluctuations in the ionic composition of the extracellular milieu can have pronounced effects upon the excitability of the presynaptic fibers. Since this phenomenon occurs well within the physiological range of hippocampal neuronal firing, extracellular potassium accumulation may prove significant in modulating hippocampal activity, especially during epileptiform discharges.

346.19 EFFECTS OF PHLORETIN ON NERVE IMPULSE VELOCITY AND MAGNITUDE, AND ON THE STRENGTH-DURATION RELATIONSHIP, IN NONMYELINATED NERVE. E.L. Roberts, Jr.* and D.M. Easton, Department of Biological Science, Florida State University, Tallahassee, FL 32306

Phloretin acts as a blocker of "energy-independent" carrier-mediated ion transport through the cell membrane (cf. Jennings, M.L., and Solomon, A.K., J. Genl. Physiol. 67: 381, 1976). For example, its action on nerve may mimic the defect in Na+-Li+ exchange reported to be present in red blood cells of manic depressives (Tosteson, D.C., Sci. Amer. 244: 164, 1981). We investigated the effects of phloretin on impulse velocity and excitability of the nonmyelinated nerve fibers constituting the olfactory nerve of the longnosed garfish (Lepisosteus osseus). Membrane potentials cannot be measured directly in these small fibers (cf. Easton, D.M. Science, 172: 952, 1971). However, because of the homogeneity of the fibers, dispersion is small, and the external record may be readily interpreted. In a typical experiment, the nerve impulse magnitude and velocity were recorded once every 2 min. for about 10 min. in a control Ringer solution, and then for about 1.5 hr. in a Ringer solution containing phloretin (0-50uM). Strength-duration curves were also determined at the beginning and end of an experiment. Rheobase and membrane time constant were found by fitting to the strength-duration data a modified Blair equation (Blair, H.A., J. Genl. Physiol., 15: 709, 1932). The magnitude and velocity of the nerve impulse and the rheobase of the strength-duration curve decreased, while the membrane time constant increased significantly as the concentration of phloretin was increased. Reversibility of the effects of phloretin was shown by recovery of velocity to better than 90% of its original value following 1 hr. wash after 50uM phloretin. The relative changes in short and long duration limbs of the strength-duration curve and in the early and late phases of the action potential lead us to conclude that phloretin affects both Na+ and K+ conductances, in particular the latter. That conclusion is consistent with the effect of phloretin on the Na+ and K+ ion conductances in the voltage clamped axon of the squid (see Strichartz, G.R., et al., Biophys. J. 31: 229, 1980). 346.20 ELECTRICAL PHENOMENA IN PLANAR MEMBRANES MADE FROM POLYMERS OF AMINO ACIDS.
A.T. Przybylski, Institute for Molecular and Cellular Evolution, University of Miami, Coral Gables, FL 33134.

Previously it has been shown that spherical cellular structures made from polymers of amino acids (proteinoids) display electrical phenomena. The potential across the membrane and electrical activity has been recorded in such structures both in the presence of phospholipid (Ishima et al., 1981) and in proteinoid-only spherules (Przybylski et al., 1982).

The increase in conductance of the planar cholesterol membranes due to deposition of amino acid polymers has been observed (Grote et al., 1978).

It is known that protein extract (Excitability Inducing Material) deposited on phospholipid membranes increases their conductance and causes spontaneous oscillations as well as membrane potential changes during stimulation (Mueller and Rudin, 1968).

The question of, whether polymers of amino acids would induce similar effects as seen with EIM on planar membranes is being investigated.

Experiments were performed with vegetable phosphatidylcholine dissolved in hexane or octanol using the Mueller-Rudin teflon chamber. Membranes were made across the 1 mm diameter hole. Solutions of the following polymers: p(asp:glu), p(asp:glu:arg), p(asp:glu:pro), p(asp:2 glu: 4 lys: 4 leu: 2 pro) and a proline-rich polymer were added to the central part of the chamber.

The conductance and electrical potential across the membrane were monitored through a M701 WPI amplifier and oscilloscope.

Deposition of the above polymers resulted in a decrease of the membrane resistance and transient appearance of electrical activity. Electrical activity was observed when the membrane resistance reached intermediary values (below $10^6$ and above $10^4$ ohmcm$^2$).

The quantitative difference between the effect of various polymers on the same kind of the phospholipid membrane in varying solvents is under study.

The very low level of electrical features in lipid bilayer vesicles (Mueller and Chien, 1983) as compared to electrical activity across the membrane in the presence of amino acid polymers advances the usefulness of these polymers in studies of the functional structure of the excitable membrane.

347.1 ACTIVITY WHEEL STRESS PRODUCES SEROTONERGIC HYPERSENSITIVITY IN RATS WORKING ON A FOOD REINFORCED OPERANT SCHEDULE. A.R. Mayeda*, J.N. Hingtgen, J.R. Simon, J.S. Gerometta*, P.A. Shea and M.H. Aprison. The Institute of Psychiatric Research and Departments of Psychiatry and Biochemistry, Indiana University School of Medicine, 791 Union Drive, Indianapolis, IN 46223.

Activity wheel stress has been shown in our laboratories to result in a reduction of serotonin (5-HT) in the cortex, hippocampal area, and the midbrain of rats subjected to these chronic stress procedures (Hellhammer et al., Psychosom. Med., 45, 115, 1983). These findings support our hypersensitive serotonergic postsynaptic receptor theory of depression (Aprison et al., In: Neuropharmacol. and Behav., Plenum, p. 23, 1978; Aprison and Hingtgen, In: Serotonin, Plenum, p. 627, 1981). This theory allows us to predict that environmental stress can be a contributing factor in the development of hypersensitive 5-HT receptors. This could occur in two stages: an increased release of 5-HT followed by activation of the autoreceptor system which reduces the level of this release. When the latter is of sufficient duration a hypersensitive system may develop. If this is the case, animals stressed with activity wheel procedures should demonstrate greater sensitivity to 5-hydroxytryptophan (5-HTP) administration (which results in behavior suppression of food reinforced responding) than non-stressed controls. To test this hypothesis, male, Wistar rats were trained to press a lever for milk reinforcement on a variable interval one minute (VI 1) schedule. Following the establishment of baseline responding, rats were then housed continuously in a cage having unrestricted access to an activity wheel. They were given food on a one hr/day schedule and water ad lib. Such procedures lead to the development of symptoms associated with stress (Pare', Brain Res. Bull. Suppl., 5, 73, 1980). Following 7-10 days of activity wheel stress the rats were then given a VI session and received an injection of 25 mg/kg D,L-5-HTP (i.p.) 15 min after the start of the session. This dose of 5-HTP typically results in a very short period (5-10 min) of depressed responding. However, stress pretreatment extended the period of behavioral depression over 5 times that observed in food control rats given the same dose of 5-HTP during a VI session. Serotonin receptor binding studies of specific brain areas obtained from the activity wheel stressed rats are now in progress and should elucidate further the influence of stress on the 5-HTP induced animal model of depression. Using other behavioral methods, Segawa et al. (New Vistas in Depression, Pergamon, p. 3, 1982) and Takahashi et al. (ibid, p. 28, 1983) have already reported finding increased 5-HT receptor sensitivity in stressed rats. (Supported in part by Indiana Department of Mental Health Grant 178-679-005 and by training grant PHS MH 17107-02, NIMH).

347.2 PROLONGED ENHANCEMENT BY SYSTEMIC CHOLECYSTOKININ OCTAPEPTIDE OF HEAD TWITCHING ELICITED BY 5-HYDROXY-L-TRYPTOPHAN IN MICE. K. J. Simansky. Dept. of Pharmacology, Medical College of Pennsylvania, Philadelphia, PA 19129.

Peripheral administration of the sulfonated octapeptide amide of cholecystokin (CCK-8) selectively increased head-twitching but not locomotor activity produced by 5-hydroxy-L-tryptophan (5-HTP) in mice (Simansky, Streisfeld & Friedberg, Neuroscience Abstracts, 1984, 10: 174). The present study examined dose- and time-effect relationships for that phenomenon and compared the action of CCK-8 with those of desulfonated CCK-8 (CCK-DS) and CCK tetrapeptide amide (CCK-4) in the head-twitch assay.

In each experiment, male Swiss-Webster albino mice were injected with carbidopa (25 mg/kg, ip) followed 30 min later by 5-HTP. In the first study, mice (n = 8/group) were also injected just prior to 5-HTP administration with one of the following doses of CCK-8 in 0.3 N $NaHCO_3$ vehicle: 0 (vehicle), 20, 28, 40, 56, 112, 160 or 224 nmol/kg, sc. An observer recorded the number of head twitches made by each mouse during the 5 min period beginning 60 min after 5-HTP (the time of peak effect). CCK-8 increased head twitching in a dose-related manner, $F(7, 56) = 159$, $p < 0.01$. For example, controls made $20.4 \pm 0.6$ head twitches whereas mice that were injected with 28 nmol/kg of CCK-8 made $29.5 \pm 0.6$ ($p < 0.05$) and those given the highest dose made $47.2 \pm 0.9$ ($p < 0.01$). In a subsequent experiment, mice were injected with 160 nmol/kg of CCK-8 either concurrently with 5-HTP or 30 min prior to 5-HTP. Regardless of the pretreatment interval, CCK-8 increased responding by approximately 3-fold during the 2-h test period ($p < 0.01$). The time courses for the behavioral responses to 5-HTP were virtually identical among the four groups (two vehicle- and two CCK-treated sets of mice), with peak effects occurring 60-80 min after 5-HTP.

The enhancement by CCK-8 of head twitching produced by 5-HTP represented a true potentiation because 40 nmol/kg of the peptide failed to elicit that response in mice injected with carbidopa but not with 5-HTP. Furthermore, the excitatory interaction of the peptide and amino acid appeared to be pharmacologically selective because doses of 40, 160 and 640 nmol/kg of CCK-4 and CCK-DS did not significantly increase head twitching during the 5 min test period beginning 60 min after 5-HTP.

Taken together, these data establish that systemically administered CCK-8 potentiates a stereotypic motor response to 5-HTP. Since the head twitch model is an assay for the activation of central 5-HT-2 type receptors, these behavioral data also suggest that CCK-8 causes a persistent increase in the sensitivity or responsiveness of neurochemical systems mediated by 5-HT-2 mechanisms. Alternatively, the potentiation by CCK-8 may reflect a pharmacokinetic interaction between the agents. These issues are are currently being explored. Supported by NIMH Grant MH40574.

347.3 POTENTIATION OF 5-HTP INDUCED DEPRESSION FOLLOWING CHRONIC RESERPINE TREATMENT, K.L. Brugge*, J.N. Hingtgen, & M.H. Aprison, The Inst. of Psychiatric Research and Depts. of Psychiatry & Biochem., Indiana University School of Med., Indianapolis, IN 46223.

As a result of studies begun in the early 1960s, Aprison, Hingtgen and coworkers, proposed a hypothesis concerning the neurochemical basis of depression in a subgroup of patients. Using their model of 5-HTP induced depression in rats and pigeons, they proposed that behavioral depression in animals is caused by an increased release of 5-HT into the synaptic cleft. Since clinical data of depression in man suggest a deficiency rather than an excess of 5-HT, they reconciled what at first appeared opposing views and hypothesized that in some types of depression, hypersensitive postsynaptic receptors develop after a period of prolonged reduction in 5-HT release. This hypothesis is supported by Fleisher et al. (J. Neurochem. 32, 1613, 1979) who showed potentiation of the 5-HTP induced behavioral depression in rats along with increased receptor affinity of ($^3$H)-5-HT in crude membrane fractions from the cerebral cortex of these animals, following chronic p-chlorophenylalanine (PCPA) treatment. Since reserpine is known to precipitate depression in up to 26% of hypertensive patients receiving it chronically, the present experiment was designed to determine whether the effects of chronic reserpine on 5-HTP induced behavioral depression were similar to that seen after PCPA. Because reserpine acts by reducing storage of monoamines, thereby causing their depletion, we predicted the development of receptor supersensitivity, including the 5-HT receptors, with a resulting potentiation of the 5-HTP induced depression. Male Wistar adult rats were trained to barpress for milk on a VI 1 reinforcement schedule. Once baseline responding was established, the rats were given a threshold dose of 25 mg/kg 5-HTP (i.p.) 15 min. after the start of a VI session. The rats were then subdivided into 3 treatment groups. Two groups were started on daily i.p. injections of 0.05 mg/kg or 0.025 mg/kg reserpine, and the third group on daily vehicle. Most of the rats of both the 0.05 mg/kg and 0.025 mg/kg treatment groups showed a significant potentiation of 5-HTP induced depression after 6 days of chronic treatment with reserpine. Three rats, however, failed to show potentiation after 6 and 13 days of treatment. When the daily reserpine dose was increased to 0.10 mg/kg, these rats also showed increased depression after a 25 mg/kg injection of 5-HTP. These data suggest that chronic reserpine produces similar effects to those of chronic PCPA thus supporting a biochemical-behavioral animal model of depression involving the serotonergic system. 347.4 THE PIPERAZINE SEROTONIN (5HT) AGONISTS m-CHLOROPHENYLPIPERAZINE (m-CPP) AND 6-CHLORO-2(1-PIPERAZINYL)PYRAZINE (MK 212) IMPAIR AVOIDANCE RESPONDING IN A DISCRETE TRIAL CONDITIONED AVOIDANCE PROCEDURE. J.A. Moyer and I. Lucki, Wyeth Laboratories, Inc., P.O. Box 8299, Philadelphia, PA 19101 and Department of Psychiatry, University of Pennsylvania, Philadelphia, PA 19104.

Serotonergic neuronal systems have been implicated in the mediation of aversive operant behavior; however, the effects of substituted piperazine 5HT agonists on conditioned avoidance performance have not been clearly defined. Therefore, the effects of the potent piperazine 5HT agonists MK 212 and m-CPP were examined in a discrete trial/lever press conditioned avoidance procedure.

Male rats were trained to avoid electric shock during trials consisting of a 15 sec warning tone (conditioned stimulus) followed by a 15 sec tone/shock period (unconditioned stimulus). A response (lever press) during the initial 15 sec period terminated the trial prior to shock delivery and was considered an avoidance response. A response which occurred during the tone/shock period was considered an escape response. Trials were presented on a variable interval schedule of 2 min and each session consisted of 60 trials. Animals were run 2-3 times weekly with control sessions always preceding drug runs.

MK 212 and m-CPP, administered i.p. 30 min prior to the test session, suppressed avoidance responding in the discrete trial conditioned avoidance procedure (avoidance block $_{50}$ = 1.46 and 3.92 mg/kg respectively). Furthermore, both of these 5HT agonists produced increases in escape responding and the ability to escape from shock was not altered by the doses used in these experiments. Additional experiments determined that pretreatment with the 5HT antagonist metergoline (2 mg/kg i.p., 90 min prior to test session) blocked both the impairment of avoidance and increase in escape responding produced by MK 212 and m-CPP. However, metergoline pretreatment did not block reductions in avoidance responding and increases in escape behavior produced by haloperidol (.25, .5, and 1 mg/kg i.p.). Metergoline and ketanserin ($5HT_2$ antagonist) had no significant effect on either avoidance or escape performance when administered alone.

The results of these studies show that the piperazine 5HT agonists MK 212 and m-CPP produce a behavioral pattern similar to antipsychotic compounds in a discrete trial conditioned avoidance procedure. However, since metergoline antagonized the effects of 5HT agonists on conditioned avoidance behavior, but not the effects of the dopamine antagonist haloperidol, 5HT agonists may impair conditioned avoidance through mechanisms which are different from the antipsychotics.

347.5 ANTICONFLICT EFFECTS OF THREE COMPOUNDS HAVING ANTISEROTONERGIC ACTIVITY: METERGOLINE, MIANSERIN, AND CLOZAPINE. J.W. Sullivan*, L. Gold*, and J. Sepinwall. Dept. Pharmacology and Chemotherapeutics, Hoffmann-La Roche Inc., Nutley, NJ 07110.

One pharmacologic characteristic of the benzodiazepine class of drugs is their ability to release - or disinhibit - behavior that is suppressed by punishment. Several reports have indicated that antiserotonergic substances also do this, and one recent report (Boast et al., Soc. for Neurosci. Abstr., 9:436, 1983) demonstrated a positive correlation between antipunishment effects and anti-serotonergic activity.

We evaluated two serotonin antagonists (metergoline and mianserin) and one antipsychotic compound with some reported antiserotonergic properties (clozapine) in rats in a 47 minute long multiple schedule conflict test comprised of alternating components of unpunished (VI30 sec. food; 5 min.) and punished (FR10 food + shock; 2 min.) responding. Metergoline ( 2.5-20 mg/kg p.o.), clozapine (5 mg/kg p.o.), and mianserin ( 0.5-7.5 mg/kg i.p.) produced statistically significant (dose-related) increases in punished response rates. All three compounds had inverted U-shaped dose-response profiles, with clear signs of non-specific rate-depressant effects occurring at the upper end of the effective dose range.

We attempted to block the anticonflict effect of metergoline by administering Ro 15-3505, an imidazobenzodiazepine derivative related to Ro 15-1788, that binds to the benzodiazepine receptor and antagonizes the pharmacologic effects of benzodiazepines. When given alone (1.25-40 mg/kg p.o.), Ro 15-3505 was devoid of any antipunishment properties but did decrease unpunished response rates. In drug combination studies, Ro 15-3505 (5 mg/kg) failed to block the anticonflict effect of 20 mg/kg of metergoline, whereas it did block the anticonflict effect of 10 mg/kg of chlordiazepoxide. Thus, compounds having serotonin antagonistic activity exert their effects at sites different from the benzodiazepines.

347.6 DISRUPTIVE EFFECT OF 5-METHOXY-N,N-DIMETHYLTRYPTAMINE (5MeODMT) ON SHUTTLEBOX CONTINUOUS AVOIDANCE BEHAVIOR IN RATS: EFFECTS OF VARIOUS BLOCKERS OF SEROTONIN (5HT) RECEPTORS. F.P. Miller, Merrell Dow Research Institute, Cincinnati, OH 45215

In rats, 5MeODMT causes a complex syndrome characterized by the occurrence of at least six discernible symptoms, some of which can be antagonized by 5HT antagonists (Jacobs, B.L., Life Sci. 19:777, 1976). The scoring of such a behavioral syndrome is highly subjective. Therefore, we investigated the use of shuttlebox continuous avoidance behavior as an objective method of assessing the response of rats to 5MeODMT.

Rats were trained on a 40 sec RS-20 sec SS schedule to avoid an electric shock through a grid floor by moving back and forth across the center of a shuttlebox. Rats trained to avoid $\geq$ 95% of the possible shocks were administered various doses of 5MeODMT, and behavior (avoidance, shocks, escape failures) was automatically recorded for 5 hours following administration with behavioral changes being evaluated hourly compared to vehicle-treated control. At doses of 1, 2 and 4 mg/kg i.p., no significant effect was seen in avoidance rate (n=4), even though at 4 mg/kg, slight signs of the 5MeODMT-induced syndrome were observed visually. Mean changes in avoidance rates, compared to vehicle controls, were -6.2%, -3.6% and -18.1%, respectively. At 5.0 mg/ kg i.p., marked disruption of avoidance behavior was seen (-43.7% compared to vehicle control during the first hour after administration), concomitant with marked symptoms of 5MeODMT-induced syndrome; these effects lasted for 15-30 min in each animal.

The avoidance deficit induced by 5MeODMT, 5 mg/kg i.p., was completely antagonized by methysergide, a known 5HT antagonist, in doses as low as 0.25 mg/kg i.p. given 30 min prior to 5MeODMT. Thus, first hour avoidance rates after 5MeODMT in animals (n=4) pretreated with methysergide at 0.25, 0.5, 1, 2 and 4 mg/kg i.p., were +21.1%, +15.1%, +21.3%, +29.2% and +57.2%, respectively, compared to vehicle controls; at 0.125 mg/kg i.p., methysergide was ineffective. Metergoline was similarly effective at doses $\geq$ 0.25 mg/kg i.p. Cyproheptadine, tested at 0.5, 1, 2, and 4 mg/kg i.p., caused antagonism (avoidance rate +1.2% compared to vehicle control) only at 2.0 mg/kg. Pipamperone was ineffective at 1 or 2 mg/kg i.p.

These results with methysergide, metergoline, and pipamperone are in substantial agreement with those reported by Lucki et al. (J. Pharmacol. Exp. Ther. 228:133, 1984) using the syndrome response elicited by 5MeODMT in rats; cyproheptadine was not examined in their studies. Further, these investigators have suggested that the behavioral response to 5MeODMT probably involves $5HT_1$ receptors. Therefore, our results in the continuous avoidance model suggest that this model provides an objective method of assessing the activities of drugs interacting with $5HT_1$ receptors.

347.7 EVIDENCE THAT SEROTONIN MEDIATES NON-CHOLINERGIC ELECTROCORTICAL ACTIVATION AND COGNITIVE ABILITIES. C. H. Vanderwolf and G. B. Baker. Dept. of Psychology, Univ. Western Ontario, London, Ontario, Canada, N6A 5C2 and Neurochemical Research Unit, Dept. of Psychiatry, Univ. Alberta, Edmonton, Alberta, Canada, T6G 2G3.

Previous research has shown that low voltage fast activity (LVFA) in the neocortex and rhythmical slow activity (RSA) in the hippocampus can result from activity in either of two ascending pathways. Activity in neurons in the basal forebrain (substantia innominata, medial septum, diagonal band) may produce atropine-sensitive (presumably cholinergic) LVFA and RSA during both Type 1 behavior (e.g., head movement, walking) and Type 2 behavior (e.g., waking immobility, face-washing, tremor). Activity in an aminergic pathway may produce atropine-resistant LVFA and RSA during Type 1 behavior only (Stewart, D. J., et al., Brain Research, 322: 219, 1984; Vanderwolf, C. H. & Robinson, T. E., Behav. Brain Sci., 4: 459, 1981). The possible role of 5-hydroxytryptamine (5-HT) in such a pathway was studied by treating rats with p-chlorophenylalanine (PCPA; 500 mg/kg, i.p.) on each of 3 successive days. Assays using HPLC and electrochemical detection indicated that 5-HT levels in the neocortex and hippocampus were reduced by 93% of normal on the fourth day while noradrenalin was reduced by 33% and dopamine by 23%. Hippocampal RSA was quantified by passage through a band-pass filter (6-12 Hz) followed by rectification and integration. Neocortical activity was scored manually in successive 1 sec intervals. Multiunit activity was also monitored in the neocortex. PCPA treatment alone had little effect on LVFA or RSA, but following PCPA and atropine (50 mg/kg) together both LVFA and RSA were attenuated or eliminated, resulting in continuous large amplitude irregular activity in the hippocampus and large irregular slow waves in the neocortex regardless of concurrent behavior. Thus, atropine-resistant LVFA and RSA may be dependent on 5-HT transmission. Tests in a water maze showed that while atropine alone or PCPA alone produced slight impairments in goal-directed behavior, the two drugs together produced a massive deficit. A combination of PCPA and atropine may produce an animal model of some forms of global human dementia.

This research was supported by grants from the Medical Research Council and the Natural Sciences and Engineering Research Council.

347.8 AGGRESSION IN WEAKLY ELECTRIC FISH - A SENSITIVE ASSAY FOR THE PHARMACOLOGY OF MONOAMINERGIC NEUROTRANSMISSION. L. Maler and W. Ellis*. Dept. of Anatomy, University of Ottawa, Ottawa, Ontario K1H 8M5 Canada.

Agonistic behaviour is a complex combination of threat signals and overt aggressive action. Weakly electric fish offer a technically simple preparation which still retains the critical features of vertebrate aggression. Apteronotus leptorhynchus (Brown Ghost knifefish) is a South American gymnotid fish. Apteronotids produce a constant high frequency (600-1000Hz) electric organ discharge (EOD) and detect their own and conspecifics EODs with specialized electroreceptors distributed over their body. Apteronotids modulate their EOD in several ways, the two most prominent being: (1) the jamming avoidance response (JAR) during which an apteronotus will shift his EOD frequency upwards away from that of a conspecific 1Hz to 10Hz lower in frequency, and (2) a brief (<100msec.) increase in frequency (5-80Hz) accompanied by a decreased amplitude of the EOD. This latter behaviour has been named a "chirp" and, because it accompanies aggressive behaviour like biting, is believed to be an aggressive signal. We curarize the fish, expose the forebrain ventricle and maintain the fish with artificial respiration for several hours. Another fish is simulated by a pair of transversely oriented carbon electrodes. We use these electrodes to produce a sine wave with a frequency 3Hz below that of the experimental animal and an amplitude of 2.5mv/cm (measured at the head); a stimulus regime of 30sec. on and 5min. off is used. Under these conditions both normal JARs and chirps can be elicited. Minute doses of serotonin (0.1µg) strongly inhibit chirping, an action consistent with evidence from mammalian species that this transmitter inhibits agression; 5-HT has no effect on the JAR indicating that sensorimotor processing is not globally affected. The same dose (0.1µg) of noradrenaline strongly enhances chirping but again has no effect on the JAR. Dopamine has more complex effects on chirping, with initial excitation sometimes followed by inhibition and also briefly enhances the JAR. Neither tryptamine nor the artificial CSF+ ascorbic acid carrier have any effect on chirping. This behaviour is easy to elicit, completely quantifiable and so sensitive to monoamines that monoamine oxidase inhibitors are not required to get these effects. Accordingly we have used this preparation to investigate several drugs believed to act on monoaminergic transmission.

Supported by the Medical Research Council of Canada.

347.9 EFFECTS OF 5-HYDROXYTRYPTOPHAN ON SCHEDULE-CONTROLLED BEHAVIOR: EVIDENCE FOR PERIPHERAL MEDIATION BY 5-$HT_1$ RECEPTORS. R.B. Carter, Dept. of Pharmacology, Georgetown Univ., Washington, DC 20007.

Recent evidence has emphasized the contribution of peripheral mechanisms to the behavioral and physiological effects observed following systemic administration of 5-hydroxytryptophan (5-HTP) (Neuropharmacology 19: 777-784, 1982; Pharmacol. Biochem. Behav. 9: 249-253, 1978; 20: 799-802, 1984). While these data suggest that the effects of 5-HTP are due to the actions of one of its decarboxylated metabolites in the periphery, they do not necessarily indicate that these effects are mediated entirely through serotonergic receptors. The effects of l-5-HTP (1.0-30.0 mg/kg, i.m.) on the responding of pigeons maintained under a multiple FR 30, FI 5-min schedule of food presentation were studied alone and in combination with the uptake blockers fluoxetine (10.0 mg/kg, i.m.), citalopram (5.0 mg/kg, i.m.) and nisoxetine (0.3 mg/kg, i.m.), the antagonists methiothepin, metergoline and LY53857 (0.01-1.0 mg/kg, i.m.) and the peripheral decarboxylase inhibitor benserazide (25.0-75.0 mg/kg, i.m.). l-5-HTP alone produced only dose-related decreases in responding under each schedule component. Fluoxetine, citalopram and nisoxetine failed to alter responding when given alone. When administered in combination, the serotonin (5-HT) uptake blockers fluoxetine and citalopram, but not the norepinepherine (NE) uptake blocker nisoxetine shifted dose-response curves for l-5-HTP to the left by a factor of 3-10. The 5-$HT_1$/5-$HT_2$, NE and dopamine antagonist methiothepin, given alone did not alter responding under the FR component, but produced dose-related decreases in FI responding. When administered in combination, methiothepin shifted dose-response curves for l-5-HTP to the right in a dose-dependent manner. The degree of shift in the FI component was limited by methiothepin's own rate-decreasing effects. Metergoline alone either did not alter or produced slight increases in responding under both components. In combination, the 5-$HT_1$/5-$HT_2$ antagonist metergoline shifted curves for l-5-HTP to the right in a dose-dependent manner. LY53857 alone either did not alter or increased rates of responding under both components. When administered in combination, the specific 5-$HT_2$ antagonist LY53857 failed to shift dose-response curves for l-5-HTP to the right, although antagonism of the effects of a low dose of l-5-HTP did occur. The peripheral decarboxylase inhibitor benserazide (25.0-75.0 mg/kg), was also studied in combination with l-5-HTP. Benserazide attenuated the effects of 30.0 mg/kg l-5-HTP in a non-dose-dependent manner. Taken together, these data suggest that the effects of high doses of l-5-HTP on schedule-controlled behavior in the pigeon are due to actions of serotonin on 5-$HT_1$ receptors outside of the blood-brain barrier. These data extend previous findings with regard to the role of peripheral mechanisms in the behavioral effects of 5-HTP to a nonmammalian species. (MH-14269 & DA-05253).

## BEHAVIORAL PHARMACOLOGY: ADRENERGIC AND HISTAMINERGIC SYSTEMS

348.1 **BEHAVIOURAL AND PHYSIOLOGICAL RESPONSES TO ACUTE TREATMENT OF AN ALPHA-ADRENERGIC AGONIST--FLA-136.** S. M. Socaranksy*, R. Vanier*, Z. Amit, S-O Ogren. Dept. of Psychology, Ctr. for Studies in Behavioural Neurobiology, Concordia University, Montreal, Canada and Astra Pharmaceutical Research Ctr., Sodertalje, Sweden.

We have previously shown that treatment with the clonidine analog FLA-136(4-amino-3-(2,6-dichloro-benzlidene-hydrazino)-1,2,4-triazole hydrocloride) can significantly suppress voluntary ethanol administration on a chronic basis. Presented here is a series of studies which set about trying to elucidate the mechanism by which such an effect may occur. In the first study effects on motor activity were investigated in rats treated with FLA-136 alone, or in addition to ethanol (.6, 1.2g/kg). FLA-136 was administered at a dose previously shown to maximally reduce ethanol intake (25 mg/kg). Motor acitivity was measured in boxes equiped with photoelectric cells attached to automated counters, the total number of counts being determined for a thirty minute period. Brain and blood samples were taken at the end of this period for determination of ethanol and, NE and MHPG levels. It was found that while FLA-136 reduced locomotor activity in and of itself it also potentiated ethanol mediated suppression of activity. These findings tended to be consistent with brain MHPG levels is each of the different groups. In the second experiment, FLA-136 was used as a conditioning drug in a conditioned taste aversion paradigm (CTA) whereby doses (15, 25 mg/kg) where administered to rats immediately after having consumed a novel solution. FLA-136 elicited an extremely reliable CTA at both doses employed. In the third experiment the effects of pretreatment with FLA-136 on an ethanol induced CTA was investigated. In this paradigm FLA-136 (15, 25 mg/kg) was administered four hours prior to the pairing of the presentation of the novel solution with administration of various doses of ethanol (1.2, 2.0 g/kg). The results of this latter study point to a potentiation of the ethanol mediated conditioned taste aversion by pretreatment with FLA-136. The sum of these findings would seem to suggest that some form of potentiation or summation exists between the down regulation of NE turnover by FLA-136 and the effects of ethanol on these same systems as evidenced by the behavioural and the biochemical data presented here.

348.2 STUDIES ON THE REINFORCING PROPERTIES OF CLONIDINE IN RATS. K.E. Asin and D. Wirtshafter. Department of Psychology, Univ. Il. at Chicago, Chicago, IL 60680.

We have recently reported (Asin & Wirtshafter, Psychopharm., 1985) that clonidine (CLON) produces a conditioned place preference (CPP) in rats. This effect was dose-dependent and was only seen with doses which have been shown to affect both $\alpha_1$ & $\alpha_2$ receptors (200 & 400ug/kg ip). This series of studies investigated the neurochemical bases of the CLON-induced CPP and also examined the effects of the drug on the establishment of a conditioned taste aversion (CTA).

Place preference conditioning was conducted in shuttleboxes with 1 end painted grey and the other painted with black & white stripes. Animals were randomly chosen to receive drug prior to confinement in the striped or grey side; vehicle (V) injections were paired with the side opposite to that of the drug. Rats were given 5 drug/stimuli pairings and 5 V/stimuli pairings. On the test day, rats were injected with V and were allowed to traverse the entire apparatus for 15min. Time on the previously drug-paired side was taken as an index of reinforcement and CPP (chance=450s). A dose of 400 ug/kg CLON, injected 3min before placement in the apparatus, was chosen for the CPP studies.

Injections of the mixed $\alpha_1/\alpha_2$ receptor antagonist phentolamine (5,10&25 mg/kg) 45min prior to CLON treatment failed to block the establishement of a CPP. Similarly, rats treated with 2 or 5 mg/kg (ip) of the $\alpha_2$ antagonist yohimbine 20min prior to CLON injections showed CPPs similar in magnitude to V+CLON treated animals. Injections of the $\alpha_1$ antagonist prazosin (.05,.1,2.5 & 5mg/kg) 20min before CLON also failed to affect the magnitude of the CPP compared to V+CLON treated rats. These results suggest that some non-noradrenergic property of CLON may underly its reinforcement efficacy. This conclusion is further supported by our failure to obtain a significant CPP using the $\alpha_2$-receptor agonist guanfacine (1, 2 & 4 mg/kg ip). Therefore, we also examined the effects of pretreatment with the opiate antagonist naloxone (2&6mg/kg, 10min pre-CLON) or the dopamine antagonist haloperidol (.3&.6mg/kg ip)(45min prior to CLON) on a CLON-induced CPP. Neither of these drugs was able to attenuate or block the CPP. These studies suggest that animals may find CLON's histaminic properties or its effects on brain epinephrine systems reinforcing. Additional studies using drugs with more specific $\alpha_1/\alpha_2$ properties will also be presented.

Finally, we examined the effects of CLON (0,50,100,200 & 400 ug/kg ip) on the establishment of a CTA to a sucrose solution in thirsty rats. CLON was found to produce a dose-dependent CTA in both 1 & 2 bottle preference tests. Thus, similar to what has been reported for drugs of abuse, such as amphetamine or morphine, CLON has both reinforcing and aversive properties. The pharmacological profile of these properties, however, remains to be determined.

348.3 SPINAL CORD NOREPINEPHRINE, NOCICEPTION AND CLONIDINE ANALGESIA: SEX DIFFERENCES? B. A. Pappas and R. Ings*. Psychology Dept., Carleton University, Ottawa, Canada K1S 5B6.

Evidence suggests a descending norepinephrine (NE) spinal pathway of supraspinal origin which inhibits nociception at the spinal level. Previous research from this laboratory has shown that this NE pathway is permanently lesioned by neonatal intraspinal injection of 6-hydroxydopamine (6-OHDA) and that this lesion, as expected, enhanced nociception as assessed by the tail flick task. Unexpectedly, however, this effect occurred in female but not male rats. This experiment reexamined this sexual dimorphism and also determined if the analgesic effect of the alpha NE agonist clonidine and the binding of clonidine to the spinal cord were altered by NE lesion in a sexually dimorphic manner.

Intraspinal 6-OHDA (10 µg) was administered to rats on days one and two of life. At about 120 days of age, nociception was assessed using the tail flick (tail lowered into 54°C water). Males (intraspinal vehicle or 6-OHDA injected) were found to have longer latencies than their corresponding females. This sex difference may be due to circulating testosterone as castration of otherwise normal males lowered their tail flick latencies. Conversely, ovariectomy did not affect female latencies.

In agreement with our earlier results, intraspinal 6-OHDA lowered latencies in females but not males. The analgesic effect of clonidine (1 mg/kg) was not eliminated but rather was augmented by the 6-OHDA lesion. This occurred only in females, however, suggesting that at least for them, behavioral supersensitivity develops in the spinal cord after the loss of NE terminals. This sex difference cannot be accounted for by differential response to 6-OHDA since both males and females showed massive losses of spinal NE (82 and 91%, respectively). Furthermore, it cannot be explained by differences in spinal alpha receptor proliferation after 6-OHDA. Receptor binding assay using ($^3$H) clonidine as ligand showed that 6-OHDA did not affect spinal clonidine binding in either sex. $B_{max}$'s for control males and females were 84.6 + 9.2 and 80.5 + 12.9, respectively, while for the comparable 6-OHDA groups they were 75.5 + 13.8 and 86.6 + 10.3. Parenthetically, these data indicate that as has been found for the cerebral cortex, the alpha 2 receptor in the spinal cord does not appear to be affixed to the NE terminal.

In conclusion, the antinociceptive role of spinal NE is more apparent in female than male rats. Second, neither clonidine analgesia nor the binding of this drug to the spinal cord requires intact NE terminals. (Supported by NSERC)

348.4 CEREBRAL DEPLETION OF NOREPINEPHRINE WITH DSP-4 FAILS TO ALTER ACQUISITION OF A CONDITIONED AVOIDANCE RESPONSE IN TWO STRAINS OF RAT. R. J. Elgin, Jr.* and G.E. Martin. Department of Biological Research, McNeil Pharmaceutical, Spring House, PA 19477-0776.

The ability to block conditioned avoidance responding (CAR) is a property of all known antipsychotic drugs. To examine the role of cerebral norepinephrine (NE) in mediating CAR, the effect of DSP-4, an agent known to deplete cerebral NE (Ross, B.J. Phar. 1976,58:520), on the acquisition of a CAR response was studied in two strains of rat, Fisher (F) and Sprague-Dawley (S/D).

DSP-4(N-(2-chloroethyl)-N-ethyl-2-bromobenzylamine), in a dose (50 mg/kg,i.p.) which produces maximal depletion of cerebral NE, was given to groups of 10-18 rats from each strain. In one control group, desmethylimipramine (DMI)(20 mg/kg,i.p.-30 min) which inhibits DSP-4's uptake was given prior to DSP-4. There were 4 treatment groups: 1) saline-saline; 2) saline-DSP-4; 3) DMI-DSP-4; 4) DMI-saline. Starting 10 days after treatment, all animals were tested for acquisition of CAR, in which a discrete trial lever press avoided a 0.7 mA shock. A test session consisted of 120 trials spaced evenly over a 1 hr period. The conditioned stimuli (paired light and tone) were presented for 15 sec followed by 10 sec of shock in the absence of a lever press. Each animal was tested once daily for nine consecutive days. Performance on each day was compared between groups using analysis of variance with Duncan's multiple range test ($p<0.05$).

Rats were sacrificed 20 days after dosing and the cerebral cortex, striatum, and brainstem were rapidly dissected on ice and homogenized for assay of NE, and dopamine (DA) levels using an HPLC with electrochemical detection. To examine DSP-4's effect on trained rats, DSP-4 or saline was given to trained rats and CAR was observed 10 days later for 4 consecutive days.

In each strain, DSP-4 produced an almost complete depletion of NE in the cortex and ca. a 50% reduction relative to control groups 1,3, and 4 in the brainstem, whereas striatal dopamine levels were unaltered. In the F strain DSP-4 clearly failed to alter CAR performance during the 9 day acquisition period. In the S/D strain there was an apparent impairment in acquiring the CAR task, although a statistically significant difference from the DMI-saline control group was the only difference detected. Furthermore, DSP-4 given to trained rats of either strain, caused no decrement in CAR activity. These data suggest cortical NE is not critical for acquisition or maintenance of CAR in F rats, but hint at a possible role in S/D rats. Further work may be required to determine whether cortical NE mediates a segment of CAR behavior in S/D rats. In this regard, Ogren et al (Neurosci: Let. 1980,20:351) have shown DSP-4-induced decrements in acquisition of a passive 1 or 2 way avoidance task in S/D rats.

348.5 DEPRESSION OF LOCOMOTOR BEHAVIOR OF MICE BY NORCOCAINE. M.E.A. Reith* and A. Lajtha. Center for Neurochemistry, N.S. Kline Institute for Psychiatric Research, Ward's Island, New York, NY 10035.

It has been found in a number of laboratories that cocaine produces an increase in spontaneous locomotor behavior of mice and rats. Recent studies in our lab on structure-activity relationships of this effect of cocaine showed that most cocaine congeners inhibit rather than stimulate spontaneous locomotion of young adult male BALB/cBy mice. Locomotor depression was observed after IP administration of norcocaine, (+)-pseudococaine, tropacocaine, or phenyltropane analogs of the WIN-series. Hypomotive effects have been reported also for $\alpha_2$-adrenergic agonists such as clonidine, presumably by interactions with central $\alpha_2$-adrenoceptors.

In the present study we tested whether central $\alpha_2$-adrenoceptors are involved in the locomotor depression produced by cocaine congeners, since cocaine has been suggested to interact with the imidazoline recognition site of the $\alpha_2$-adrenoceptor in the CNS. Spontaneous locomotion was measured by placing individually housed mice in their home cages in an Opto-Varimex-Minor activity monitor (Columbus Instruments) equipped with infrared beams. The behavioral data were based on interruptions of consecutive beams only. Each animal was monitored for 40 min to establish his baseline. The animal was then injected with an antagonist or saline and monitored for 20 min. Subsequently he received an injection of agonist, norcocaine, or saline, and was monitored for another 30 min. The inhibition of locomotion by norcocaine (10 mg/kg IP) was not antagonized by the adrenoceptor antagonists yohimbine (2 mg/kg SC) and phentolamine (0.3 mg/kg IP). In contrast, these doses were effective in reducing the hypomotility induced by clonidine (0.1 mg/kg IP). It is therefore unlikely that central $\alpha_2$-adrenoceptors are involved in the hypomotive effect of norcocaine. Since presynaptic dopamine receptors have been implicated also in hypomotive effects of drugs, we studied the effect of haloperidol (0.1 mg/kg IP) and spiperone (0.05 mg/kg IP) on the norcocaine-induced inhibition. These low doses aimed at presynaptic dopamine receptors did not decrease the locomotor inhibition. The data so far are consonant with the view that the locomotor inhibition observed with IP norcocaine and other cocaine congeners is due to the local anesthetic potency of cocaine-related structures, and is not mediated by either central $\alpha_2$-adrenoceptors or presynaptic dopamine receptors.

348.6 EFFECTS OF CENTRALLY ADMINISTERED HISTAMINERGIC AGENTS IN THE BEHAVIORAL DESPAIR TEST. K.A. O'Neill and S.B. Gertner*. Dept. of Pharmacology, UMDNJ - New Jersey Med. Sch. Newark, NJ 07103

Antidepressant drugs (AD), electroconvulsive shock and REM sleep deprivation significantly increase the swimming time of mice and rats in the behavioral despair test. Other agents which have shown similar activity include the classical $H_1$ antagonists. These drugs are of particular interest because both tricyclic and atypical antidepressants potently block mepyramine binding at the $H_1$ receptor (Hall & Ogren, Eur.J.Pharmac.,70:393,1981). In addition, $H_2$ receptor mediated stimulation of hippocampal adenylate cyclase is also blocked by AD (Green & Maayani, Nature,269:163, 1977). These observations suggest that central histaminergic systems may be involved in depression.

To explore the behavioral significance of these effects, experiments were conducted to determine the actions of specific histamine agonists and antagonists in the behavioral despair test. CD-1 male mice received intracerebroventricular (ICV) injections of drugs or vehicle (distilled $H_2O$ or artificial cerebrospinal fluid) into the lateral ventricles, in a constant volume of 5 ul. Mice were placed in beakers of 25°C water 2-15 min after injections, for 6 min, and swimming behavior was rated and ranked for the final 4 min. Data shown are ranks, and were analyzed by the Mann-Whitney U test.

Control mice tested at different times after injections did not show significantly different swimming behavior. Therefore, control group data were combined yielding a mean rank of 5.3. The $H_2$ antagonist, cimetidine (10,25 & 50 ug) caused a dose-related reduction in swimming (4.0,2.4, & 2.5), as did the non-imizadole $H_2$ antagonist, BMY 25,368 (10,20 & 25 ug; 3.4,2.5 &2.0), 15 min after administration. This effect was attenuated by the $H_2$ agonist, impromidine (25 & 50 ug), and surprisingly, by the $H_1$ antagonist, chlorpheniramine (50 & 100 ug). Histamine (HA) (1,2.5,5 & 10 ug) had no effect on swimming 2 min after injection (5.4,3.8,3.6 & 4.0). HA (5 ug) given with the HA methyl transferase inhibitor SKF 91488 slightly reduced swimming (3.0), and the two compounds together had no effect on the actions of the $H_2$ antagonists. The specific $H_1$ agonist, pyridylethylamine (50 & 100 ug), and the $H_2$ agonist, impromidine (25 & 50 ug) were also without effect at 2, 5 & 10 min. Although others have shown that $H_1$ antagonists given peripherally are active, chlorpheniramine at 50 or 100 ug ICV had no effect on swimming.

These results suggest that $H_1$ and $H_2$ receptors may mediate opposing actions within the CNS. $H_2$ receptor blockade induced a depressive like state, which was attenuated by a specific $H_2$ agonist, as well as an $H_1$ antagonist. Taken together, these data suggest that disturbances of CNS histaminergic systems may play a role in depression.

348.7 HISTAMINERGIC (H1) INVOLVEMENT IN VISCERAL LEARNING. P. S. Lasiter, M. D. Holder* and J. Garcia*. Dept. of Psychology and Brain Research Inst., Univ. of Calif., Los Angeles, CA 90024.

Histamine receptors, neurons and terminal endings are distributed within brain regions that contribute to special visceral functions. These regions include the amygdala, hypothalamus, dorsolateral parabrachial region, and the caudal solitary nucleus (e.g., Palacios, J.M., et al., Neurosci., 6: 15, 1981; Watanabe, T., et al., Brain Res., 295: 13, 1984). Our experiments examined the involvement of histaminergic systems in one form of visceral learning, namely, conditioned taste aversion (CTA) learning. In this conditioning procedure, taste consumption is followed by illness; Rats subsequently exhibit robust aversions to a taste that is consumed prior to illness. In Experiment 1, distinct groups of male hooded rats received intraperitoneal injections of either pyrilamine maleate (10, 15, 20 or 30 mg/kg), triprolidine HCl (10, 20 or 25 mg/kg), chlorpheniramine maleate (5, 10 or 15 mg/kg) [histamine H1 ligands], or cimetidine (50 or 100 mg/kg) [histamine H2 ligand]. Control animals in each group received vehicle injections only. Forty-five minutes following injections one-half of the experimental and the control animals drank 100 mM LiCl to induce illness and the remaining animals drank 100 mM NaCl to assess normal taste preferences to a "salty" taste (Lasiter, P.S., Behav. Neural Bio., 39: 149, 1983). Two days following conditioning all animals received 100 mM NaCl or distilled water on an alternating daily schedule to evaluate CTAs. Results showed that H1 and H2 ligands did not obviously alter normal taste preferences to 100 mM NaCl nor gastrointestinal reactivity to 100 mM LiCl, yet CTA learning was impaired in a dose-dependent manner only in animals receiving H1 ligands. Experiment 2 determined if injections of histamine ligands produced gastrointestinal disturbances in Experiment 1. Rats drank 100 mM NaCl prior to injections of pyrilamine (20 mg/kg), triprolidine (20 mg/kg), cimetidine (100 mg/kg), or LiCl (67 mg/kg). Injections of histamine ligands following taste consumption did not produce CTAs, indicating that the ligands did not produce illness at the specific doses used in Experiment 1. In Experiment 3 rats received injections of either alpha-hydrazino histidine (a-HH), a histamine synthesis inhibitor, (3 injections; 100 mg base/kg/12 hr), l-histidine HCl (3 injections; 100 mg base/kg/12 hr), or saline prior to CTA conditioning. Results showed that only a-HH injections impaired CTA learning. Thus, attenuation of histamine synthesis yielded behavioral effects similar to those obtained with H1 ligands. These results indicate that H1 histaminergic systems can be classified as at least one substrate for visceral learning functions. Although "antihistamines" have been classified as antiemetic agents, our results suggest that H1 ligands may affect the higher-order interpretation of illness, rather than mechanisms of the emetic response per se. ## BEHAVIORAL PHARMACOLOGY: NEUROLEPTICS AND DOPAMINE

349.1 SOME EFFECTS OF PIMOZIDE ON NONDEPRIVED RATS LEVER PRESSING FOR A SUCROSE SOLUTION IN AN ANHEDONIA PARADIGM. S.E. Gramling*, S.C. Fowler, and J.P. Tizzano*. Dept. of Psych., Univ. of Miss., University, MS 38677.

The apparent similarities in patterns of responding occasioned by either neuroleptic treatment or by extinction procedures in operant appetitive tasks is often cited to support the "anhedonia" (reward-reducing) interpretation of neuroleptics rate reducing effects. A recent study (Gramling, S.E., Fowler, S.C., & Collins, K.R., Pharmacol Biochem Behav, 21, 617-624, 1984) which tested rats in a "traditional" anhedonia paradigm reported that nondeprived rats trained to lick a 32% sucrose solution did not produce extinction-like patterns of responding across eight consecutive days of treatment with pimozide (PIM). The present experiment extended this research by testing nondeprived rats in a similar procedure but employing a leverpress response.

Thirty nondeprived rats leverpressed at stable rates for a 32% sucrose solution reward on a CRF schedule and were then randomly assigned to one of five treatment conditions. Rats in the reward (RWD) condition received vehicle injections and responded for 32% sucrose solution in the test situation. Rats in an extinction (EXT) condition received vehicle injections but no sucrose. Two additional groups received injections of PIM (0.25 mg/kg or 0.5 mg/kg) and responded for normal reward in the test situation. All rats received their respective treatments for eight consecutive days and all injections preceded data collection by four hours. Response rate and duration data were collected via a laboratory computer system.

Rats in the EXT condition exhibited a monotonic decrease in rate across the eight test days. Rats in both drug groups, however, exhibited a significant curvilinear pattern wherein initial rate decreases were followed by a trend towards recovery across the final three days of testing. The duration data also revealed differences between PIM treatment and extinction procedures in that PIM treatment did not lengthen response duration to the same extent as extinction procedures.

Both the present experiment and the Gramling et al. (1984) study observed across-session curvilinear patterns of responding in PIM treated rats. These two experiments differed from other tests of the anhedonia hypothesis in their use of nondeprived rats, a natural reinforcer of high hedonic value, and an extended dosing regime. The failure to obtain extinction-like patterns of responding with these procedures suggests that anhedonia may not be an adequate explanation of PIM's extinction-like effects observed in other settings.

349.2 THE EFFECTS OF PIMOZIDE ON STIMULUS DISCRIMINATION AND REWARDING ELECTRICAL BRAIN STIMULATION. M. Bird* and C. Kornetsky. Lab. Behav. Pharmacol., Boston Univ. Sch. Med., Boston, MA 02118

Pimozide, a selective dopaminergic antagonist, has been shown to cause a dose dependent inhibition of intracranial self-stimulation (Wise, R.A. Pharmacol. Biochem. Behav. 13:213-223, 1980). This phenomenon has often been interpreted as the result of selective pharmacologic blockade of the rewarding quality of brain stimulation and not a function of generalized disruption of performance capabilities.

In an attempt to more conclusively address these issues, intracranial rewarding stimulation and detection thresholds were measured after intraperitoneal injection of pimozide. The threshold level of stimuli employed in the detection procedure were neither positively or negatively reinforcing and were used solely as a discriminative cue.

Bipolar stainless steel electrodes aimed at the medial forebrain bundle - lateral hypothalamic area (MFB-LH) were stereotaxically implanted in male albino rats (CDF - Charles River Laboratories). Following surgery the animals were trained on a rate-free method of determining the threshold for rewarding brain stimulation (Esposito, R.U. and Kornetsky, C. Science, 195:189-191, 1977) and the effects of pimozide intraperitoneally administered on this threshold were determined. The same animals then were trained on a method for determining the threshold for detecting non-rewarding intracranial stimulation. The procedure required the animal to make an instrumental response to a 0.5 sec, low intensity, non-rewarding cue (S1) to the same brain site used in the reward procedure (Wheeling, H.S. and Kornetsky, C. Brain Res., 272:13-19, 1983). Responding to the cue within 5 sec was maintained by the delivery of a reinforcing stimulus (S2) via the same electrode. Absolute detection threshold were determined by varying the current intensity of the brain stimulation cue (S1) according to a modification of the psychophysical method of constant stimuli. The reinforcing stimulus (S2) remained at a fixed intensity level clearly above the reward threshold previously determined after moderate doses of pimozide.

Preliminary results indicate that moderate doses of pimozide (0.2 mg/kg) cause an increase in the threshold for both reward and detection brain stimulation. However, the ability of the animals to discriminate between the intensity of stimulation was more impaired in the detection than the reward paradigm. The differential effects of pimozide on the reward and detection threshold profiles suggest that pimozide not only decreases the rewarding value of reinforcing brain stimulation but also impairs the perception and discrimination processing of non-rewarding stimuli. (Supported in part by NIDA grant DA 02326 and NIDA Research Scientist Award (CK) K05 DA 00099).

349.3 COCAINE SELF-ADMINISTRATION AND HORMONAL STATUS: THE ESTROUS CYCLE AND THE ANTIESTROGEN TAMOXIFEN. J.C.H. Dalton*, G.J. Vickers* and D.C.S. Roberts. Dept. of Psychology, Carleton Univ., Ottawa, Canada, K1S 5B6.

Rats pretreated with small doses of antipsychotic drugs show an increase in cocaine self-administration, and this increase has been shown to strongly correlate with clinical dosage (Roberts & Vickers, Psychopharm. 82:135, 1984). We have suggested that the mechanism which causes this increase in cocaine intake may be distinct from extrapyramidal effects, and therefore this procedure may provide a useful model for investigating the therapeutic effects of neuroleptic drugs. Both clinical and basic research now indicates that female sex hormones can affect the response to dopamine antagonists. We have employed the cocaine self-administration procedure to characterize the role of female hormonal status on the "therapeutic potency" of neuroleptic drugs.

We have previously shown that ovariectomy (OVX) attenuates haloperidol-induced increases in cocaine self-administration but does not affect baseline intake as compared to control animals (Neurosci. Abstr. #245.11, 1984). We now report that the potency of haloperidol fluctuates across the estrous cycle. Female Wistar rats were implanted with chronic jugular cannulae and permitted to self-administer cocaine (1.5 mg/kg/inj for 4 hrs/day). The effect of haloperidol pretreatment (0.1 mg/kg, one hr prior to testing) was examined in animals which showed a stable intake of cocaine, and displayed a regular estrous cycle. Haloperidol was found to produce a significantly greater increase in cocaine intake during diestrous (97%) compared to animals tested during either proestrous (75%) or metestrous (78%).

In a separate experiment, it was shown that the increase in cocaine self-administration normally produced in female animals (counter-balanced across the estrous cycle) was attenuated by a single injection of the antiestrogen tamoxifen (1.0 mg/kg, 24 hrs prior to testing).

These data demonstrate that normal physiological fluctuations in hormonal balance or pharmacological inhibition of estrogen function can affect the response to neuroleptic drugs, and indicate that hormonal status may be a significant influence on neuroleptic efficacy. (Supported by the Medical Research Council).

349.4 EFFECTS OF THE FATTY ACID CONJUGATE PALMITOYLCODEINE ON BEHAVIORAL AND NEUROCHEMICAL MEASURES IN THE RAT. G.C. Haggerty*, R. Deskin, A.F. Fentiman* and E.Leighty*. Battelle Columbus Laboratories, Columbus, OH 43201.

Studies have shown that palmitic acid can be conjugated with codeine in an in vitro coenzyme A fortified rat microsomal incubation system to form palmitoylcodeine (Leighty et al, J. Pharm. Pharmacol. 35: 260-261, 1983). The objective of the present studies was to determine if palmitoylcodeine is pharmacologically active in the rat. For comparison purposes, a codeine dosed group was included as a positive control. Both codeine and palmitoylcodeine (2 or 4 times the equimolar dose of codeine) decreased thermal sensitivity and spontaneous motor activity at 1 hr, and induced a state of catalepsy up to 2 hr in rats following intravenous administration. Palmitoylcodeine-induced changes in thermal sensitivity and motor activity followed a temporal pattern of response similiar to that seen with codeine, but the effects were less pronounced. While the catalepsy produced by codeine was seen almost immediately after injection, the palmitoylcodeine-induced response developed more slowly. Although neither compound exerted an effect on hypothalamic norepinephrine (NE) uptake at 2 hr post administration, striatal dopamine (DA) uptake was significantly ($P<0.05$) decreased in the codeine dosed group and tended also to be depressed in palmitoylcodeine-treated animals. These effects on DA uptake are of interest since dopaminergic mechanisms are believed to play a role in the development of both catalepsy and locomotor activity. To further characterize the observed palmitoylcodeine-induced behavioral changes, animals were intracisternally injected with codeine or the fatty acid conjugate. In contrast to the sedation observed after intravenous administration of these compounds, animals from both the codeine and palmitoylcodeine groups were agitated and exhibited an increase in spontaneous motor activity. The results of these studies demonstrate that palmitoylcodeine is psychoactive. The fatty acid conjugate produced effects similar to those of codeine, and, for both compounds, the route of administration appeared to be an important determinant of the type of behavioral effects induced. The observed behavioral responses may be due to the pharmacological activity of palmitoylcodeine itself and/or its metabolic conversion to psychoactive codeine (supported by NIDA Grant No. DA00793-07).

349.5 A COMPARISON OF THE EFFECTS OF APOMORPHINE, (+)- and (-)-3-PPP AND HALOPERIDOL ON THE FIGHTING BEHAVIOR AND MOTOR ACTIVITY OF DIFFERENTIALLY HOUSED MICE. T. Fico, C. Wilmot, and C. VanderWende. Rutgers Univ., Dept. Pharmacology, PO Box 789, Piscataway, NJ 08854

The individual housing of male mice is noted for producing a prominent fighting behavior, a heightened reactivity and an increased monoamine turnover in response to a novel environment. The present study was conducted to determine (1) if the fighting behavior could be modulated by low doses of the DA agonists, apomorphine (APO) and (+)-3-PPP, the mixed agonist (-)-3-PPP and the DA antagonist haloperidol (HAL), (2) the relationship between the effects of these agents on motor activity and fighting behavior and (3) to compare the motor activity response of group housed (GH) and individually housed (IH) mice. Male CF-1 mice were housed either individually or in groups, 15/cage, for 4 wks, starting at 34-38 days of age. IH mice were tested for fighting behavior with an olfactory bulbectomized stimulus mouse, which does not initiate a fight nor retaliate. Motor activity was measured in separate groups of age-matched GH and IH mice.

APO, 0.01875-0.3 mg/kg, and (+)-3-PPP, 0.7-4.0 mg/kg, significantly reduced the activity of IH mice, whereas fighting behavior was affected only by higher doses, 0.3 - 0.6 mg/kg APO and 4.0-12.0 mg/kg (+)-3-PPP. In contrast, (+)-3-PPP, 0.7-4.0 mg/kg, reduced both the number of mice fighting and motor activity. HAL, 0.5 mg/kg, inhibited fighting, however, 0.125-0.5 mg/kg HAL reduced motor activity. IH mice were more sensitive than GH mice to the activity-reducing effects of APO and both enantiomers of 3-PPP. These results indicate that low doses of DA agonists selectively reduce motor activity and only higher doses reduce fighting behavior. Also, individual housing produces an increased sensitivity to the hypomotility response to DA agonists.

349.6 EFFECTS OF NUCLEUS ACCUMBENS 6-HYDROXYDOPAMINE LESIONS ON RESPONDING CONCURRENTLY MAINTAINED BY FOOD, WATER AND MORPHINE. J.E. Smith, K. Schultz* and S.I. Dworkin. Psychiatry Research Unit, Departments of Psychiatry and Pharmacology, Louisiana State University Medical Center, Shreveport, LA 71130.

The neurotoxin, 6-hydroxydopamine (6-OHDA), has been used to investigate neurobiological aspects of reinforcement. 6-OHDA can be used to selectively destroy dopamine containing neurons in discrete brain regions. Such lesions of the nucleus accumbens affect food, water and drug self-administration. 6-OHDA lesions of this structure decrease or eliminate cocaine and amphetamine self-administration and either increase or do not affect opiate self-administration in rats with unrestricted access to food and water. However, there have been very few investigations of the effects of neurotoxin lesions on responding simultaneously maintained by several different reinforcers. This study reports the effects of 6-OHDA lesions of the nucleus accumbens on responding concurrently maintained by food, water and morphine.

Eight male rats were trained on a concurrent fixed-ratio 10 schedule of reinforcer presentation with continuous access. Three response levers were available to the subject. A single response on any lever resulted in the retraction of the other two. Nine additional responses resulted in the delivery of either a 45 mg food pellet, 0.1 ml of water or 10.0 mg/kg infusion of morphine, depending on the lever selected. After stable patterns of responding maintained by the three reinforcers were obtained, dose-effect curves for morphine were obtained. Other doses of morphine (2.5-40 mg/kg) were substituted for the 10.0 mg/kg dose for 24-hour periods. The effects of both sham vehicle and 6-OHDA (4 ug in 0.5 ul delivered over 7 minutes) lesions were then determined and the dose-effect evaluations repeated.

6-OHDA lesions did not significantly affect responding maintained by food, water or morphine. This is in contrast to previous reports of the neurotoxin on drug self-administraton procedures. The absence of an effect is most likely not the result of an insensitive baseline. Kainic acid lesions produce a selective decrement in morphine self-administration using this procedure.

Although these data appear contradictory to those obtained using one reinforcer, they may not be. This lesion may initially severely attenuate responding maintained by a variety of reinforcers. However, in this procedure, a decrement in food and water intake could have fatal consequences. Therefore, previously redundant secondary systems may be elaborated. (Supported in part by USPHS Grant DA 01999-08).

349.7 SEX DIFFERENCES IN NEUROLEPTIC-INDUCED CATALEPSY. M.H. Lewis, M.F. Keresztury*, R.B. Mailman. Department of Psychiatry, University of Medicine and Dentistry of New Jersey - School of Osteopathic Medicine, Camden, NJ 08103 and Biological Sciences Research Center, University of North Carolina, Chapel Hill, NC 27514.

Gonadal steroids, particularly estrogen, have been reported to modulate dopamine neurotransmission, although data on the nature of such modulation are contradictory.

The present study examined sex differences in the cataleptogenic potency of three structurally dissimilar dopamine antagonists: thioridazine, haloperidol and SCH23390. Following intraperitoneal (ip) drug administration, intact male and female Sprague-Dawley rats were tested by placing the animal's forepaws on a 10 cm high metal bar. Dose-response relationships were evaluated by measuring the latency to placement of both forepaws on the table surface at 15 minute intervals following drug treatment.

Thioridazine was found to be weakly cataleptogenic although significantly more potent in males ($ED_{50}$=ca. 85 mg/kg) than females. To test whether this difference may have been due to differential drug metabolism, blood and brain concentrations of thioridazine and its active metabolites were quantified in male and female rats by HPLC. Also, catalepsy was assessed following administration of mesoridazine, an active S-oxidized metabolite of thioridazine. Mesoridazine was approximately twice as potent as thioridazine in inducing catalepsy yet equipotent in males and females. Additionally, thioridazine proved to be equipotent in inducing catalepsy in male versus ovariectomized female rats.

Haloperidol was found to be significantly less potent in male than in female ($ED_{50}$=ca. 0.5 mg/kg) rats. In order to determine if the observed difference was due to the effect of gonadal steroids on drug metabolism, haloperidol was injected intracerebroventricularly (icv) into intact males and females. The sex difference previously observed after ip injection was no longer apparent following icv administration.

No significant sex differences in cataleptogenesis were observed following ip administration of the purportedly selective D1 antagonist SCH23390 ($ED_{50}$=ca. 0.1 mg/kg). Drug concentrations in blood and brain of male and female rats as determined by HPLC complemented the behavioral results observed.

It appears that gonadal steroids may alter substantially the bioavailability of at least some dopaminergic drugs. Such action may explain, in part, the contradictory data on the modulatory role of gonadal steroids on dopamine function.

(Supported, in part, by HD16834, MH40537, and MH37404).

349.8 HALOPERIDOL-INDUCED DEFECATION IN LABORATORY RATS: PERIPHERAL OR EMOTIONAL EFFECT? S.H. Hagenmeyer, K.H. Russell,* M.D. Bunsey* and P.R. Sanberg, Behavioral Neuroscience Laboratory, Dept. of Psychology, Ohio University, Athens, OH 45701.

Given under certain conditions, the dopamine (DA) receptor blocker haloperidol (HAL) produces increased defecation, as measured by the number or weight of fecal boli in laboratory rats. Although defecation is used an an index of emotionality in animals, the fact that a major tranquilizer can increase defecation suggests the need for an examination of the underlying mechanisms for this drug-induced phenomenon. The present study examined whether the HAL effect was related to peripheral DA receptors or emotionality by using the peripheral DA receptor blocker, domperidone, and the antianxiety agent, diazepam, respectively.

Male Sprague Dawley rats (about 370 gm) were injected i.p. in their homecage with either 0.1 or 1.0 mg/kg of HAL or domperidone. Fecal boli counts were taken hourly and massed at the end of a three hour test session. Other studies were performed on the effects of HAL on day vs night and homecage vs openfield defecation. Finally, defecation was studied in animals pre-injected i.p. with diazepam (0.5, 1.0, or 2.0 mg/kg) and given HAL (1.0 mg/kg) or vehicle one hour later.

The results indicated an overall increase in defecation measures with HAL but not domperidone. Nocturnal fecal excretions were consistently greater than those during the daytime. However, the nocturnal animals defecated the most during the third hour post-injection (22:00-23:00) in comparison to the daytime where the first hour showed the largest defecation rates. This may be related to the fact that one of the periods of greatest locomotor activity falls between 22:00 and 23:00. Following a five hour habituation period, the open-field vs homecage defecation study demonstrated significantly more defecation in the homecage. Finally, rats injected with diazepam and HAL defecated significantly less than those animals which received HAL alone. There were no differences between the diazepam/HAL group and the diazepam/vehicle group.

These findings reveal that a peripheral DA receptor blocker does not significantly increase defecation behavior in rats. This suggests that the underlying mechanism for HAL-induced defecation is not an effect on peripheral DA receptors located in the gastrointestinal tract. On the other hand the differences in homecage vs open field defecation suggest that the neuroleptic may be enhancing emotionality in the rat. This is further supported by the results that those animals which received both diazepam and HAL had normal fecal excretions. It is suggested that the involuntary restruction of locomotor mechanisms in the animal by HAL may produce high levels of anxiety, thereby increasing defecation.

349.9 CHRONIC, BUT NOT ACUTE, ESTRADIOL TREATMENT ALTERS THE APOMORPHINE "CUE". J. T. Concannon and M. D. Schechter. Program in Pharmacology Northeastern Ohio Universities College of Medicine, Rootstown, OH 44272.

Adult male rats were trained to discriminate the interoceptive cue produced by intraperitoneally administered apomorphine (APO) in a 2-lever, food-motivated operant task. After reaching a criterion of 90% drug-appropriate responses at the training dose of 0.16mg/Kg, animals were injected subcutaneously with 100µg/Kg/day estradiol benzoate for 3 consecutive days. The first injection was administered 1 hr prior to the apomorphine training dose, whereas the second dose was administered 1 hr prior to saline. The results of first two injections showed that "acute" estradiol administration did not affect the cue produced by either the training dose of apomorphine or saline. The experiment was continued by administering a third dose of estradiol the next day, and then testing the response to a previously-determined ED50 (0.08mg/Kg) dose of apomorphine 1, 2, 4, and 8 days after estradiol "withdrawal".

The results of the chronic experiment are shown in the table:

| Post-estradiol day | Dose | %APO Lever Selection |
|---|---|---|
| 1 | 0.08 APO | 60.0 |
| 2 | 0.08 APO | 100.0 |
| 4 | 0.08 APO | 60.0 |
| 8 | 0.08 APO | 60.0 |

It was thus observed that the 3 consecutive estradiol injections augmented the animals' response to the 0.08mg/Kg APO dose, i.e., there was behavioral supersensitivity. Furthermore, this supersensitivity was time-dependent, emerging 2 days after the last estradiol injection, and disappearing just 2 days later. These results are formally similar to those produced by chronic antipsychotic (anti-dopaminergic) drug administration, which also produces behavioral supersensitivity to dopamine agonists in a time-dependent manner. This similarity leads to the suggestion that estradiol may be anti-dopaminergic. Further research is needed, however, to determine the underlying neuropharmacological mechanism of estradiol's action in order to test the validity of this inference.

349.10 STRENGTHENING OF ONGOING ACTIVITY BY APOMORPHINE: EFFECT ON SEXUAL BEHAVIOR. Henry Szechtman. Dept. of Neurosciences, McMaster Univ., Hamilton, Ont., CANADA, L8N 3Z5.

Dopaminomimetic drugs have been shown to induce stereotyped behavior that reflects "the behavioral pattern which was ongoing when the first infusions of drug were received" [1]. Also, self-administration studies have shown that these drugs have reinforcing effects [2]. These findings have been taken to support the hypothesis that dopaminomimetic drugs reinforce "the behavior displayed during the onset of drug action" [3]. This study tests the generality of this hypothesis by determining whether the dopamine agonist, apomorphine, strengthens ongoing sexual behavior. Contrary to the hypothesis, the findings indicate that the drug diverts the rats' attention from sexual activity to performance of behaviors typically exhibited by rats injected with apomorphine.

Twenty-six male Sprague-Dawley rats received extensive sexual experience (10 weekly 20 min sessions). They were administered apomorphine (1.25 mg/kg s.c.), or saline, on mating sessions #11 and #12. Half the animals received the drug first, and the other half, saline first. Injections were given after the males achieved the second intromission; testing ended 20 min later.

All males ejaculated at least once after injection of saline (mean ± sem number of ejaculations: 2.0 ± 0.2). However, after injection of apomorphine, 17 rats did not continue to copulate until ejaculation; the remaining 9 rats ejaculated only once. All animals showed behavior typical of apomorphine-treated rats, ie., snout contact fixation, forward progression, and turning [4].

These results indicate that there is a limit to the kind of ongoing behavior that can be reinforced by apomorphine. Furthermore, the fact that males ceased to copulate, an activity that is not interrupted by the availability of food in severely starved rats [5], suggests that apomorphine is extremely potent in redirecting the animals' responsiveness to some unique range of stimuli. 349.11 **THE EFFECT OF DOPAMINE AUTORECEPTOR AGONISTS ON EXPLORATORY AND DRUG-STIMULATED LOCOMOTOR ACTIVITY IN RATS.** P.J.K.D.Schreur and N.F.Nichols*, CNS Research, The Upjohn Company, Kalamazoo, MI 49001.

In several areas of the brain, dopamine secreted from neuron terminals acts on "autoreceptors" on the same terminals to decrease their further release of dopamine. Thus, transmission at dopaminergic synapses can be inhibited by administration of either a dopamine autoreceptor agonist or a postsynaptic antagonist (e.g., a neuroleptic).

**Methods.** The locomotor activity of male Sprague-Dawley rats was measured automatically in Omnitech Digiscan activity monitors. Drug-stimulated behavior (d-amphetamine $SO_4$ 0.3 mg/kg or apomorphine HCl 0.5 mg/kg s.c.) was tested for 60 min after drug injections, in rats which had been habituated to the cages for 40 min in the light (n = 8-11). Exploratory behavior was tested for 10 min in the dark, in naive rats which had been preinjected with drug in the home cage (n = 8).

**Results, Exploratory Activity.** The potential autoreceptor agonists apomorphine HCl, NPA (N-n-propylnorapomorphine), and PPP (N-n-propyl-3-(3-hydroxyphenyl)-piperidine) and its enantiomers decreased the total distance travelled by exploring rats while at the same time paradoxically increasing the number of discrete movements. This is a very different pattern from that of the typical antipsychotic drugs haloperidol and chlorpromazine, and the atypical antipsychotic drug clozapine, which also decreased the total distance travelled but decreased the number of movements. Both groups decreased the distance/movement.

**Results, Drug-stimulated Activity.** Apomorphine (0.001-0.1 mg/kg), NPA (0.001 mg/kg), and (+)-PPP (1 mg/kg) antagonized amphetamine-stimulated locomotor behavior (total distance) without antagonizing apomorphine-stimulated behavior, suggesting a presynaptic dopamine autoreceptor agonism. On the other hand, haloperidol, chlorpromazine, and clozapine decreased both amphetamine- and apomorphine-stimulated behavior, suggesting a postsynaptic dopamine antagonism. PPP and (-)-PPP showed neither pattern in this test.

349.12 **DISCRIMINATION OF A COMPOUND DRUG STIMULUS: AMPHETAMINE PLUS LSD VERSUS SALINE.** J. M. Hanlin* and J. B. Appel. Behavioral Pharmacology Laboratory, Department of Psychology, University of South Carolina, Columbia, SC 29208.

To test the hypothesis that animals can discriminate pharmacologically distinct components of drug-induced cues, rats (N=12) were trained to discriminate a combination of (+)-amphetamine (1.0 mg/kg, i.p.) and LSD (0.08 mg/kg, i.p.) from saline. A two-lever procedure involving an FR 10 schedule of water reinforcement was used.

The discrimination was learned rapidly and was maintained at a high level of accuracy. In subsequent substitution (generalization) and antagonism tests, the training doses of amphetamine and LSD consistently elicited about 80% and about 20% drug-lever responding, respectively; the dopamine (DA) antagonist haloperidol blocked the effect of amphetamine but increased that of LSD, whereas the serotonin-2 (5HT-2) antagonist ketanserin blocked the effect of LSD but did not alter that of amphetamine. The amount of antagonism of the amphetamine-LSD combination by ketanserin was proportional to the amount of generalization of the combination to the training dose of LSD (about 20%). Haloperidol partially antagonized the combination (to 54.0%) at a dose of 0.5 mg/kg; higher doses were less effective. These results support the hypothesis that components of drug cues can be discriminated.

Results of tests with lower and higher doses of the two training drugs suggest that the LSD-like portion of the compound cue may be larger than the serotonergic portion, i.e., that amphetamine may contribute to the LSD-like component through a non-serotonergic mechanism. Generalization of the training combination to LSD occurred with a steep slope and peaked at 74.5% at a dose of 0.32 mg/kg; generalization to amphetamine also occurred with a steep slope and reached 99.2% at 1.5 mg/kg. In rats trained with (+)-amphetamine (1.0 mg/kg) alone, generalization to LSD occurred with a shallow slope and peaked at 38.6% at a dose of 0.24 mg/kg. Such results suggest that amphetamine (given subchronically) may have two discriminable effects, a DA-mediated central stimulant effect that is of relatively high salience (is more discriminable) and a DA-mediated LSD-like effect that is of relatively low salience (is less discriminable); addition of LSD to the amphetamine training regimen appears to increase the salience of the LSD-like component of the amphetamine cue.

## NEUROTOXICITY IV

350.1 PRENATAL CARBON MONOXIDE EXPOSURE CAUSING LOW LEVEL HYPOXIA LEADS TO A SIGNIFICANT INCREASE IN STRIATAL DOPAMINE (DA), A DECREASE IN DA SYNTHESIS, BUT NO CHANGE IN DA METABOLITE LEVELS. M.J. Kaufman, M.B. Upchurch*, and L.D. Fechter. Neurotoxicology Program, Johns Hopkins University School of Hygiene and Public Health, Baltimore, MD 21205.

The developing central nervous system seems to be quite sensitive to hypoxia, as shown by behavioral changes and learning and memory deficits (Mactutus and Fechter, 1984; Science 223:409-411). The striatum in particular appears vulnerable to hypoxia, especially to that induced by carbon monoxide (CO) exposure. Further, tyrosine hydroxylase, the rate limiting enzyme in catecholamine biosynthesis, is oxygen requiring and might be affected if oxygen tension is reduced. The present experiment was designed to study the effects of CO-induced hypoxia on catecholamine and metabolite levels in the developing striatum.

Pregnant Long-Evans hooded rats were exposed from day 1 of gestation to postnatal day 10 with their litters to either 0, 75, 150, or 300 ppm CO. Striata from pups sacrificed at postnatal ages 10, 14, or 21 days were collected for subsequent assay of catecholamines and metabolites by HPLC-EC. Additional 0 or 300 ppm CO-exposed, 21-day-old rats were pretreated with m-hydroxybenzylhydrazine to inhibit dopa decarboxylase activity 0, 10, 20, or 30 minutes before sacrifice. Accumulation of dopa was measured in these animals as an estimate of the rate of DA synthesis.

DA levels were significantly increased in a dose-response fashion in 21-day-old rats (one way ANOVA: $F(3,28) = 3.12$, $p < 0.05$). In addition, a two way ANOVA indicated that CO exposures increased DA levels across all ages of sacrifice ($F(3,71) = 4.149$, $p < 0.01$). The rate of DA synthesis, however, was significantly reduced in 300 ppm exposed animals. DA metabolite levels were not increased, suggesting the possibility that excess DA is stored and unused. Since these elevations in DA levels and reductions in DA synthesis rates are seen at postnatal day 21, long after termination of CO exposure, they are indications of persisting damage sustained by the nigrostriatal dopaminergic projection system.

350.2 A-METHYLPARATYROSINE (AMT) PREVENTS THE METHYLAMPHETAMINE (MA)-INDUCED FORMATION OF ENDOGENOUS 5,6-DIHYDROXYTRYPTAMINE (5,6DHT) IN RAT HIPPOCAMPUS. K.J. Axt*, D.L. Commins*, L.S. Seiden. (SPON: S.P. Grossman), Department of Pharmacol. & Physiol. Sci., University of Chicago, Chicago, IL 60637.

We now report that a single high dose of MA (100 mg/kg s.c.) produces a significant depletion of serotonin (5HT) in the hippocampus of the male Sprague-Dawley rat. These 5HT depletions average across experiments to 50% of control values when measured 2 weeks after drug administration. In addition, we have found that acute MA administration causes the endogenous formation of 5,6DHT which is blocked by AMT.

Prior administration of the catecholamine synthesis inhibitor AMT (150 mg/kg s.c., 6 and 1 hr prior to MA) prevents MA-induced long-term hippocampal 5HT depletions. 5HT levels in AMT+MA rats are 94% of those of the AMT+saline controls whereas 5HT levels of the saline+MA rats are 25% of those of the saline+saline controls. However, pretreatment with a dose of the 5HT synthesis inhibitor parachlorophenylalanine (PCPA, 300 mg/kg i.p., 48 and 24 hrs prior to MA) which reduces hippocampal 5HT levels to less than 1% of control values at the time of MA injection, fails to block the MA-induced 5HT depletion. 5HT levels in PCPA+MA rats are 69% of those in PCPA+saline controls, compared to 5HT levels in vehicle+MA rats which are 65% of those in the vehicle+saline controls. In light of our recent observation that the 5HT neurotoxin 5,6DHT is formed endogenously in rat hippocampus after MA administration, with peak values at 1 hr (Commins et al., 1985, submitted for publication), we have attempted to determine whether this endogenous 5,6DHT might mediate the hippocampal 5HT depletions seen after MA. This question was addressed in regard to the effects of AMT and PCPA on the long-term depletions. Rats were pretreated as indicated above with AMT or saline and then were given MA or saline in a latin square design. The animals were sacrificed 1 hr after MA administration. The amount of 5,6DHT detected in the hippocampi of the saline+MA group was 0.014 ± .006 ng/mg tissue (mean ± S.E.M., n=10). No 5,6DHT was detectable for the AMT+MA group, nor for either control group. Parallel studies are being carried out using PCPA.

Endogenous 5,6DHT is produced in rat hippocampus in the presence of MA. The results of this experiment raise the question as to whether this formation of 5,6DHT is an expression of an alternative metabolic pathway in the normal animal which may be accelerated in diseases of the central 5HT system. This research is supported by Mental Health Training Grant MH-14274; PHS DA-00250; L. Seiden is the recipient of an RSA Award MH-10562.

350.3 DOPAMINE UPTAKE INHIBITORS AND METHAMPHETAMINE NEUROTOXICITY. Gerard Marek* and Lewis S. Seiden. Dept. Pharmacol. & Physiol. Sci. University of Chicago, Chicago, IL 60637.

Previous studies have demonstrated that amfonelic acid, a dopamine (DA) blocker, was able to antagonize long-term depletion of striatal DA following a single amphetamine and iprindole injection (Fuller, R.W. and Hemrick-Luecke, Science 209:305(1980); Steranka, L., Brain Res. 234:123-136(1982) and multiple methamphetamine injections (Schmidt, C.J. and Gibb, J.W., Eur. J. Pharm. 109:73-80(1985). However, since amfonelic acid and other non-amphetamine stimulants seem to have effects on DA storage pools that might be independent of blocking the uptake of DA across the neuronal membrane (Shore, P.A., J. Pharm. Pharmac. 28:355(1976); Fuller, R.W., Perry, K.W., Bymaster, F.P. and Wong, D.T., J. Pharm. Pharmac. 30:197-198(1978), we are studying the effects of other DA uptake blockers such as benztropine, mazindol, and nomifensine as well as amfonelic acid on the neurotoxicity engendered by a large single injection (100 mg/kg s.c.) of methamphetamine (MA).

Amfonelic acid (10 mg/kg i.p.), Mazindol (20 mg/kg i.p.) or benztropine (25 mg/kg i.p.) were injected simultaneously with MA (100 mg/kg s.c.) or vehicle in male Sprague-Dawley rats of approximately 200-250 gms. Rats were sacrificed two weeks following these injections and the striata were subsequently assayed by reverse phase chromatography with electrochemical detection for DA, dihydroxyphenylacetic acid (DOPAC), homovanillic acid (HVA), serotonin (5HT) and 5-hydroxyindole acetic acid (5HIAA). Amfonelic acid completely antagonized the MA-induced depletion of striatal DA, DOPAC and HVA. Mazindol partially protected against striatal DA depletions, but benztropine was ineffective. None of the DA uptake inhibitors antagonized the MA-induced neurotoxicity upon the serotonergic system.

Since it has been hypothesized that the MA-induced neurotoxicity is mediated via the formation of 6-hydroxydopamine (6OHDA) following massive release of DA into the synaptic cleft, (Seiden, L.S. and Vosmer, G., Pharmacol. Biochem. Behav. 21:29-31 (1984), it is of interest to compare the potency of DA uptake inhibitors in antagonizing intraventricular 6OHDA dopaminergic neurotoxicity vs. long-term MA-induced DA depletions. Preliminary evidence suggests dopamine uptake inhibitors exhibit a similar potency relationship for blocking ivt. 6OHDA neurotoxicity as they do for antagonizing MA-induced neurotoxicity. This research supported by PHS DA-00250; PHS 5T32 GM07281 MSTP; L. Seiden is the recipient of a RSA MH-10562.

350.4 **IN VITRO EFFECTS OF DOPAMINE ACTIVE COMPOUNDS ON MITOCHONDRIAL RESPIRATION AND OXIDATIVE PHOSPHORYLATION FROM RAT CORTEX, STRIATUM AND LIVER.**

J.H. Thakar,* M.N. Hassan* and J.D. Grimes.* (SPON:J. de la Torre) Parkinson Disorder Laboratory, Ottawa Civic Hospital, 737 Parkdale, Ottawa, Ontario Canada K1Y 1J8.

Neuroactive substances such as 6-hydroxydopamine (6OHDA), 1-methyl, 4-phenyl-1,2,3,6 tetrahydropyridine (MPTP) etc. have been used to evaluate the dopaminergic systems in animal models of movement disorders including parkinsonism. These are potent neurotoxic substances. For example, unilateral injection of 6OHDA in the substantia nigra of rodents produces parkinsonism. On the other hand MPTP is shown to produce parkinsonism in men, monkeys and mice. The exact mechanisms of action of these compounds at subcellular level are not yet well understood. We have investigated the effect of these compounds as well as dopamine (DA) and apomorphine (APO) on mitochondrial oxidative phosphorylation in vitro.

The mitochondrial preparations were isolated from cerebral cortex, neostriatum and liver. The homogenizing medium was made of 0.23M mannitol, 0.07M sucrose and 0.1mM EDTA at PH 7.4. The organelles were separated by differential centrifugation at 9,000g after removing the unbroken cells and cellular debris. The oxygen consumption and ATP synthesis were measured at 30°C using YSI oxygen monitoring system.

The preliminary observations in our study have shown that MPTP at concentrations of 0.1 to 0.4mM had little effect on respiration or on oxidative phosphorylation in organelles from striatum, cortex or liver. On the other hand, 6OHDA stimulated the oxygen consumption at concentrations above 10uM, without influencing the phosphorylation, i.e., ATP synthesis. Dopamine and APO did not have any significant effect on respiration and on oxidative phosphorylation at concentrations lower than 0.2mM. At higher concentrations, DA (0.7mM) and APO (0.45mM) produced some stimulation of oxygen consumption rates.

It is of interest to note that the stimulation of oxygen consumption produced by 6OHDA may be of significance in rendering its neurotoxicity. This particular property of 6OHDA has not been explored in any detail. Data on oxidative phosphorylation and respiration will be presented and discussed in detail.

(Supported by the Parkinson Disease Society of Canada).

350.5 **DOPAMINERGIC AGONISTS INDUCE IPSILATERAL ROTATION IN RATS AFTER INTRASTRIATAL INJECTIONS OF IMINODIPROPIONITRILE (IDPN).** J.L. Cadet* and W.J. Freed. Preclinical Neurosciences Section, Neuropsychiatry Branch, NIMH, Saint Elizabeths Hospital, Washington, D.C. 20032.

**Introduction:** Chronic intraperitoneal injection of IDPN in rodents causes a persistent behavioral syndrome characterized by excitability, hyperactivity, and spasmodic dyskinetic movements which lasts throughout the lifespan of the animals. This syndrome is exacerbated by dopaminergic agonists and blocked by dopamine (DA) antagonists. Chronic treatment with IDPN leads to loss of both high and low affinity spiroperidol binding in the striatum (Diamond B, et al., Ann. Neurol. 12:97-98, 1982). In order to evaluate further the effects of IDPN on the DA system, we undertood this study on its influence on rotational behavior in rats.

**Materials and Methods:** Adult rats (175-200 g) were injected stereotaxically with saline or IDPN (250 $\mu$g in 10 $\mu$l, Eastman Kodak) into the right caudate-putamen using routine surgical techniques. Coordinates were 2 mm anterior to bregma, 2.5 mm lateral to midline, and 4.5 mm ventral to the surface of the skull. The animals were then challenged in random order with either apomorphine (1 mg/kg) or amphetamine (3 mg/kg). At least 2 days were allowed between testing. The results are expressed as means $\pm$ SEM.

**Results:** Both drugs induce significant ipsilateral turning behavior 5 to 25 days after IDPN treatment as compared to animals treated with saline: (APO: IDPN (49.1 $\pm$ 26.89, n=10); saline (4.01 $\pm$ .88, n=7, p .0005, t-test); (AMPH: IDPN (122.2 $\pm$ 27.05, n=10), saline (5.29 $\pm$ 1.48, p .0005, t-test). After 4-5 weeks, there was a reversal of the rotational behavior back to control levels.

**Discussion:** These results indicate that in the IDPN model both indirect (amphetamine) and direct (apomorphine) agonists influence rotation in a similar way, in contrast to rats with unilateral lesions of the substantia nigra. This suggests that IDPN interferes with dopamine-receptive neurons or DA receptors themselves, and causes an impairment of striatal function. Thus agonist agents stimulate the contralateral striatum and lead to rotation towards the side of IDPN infusions. This interpretation is consistent with other findings that intraperitoneal injection of IDPN causes a marked increase in HVA levels in the striatum (to be submitted), similar to the increase in HVA levels induced by neuroleptics.

350.6 STUDIES ON THE CAUSES FOR THE DOPAMINERGIC SELECTIVITY OF MPTP TOXICITY IN MICE. E.Melamed,J.Rosenthal*, O. Cohen*, M.Globus*, and A. Uzzan*. Dept. of Neurology, Hadassah University Hospital, Jerusalem, Israel.

The causes for the preferential toxic effect of MPTP on DA neurons are undetermined.Conversion of MPTP to MPP+ by MAO-B,is an important but probably not the only factor.MPTP DA toxicity may be dependent on additional biochemical processes unique for DA neurons.We therefore examined in mice the effects of various pharmacological manipulations of central DA metabolism including acceleration and suppression of DA turnover,DA depletion from nerve-terminals,and inhibition of DA uptake on the long-term decreases in striatal DA induced by MPTP.In C57 black mice,MPTP(30mg/kg,once daily x2,s.c.) produced marked falls in striatal DA levels which persisted up to 30 days after treatment.Mice were then given MPTP alone(30mg/kg x2, s.c.)or in combination with one of the following drugs(i.p.):haloperidol(2mg/kg),chlorpromazine(10mg/kg),apomorphine(5mg/kg),bromocriptine(2.5mg/kg),reserpine(0.1mg/kg),nomifensine,desipramine,clomipramine or fluoxetine(25mg/kg of each),amphetamine(5mg/kg)or L-dopa (50mg/kg with carbidopa 10mg/kg).All drugs were given for two days before,for two days in conjunction,and for two days after MPTP except for reserpine which was given for 4 days.Animals were decapitated 30 days after last injection.Enhancement(by haloperidol and chlorpromazine)or attenuation(by apomorphine and bromocriptine)of impulse flow in,and DA turnover by DA neurons did not affect decreases in striatal DA induced by MPTP.Likewise,depletion of vesicular DA from DA terminals by reserpine did not prevent toxic effects of MPTP.Nomifensine,a specific inhibitor of DA reuptake,completely abolished the MPTP-induced striatal DA depletions.By contrast,uptake inhibitors of NE(desipramine)or of 5-HT(clomipramine and fluoxetine)were ineffective.These findings suggest that MPTP(or a byproduct of its metabolism)is a substrate for the DA reuptake system and that its specific transport into nigrostriatal DA terminals may be a mandatory determinant for its selective DA toxicity.Cotreatment with amphetamine completely prevented MPTP toxicity. The protectivity of amphetamine is probably not linked to its effects on DA release(since reserpine was ineffective)but may be due to inhibition of DA reuptake and/or of MAO activity.Once inside the DA terminal,MPTP may cause neuronal damage via formation of free radicals such as superoxides.However,combined administration of MPTP with the antioxidants ascorbic acid and alphatocopherol and with dimethylsufoxide,a scavenger of hydroxyl radicals,did not affect MPTP toxicity.Autooxidation of L-dopa generates free radicals and it might augment toxic effects of MPTP.However,cotreatment with L-dopa partially suppressed MPTP-induced striatal DA reductions.Protective effect of exogenous L-dopa may be linked to competition of the formed and released DA molecules with MPTP on the DA reuptake system and/or on MAO-B.

350.7 NEUROTOXICITY OF SYSTEMIC MONOSODIUM GLUTAMATE IN THE ADULT RAT: ANALYSIS WITH SILVER STAIN DEGENERATION TECHNIQUES. S. Meharg,* T.T. Dinh* and S. Ritter. College of Veterinary Medicine. Washington State University, Pullman, WA 99164

Glutamate is an excitotoxic substance capable of destroying neuronal cell bodies when administered in high doses. Olney and his colleagues have established that systemic administration of monosodium glutamate (MSG) damages circumventricular organs (CVOs). Since glutamate does not readily enter the brain, it has been generally accepted that the toxicity induced by systemic administration of MSG is limited to circumventricular structures. However, the pattern of neuronal degeneration in the brain after systemic administration of MSG has not been fully analyzed. Since silver impregnation methods selectively label degenerating neurons, we felt that this technique might provide useful information regarding the neurotoxicity of systemic MSG for neural structures both within and outside the blood-brain barrier. Therefore, we injected adult female Sprague-Dawley rats with MSG (2 or 6 g/kg, s.c.) or equiosmotic concentrations of NaCl, sacrificed them 0, 6, 20, 36 and 120 hrs later, and prepared the brain tissue for microscopic analysis using a modification of the Carlsen-de Olmos cupric silver technique.

Neuronal degeneration was observed in MSG-treated rats, but not in NaCl-treated rats. Both doses of MSG produced marked degeneration with a similar anatomical distribution. As expected from previous work, MSG caused extensive degeneration within the CVOs. In the CVOs, the degeneration was most evident between 6 and 20 hrs after injection but was extensively present in these structures as soon as 20 min after MSG. In addition, axon and terminal staining, especially at the later time points, occurred in several structures known to receive afferent input from the subfornical organ. These sites include the bed nucleus of the stria terminalis, the nucleus medianus, the OVLT, and the paraventricular nucleus of the hypothalamus. Furthermore, discretely localized degeneration was present in a rather large number of sites throughout the brain, and the affected sites were highly reproducible across subjects. These sites include the dorsomedial aspect of the inferior colliculus, nuclei gracilis and cuneatus, the intercalated nucleus of the amygdala, endopyriform nucleus, and the accumbens.

Our silver stain degeneration studies confirm the results of other techniques regarding the neurotoxicity of MSG for circumventricular organs. Furthermore, they provide additional new data regarding the distribution of MSG effects throughout the brain.

350.8 GLIOTOXIN, α-AMINOADIPIC ACID, PROTECTS AGAINST KAINIC ACID NEUROTOXICITY IN THE STRIATUM. T. Hattori and M. Takada*. Dept. of Anatomy, Univ. of Toroto, Toronto, Ontario, Canada M5S 1A8.

Treatment with L-α-aminoadipic acid (L-α-AA), a six-carbon chemical analogue of glutamate, has been shown to cause degeneration of astrocytes in cell culture of dissociated mouse cerebellum. The specific toxic effect on astrocytic population was confirmed by indirect immunofluorescence labeling with anti-human glial fibrillary acidic protein antiserum (Huck et al., Neurosci., 12: 783, 1984).

At 1-3 day survival period following in vivo stereotaxic injections of 50-500 nmol L-α-AA in 1μl of 0.05M phosphate buffer (pH 7.4) into the rat striatum, clear and intense astrocytic degeneration was observed at the fine structural level. This phenomenon was quite specific in the sense that only astrocytes were destroyed. There was a considerable amount of cytoplasmic vacuolization in astrocytes, without any noticeable effect on neighboring neurons, oligodendroglia, microglia or endothelial cells.

Three days after coinjections of 2-5 nmol kainic acid (KA) and 50-125 nmol L-α-AA in 1μl of 0.05M phophate buffer (pH 7.6-8.0) into the striatum, the degree of KA destruction was significantly reduced as compared with the contralateral striatum, which received 2-5 nmol KA alone. D-isomer of α-AA neither caused astrocytic degeneration nor protected against KA neurotoxicity.

The present results indicate that astrocytic function plays a critical role in the early stages of KA induced degeneration in the rat striatum.

350.9 PRENATAL EXPOSURE TO AMPHETAMINE OR RESERPINE ALTERS CONSUMMATORY BEHAVIOR IN ADULT RATS. R. Holson (SPON: J. Buelke-Sam), National Center for Toxicological Research, Division of Reproductive and Developmental Toxicology, Jefferson, AR 72079.

There is considerable evidence for central and peripheral monoaminergic modulation of food intake and body weight. Reserpine (R) and amphetamine (Amph) acutely affect monoaminergic neurotransmission and food intake in adults. If prenatal exposure to these drugs alters monoaminergic system development, then such alterations may be expressed in consummatory behavior. Moreover, since R and Amph have diametrically opposite effects upon central monoamines, any changes in consummatory behavior should be in opposite directions. To test this hypothesis, pregnant CD rats were given sc injections of Amph (3 mg/kg), R (0.375 mg/kg), or vehicle on gestational days 12 through 15. Two male and two female offspring from each litter were isolation-caged at postnatal day (PND) 70, and subsequently tested for: (1) baseline food and water intake (various ages); (2) intake of sweetened solutions (PND 80-90 and again after PND 210); (3) weight gain on a "junk food" diet (PND 100-120); (4) weight loss from quinine adulteration of water or restricted temporal food access (PND 127-133 and 145-155, respectively); and (5) acute anorexia caused by ip Amph or fenfluramine. Litter means were used as the statistical unit in all data analysis. It was found that prenatal Amph or R did not alter baseline body weight or food and water intake. Further, neither treatment altered weight loss under any of the above challenges. Prenatal R and Amph exposure did increase intake of sweetened solutions by 40%, (0.25% saccharin plus 3% glucose in particular) and this effect could still be seen on PND 210. R but not Amph exposure also elicited a 20% greater weight gain on the "junk food" diet. It is concluded that prenatal exposure to drugs which alter monoaminergic neurotransmission can elicit enduring changes in some measures of consummatory behavior.

350.10 STIMULATION OF CENTRAL ADRENERGIC RECEPTORS REDUCES CHOLINESTERASE INHIBITOR TOXICITY IN MICE. J.J. Buccafusco and R.S. Aronstam. Dept. Pharmacology and Toxicology, Medical College of Georgia and V.A. Medical Center, Augusta, GA 30912.

Recent studies in this laboratory have demonstrated that clonidine, a centrally-active $\alpha_2$-adrenergic agonist, affords protection against the toxic manifestations of physostigmine (J. Pharmac. Exp. Ther. 222, 595, 1982). This protection is mediated through stimulation of central $\alpha_2$-adrenergic receptors which decreases acetylcholine synthesis. This study was designed to determine whether stimulation of central adrenergic receptors affords protection against the irreversible inhibitor, soman (GD). ICR mice (25-34g) were injected s.c. with drugs administered in a volume of 5ul/g body weight. Lethal dose-response curves were constructed using 3-5 doses of GD. $LD_{50}$ values were obtained by linear regression analysis of log dose vs probit of % lethality plots ($r > 0.9$ in all cases). The LD curve for GD occurred over a very narrow dose range (0.1-0.2mg/kg) with an $LD_{50}$ of 0.156. Pretreatment with clonidine (CL) 5 min prior to GD afforded protection against the lethal effects of the cholinesterase inhibitor. Protection was maximal at 1mg/kg of CL. This dose shifted the LD curve for GD 1.25 fold to the right. Pretreatment with atropine (25mg/kg) also afforded protection against GD lethality, shifting the LD curve for GD 1.22 fold. When CL (1mg/kg) and atropine (25mg/kg) were combined in a pretreatment regimen, the LD curve for GD was shifted 1.8 fold. This shift for combined treatment is greater than that expected from the sum of the individual protective actions. Guanfacine (GF), a clonidine-like drug also inhibited the lethal effects of GD. The most effective dose of GF was 5mg/kg. Pretreatment with GF shifted the LD curve for GD 1.78 fold. In combination with atropine, GF shifted the LD curve for GD 2.33 fold. Methyldopa (MD) is a centrally-acting adrenergic agonist which is structurally dissimilar from CL. MD also is transformed within central neurons to its active metabolite, methylnorepinephrine. MD exhibited maximal protection against GD-induced lethality at 500mg/kg. Pretreatment with MD shifted the LD curve for GD 1.93 fold to the right. In combination with atropine, MD shifted the LD curve for GD 2.79 fold. For the 3 $\alpha_2$-adrenergic agonists tested, the order of effectiveness, alone, or in combination with atropine, was: MD > GF > CL. The order of potency was the reverse Combined treatment with atropine potentiated the protection afforded by the adrenergic agonists. These results support the validity of using combinations of pre-and post-synaptic inhibitors of cholinergic transmission to maximize protection from irreversible, organophosphate cholinesterase inhibitors. Supported by DAMD17-84-C-4117 and the Veterans Administration Medical Center.

350.11 GUANETHIDINE IS TOXIC TO NORADRENERGIC AND DOPAMINERGIC NEURONS IN CULTURES FROM RAT LOCUS CERULEUS AND SUBSTANTIA NIGRA. L. Friedman* and C. Mytilineou (SPON: M.D. Yahr), Department of Neurology, Mount Sinai Sch. of Med., New York, NY 10029.

Guanethidine is a ganglionic blocking agent which destroys the peripehral adrenergic neurons after in vivo administration to rats. Degeneration of sympathetic neurons occurs also in tissue culture, after treatment with 100 uM guanethidine, but only if the incubation medium is alkaline (pH 8.0) during the first 48 hrs of exposure to the drug (Wakshull et al., J. Cell Biol., 79:121, 1978). Intracranial injections of guanethidine have failed to induce toxicity to the neurons of the locus ceruleus.

We now report that guanethidine can be toxic to central norepinephrine (NE) and dopamine (DA) neurons in culture, at concentrations from 10 to 100 uM and physiological pH (7.2). Dissociated cultures were established from the dorsal pontine area (locus ceruleus) and ventral midbrain (substantia nigra) from fetal rat brains during the 14th day of gestation. From days 7 to 20 in vitro, cultures were treated with guanethidine at concentrations of 10 to 100 uM. Treated cultures were indistinguishable from controls by phase contrast microscopy during the entire period of treatment, indicating no generalized cytotoxic effect. On day 21 both control and guanethidine treated cultures were examined by CA histofluorescence after incubation with 10 uM alpha-methyl-NE for 30 min, to assure visualization of all CA neurons present. Exposure to 10 uM guanethidine resulted in reduced number of fluorescing neurons, while at 100 uM the cultures contained either none or very few faintly fluorescing neurons. The efficacy of guanethidine to use the CA uptake pump was tested by measuring the inhibition of 3H-NE and 3H-DA uptake in cortical and striatal synaptosomal preparations from adult rats. A potent inhibition was observed in the cortex (50% inhibition at 0.5 uM), while in the striatum inhibition occured only at guanethidine concentrations of 10 uM or higher. However, the cytotoxic effect of guanethidine in culture was similar to both NE and DA neurons.

It has been suggested (Manning et al., J. Neurosci., 3:714, 1983) that the sympathectomy produced by in vivo administration of guanethidine to rats results from an immune reaction of this animal species to the drug accumulated within the sympathetic neurons. Our results indicate that guanethidine can induce toxicity to central CA neurons in culture, via a mechanism that does not involve participation of the immune system. (Supported by NIH grant NS 18979).

350.12 A BEHAVIORAL TERATOGENIC INVESTIGATION OF THE ADRENERGIC AGONISTS CLONIDINE AND LOFEXIDINE IN THE RAT. W. J. Pizzi, R. Holson*, M. Giacinto* and S. Tarchala*. Division of Teratogenesis Research, National Center for Toxicological Research, Jefferson, AR and Department of Psychology, Northeastern Illinois Univ., Chicago, IL 60625.

Clonidine is a widely used antihypertensive agent with a potential for expanded therapeutic application in combating drug withdrawal symptoms in opiate and alcohol addiction. Recently, clonidine (CLO) and an analogue lofexidine (LOF) have been shown to block the opiate withdrawal syndrome in a variety of species, including man. One new application of these agents may be as an alternative to methadone maintenance with pregnant opiate addicts. Any consideration along these lines will require screening for reproductive outcome and behavioral teratogenic effects.

Dame were given s.c. injections of CLO (0.16 or 0.64 mg/kg) or LOF (0.64 or 2.56 mg/kg) once daily from GD 8-20. The doses employed were sufficiently high to cause a dose-related decrease in maternal weight gain. Pups also showed a decrease in birth weights which was still evident at PND-15 in all drug conditions. No significant differences were obtained on negative geotaxis, an auditory startle test, or a series of swimming immobilization tests across the periadolescent period. A series of activity measures carried out on PND-12, 14, 16, and 18 showed minor differences, probably related to decreased body weights in the high dose LOF male animals, but not in any of the other drug-treated groups.

A second set of experiments utilized clonidine and the ALZET osmotic minipump. On GD-9, three groups of animals were implanted s.c. with 14-day pumps, and CLO was infused at an initial dose of either 30, 60, or 120 mcg/kg/day. Three additional groups received the same doses via s.c. injections. Assessment of reproductive outcome and developmental landmarks was carried out, as well as administration of a series of developmental screening tasks for behavioral teratology (similar to those described above). No remarkable differences were seen on any of these measures. The offspring of an F-1 mating of these groups also failed to show reproductive or behavioral teratology.

Based on these developmental and behavioral data, along with normal litter sizes and survival rates, it is tentatively concluded that clonidine and lofexidine are not potent behavioral teratogens.

350.13 ORAL POLYCHLORINATED BIPHENYLS ELEVATE URINARY HOMOVANILLIC ACID: DETERMINATION OF CENTRAL CONTRIBUTIONS. K. O. Brosch* and R. F. Seegal. (Spon: J. Peck). Wadsworth Center for Labs and Research, N.Y. State Department of Health, Albany, NY 12201.

Occupational exposure to polychlorinated biphenyls (PCBs) induces neurological dysfunctions (Fischbein et al., Ann. NY Acad. Sci., 320:703,1979; Chia and Chu, Prog. Clin. Biol. Res., 137:117,1984) and experimental exposure induces neurochemical changes in laboratory animals (Agrawal et al., Toxicol. Lett. 7:417,1981; Seegal et al., Neurotoxicol., 6 :13,1985). We have reported (Seegal et al.,NSA, 8:83,1982; J. Tox. Envir. Hlth.,in press) that exposure to PCBs results in elevation of urinary homovanillic acid (HVA), a major metabolite of dopamine. We now report that the PCB-induced elevation in urinary HVA is due to increased central production of HVA.

Adult male rats were gavaged with either corn oil (controls) or corn oil containing Aroclors 1254 and 1260 at a final dose of 1000 mg/kg (approximately 1/10th the oral $LD_{50}$). 24h urine collections were made on alternate post-gavage days. On days 10 and 11, PCB and control animals received a single IP injection of debrisoquin sulfate (20 mg/kg). Debrisoquin is a peripheral monoamine oxidase inhibitor that does not cross the blood-brain barrier (Kendler et al., Eur. J. Pharm., 71:321, 1981) and results in suppression of peripheral HVA production. Thus, after treatment with debrisoquin, any HVA measured in the periphery should be of central origin. Concentrations of HVA were determined by high-performance liquid chromatography with electro-chemical detection. Results are expressed as µg HVA/24h.

PCB exposure led to a decrease followed by a prolonged elevation in urinary HVA. Debrisoquin induced a 20 µg/24h decrease in urinary HVA production in both groups. This reduction is approximately equal to 30% of the total HVA measured in the periphery and is similar to the percentage of peripheral over total HVA measured in the periphery by Kendler et al., (1981). The PCB/debrisoquin-treated animals continued to demonstrate a significant elevation in urinary HVA compared to corn-oil/debrisoquin controls. 48h after the last injection, both groups returned to their pre-injection HVA levels.

Thus, the continued elevation of HVA in the PCB/debrisoquin-treated animals is presumably central in origin and suggests that the PCB-induced elevation in urinary HVA is due to altered central factors rather than to increased peripheral production of HVA. These results strengthen the case for the measurement of peripheral concentrations of monoamine metabolites as useful indicators of central function.

350.14 SEXUAL DIFFERENTIATION OF NEURAL AND NONREPRODUCTIVE BEHAVIORAL FUNCTION: EFFECT(S) OF DEVELOPMENTAL CHLORDECONE EXPOSURE. C.F. Mactutus, Lab. Behav. Neurol. Toxicol., NIH-NIEHS, Research Triangle Park, NC 27709.

The neurotoxic profile produced by developmental exposure to chlordecone has been previously shown to vary as a function of a number of factors including gender of the animal and prior test experience. While the estrogenic-like activity of chlordecone remains the putative explanation for the occurrence of its sex-dependent sequelae, little effort has been made to dissociate any enduring effects of this compound from its long half-life. The purpose of the present study was to determine the influence of developmental exposure to chlordecone on sexual differentiation with respect to neural and nonreproductive behavioral function. If chlordecone has an organizational effect on neural tissue, a neonatal day 4, but not a day 11 exposure should produce sexually-dimorphic alterations. If the consequences of chlordecone exposure, however, are more likely attributable to its presence in neural tissue (an activational effect), the alterations following day 11 exposure should be greater than those after day 4 exposure.

Fischer-344 rat pups, bred in our laboratory, were administered a single s.c. injection (20 µl) of either corn oil or of 1 mg/10 g chlordecone dissolved in corn oil. The pups of eight litters were injected on postnatal day 4, while the offspring of eight other dams were injected on day 11. Because of the potential influence of early and/or prior test experience, only one half of the pups of each litter were tested as preweanlings; all animals were tested upon maturation to adulthood. Early body weights were significantly depressed by the chlordecone, and to a greater extent by the earlier exposure. Consistent with an organizational effect, chlordecone induced a sexually-dimorphic alteration of adult body weight following the day 4, but not day 11, injection. An enhancement of the auditory startle response (day 20) by chlordecone as well as a long-term alteration in low-frequency body movement (day 120) also displayed sex-dependent effects following the earlier, but not later, exposure. On the other hand, chlordecone-induced tremor was significantly greater in animals exposed on day 11 than on day 4 (days 14 and 20). Other evidence consistent with an activational effect was noted on early measures of activity in a novel environment (day 15) and a lack of suppression of activity during the presentation of a novel tone (day 19). In no instance were long-term alterations detectable which were readily attributable to an activational effect, i.e., a persistent effect after the day 11, but not day 4, injection. Pronounced effects of prior test experience, however, were observed and interacted with the early chlordecone exposure. These latter findings suggested the choice of experimental design is an important determinant of the expression of subtle long-term functional alterations.

350.15 PROCONVULSANT AND ANTICONVULSANT PROPERTIES OF ISOMERS OF HEXACHLOROCYCLOHEXANE IN AMYGDALOID-KINDLED RATS. L.G. Stark, T.E. Albertson and R.M. Joy. Health Sciences Neurotoxicology Unit, Schools of Medicine and Veterinary Medicine, University of California, Davis, Ca. 95616.

Our previous studies have shown that treatment of rats with gamma-hexachlorocyclohexane (lindane) produces a dose-dependent increase in brain excitability which facilitates the acquisition and retention of kindled amygdaloid seizures. There is evidence from Matsumura and Tanaka (Cellular and Molecular Neurotoxicology, Ed. by T. Narahashi, New York, Raven Press, 1984, pp.225) that there may be important differences in the activity of the isomers of hexachlorocyclohexane (HCH) in insect muscle and rat superior cervical ganglion. The purpose of the work reported here was to compare several of the isomers of HCH with respect to their influence on the acquisition and expression of kindled amygdaloid seizures. In the first study, rats in 4 treatment groups (corn oil vehicle, or 5 mg/kg daily exposures to gamma-, beta-,or alpha-HCH) were given once-daily amygdaloid stimulations for 15 days and measurements of afterdischarge duration and seizure severity were recorded. The results confirmed previous work in the case of gamma-HCH showing proconvulsant activity and shorter times for acquisition of the kindled response. Alpha- and beta-HCH treated rats did exhibit delayed rates of kindling acquisition with the most notable difference in the beta-HCH group. The second study expanded the inital observations by comparing corn oil treatment with 3 dose-levels of exposure to the beta isomer (5,10 and 20 mg/kg). All rats were pretreated for two days before amygdaloid stimulations were begun and the combined treatment/stimulation protocol was continued for 12 more days. There was a dose-dependent decrease in the rate of acquisition of the kindled response due to the treatment with beta-HCH and both the average seizure severity and afterdischarge duration were diminished in a dose-dependent manner. Once treatment with the isomer was stopped, rats in the 3 groups did kindle with additional stimulations. These findings extend to whole brain the observation that significant differences do exist among the isomers of HCH with respect to their proconvulsant and anticonvulsant effects in the mammalian central nervous system.

350.16 GLUCOSE UPTAKE IN THE DEVELOPING RAT BRAIN UPON PRE- AND POSTNATAL EXPOSURE TO TRICHLOROETHYLENE. E.A. Noland-Gerbec*, R.J. Pfohl, D.H. Taylor*, and R.J. Bull§. Dept. of Zoology, Miami University, Oxford, OH 45056 and §College of Pharmacy, Washington St. University, Pullman, WA 99164.

Trichloroethylene (TCE) is a widespread contaminant of drinking water sources. The effects of TCE on glucose uptake by brain tissue were examined in pups from rat dams exposed to TCE in their drinking water. The pups were exposed throughout gestation and lactation. Glucose uptake in the cerebellum, hippocampus, and whole brain of pups during the first 21 days of life was measured with the $^{3}$H-labeled 2-deoxy-D-glucose dissection/scintillation counting technique. We determined that 312 mg TCE/l significantly depressed glucose uptake in the whole brains and cerebella of 7- to 21-day old pups. Glucose uptake was also lower in the hippocampus of exposed pups at 7, 11, and 16 days, but recovered to control levels by 21 days. No overt toxicity, such as lower body or brain weight, was observed at this exposure level.

## OPIOIDS: PHYSIOLOGICAL STUDIES IV

351.1 THE EFFECT OF MORPHINE ON CELL SURVIVAL AND ACETYLCHOLINE METABOLISM IN THE CULTURED AVIAN CILIARY GANGLION. D.B. Gray, Dept. of Physiology and Neurobiology, Univ. of CT, Storrs, CT 06268.

Morphine, as well as enkephalins, is known to have neuromodulatory activity including postsynaptic hyperpolarization and presynaptic inhibition of transmitter release, both in vivo and in cultured ciliary ganglion neurons.[1] Since cultured ciliary ganglion cells contain enkephalin-like immunoreactivity,[2] it is possible that apiates may modulate transmitter release or synthesis at neuromuscular synapses. In order to determine if morphine had any effect on neuromuscular transmission in vitro, E9 chick ciliary ganglion neurons were dissociated and plated with E11 striated muscle cells. These cultures have been previously used as a sensitive measure of presynaptic ACh release at neuromuscular synapses,[3] by measuring ACh synthesis after high K+ (56mm) preincubation. In control co-cultures, neuronal ACh synthesis increased by >60% immediately after high K+ stimulation in order to compensate for transmitter release (not seen in cultures of neurons alone). When 5 µm morphine was added to the high K+ preincubation, ACh synthesis rates did not increase but decreased by 17%. This effect appears to be mediated through a presynaptic opiate receptor since addition of both morphine and naloxone (at 5 µm) to the preincubation solution restores the compensatory increase in ACh accumulation. In support of this data, addition of 5 µm morphine to co-cultures significantly reduces the total recoverable ACh secreted into the incubation solution follwoing stimulation by high K+ Tyrodes.

Effects of chronic administration of morphine were also examined since it is known that daily injection of opiates can delay cell death in the developing chick ciliary ganglion (Meriney & Pilar, this volume). In cultures of E9 neurons alone, addition of chick embryo extract is necessary for survival past 2-3 days. In order to determine whether a classic opiate can replace chick embryo extract in vitro, growth media containing morphine sulphate (5 to 50 µm), but not chick embryo extract, was given to E9 chick embryo ciliary ganglion neurons plated upon dried collagen-coated microwells. More than 80% of neurons died within 72 hours after plating, and showed no significant difference from cultures without either extract or morphine. Thus it is clear that morphine cannot replace chick embryo extract in these cultures. These results appear not to be due to a toxic effect of morphine since cultures grown in media with both 10% embryo extract and 50 µm morphine are normal in appearance and number over all times examined. Supported by BSN 8410581.

351.2 INCREASES IN MEDIAN EMINENCE GLUCOSE UTILIZATION AND SUPPRESSION OF PLASMA PROLACTIN LEVELS BY NALOXONE IN RATS. R.C. Walovitch, M.K. Selmanoff, F. Snyder* and E.D. London. Neuropharmacology Lab., NIDA Addiction Research Ctr., Baltimore, MD 21224 and Dept. of Physiology, Univ. of Maryland, Sch. of Medicine, Baltimore, MD 21201.

Opioids stimulate prolactin secretion in mammals (Shaar, C.J. and Clemens, J.A., Fed. Proc., 39:2539, 1980). This effect is suppressed by opioid antagonists, which alone can decrease basal levels and stress-induced elevations of prolactin (Blank, M.S. et al., J. Endocrinol., 85:307, 1980; Ragavan, V.V. and Frantz, A.G., Life Sci., 28:921, 1981). The opioid-induced increase in prolactin secretion may be mediated by inhibition of dopamine release from the tuberoinfundibular dopaminergic (TIDA) neurons (Gudelsky, G.A. and Porter, J.C., Life Sci., 25:1697, 1979).

In order to study further the relations between endogenous opioid systems, the activity of TIDA neurons and prolactin secretion, we administered naloxone (1, 10, or 20 mg/kg, iv) to 4-6 months old male Fischer-344 rats, and measured plasma prolactin levels and glucose utilization in the arcuate nucleus and median eminence, brain regions which contain the TIDA neuronal cell bodies and terminals, respectively. Plasma prolactin concentrations were measured using a double antibody radioimmunoassay in samples taken prior to, and at 5, 10, 15, and 30 min after naloxone administration. Glucose utilization was measured using the 2-deoxy-D-[1-$^{14}$C]glucose ([$^{14}$C]DG) method (Sokoloff, L. et al., J. Neurochem., 28:897, 1977). All animals used in the study were partially immobilized for 3-4 hr and received [$^{14}$C]DG (125 µ Ci/kg, iv) 5 min after placebo or naloxone.

Mean plasma prolactin concentrations doubled during the first 15 min following the placebo injection. This increase was attributed to stress associated with handling of the rats and blood sampling before and during the [$^{14}$C]DG procedure. At doses of 1 mg/kg or 10 mg/kg, naloxone reduced the stress effect on plasma prolactin; whereas, 20 mg/kg naloxone reduced prolactin levels by 40% below the baseline at all times sampled. Glucose utilization in the arcuate nucleus was unaffected by naloxone treatment. In contrast, all doses of naloxone increased glucose utilization in the median eminence by approximately 30%. The increase in glucose utilization of the median eminence is consistent with a blockade by naloxone of the tonic inhibition of TIDA neurons by central opioid systems. The metabolic activation of the median eminence also may reflect an opioid modulation of other neurotransmitter systems which project to the median eminence. (Supported in part by a fellowship from E.I. DuPont De Nemours and Co. to RCW)

351.3 THE HOT PLATE, TAIL-FLICK AND ABDOMINAL CONSTRICTION (WRITHING) TESTS OF ANALGESIA ARE NOT MEASURING THE SAME PHENOMENA. J.K. Belknap, P.W. Danielson* and J. Buegel.* Dept. of Pharmacology, Univ. of North Dakota, School of Medicine, Grand Forks, ND 58202.

Mice were selectively bred to be either highly sensitive (high response line) or highly resistant (low response line) to the antinociceptive effects of i.p. levorphanol (a morphine-like analgesic) on the hot plate assay (52.5°C). Over each of seven generations, all animals were hot plate-tested (N=200-260) and the highest scoring quartile of the high response line and the lowest scoring quartile of the low response line were bred to produce each succeeding generation in the high and low lines (lineages), respectively. This resulted in about a 3-fold difference between the lines in the i.p. or i.c.v. dose of levorphanol (and also morphine) required to produce an equivalent degree of analgesia in Generation 7. Since all of these animals were raised and tested under equivalent conditions, these differences between the high and low response lines are genetic in origin. These selection lines differ only slightly in hot plate latencies following saline injections, and they do not differ at all in brain levorphanol or morphine concentrations following equivalent i.p. doses of either narcotic analgesic.

We sought to determine if these large differences (∿300%) in analgesia bred into the high and low response lines with respect to the hot plate assay would generalize to two other commonly used tests of analgesia, namely the tail-flick and abdominal constriction tests. The tail-flick test was administered 20 min following a single 0 - 2.0 mg/kg i.p. dose of levorphanol tartrate. Only a 10-25% difference between the high and low lines was seen in either latency to respond or in the temperature at which a tail-flick occurred. The abdominal constriction test was administered in separate groups of mice by counting the number of abdominal constrictions following 0.6% acetic acid i.p. and 0-.8 mg/kg levorphanol tartrate s.c. Only small differences (20-40%) between the high and low lines were seen.

In sum, animals selectively bred to show either very high and very low analgesic responses on the hot plate assay showed rather small differences (although in the expected direction) when tested on two other tests of analgesia. These data suggest that the mechanisms causing the hot plate assay differences between highs and lows are largely different from those operating with the other two tests of analgesia. Thus, there appears to be little commonality in the mechanisms underlying hot plate-assessed analgesia vis a vis the tail-flick and abdominal constriction assays. (Supported by PHS Grant DA 02723)

351.4 INCREASED ADENYLATE CYCLASE ACTIVITY IN MOUSE SPINAL CORD-DORSAL ROOT GANGLION(DRG) EXPLANTS RENDERED TOLERANT BY CHRONIC EXPOSURE TO MORPHINE. B.Dvorkin*, S.M.Crain#, and M.H.Makman (SPON:E.J.Simon). Depts. of Biochemistry, Neuroscience# and Molecular Pharmacology, Albert Einstein College of Medicine, Bronx, N.Y. 10461.

Acute exposure of fetal mouse cord-DRG explants to morphine and other opioids results in naloxone-reversible depression of DRG-evoked dorsal-horn synaptic-network responses. After chronic opiate exposure (1uM) for 2-3 days, these dorsal cord networks become tolerant even to much higher opioid concentrations (Crain etal ´79). A similar "acute tolerance" to opioids is elicited by brief exposure of explants to forskolin or high levels of cyclic AMP (Crain etal ´84), suggesting that tolerance following chronic exposure to opioids is mediated by enhancement of the adenylate cyclase/cyclic AMP (AC/cAMP) system (e.g. Sharma etal´75).

For measurements of AC, 6-8 fetal mouse cord-DRG cultures (ca. 3 wks in vitro) were pooled and homogenized for assay of the particulate(membrane) fraction. AC activity of control homogenates was stimulated by addition of forskolin (+204%) and naloxone (+68%); forskolin-stimulated AC was inhibited by levorphanol but not by dextrorphan. Chronic exposure of cord-DRG cultures to 1uM morphine for 4-7 days, starting at 2 wks in vitro, resulted in enhanced basal (+46%), as well as forskolin-stimulated (+70%), and naloxone-stimulated (+68%) AC activity; also, levorphanol no longer inhibited forskolin-stimulated AC.

There is increasing evidence that opioid effects on AC are mediated by a GTP-regulatory protein, $G_i$, and that these effects are blocked by pertussis toxin(PT)-induced ADP-ribosylation of $G_i$. In preliminary experiments, treatment of cord-DRG cultures for 5 days with PT (1ug/ml) led to enhancement of basal- and forskolin-stimulated AC, comparable in magnitude to that produced by chronic morphine; also, opioid inhibition of forskolin-stimulated AC was greatly diminished. It is postulated that $G_i$ normally mediates tonic inhibition of AC by endogenous opioids and/or other modulators in cord-DRG cultures. This interpretation is supported by the ability of naloxone to stimulate AC (see above) and to enhance dorsal-horn responses (Crain etal ´77) in control cultures. Chronic opioid exposure may then increase tonic inhibition of AC by endogenous opioids, which in turn results in compensatory enhancement of the AC/cAMP system.

Since opioid-sensitive AC and opioid receptors are widely distributed in cord-DRG cultures, further studies are required to determine if chronic opioid treatment induces specific alterations in AC activity and cAMP levels of the dorsal-horn regions which result in the physiologic expression of tolerance. 351.5 Ovarian Steroids Decrease the Hypothermic and LH Responses to Morphine L.A. Berglund*, W.R. Anderson, M.J. Katovich and James W. Simpkins, Department of Pharmacodynamics, College of Pharmacy, University of Florida, Gainesville, FL 32610.

Studies were undertaken to determine the effects of an ovarian steroids regimen, which induced a surge in LH secretion, on the ability of morphine to suppress LH release and to induce hypothermia in the female rat. Two weeks after ovariectomy, rats received no steroids (OVX) or a steroid regimen consisting of 7.5 ug estradiol benzoate s.c. in oil at 1000 h and 5 mg progesterone, s.c. in oil 48 hours later. In the first experiment, serum LH concentrations were determined at 1600 h, 30 min after the administration of saline or 7.5 to 20 mg morphine sulfate/Kg BW. In OVX rats, morphine caused a dose-dependent decrease in serum LH concentrations. (Serum LH = 5.8± 0.8 ng/ml for saline; 2.8±0.4 ng/ml for 7.5 mg morphine/Kg BW, and 1.4±0.3 ng/ml for 10.0 mg morphine/Kg BW). In contrast, morphine, at doses as high as 20 mg/Kg BW, did not significantly alter serum LH levels during the steroid-induced LH surge at 1600 h. (Serum LH = 51.4±8.7 ng/ml for saline; 53.1±9.7 ng/ml for 10 mg morphine/Kg BW: and 49.8±10.8 ng/ml for 20 mg morphine/Kg BW). In a second experiment we determined if also the hypothermic effects of morphine were altered by steroid treatment. OVX rats were treated with gonadal steroids as indicated above and were compared to OVX rats which received no steroid treatment. At 1630 h, animals were lightly restrained, fitted with rectal thermistor probes and allowed 0.5h to acclimate. Then rats were administered morphine sulfate (20 mg/Kg BW, sc) and rectal temperatures were monitored at 2-5 min intervals for an additional 3 h. In OVX rats, morphine caused a 1.85±0.35° C decrease in rectal temperature. In contrast, in rats treated with steroids, the morphine-induced decline in rectal temperature was 0.64±0.2°C. Collectively, these data indicate that a gonadal steroid regimen, which is stimulatory to LH secretion, abolishes the capacity of morphine to suppress LH release and to lower core body temperature. It would appear that the brain opiate receptors which mediate the effects of morphine on LH secretion and body temperature are rendered insensitive during the steroid-induced LH surge. This may contribute to the series of neuronal events which mediate steroid-induced LH hypersecretion and the change in core body temperature associated with ovulation. (Supported in part by NIH grants AGO2021 and HD 18133).

351.6 THE EFFECTS OF RESTRAINT AND NALTREXONE ON THE HEART-RATE RESPONSE TO MORPHINE. K.S. Schwarz*, J. Peris, * & C.L. Cunningham* (SPON. J. O'Brien). Dept. of Medical Psychology Oregon Health Sciences Univ., Portland, OR 97201

Previous reports about the heart-rate effects of morphine in rats suggest that only a decrease in heart rate (bradycardia) occurs following intravenous (i.v.) administration. However, our studies show that when a freely-moving rat is allowed time to habituate to the apparatus, morphine causes a transient bradycardia followed by a large increase in heart rate (tachycardia).

In each experiment, two cardiac electrodes and one jugular-vein cannula were surgically implanted into male albino rats a few days before the start of testing. During all test sessions, rats were put into chambers 1 hr before i.v. morphine infusion and remained there for 2 more hrs. Heart rate was recorded for each minute of each session.

Experiment 1 assessed the effects of five doses (0, 0.5, 2.0, 5.0 & 10.0 mg/kg) of morphine in restraint-stressed and freely-moving rats. The restraint condition elevated baseline heart rate (406 vs 353 bpm). Overall, morphine resulted in a biphasic response: bradycardia followed by tachycardia relative to pre-infusion baseline. Both the magnitude and duration of bradycardia were enhanced by restraint. In freely-moving rats, the initial bradycardia was quickly replaced by a longer-lasting, greater-magnitude tachycardia. These effects increased as dose increased. These results suggest that the level of stress may be an important factor in determining the predominant direction of the heart-rate response to morphine.

Experiments 2 & 3 attempted to determine if the bradycardia and tachycardia were direct morphine effects. Only freely-moving rats were used. In Experiment 2, saline or naltrexone (5 mg/kg) was injected subcutaneously before placement into the chamber. Naltrexone blocked both the bradycardic and tachycardic reactions of the 8 mg/kg dose of morphine. These results suggest that both the decrease and increase are direct morphine effects; however, we could not eliminate the possibility that the increase in heart rate was simply dependent on the occurrence of the initial bradycardia. We tested this in Experiment 3 by delaying the infusion of naltrexone until after morphine-induced bradycardia had occurred. Specifically, morphine (8 mg/kg) was infused i.v. and was followed 45 min later by an i.v. infusion of saline or naltrexone (5 mg/kg). We conclude that both the bradycardia and tachycardia are opiate-mediated and, furthermore, that the tachycardia is independent of the bradycardia.

351.7 INVOLVEMENT OF THE CENTRAL SEROTONERGIC SYSTEM IN MORPHINE-INDUCED INHIBITION OF TSH RELEASE IN THE RAT. W.J. Litto and J. Rabii. Dept. of Biological Sciences and Bureau of Biological Research, Rutgers Univ., Piscataway, NJ 08854

It has been shown that morphine (MS), acting at a hypothalamic site, inhibits TSH release in the rat. Although the exact mechanism by which MS inhibits TSH release has not been determined, the involvement of biogenic amines in this action has been postulated. In the present study we have looked at the effects of pharmacological and surgical manipulations of the central serotonergic system on the ability of MS to inhibit TSH release in adult male rats. Animals in these experiments were implanted with chronic right atrial cannulae, under light ether anesthesia, at least 48 hours prior to MS challenge (intravenous). In the first experiment, animals were treated with either p-chlorophenylalanine (PCPA; 250 mg/kg IP), or saline. Forty-eight hours later a blood sample was withdrawn followed by a MS injection (7 mg/kg). Subsequent blood samples were then withdrawn 30 and 60 min after MS injection. In a second experiment, groups of animals were subjected to either dorsal raphe nucleus (DR) lesions (electrolytic), or were sham-operated. One week following surgery, an initial blood sample was taken followed by 1 mg/kg MS. Subsequent blood samples were withdrawn 15, 30, and 60 min following MS injection. In a third experiment, following an initial blood sample, animals were treated with SQ-10631 (10 mg/kg) or vehicle. Sixty min following this treatment, a second blood sample was taken, followed by MS injection (1 mg/kg). Subsequent blood samples were then taken 30 and 60 min following MS treatment. In all experiments, blood samples were centrifuged and the plasma collected and stored frozen until assayed for TSH by RIA. In the first experiment, MS produced significant inhibition of TSH release in the vehicle-treated animals, but did not effect TSH release in PCPA-treated rats. In the second experiment, MS produced significant declines in TSH at all times tested in the sham-operated group, but had no effect on TSH in the DR-lesioned animals. In the third experiment, pretreatment with SQ-10631 eliminated the inhibition of TSH produced by MS that was observed in the vehicle pretreated group. In conclusion, the inhibition of TSH release produced by MS may involve the central serotonergic system. (Supported by the Busch Memorial Fund.)

351.8 FURTHER CHARACTERIZATION OF THE TEMPORAL EFFECTS OF MORPHINE ON PROLACTIN RELEASE IN MALE RATS. J. Janik*, P. Callahan*, L. Grandison and J. Rabii. (SPON: M.T. Spoerlein). Dept. Bio. Sci., Rutgers Univ. and Dept. Physiol., UMDNJ, Piscataway, N.J. 08854.

We have previously demonstrated that a single injection of morphine has temporal effects on the tuberoinfundibular dopaminergic neurons and that these effects are reflected in the prolactin secretory response. Treatment with morphine sulfate (MS) initially stimulates prolactin release but by 4 hours it attenuates the response to physiological and neuropharmacological stimuli of this hormone. This study was designed to further characterize the delayed, inhibitory effects of MS on prolactin release. First we examined the dose of MS which would attenuate a subsequent MS induced prolactin secretory response 4 hours later. Animals received 2.5, 5, 10, 15 or 20 mg/kg,sc MS and the prolactin secretory responses to the initial and second (challenge) injection were determined. Blood samples were obtained immediately before and 30, 45 and 60 minutes after each injection. At all doses of MS, the prolactin secretory response to the challenge injection was attenuated. MS at 2.5 and 5 mg/kg produced partial attenuation and doses of 10 and above produced complete inhibition of the prolactin response. However, the GH response to the challenge injection was not attenuated in these rats. Next, we examined whether or not the delayed inhibitory effect of morphine could be blocked by the opiate receptor antagonist naloxone. When naloxone (2 mg/kg,ip) was administered before the initial MS injection (15 mg/kg,sc), the prolactin secretory response to the challenge was no different from controls. In conclusion, MS produces a biphasic effect on prolactin secretion. There is an initial stimulation of release but by 4 hours a subsequent stimulus induced prolactin increase is blunted. These observations indicate that the delayed (4 hour) response is an opiate receptor mediated process (i.e. naloxone reversible). Furthermore, this attenuated response to the challenge is produced by morphine in a dose dependent manner. (Supported by the Busch Memorial Fund.)

351.9 ALTERATIONS IN THE SENSITIVITY OF THE PROLACTIN REGULATORY MECHANISM TO OPIATES DURING LACTATION. P. Callahan*, J. Janik*, L. Grandison and J. Rabii. Dept. Bio. Sci., Rutgers Univ., and Dept. Physiol., UMDNJ, Piscataway, N.J. 08854.

It is well established that opiate administration produces a significant increase in circulating prolactin and GH levels in male and non-lactating female rats. One of the mechanisms involved in opiate induced prolactin release is inhibition of the tuberoinfundibular dopaminergic (TIDA) neurons. We have previously reported that the morphine induced prolactin increase is not observed in lactating female rats after 2 hours of pup separation when circulating prolactin is maintained at low levels. We have attempted to further characterize the sensitivity of the lactating female model to opiate stimulation. Female rats, between 4 and 10 days postpartum, received a single injection of saline or morphine sulfate (5 mg/kg,iv or 10 or 15 mg/kg,sc). Blood samples were withdrawn and assayed for GH. In contrast to the lack of a stimulatory influence of morphine on prolactin release, a single injection of morphine produced a significant increase in GH levels at all doses. It was of interest to determine whether or not the lack of a morphine induced prolactin increase was due to the physiological state of the animal, i.e. suckling. When animals received saline on day 6 postpartum and continued nursing their pups through day 10, there was no increase in circulating prolactin levels in response to a single injection of morphine (15 mg/kg,sc) on day 10. Similarly, if animals received MS on day 6 and continued nursing, a morphine induced prolactin increase was not observed on either day 6 or 10. Animals on day 6 postpartum did not show an MS induced prolactin response following 2 hours of pup separation. However, on day 10, after 4 days of pup separation, 50% of the animals in this group showed a morphine induced prolactin increase. This is the only group in which any increase in prolactin was observed. There may be a period of recovery which is necessary before a morphine induced prolactin increase can be observed. These results indicate that the lactating female model is insensitive to morphine stimulation of prolactin, but not GH release. They also suggest that this lack of sensitivity is due to the physiological state of the animal, i.e. suckling. (Supported by the Busch Memorial Fund).

351.10 DISTINCT REPONSES TO LEU-ENKEPHALIN AND FMRFAMIDE ON IDENTIFIED NEURONS OF THE APLYSIA CEREBRAL GANGLION. K. S.-Rozsa* and D. O. Carpenter. NY State Dept. of Health, Albany, NY 12201 and Biol. Res. Inst., Hungarian Acad. Sci., Tihany, Hungary.

Neurons of the B cluster of the cerebral ganglion of Aplysia were recorded with two electrodes under current or voltage clamp and responses examined to leu-enkephalin ($10^{-4}$ M to $10^{-3}$ M) and FMRFamide ($10^{-5}$ to $10^{-4}$ M), applied by brief pressure pulses. Both substances induced a variety of responses on different neurons. By careful dissection and drawings of the ganglia it was possible to regularly identify 16 different neurons on each side within the cluster, and demonstrate a consistent response to each of the peptides on single identified cells. Of the 16 neurons in each cluster which could be identified more than half responsed to leu-enkephalin. Of the responsive neurons about half were depolarized, a quarter were hyperpolarized and the remainder showed biphasic or polyphasic responses. The depolarization was associated with an increase in membrane conductance and was reduced when $Na^+$ was replaced with choline or glucosamine. The hyperpolarizing response was slow (lasting usually 30-60 sec), was depressed by 5 mM 4-aminopyridine and sometimes could be reversed near to the $K^+$ equilibrium potential. The responses to leu-enkephalin often showed rapid and long-lasting receptor desensitization. FMRFamide elicited a depolarizing response on most of the B cells, but some neurons did not respond and some showed hyperpolarization or multiphasic responses. FMRFamide responses did not desensitize as readily as those to leu-enkephalin. While the responses to the two peptides had similar appearances, some neurons were depolarized by one and hyperpolarized by the other, indicating distinct receptors. The leu-enkephalin response was sensitive to naloxone, but only at relatively high concentrations ($5X10^{-3}$ M) which depressed the FMRFamide response to a lesser degree. These results support a possible transmitter function for both classes of peptides in Aplysia ganglia.

351.11 EFFECT OF MORPHINE ON ENKEPHALIN RELEASE. Y.Y.T. Su. Cullen Eye Institute, Baylor College of Medicine, Houston, Texas 77030.

We have recently shown that exogenously applied enkephalins inhibit $^3$H-GABA release from GABAergic amacrine cells of the chicken retina. Anatomical localization studies, using double staining techniques, further demonstrated that some GABAergic amacrine cell populations also contain enkephalin immunoreactivity (Watt et al., Nature, 311:761, 1984). These results suggested that the enkephalins may inhibit $^3$H-GABA release from those amacrine cells containing only GABA and those containing both GABA and enkephalins. In this report we show the effect of morphine on enkephalin release from the retina.

The newly synthesized enkephalins in chicken retinas were labeled with $^3$H-methionine by a pulse-labeled and chase technique described earlier (Su et al., J. Neurosci., 5:851, 1985). Briefly, the isolated retinas were incubated in oxygenated avian Ringer's solution (200 µl) containing 50µCi $^3$H-methionine (specific activity = 80 Ci/mmol) for 2 hrs. After 3 washings, the tissues were incubated in the oxygenated Ringer's solution containing methionine (0.1mg/ml) for another 2 hrs. The tissues were then utilized to study $^3$H-Met$^5$-enkephalin release.

The labeled tissues were incubated in high $K^+$ (30 mM) Ringer's solution with or without (as control) 1µM morphine, followed by several washings in normal Ringer's solution. After the release experiment the soluble radioactively-labeled compounds were extracted in 2 N acetic acid. The tissue extract was lyophilized and resuspended in PBS. Six hundred microliters of the eluent and the tissue extract were mixed with 100µl of a monoclonal anti-enkephalin IgG in ascites fluid (1:20 dilution in PBS) and incubated overnight at 4°C. The antigen-antibody complexes were precipitated with equal volume of saturated ammonium sulfate solution and resuspended in 200µl of water. The activity was measured in a scintillation counter. $^3$H-Met$^5$-enkephalin released was expressed as percentage of the total enkephalin-immunoreactivity present in the tissue.

In the presence of 1µM morphine, the high $K^+$-induced $^3$H-Met$^5$-enkephalin release was reduced to 62% of the control. These results suggest that some opiate receptors may be present on the enkephalinergic amacrine cell processes and that morphine may function as a presynaptic inhibitor as it binds to these opiate receptors. However, the inhibition induces from an indirect serial synaptic interactions can not be excluded. More studies are required to elucidate the mechanisms of the inhibition of enkephalin release.

(Supported by NIH grant EY03701).

351.12 EFFECTS OF ENKEPHALINES ON DARK ADAPTATION IN ISOLATED RETINA OF CRAYFISH. J. Flores*, P. Freijo*, I. Marquez* and N. Blazquez* (SPON:J.Hernandez). Dept. of Neurosciences, ENEP Iztacala UNAM. Los Reyes Iztacala Ap. Post. 314-54030 Edo. de Mex., México.

The presence of leucine-enkephalin (leu-enk) has been demonstrated with immunocytochemical methods in the eyestalk of Palinurus interruptus and Procambarus clarkii. It is localized in retinular cells, lamina ganglionaris, medulla interna, third optic chiasma and medulla terminalis (Mancillas, J. P., Mc. Cinty, J. F., Selverston, A. I., Karten, H. and Bloom, P. E. Nature 293:576-578, 1981). The influence of enkephalines on visual function is not clear. The aim of this study is to evaluate the possible role of leu-enk and methionine-enkephalin (met-enk) on dark adaptation.

Experiments were conducted in adult crayfishes Procambarus clarkii of either sex in C or D stage of molting cycle. The control retinas were left on physiological saline and the experimental groups on leu-enk, met-enk and naloxone salines ($10^{-6}$M to $10^{-4}$M). Electroretinograms were recorded on constant dark, using suction electrodes. Light pulses were delivered from an incandescent source (aproximate intensity of 3.16 candle/ft$^2$ and duration of 100 msec) each 3 minutes.

Leu-enk and met-enk incubated retinas showed a significant increase in the rise time of the dark adaptation curve. The effect was blocked by naloxone ($10^{-5}$M). These results suggest a possible opioid effect on dark adaptation processes.

Supported by CONACyT, México.

351.13 STEREOSPECIFIC EFFICACY OF THE OPIATE ANTAGONIST WIN44,441-3 IN THE TREATMENT OF HEAD INJURY IN THE CAT. T.K.McIntosh, V.M.Agura* M.Hellgeth‡ H.Rittner‡ A.I.Faden and R.L.Hayes. Dept. of Neurology, Univ. California Med Cntr., San Francisco, CA 94143 and Division of Neurosurgery, Medical College of Virginia, Richmond, VA 23298.

Traumatic injury to the central nervous system (CNS) may cause functional deficits through the release of endogenous factors, including endogenous opioids. Antagonism of such factors may therefore serve to limit the extent of injury, thus improving outcome. We have provided evidence that the kappa receptor and the dynorphin opioid system may play a pathophysiological role in traumatic spinal injury. Moreover, the non-selective antagonist naloxone has been found to improve several physiological parameters after fluid percussion (FP) head injury in cats. The present study compared the effectiveness of the opiate antagonist WIN44,441-3(-) (which has enhanced activity at the kappa receptor) with its inactive stereoisomer WIN44,441-2(+) in FP head injury in cats. FP simulates a number of features of concussive brain injury in humans including systemic hypotension and alteration in cerebral blood flow (CBF). Cats (2.75-3.25kg) were anesthetized with brevital (20mg/kg), intubated, paralyzed with pancuronium (0.6mg/kg) and artificially ventilated with 70%$N_2$O/30%$O_2$. Mean arterial pressure (MAP) and intracranial pressure (ICP) were monitored via a femoral arterial catheter and epidural bolt, respectively. 15 minutes following FP (3.2-3.6atm), animals were randomly assigned to treatment with an IV bolus of either WIN(-) (0.2mg/kg,n=5) or its inactive stereoisomer WIN(+)(0.2mg/kg,n=4). Sequential measurement of CBF using radiolabeled microspheres was performed 10 min prior to injury, 15 min after injury (immediately prior to drug administration) and 30 min, 1h and 2h following drug treatment.

Following a brief hypertensive event (1-3min), FP induced a significant decrease in MAP (from 150±7 to 104±8mmHg, $p < 0.05$) and whole brain blood flow (from 52±12 to 40±6ml/100g/min, $p < 0.05$). No significant change was observed in ICP. Administration of WIN(-) caused a significant increase in MAP within 5 min (mean incr=55mmHg $p < 0.05$) that was maintained for up to two hours with a concomitant increase in whole brain blood flow ($p < 0.01$). Blood flow was significantly increased to the midbrain ($p < 0.05$), brainstem ($p < 0.01$) and cerebellar regions ($p < 0.05$) where injury, evidenced by histological changes, was most severe. WIN(-) also caused a small but nonsignificant increase in ICP. Administration of WIN(+) was without effect on MAP and CBF which continued to decline over the two hour period. These results suggest that endogenous opioids, through actions at specific opiate receptors, contribute to the pathophysiology of head injury and indicate that opiate antagonists with increased activity at kappa sites may be effective in the treatment of low flow states associated with acute head injury.

351.14 IRRADIATION MODIFIES THE ANALGESIC EFFECTS OF MORPHINE. J. Aronowski*, P.M. Dougherty*, T. Samorajski, N.R. Pellis and N. Dafny (SPON: P.T. Kelley). Department of Neurobiology and Anatomy and Department of Surgery and Organ Transplantation, University of Texas Medical School and Texas Research Institute of Mental Sciences, Houston, Texas 77030.

Previous studies using the immunomodulators, α-interferon, cyclosporine A and cyclophosphamide) prior to and after subcutaneous implantation of a 75 mg morphine pellet demonstrated that the immunomodulator agents altered the opiate addiction liability as assessed by naloxone induced abstinence in morphine addicted rats. Moreover, selective ablation of the immune system via whole body irradiation of 500 rads prior to and after chronic morphine treatment had the same effect as α-interferon, cyclosporine A and cyclosphosphamide. Therefore, immunomodulator agents and irradiation alter the chronic effects of morphine and the opiate withdrawal symptoms. The investigation herein was initiated to study the effects of immunomodulator agents and the whole body irradiation on the acute effects of morphine as measured by analgesia in the tail immersion procedure.

Ten groups of male Sprague-Dawley rats (10/group) weighing 180-200 grams were treated as follows: 1) control saline, 2) Morphine (5 mg/kg ip) group, 3) α-interferon (150 units/gr/body weight); 4) 15 mg/kg cyclosporine A ip group, 5) 500 rads total irradiation, 6) three days food abstinence, 7) interferon and morphine, 8) cyclosporine A and morphine, 9) irradiation and morphine and 10) morphine in fasted animals. The reaction time observed in saline, α-IFN, cyclosporine A, irradiation and starvation (groups 1, 3, 4, 5, and 6) were identical. Groups 7, 8 and 10 (α-IFN and morphine as well as cyclosporine A and morphine) were significantly suppressed and identical to group 2, i.e. to morphine alone. In group 9, irradiation prior to morphine treatment, the analgesic effects of morphine were prevented as assessed in the tail immersion test. In conclusion, immunomodulator agents known to modify the chronic effects of morphine (opiate addiction) failed to modify the acute effects (analgesia) of the drugs. However, ablation of the immune system by whole body irradiation revealed involvement of the immune system in the analgesic effects of morphine. Therefore, the interaction of the immune system in morphine induced analgesia involves mechanisms exclusive those acted on by α-interferon, cyclosporine A, and cyclophosphamide.

351.15 EVIDENCE THAT OPIATE ADDICTION INVOLVES AN IMMUNE RESPONSE. N.E. Kletzly*, P.M. Dougherty*, J. Aronowski*, N.R. Pellis* and N. Dafny (SPON: D.A. Redburn). Department of Neurobiology and Anatomy, UTHMS, Department of Surgery and Organ Transplantation, UTHMS.

We previously reported that selective ablation of the immue system by exposure to ionizing radiation prior to and after chronic morphine treatment (pellet implantation) modified the abstinence syndrome elicited by naloxone. These observations suggest that the immune system is involved in morphine dependence and withdrawal phenomena. The present study was initiated to further assess the role of the immune system in the withdrawal from opiate addiction by selective ablation of immunocompetent cells prior to administration of morphine. Two groups of in-bred male Lewis rats (N=4) were irradiated with $^{137}Cs$ for 0.93 minutes for a total degree of 500 rads. One group received no further treatment. In the other group, the immune system was reconstituted by adoptive transfer of spleen and lymph node cells from two normal donors to one recipient. A 75 mg pellet of morphine base was subcutaneously implanted into each rat and into animals in an additional non-irradiated group (N=12). Seventy-two hours later naloxone (1 mg/kg) was administered intraperitoneally to induce the abstinence syndrome and thereby assess the degree of morphine dependence. Seven behavioral measurements were scored: Wet dog shakes, teeth chatterings, formed stools, diarrhea, hyperactivity, exploratory behavior, and scream-to-touch. Experimental groups were compared to controls implanted with placebo pellets and challenged with saline. Results showed that irradiation suppressed withdrawal in subjects that the immune system was not reconstituted. Statistical evaluation revealed no significant difference between the non-irradiated, normal placebo controls and the irradiated rats given morphine. Furthermore, there was no significant statistical difference among morphine addicted rats whether normal or irradiated and adoptively reconstituted with immunocompetent cells. In conclusion, the present study demonstrated that 1) irradiation suppresses the opiate withdrawal syndrome, and 2) reconstitution of the immune system after whole body irradiation of 500 rads restores the classical naloxone precipitated withdrawal in morphine addicted animals. These observations are evidence that the immune system participates in opiate addiction.

351.16 SPINAL CORD BLOOD FLOW FOLLOWING TRAUMA: EFFECTS OF NALOXONE. G.E. Hollinden* and B.T. Stokes. (SPON: W.E. Hunt) Dept of Physiology, The Ohio State Univ. Sch. of Med., Columbus, OH 43210

Spinal ischemia following spinal cord injury has been associated with distinct pathological alterations in the spinal microenvironment. The resulting lack of molecular oxygen, incipient hypocalcia, and the cascade of rapidly occuring neuropathological events would all augur for a reversal of the ischemic insult. It has been suggested that one of the beneficial effects of the opiate antagonist naloxone might be to prevent this ischemic insult by maintaining spinal cord blood flow at control levels subsequent to injury. We have also reported a reversal of the dramatic injury-induced extracellular hypocalcia after such high dose naloxone regimens. Because of certain discrepancies in previous reports relating spinal blood flow to naloxone therapy and the appearance of newer more quantitative blood flow techniques, we have monitored blood flow in spinal gray and white matter after impact injury and naloxone intervention.

Spinal cord blood flow was measured using the diffusable tracers technique developed by Kety (1960) as modified by Zivin (1983). Random source mongrel dogs were anesthetized and cannulated. A monofilament ligature is placed around the aorta at the branching of the common carotid and exteriorized. The chest is then closed and normal respiratory and blood gas parameters reestablished. A laminectomy is performed and the animal is suspended from a rigid spinal frame and traumatized (400 gm-cm; Allen Drop Technique). Naloxone hydrochloride (10 mg/kg) is administered twenty minutes post-trauma according to our established protocol. At the measurement time, approximately 10 uCi/kg are injected in a IV bolus and blood samples are collected at five second intervals from a branch of the caudal auricular artery over a two minute period. At the end of the two minute period, the aorta is severed with the ligature rapidly terminating blood flow. The spinal cord is quickly removed, frozen and sectioned into gray and white samples. The blood and tissue samples are then processed and counted. The results at sampling times of 30 min., 1.0 hr., and 2.0 hrs. post-trauma were as follows (all flows are expressed as ml/100g/min):

| | 30 MIN. | | 1.0 HR | | 2.0HR | |
|---|---|---|---|---|---|---|
| | Gray | White | Gray | White | Gray | White |
| CONTROL: | 31.5±2 | 14.4±2 | 30.9±3 | 15.7±1 | 48.1±5 | 15.9±.5 |
| TRAUMA: | 10.2±3 | 9.4±1 | 11.1±2 | 14.5±1 | | |
| NALOXONE: | 43.0±3 | 16.1±1 | 33.5±3 | 10.6±1 | 36.4±3 | 7.7±.3 |

After trauma, the blood flow drops significantly and remains depressed for the entire period studied. Naloxone has little effect on blood flow by itself and after trauma. We conclude, therefore, that naloxone must exert its effect on neurologic improvement and resolution of extracellular hypocalcia by mechanisms other than a prevention of the ischemic insult. (Supported by USPHS NS-10165).

351.17 AN INTERACTION OF THE IMMUNE SYSTEM AND OPIATE DEPENDENCE: ADOPTIVE TRANSFER OF CYCLOSPORINE'S ATTENUATING EFFECT UPON THE WITHDRAWAL SYNDROME. P. Dougherty,* J. Aronowski,* D. Drath* and N. Dafny (SPON: R. Wiggins). Department of Neurobiology and Anatomy, UTHMS, Department of Surgery and Organ Transplantation, UTHMS.

A detailed mechanism for the development of opiate dependence and the expression of the withdrawal syndrome associated with the drug's interruption has not yet been fully elucidated despite many theories which attempt to explain these phenomena. One theory, suggesting immunologic involvement in opiate dependence, has gained additional support recently by previous studies from our group which have demonstrated an attenuation of the withdrawal syndrome by various immune modulating agents such as cortisol, α-interferon, cyclophosphamide, and cyclosporine-A. The present study was undertaken to further define the mode whereby cyclosporine exerts this effect and to determine if this drug induces a soluble or transferable factor that modifies the development of opiate dependence.

Fischer 344 male rats were divided into 4 basic groups, each consisting of 16 animals. The separate groups were treated with either a placebo regimen or a drug regimen consisting of either cyclosporine, morphine sulfate, or a combination of cyclosporine and morphine, for a time period of three days, the period of continuous exposure necessary to establish a state of dependence. Each group was then divided into two identical groups, half of which were used for behavioral studies and the other half sacrificed and harvested for their spleen populations. Spleen cells were then adoptively transferred to 4 additional recipient groups (N=8) which had undergone prior treatment with placebo regimes or drug regimens. Recipient animals were then assessed for opiate dependence via naloxone administration and scored for 10 common behavioral signs of antagonist-precipitated withdrawal. Results were compared to scores from behavioral animals which received only the various drug treatments followed by naloxone. The results we obtained demonstrated that only splenic cells from cyclosporine treated groups were able to attenuate the withdrawal syndrome. This attenuation was similar to that observed in non adoptively transferred rats receiving cyclosporine and morphine combinations as described previously. In conclusion, the present study demonstrates that the effect of withdrawal attenuation induced by cyclosporine can be transferred from one animal to another by immune components. This observation further suggests an involvement of the immune system in the development of opiate addiction.

351.18 ANALYSIS OF REGIONAL BRAIN UPTAKE AND ACCUMULATION OF MORPHINE BY MASS FRAGMENTOGRAPHY. G.N. Fuller, S.-N. Lin*, R.M. Capriola*, R.C. Wiggins and N. Dafny. Dept. of Neurobiology and Anatomy and The Analytical Chemistry Center, The Univ. of Texas Med. Sch. at Houston, Houston, Tx. 77025.

The regional distribution of morphine has been investigated by numerous laboratories under a number of different experimental conditions, with prominent variables including route of administration, dosage, species, and morphine detection method. However, the regional uptake and accumulation of morphine following an incremental dosage regimen (commonly employed in neurophysiological experimentation) has never been examined. In the present study, morphine distribution was measured in eight brain areas (cerebral cortex, hippocampus, striatum, midbrain, hypothalamus, thalamus, medulla and cerebellum) following with single dose or cumulative doses. For single dose studies, six groups of four animals each received a single, i.p. injection of either phosphate buffered saline, or of morphine sulfate at a dose of 0.5, 1.0, 5.0, 10.0 or 30.0 mg/kg. All injections were in 1 ml total volume. For cumulative dose studies, animals received incremental doses of morphine sulfate (0.5, 1.0, 5.0, 10.0, 30.0 mg/kg), injected i.p. at intervals of 30 min, with groups of four animals being sacrificed after the 0.5, 1.0, 5.0, 10.0 and 30.0 mg/kg doses. For each experimental group, animals were anesthetized with sodium pentobarbital at 15 min after the last morphine injection and quickly perfused for 1 min with 10% formalin solution to clear blood from the brain. Animals were decapitated, the brains dissected into eight regions, and the regions massed on a Mettler PN 1210 analytical balance and frozen in air tight glass vials at -50°C. Regional morphine levels were subsequently determined by gas chromatography-mass spectrometry with chemical ionization detection. Following single dose administration, all brain regions show similar patterns of uptake with increasing dose, with the notable exception of the hypothalamus which demonstrated a linear uptake and the highest concentrations of morphine for any given dose. Following cumulative dose administration, regional morphine uptake profiles show three distinct patterns. Hippocampus, cerebellum, medulla and cerebral cortex show a linear uptake pattern, whereas thalamus, midbrain and striatum show a non-linear profile. As also seen with single dose administration, the hypothalamus is distinctive in its markedly higher morphine concentrations at all dosage levels. The present experiments thus provide evidence for dose-dependent differential uptake and accumulation of morphine in specific regions of rat brain following incremental morphine administration.

352.1 EFFECTS OF L-TYROSINE AND OTHER AMINO ACIDS ON THE TYRAMINE-INDUCED CHRONOTROPIC RESPONSE IN THE ISOLATED RAT HEART. J.M.B. Pinto* and T.J. Maher. Department of Pharmacology, Massachusetts College of Pharmacy, Boston, MA 02115.

The synthesis of catecholamines from the precursor amino acid L-tyrosine (TYR) is regulated by the rate-limiting enzyme tyrosine hydroxylase (TH). Under resting conditions, the activity of TH is dependent upon the availability of the tetrahydrobiopterin cofactor and not the availability of its substrate TYR. When noradrenergic neurons are activated (i.e., firing-frequently), TH is phosphorylated via a protein kinase and the availability of the cofactor no longer limits TH activity, while the concentration of TYR is now the limiting factor. The precursor-dependence phenomenon has been demonstrated in situations where neurons are activated such as hypertension, hypotension, tail-shock stress and electrically-stimulated striatal slices. As expected, when neurons are at rest, no increase in catecholamine synthesis is seen when TYR concentrations are increased. To determine if TYR is capable of enhancing the synthesis of catecholamines in activated neurons in the heart, we compared the tyramine-induced increase in chronotropy in the isolated rat heart perfused with or without TYR.

Isolated hearts were perfused with Chenoweth-Koelle solution according to the Langendorff procedure and positive chronotropic responses evoked with 350 µg tyramine at 10 min. intervals for 60 min. The addition of 50 µM TYR into the perfusion solution did not alter the basal heart rate when compared to control. Tachyphylaxis to tyramine always occurred after the 1st or 2nd injection in control-perfused hearts, while the inclusion of TYR prevented tachyphylaxis for the 60 min. period (TYR-perfused hearts responded to tyramine for up to 8 hrs.). Norepinephrine, a direct agonist, produced a chronotropic response in control-perfused tachyphylactic hearts suggesting that the tyramine-induced unresponsiveness was due to a depletion of stored catecholamines. The inclusion of equimolar concentrations of the L-amino acids: phenylalanine, valine, serine, glutamic acid, aspartic acid, arginine and lysine, or the D-amino acids: tyrosine and tryptophan failed to prevent the onset of tachyphylaxis indicating that a nonspecific effect of amino acids was not responsible for our observations. 3-Iodo-L-tyrosine and alpha-methyl-para-L-tyrosine prevented the TYR-induced response indicating the requirement for catecholamine synthesis. d,l-Propranolol also blocked the TYR-induced response, most likely at the postsynaptic receptor.

We have shown that a peripheral organ in vitro, the isolated rat heart, is dependent upon TYR availability for catecholamine synthesis when neurons fire frequently.

352.2 EFFECT OF CHRONIC COLD ON TYROSINE HYDROXYLASE AND PHENYLETHANOLAMINE-N-METHYLTRANSFERASE mRNAS IN RAT ADRENAL GLAND. M.K. Stachowiak, R. Sebbane*, E.M. Stricker, M.J.Zigmond, and B.B. Kaplan. Depts. of Psychiatry, Psychology, and Biological Sciences, University of Pittsburgh, Pittsburgh, PA 15260.

Adaptation of animals to chronic cold involves increased secretion of adrenal catecholamines, which is sustained by increased activity of tyrosine hydroxylase (TH), the rate-limiting enzyme in catecholamine biosynthesis (Thoenen, Nature 228:861, 1970; Fluharty et al., J. Pharm. Exptl. Ther. 233:32, 1985). The activity of phenylethanolamine-N-methyltransferase (PNMT) also increases slightly during prolonged exposure to cold (Kvetnansky et al., Am. J. Physiol. 220: 928, 1971). Cold-induced increases in the TH activity were found to reflect an increased rate of enzyme synthesis (Chuang & Costa, Proc. Natl. Acad. Sci. 71:4570, 1974). The purpose of this study is to investigate further the mechanism of TH and PNMT induction in cold-adapted rats by examining levels of TH and PNMT mRNAs. Sprague-Dawley male rats with clipped fur were placed in a 5°C chamber for 1 week. Control rats were kept in a temperature controlled environment at 22°C. Total RNA was isolated from adrenal medulla pooled from 10 rats. Estimates of the relative amounts of the TH and PNMT RNAs were obtained by RNA dot-blot hybridization analysis using cloned TH and PNMT cDNAs as hybridization probes (Lewis et al., J. Biol. Chem. 258:14632, 1983; Kaplan et al. In "Gene Expression in Brain," C. Zomzely-Neurath and W.A. Walker, Eds., Wiley Interscience, New York, NY, 1984, pp. 1-22). Specificity of the hybridization reactions was verified by hybridization to total RNA isolated from the rat caudato-putamen, a brain region which apparently does not contain catecholaminergic cell bodies. After 7 days of cold exposure, we observed a 4.8-fold increase in the amount of adrenomedullary RNA which hybridized to TH cDNA. Similar results were obtained by northern analysis using adrenal poly(A+)RNA. The amount of TH cDNA which hybridized to TH RNA had increased 4-fold, demonstrating that the relative abundance of TH mRNA in the cold-exposed rats had increased considerably. The cold-induced increase in adrenal TH mRNA appears rather specific. Results of dot-blot hybridization experiments and northern analysis have shown that the relative abundance of adrenomedullary PNMT mRNA increases by only 20-60% in rats subjected to cold stress. The fact that the changes found in our experiments are similar in magnitude to the reported effects of cold on TH and PNMT activity is consistent with the hypothesis that the changes in enzyme activities are mediated by alterations in the corresponding mRNAs levels. Further investigation will be necessary to determine whether cold-induced changes in the abundance of TH mRNA results from an enhanced rate of transcription, alterations in RNA processing or nuclear-cytoplasmic transport, or decreased rates of mRNA degradation.

352.3 REGULATION OF TYROSINE HYDROXYLATION IN STRIATAL AND PREFRONTAL CORTICAL BRAIN SLICES. M. E. Wolf and R. H. Roth, Yale University School of Medicine, Depts. of Pharmacology and Psychiatry, New Haven, CT 06510.

A number of in vivo biochemical studies have suggested that DA neurons innervating the prefrontal cortex lack synthesis modulating DA autoreceptors. However, apomorphine has been reported (Fadda et al., Brain Res., 1984) to inhibit prefrontal DOPA accumulation in rats pretreated with a decarboxylase inhibitor. Recent work in our lab suggests that this effect is linked to the ability of agonists to modulate intraneuronal levels of DA thereby indirectly regulating the level of feedback inhibition to which tyrosine hydroxylase is subjected. It has been proposed that DA agonists act at release modulating autoreceptors to inhibit ongoing DA release and thereby slow the rapid decline in endogenous DA levels which occurs in prefrontal DA terminals following decarboxylase inhibition. In contrast, nigrostriatal DA terminals appear to possess autoreceptors which modulate tyrosine hydroxylation directly, independent of effects on intraneuronal DA levels. Brain slices provide a potentially useful model system in which to investigate this hypothesis, since 1) there is presumably less impulse flow-dependent DA release in slices, making it possible to assess the effects of DA agonists and antagonists on synthesis modulating autoreceptors without the confound of drug-induced changes in release and therefore in intraneuronal DA levels 2) one can isolate drug effects on the nerve terminal.

Addition of the DOPA decarboxylase inhibitor NSD-1015 (200uM) to striatal or prefrontal cortical brain slices resulted in an accumulation of DOPA that was linear for at least 30 min. DOPA accumulation was stimulated in both regions in the presence of 30mM potassium. The DA antagonist l-sulpiride enhanced $K^+$-stimulated DOPA accumulation in striatal slices, presumably by preventing the activation of synthesis modulating autoreceptors by endogenous DA. Sulpiride had no effect on $K^+$-stimulated DOPA accumulation in prefrontal cortical slices. The non-catechol DA agonist EMD 23 448 produced a dose-dependent inhibition of both basal and $K^+$-stimulated DOPA accumulation in striatal slices. In contrast, concentrations of EMD 23 448 which resulted in greater than 60% inhibition of basal DOPA accumulation in striatal slices had no effect on basal prefrontal DOPA accumulation. However EMD 23 448 did reverse the $K^+$-stimulated enhancement of DOPA accumulation in prefrontal slices. Since $K^+$-stimulated synthesis is presumably associated with greater DA release than is basal synthesis, the effect of EMD on $K^+$-stimulated DOPA accumulation may involve activation of release modulating autoreceptors. These in vitro findings are therefore consistent with the proposed lack of synthesis modulating autoreceptors on mesoprefrontal nerve terminals. (Supported in part by USPHS Grant MH 14092 and the State of Connecticut)

352.4 PHORBOL ESTER ACTIVATES TYROSINE HYDROXYLASE IN THE PERFUSED RAT ADRENAL GLAND. J. P. Mitchell* and P. R. Vulliet (SPON: G. Frye). Dept. of Veterinary Physiology and Pharmacology, Texas A&M University, College Station, TX 77843.

The isolated perfused rat adrenal preparation (Wakade, A. R., J. Physiol., 313: 463, 1981) was used to study the regulation of tyrosine hydroxylase (TH) by acetylcholine and by the phorbol ester 4 -phorbol 12 -myristate 13 -acetate (PMA), a potent activator of protein kinase C. The left adrenal gland of anesthetized (pentobarbital, 60 mg/kg, i.p.) male Sprague-Dawley rats (200-300 g) was perfused by inserting a PE 10 catheter into the adrenal vein, ligating all side branches of the vein, and making a small incision through the connective tissue capsule to allow perfusate to escape. The adrenal was perfused with oxygenated Krebs-bicarbonate buffer at a rate of 0.36 ml/min and maintained at 37°C throughout the experiment. In some experiments, the perfusate was collected and analysed for epinephrine and norepinephrine content by HPLC with electrochemical detection. Inclusion of acetylcholine in the perfusion buffer resulted in a large increase in catecholamine release and a significant increase in TH activity. This increase in activity resulted primarily from a decrease in the Km for the cofactor 6-methyl-5,6,7,8-tetrahydropterine ($MPH_4$). The acetylcholine induced activation of TH and release of catecholamines could be blocked by a combination of hexamethonium and atropine, nicotinic and muscarinic cholinergic antagonists, respectively. Perfusion of the adrenal by PMA also resulted in a significant increase in TH activity that resulted from a reduction in the Km of TH for $MPH_4$. These findings suggest that protein kinase C may be involved in the regulation of TH in vivo.

352.5 ACTIVATION OF TYROSINE HYDROXYLASE IN THE RAT SUPERIOR CERVICAL GANGLION BY PEPTIDES OF THE GLUCAGON-SECRETIN FAMILY. M.A. Schwarzschild,* J. Rivier,* W.W. Vale, N.Y. Ip, and R.E. Zigmond. Dept. of Pharmacology, Harvard Med. School, Boston, MA 02115 and Peptide Biology Laboratory, The Salk Institute, San Diego, CA 92138

Preganglionic nerve stimulation has been shown to increase the rate of dopa synthesis measured in intact rat superior cervical ganglia maintained in vitro in the presence of the dopa decarboxylase inhibitor brocresine. This effect is only partially blocked by nicotinic and muscarinic antagonists, suggesting the involvement of a non-cholinergic preganglionic neurotransmitter (Ip et al., PNAS 80:2081, 1983). It was subsequently found that three peptides of the glucagon-secretin family--vasoactive intestinal peptide (VIP), secretin, and PHI also increase dopa synthesis in the ganglion by 4-, 3-, and 2-fold respectively at a concentration of 10 μM . Other peptides in this family, namely glucagon, gastric inhibitory peptide and human growth hormone-releasing factor (hGRF), and many unrelated peptides have no effect when tested under the same conditions (Ip et al., Peptides 5:309, 1984).

To determine the mechanism of the peptidergic stimulation of dopa synthesis, ganglia were incubated with various peptides at 37°C for 30 min without brocresine and then homogenized. The tyrosine hydroxylase (TH) activity of the homogenates was assayed at pH 7.0 in the presence of a subsaturating concentration of pterin cofactor (30 μM 6-methyltetrahydropterin). VIP (10 μM), secretin (10 μM), and PHI (30 μM) increased TH activity by 4-, 3-, and 3-fold respectively, while glucagon (10 μM) had no effect. Further experiments with VIP and secretin demonstrated that these peptides also shifted the pH optimum of ganglionic TH from 5.8 to 6.4. These data suggest that the peptidergic stimulation of dopa synthesis in intact ganglia results from an activation of TH.

Recently GRF from rat hypothalamus (rGRF) has been isolated and sequenced and found to be a member of the glucagon-secretin family. rGRF has 67% sequence homology with hGRF. rGRF (30 μM) increased the rate of dopa synthesis in intact ganglia by 3-fold and increased TH activity in ganglion homogenates by 2.5-fold. rGRF(1-29)$NH_2$ (10 μM) also increased dopa synthesis by 2-fold, while hGRF(1-29)$NH_2$ had no effect. Since the N-terminal residue of hGRF is tyrosine while that of rGRF is histidine, [$Tyr^1$]rGRF(1-29)$NH_2$ was tested, and it was found to produce a 1.4-fold increase in dopa synthesis. hGRF was also examined for its ability to antagonize the effect of rGRF. Addition of hGRF(1-40)OH (30 μM) did not increase the rate of dopa synthesis nor did it antagonize the effect of rGRF (10 μM). rGRF and the various rGRF fragments tested also increased ganglionic cAMP, while hGRF and the fragments of hGRF tested did not. These data are consistent with our hypothesis that the peptidergic stimulation of ganglionic TH activity is mediated by an increase in cAMP accumulation (Ip et al., J. Neurosci., In press). Supported by grants NS12651 and MH00162.

352.6 CHRONIC ADMINISTRATION OF METHAMPHETAMINE DEPLETES TYROSINE HYDROXYLASE IMMUNOREACTIVITY IN THE NIGROSTRIATAL AND MESOLIMBIC DOPAMINE SYSTEMS IN THE RAT BRAIN. M.E. Trulson, M.S. Cannon,* T.S. Faegg*[1] and J.D. Raese[2]. Department of Anatomy, College of Medicine, Texas A&M University, College Station, TX 77843, [1]E. Leitz, Inc., Rockleigh, N.J. 07647 and [2]Schizophrenia Research Center, Southwestern Medical School and V.A. Medical Center, Dallas, TX 75216.

Chronic methamphetamine administration (20 mg/kg, i.p., every 12h for 10 consecutive days) produced a large decrease in tyrosine hydroxylase staining axons and terminal boutons in the caudate nucleus, nucleus accumbens, and frontal cortex in rats when examined 60 days following the final methamphetamine injection, as compared to saline-injected control rats. This effect was quantitated using the Leitz Data Acquisition and Display System (DADS), which revealed that there was a 77% decrease in tyrosine hydroxylase positive nerve terminal processes in the caudate nucleus, and a 66% and 62% decrease in tyrosine hydroxylase positive nerve terminal processes in the nucleus accumbens and frontal cortex, respectively. Furthermore, this chronic methamphetamine treatment regimen also produced a large decrease in the number of tyrosine hydroxylase positive staining neuronal parikarya in the pars compacta of the substantia nigra and in the ventral tegmental area. This latter effect was also quantitated using the Leitz DADS system, which revealed a decrease of 72% in tyrosine hydroxylase positive material in the substantia nigra and a 69% decrease in tyrosine hydroxylase positive material in the ventral tegmental area. Despite these large depletions of brain dopamine, the rats appeared relatively normal upon gross examination 60 days following termination of methamphetamine treatment. These data demonstrate that chronic administration of methamphetamine produces a long term loss of tyrosine hydroxylase enzyme in both the cell bodies of the substantia nigra and the ventral tegmental area and the nerve terminals in the caudate nucleus, nucleus accumbens and frontal cortex. Whether these effects are due to the degeneration of neurons or some metabolic or biochemical effect is currently under investigation.

352.7 TYROSINE HYDROXYLASE ACTIVITY IN POST-MORTEM SAMPLES OF HUMAN PUTAMEN AND CAUDATE NUCLEUS. D.L.Sparks and J.T. Slevin.Veterans Administration Medical Center and the Depts. of Neurology and Pharmacology and the Sanders-Brown Research Center on Aging, University of Kentucky, Lexington, Kentucky 40536

Several neurological disorders, e.g. Parkinson's Disease, include an alteration of dopaminergic synaptic activity in basal ganglia. Tyrosine hydroxylase (TH), which catalyzes the conversion of tyrosine to dopa, plays a central role in the modulation of catecholamine biosynthesis. TH activity is the rate-limiting step in catecholamine synthesis and is subject to end-product inhibition. In order to study TH activity in human post-mortem tissue, it is important to know the effect of several parameters (e.g. age of the subject, time from death to tissue analysis, ambient temperature) on the enzyme's activity. To insure consistency and facilitate the handling of large numbers of samples, it is important to have a simple, quick and easily-reproduced method.

We have recently developed a method for determining TH activity by liquid chromatography with electrochemical detection (LCEC) which requires no elaborate preparation, pre-column "clean-up", or recovery studies. Data relating TH activity in human caudate nucleus and putamen to the post-mortem interval (from cardiorespiratory death to sample analysis) and to age will be presented. As in rat (Black, I., Arch.Neurol. 32:47, 1975), post-mortem TH activity in human putamen and caudate nucleus is stable for a short time (< 24 hours), after which activity decreases precipitously. Comparisons between our method and a widely used radiometric assay (Coyle, J.T., Biochem.Pharmacol. 21:1935, 1972) and LCEC assay (Lin, P.Y.T. et al., J.LiquidChrom. 7:509, 1984) are made.

Supported in part by the Veterans Administration Research Service, the NIH (TIDA 00732 - JTS), Univ. of Kentucky PSP Fellowship (DLS) and ADRDA (DLS).

352.8 GENETIC CORRELATION ANALYSIS OF HYPOTHALAMIC AND MIDBRAIN TYROSINE HYDROXYLASE ACTIVITY. L.R. Murthy,* I. Sziraki,* A. Lajtha and Cs.Vadasz*). (SPON: S. P. Bagchi). Lab. of Neuro-behavior Genetics, Neurochemistry Div., Nathan Kline Institute, Orangeburg, NY 10962.

Differences in tyrosine hydroxylase (TH) activity in hypothalamus (HT) and midbrain (substantia nigra - A-10 region, SN) were reported between male mice of BALB/cJ(C), and CBA/J strains (Ross et al. Nature, 264:654, 1976; Baker et al. J. Neurosci., 3:832,1983). Our studies using reciprocal F1 hybrids indicated significant genetic additive effects in SN ($p<0.05$), significant additive and maternal effects in hypothalamus (Vadasz et al. 1985, in press).

Comparison of these two strains and their hybrids showed that higher levels of TH activity in SN (TH/SN) and hypothalamus (TH/HT) were associated with the BALB/cJ strain, indicating the possibility of common genetic control.

To study further the genetic control over central dopamine systems, strains with high (BALB/cJ) and low (CXBI/J)(I) TH/SN were chosen and each were crossed with a strain of intermediate TH/SN (C57BL/6ByJ) (B6).

Intercrossing the (B6XI)F1 and (B6XC)F1 generations, produced replicated (B6XI)F2 and (B6XC)F2 segregating populations, thereby providing an opportunity to estimate the environmental and genetic sources of the phenotypic correlations between TH/HT and TH/SN and also between TH/HT and TH activity in corpus striatum (TH/CS). The two types of crosses (B6XI) and (B6XC) yielded different results:

a) significant differences were found in TH/HT between B6, C and (B6XC)F1 with high heritability of TH/HT for (B6XC)$F_2$ ($h^2_b = 0.66$);
b) no significant differences were found in TH/HT between B6,I and (B6XI)F1 with low or negligible heritability of TH/HT for (B6XI)$F_2$ ($h^2_b=0.01$).

Consequently, phenotypic ($r_P$), environmental ($r_E$) and genetic ($r_G$) correlation coefficients were determined only for the (B6XC)F2 generation.

| | $r_P$ | $r_E$ | $r_G$ |
|---|---|---|---|
| TH/HT and TH/SN | 0.25 | -0.096 | 0.45 |
| TH/HT and TH/CS | 0.33 | 0.10 | 0.51 |

Significant differences were reported in TH/SN between $B_6$ and I (Vadasz et al., Brain Res., 234: 1-9, 1982), but not in TH/HT, as measured in this study, suggesting a difference in the genetic control of the hypothalamic and nigrostriatal catecholamine systems. However, the significant genetic correlations found in the present studies, demonstrate that there is also a set of common genes which influence TH activities in all three regions (HT,SN,CS) through pleiotropy or linkage of genes.

352.9 GENETIC CORRELATION ANALYSIS OF THE NIGROSTRIATAL DOPAMINE SYSTEM. I. Sziraki*, L.R. Murthy*, A. Lajtha and Cs. Vadasz*(SPON: R. Squires). Lab. of Neuro-behavior Genetics, Neurochemistry Div., The N. S. Kline Inst. for Psychiatric Research, Orangeburg, NY 10962

In recent experiments with Recombinant Inbred Strains significant and positive between-strain correlation (r=0.82) was found between tyrosine hydroxylase (TH) activities in substantia nigra (SN) -A-10 area and corpus striatum (CS). These results suggested that there is a common set of genes influencing both number of dopamine (DA) neurones in substantia nigra-A-10 region and axonal arborization of nigral DA neurones in corpus striatum (Vadasz et al., Brain Research, 234,1., 1982).

In the present study we investigated the correlation between TH activities in SN-A-10 region and CS further. On the basis of the previous results those strains were selected which had the lowest (CXBI/J) and highest (BALB/cJ) TH activity in SN-A-10 area. These strains were crossed with a strain of intermediate TH activity in SN (C57BL/6ByJ). The resulted (B6I)F1 and (B6C)F1 hybrids were intercrossed within their own generation to produce (B6I)F2-ALPHA, (B6I)F2-BETA, (B6C)F2-ALPHA and (B6C)F2-BETA segregating populations. The analysis of the statistically nontransformed data indicates that in TH activity of SN the B6 strain is dominant (or partially dominant) in both types of crosses (B6XI and B6XC). Phenotypic variances in B6IF2-ALPHA and B6IF2-BETA are smaller than the enviromental variance estimated from the genetically homogenous populations. Heritabilities are high and the estimates of minimum number of genes are low for B6CF2-ALPHA and B6CF2-BETA segregating populations.

Similarly, in the TH activity of CS the B6 strain is dominant (or partially dominant) in both crosses and the range of heritabilities is between 0.20 (B6IF2-BETA) and 0.64 (B6CF2-ALPHA). The estimates of minimum number of genes involved are smaller for the B6CF2 generations than for the B6IF2 generations.

Correlation analysis of the TH activities in SN and CS using more than 200 animals of the progenitor strains, hybrids and F2 generations indicates low and nonsignificant enviromental correlation ($\bar{r}_E$=0.15) and high and significant genetic correlations in the B6CF2 generations (0.71 and 0.82).

These results demonstrate that:

1.) the genetic properties of the B6XI and B6XC type crosses in controlling TH activities of the nigrostriatal system are different

2.) the genetic correlation coefficients, obtained from large segregating populations, are high and significant providing further support to the hypothesis of common genetic control of number of DA neuron cell bodies in SN-A-10 area and axonal arborization of DA neurones in corpus striatum.

352.10 MONOCLONAL ANTIBODIES DIRECTED AGAINST TYROSINE HYDROXYLASE. S.W.Snell*, S.Kwan*, C.W.Abell*, R.M.Denney*, and P.R.Vulliet . Dept. of Vet. Phys. and Pharmacol., Texas A&M Univ., College Station, TX 77843 and Dept. of Human Biological Chemistry and Genetics, The Univ. of Texas Med. Branch, Galveston, TX 77550.

Monoclonal antibodies directed against tyrosine hydroxylase (TH) were prepared by injection of 20 ug of the highly purified rat pheochromocytoma enzyme into mice. Lymphocytes were isolated from the spleen and fused with P3/X63Ag8 myeloma cells using polyethylene glycol. Viable cells secreting IgG were selected using aminopterin and ELISA techniques. Clones secreting antibody directed against TH were screened using secondary immunoprecipitation with S. aureus protein A. Disappearance of TH activity from the supernatant and appearance of the activity in the pellet was demonstrated.

Monoclonal antibodies from clone 2D8 were linked to Sepharose 4B using a cyanogen bromide coupling procedure. The antibody-Sepharose complex was equilibrated with phosphate buffered saline (PBS) (0.20g KCl, 0.20g $KH_2PO_4$, 1.14g $Na_2HPO_4$, 8.00g NaCl per liter) and washed thoroughly with a 0.1% BSA solution. $^{125}$I-TH was run over the Sepharose 4B-IgG column. Following washes with PBS, 2 M sodium bromide, and 4 M potassium thiocyanate, the $^{125}$I counts were eluted off the column with 200 mM glycine/HCl, pH 3.0. TH activity was present in the fractions containing the $^{125}$I label. The TH peak was pooled and run on a SDS-PAGE gel. Two bands appeared: 66,000 daltons (BSA) and 60,000 daltons (TH).

Rat adrenal homogenate was then run over the Sepharose 4B-IgG column. After collecting the appropriate fractions from the 200 mM glycine/HCl pH 3.0 eluate, SDS-PAGE gels were run. Again, only 66,000 and 60,000 dalton bands appeared.

Therefore, these antibodies can be used for extracting TH from adrenergic tissues using immunoaffinity chromatography.

352.11 CYCLIC AMP AND GLUCOCORTICOIDS INCREASE THE ENZYME LEVEL AND RATE OF SYNTHESIS OF TYROSINE HYDROXYLASE AND THE LEVEL OF mRNA FOR TYROSINE HYDROXYLASE IN A RAT PHEOCHROMOCYTOMA CELL LINE. A.W. Tank, L.N. Ham* and P. Curella*. Univ. Colorado Health Sci. Ctr, Denver, CO 80262.

Tyrosine hydroxylase (TH) activity and RNA coding for TH ($mRNA^{TH}$) have been shown to be elevated in rat pheochromocytoma cells treated with either glucocorticoids or 8-bromocyclic AMP (J. Biol. Chem. 258, 14,632 1983). In the present report we characterize further the effects of cyclic AMP and glucocorticoids either alone or in combination on the enzyme levels and rates of synthesis of TH and the levels of $mRNA^{TH}$ in rat pheochromocytoma PC18 cells, a subclone of the rat pheochromocytoma PC12 cell line. In these studies TH activity was measured by the coupled decarboxylase assay (Anal. Biochem. 43, 558 1971). The rate of synthesis of TH was measured by incubating cells in the presence of $^3$H leucine and isolating radiolabeled TH by immunoprecipitation using monospecific antiserum to TH. $mRNA^{TH}$ was measured by hybridization to the cloned cDNA probe pTH.4 (J. Biol. Chem. 258, 14,632 1983).

TH activity in the PC18 cells is increased by treatment with either 8-bromocyclic AMP or glucocorticoids. This increase in activity is due to an increase in enzyme protein, as demonstrated by immunoprecipitation studies. Time course studies demonstrate that the enzyme levels rise slowly to a level 6-7-fold greater than that observed in control cells after 4 days of treatment with either 8-bromocyclic AMP or dexamethasone alone. In contrast, the rate of synthesis of the enzyme increases more rapidly, reaching a level 6-7-fold greater than that observed in control cells after 12 hours of treatment with either inducing agent alone. The level of $mRNA^{TH}$ in the cells increases at approximately the same rate as the rate of synthesis of the enzyme to a level 6-7-fold greater than that observed in control cells after 12 hours of treatment with either inducing agent alone. This data strongly supports the hypothesis that cyclic AMP and glucocorticoids increase the level of $mRNA^{TH}$, which results in an increase in the rate of synthesis of the enzyme in the cells. The slow rate of increase in enzyme levels is due most likely to the relatively long half-life of the enzyme in the PC18 cells (half-life = 25-30 hours).

When PC18 cells are treated simultaneously with both 8-bromocyclic AMP plus dexamethasone, the increases in the enzyme level and rate of synthesis of TH are approximately equal to the sum of the increases in these parameters observed in cells treated with either inducing agent alone. In contrast, the increase in the level of $mRNA^{TH}$ in cells treated with both 8-bromocyclic AMP and dexamethasone is equal to the greatest increase observed in cells treated with either inducing agent alone. There is no additive increase in the levels of $mRNA^{TH}$ in cells treated simultaneously with both inducing agents. This surprising observation suggests that in the presence of elevated levels of both cyclic AMP and glucocorticoids, TH is regulated by both transcriptional and post-transcriptional mechanisms. Supported by USPHS grant NS19749.

352.12 FEEDBACK INHIBITION OF PTERIN BIOSYNTHESIS IN THE ADRENERGIC NEUROBLASTOMA N1E115 BY TETRAHYDROBIOPTERIN. G. Kapatos. Laboratory of Neurochemistry, Center for Cell Biology Sinai Hospital of Detroit, 6767 West Outer Drive, Detroit, MI 48235.

The adrenergic neuroblastoma N1E115 synthesizes both D-erythro-neopterin (Neo) and L-erythro-biopterin (Bio) as determined by sequential reverse-phase and cation-exchange HPLC techniques. Determination of intracellular volume showed the average intracelluar concentration of Bio and Neo to be approximately 115 uM and 5 uM, respectively. Neo was present primarily as the completely oxidized or 7,8-dihydro species. By contrast, over 95% of Bio was found to be 5,6,7,8-tetrahydrobiopterin. The level of either pterin in these cells was not dependent on cell cycle or on the concentration of fetal calf serum. Pterin content was therefore independent of cellular differentiation and the alterations in the specific activity of tyrosine-3-monooxygenase reported to occur in this cell line as cell division subsides. In order to investigate the regulation of pterin biosynthesis the initial precursor, guanosine triphosphate, was labelled with [$^{14}$C]guanosine. The biosynthesis of [$^{14}$C]pterins determined by incubation with [$^{14}$C] guanosine was linear for up to 1 hour. Initial rates of synthesis of [$^{14}$C]Neo and [$^{14}$C]Bio from [$^{14}$C] guanosine were inhibited in a concentration-dependent manner by addition of exogenous (6R)-tetrahydrobiopterin to the culture medium, with an $IC_{50}$ of less than 50 uM. This decrease in synthesis was not the result of either: 1) a decline in the labeling of [$^{14}$C]GTP from [$^{14}$C] guanosine, 2) an increase in [$^{14}$C]pterin degradation or 3) a stimulation of [$^{14}$C]pterin efflux into the culture medium. Inhibition of [$^{14}$C]pterin synthesis was also manifest following incubation with similar concentrations of 6-lactyl-7,8-dihydropterin (sepiapterin), or 7,8-dihydrobiopterin, compounds which were rapidly converted to tetrahydrobiopterin within these cells. Studies with a semi-purified preparation from these cells of the first enzyme in pterin biosynthesis, GTP cyclohydrolase, indicated that these pterins directly inhibit this enzyme and display $IC_{50}$ values ranging between 500 and 800 uM. Similar studies are presently being performed using primary neuronal cultures derived from the embryonic mouse. Preliminary data indicate that neurons in spinal cord cultures synthesize substantial quantities of tetrahydrobiopterin and may be a model system for studying the regulation of pterin biosynthesis in a nontransformed cell type.

352.13 TETRAHYDROPTERIN ANALOGS WHICH REPLACE TETRAHYDROBIOPTERIN AS COFACTORS FOR TYROSINE HYDROXYLASE AND WHICH DO NOT CHANGE AFFINITY FOR TYROSINE. J. F. Reinhard, Jr., G. K. Smith*, E. C. Bigham*, R. C. Morrison, Jr.* and C. A. Nichol*. The Wellcome Research Laboratories, Research Triangle Park, NC 27709.

As part of a research program on the potential of biopterin cofactor replacement therapy to stimulate dopamine synthesis in Parkinson's disease (PD), we have synthesized and tested tetrahydropterins with different physicochemical and pharmacokinetic properties. Dopamine (DA) synthesis requires adequate amounts of the co-substrates tyrosine and oxygen and of tetrahydrobiopterin ($BH_4$) as cofactor. Previous reports have established that $BH_4$ levels are diminished in the cerebrospinal fluid of patients with PD (LeWitt, P. A. *et al.*, *Adv. Neurology*, **40**:459-462, 1984). Other work suggests that the tyrosine substrate may also be limiting (Growdon, J. H. *et al.*, *Life Sci.*, **30**:827-832, 1982). Since previously known synthetic $H_4$pterin cofactors for TH increase the $K_m$ for tyrosine, *in vivo* they may increase the requirement for a potentially limiting substrate. We now report the discovery of a new class of synthetic $H_4$pterin cofactors which do not significantly elevate the tyrosine $K_m$ for TH. Additionally, some of these cofactors appear selective for TH, relative to phenylalanine hydroxylase (PH). The TH was prepared from bovine adrenal medulla by partial trypsin digestion and ammonium sulfate fractionation. The activity of TH was measured by the release of $^3H_2O$ from L-3,5-[$^3$H]-tyrosine. The phenylalanine hydroxylase preparation was purified from rat liver by hydrophobic column chromatography, and assayed by measurement of the tyrosine produced using liquid chromatography with fluorescence detection. The $H_4$pterins differ in the substituents at the C6 position (R). The $K_m$ values are micromolar and the $V_{rel}$ values are percentages of the $V_{max}$ values obtained with $BH_4$.

| R | TH | | | PH | |
|---|---|---|---|---|---|
| | $V_{rel}$ | $K_{m_{ptr}}$ | $K_{m_{tyr}}$ | $V_{rel}$ | $K_{m_{ptr}}$ |
| $BH_4$ | 100 | 107 | 15 | 100 | 6 |
| $CH_3$(6-MPH$_4$) | 154 | 133 | 51 | 238 | 21 |
| 6,6-$(CH_3)_2$ | 119 | 77 | 105 | 39 | 29 |
| $CH_2$-O-Methyl | 126 | 84 | 22 | 138 | 17 |
| $CH_2$-O-Ethyl | 154 | 52 | 23 | 155 | 21 |
| $CH_2$-O-Propyl | 92 | 28 | 22 | 32 | 16 |
| $CH_2$-O-Butyl | 135 | 95 | 25 | 22 | 21 |

As can be seen, all of the substituted $H_4$pterins supported tyrosine and phenylalanine hydroxylation. Affinities for TH approached or exceeded that of the natural cofactor and yielded substrate $K_m$ values which were not radically different from the substrate $K_m$ values obtained when $BH_4$ was used as a cofactor for TH. In contrast, the commonly used 6-MPH$_4$ yielded a substrate $K_m$ some 3-fold higher than the substrate $K_m$ obtained using $BH_4$ and the substrate $K_m$ obtained when 6,6-dimethyl-$H_4$pterin was used as cofactor was nearly 10-fold higher than that produced by $BH_4$. Additionally, the 6-butyloxymethyl-$H_4$pterin yielded higher $V_{max}$ values for TH than for PH, and thus appeared selective for TH. The *in vivo* effects of these new pterins should be greater than that of previously synthesized pterins since they are less likely to cause tyrosine to become limiting.

## CATECHOLAMINES: SYNTHESIS AND METABOLISM

353.1 A NEW TECHNIQUE FOR NAFION COATING CARBON FIBER ELECTRODES FOR IN VIVO ELECTROCHEMISTRY. M.P. Brazell*, B. Moghaddam* and R.N. Adams, Depts. of Physiology and Pharmacology, Univ. of Nottingham Medical School, Nottingham, England, and Dept. of Chemistry, University of Kansas, Lawrence, KS 66045.

A well-recognized problem with in vivo electrochemistry is its lack of compound specificity. Many compounds found in brain such as dopamine (DA), 3,4-dihydroxyphenylacetic acid (DOPAC) and ascorbic acid (AA) oxidize at very similar potentials. Thus it is not possible to resolve between the current generated by their oxidations. A year ago we reported a major improvement in the selectivity of small graphite epoxy capillary (GEC) electrodes used for in vivo electrochemistry (Gerhardt, G.A. et al., Brain Res., 290: 390, 1984). These electrodes were dip-coated with Nafion, a perfluorosulfonated polymer. The anionic Nafion is highly permeable to cations such as DA and norepinephrine (NE), but impermeable to anions such as AA and DOPAC. For the large (200-300 µm tip dia.) GEC electrodes, one or two simple dippings in Nafion and air-drying between dips produces electrodes that are sensitive to neurotransmitters such as DA and insensitive to their metabolites and AA. For the smaller carbon fiber electrodes, because of their smooth surface, such a dipping process gives poor Nafion coatings and thus electrodes without the desired characteristics. We wish to report a simple method for coating the small carbon fiber electrodes (40 µm o.d.). To produce well-coated fiber electrodes, they are washed with double-distilled water and dried gently for 90 sec with a hair-dryer. The electrodes are then horizontally immersed in a Nafion drop placed on a platimum wire. A potential of +0.1 V is applied to the electrode for 5 sec. The electrode is then gently blow-dried for 10 sec. Two further horizontal dips are usually required to produce a sufficient coat; however, these are done without a potential being applied to the electrode.

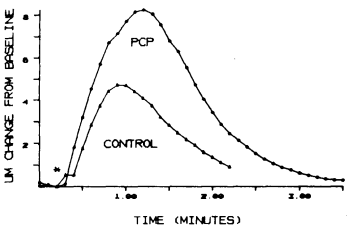
The responses of coated and uncoated fiber electrodes have been tested and compared in vivo by pressure ejection of various mixtures of anionic and cationic oxidizable species next to the electrodes. The same "electroplating" procedure has been successfully used to Nafion-coat GEC electrodes (supported by the British Medical Research Council and National Institutes of Health).

353.2 **PRESYNAPTIC ACTION OF PHENCYCLIDINE (PCP) IN THE RAT STRIATUM DEFINED USING IN VIVO ELECTROCHEMICAL METHODS.** G. Gerhardt[1] and G. Rose[1,2]. [1]Dept. of [2]Pharmacol., University of Colorado Health Sciences Center and [2]Medical Research, VAMC, Denver, CO 80262.

Local application of PCP potentiates catecholaminergic transmission in the CNS. While the mechanism by which this occurs is still unclear, current work in our laboratory suggests that this action of PCP is effected either by eliciting transmitter release, or preventing its reuptake, by presynaptic elements. In an effort to distinguish between these two possibilities, we have used in vivo electrochemical recording methods to examine the effects of PCP upon the dopamine-containing afferents in rat striatum.

Animals were anesthetized with chloral hydrate; chronoamperometric recordings were made using Nafion-coated graphite epoxy capillary (GEC) electrodes, which are very selective for the monoamine neurotransmitters (Gerhardt et al., Brain Res., 290; 390). Local application of PCP and other agents was accomplished using single- or multi-barrel glass micropipettes which were fixed to the GEC electrodes with wax; drugs were applied using micro pressure-ejection.

Application of PCP (barrel concentrations $10^{-4}$ M and $10^{-5}$ M) did not cause an increase in baseline electrochemical signals recorded from the striatum. However, marked increases in both the magnitude (50%) and timecourse (30%) of monoamine releases evoked by local application of $K^+$ were observed if PCP was applied preceeding the $K^+$ bolus (see figure below). Interestingly, excessive application of PCP, or the use of $10^{-3}$ M barrel concentration of this compound, greatly attenuated or abolished $K^+$-evoked releases of monoamines. PCP-induced alterations in the magnitude and temporal dynamics of $K^+$-evoked signals were mimicked by local application of the putative dopamine reuptake blocker nomifensine. Magnitudes and timecourses of electrochemical signals recorded as a consequence of direct local application of dopamine into the striatum from another pipette barrel were also augmented following local PCP administration.



Taken together, these data support the idea that the primary mechanism by which PCP augments catecholaminergic transmission is via interference with neurotransmitter reuptake processes. (Supported by UPSHS grants DA 02429, DA 07043 and the VA Medical Research Service.)

353.3 HABENULAR STIMULATION INCREASES DOPAMINE UTILIZATION AND LOCOMOTOR ACTIVITY. G. R. Christoph*, K. S. Wilcox*, S.-Y. Tam, B. A. Burkhart*, and R. H. Roth. (Spon: J. S. Schwaber) Central Research & Development Department, E. I. du Pont de Nemours & Company, Wilmington, DE and Department of Pharmacology, Yale University, New Haven, CT.

Neurons of the habenula project to the ventral tegmentum where A10 dopamine (DA)-containing neurons are located. The function of this projection was studied by stimulating the habenula and then measuring DA and DOPAC concentrations in the prefrontal cortex (PF), nucleus accumbens (NA), and striatum (ST). Two weeks after unilateral implantation of bipolar electrodes, rats (N=14) received habenular stimulation (250 μA, 250 μsec, 20 Hz) for 30 min in a locomotor activity test chamber. The implanted control group (N=13) was not stimulated. The rats were immediately decapitated and the brains were removed and dissected over ice. HPLC electrochemical detection methods were used to determine DA and DOPAC concentration. Electrode locations in the habenula were verified histologically. In PF samples stimulation caused a significant increase in DOPAC (54%, $P<.03$) compared to control. Stimulation decreased DA in NA by 26% ($p<.001$). ST values were unaffected. Locomotor activity counts were markedly increased by stimulation (366%, $p<.001$). Wet dog shakes were often noted in the stimulated group and never occurred in control rats. As a control for current spread to thalamic nuclei, stimulation of medial dorsal thalamus in another group of rats (N=6) had no effect on the behavioral measures, and unlike habenular stimulation, it only increased DA in PF. The results indicate that habenular stimulation affects mesolimbic and mesocortical dopaminergic function and, in particular, increases dopamine utilization in cortex. Interestingly, the neurochemical and behavioral effects of habenular stimulation are similar to those of infusing substance P analogs into the VTA. Since the medial habenula may be a source of substance P-like compounds in the region of the VTA, we suggest that activation of this peptidergic system is responsible for our results.

353.4 COMPARISON OF DOPAMINERGIC NEURONAL ACTIVITIES IN THE HYPOTHALAMUS AND POSTERIOR PITUITARY GLAND OF MALE AND FEMALE RATS: EFFECTS OF CASTRATION. J.W. Gunnet*, K.J. Lookingland and K.E. Moore. Dept. of Pharmacology/Toxicology, Michigan State Univ., East Lansing, MI 48824.

Sexual differences have been found in the activity of tuberoinfundibular dopaminergic (TIDA) neurons in the rat, with greater activity in the female. The goals of this study were to: 1) compare the activities of TIDA, tuberohypophysial dopaminergic (THDA) and incertohypothalamic dopaminergic (IHDA) neurons in Long-Evans male and female rats and, 2) to determine the effects of castration upon the activity of these 3 dopaminergic systems.

Dopaminergic neuronal activity was estimated by measuring the decline in tissue dopamine (DA) concentrations 0, 30 and 60 minutes after α-methyltyrosine injection (250 mg free base/kg, i.p.) by radioenzymatic assay. DA turnover rates were calculated from DA concentrations in tissue samples collected by means of a modified punch dissection technique. Several brain regions (nucleus accumbens, rostral periventricular nucleus ($A_{14}$), preopticosuprachiasmatic nucleus, medial preoptic nucleus, medial zona incerta ($A_{13}$), dorsomedial nucleus, median eminence) and both intermediate and neural lobes of the pituitary gland were sampled.

As previously reported, the DA activity of TIDA neurons within the median eminence was 2 to 3 times greater in diestrous female rats than intact male rats. The THDA neurons terminating in the intermediate lobe showed no sex differences while those innervating the neural lobe did express a higher DA turnover rate in intact males. Rostral but not caudal IHDA neurons (e.g., neurons within the medial preoptic nucleus versus neurons in the dorsomedial nucleus) exhibited greater activity in the diestrous female versus the intact male. These data demonstrate that the diestrous female when compared to the intact male, has greater DA turnover (i.e., activity) in the TIDA and rostral IHDA systems but lower DA turnover in the THDA neurons of the neural lobe. In the male rat orchidectomy reduced the turnover rate of DA in rostral IHDA neurons and increased the turnover rate of DA in TIDA neurons. Ovariectomy of the female rat decreased TIDA activity and increased the DA turnover in both rostral IHDA neurons and THDA neurons of the neural lobe. These findings indicate that the neurons of the IHDA and THDA systems respond differently to castration in male and female rats and suggest that the hypothalamic DA systems of the female are more responsive to the effects of castration than those of the male. (Supported by USPHS grant NS15911.)

353.5 ANXIOGENIC BETA-CARBOLINE SELECTIVELY INCREASES MONOAMINE METABOLISM IN THE PREFRONTAL CORTEX AND THE HYPOTHALAMUS. S.-Y. Tam, A. Y. Deutch, J.-X. Yang*, M. J. Bannon and R. H. Roth, Departments of Pharmacology and Psychiatry, Yale University School of Medicine, New Haven, Connecticut 06510

We have recently shown that the selective increase in dopamine (DA) metabolism induced in the mesoprefrontal DA neurons by mild footshock stress is modulated by central benzodiazepine (BZ) receptors. Beta-carbolines are specific BZ receptor ligands, some of which have been shown to be anxiogenic in animals and humans. We have examined whether the anxiogenic beta-carboline FG 7142 is able to selectively activate the mesoprefrontal DA neurons in a similar fashion to that induced by stress or conditioned fear.

FG 7142 administered at 5, 10, 15, and 20 mg/kg, i.p., 30 minutes prior to sacrifice, produced a significant dose-dependent increase in DOPAC levels in the prefrontal cortex (PFC). However, DOPAC levels in other mesocortical terminal fields such as the cingulate and piriform cortices were not affected. At 10 mg/kg, DOPAC levels in both the olfactory tubercle and the striatum were significantly decreased, but no change was observed in the nucleus accumbens. The effects of FG 7142 in the PFC were not seen 15 minutes after drug treatment, and disappeared 60 minutes after FG 7142 administration. Moreover, when rats were pretreated with the BZ receptor agonist diazepam or BZ receptor antagonists such as RO15-1788 or CGS 8216, the beta-carboline induced increase in PFC DOPAC levels was significantly antagonized by 75%. At a dose of 15 mg/kg, FG 7142 caused a significant increase in DOPAC levels in the ventral tegmental area (VTA); however, levels of the DA metabolite in the substantia nigra (SN) were significantly decreased. While footshock stress causes a reduction of substance P levels in the VTA, neither substance P nor substance K levels in the VTA or SN were changed 30 minutes after FG 7142 administration. Levels of the norepinephrine metabolites, MHPG and DHPG, were also determined in hypothalamus, cerebral cortex, hippocampus and cerebellum 30 minutes after FG 7142 administration. Significant increases in both MHPG and DHPG levels were observed in the hypothalamus, but not in any other brain region examined. Moreover, the effects of FG 7142 on the hypothalamus were time-dependent and were sustained 60 minutes after drug treatment.

These data demonstrate that the mesoprefrontal DA neurons which are selectively activated by stress, are also selectively activated by the anxiogenic BZ receptor inverse agonist, FG 7142. Since FG 7142 did not appear to activate the substance P input to the VTA, we suggest that the beta-carboline may exert its effects on the mesoprefrontal DA neurons by directly acting on BZ receptors in the VTA. These studies are consistent with multiple types of regulatory mechanisms controlling the function of VTA DA neurons. (Supported by USPHS Grant MH 14092 and the State of Connecticut)

353.6 PHARMACOLOGY AND REGULATION OF MESOAMYGDALOID DOPAMINE NEURONS. C.M. Anderson*, D.L. Knight*, L.E. Elliott*, T.D. Ely* and C.D. Kilts* (Spon.: D. Hernandez). Duke Univ. Med. Ctr., Durham, NC 27710.

The study of dopamine (DA) neuronal innervation of limbic brain structures has been overly focused on the DA-rich nucleus accumbens (NA) and olfactory tubercles (OT). We have previously reported on the significant and heterogeneous DA innervation of the amygdala, and the atypical representation of DA mechanisms thought to be operative in terminal regions of other DA systems (Kilts et al., Neurosci. abst. 10:881, 1984). Whether these differences compared to more conventional DA systems impart a unique pharmacology to the mesoamygdaloid DA neurons, perhaps as a function of unconventional neuronal regulatory mechanisms, was the focus of this investigation.

The effects of drug treatments on biochemical estimates of the functional activity of DA neurons involved determination of (1) the concentration of DOPAC and HVA, (2) DA turnover or utilization following synthesis inhibition and (3) in vivo tyrosine hydroxylase activity estimated by DOPA accumulation following decarboxylase inhibition. All determinations were performed at the level of discrete brain nuclei micropunched from frozen coronal rat brain slices (Palkovits, Brain Res. 59: 449, 1973). DOPA, DA, DOPAC and HVA concentrations were determined by novel on-line trace enrichment HPLC-electrochemical detection methods.

Of the amygdaloid nuclei, the central amygdaloid nucleus (CNA) receives the densest DA innervation. DA neurons innervating the CNA respond to a gammabutyrolactone(GBL)-induced loss of impulse activity with an atypical decrease in DOPA accumulation, an effect enhanced by prior apomorphine (APO) treatment (1 mg/kg, s.c.). In the medial amygdaloid nucleus (MNA), GBL produced an APO-reversible increase in DOPA accumulation similar to that seen in the NA, OT and caudate nucleus (CN). These data suggest that the DA terminals innervating the CNA, like those projecting to the medial prefrontal cortex, lack DA synthesis regulating autoreceptors and thereby differ from neuronal terminations in the NA, OT, CN and MNA. Like the NA, OT and CN the acute administration of haloperidol (1 mg/kg, i.p.) increased all three biochemical estimates of DA neuronal activity in the CNA.

These data further indicate that there are fundamental pharmacological and neuroregulatory differences both within and between limbic structures. An obvious corollary is that the study of DA mechanisms in the NA and OT should not be generalized to DA function in the limbic system when testing the hypothetical involvement of DA in limbic psychopathology. (Supported by NIHM MH-39967.)

353.7 RAPID POST-MORTAL INCREASE IN EXTRACELLULAR CONCENTRATION OF DOPAMINE IN THE RAT BRAIN AS ASSESSED BY INTRA-CRANIAL DIALYSIS. Arnold G. Vulto*, Trevor Sharp and Urban Ungerstedt (SPON: European Neuroscience Association) Department of Pharmacology, Karolinska Institute, P.O.Box 60400, S-104 01 Stockholm, Sweden. *Present address: Rudolf Magnus Institute for Pharmacology, Medical Faculty University of Utrecht,Vondellaan 6, 3521 GD Utrecht,The Netherlands

Measurement of the release of endogenous or preloaded, labelled dopamine (DA) from rat brain slices is commonly used in neuropharmacological studies. Whilst it is known that preloaded DA is preferentially released, it is assumed, that release of endogenous DA in vitro represents the true physiological releasable pool. However, little is known about changes in intraneuronal pools of the endogenous neurotransmitter postmortem. Recently we have shown rapid postmortem increases in the concentration of the DA metabolite 3-methoxytyramine (Vulto et al., 9th IUPHAR congress London, 1984, abstract 1153) which could reflect the release of endogenous DA at death. We have now directly examined this possibility by following changes in the extracellular concentrations of endogenous DA before and after death in the rat brain using a recently developed intracerebral dialysis method in combination with HPLC-ECD (Zetterström et al., J. Neurochem., 41:1769, 1983). Dialysis probes were implanted into the nucl. accumbens of halothane-anaesthetised rats and DA and its metabolite DOPAC were measured in perfusates collected before and after cervical dislocation. Before death typical recoveries in a 20 min perfusate were 0.1-0.2 pmol of dopamine and 25-50 pmol of DOPAC. After death, we sampled every minute. After 2 to 4 min the output of dopamine increased rapidly to more than 1 pmol per min. The dopamine concentration peaked rapidly, 2 to 3 min after the onset of rise,with a gradual decline afterwards. DOPAC showed a small increase in the first minute after death with a subsequent continuous decline. A number of factors could contribute to the explanation of the observed phenomena. Cervical dislocation may cause a widespread stimulation or disinhibition of neuronal activity in the brain with subsequent release of transmitters. Due to anoxia, re-uptake may fail, neuronal membranes start to disintegrate and the extracellular concentration of transmitters will rise. Metabolism is probably also hampered because of the failing reuptake and lack of oxygen (both requisites for dopamine deamination by MAO). The results indicate a rapid massive release of DA in the brain immediately following death. This suggests that the releasable and non-releasable pools of endogenous DA may be dramatically altered by a large post-mortem redistribution of the neurotransmitter. Furthermore, DA (auto)receptors and coupled mechanisms (like tyrosine hydroxylase activity) may be changed as a consequence of a massive postmortem receptor stimulation.
[Arnold G. Vulto was in receipt of a European Training Programme in Brain and Behaviour Research short-term fellowship]

353.8 PROLACTIN-INDUCED ACTIVATION OF TUBEROINFUNDIBULAR DOPAMINE NEURONS IS MEDIATED BY THE ANTERIOR HYPOTHALAMUS. Anne C. Gredler and Keith T. Demarest. Departments of Pharmacology/Toxicology and Physiology, Michigan State University, East Lansing, MI 48824

The neurosecretory activity of tuberoinfundibular dopamine (TIDA) neurons is regulated by the feedback of circulating levels of prolactin (Neuroendocrinology 38:467, 1983). Previous studies have demonstrated sexual differences in the activity of TIDA neurons which are due, at least in part, to a difference in the responsiveness of TIDA neurons to the action of prolactin (Neuroendocrinology 33: 230, 1981). The present study was undertaken to determine whether the action of prolactin to stimulate TIDA neuronal activity is mediated by an intra- vs extra-hypothalamic origin and if anterior hypothalamic influences differ in male vs female rats. In these studies the effect of complete and partial hypothalamic deafferentation on the neurosecretory activity of TIDA neurons and their responsiveness to prolactin was examined. Hypothalamic deafferentations consisted of a complete medial basal hypothalamic island (MBH lesion) or an extended anterior retrochiasmatic cut (RC lesion) (Endocrinology 80: 608, 1967). The synthesis and turnover of DA in the median eminence was used as an index of TIDA neurosecretory activity and was estimated by the rate of DOPA accumulation following NSD 1015 (100 mg/kg, i.p.) or by the alpha-methyltyrosine (AMPT; 250 mg/kg free base i.p.) induced decline of DA after 0, 30 and 60 min. Both the MBH and RC lesions decreased the rate of DOPA accumulation and DA turnover in the median eminence of female, but not male rats. These results suggest that in the female rat TIDA neuronal activity is tonically stimulated via an anterior hypothalamic afferent influence, while this influence is either absent or repressed in the male. Since previous studies have demonstrated that TIDA neurons in female rats are tonically stimulated by circulating prolactin, these results may suggest that the action of prolactin to stimulate TIDA neurons is mediated via the anterior hypothalamus. In support of this hypothesis is the demonstration that the increase in DOPA accumulation in the median eminence, induced by either haloperidol (2.5 mg/kg, s.c.; 16 h prior to sacrifice) or ovine prolactin (10 mg/kg, i.p. x 3 d) administration, was blocked by a RC lesion in both female and male rats. These results suggest that the greater activity of TIDA neurons in the female rat is the consequence of a tonic stimulatory influence from the anterior hypothalamus. In addition, the action of prolactin to stimulate TIDA neurons in both male and female rats appears to be mediated via an anterior hypothalamic pathway. (Supported by NIH grant AG02644).

353.9 HEMORRHAGE INCREASES THE NEUROSECRETORY ACTIVITY OF TUBEROHYPOPHYSEAL DOPAMINE NEURONS. Keith T. Demarest. Depts. of Pharmacology/Toxicology and Physiology, Michigan State Univ., E. Lansing, MI 48824

Previous studies have demonstrated that several days of dehydration (Neuroendocrinology 31: 112, 1980) or acute injections of hypertonic saline (Neuroendocrinology 35: 469,1982) increase the rate of dopamine (DA) synthesis in the neurointermediate lobe (NIL) of the pituitary. Thus the activity of tuberohypophyseal (TH) DA neurons appear to be regulated, at least in part, by sodium or osmoreceptors. The present studies were undertaken to determine if hemorrhage, which alters blood volume and pressure, influences the synthesis and turnover of DA in the NIL. Male rats were hemorrhaged under ether anesthesia via a retrograde orbital sinus puncture of 1-2 min duration. The synthesis of DA in the NIL, median eminence and striatum was estimated by measuring the rate of dihydroxyphenylalanine (DOPA) accumulation 30 minutes after the administration of the decarboxylase inhibitor, NSD 1015 (100 mg/kg, i.p.). The turnover of DA and norepinephrine (NE) was determined by the rate of the alpha-methyltyrosine (AMPT; 250 mg/kg free base i.p.) induced decline of amine concentrations after 0, 30 and 60 minutes. The rate of DOPA accumulation in the NIL increased within 30 minutes following a hemorrhage of 1.5 ml/kg (0.75 $\pm$ 0.08 to 1.21 $\pm$ 0.08 ng/mg protein), but returned to control values by 4 h after the onset of the hemorrhage. This treatment did not alter DA or NE concentrations in the NIL or other regions examined. The rate of the AMPT-induced decline of DA increased 2-3 fold in the NIL (0.37 $\pm$ 0.02 vs 1.11 $\pm$ 0.04 ng/mg protein/h) immediately following a hemorrhage of 1.5 ml/kg, while that of NE was unchanged (0.14 $\pm$ 0.02 vs 0.12 $\pm$ 0.02 ng/mg protein/h). No change in the rate of DOPA accumulation or DA and NE turnover was observed in the median eminence or striatum at anytime after hemorrhage confirming that this treatment was selective for the NIL and did not alter the absorption or distribution of either NSD 1015 or AMPT. In addition, the ether anesthesia and orbital sinus puncture alone without hemorrhage were without effect. The hemorrhage-induced increase in TH DA neuronal activity was volume dependent; increasing the volume bled (0.5-2.0 ml/kg) resulted in a graded increase in DOPA accumulation in the NIL. These results demonstrate that hemorrhage induces an acute selective increase in the neurosecretory activity of TH DA neurons. This study also suggests that, in addition to osmoreceptor mediated mechanisms, the TH DA system may be regulated by a baroreceptor mechanism(s). (Supported by NIH grant AG02644).

353.10 LONG-TERM ESTRADIOL TREATMENT INDUCES IRREVERSIBLE DAMAGE TO TUBEROINFUNDIBULAR DOPAMINERGIC NEURONS IN FISHER 344 RATS BUT NOT IN LONG-EVANS RATS. Gail D. Riegle*, Kenneth E. Moore, Kathryn L. Lovell, and Keith T. Demarest (SPON: G.M. Lew). Depts of Pharmacology/Toxicology, Physiology and Anatomy, Michigan State Univ., E. Lansing, MI 48824

Previous studies have demonstrated that long-term estradiol treatment of female ovariectomized Long-Evans rats induces reversible alterations in tuberoinfundibular dopaminergic (TIDA) neurons which are characterized by decreased DA content and synthesis in the median eminence and by a decrease in the responsiveness of these neurons to prolactin (Neuroendocrinology 39: 193, 1984). Since other investigators have suggested that estradiol treatment induces irreversible damage to TIDA neurons in Fisher 344 rats, the present studies were undertaken to compare the effects of the long-term estradiol treatment of intact female rats of the Long-Evans versus Fisher 344 strains. Intact female rats of both strains were implanted with silastic capsule containing estradiol benzoate (5 mm exposed length of 0.062 in ID, 0.175 in OD silastic tubing). Estradiol treatment increased serum prolactin concentrations in both strains. This increase was of a 5-10 fold greater magnitude in the Fisher 344 rats. The increase in prolactin was associated with a dramatic increase in anterior pituitary size; the increase was 3-4 fold larger in the Fisher 344 rats. Estradiol treatment decreased the concentrations of DA and the rate of DA synthesis in the median eminence by 36 days in both strains. No change in norepinephrine (NE) concentrations were observed in the median eminence of Long-Evans rats, but a dramatic decrease was observed in the Fisher 344 rats. Similarly, DA-NE content and DA synthesis in the neurointermediate lobe of the pituitary (NIL) were not changed in the Long-Evans rats, but were decreased in the Fisher 344 rats. These changes in NE content in the median eminence and DA-NE content in the NIL are apparently non-selective and are most likely due to the severe compression associated with the estradiol-induced hypertrophy of the anterior pituitary as demonstrated by histological analysis. The DA concentration in the median eminence of Long-Evans rats returned to control values by 18-36 days following removal of the estradiol-containing capsule. DA and NE content in the median eminence and NIL of the Fisher 344 rats was decreased following termination of estradiol treatment for as long as 36 days. These results suggest that the irreversible damage associated with long-term estradiol treatment in the Fisher 344 rats is most likely due to the hypertrophy of the anterior pituitary gland and not as direct "neurotoxic" action of estradiol or prolactin on TIDA neurons. (Supported by NIH grant AG02644 and NS 09174).

353.11 DIFFERENTIAL RESPONSE OF TUBEROINFUNDIBULAR DOPAMINE NEURONS TO CASTRATION IN MALE VERSUS FEMALE RATS. Mary Lynn Bajt and Keith T. Demarest. Depts. of Pharmacology/Toxicology and Physiology, Michigan State Univ., E. Lansing, MI 48824

Previous studies have demonstrated a greater rate of DA synthesis and turnover in the median eminence of female versus male rats which is due, at least in part, to a greater responsiveness of tuberoinfundibular dopamine (TIDA) neurons in the female rat to the stimulatory actions of prolactin (Neuroendocrinology 32: 108, 1981; 33: 230, 1981). The present studies were undertaken to determine the effect of endogenous gonadal steroids on the activity of TIDA neurons. Adult male and female rats of the Long-Evans strain were castrated 1 week prior to sacrifice. Intact female rats were sacrificed on the second day of diestrus. The synthesis of DA was estimated by measuring the rate of dihydroxyphenylalanine (DOPA) accumulation 30 minutes after the administration of NSD 1015. The turnover of DA and norepinephrine (NE) was determined by the rate of the alpha-methyltyrosine-induced decline of amine concentrations after 0, 30 and 60 minutes. DA synthesis was approximately 3 times greater in the median eminence of intact female vs male (16.8 ± 2.1 vs 4.8 ± 0.9). Following castration, the rate of DA synthesis in the median eminence of female rats was decreased but in male rats it was increased; resulting in similar rates of DA synthesis in the castrate male and female groups. Following castration, the rate of DA turnover in the median eminence of female rats was unchanged while the rate of NE turnover increased 2 fold. In male rats, castration caused a 2 fold increase in both DA and NE turnover in the median eminence. These results demonstrate a differential effect of castration on DOPA accumulation in the median eminence of male vs female rats. In the male, the castration induced increase in DOPA accumulation appears to be the result of an increase in both DA and NE turnover. However, the decrease in DOPA accumulation in the female is not consistent with the lack of change in DA turnover and the apparent increase in NE turnover. The changes in DA turnover in the female are somewhat confounded by an increase in DA steady-state concentrations associated with castration which is not observed in the male. The observed male-female differences in TIDA neuronal activity cannot be explained on the basis of differences in circulating prolactin concentrations since serum prolactin concentrations, determined in a separate group of rats, were not dramatically different between intact versus castrate female. These results suggest that the male-female difference in TIDA neuronal activity may be mediated by the presence of endogenous gonadal steroids. (Supported by NIH grant AG02644).

353.12 EFFECTS OF 3-PPP ENANTIOMERS, SKF-38393, AND 8-OH-DPAT ON SYNTHESIS IN MESOCORTICAL DOPAMINE NEURONS, D. Clark*, and M.P. Galloway, (SPON: M. Stanley), Laboratory of Neurophysiology, Center for Cell Biology, Sinai Hospital, Detroit, MI 48235, and Neurochemical Pharmacology Research Unit, Lafayette Clinic, Dept. of Psychiatry, Wayne State University, Detroit, MI 48207

Biochemical and electrophysiological evidence suggests that mesencephalic dopamine (DA) neurons projecting to the medial prefrontal cortex (MPF), unlike those innervating and striatum (STR) and limbic structures, lack functional terminal autoreceptors regulating DA synthesis, and somatodendritic DA autoreceptors controlling impulse flow. Although low doses of apomorphine can inhibit DOPA accumulation in MPF cortex, it has been proposed that this effect on synthesis is mediated indirectly by activation of DA release modulating autoreceptors with a subsequent increase in end-product inhibition of tyrosine-3-monooxygenase. In light of the possible functional implications of regulatory differences between DA systems, we have compared the regional effects of other monoamine agonists on DA synthesis.

The D2 agonist (+)-3-PPP (0.5-5.0 mg/kg, sc) reduced DA synthesis rate (measured in vivo as the accumulation of DOPA following decarboxylase inhibition by NSD 1015) in rat STR, nucleus accumbens (NAC) and MPF. In contrast the D1 agonist SKF 38393 (1-3 mg/kg) was ineffective in these areas whereas the 5HT agonists 8-OHDPAT (0.1 mg/kg) and TFMPP (1 mg/kg) slightly elevated (20-40%) DOPA accumulation. (-)-3-PPP, which acts as a partial agonist at normosensitive DA autoreceptors but as an antagonist at normosensitive postsynaptic DA receptors, exerted variable actions on DA synthesis. A low dose of (-)-3-PPP (0.5 mg/kg)reduced NAC DOPA but no effect was observed after 5.0 mg/kg. In the STR, DOPA was not influenced by the low dose of (-)-3-PPP and actually increased after the higher dose. In contrast, DOPA accumulation in the MPF was uniformly inhibited by both doses of (-)-3-PPP. In animals pretreated with reserpine, 3-PPP enantiomers strongly reduced STR and NAC DOPA levels but were without effect in the MPF cortex.

The fact that reserpine abolishes the inhibitory action of the 3-PPP enantiomers (and apomorphine) on MPF DA synthesis supports the hypothesis that DA agonists inhibit MPF synthesis indirectly via stimulation of D2 autoreceptors regulating DA release. The different effects of (-)-3-PPP in the MPF of normal animals, relative to those in the STR and NAC, may suggest that DA sensitive long-loop feedback pathways exert only a weak influence on impulse flow of mesoprefrontal DA neurons. Supported by Dept. of Mental Health, State of Michigan.

353.13 DOSE-RESPONSE AND TIME COURSE CHARACTERISTICS OF THE DOPAMINERGIC RESPONSE TO ACUTE COCAINE. S. M. Lasley, M. W. Emmett-Oglesby and J. D. Lane. Dept. of Pharmacology, Texas College of Osteopathic Medicine, Ft. Worth, TX 76107.

The primary mechanism of cocaine (COC) action is thought to involve an interaction with the monoamine synaptic reuptake site, particularly at dopaminergic nerve terminals. However, much evidence in support of this proposal is based on in vitro studies in which it is difficult to distinguish the releasing and reuptake blocking properties of an agent. Furthermore, a systematic in vivo analysis of the dose-response and time course characteristics of dopamine (DA) metabolism after acute administration of COC is not available, and would further elucidate the drug's effects. Such data is necessary for further studies investigating the changes resulting from chronic COC administration.

Separate groups of 100-day old male Long-Evans hooded rats were given i.p. injections of COC in doses ranging from 1.25-40 mg/kg and were sacrificed 20 min later. Additional groups of animals were injected i.p. with 10 mg/kg COC and sacrificed at periods 10-60 min post-injection. Brains were dissected at -20°C and medial prefrontal cortex, nucleus accumbens, caudate nucleus, hypothalamus, substantia nigra, and ventral tegmental area removed for quantitation of DA, dihydroxyphenylacetic acid (DOPAC), and homovanillic acid (HVA) by liquid chromatography with electrochemical detection. COC levels in plasma were determined in the same rats by gas chromatography with thermionic detection.

At higher doses or intermediate time intervals DOPAC content was decreased and HVA content was increased in a manner consistent with COC's actions as a reuptake blocker. However, at lower doses or shorter time intervals DOPAC concentrations were increased while HVA concentrations were essentially unchanged, suggesting that the drug also possesses releasing properties. Increases in DA content in nucleus accumbens and caudate nucleus did not exceed 15% and were substantially less than those that have been observed with d-amphetamine, another psychomotor stimulant. Plasma levels of COC increased linearly from 0.07 µg/ml at the lowest dose to 2.73 µg/ml at the highest dose. Subsequent work will compare these changes to those occurring after various protocols of chronic COC administration.

353.14 EFFECTS OF ACUTE $\Delta^9$-TETRAHYDROCANNABINOL (THC) EXPOSURE ON HYPOTHALAMIC NEUROTRANSMITTER SYSTEMS CONTROLLING PROLACTIN AND GONADOTROPIN RELEASE. S. Dalterio and R. Steger. Departments of Pharmacology and OB-GYN, University of Texas Health Science Center, San Antonio, Texas 78284.

Administration of THC, the major psychoactive component of marihuana, markedly inhibits circulating androgen, gonadotropin and prolactin levels in male and female mice. In previous studies we have shown that in addition to its effects in decreasing levels of these hormones, treatment with the non-psychoactive cannabinol (CBN), also reduced the concentration of norepinephrine (NE) in the median eminence (Life Sci. 36,1299, 1985). The present experiments were conducted to determine the acute effects of a 50 mg/kg oral dose of THC on NE, dopamine (DA), serotonin (5-HT),and 5-hydroxyindole acetic acid (5-HIAA) content in specific hypothalamic regions of mouse brain. Hypothalamic amines were assayed using HPLC and electrochemical detection. In addition, the effects of THC on NE and DA turnover was estimated by measuring the depletion of these amines after the inhibition of tyrosine hydroxylase with α-methyl-p-tyrosine (α-MPT). THC significantly increased median eminence (ME) DA content and turnover (0.154 ± 0.011 vs 1.806 ± 0.258 ng DA/ ME/hr) within 60 of THC treatment in intact male mice. In castrated male mice, DA content was elevated 15 min post-treatment with THC and remained elevated for at least 90 mins. Dopamine turnover in the medial basal hypothalamus (MBH) was decreased after THC treatment in intact mice, while levels in the medial preoptic area (MPOA) were unaffected. The NE content in ME, MBH or MPOA in intact or castrated mice was not significantly affected by THC treatment, but NE turnover tended to be decreased in the ME region of intact THC-treated mice. Serotonin content was not affected by THC administration in any of these studies, but this does not rule out possible THC-induced changes in 5-HT metabolism. In the final experiment, basal or NE-stimulated (60µM) LHRH release from ME fragments incubated in vitro were not affected by oral administration of THC at 60 min before sacrifice and incubation, or by the addition of THC (250 ng/ml) to the incubation media. This data, together with that obtained after repeated CBN exposure, suggests that cannabinoid-induced inhibition of prolactin secretion may be mediated, in part, by its ability to inhibit the tuberoinfundibular dopaminergic system regulating pituitary prolactin release. The effect of THC on gonadotropin secretion may also be due, at least in part, to inhibition of hypothalamic NE metabolism, but does not appear to be due to a direct effect of THC on LHRH neurons. It is also possible that THC may affect gonadotropin secretion through changes in DA metabolism, but further studies are required to evaluate this hypothesis.

353.15 ENHANCEMENT OF CATECHOLAMINE SYNTHESIS IN Na-DEPRIVED MEDIUM IN CULTURED BOVINE ADRENAL MEDULLA CELLS.
N. Yanagihara, K. Yokota*, A. Wada* and F. Izumi*
Department of Pharmacology, University of Occupational and Environmental Health, School of Medicine,Kitakyushu 807, Fukuoka, JAPAN.

In adrenal medulla cells, carbachol stimulates the secretion and synthesis of catecholamines which are both dependent on extracellular Ca. Recently, we reported that carbachol caused the influx of Na to the cultured bovine adrenal medulla cells via acetylcholine receptor mediated Na-channels and that influx of Na to the cells is a requisite for influx of Ca and the secretion of catecholamines (Neuroscience Lett., 47:78, 1984, Neuroscience, in press).

In the present study, we examined the effect of Na-deprivation from the incubation medium on the synthesis of catecholamines in order to investigate the role of extracellular Na in the regulation of catecholamine synthesis. Cultured adrenal medulla cells were incubated with L-[U-$^{14}$C] tyrosine for 30 min at 37°C and formed $^{14}$C-catecholamines were separated by ion exchange column chromatography using Duolite C-25. Intracellular pH was measured by the uptake of$^{14}$C-5,5-dimethyloxazolidine -2,4,-dione.

In Na-deprived sucrose-enriched medium, synthesis of $^{14}$C-catecholamines was much enhanced, while uptake of $^{14}$C-tyrosine to the cells was reduced. Enhancement of catecholamine synthesis by Na-deprivation was observed even if Ca was omitted from the medium. Dibutyryl cyclic AMP (2mM) increased the synthesis of $^{14}$C-catecholamines irrespective of the existence of Na in the medium. In control cells, the intracellular pH was 7.16 and it was shifted to 6.75 in Na-deprived medium, a condition which favors the activity of tyrosine hydroxylase, since the optimal pH for this enzyme is known to be 5.8 - 6.3.

These results suggest that Na-deprivation from the incubation medium enhances the synthesis of $^{14}$C-catechoamines from $^{14}$C-tyrosine probably through the decreas in intracellular pH in cultured bovine adrenal medulla cells.

353.16 NICOTINIC ACETYLCHOLINE RECEPTOR-ASSOCIATED Na-CHANNELS AND Na,K-ADENOSINE TRIPHOSPHATASE IN CULTURED BOVINE ADRENAL MEDULLA CELLS.
A. Wada*, N. Yanagihara, H. Kobayashi* and F. Izumi* (SPON:H.KANNAN). Department of Pharmacology, University of Occupational and Environmental Health, School of Medicine, Kitakyushu 807, Fukuoka, JAPAN.

In adrenal medulla cells, sodium ion (Na) has been considered not to be important in the secretory process of catecholamines mediated by acetylcholine receptor. Recently, we reported that in cultured bovine adrenal medulla cells, $^{22}$Na influx via the nicotinic receptor-associated Na-channels is intimately involved in $^{45}$Ca influx, a requisite for triggerring the secretion of catecholamines (Neuroscience Lett, 47:75-80, 1984, Neuroscience, in press).

In this paper, we examined whether inhibition of Na pump by ouabain or extracellular K deprivation modulates carbachol-induced cell responses. We also measured $^{86}$Rb uptake by the cells as index of Na, K-ATPase activity. (1) Carbachol caused rapid and transient influx of $^{45}$Ca and secretion of catecholamines which were not inhibited by tetrodotoxin, but were significantly reduced in Na free medium. (2) Carbachol evoked rapid and transient influx of $^{22}$Na which was inhibited by hexamethonium and d-tubocurarine, but not by tetrodotoxin. Concentration-response curve of carbachol for $^{22}$Na influx was almost identical to that for $^{45}$Ca influx. (3) Ouabain or K removal remarkably potentiated carbachol-induced $^{22}$Na influx, $^{45}$Ca influx and secretion of catecholamines. (4) Carbachol caused an increase of $^{86}$Rb uptake to the cells. In Na free medium, carbachol did not increase the uptake of$^{86}$Rb. (5) Ouabain inhibited carbachol-induced uptake of $^{86}$Rb in a concentration-dependent manner as it caused cellular accumulation of $^{22}$Na.

These results suggest that nicotinic acetylcholine receptor-associated Na-channels and Na, K-ATPase, both modulate influx of Ca and secretion of catecholamines through a cooperative regulation of intracellular Na concentration.

353.17 NOREPINEPHRINE TURNOVER IN CEREBELLUM AND OTHER BRAIN·REGIONS OF pcd MUTANT MICE. Kenneth W. Perry*, Ray W. Fuller and Bernardino Ghetti. Lilly Research Laboratories, Eli Lilly and Company and Indiana University Medical Center, Indianapolis, IN 46285 & 46223.

In the Purkinje cell degeneration (pcd) mutant mouse, Purkinje cells in the cerebellum begin degenerating at about 17 days of age, and 99% are lost by 45 days. The Purkinje cells are target cells for brain stem norepinephrine (NE) neurons. The degeneration of the Purkinje cells leads to a decrease in cerebellar weight and an increase in NE concentration with no change in the total content of NE per cerebellum (Ghetti et al, Brain Res. Bull. 7, 711-714, 1981). We have now evaluated NE turnover in cerebellum, hypothalamus and brain stem of pcd mice by measuring MHPG (3-methoxy-4-hydroxy-phenylethyleneglycol) and the ratio of MHPG/NE and by measuring 3,4-dihydroxyphenylalanine (DOPA) accumulation after decarboxylase inhibition.

Tissues from 5-6 mice per group were homogenized in 0.1 M trichloroacetic acid, and assays were performed on the supernatant fraction. The catechols (DOPA and NE) were assayed by liquid chromatography with electrochemical detection (LCEC) after adsorption onto and elution from alumina. DOPA was measured 30 min after injection of NSD 1015 (m-hydroxybenzylhydrazine), 100 mg/kg i.p. MHPG was assayed by LCEC using Bond-Elute CH columns for preliminary isolation, then injecting the eluate onto the C18 column with 0.1 M Na2PO4, 0.05 M citric acid as a mobile phase.

The content of MHPG in cerebellum and the ratio MHPG/NE were decreased in 3, 6 and 9 month old pcd mice compared to controls. The content of NE (amount per cerebellum) was unchanged, but the concentration of NE was increased due to the reduction in cerebellar weight in pcd mice. DOPA accumulation was decreased in cerebellum to 69%, 53% and 37% of control values, respectively, at 3, 6 and 9 months in pcd mice, but was not changed in brain stem and was only slightly decreased in hypothalamus. No decrease in MHPG (content or concentration) or in the ratio MHPG/NE was found in brain stem. In hypothalamus, NE concentration and content were slightly increased in pcd mice at all ages, and the ratio MHPG/NE was decreased in 6 and 9 month old pcd mice.

Although NE axons in the cerebellum are maintained in pcd mice after Purkinje cell degeneration, NE turnover was decreased. NE turnover was decreased slightly in hypothalamus but not in brain stem, though in both regions NE concentration was increased slightly. Apparently the NE projections to the cerebellum are intact, but the NE neurons do not synthesize and release their neurotransmitter at normal rates when their target Purkinje cells have degenerated. Since NE may act as a modulator in conjunction with other neurotransmitters, these data might suggest that some regulatory mechanisms of NE neurons operate to decrease function of the cerebellar NE axons when target cells are lost.

353.18 PHENYLETHANOLAMINE N-METHYLTRANSFERASE CONTAINING CELLS IN RAT RETINA: IMMUNOHISTOCHEMISTRY, IMMUNOCHEMISTRY AND MOLECULAR BIOLOGY. D.H. Park, G. Teitelman, M. Evinger, J. Woo*, D. Ruggiero, V. Albert, E. Baetge, V. Pickel, D. Reis and T.H. Joh. Depart. of Neurology, Cornell Univ. Med. Coll., New York, NY 10021.

Biochemical and indirect immunofluorescence histochemistry indicated the presence of epinephrine synthesizing enzyme, phenylethanolamine N-methyltransferase (PNMT) in the inner nuclear layer (INL), inner plexiform layer (IPL) and ganglion cell layer (GCL) of rat retina (Hadjiconstantinou et al., Neurosci., 1984). It has been reported that hypophysectomy resulted in decrease of adrenal PNMT but no change of retinal PNMT. In order to further characterize these cells, we investigated: (1) the anatomical details of PNMT neurons using PAP-immunohistochemical techniques and antibody double label methods; (2) whether other catecholamine biosynthetic enzymes, specifically tyrosine hydroxylase (TH), DOPA-decarboxylase (DDC), and dopamine B-hydroxylase (DBH), are present in the same cells; (3) whether retinal PNMT possesses immunochemical and biochemical properties similar to adrenal PNMT; and finally (4) whether PNMT mRNA can be identified in the retina, thereby confirming PNMT biosynthesis in retina. Immunohistochemistry using bovine adrenal PNMT antibody showed that cell bodies containing PNMT as the only CA-synthesizing enzyme were mainly localized in the INL of retina. A small population of exclusively PNMT-positive cell bodies were also observed in the GCL. Both PNMT cell bodies in the INL and GCL sent their dense processes to the IPL. Lightly stained PNMT-containing varicosities from cells of the INL were distributed in the outermost stratum of the IPL. Antibody double labeling method was used to determine whether other catecholamine enzymes, namely TH, DDC and DBH, coexist with PNMT in these cells. The fact that antibodies to other catecholamine enzymes failed to stain these cells indicated that these cells are PNMT specific cells. The exception was a small percentage of PNMT-staining cell bodies in the INL which were stained for TH and DDC, but not DBH. These cell bodies send their fibers to the outermost striatum of the IPL. PNMT ac tivity in rat retina was 10 pmole/mg prot./15 min at 37°C (Sprague Dawley, male rats). Although hypophysectomy did not alter PNMT activity in retina unlike adrenal enzyme, polyclonal antibodies raised in rabbits against bovine adrenal PNMT cross reacted with rat retina PNMT in similar fashion as with bovine adrenal PNMT in immunochemical titration experiment. The presence of PNMT mRNA in the retina as well as adrenals was identified by dot blot analysis using $^{32}$P-labeled PNMT cDNA probe. Thus, we conclude that the majority of the PNMT containing cells in the rat retina are PNMT specific cells, which do not contain other catecholamine enzymes. However, only the small portion of PNMT-containing cells in the INL contain the other CA-synthesizing enzymes TH and DDC but not DBH. Biochemical and PNMT cDNA dot blot analyses confirm that PNMT protein synthesis occurs in retina. (Supported by NIH grants, NS19002 and HL18974, and NIMH grant, MH24285.)

353.19 TIME COURSE OF THE DEPLETION OF BRAIN AND HEART NOREPINEPHRINE AFTER INTRAVENOUS ADMINISTRATION OF DSP4. M.C. Bennett, B.J. Vasquez, P. McNeeley*, L. Cahill* and J.L. McGaugh. Center for the Neurobiology of Learning and Memory and the Department of Psychobiology, University of California, Irvine, CA 92717 and V.A. Med. Center and Loma Linda University, Loma Linda, CA 92357.

Male CFW mice, 60 days of age, were housed (6 per cage) in an environmentally-controlled laboratory (LD 12:12, light on at 7 a.m.) with food and tap water available ad libitum. One week after arrival, the mice were injected i.v. (tail vein) with 25 mg/kg of the noradrenergic neurotoxin DSP4 (Hoechst). The drug was dissolved in cold physiological saline (2.5 mg/ml) in aliquots sufficient to inject one group of six mice and it was kept on ice during the entire procedure. Groups of six mice each were sacrificed 1, 2, 4, 12, 24 and 48 hours, 7, 14 and 28 days after injection. A control group which received a volume of 10 ml/kg saline was sacrificed one hour after injection. All animals were sacrificed between 10 a.m. and 12 noon to minimize the circadian variability in monoamine levels.

Monoamine levels were assayed in brain (minus cerebellum) and heart tissue by HPLC-EC. The tissues were briefly sonicated at minimum power in cold 0.1 M perchloric acid containing sodium metabisulfite. After centrifugation the supernatants were analyzed on a reverse phase ultrasphere C-18 column (Altex) and an LC-4A amperametric detector (BAS, Inc.) at an applied voltage of +0.7V. The mobile phase used was a citrate-phosphate buffer (PH4) with 10% methanol.

A significant reduction of norepinephrine (NE) was found in brain and heart tissue within 4 hr of DSP4 administration. Brain NE levels remained significantly depleted at the last time point measured, 28 days, while the peripheral tissue recovered to control levels within 14 days posttreatment.

The depletion from the 25 mg/kg i.v. dose of DSP4 was more robust and less variable than that found previously after 50 mg/kg i.p. administration. Further, large and significant depletion was found within hours of drug treatment. These results suggest that behavioral measurements may be done within hours, not days, after drug treatment, thus making them more comparable to those obtained after treatment with drugs that produce acute depletion of NE. Moreover, such findings may be less likely to be confounded by denervation supersensitivity.

This research is supported by USPHS Research Grants MH 12526 and the Office of Naval Research N00014-84-K-0391 (to JLMcG) and Southern California Edison Company.

353.20 EFFECTS OF DIFFERENT STRESS PARADIGMS ON CENTRAL DOPAMINE AND NOREPINEPHRINE METABOLISM. J.-X. Yang*, A. M. Knorr*, Kenan Onel*, S.-Y. Tam, A. Y. Deutch, L. Lubich* and R. H. Roth (SPON: J. A. Holley), Department of Pharmacology, Yale University School of Medicine, New Haven, Connecticut 06510

The mesocortical dopamine (DA) system has been implicated in emotional responses to stress. Stress paradigms such as footshock and conditioned fear increase DA metabolism in the prefrontal cortex (PFC), while the mesolimbic and nigrostriatal DA systems are largely unaffected. We have examined the effects of two other stressors on central DA metabolism and compared the results to those observed in response to footshock or conditioned fear paradigms. Changes in central norepinephrine (NE) metabolism under the various stress paradigms were assessed by measuring levels of the NE metabolites, DHPG and MHPG, by GC/MS.

Rats subjected to a 5-minute swim stress exhibited a significant increase in levels of the DA metabolite DOPAC in the PFC; other mesocortical, mesolimbic and nigrostriatal areas were unaffected. In the restraint stress paradigm a significant and selective increase in PFC DOPAC levels was observed. Thus, both the swim stress and restraint paradigms effected selective increases in PFC DA metabolism. This selectivity is similar to that observed in both footshock and conditioned fear paradigms: DOPAC levels are increased in the PFC and ventral tegmental area (source of the mesocortical DA innervation), but not altered in mesolimbic or nigrostriatal areas. Furthermore, the selective increase in PFC DOPAC levels is prevented by pretreatment with diazepam.

Both the swim stress and restraint procedures resulted in specific and selective changes in central NE metabolism. Swim stress effected a selective increase in DHPG, but not MHPG, levels in the hypothalamus. In contrast, both NE metabolites in the hypothalamus were elevated following restraint. Neither DHPG nor MHPG levels were altered in dorsal-bundle innervated regions, such as the PFC. The swim stress-elicited increase in DHPG levels was prevented by subacute treatment with tricyclic antidepressants.

These studies demonstrate that the mesoprefrontal DA system is uniformly activated under all four stress paradigms examined. The central noradrenergic systems, in contrast, do not respond to mild footshock stress, but are regionally activated by swim stress or restraint. Observed alterations in NE metabolism are confined to the ventral NE hypothalamic projection field. These data therefore suggest that the prefrontal cortical dopaminergic system may be critically involved in stress activation, even under such mild conditions that minimal hypothalamic-hypophyseal noradrenergic activation is observed. These data further indicate that the prefrontal cortical activation in response to stress exposure is confined to the DA system and does not involve concomitant changes in PFC NE systems. (Supported by MH 14092 and the State of Conn.)

353.21 NEUROTRANSMITTER TURNOVER RATE CHANGES IN BRAIN REGIONS OF RATS EXPOSED TO PUNISHMENT. T. Miyauchi*, S.I. Dworkin, C. Co* and J.E. Smith (SPON: G.F. Guerin). Psychiatry Research Unit, Departments of Psychiatry and Pharmacology, Louisiana State University Medical Center, Shreveport, LA 71130.

The neurobiological effects of punishment are not well understood. Several of the difficulties in such investigations involve controlling for response rate, reinforcement density and the direct effects of the punisher. This experiment determined neurotransmitter turnover rates in brain regions of rats exposed to punishment and controlled for the above non-specific factors.

Eight triads of male littermate rats were used. One littermate was trained on a conjoint random-ratio food, random-ratio shock schedule while the second rat's random interval schedule of food presentation was yoked to the subject on the ratio contingency. A third rat received food and shock response independently when ever they were presented to the subject on the ratio contingencies. Similar rates of responding and reinforcement densities were obtained from the rats on the punished-ratio and unpunished-interval contingencies while the third littermate was a control for the nonspecific effects of food and electric shock. The subjects were trained on the procedures and then implanted with chronic jugular catheters. After recovery of baseline responding the subjects were injected with 1 mCi [$^{3}$H]-tyrosine, 0.5 mCi [$^{3}$H]-tryptophan and 0.2 mCi [$^{14}$C]-glucose through jugular catheter immediately before the behavioral session. After either 60 or 90 min exposure to the appropriate behavioral condition, they were sacrificed by total freezing in liquid nitrogen. Brains were removed and dissected into 22 brain regions and the turnover rates of dopamine, epinephrine, norepinephrine, serotonin, aspartate, glutamate and gamma-amiobutyric acid determined by high-pressure liquid chromatography and liquid scintillation spectrophotometry. Significant changes in turnover rates of specific neurotransmitters in discrete brain regions were correlated with the different behavioral conditions. Discrete neuronal pathways and circuits may mediate punished responding. (Supported in part by USPHS Grant DA-01999).

354.1 DIFFERENTIATION OF STRIATAL NEURONS IN PRIMARY CULTURE. S. Weiss*, M. Sebben*, J.P. Pin*, F. Sladeczek*, P. Greengard, J. Gabrion* and J. Bockaert* (SPON : C. Chevillard) Centre CNRS-INSERM de Pharmacologie-Endocrinologie, BP 5055, 34033 Montpellier Cedex France and Laboratory of Molecular and Cellular Neuroscience, Rockefeller University, New York, NY 10021, U.S.A.

The biochemical and morphological properties of striatal neurons, generated from the foetal mouse brain and raised in primary culture, were examined. Recent advances in our laboratory now permit the maintenance of these neurons for 18-21 days in vitro (DIV), in a serum-free medium, devoid of non-neuronal cell types. Electron microscope (EM) observations revealed a synthesis and axonal migration of synaptic vesicles within 3 to 6 DIV. After 10-11 DIV synapse formation was observed, as determined by the presence of vesicles in nerve terminals and pre- and post-synaptic densities between contacting structures. These findings were complemented with the immunofluorescent detection of Synapsin I. After 3 DIV Synapsin I was present only in nerve cell perikarya. At 6 DIV immunostaining was detectable in both perikarya as well as in varicosities along extended axons. After 11-13 DIV, Synapsin I was undetectable in perikarya, yet displayed a concentrated immunofluorescence at contact points between axon terminals and post-synaptic sites on dendrites and perikarya.

Neurotransmitter-stimulated biochemical responses were studied by examination of intracellular cyclic AMP and inositol phosphate formation in intact neurons. Although clearly detectable within 3 DIV, the formation of both putative second messengers increased dramatically between 6 and 10 DIV, at which point the response reached a plateau. Endogenous GABA release from striatal neurons was examined with HPLC analysis. $K^+$ (56mM) depolarization resulted in a 2-fold increase in GABA release, 50 % of which was $Ca^{2+}$ dependent, between 3-11 DIV. Between 11-14 DIV, subsequent to synapse formation revealed by EM, release evoked by 56 mM $K^+$ increased up to 5-fold, 75% of which was $Ca^{2+}$-dependent.

The findings of this study suggest that striatal neurons in primary culture, grown in serum-free media, provide an excellent model for the study of the physiological and regulatory mechanisms involved in nerve cell development.

Supported by an Alberta Heritage Foundation for Medical Research Post-doctoral Fellowship to S.W. and grants from CNRS and INSERM.

354.2 DISTRIBUTION OF CALCINEURIN-IMMUNOREACTIVITY IN DEVELOPING RAT BRAIN. K.L. Valentino and L.F. Reichardt. Dept. Physiol., UCSF, San Francisco, 94143.

Calcineurin, a $Ca^{++}$-dependent/calmodulin activated protein phosphatase, has been shown to exist in high levels in bovine neostriatum (Wallace et al., Biochem. 19: 1931, 1980) and is associated with postsynaptic densities in a certain population of synapses (Wood et al., J Cell Biol. 84:66, 1980, Valentino et al., J Histochem. Cytochem., in press). In an attempt to determine the role this phosphatase might play in synapse formation, immunocytochemical studies were performed in postnatal rats, using a polyclonal antiserum to both subunits of the enzyme.

Neonatal and adult rats were perfused with 4% paraformaldehyde and 0.1% glutaraldehyde in 0.1M Na cacodylate buffer. Following postfixation, brains were placed into 30% sucrose prior to cryostat sectioning or embedded in Lowicryl for electron microscopic studies. Fresh brains were homogenized in .32M sucrose, 0.1uM pepstatin, 2mM EDTA in 25mM Tris buffer. Samples were run on 10% SDS-PAGE gels and transferred to nitrocellulose paper. Detection of antibodies on sections and blots was with peroxidase conjugated second antibodies.

In adult rats immunoperoxidase staining of frozen sections with anti-calcineurin was heaviest in the neostriatum. In developing rats, the amount of immunoperoxidase staining in the neostriatum gradually increased to adult levels during the second and third postnatal weeks.

Immunocytochemical staining of calcineurin could also be detected in adult rat olfactory bulb. The heaviest calcineurin immunoreactivity was found in the external plexiform layer, with some staining of the glomerular layer and of some mitral cell bodies. Immunoblots of homogenates of adult olfactory bulb showed the presence of calcineurin. Calcineurin immunoreactivity could also be detected in newborn rats. At this age, heaviest staining appeared in the olfactory bulb, especially the developing external plexiform layer, and in the anterior olfactory nucleus. The presence of calcineurin in newborn brain was confirmed by immunoblots of homogenates of both whole brain and olfactory bulb and cortex. Both the phosphatase subunit and $Ca^{++}$ binding subunit of calcineurin were detected on the blots. Electron microscopic studies are in progress to determine the precise localization of calcineurin in both the adult and neonatal olfactory bulb.

354.3 NEUROFILAMENT PHOSPHORYLATION IS A LATE EVENT FOLLOWING NEUROFILAMENT EXPRESSION IN DEVELOPMENT AND REGENERATION. D. Dahl and A. Bignami, Harvard Medical School and Veterans Administration Medical Center, West Roxbury, MA 02132.

Axon specific neurofilament (NF) antibodies, i.e. antibodies not decorating NF in perikarya and dendrites, have been reported in this laboratory (Dahl et al. J. Comp. Neur. 195:659 1981). Axon specific polyclonal and monoclonal antibodies staining NF 150 kDA and/or NF 200 kDa on immunoblots were shown to react with phosphorylated epitopes according to the criteria of Sternberg and Sternberg (Proc. Natl. Acad. Sci. USA 80:6126, 1983). The staining was abolished by dilution of the antibodies in phosphate buffer and by digestion of the sections with phosphatases. Conventional monoclonal and polyclonal antibodies, i.e. antibodies decorating NF regardless of their location (axons, perikarya and dendrites) were not affected by these treatments with one exception. On cryostat sections trypsin abolished the NF immunoreactivity of both axon-specific and conventional antibodies. Phosphatase treatment did not restore the staining. Compared to conventional NF antibodies, staining with axon-specific NF antibodies was a late phenomenon in chick embryo development. The distribution of immuno-reactive material was studied in cryostat sections double labeled with NF antibodies raised in 2 different species, i.e. axon-specific mouse antibodies and rabbit conventional NF antisera. Axon-specific immunoreactivity was first observed in peripheral nerves and in the anterior columns of the spinal cord on day 10. Sensory ganglia and optic nerve fibers were negative. With conventional NF antibodies, these structures were stained on day 4 and 5, respectively. Up to day 16, bundles of thin peripheral nerve fibers, strongly decorated by conventional NF antibodies, did not stain with axon specific antibodies in double labeling experiments. Nerve bundles emerging from sensory ganglia were also negative. Axon-specific immunoreactivity was first observed on day 17 in the optic nerve and in the layer of optic nerve fibers. At this time, staining was confined to the bundle emerging from the temporal side of the retina. Another finding was the late appearance of axon-specific immunoreactivity in regenerated nerve. As a specific example, on day 10 the distal stump of crushed rat sciatic nerve was filled with bundles of regenerating axons strongly stained with conventional NF antisera. Only few of these bundles reacted with axon-specific antibodies. (In the proximal stump as in normal nerve, the distribution of immunoreactivities was the same). Whether NF phosphorylation plays a role in axonal maturation, remains a matter for future investigation. Supported by NIH grant NS 13034 and by the Veterans Administration.

354.4 DEVELOPMENT OF A NEURONAL PROTEIN DATABASE USING PC12: THE EFFECTS OF NERVE GROWTH FACTOR (NGF) AND GLUCOCORTICOIDS. M. McTigue*, S. Halegoua*, and M.C.Bohn (SPON:J.Levine) Department of Neurobiology & Behavior, State University of New York, Stony Brook, New York 11794.

The PC12 clonal cell line synthesizes catecholamines and displays other characteristics of sympathetic neurons. For example, these cells respond to NGF by extending neuronal processes and increasing the synthesis and activity of specific neural proteins. PC12 have been used extensively to study expression and regulation of neuronal phenotypes. To identify and study proteins important in the establishment and maintenance of neuronal characteristics, we are using PC12 and quantitative 2-D gel electrophoresis to create a protein database.

Protein metabolic labeling can be quantitatively analyzed using newly developed computer techniques following separation of proteins by 2-D gel electrophoresis (Garrels, J., Meth. Enzymol. 100, 411;1983). The ability to make composites of protein patterns from different gels allows the analysis of up to 3,000 proteins. Differences in the metabolism of each protein in cells grown under different conditions can be quantified by comparing gel composites. Consequently, protein databases for identified cells can be established.

Our initial experiments to set up a neuronal protein database were carried out in PC12 cells grown under different conditions in the presence of 35S-methionine. The effects of NGF and glucocorticoids on protein metabolism were determined. To define the optimal growth conditons for labeling and treatment of the cells by these agents, the PC12 growth state was defined with respect to passage number and days within a passage for cells grown with serum or in defined medium. Alterations in the metabolism and post-translational modification of specific proteins resulting from different growth conditions and exposure to NGF or glucocorticoids will be presented.

These data provide a framework for identifying proteins specific to the nervous system. They also establish a basis for future investigation of other factors important in nerve cell differentiation and regulation.

Supported by Protein Databases, Inc., the Center for Biotechnology, S.U.N.Y. at Stony Brook, and the New York State Science and Technology Foundation.

354.5 UNIQUE NUCLEUS-ASSOCIATED PROTEINS IN DIFFERENT CELL TYPES IN THE DEVELOPING AND ADULT BRAIN REVEALED WITH MONOCLONAL ANTIBODIES. E. Pawlak-Byczkowska and P. Levitt. (SPON: A. Grigonis). Dept. Anatomy, Medical College of Pennsylvania, Philadelphia, Pa. 19129.

Non-histone chromosomal proteins have been suggested to participate in the regulation of cell differentiation in several organ systems, including the central nervous system (CNS). In order to determine the extent of unique nucleus-associated proteins in the developing brain, monoclonal antibodies were generated against sonicated, histone-depleted nuclei from fetal and adult rat brain. Both in vivo and in vitro immunization protocols were used for production of hybridomas. The supernatants from the clones were screened immunocytochemically on paraformaldehyde-fixed frozen sections from fetal rat brain to determine the cellular distribution of the antigens. The antibodies were classified into two principal groups; one set recognized antigenic determinants specific to cell nuclei and the second crossreacted with antigens present in both nuclei and cell processes. Of the nucleus-specific antibodies, one stained in a punctate pattern in mitotic and postmitotic cells of late gestation fetal cortical and subcortical regions. This same antibody was completely unreactive in all areas of the adult brain. A second nucleus-specific antibody stained a small number of cells scattered in the ventricular and subventricular zones of the late fetus. We suggest that this antibody marks a glial precursor cell because the large number of immunoreactive cells in the adult reside almost entirely in white matter. Monoclonal antibodies comprising the second principal group also displayed characteristic changes during development. Two antibodies revealed different nuclear staining patterns in similar and widespread populations of fetal mitotic and postmitotic cells. Only one continued to stain adult brain cell nuclei. These same antibodies were immunoreactive with radial glial fibers and both continued to stain astrocytes in the adult, consistent with the suggestion that nuclear and cytoscaffold proteins can share antigenic determinants. Other antibodies demonstrated a similar relationship among neuronal fibers and cell nuclei. Western blot analysis of total nuclear proteins from fetal and adult cerebral hemispheres was used to localize reactive protein bands. Preliminary results with one antibody that recognized nuclei and astrocytes stained a single band of approximately 140 kd. The monoclonal antibodies demonstrate the existence of a complex array of nuclear-associated proteins in different cell populations of the CNS and also suggests that the expression of these proteins changes substantially during development.

354.6 AN INVESTIGATION OF NEURODEVELOPMENT IN THE CEREBELLUM USING NOVEL MARKER PEPTIDES. J. Hempstead*, J. R. Slemmon*, [1]R. W. Blacher* and J. I. Morgan* (SPON: W. D. Horst). Dept. Physiol. Chem. & Pharm., Roche Inst. of Molec. Biol., Roche Research Center, Nutley, NJ 07110, [1]Dept. Protein Chemistry, Applied Biosystems, Inc., Foster City, CA. 94404.

Three peptides, cerebellin, des-Ser[1]-cerebellin and des-Ser-Gly-cerebellin have been isolated from both rat and mouse cerebellum. The peptides have been sequenced and synthesized and sequence-directed antibodies raised against them in rabbits. Both direct chemical analysis and radioimmunoassay show the cerebellins to be at least 20 to 50 times more abundant in cerebellum than any other brain region, the olfactory bulb being the only significant extracerebellar source of the peptides. The cerebellins have been localized to the Purkinje cells of both rat and mouse cerebellum by immunocytochemistry, for which they are markers.

During development, the cerebellins may be first detected 4 to 5 days after birth in both cerebellum and olfactory bulbs. Peptide levels subsequently rise to a maximum in both structures at about the twenty-fifth day post partum. Thereafter, the cerebellin concentrations in cerebellum decline to a stable adult value. This time course of appearance of cerebellins is mirrored in the immunochtochemical picture of cerebellin expression in developing Purkinje cells. Based upon this analysis we have proposed that the initial expression of the cerebellin gene is triggered by the interaction of climbing fibres with immature Purkinje cells. The amplification of cerebellin biosynthesis is suggested to be mediated by granule cells via parallel fibre synapses. the fall of cerebellin levels may be linked to the remodeling of the Purkinje cell dendritic arbors with a concomitant loss of parallel fibre synapses..

Evidence to support the above model of the developmental regulation of cerebellin expression has come from studies involving mutant mice. Thus mutants which have reduced granule cell numbers such as Reeler and Weaver have large deficits in cerebellin levels. This suggests some direct relationship between granule cell numbers and cerebellin levels. The immunocytochemical analysis of these same granule cell-deficient mutants shows cerebellin immunoreactivity to be concentrated in Purkinje cells associated with groups of surviving granule cells, lending further support to the notion of transcellular regulation of cerebellin metabolism. The model is being further tested using lesioning and in vitro organotypic cultures of cerebellum.

354.7 PEPTIDE MARKERS OF NEURONAL DEVELOPMENT IN MAMMALS. R.Ziai* and J.I.Morgan* (SPON.R.Chizzonite). Dept.Physiol.Chem.,Roche Inst. Mol.Biol.,Roche Res.Center,Nutley,NJ 07110.

In an effort to isolate peptides useful as markers of neural development in mammals,extracts of various rat brain regions at different stages of development were analyzed by reversed phase HPLC.Two developmentally regulated peptides were detected by comparing the chromatograms obtained from neonatal and young adult brains.A neonatal brain-specific peptide (NSP) was present in the brains of embryonic and newborn rats at approximately 40-50µg/g tissue.However,its concentration fell to 3-5µg/g tissue between days 4 and 21 post partum .NSP is at least 10-fold more abundant in the neonatal brain than any other tissue examined.This peptide is present in,and actively synthesized by cultured rat neuroblastoma cells.It could not be demonstrated in astrocytoma cells, indicating that the peptide is likely to be of neuronal origin. NSP has been purified to homogeneity and interestingly,has a primary amino acid sequence that is about 80% homologous with a series of peptides(thymosins) synthesized in immunocompetent tissues: the thymosins have been suggested to be immune regulators.Antibodies to the thymosin peptides cross-react with NSP in western blots.However,NSP was not present in the immunocompetent tissues examined and no thymosins exhibited a temporal modulation comparable to NSP.

A second develòpmentally controlled neuropeptide ,designated PEP-19,was purified to homogeneity and was shown to have a restricted distribution in the adult rat brain.It was predominantly present in the adult rat cerebellum and in lower concentration in the olfactory bulb.It was undetectable in the cortex or brain stem and several other non-neural tissues examined.The concentration of PEP-I9 in the cerebellum increased by approximately sevenfold from day 2 to day 12 post partum and remained steady thereafter.Preliminary investigations have shown that the peptide has 60 amino acid residues with a molecular weight of 8 kilodaltons on SDS-PAGE.In view of the maturation profile of PEP-19,this peptide may prove to be a marker for granule cells.The sequencing of this putative peptide marker is in hand.

354.8 TRANSFERRIN PROTECTS RETINAL NEURONS FROM GLUTAMATE TOXICITY AT EARLY STAGES OF DEVELOPMENT. Gail D. Zeevalk, Carlos H. Zambrano and Arnold G. Hyndman, Rutgers Univ. Dept.Biol.Sci. Piscataway, N.J. 08854

Glutamate toxicity in CNS neurons is thought to be the result of excitotoxic interactions with glutamate receptors. Our in vitro work with cultures of purified retinal neurons from 8 day chick embryos (E8) using either glutamate or glutamate agonists or antagonists indicates that glutamate toxicity in these retinal neurons occurs via a similar phenomena. Recently, we found that this toxic response can be modified by the culture environment (ARVO,'84). Retinal neurons grown in basal medium containing insulin (Ø.83uM) and catalase (5.6U/ml)(CI) are sensitive to glutamate exposure when assayed at 72h in vitro (C3), while those grown in the defined medium supplement N1, containing insulin, transferrin (62.5nM), progesterone (36nM), putrescine (100uM) and selenium (30nM) are glutamate resistant. In view of recent reports indicating that transferrin may play a broader role in cellular development and physiology than previously thought, we investigated whether transferrin may be involved in protecting neurons from glutamate toxicity.

When transferrin was included in CI medium, survival of E8-C3 retinal neurons after exposure for 24h to 5mM glutamate was 86% of control (vs. 50% when grown in CI). The protective effect of transferrin was examined for transferrin concentrations ranging from Ø to 312.5nM. Protection exhibited dose response characteristics with significant protection beginning at 62.5nM transferrin. While overall survival was slightly greater in transferrin containing medium, the difference in response to glutamate was not due to differential survival since transferrin protection could be seen when cells were grown for 48h in CI medium and transferrin added 20min prior to glutamate treatment (77% of control). Conversely, when cells were grown in transferrin containing medium and switched at 48h to medium lacking transferrin, protection was still seen after glutamate exposure (90% of control). The ability of transferrin to protect retinal neurons from glutamate toxicity appears to be linked developmentally, since cultures from older retinal neurons (E11-C3) were not protected. We are currently investigating the role transferrin plays in normal neuronal development.

354.9 TRANSFERRIN BINDS TO EMBRYONIC RETINAL NEURONS AND ALTERS GLUCOSE METABOLISM. A.G. HYNDMAN & G.D. Zeevalk, Rutgers Univ. Dept. Biol. Sci., Piscataway, N.J. 08854

Recent evidence from several laboratories has implicated transferrin as an important factor in regulating neural differentiation. We have found that transferrin can protect some retinal neurons from glutamate toxicity (Zeevalk, et al., Neurosci. Abs.,1985) In this study we begin to examine transferrin's role in cellular physiology, using monolayer cultures of 8 day embryonic neural retina from chick.

Utilizing immunohistochemical techniques we have found that transferrin binds to neurons, but not glia. Transferrin binding was visualized in mixed cultures of neurons and glia and in purified neuronal cultures by exposure of the culture to transferrin followed by FITC-anti-transferrin anti-body or by the peroxidase anti-peroxidase method. Preliminary observations indicate that transferrin binding is most concentrated on the cell soma.

We also examined the effects of transferrin on glucose uptake in purified neuronal cultures. Cultures were maintained for 72h prior to the assay in basal medium supplemented with glucose (28mM), insulin (0.83mM) and catalase (5.6 U/ml) (CI) or CI plus transferrin (62.5nM)(CIT). The non-metabolized analog 3-O-methyl-glucose was used to measure glucose uptake. Following a 30min incubation in low glucose medium, cultures were incubated in various amounts of cold ligand plus 14C labeled 3-O-methyl glucose for 10min in the presence or absence of transferrin. The amount of label uptake was determined in the presence of four concentrations of cold ligand 8mM, 10.5mM, 15.5mM & 25.5mM. In cultures maintained in CI, uptake increased linearly throughout the concentration range. Uptake was 9.2, 22,6, 47.3, 88.9 fmol/cell/min respectively. Cultures grown in CIT showed uptake 1.5 to 4 times greater than cultures grown in CI. When transferrin was added to cultures maintained in CI, 30min before the assay, there was an 1.6 fold increase in uptake compared to controls. Transferrin induced enhancement of glucose uptake may be developmentally linked since uptake in cultures from older retinal neurons (11 day embryonic retina) was not altered by transferrin. This study suggests that one mechanism by which transferrin may regulate neuronal differentiation or sensitivity to glutamate is by altering glucose metabolism.

354.10 DEVELOPMENTAL CHANGES IN NOREPINEPHRINE-INDUCED THERMOGENESIS IN WEANLING RATS. E. Thiels* and J. R. Alberts* (SPON: R. D. Devoe). Dept. of Psychology, Indiana University, Bloomington, IN 47405.

Brown adipose tissue (BAT) is the principal site of nonshivering thermogenesis in cold-acclimated adult rats (Foster and Frydman, Can. J. Physiol. Pharmacol., 56:110, 1978) , and appears to be the effector of increased heat production following a single meal (Glick, Teague and Bray, Science, 213:1125, 1981), as well as during chronic overfeeding (Rothwell and Stock, Nature, 281:31, 1979). Both cold- and diet-induced activation of BAT are mediated by the release of norepinephrine (NE) from sympathetic terminals innervating brown adipocytes (Rothwell and Stock, Can. J. Physiol. Pharmacol., 58:842, 1980). In the present study, we investigated the thermogenic capacity of BAT in weanling-aged rats, for which a thermal and food-efficiency regulatory system independent of maternal resources becomes increasingly important.

Pairs of 15- and 20-day old pups were placed into incubators maintained at 29°or 28°C, respectively, and given a 15-min adaptation period before receiving an i.p. injection of one dose of l-NE (0.1, 0.2, 0.4, 0.8, 1.6, or 3.2 mg/kg), or an equivalent volume of normal saline. Five min before and at four 20-min intervals following injection, interscapular BAT (IBAT) temperature was measured with a thermocouple placed on the overlying skin. In general, dosages above 0.2 mg/kg produced a significant elevation in IBAT temperature relative to both pre-injection temperatures and temperatures of control pups. These changes developed rapidly and reached maximum within 60-min post-injection in both age groups. Maximal temperature as well as the magnitude of the temperature increment increased with dosage in pups of both ages, with the exception of a significant decrease of IBAT temperature in 15-day-olds receiving the highest dosage. Throughout the effective dose range, younger pups displayed greater responsiveness to NE than did older pups: dose-dependent temperature maxima were 1°-2°C higher and temperature increments 2-3 times larger in 15-day-olds compared to 20-day-olds. These results show that sympathetic activation of BAT has powerful thermogenic effects in weanling-aged rats, and that the calorigenic potential of this source of heat production decreases as additional thermoregulatory mechanisms emerge.

This research was supported by PHS Grants MH-28355 and MH-00222 (JRA).

354.11 SEROTONERGIC AGONIST AND ANTAGONIST EFFECTS ON MOUTHING AND INGESTION INDEPENDENT OF THE DAM IN 3-4 AND 10-11 DAY OLD RAT PUPS. E.K. Enters* and L.P. Spear. Dept. of Psychology and Center for Neurobehavioral Sciences, State Univ. of New York at Binghamton, Binghamton, NY 13901

Serotonergic antagonists have been shown to block suckling in 3-4 and 7-8 day old, but not older, rat pups, presumably by interfering with the mouthing and licking that precedes attachment (Spear & Ristine, 1982; Ristine & Spear, 1984). Serotonergic antagonists have also been observed to attenuate mouthing induced by the serotonergic agonist quipazine, or by intraoral milk infusions, in 3-4 day old deprived rat pups (Caza & Spear, 1981; Ristine & Spear, 1985). If the blockade in suckling induced by serotonergic antagonists during approximately the first postnatal week is related to a drug-induced disruption of the mouthing component of attachment, it might be expected that serotonergic manipulations would have less pronounced influences on mouthing behavior during the second postnatal week, an age when these drugs do not affect suckling. The present study compared the effects of serotonergic agonists and antagonists on mouthing in 3-4 and 10-11 day old pups in an independent ingestion paradigm. Because of recent controversy regarding the relationship between mouthing and amount ingested in this paradigm, weight gain was also assessed.

Male and female, 3-4 and 10-11 day old offspring of Sprague Dawley derived breeding pairs were used. Half of the pups were deprived of food and the dam for 24 hrs. prior to testing; the remaining pups were non-deprived. Pups were injected subcutaneously with either a 0 (0.9% saline), 1, 2.5, 5, or 10 mg/kg dose of the serotonergic agonist quipazine, or of the antagonist methysergide. Ten min. later, pups were placed in an apparatus without milk, where baseline behaviors were observed for 5 min. Pups were then placed for 10 min. in a test apparatus containing Half and Half puddled on a terrycloth floor to allow ingestion, and their behavior and post-test body weights were recorded. As expected, deprivation increased both mouthing and ingestion, and the presence of milk increased mouthing. In 3-4 day old rat pups, quipazine increased, and methysergide decreased, mouthing. At 10-11 days postnatally, both quipazine and methysergide appeared to slightly attenuate milk-induced mouthing. Thus, it appears that serotonergic manipulations may influence mouthing differently in 3-4 and 10-11 day old rat pups. The amount ingested was not observed to be associated with amount of mouthing in 3-4 day old pups, with both quipazine and methysergide decreasing ingestion at this age. At 10-11 days postnatally, decreases in ingestion were closely associated with drug-induced attenuations in mouthing.

354.12 BEHAVORIAL RESPONSES TO D-1 AND D-2 DOPAMINE AGONISTS IN NEONATALLY-6-HYDROXYDOPAMINE (6-OHDA) TREATED RATS. G.R. Breese, A. Baumeister*, T.C. Napier, G.D. Frye, G. Duncan* and R.A. Mueller. UNC Sch. of Med., Chapel Hill, NC 27514 and Texas A&M Coll. of Med., College Station, TX 77840.

In an earlier study (JPET, 231:343, 1984), it was found that L-DOPA-induced self-biting in neonatally-6-OHDA-treated rats was antagonized by cis-flupentixol, a compound with actions on D-1 and D-2 dopamine receptor sites. Since the D-2 dopamine antagonist, haloperidol, was less effective in reducing the incidence of self-biting than cis-flupentixol, it seemed possible that a subpopulation of dopamine receptors is being selectively altered in neonatally-6-OHDA-treated rats. To explore this hypothesis, behavioral responses after administration of the D-2 agonist, LY-171555, or the D-1 agonist, SKF-38393, were evaluated in neonatally-6-OHDA-treated rats. Behaviors observed in neonatally-6-OHDA-treated rats after the D-1 agonist included self-biting, "taffy pulling", licking, sniffing, rearing, paw treading, head nodding, digging and grooming. SKF-38393 produced no significant behavioral changes in untreated rats indicating that the dopamine receptors being stimulated were functionally supersensitive in the neonatally-6-OHDA treated rats. In spite of this functional supersensitivity to the D-1 agonist, $^3$H-SCH-23390 binding was not altered in striatum. Many of the behaviors observed after SKF-38393 were also observed after LY-171555 administration. Behavioral responses to D-1 and D-2 agonists did not show the same profile in adult- and neonatally-6-OHDA-treated rats, providing support for the view that the age at which dopaminergic neurons are destroyed can have differing effects on motor output. The self-biting observed after L-DOPA was also induced by SKF-38393, but not LY-171555. Furthermore, the self-biting was antagonized by SCH-23390, a D-1 antagonist. There was a high correlation between the occurrence of L-DOPA induced self-biting and supersensitive locomotor responses to SKF-38393 (Fed. Proc., 43:923, 1985) in rats treated neonatally with 6-OHDA. These data support the hypothesis that neonatally-6-OHDA treated rats have functionally supersensitive D-1 dopamine receptors which are critical for self-biting and which can contribute to locomotion as well as other behavioral responses induced by agonists such as L-DOPA or apomorphine after this treatment. (Supported by HD-03110, HL-31424, and MH-36294).

354.13 PRENATAL EXPOSURE TO NICOTINE INDUCES ACUTE AND PERSISTENT CHANGES IN RAT BRAIN CATECHOLAMINES AND THEIR METABOLITES.

W. Lichtensteiger, U. Ribary* and M. Schlumpf. Institute of Pharmacology, University of Zürich, CH-8006 Zürich, Switzerland

Prenatal exposure to nicotine can result in behavioral dysfunctions both in laboratory animals and in man. We recently found that the drug also affects the gonadal axis of the male rat fetus and a sexually dimorphic behavior (Lichtensteiger et al., Monogr. neural Sci., Vol. 9, 213, 1983; Pharmacol. Biochem. Behav., in press). The neurochemical basis of these functional alterations is not known. We investigated possible prenatal effects of nicotine on central catecholamine and serotonin systems. Fetal or postnatal rat forebrain was assayed for catecholamines by a thinlayer radioenzymatic method and for metabolites of catecholamines and serotonin by HPLC-EC. The study was conducted mainly on Long Evans (LE) rats; some differences were noted between LE and Sprague Dawley fetuses.

Amine metabolite concentrations rise slowly from gestational day (GD) 17 - except for an elevation at birth, with similar values in male and female fetuses. In both sexes, a single injection of nicotine (1 mg/kg s.c., 30 min) given to the pregnant dam at GD 21, increased DA, DOPAC, HVA and 5-HIAA in fetal forebrain. On postnatal day (PN) 6, the drug (0.3 or 1 mg/kg) affected MOPEG and the DA metabolites but not 5-HIAA. For chronic prenatal administration of nicotine, pregnant LE rats were implanted s.c. at GD 12 with an osmotic minipump (Alzet) which delivered nicotine at a rate of 0.25 mg/kg x hr for one week (see ref.). When checked at GD 18, the effects of this treatment differed from the acute condition; MOPEG was now increased in male and female fetuses. The metabolic pattern of the pregnant dam was different from that of her fetuses. At postnatal stages, persistent alterations in catecholamine metabolites were seen after prenatal drug exposure. The metabolite pattern of nicotine-treated offspring changed from GD 18 (when the drug was still present) through PN 15 until adulthood and differed between sexes. Adult male offspring exhibited reduced levels of MOPEG, DOPAC and HVA in forebrain, while their female littermates showed but a reduction of HVA. An analysis of cross-fostering data revealed that the changes were due to prenatal influences.

These observations demonstrate 1) that central monoamine systems of the fetus are responsive to acute administration of nicotine and 2) that prolonged prenatal exposure to the drug can result in persistent alterations in catecholamine metabolites especially in the male.

354.14 COMPARISON OF PRENATAL AND POSTNATAL NICOTINE ADMINISTRATION ON NEUROMUSCULAR MATURATION, K. J. Rose* and F. L. Strand. Biology Department, New York University, Washington Square, New York, NY 10003.

A study was undertaken to investigate whether nicotine administration to pregnant rats and/or their offspring influences the character and maturation of the neonatal neuromuscular system. The in situ extensor digitorum longus (EDL) muscle and peroneal nerve complex was used as a model. Pregnant females received either nicotine tartrate (0.5 mg/kg) or saline as control twice daily i.p. from day 3 to day 18 of gestation, then once daily until parturition. Pups were injected with either nicotine tartrate (0.05 mg/kg/day s.c.), or saline as control. All pups were tested on the 14th and 15th day after birth. Animal subgroups consisted of 4-7 pups.

Pups treated with nicotine during prenatal and postnatal life as compared to those pups treated with saline throughout, showed no change in mean motor unit size or number, nor was there a change in tetanic or twitch contraction amplitude. However, the durations of twitch contraction and half-relaxation were decreased, indicating a more rapid twitch. Tetanic contraction time increased and half-relaxation time remained constant, indicating an improved ability to sustain tetanus. No nicotine-induced changes occurred in post-rest or post-tetanic potentiation.

Pups treated with nicotine during both prenatal and postnatal life showed a significant decrease in tetanic half-relaxation time when compared to pups that received nicotine prenatally only. Other contractile parameters were essentially the same as in pups exposed to nicotine throughout. Thus, twitch times for pups treated with nicotine postnatally only had faster twitches than saline controls.

Offspring receiving nicotine pre- and postnatally had a significantly shorter twitch half-relaxation time than pups receiving nicotine postnatally only. Similarly, tetanic contraction time is longer in those animals that received nicotine throughout. Postnatal nicotine administration did not significantly alter contractile parameters when compared to saline controls.

During normal development, in those muscles destined to become predominantly fast muscle, such as the EDL, contractile parameters are initially the same as those of slow fibers. Nicotine administration during prenatal life appears to accelerate this maturation process, whereas postnatal administration has relatively little effect as seen two weeks after birth. The possibility that such changes may be mediated through nicotine-evoked ACTH release is being investigated.

We thank The Council for Tobacco Research for their support of this study.

354.15 THE EFFECT OF PRENATAL EXPOSURE TO PHENCYCLIDINE ON THE POSTNATAL CONCENTRATION OF ACETYLCHOLINE AND CHOLINE IN THE RAT.

H. Takeda*, R.A. Gazzara and S. Howard. Dept. of Pharmacology and MRRC, UCLA Sch. of Med., Los Angeles, CA 90024.

Phencyclidine (PCP) has been demonstrated to have a biphasic effect on dopamine (DA) release in the caudate nucleus. PCP is thought to be an indirectly acting DA agonist at low doses, however it has been shown that at high doses PCP inhibits DA release. This pharmacological perturbation of DA release by PCP has also been shown to effect the endogenous levels and rate of synthesis of acetylcholine (ACh) in various brain regions. In this study we have examined the effect of pre- and postnatal exposure to PCP on endogenous and newly synthesized ACh in the 21 and 35 day old rat pup.

Female Sprague-Dawley rats were injected with PCP (0.5 mg/kg s.c.) throughout gestation. The subsequent litters of rat pups were treated with PCP daily (0.5 mg/kg s.c.) either from 0-21 days postnatal or from 0-35 days postnatal. Rat pups were sacrificed by microwave irradiation after a pulse injection of deuterium-labelled choline (20 umol/kg i.v.). The concentrations of endogenous and deuterium-labelled ACh and choline were measured using a GC-MS assay.

The concentration of both endogenous and deuterium-labelled ACh was increased in the 21 day old rat pups that were exposed to PCP pre- and postnatally. A similar response was seen in the frontal cortex. After 35 days, the effect of chronic pre- and postnatal PCP treatment on endogenous ACh levels was no longer significantly different from control values. However synthesis, as measured by deuterium-labelled ACh, was significantly increased over control values.

These data suggest that pre- and postnatal exposure to PCP markedly effects the cholinergic system in the caudate nucleus and frontal cortex of the developing rat pup.

Supported by USPHS grant DA 031518.

354.16 ALTERED NOCICEPTIVE RESPONSIVENESS IN ADULT RATS FROM PRENATAL EXPOSURE TO MORPHINE OR CLONIDINE. E. LaCrosse*, B. Consoliver* and B. Culver Neurosci. Prog., School of Pharm., Univ. Wyoming, Laramie, WY 82071

Previous studies in our laboratory demonstrated an antinociceptive effect produced by infusion of adult animals with the alpha-2 adrenergic agonist clonidine. Interestingly, this effect was seen in rats when tested not only during the 1 week infusion period, but also for 2 weeks following discontinuation of the drug. Enduring antinociceptive reactions have also been reported for adult offspring of rats given opiates during pregnancy. Experiments in this study were designed to extend these findings to compare the effects of prenatal exposure of rats to clonidine and to morphine.

Sixteen pregnant female rats were assigned to one of 4 groups (4 rats/group) on day 14 of gestation. Rats in one group (CL) received clonidine infusions (2µg/hr) from s.c. implanted osmotic pumps. Paired control rats (CO) were subjected to identical surgical procedures. Another group of rats (MS) were implanted with sialastic morphine pellets (100 mg. morphine $SO_4$/pellet) on gestation days 14 (1 pellet) and 17 (2 pellets). A paired control group of rats (LA) were implanted with sialastic lactose pellets on the same days. At 2 mo of age litters were grouped by sex and CL and MS groups were paired for study with animals in the CO and LA, respectively, control groups. The animals were studied for 4 consecutive days using tail flick (TF) and paw lick (PL) tests. Latency to the TF response was significantly elevated in CL groups, both male and female, compared to CO groups. MS groups also showed an increased latency to response in TF compared to LA groups. There were no differences found with the PL test but this may have been due, at least in part, to the high variability of this data.

The findings of similar effects from prenatal exposure to clonidine or morphine suggest the drugs share a common action resulting in altered nociceptive responsiveness in the adult. Since both clonidine and the opiates have been shown to inhibit firing of noradrenergic neurons in the locus coeruleus, it is tempting to speculate that the underlying mechanism of the observed effect involves an interaction at presynaptic noradrenergic sites.

354.17 FAILURE OF NEONATAL RATS TO DEVELOP TOLERANCE AND WITHDRAWAL SYMPTOMS FOLLOWING REPEATED EXPOSURE TO MORPHINE. C. P. Cramer and M. S. Fanselow*. Department of Psychology, Dartmouth College, Hanover, NH 03755.

Adult rats exposed to moderate doses of opiates are initially analgesic; however, after additional exposures they become tolerant, as indicated by a reduction or elimination of analgesia. Furthermore, when tolerant adults are challenged with opiate antagonists such as naloxone, they show signs of withdrawal, such as "wet dog shakes" and diarhhea. In the present studies, we explored the development of tolerance to opiates in neonatal rats. Our findings suggest that neonates do not develop either tolerance or withdrawal symptoms, even after 21 days of repeated morphine exposure.

Beginning on the day after birth, infant rats were injected daily with either morphine sulfate (10 mg/kg, i.p.) or vehicle (saline). Twenty minutes after injection, they were tested by manually supporting them above a 52°C hotplate and allowing the bottom of one hindpaw to come in contact with the plate. Latency to lift the paw was used as a measure of analgesia. Saline-injected pups consistently lifted their paws with a latency of 2-4 seconds; performance did not change with age. The mean latency to pawlift among morphine-treated animals was at or near the 15 sec. cut-off latency throughout the 21 day exposure period. To directly compare analgesic responses, on Day 22 both morphine-treated rats and previously saline-injected controls received 5 mg/kg doses of morphine (to avoid ceiling effects). Both groups showed an equivalent and profound analgesic response to the drug. On Day 23, all pups were challenged with naloxone. Even those animals that had received 22 previous exposures to morphine did not show any evidence of withdrawal symptoms.

We obtained similar results using a lower dose of morphine (5 mg/kg) throughout the exposure period. In addition, another group of rats received daily exposure to either morphine (5 mg/kg) or saline beginning at 5 days of age. Those treated with morphine grew at normal rates but continued to be highly analgesic from Days 5 to 20 postpartum, indicating that our previous results were not due to retarded growth.

Thus, neonatal rats failed to exhibit tolerance and abstinence-related behaviors, despite extensive experience with low and moderate doses of morphine. These data suggest that phenomena associated with prenatally developed tolerance and withdrawal should be re-examined.

354.18 NEONATAL MORPHINE EXPOSURE ALTERS ADULT MOTOR BEHAVIOR IN RATS. G.E. Handelmann, Lab. of Developmental Neurobiology, NICHD-NIH, Bethesda, MD 20205.

Exposure to opiates during development in humans has a detrimental effect on motor behavior. Children exposed to narcotic drugs in utero show retarded motor development, perform poorly on perceptual motor tasks, and have poor fine-motor coordination (e.g. Wilson et al., J. Ped. 98: 716, 1981; Strauss et al., J. Ped. 89: 842, 1976). These findings suggest that exposure to opiates adversely affects development of motor regions of the brain. We showed previously that, in the rat, neonatal exposure to morphine increased the number of mu opiate receptors in the adult basal ganglia (Handelmann and Quirion, Eur. J. Pharm. 94: 357, 1983). The increase in receptors was correlated with a decrease in 2-deoxy-glucose uptake in this and other motor areas, suggesting decreased activity (Handelmann and Dow-Edwards, Peptides, in press). The present experiments were performed to determine whether these changes in function in brain motor areas are of behavioral significance to the rat.

Neonatal albino rats were injected subcutaneously with either morphine (1 µg/ pup in phosphate-buffered saline [PBS]) or PBS on days 1-7 after birth. When the rats were at least 60 days old, they were tested on several measures of rat motor behavior: motor coordination on a rotor rod, gait, and spontaneous activity in an open field. The rats treated as neonates with morphine were unable to remain on the rotating rod as long as the PBS-treated rats (2.7 ± 0.4 vs. 5.8 ± 1.0 secs, $p<.05$). In addition, their gait while walking in a straight alley was different from the controls. Their stride length was longer, and their foot placement relative to the direction of the track was unusual: they tended to walk with their feet turned out in a "duck-footed" gait. Finally, the rats treated as neonates with morphine were no more active in an open field than were the controls, but they were more likely to enter the center portions of the field.

These results indicate that neonatal exposure to morphine in the rat has long-lasting effects on motor behavior. Some of the behavioral effects are consistent with abnormal function of the basal ganglia, suggesting that the opiate receptor and metabolic changes in this region due to early morphine exposure are of physiological significance to the animal.

## RETINA IV

355.1 GABA AND GAD IMMUNOREACTIVITY IN PHOTORECEPTOR TERMINALS OF THE RHESUS MONKEY RETINA: ELECTRON MICROSCOPIC ANALYSIS. Y. Nishimura*, M.L. Schwartz and P. Rakic. Section of Neuroanatomy, Yale Univ. Sch. Med., New Haven, CT 06510.

Our previous light microscopic immunocytochemical analysis of the monkey retina (Nishimura, Schwartz and Rakic, 1985) consistently revealed immunoreactivity to gamma amino butyric acid (GABA) and L-glutamic acid decarboxylase (GAD) that was situtated in a narrow band within the outer half of the outer plexiform layer (OPL). In the present study, we examined the localization and possible sources of this immunoreactivity at the electron microscopic level. Retinas from 16 rhesus monkeys (Macaca mulatta) were fixed by perfusion with various combinations of aldehydes in phosphate buffered saline (PBS). Vibratome sections, 50 um thick, were cut through the perifoveal region of the retina and reacted with either anti-GABA serum (Immunonuclear Corp.) or anti-GAD serum (Ortel et al., Neurosci. 6: 2689, 1980) using the avidin-biotin-peroxidase conjugation method. Reacted retinas were postfixed, embedded, and prepared for EM analysis. We also conducted several control experiments including incubation of retinas with normal rabbit serum (for GABA) or normal sheep serum (for GAD) in place of the primary antiserum, as well as incubation in anti-GABA serum that had been preabsorbed with GABA. No immunoreactivity was seen in the OPL in any of these controls.

Electron microscopic examination of the OPL revealed the presence of a considerable number of GABAergic terminals in retinas reacted against either anti-GABA or anti-GAD sera. Dense immunoreactivity was found in some terminal profiles while other terminals in the same section were completely devoid of GABA or GAD labeling. Frequently, immunoreactivity was localized in the subclass of synaptic terminals having the size and morphology characteristic of rod spherules including the presence of electron dense synaptic ribbons surrounded by synaptic vesicles. In some sections of the perifoveal region, as many as 25% (n=312) of these profiles contained immunoreactive product. In some instances, immunopositive profiles could be followed in serial sections from the terminal bouton through the inner portion of their connecting fibers. However, the perikarya of photoreceptor cells were invariably unstained. Moreover, only a few cone terminals identified by their wide based pedicles, multiple indentations, and multiple synaptic junctions were positive. The pattern of GABA and GAD immunoreactivity that we have observed in a large number of monkey retinas suggests that a class of photoreceptors, primarily rods, contains the inhibitory neurotransmitter GABA. Thus, our results indicate that, in addition to the cells within the inner nuclear and ganglion cell layers previously reported to be GABAergic, some photoreceptors in the primate retina also may use GABA as a neurotransmitter. Supported by grant EY02593.

355.2 GABA-LIKE IMMUNOREACTIVITY IN HORIZONTAL CELLS OF THE CAT RETINA J. Bolz* and B.A. McGuire, Laboratory of Neurobiology, The Rockefeller University, New York, NY 10021

The identification of presumed GABAergic neurons in the retina was originally based on the autoradiographic localization of neurons that accumulate tritiated GABA. In lower vertebrates, horizontal, amacrine, and displaced amacrine cell populations accumulated GABA. In mammals, amacrines, displaced amacrines, and interplexiform cells showed GABA uptake, but the horizontal cells did not. A similar pattern of labeling has been reported in more recent immunohistochemical studies with antibodies against glutamic acid decarboxylase (GAD), the rate-limiting enzyme of GABA synthesis.

In the present study we have attempted to localize putative GABAergic neurons in the cat retina using an antiserum directed against GABA. Similar to the results from the uptake experiments, we found GABA-positive amacrines, displaced amacrines and interplexiform cells. However, we also found GABA-like immunoreactivity in horizontal cells. Specificity of the staining was assessed by preabsorbtion of the primary antiserum with synthetic GABA. This procedure blocked the immunolabeling of all cell classes. The morphology and distribution of the horizontal cells was studied in tangential sections processed for GABA-like immunoreactivity with the peroxidase-anti-peroxidase technique. In the axonless A-type horizontal cells reaction product was found in somata and dendrites, whereas in B-type horizontal cells the label was seen in the somata and axon terminal systems but not in the dendrites. We found the same number of labeled A- and B-type horizontal cells as Wässle et al. in their reduced silver and Nissl stained material (Proc. R. Soc. Lond. B 203: 269-291,1978), indicating that all horizontal cells show GABA-like immunoreactivity.

To obtain further support for the suggestion that GABA may be the transmitter for horizontal cells, we have looked for GAD-like immunoreactivity in retinal sections using an antibody kindly provided to us by Dr. W. Oertel. We always found immunoreactive amacrine cells, whereas horizontal cells were only occasionally labeled. The reason for this inconsistency is unclear. It remains to be determined whether cat retinal horizontal cells do indeed lack an active uptake mechanism for GABA or whether the uptake is masked, for example, by the prominent uptake of GABA into Muller cells. Nevertheless, the consistent labeling of horizontal cells by the GABA antibody does suggest that GABA might be the transmitter of horizontal cells in the cat retina, and this would be in accordance with the inhibitory roles attributed to these cells such as surround inhibition.

Supported by the Max-Planck Society and grants EY05253 & EY04782

355.3 DISTRIBUTIONS OF ASPARTATE AMINOTRANSFERASE AND PHOSPHATE-DEPENDENT GLUTAMINASE ACTIVITIES AMONG RETINAL LAYERS.
C. David Ross, Marc Bowers*, and Donald A. Godfrey (SPON: J.E. Norvell). Department of Physiology, Oral Roberts Univ., Tulsa, OK 74171

The total activity of aspartate aminotransferase (tAAT= combined activities of mitochondrial (mAAT) and cytosolic (cAAT) isoenzymes) was determined in retinal layers from rat, guinea pig, turtle, and frog. In addition, the activities of the cAAT isoenzyme (Parli, et al., Soc. Neurosci. Abstr., this volume) and phosphate-dependent glutaminase (PDG) were determined in retinal layers from rat and guinea pig. tAAT activity was highest in the photoreceptor inner segments (IS) in all 4 species, was high in the outer plexiform layer of rat and, especially, frog, and was relatively high in the inner plexiform layer of rat and frog. tAAT activities in layers deep to IS were low in guinea pig and turtle. The magnitude of cAAT activity varied about two-fold across layers in guinea pig and rat while the mAAT activity (taken as = tAAT - cAAT activity) varied about 10-fold in guinea pig and about 5-fold in rat. cAAT activity relative to tAAT activity had its lowest percentage in IS (15-30%) and highest in outer nuclear layer (60-75%), with intermediate values in the other retinal layers.

PDG activity was much higher in IS than in any other layer examined in both rat and guinea pig.

(Supported by NIH grant EY 03838 and by ORU intramural funds.)

355.4 MONOCLONAL ANTIBODIES AGAINST GOLDFISH RETINAL CELLS.
Y.Peng*, J.Julian, S.Glasser and D.M.K.Lam. Program in Neuroscience* Cullen Eye institute and Department of Cell Biology, Baylor College of Medicine,Houston, Tx 77030.

We have used monoclonal antibodies as immunological probes to study the functional organization and development of the vertebrate retina. By immunizing mice with dissociated goldfish retinal cells (using the methods of Sarthy and Lam, Brain Res. 176:208, 1979), we have produced several monoclonal antibodies that recognized discrete cell types in the goldfish retina. The antibodies obtained were screened using immunofluorescence and immunoperoxidase methods.

One of the monoclonal antibodies, MH1, labeled Müller(glial) cells and a population of horizontal cells of many vertebrate retinas. In some species, only Müller cells or certain horizontal cells, but not both, were stained. We have attemped to characterize the antigen recognized by MH1 by immunoblotting. When purified vimentin and desmin were run with a goldfish retinal protein preparation on SDS polyacrylamide gels and transfered to nitrocellulose paper, antibody MH1 selectively labeled a band of goldfish retinal protein which has a molecular weight very similar to the mammalian vimentin protein. However, MH1 did not stain the mammalian vimentin protein. Conversely an antibody against mammalian vimentin also did not bind to this band of goldfish retinal protein. These studies suggest that (1) MH1 recognizes a retinal protein that shares some of the properties of mammalian vimentin, and (2) in some retinas, certain horizontal cells, which are interneurons, may possess a common antigen with glial(Müller) cells.

Additionally, we have a monoclonal antibody which only recognized Müller cells of the goldfish retina. Finally, we have produced a monoclonal antibody, GC1, which recognized some of the somas in the ganglion cell layer and their axons as well as some cells in the inner nuclear layer. These and other monoclonal antibodies are being further characterized in our laboratory. They may provide a useful tool to study the structure, function and development of vertebrate retinal cells.

Supported by the Retina Research Foundation (Houston).

355.5 **MONOCLONAL ANTIBODIES AGAINST SPECIFIC STRUCTURES IN THE RETINA OF RAT, CAT AND RABBIT.**
E.J. Tancred*, Z. Dreher* and J. Stone. School of Anatomy, University of New South Wales, Kensington, N.S.W., Australia.

Monoclonal antibodies have been developed which bind to specific structures in the retinas of several mammalian species. These antibodies have proved effective markers in the study of retinal development and structure.

The first antibody, ZD-14, binds to an antigen found in the inner and outer plexiform layers of the rat retina. It is a sensitive marker for the development of synaptic layers in the rat, demonstrating the formation of the outer plexiform layer at postnatal day (P) 8.

A second antibody, ZD-11, binds to restricted parts of Muller cells in the retina of the rat and rabbit but not cat. In the rat it binds to the inner processes and end feet whereas in the rabbit it binds to the outer processes of the Muller cells. On immunoblots from SDS-polyacrylamide gels its antigen stains a band of 45K - 66K daltons and is first expressed in the rat retina at P7.

A third antibody, ZD-1, binds to astrocytes in the nerve fibre layer of the rat, rabbit and cat, demonstrating what may be the entire extent of these cells. It also binds to restricted segments of Muller cells in the cat and rabbit, but not in the rat. ZD-1 binds in a similar manner to anti-GFAP antiserum, but is slightly more specific. It has proven effective in demonstrating developing astrocytes in the rat retina, becoming positive in the rat at about P14.

ZD-1 has also been applied successfully to wholemounts of retinas of all three species. It demonstrates that astrocytes (1) invest blood vessels extensively adapting their morphology to the shape of neighbouring vessels, (2) invest fiber bundles adapting their morphology to the orientation and size of the bundles, (3) are stellate in form where vessels and nerves are sparse, and (4) are absent from avascular areas of retina.

This latter finding is particularly clear in the rabbit retina in which the retinal circulation extends only over a 'streak' of myelinated axons extending horizontally from the optic disc. ZD-1 (and GFAP) positive astrocytes are restricted in distribution to this vascular region. The finding was confirmed by examination of the retina of the Australian possum, Trichosurus vulpecula, which is avascular, except for a few vessels at the optic disc. In this animal, ZD-1 (and GFAP) positive astrocytes could only be found at the optic disc and its margin.

355.6 QUANTITATIVE ANALYSIS OF NEUROPEPTIDE-Y CONTAINING AMACRINE CELLS IN THE TURTLE RETINA.
W.D. Eldred, E. Howard* and J.M. Polak. Dept. of Biology, Boston Univ., Boston, MA 02215; Dept. of Histochemistry, Royal Postgraduate Med. Ctr., Hammersmith Hosp., London, England W12 OHS

This study used antiserum directed against neuropeptide-Y (NPY) to selectively label amacrine cells in the turtle retina. Retinal reconstructions were performed to determine the regional densities. There were no clear differences in regional density, except for a slight increase toward the nasal region. The number of neurons ranged from 15-47 per 0.5mm squared. Cell bodies were located in the third tier of the inner nuclear layer and the cell processes were found in laminae 1, 3, and at the border of 4 and 5 within the inner plexiform layer (IPL). Processes in lamina 1 were sparse and delicate, with small synaptic boutons. Processes in lamina 3 were numerous and often coarse, with many large and small synaptic boutons. At the border of laminae 4 and 5 the processes were frequently numerous but slender, with many small synaptic boutons.

Twenty neurons from various regions of the retina were drawn in detail using a camera lucida attachment. Circular distribution statistics were used to quantitatively characterize the dendritic arborizations of these neurons. It was possible to statistically classify the cells as monopolar, bipolar, bipolar skewed, or multipolar. Although each catagory was represented, monopolar and multipolar cells were found to be more common than bipolar and bipolar skewed cells. In addition to the overall dendritic orientation for a given neuron, it was possible that there were specific orientations for the dendritic arborizations within individual lamina of the IPL. This study indicated that circular distribution statistics were effective for analyzing the morphology of individual neurons. It further suggested that a given neuropeptide may be found in more than one anatomically distinct class of amacrine cells. Supported by EY04785 to WDE.

355.7 SEROTONIN-LIKE IMMUNOREACTIVITY IN AMACRINE CELLS OF THE LIZARD RETINA. G. A. Engbretson, K. J. Anderson*, and B. -A. Battelle†. Institute for Sensory Research, Syracuse University, Syracuse, NY 13210 and †C. V. Whitney Laboratory, University of Florida, St. Augustine, FL 32086.

A population of amacrine cells in the retina of the lizard, *Uta stansburiana*, exhibits immunoreactivity to a highly specific antibody (Immunonuclear) directed against serotonin (5-HT). Cryostat sections of fixed retinas were incubated in diluted antibody and then processed by immunofluorescence or peroxidase-antiperoxidase secondary antibody techniques. The 5-HT-like immunoreactivity was localized to a population of amacrine cells with somata (≈10 μm dia.) in the inner nuclear layer just adjacent to the boundary of the inner plexiform layer (IPL). Processes emanated from the soma and branched, sending arborizations to both sublamina 1 and to sublaminae 4 and 5 of the IPL. In control experiments where the antibody was preincubated with its antigen (5-HT conjugated to bovine serum albumin) before use, immunoreactivity of the amacrine cells was blocked completely.

Golgi-stained retinas of this lizard contain amacrine cells which appear identical in size, position, and branching pattern to those cells which exhibit 5-HT-like immunoreactivity.

Preliminary analyses of acidic extracts of lizard retinas by high performance liquid chromatography and electrochemical detection revealed the sharp peak of a substance which eluted with the same retention time as 5-HT. These preliminary analyses suggest that the retina of *U. stansburiana* contains endogenous 5-HT in the amount of at least 1.5 ng/retina and that the 5-HT is confined to a population of amacrine cells.

Supported by NIH grant #EY-03359 and the C. V. Whitney Laboratory.

355.8 **SUBSTANCE P (SP) IN THE PIGEON RETINA: A QUANTITATIVE ASSESSMENT.** Kent T. Keyser* and Harvey J. Karten, Depts. of Psychiatry and Neurobiology, State University of New York, Stony Brook, NY 11794.

Biochemical and immunohistochemical studies have demonstrated the presence of SP within retinal amacrine cells in the retinae of many vertebrates, including pigeons (Karten and Brecha, 1980). The regional distribution and the variety of cell types have, however, been less clear. In particular previous studies in the pigeon have suggested that SP amacrine cells occur primarily in the peripheral retina and are either markedly diminished or absent from central retinal regions, such as the fovea and Red Field. We have examined retinal flat mounts and horizontal sections processed with monoclonal antibodies against SP (Sera-Labs) combined with avidin-biotin peroxidase staining. As suggested by Ishimoto, et al. (1981), at least two major types of SP containing amacrine cells were noted: large cells, ca. 8-9 um diameter, and a second group, ca. 6um in diameter. The larger cells stained more intensely and arborized in layer 3b. The smaller cells were lightly stained with arbors in layer 1, and occasional processes into layer 5. However, both types of cells were found in all regions of the retina, although there were some differences in total density in different regions of the retina. In representative samples of the central portion of the Red Field the total density of large and small cells was 500-800/mm$^2$ with large cells slightly more common. The combined density in the central Yellow Field was 1200-2000/mm$^2$, with large and small cells present in approximately equal numbers. In addition a third population of SP amacrine cells, possibly a variant of one of the above types, was noted in the region of the pecten oculi. This study indicates that SP amacrine cells are more numerous in all regions of the pigeon retina than previously appreciated. We suggest that the SP populations in other vertebrate retinae may also require re-evaluation.

(Supported by a Grant from the National Eye Institue EY-04796 to H.J.K.).

355.9 DEVELOPMENT OF CHOLINE ACETYLTRANSFERASE-LIKE IMMUNOREACTIVITY AND ACETYLCHOLINESTERASE IN THE CHICK RETINA. A.W. Spira, T.J. Millar, I. Ishimoto* and I.G. Morgan. Dept. of Behavioural Biology, RSBS, Australian National University, ACT, Australia, 2601.

Whereas the biochemical development of the cholinergic transmitter system of the retina has been extensively studied in the chick embryo, morphologic studies heretofore have described only the localization of acetylcholinesterase (AChE) activity. We describe here sites of potential synthesis of acetylcholine detected by the application of antisera against chicken choline acetyltransferase to cryostat-sectioned and flat-mounted retinas of chick embryos. Retinal samples were analyzed from the sixth to eighteenth days of incubation (H-H stages 30-44) and during the first week after hatching. The presence of choline acetyltransferase-like immunoreactivity (ChAT-IR) was appraised vis-a-vis AChE activity (Karnovsky-Roots method) and histologic appearances (cresyl violet staining).

ChAT-IR and AChE staining was followed through five successive steps. 1) Days 6-7. All cells lie within a single neuroblast layer (NBL). ChAT-IR and AChE were initially limited to one to two cell layers at the inner border of the NBL. ChAT-IR cells were subsequently present at some distance from the inner retinal surface and in central regions of flat-mounted retinas. AChE-stained cells then comprised the inner one-third of the NBL. 2) Days 7-8. The inner plexiform layer (IPL) forms and separates cells into a ganglion cell layer (GCL) and an inner nuclear layer (INL). A row of ChAT-IR cells bordered both sides of the IPL. AChE was present in both the GCL and INL and in a diffuse band in the IPL. 3) Days 8-11. The outer plexiform layer forms and the IPL thickens. Some cells of the GCL are temporarily "trapped" in an intra-IPL position. ChAT-IR cells were found at the innermost part of the INL and in the intra-IPL position. ChAT-IR cells were evident in all regions of flat-mounted retinas. Their processes spread laterally forming two bands in the IPL. These corresponded in position to AChE-stained laminae. AChE was present in the two separated groups of GCL cells. 4) Days 11-15. Photoreceptor cell differentiation begins with formation of their inner segments. The major period of ganglion cell degeneration occurs. ChAT-IR laminae in the IPL were further distant from their cells of origin. AChE cells in the GCL were in one stratum. 5) Days 15-early post-hatch. Photoreceptor cells develop outer segments and mature. ChAT-IR cells were added in the middle of the INL to the pre-existing reactive INL cells. AChE activity arose in two intermediate lamellae of the IPL.

ChAT-IR retinal cells thus appeared before the formation of the IPL and the onset of synaptogenesis (day 10). Changes in their appearance and prevalence was limited to an early increase in their spacing and the late addition of cells to the INL. (A.W.S. was supported by the MRC and NSERC of Canada).

355.10 EPINEPHRINE REGULATES SYNAPTIC TRANSMISSION MEDIATED BY CHOLINERGIC NEURONS OF THE RAT RETINA. *W-H. Tsai, M. S-W. Koh* & D.C. Puro.* Laboratory of Vision Research, National Eye Institute, National Institutes of Health, Bethesda, MD and Bascom Palmer Eye Institute, University of Miami, Miami, FL.

The purpose of this study was to investigate the effects of epinephrine on the function of synapses formed by cholinergic neurons derived from the rat retina. We used an experimental culture system in which striated muscle cells served as postsynaptic targets for cholinergic neurons of the embryonic retina. This culture system permitted the physiological monitoring of acetylcholine release at synapses formed by retinal neurons.

Trypsin-dissociated retinal cells from embryonic day 21 rats were co-cultured with rat striated muscle cultures. Functional retina-muscle synapses form rapidly, as determined by the presence of spontaneous synaptic potentials detected by intracellular recordings from the muscle cells. At 2 days of coculture approximately 70 % of the innervated myotubes could be demonstrated to have synaptic input that could be evoked by the microiontophoretic application of glutamate. Here, we report that epinephrine can regulate the efficacy of stimulus-evoked transmission across retina-muscle synapses.

Our electrophysiological experiments indicate that the microiontophoretic application of epinephrine had no effect on spontaneous transmission at retina-muscle synapses. However, after a 1 minute exposure to epinephrine, glutamate-evoked transmission across these synapses could be facilitated. A greater than two-fold increase in the number of evoked postsynaptic events was declared a facilitory effect. Such an effect of epinephrine on glutamate-evoked transmission was found in 80 % (12/15) of the cases examined. The facilitation by epinephrine is reversible, can be mimicked by isoproterenol (a $\beta$-agonist) and blocked by propranolol (a $\beta$-blocker). Neither the $\alpha_2$-blocker, yohimbine, nor the dopamine receptor antagonist, haloperidol, blocked this effect of epinephrine. Since epinephrine was not found to influence the membrane potential of muscle cells nor the responses of myotubes to microiontophoretically applied acetylcholine, epinephrine appeared to have mediated its effect on cholinergic transmission by affecting retinal neurons. Because our previous findings indicated that cAMP may be involved in the regulation of evoked transmission at retina-muscle synapses, the effect of epinephrine on cAMP levels was investigated. Biochemical studies demonstrated that epinephrine (5 $\mu$M) could increase cAMP levels in retinal cell cultures by more than 10-fold within one minute. The elevation of cAMP levels by epinephrine could be blocked by propranolol, but not by yohimbine nor haloperidol.

In summary, epinephrine can mediate a marked facilitory effect on stimulus-evoked cholinergic transmission in our cell culture system. This effect of epinephrine appears to be mediated via a $\beta$-receptor and may involve an increase in cAMP levels.

355.11 STARBURST-LIKE AMACRINE CELLS IN CAT RETINA ARE CHOLINERGIC. R.G. Pourcho and K. Osman* . Dept. of Anatomy, Wayne State Univ. School of Medicine, Detroit, MI 48201.

A large volume of evidence implicates acetylcholine (ACh) as a neurotransmitter in vertebrate retinas. In the rabbit, cholinergic cells are particularly well developed and exist in matching subpopulations of amacrine and displaced amacrine cells which give rise to processes ramifying in strata 2 and 4 of the inner plexiform layer (IPL) [Masland and Mills, J. Cell Biol., 83:159, 1979]. In Golgi preparations, these cells exhibit a characteristic starburst appearance (Famiglietti, Brain Res., 261: 138, 1983). Golgi studies in our laboratory have shown that the cat has a population of starburst-like amacrine and displaced amacrine cells which resemble the cholinergic cells of the rabbit although their branching pattern is relatively sparse. The somas of these cells measure 8-10 um in diameter and give rise to 1-4 primary dendrites which branch dichotomously within a narrow stratum into 3-5 generations of processes to cover a dendritic field of 300-400 um. Computer-assisted analysis showed that processes of the amacrine layer cells ramify in stratum 2 of the IPL whereas those of the displaced amacrines ramify in stratum 4. The displaced amacrines resemble the A14 amacrine cells of Kolb et. al. ( Vision Res., 21:1081, 1981). We have employed autoradiography and immunocytochemistry to determine whether these cells are cholinergic.

For autoradiography, retinas were incubated in 0.3 uM ($^3$H)choline followed by a chase in unlabeled choline with 20 mM Mg++ and 30 uM physostigmine to allow for synthesis of ($^3$H)ACh. The tissue was fixed in 3% phosphomolybdic acid (Tsuji, Neurosci. Lett., 45:151, 1984) with 2% glutaraldehyde, postfixed in osmium, dehydrated, and embedded in Epon. Small neurons on either side of the IPL were heavily labeled. Additional labeling was seen in photoreceptor outer segments and in large ganglion cells. For immunocytochemistry, retinas were fixed in 4% paraformaldehyde, rinsed in PBS, and sunk in 30% sucrose. Tissue was preincubated in 0.3% Triton X-100 prior to incubation for 24-48 h in a monoclonal antiserum against ChAT (Boehringer- Mannheim). Immunoreactivity was visualized by the peroxidase antiperoxidase technique. Staining was confined to amacrine cells and displaced amacrines with processes ramifying in strata 2 and 4, respectively, of the IPL. The density of ChAT-containing displaced amacrine cells was approximately 600 cells per mm$^2$, exceeding the amacrine layer cells by nearly 3:1. Camera lucida drawings of ChAT immunoreactive cells show the same morphological features as the Golgi preparations of A14 or starburst-like cells. We conclude that these cells are cholinergic.

355.12 SYNAPTIC ORGANIZATION OF CHOLINERGIC NEURONS IN THE CHICKEN RETINA. I.G. Morgan, I. Ishimoto* and T.J. Millar*. Department of Behavioural Biology, RSBS, Australian National University, Canberra, ACT 2600, Australia.

We have investigated cholinergic neurons in the chicken retina, particularly their synaptic organizations, using immunohistochemical techniques with an antiserum against chicken choline acetyltransferase. Immunoreactivity was found in cells in the inner nuclear layer; cells in the ganglion cell layer; two compact fiber bands between sublaminas 1 and 2 and sublaminas 3 and 4 of the inner plexiform layer; and in scattered varicose fibers in sublaminas 4 and 5 of the inner plexiform layer.

Immunoreactive cells in the inner nuclear layer comprised two populations. One population was located at the border of inner nuclear and inner plexiform layers, and dendrites from these cells produced the compact fiber band between sublaminas 1 and 2. The other population was located 3-4 cell layers from the border. By using selective lesioning of retinas with cholinergic neurotoxin AF64A, it was established that dendrites from this population of cells were the main source of varicose fibers in sublaminas 4 and 5. The immunoreactive cells in the ganglion cell layer were displaced amacrine cells and their dendrites gave rise to the compact fiber band between sublaminas 3 and 4.

Although quantitative evaluation is still preliminary, the most striking ultrastructural feature was the large number of cholinergic/cholinergic synapses. This was apparent in both compact immunoreactive fiber bands. Other input to cholinergic processes was from bipolar cells. Cholinergic outputs onto ganglion cells and non-labelled amacrine cells were seen in both compact bands, whereas output to bipolar cells was only seen in the compact immunoreactive fiber band between sublaminas 1 and 2 of the inner plexiform layer.

We suggest, because of the large number of cholinergic/cholinergic synapses, that cholinergic cells have directional sensitive functions in the retina.

355.13 PATCH-CLAMP RECORDINGS FROM GANGLION CELLS ISOLATED FROM GOLDFISH RETINA: RESPONSES TO ACETYLCHOLINE S. Naghshineh*, M.J. Fain* and G.L. Fain, Department of Ophthalmology, Jules Stein Eye Institute, UCLA, Los Angeles CA 90024.

Although cells in the inner plexiform layer of vertebrate retina have been shown to contain a large variety of transmitter substances, there is little evidence to indicate what these transmitters do. In order to explore this question in detail, we have begun making patch-clamp recordings from ganglion cells in cultures of adult goldfish retina. Using methods we have described (Fain et al. Vision Res. 23, 1239, 1983), we have isolated ganglion cells and maintained them in a HEPES-based minimal medium (high-K$^+$ Ringer with 10% Medium 199) at 11$^o$C. We injected the dye fast blue into the optic nerve prior to dissociation in order to identify ganglion cells. Control experiments with dye-injected intact retinas indicated that only ganglion cells were marked by this procedure. Cells identified as ganglion cells in this way had spherical or ellipsoidal cell bodies with many fine processes. The nuclei of these cells were clearly visible and contained enlarged, dark nucleoli under phase contrast. Cells were viable for several weeks though recordings were usually made within 10 days of isolation. Patch-clamp recordings were made conventionally with a List EPC 7. On-cell patches contained voltage-activated channel activity at both positive and negative pipette voltages. In whole-cell recordings, trains of action potentials could be elicited with positive current, and responses to voltage steps revealed voltage-dependent inward and outward currents which we have not as yet characterized in detail.

We have begun our investigation of the effects of putative transmitter substances on these cells with acetylcholine (Ach), since considerable evidence indicates that a subset of retinal amacrine cells contains Ach and makes direct contacts onto ganglion cells. In loose-clamp recordings, we have observed that pressure injection of 10 $\mu$M Ach onto cells in culture produces bursts of action potentials which rapidly desensitize. We investigated this response in ganglion cells recorded under voltage clamp in the whole-cell mode. The internal (pipette) solution contained 100 mM KCl or CsCl, 10 mM NaCl, 2 mM $MgSO_4$, $10^{-8}$ M free Ca, and 10 mM HEPES, pH 7.0. The external solution was normal Goldfish Ringer. When cells were voltage clamped at the resting membrane potential (-71$\pm$10 mV, n=10), Ach produced an inward current which decreased as the holding potential was made more positive and reversed near zero. Similar results were obtained when KCl in the internal solution was substituted with CsCl. These observations indicate that Ach produces an increase in conductance probably to both Na and K which would normally depolarize the cell in vivo. This result is consistent with the excitatory effects of exogenous Ach on ganglion cells in intact retina (e.g. Glickman et al., Brain Res. 234, 81).

355.14 THE PRESENCE OF ENKEPHALIN, NEUROTENSIN AND SOMATOSTATIN IN GLYCINE-ACCUMULATING AMACRINE CELLS OF THE CHICKEN RETINA. Carl B. Watt*, Hai-Biao Li and Dominic M.K. Lam. Cullen Eye Institute, Baylor College of Medicine, Houston, Texas 77030.

Recent reports have shown both peptide-transmitter (Weiler and Ball, 1984; Watt, Su and Lam, 1984) and peptide-peptide (Li, Watt and Lam, 1985) colocalization in subpopulations of retinal amacrine cells. We have continued these studies by examining the extent to which transmitter substances are colocalized in amacrine cells of the chicken retina. A comparative analysis indicated that in the chicken retina, the somas of certain enkephalin-, neurotensin- and somatostatin-immunoreactive amacrine cells are similar in size, shape and location to the somas of at least a portion of the population of cells which accumulate glycine. Taken together, these similarities were indicative of the presence of each of these neuroactive peptides in glycine-accumulating amacrine cells. A direct method to examine these possible relationships was to visualize putative peptidergic- and glycine-amacrine cells in the same retinal sections. Immunohistochemistry was used to identify enkephalin-, neurotensin- and somatostatin-cells, whereas glycine-cells were localized by high affinity $^3$H-glycine uptake-autoradiography. Such double-label studies revealed that although some amacrine cells were labelled only for glycine-uptake, others were labelled for both glycine-uptake and either enkephalin-, neurotensin- or somatostatin-immunostaining. These results, therefore, provide evidence for the presence of three subpopulations of glycine-amacrine cells which can be categorized by the coexistence of either enkephalin, neurotensin or somatostatin with glycine in these cells. Based on the earlier observation that enkephalin and neurotensin are colocalized in some amacrine cells of the chicken retina (Li et al., 1985), studies are presently underway to determine if more than one of these neuroactive peptides (enkephalin, neurotensin or somatostatin) are present in the same glycine-accumulating amacrine cell.

355.15 ENKEPHALINS IN THE GOLDFISH RETINA: ANATOMICAL LOCALIZATION AND BIOCHEMICAL STUDIES. K.R. Fry, Y.Y.T. Su, C.B. Watt* and D.M.K. Lam. Cullen Eye Institute, Baylor College of Medicine, Houston, Texas 77030.

Studies using electrophysiological techniques have demonstrated that exogenously applied enkephalin or enekphalin analogues influence the activity of goldfish ganglion cells (Djamgoz et al., Nature 292:628, 1981). Immunohistochemical studies, however, have demonstrated only sparsely distributed enkephalin-like immunoreactive (Enk-LI) processes and, unfortunately, have been unable to identify their origin. We report here on the anatomical localization, synthesis and calcium-dependent release of enkephalin in the goldfish retina.

For immunohistochemical studies, light-adapted goldfish (Carassius auratus) retinas were fixed overnight in 4% paraformaldehyde and 0.1% glutaraldehyde in 0.1 M phosphate buffer. Vibratome sections (50-75μm) were prepared and immunostained with an antibody prepared against Leu$^5$-enkephalin (Batch A206, generously supplied by Dr. K.-J. Chang). The binding sites were visualized using the ABC-peroxidase method. Enk-LI was localized to a discrete population of amacrine cells located along the inner border of the inner nuclear layer. Processes extended into the inner plexiform layer and ramified predominantly in sublaminas 1, 3 and 5.

To study enkephalin synthesis, isolated fish retinas were incubated with $^{35}$S-methionine, homogenized in acetic acid, boiled and centrifuged at 40,000xg for 45 min. Synthesis of labelled enkephalin in the tissue was demonstrated by radioimmunoassay, thin layer chromatography and high pressure liquid chromatography. The opioid nature of the synthesized compound was confirmed in binding studies with mouse brain membrane preparations.

Enkephalin release was studied by incubating the above labelled tissue in high $K^+$ (60mM) Ringer's solution followed by repeated washings in normal Ringer's solution. The solutions were then concentrated and assayed. Approximately 8-10% of the total labelled enkephalin which had been synthesized in the tissue was found to be released. This release could be completely suppressed by 5mM $Co^{+2}$ suggesting a calcium dependent nature.

The present findings of anatomical localization, synthesis and release of enkephalin when combined with previous reports of physiological activity suggest strongly that enkephalin may be a neurotransmitter candidate for certain amacrine cells in the goldfish retina.

355.16 IDENTIFICATION OF SUBSTANCE P IMMUNOREACTIVE GANGLION CELLS IN THE RABBIT RETINA. N. Brecha, M. Cilluffo and J. Bolz*. Dept of Medicine, Jules Stein Eye Institute, Brain Research Institute and Center for Ulcer Research and Education, UCLA School of Medicine, LA, CA 90024 and VA Medical Center, Wadsworth, LA, CA 90073.

Several neuropeptides including substance P (SP) have been localized to the mammalian retina. The majority of peptide containing retinal cells are amacrine cells. In addition, peptide containing somata in the ganglion cell layer (GCL) suggest the existence of peptidergic ganglion cells and/or displaced amacrine cells.

Normal and intraocular colchicine-treated rabbit retinas were fixed in paraformaldehyde. Sections cut perpendicular to the vitreal surface and whole retinas were incubated in a rat monoclonal antibody directed to SP and processed for either immunofluorescence or peroxidase-antiperoxidase immunohistochemistry. In several rabbits, the superior colliculus and pretectal area were injected with Fast Blue (FB) or rhodamine (TRITC) impregnated microspheres. Following a 2-5 day survival period the eye contralateral to the injection sites was treated with colchicine and subsquently fixed and processed for SP immunohistochemistry.

As we reported earlier, SP immunoreactivity in normal and colchicine-treated retinal sections is present in processes distributed to laminae 1, 3 and 5 of the inner plexiform layer (IPL). SP positive somata are present in the inner nuclear layer (INL) at the IPL border and give rise to processes to the IPL. Some of these somata also give rise to a single fine process that crosses the INL to ramify in the outer plexiform layer. A greater number of SP positive somata are present in the GCL and they also give rise to processes to the IPL. Scattered axon-like processes are observed in the optic nerve layer and optic nerve head. In retinal whole mounts this same general distribution of somata and processes is seen in all retinal regions. The highest density of immunoreactive somata is in the region of the visual streak. Well-labeled somata, which are likely to be ganglion cell bodies were observed in the GCL following injection of either FB or TRITC microspheres into midbrain visual centers. In those regions of the GCL having a dense and continuous labeling of retrogradely filled somata, some labeled somata also contained SP immunoreactivity. SP postive somata which are not retrogradely filled are also observed.

These studies confirm the presence of SP immunoreactive amacrine, displaced amacrine and interplexiform cells and directly demonstrate the presence of SP-containing ganglion cells in the rabbit retina.

## CHEMICAL SENSORY SYSTEMS II

356.1 PROBOSCIS EXTENSION IN THE BLOWFLY: POSITIONAL EFFECTS OF CHEMORECEPTORS. S. Yetman* and G.S. Pollack (SPON: J. Marsden). Dept. of Biol., McGill Univ., Montreal, Quebec, Canada H3A 1B1.

The fly posesses several hundred chemosensilla on its labellum which are important in controlling its feeding behavior. Among these are a population of 22 identified sensilla trichodea (11 on each labellar lobe) called the "largest hairs", which are arranged along an anterior to posterior axis with largest hair #1 most anterior and #11 most posterior. We wanted to determine whether the fly made use of the positional information these hairs may be providing. Stimulation of a single largest hair with sucrose elicits proboscis extension. We tested the role of positional information by measuring the relationship between the identity of the stimulated hair and the direction of the resultant proboscis extension. Stimulation of anterior hairs elicited an anterior and slightly lateral extension of the proboscis, whereas stimulation of more lateral or posterior hairs resulted, respectively, in more laterally or posteriorly directed extension. Quantitative analysis revealed that the direction of proboscis extension is continuously graded according to the position of the hair stimulated.

To determine whether the positional information provided by the hairs had an anatomical correlate in the central nervous system, the neurons innervating each largest hair were stained by positioning a micropipette filled with cobaltous lysine on the terminal pore of the sensillum. The axons of the neurons were found to course through the labial nerve and terminate in the suboesophageal ganglion. Three distinct types of central projections were observed, each associated with a different group of hairs. The axons from hairs 1 and 2 branch in the ipsilateral hemiganglion and also project contralaterally at three distinct dorso-ventral levels. The neurons innervating hairs 3-8 terminate primarily in the ipsilateral hemiganglion where they form a 'Y' shaped pattern when viewed in the frontal plane, and have a single, dorsal contralateral projection. Finally, the neurons innervating hairs 9-11 terminate within a restricted region of the ipsilateral hemiganglion and send two projections contralaterally.

In conclusion, our behavioral observations show that the fly makes use of the positional information provided by the largest hairs. However, the directionality of the behavior cannot be explained solely by the observed projection patterns since neurons from hairs within a single morphological group have branching patterns which are indistinguishable, but nevertheless elicit differently directed extensions.

356.2 ADAPTATION OF PRIMARY CHEMORECEPTOR CELLS: PARALLEL SHIFT OF DOSE-RESPONSE FUNCTIONS AND REDUCED VARIANCE. P.F. Borroni* and J. Atema, Boston University Marine Program, Marine Biological Laboratory, Woods Hole, MA 02543

Chemoreceptors must extract normally signals in a noisy environment of varying background intensity. Adaptation to background conditions is a common feature of receptor cells but poorly studied in chemoreception. We used the narrowly tuned $NH_4$ cells of lobster (Homarus americanus) legs to measure the effects of self-adaptation on dose response functions over the natural range of stimulus and background concentrations. $NH_4$-sensitive cells compose the second most common narrowly tuned receptor cell population in the lobster walking legs (Johnson et al. 1984, J. Comp. Physiol. 155A:593-604). These taste organs are essential for lobster feeding behavior, and among all the compounds for which narrowly tuned receptors are known to exist, $NH_4$ is the only one that elicits feeding motions in a leg-specific behavioral bioassay (Borroni et al. submitted). During feeding the $NH_4$ receptors may encounter peak $NH_4$ concentrations as high as 20 mM in the prey tissue itself, against backgrounds of $NH_4$ varying from uM to mM.

Single cells were identified by stimulation with 5uM $NH_4Cl$ in artificial seawater containing a background of 1.6 uM $NH_4$. Extracellular chemosensory responses were recorded and counted as the number of spikes in the first 10 seconds. Dose response functions were obtained from an ascending $NH_4$ concentration series (.03uM to 30mM), in backgrounds of 1.6, 4.4, 38 and 350uM $NH_4$. Single cell dose response functions varied greatly in slope and shape and ranged over the entire 4-6 log steps tested without saturating; the variance of the response mean increased with stimulus concentration. Elevating the $NH_4$ concentration in the background had two major effects: 1) it caused a horizontal parallel shift of the dose response functions, i.e. the response to all stimulus concentrations tested was nearly equally affected; 2) it reduced single cell response intensities, suppressing mostly the cells with the strongest response. The resulting reduction in the variance of the receptor population mean response may be the main function of adaptation in these cells, which show no obvious saturation but increased variance at high stimulus intensities. In this way adaptation could extend the useful operating range of the receptors.

356.3 ORGANIC CALCIUM ANTAGONISTS AND CERTAIN INORGANIC CATIONS INHIBIT OLFACTORY TRANSDUCTION. B.D. Winegar, E.R. Rosick, and R. Schafer. Department of Biological Sciences, North Texas State University, Denton, TX 76203.

The role of $Ca^{2+}$ in olfactory transduction was explored by aerosol application of inorganic cations and organic calcium antagonists onto the olfactory epithelium of the frog during extracellular recording. Inorganic cations that block inward calcium currents in other tissues inhibit electroolfactogram (EOG) responses. The rank order of potency of the chloride salts is $La^{3+}>Zn^{2+}>Cd^{2+}>Ca^{2+}>Al^{3+}>Sr^{2+}>Co^{2+}$. Application of $10^{-9}$ mol of $La^{3+}$ in a 2 sec aerosol mist virtually eradicates EOG responses, with only partial recovery occurring over a period of hours. $Co^{2+}$ has the least effect, producing slight and rapidly reversible inhibition at the same dosage. $Mg^{2+}$ has no effect. Brief enhancement of EOG amplitudes was observed upon application of $Ba^{2+}$, which gives greater currents than $Ca^{2+}$ in other tissues. Unexpectedly, $Ca^{2+}$ itself was inhibitory.

The organic calcium antagonists verapamil and diltiazem (2 x $10^{-10}$ mol applied over 2 sec) inhibit by approximately 70% and 50%, respectively, at 100 sec following application. The effects of both agents are reversible, with complete recovery occurring within 90 min. Another organic calcium antagonist, nitrendipine, has no action at this dosage level. Recovery from verapamil and diltiazem inhibition appears to follow a linear pattern, as does recovery from many of the inorganic cations.

The calmodulin antagonists N-(6-aminohexyl)-5-chloro-1-naphthalenesulfonamide (W-7), trifluoperazine (TFP), and chlorpromazine (CPZ) depress EOG amplitudes with no apparent correlation to their anti-calmodulin potency. With the same dosage level as above, W-7 (the most potent calmodulin antagonist tested) has only a slight and reversible depressive action while TFP and CPZ produce apparently permanent EOG inhibition. At 100 sec after application, CPZ produces approximately 85% inhibition and TFP depresses EOGs by about 55%. Recovery from these agents approximates a hyperbolic curve, leveling off at about 25% below the pretreatment baseline for CPZ and about 45% below for TFP.

These data support the hypothesis that $Ca^{2+}$ is a current carrier and/or a second messenger in olfactory transduction. The inorganic cations inhibit EOGs in a way consistent with their blocking effectiveness on calcium channels in other tissues. The EOG enhancement observed with $Ba^{2+}$, as well as the inhibitory action of verapamil and diltiazem also support the idea that calcium channels mediate one or more components of the mechanism of olfactory transduction. An explanation for the inhibitory action of CPZ and TFP is that their amphipathic properties might enable them to disrupt hydrophobic regions of protein and lipid in the cell membrane, thus limiting the ability of receptor neurons to normally respond to odorous stimuli.

356.4 IMMUNOHISTOCHEMICAL LOCALIZATION OF AN ODORANT BINDING PROTEIN FROM BOVINE NASAL EPITHELIUM. P.B. Sklar*, J. Pevsner* and S.H. Snyder (SPON: A.L. Gundlach). The Johns Hopkins University School of Medicine, Department of Neuroscience, Baltimore, MD 21205.

Using the procedure described by Pevsner et al. (Proc. Natl. Acad. Sci. USA 82:3050-3054, 1985), we have purified a protein from bovine nasal epithelium that binds the bell pepper odorant, 2-isobutyl-3-methoxypyrazine. Rabbits were immunized with the purified protein and the resulting antiserum, when tested by immunoblotting, recognized a 19 kD polypeptide along with a minor component at 65 kD. The 65 kD contaminant cross-reacted with antiserum against bovine serum albumin. Anti-BSA antiserum, however, did not cross-react with the 19 kD band, which previously has been shown to account for the binding of [$^3$H]2-isobutyl-3-methoxypyrazine.

Immunohistochemical localization using an indirect peroxidase-antiperoxidase method in cryostat sections of bovine nasal mucosa reveals heavy staining of the glands in the lamina propria. Control experiments with normal rabbit serum and bovine serum albumin antiserum confirmed that this observed immunohistochemical pattern is specific for the odorant binding protein. The precise physiological function of this odorant binding protein still remains unclear. Its localization to the nasal glands suggests a possible role in mediating odor induced secretion. (Supported by a grant from International Flavors and Fragrances, Incorporated.)

356.5 COMPARATIVE STUDY OF ELECTROPHYSIOLOGICAL PROPERTIES OF DEVELOPMENTALLY SYNCHRONIZED POPULATIONS OF YOUNG AND MATURE OLFACTORY NEURONS IN ADULT FROG. M.S. Lidow, S.J. Kleene*, and R.C. Gesteland. Northwestern University, Evanston, IL 60201.

Because cells in the normal olfactory epithelium of adult animals are continuously turning over, it always contains not only mature receptor cells (which have established synapses with olfactory bulb cells), but also a rather large population of young receptor cells (which have not yet established such synapses). In this work we have conducted a comparative study of the electrophysiological properties of young and mature receptor cells in order to understand their contributions to the electrophysiological properties of normal frog olfactory epithelium. For this purpose we used olfactory epithelia with developmentally synchronized populations of receptor cells. To obtain such epithelia, we first ablate the epithelia by perfusing the frog nasal cavity with 0.15 M zinc sulfate ($ZnSO_4$) for 3 min. Then we allow the epithelia to regenerate for 10 days. After this, we continuously flow 50 mM hydroxyurea in Ringer (0.40 ml/day) into the nasal cavity. Thus the epithelia contain only those receptor cells which originated during the short period of time prior to hydroxyurea treatment. Since regeneration of receptor cells starts on the sixth day after $ZnSO_4$ treatment, the ages of most of these cells fall within a 4-day range. Two groups of 5 olfactory epithelia were used in the study. One group was subjected to the hydroxyurea treatment for 8 days, and thus contained only young olfactory receptor cells 8-12 days old, the axons of which presumably have not yet reached the olfactory bulb. Another group was subjected to hydroxyurea treatment for 24 days and contained a population of mature olfactory receptor cells 24-28 days old which should have synapses in olfactory bulb. The electroolfactograms (EOGs) recorded from both groups of olfactory epithelia showed no differences in polarity or shape. However, the amplitudes of EOGs recorded from epithelia with mature olfactory receptor cells were generally higher than those from young cells. We attribute this to the fact that mature frog receptor cells have much longer cilia and as a consequence larger receptor area. Extracellular recording of single cell activity showed that olfactory receptor cells of adult frogs do not pass through a stage during which they unselectively respond to all odorants. Such a stage in development has been described for embryonic rat olfactory receptor cells. When compared to more mature olfactory receptor cells, young cells had much lower (sometimes zero) spontaneous activity. Odorous stimulation of young cells evoked on the average fewer spikes, and they were much less tuned to a specific range of concentration of odorants.

This work was supported by NIH grants NS18490, NS07223, and NS14663 and by NSF grants BNS8117075 and BNS8316827.

356.6 MITRAL-GRANULE CELL INTERACTIONS UNDERLIE RAT OLFACTORY BULBAR EEG. F.H. Eeckman* and W.J. Freeman (SPON: M.C. Diamond). Dept. of Physiol.-Anatomy, U.C. Berkeley, Berkeley, CA 94720.

We performed simultaneous recordings of unit pulses and EEG at various locations in the olfactory bulb of anesthetized rats. No electrical or olfactory stimulation was used. The EEG was recorded on the surface of the exposed OB with a 250 μ electrode. Using stereotaxic coordinates, a tungsten micro-electrode was positioned in the mitral cell layer directly underneath the surface electrode. (Interelectrode distance was no greater than .8 mm, which corresponds to the depth of the mitral cell layer.) The EEG was digitized at 1 msec. intervals, bandpass filtered at .3 cps to .3 kcps and stored with the pulse train. The latter was analyzed with a threshold comparator, set to emit a standard pulse 5 V, 1 msec for every signal above twice the noise level. The traces often showed 3 to 4 distinct action potential waveforms. We recorded multi-unit as well as single unit traces. Data were stored on tape and processed off line on a digital computer (Perkin Elmer 3220 mini). Power spectra were computed using the FFT algorithm. They showed 3 dominant frequency peaks in the EEG. One corresponds to the respiratory wave at 1.5 Hz. This component was filtered out using a digital filter. The second component was at 20 Hz, the third at 50-58 Hz. We used the 2 dimensional conditional pulse probability table (Freeman 1975) to find correlations between unit pulses and EEG wave amplitudes.

In all locations tested, units were found that fired with a quarter-cycle phase lead relationship to the ongoing 50 Hz frequency band of the EEG. It was noted, however, that units could be most reliably recorded from a 3 mm segment on the intermediolateral surface of the OB. Pulses correspond to mitral cell firings. The EEG trace is generated by the granule cell responses; all other cells in the bulb generate closed fields. The mitral and granule cell groups are reciprocally interconnected with excitatory-inhibitory synapses (Rall & Shepherd, 1968). A model was proposed by Freeman to explain EEG bursts on the basis of this connectivity (Freeman, 1975). Our data showing a fixed time relationship with quarter-cycle time lead for pulses to waves provide further evidence for this model, as well as extending this evidence to another species.

356.7 TIME-SERIES ANALYSIS OF RABBIT OLFACTORY BULB EEG: BURSTS AND INTERBURSTS. K.A.Grajski and W.J.Freeman. Group in Biophysics. Dept. of Physiology. UC Berkeley. Berkeley, CA 94720.

The olfactory bulbar EEG of waking rabbits alternates between bursting and interbursting states. The alternation occurs at the respiratory rate (2-8Hz) with bursts occurring with inhalation. As an initial assay in the search for odor-specific neural activity manifest by the EEG of rabbits trained with odor CSs, we evaluated the differential temporal, spectral and spatial characters of these states in naive rabbits.

The bulbar field potentials were recorded epidurally from the lateral aspect of the olfactory bulb of chronically implanted rabbits (N=7) with an 8 by 8 electrode array. From successive 6 second trials, burst and interburst segments (100ms) were selected. For statistical analysis, the sample of bursts and interbursts each form a class. The correlation (Fisher z-transformed) between the mean burst and interburst spatial patterns of RMS amplitude averaged 1.35 across animals. Pairwise correlations of spatial patterns within classes averaged 0.92 +/- 0.4 and 0.7 +/- 0.4 for bursts and interbursts, respectively. These results suggest that the spatial distribution of EEG in the bulb is common to both states, and in each segment there is a global waveform.

The averaged time series power spectrum for bursts and interbursts had characteristic peaks. For burst segments, maximal power occurred at 50-70Hz, a half-maximal peak near 20-40Hz and rapid decline near 90Hz. For interburst segments, broad peaks of equal height occurred near 50-70Hz and 20-40Hz, but were never greater than burst segment peaks. Spread of peaks, as measured by one-half maximal peak power, averaged 30Hz for bursts and 80Hz for interbursts. In short, the burst spectra are focused near a recurring peak frequency, while interbursts show a broad power spectrum.

Recent work suggests that odor-specific information is restricted to particular frequency domains of the EEG. It is manifested by statistically stable temporal, spectral and spatial-spectral properties across burst segments recorded weeks apart. The generation of EEG is modelled by a set of nonlinear differential equations which display equilibrium, limit cycle and chaotic states. Bursts correspond to limit cycle activity, interbursts to chaos. The alternation of burst and interburst activity is interpreted as the repeated emergence and collapse of an ordered state from a chaotic state driven by the periodic surge of receptor activity with inhalation.

356.8 GLOMERULAR TERMINATIONS OF OLFACTORY RECEPTOR AXONS IN A SNAIL TENTACLE. Barbara Tolloczko* and R. Chase. Department of Biology, McGill University, Montreal, Quebec, H3A 1B1, Canada.

One of the most striking examples of evolutionary convergence in neuroanatomy is the synaptic glomeruli which constitute the terminal sites for olfactory afferent fibers in both vertebrates and crustacea. In order to determine whether the generality of this observation extends also to the molluscs, we have investigated the course of receptor axons in the tentacular olfactory system of the terrestrial snail, Achatina fulica. The receptor neurons were selectively labelled by application of HRP crystals to the surface of the olfactory epithelium or by iontophoretic injection of HRP into the sub-epithelial lobules containing receptor cell somata. The tentacles were examined in serial sections with both LM and EM.

The receptor axons terminate at three different locations: 1) the tentacle ganglion, 2) the digit-like peripheral extensions of the tentacle ganglion, and 3) the procerebral lobe of the brain. We have observed glomeruli only in the digits. Here, when seen in transverse sections, they consistently occupy a medial and ventral position. The fasciculated axon bundles stream down from the lobules above, turn nearly 90° to head towards the tentacle ganglion, and then terminate in one of the glomeruli. The glomeruli are recognized by their glial wrapping, the absence of cell bodies, and the prevalence of synaptic contacts. The ultrastructure of the synapses is similar to that of central chemical synapses in other gastropod ganglia, with symmetrical membrane thickenings and asymmetrical accumulations of predominately small (50 um) lucent vesicles. The cell bodies of interneurons sometimes occupy periglomerular positions. The glomeruli measure about 25 µm by 50 µm in cross section, and extend 60-190 µm along the length of the digit. There are about 6 glomeruli in each of the 5 digits which underlie the sensory epithelium.

The morphological features of the glomeruli in the snail tentacle are similar to those present in the vertebrate olfactory bulb and in the insect deutocerebrum . It therefore appears that there is a compartmentalization of afferent inputs in all well-developed olfactory systems. The generality of this structural plan suggests a relationship to the requirements of information processing in olfaction.

356.9 ROLE OF OLFACTORY AND VOMERONASAL SENSES ON GARTER SNAKE RESPONSE TO AIRBORNE ODORANTS. J.Halpern*, E. Erichsen* and M. Halpern. Department of Anatomy and Cell Biology, Downstate Medical Center, Brooklyn, N.Y. 11203.

Twenty garter snakes were tested for responsiveness to airborne odorants in an olfactometer (designed and constructed by B. Slotnick). Dry, deodorized air was passed through saturation tubes containing concentrated amyl acetate, limonene, earthworm wash, fish water, distilled water or through tubes containing a live earthworm or a live fish. This odorized air, mixed with a constant stream of air, passed directly into a 1 liter glass chamber in which the snake was tested. A test session consisted of a 5 minute adaptation period followed by 2 trials separated by a 3 minute intertrial interval. A trial consisted of 3 one minute intervals in which tongue flicks were counted prior to, during and following a one minute odor or control ($dH_2O$) stimulus. In any given session an odor was always tested with a control stimulus. The order of testing was systmatically varied. All snakes were tested once with each odor prior to surgery and once with each odor following surgery. Preoperatively, snakes significantly increased tongue flick rates(TFR) during presentation of all six odor stimuli. TFR increases were greatest during limonene and amyl acetate and least during earthworm wash presentations. After preoperative testing the snakes were tested for locomotor activity in an open field apparatus and then subjected to either bilateral vomeronasal (N=7), bilateral olfactory (N=7) nerve cuts or sham (N=6) surgery. Following surgery snakes were again tested in an open field apparatus. There was a slight postoperative decrease in locomotor activity for all groups following surgery with no differential lesion effects. Snakes with sham lesions retained differential responding to odor stimuli following surgery. Both vomeronasal and olfactory nerve groups showed a significant decrement in TFR to odor stimuli postoperatively, however, the olfactory nerve group did not significantly increase TFR in the presence of odor whereas the vomeronasal nerve group did to a slight, but significant, extent.

These results suggest that the increased TFR in response to airborne odorants observed previously (Burghardt, 1977;1979; Halpern & Kubie, 1983 ) may be mediated by both olfactory and vomeronasal systems in snakes. Since olfactory nerve lesions appear to have a more devastating effect on the response to airborne odorants, it is possible that the initial increase in TFR following odor stimulation depends on it, whereas the maintained increase in TFR depends on a functional vomeronasal system. This is the first demonstration of a deficit following olfactory nerve lesions in snakes and is consistent with the idea that the olfactory system is involved in the detection of volatile odorants.

356.10 OLFACTORY STIMULI AND THE EFFECTS ON GLUCOSE, INSULIN AND GROWTH HORMONE IN CHICKENS. D.H. Krestel-Rickert, and C.A. Baile. Washington University School of Medicine, Dept. of Preventive Medicine, St. Louis, MO 63167.

Olfaction has been proposed as a means of determining growth rate and affecting hormones in some animals. In this study several classes of olfactory stimuli (Ketones, esters, alcohols, etc.) were investigated for their potential to alter hormonal (eg. growth hormone) and metabolite (eg. glucose) concentrations in chickens. In addition, insulin concentrations were also considered during the fed and fasted states. Blood samples were drawn from broiler chicks (4-9 weeks) at -4 hr (after access to food and 4 hr prior to odor), 0 min (time of odor exposure and end of 4 hr fast) and post-meal/odor states of +15 and +30 minutes. At time 0, birds were allowed access to food as an olfactory stimulus was delivered to the nares of the chicken at a flow rate of approximately 4 ml/min. Chicken plasma was assayed using a chicken standard (Litron Labs, 50 IU/mg) in a heterologous RIA. Five replications for 10 birds/day were made for each odorant tested. Growth hormone levels for all odors tested except butyric acid (an aliphatic acid) were not significantly altered. Mean values of GH for butyric acid were significantly decreased from time 0 (odor/meal exposure) to time 15 (15 min post odor/meal: 72.65 ng/ml vs 31.95 ng/ml, $p<.05$). No significant differences existed for either glucose or insulin concentrations for butyric acid. This decrease may be attributed to butyric acid since similar changes in GH concentration were not associated with other odorants tested or the fed/fasted state. The possibility exists that some olfactory stimuli may alter growth hormone concentrations in poultry and in turn effect the normal growth pattern over time; on the other hand, feed odorants could provide a means of stimulating pituitary hormones to effect both behaviors and metabolism.

356.11 BEHAVIORAL CONSEQUENCES OF THE AMILORIDE-SUPPRESSED SALT TASTE RESPONSE. B. K. Formaker*, K. S. White* and D. L. Hill, (SPON: E. DuBrul), Dept. of Psychology, Univ. of Toledo, OH 43606

Neurophysiological recordings from the rat chorda tympani nerve reveal that lingual application of amiloride suppresses gustatory responses to NaCl. The effects of amiloride are proposed to be specific to sodium transduction processes. Although the magnitude of response suppression to NaCl is as much as 80%, complete suppression has not been achieved. This indicates that additional transduction processes must occur. To learn if the residual NaCl response after amiloride is qualitatively similar to the unsuppressed NaCl response, a conditioned taste aversion procedure was used.

Adult rats were maintained on a 23.5 hr. water deprivation schedule throughout the experiment. The number of licks/10s were measured to the following randomly presented 10 stimuli: 0.1M and 0.5M NaCl, $NH_4Cl$ and KCl; 0.1M Na-saccharin, 0.1M citric acid, 1.0M sucrose and 0.01N HCl. This measurement was taken one day before and one day after aversion conditioning. Avoidance training in rats preexposed to amiloride was conducted by first exposing the animal to ten, 10s trials of 100 μM amiloride hydrochloride. Preexposure to amiloride was immediately followed by alternating 10s amiloride trials with 10s of either 0.1M NaCl, 0.5M NaCl or 0.1M $NH_4Cl$ for a total of 20 CS presentations. Immediately after the last CS presentation, the animal was injected with 0.3M LiCl (1% B.W.' i p.). Conditioning without amiloride preexposure consisted of alternating the same stimuli described above with distilled water for a total of 30 CS presentations. Six rats were used in each group. Suppression ratios were measured by dividing the mean number of post-test licks by the mean number of pre-test licks. Generalization curves for each CS was obtained by comparing the suppression ratio for that stimulus to the suppression ratios for each of the remaining nine stimuli.

Rats trained to avoid 0.1M $NH_4CL$ or 0.5M NaCl after amiloride learned aversions similar to rats that were not preexposed to amiloride. In contrast, rats trained to avoid 0.1M NaCl after amiloride were similar to saline-injected controls. Unexpectedly, rats conditioned to avoid 0.5M NaCl after amiloride suppressed to all salts with the exception of 0.1M NaCl. This is in contrast to rats conditioned to 0.5M NaCl alone, which only suppressed to 0.1M and 0.5M NaCl. These results indicate that the residual response to 0.1M NaCl after amiloride is not sufficient to condition a taste aversion and that the residual response to 0.5M NaCl is qualitatively different than 0.5M NaCl alone.

356.12 TIME COURSE OF RESPONSES TO SUCROSE AND NACL ELICITED FROM STIMULATING THE ANTERIOR TONGUE AND NASOINCISOR DUCTS. S.P. Travers and R. Norgren. Dept. of Behavioral Science, College of Medicine, Pennsylvania State University, Hershey, PA 17033.

Previous work from this laboratory has established that, for gustatory neurons in the nucleus of the solitary tract (NST) of the rat, the optimal sapid chemical may vary depending upon which subpopulation of oral taste receptors is stimulated. Specifically, of the four basic taste stimuli, sucrose is most effective for nasoincisor duct, and NaCl is most effective for anterior tongue stimulation. These initial observations were based on the magnitude of these responses, defined as the number of impulses/5s. The present analysis demonstrates that the time course of these responses also differs. We analyzed responses of 26 single neurons in the NST to 1.0M sucrose and 0.3M NaCl applied to the anterior tongue and nasoincisor ducts. Impulses were accumulated in post-stimulus time histograms (PSTH, 500ms bins) for 10s following stimulus onset. PSTHs were averaged across animals to obtain mean time courses. When the anterior tongue was stimulated with sucrose, the response peaked slowly, in the 13th bin (6.0-6.5s) following response onset and a greater number of spikes occurred during the second, as compared with the first, 5s of the response. In contrast, when sucrose was applied to the nasoincisor ducts, the activity of NST neurons peaked in the third bin (1.0-1.5s) following response onset and more impulses occurred in the first 5s of the response. Sodium chloride applied to the anterior tongue also elicited a relatively rapid response that peaked in the second bin (0.5-1.0s) following response onset. Similarly, the response to NaCl applied to the nasoincisor ducts peaked in the second bin, but the magnitude of this response was much smaller than any of the previously discussed responses. These time course differences were confirmed using correlation coefficients (Pearson's r). The time course of the nasoincisor duct response to sucrose was negatively correlated with the response to sucrose applied to the anterior tongue ($r=-.39$, n.s.) but positively correlated with the response to NaCl applied to the anterior tongue ($r=+.78$, $p<.05$). Behavioral studies have demonstrated that rats can discriminate taste quality within 200-700ms following stimulation (Halpern and Tapper, 1971; Scott, 1974), which suggests that the early portion of the neural taste response is sufficient for coding taste quality. The robust phasic response to stimulation of the nasoincisor ducts with sucrose is consistent with the hypothesis that these receptors are important for coding the sweet quality, particularly for initial detection. The location of nasoincisor duct receptors in the anterior oral cavity would further enhance their effectiveness in the rapid discrimination of sweet-tasting substances. (Supported by NIH NS07121 and NS20397.)

356.13 POLYSACCHARIDE TASTE AND APPETITE IN THE RAT. A. Sclafani, H. Hertwig*, J.W. Nissenbaum* and M. Vigorito (SPON: I. Abramov). Dept. of Psychology, Brooklyn College and Graduate School of City University of New York, Brooklyn, NY 11210.

Rats display an avid appetite for starch-derived polysaccharides (eg., Polycose). In fact, at low molar concentrations rats are more attracted to Polycose solutions than they are to sucrose solutions as indicated by two-bottle preference tests. This appetite is due to the oral rather than the postingestive effects of Polycose since rats consume large amounts of a Polycose solution even when it drains out an open gastric fistula. That it is the taste rather than the smell of Polycose that rats find attractive is indicated by the findings that experimentally- produced aguesia suppresses Polycose intake much more than does experimentally-produced anosmia. Conditioned taste aversion experiments revealed that rats taste Polycose as qualitatively different from sucrose.

Polycose contains saccharides (glucose polymers) of varying chain lengths and it is not clear which saccharides rats find the most "tasty." This question was addressed by measuring the taste preferences of adult female rats during brief (3-min) two-bottle preference tests. The rats were given the choice of solutions (.0125 molar) containing one of the following saccharides: glucose (a monosaccharide), maltose (a dissaccharide), maltotriose (a trisaccharide), maltooligosaccharide (a mixture of saccharides 4 to 8 glucose units in length), and Polycose (a mixture containing saccharides of 1 to 30+ glucose units in length).

The results indicated that the rat's order of preference for the shorter saccharides was as follows: maltooligosaccharide > maltotriose = maltose > glucose. The rats displayed a nonsignificant preference for maltooligosaccharide over Polycose. These findings demonstrate that saccharides of four or more glucose units in length maximally stimulate the rat's polysaccharide appetite, while shorter saccharides are less effective.

In another experiment nondeprived rats were given a 30-min two-jar choice test using powdered Polycose vs. corn starch, the latter contains only large polysaccharide molecules. The rats significantly preferred the corn starch to the Polycose. This finding was unexpected in view of the solution results and whether it is the taste or some other property of starch (texture, smell) that rats find attractive remains to be established.

Taken together, these behavioral findings indicate that rats, in addition to their well known taste for sugars, also have a taste and appetite for starch-derived polysaccharides.

356.14 THE EFFECTS OF STIMULUS SELECTION AND CLASSIFICATION CRITERIA ON THE EXISTENCE OF GUSTATORY NEURON TYPES IN THE RAT NTS. G. P. Mark* and T. R. Scott. Dept. of Psychology and Inst. for Neuroscience, Univ. of Delaware, Newark, DE, 19716.

We studied the impact of two factors on conclusions regarding the existence of gustatory neuron types in the rat nucleus tractus solitarius (NTS): (1) The stimulus array used to generate neuronal response profiles, and (2) The criterion for defining a related cluster of such profiles. Records were taken from 42 NTS cells responding to an array of 16 naturally occuring compounds. Profiles for each cell were determined according to (a) it's responses to this full array, or (b) to a condensed set composed of the four prototypical stimuli (NaCl, sucrose, HCl, quinine HCl). In each condition, profiles among all neurons were intercorrelated and multidimensional scaling techniques and hierarchial cluster analyses were used to study similarities among them. The tendency of response profiles to fall into groups was assessed by asking two statistical questions: (a) Are the profiles randomly distributed across the taste domain? or the reverse, (b) Is each profile identical to all others within a local cluster? When profiles were based only on responses to the four prototypical stimuli, the answer to the first question was decidedly negative. The probability that neuronal profiles were randomly distributed was $p<.01$. The answer to the second question was rather positive. Thirty-eight of the 42 neurons could not be excluded from membership in one of only four clusters of profiles. This represents support for the existence of gustatory neuron types. However, when profiles were based on responses to all 16 stimuli, clustering was less evident. The first question was still answered in the negative: neuronal response profiles are not randomly distributed ($p<.05$). However, the answer to the second became more equivocal: only 12 of 42 neurons were not excluded from four clusters when the membership criterion was that profiles be identical to within the limits of experimental error. It is not clear why an enlarged stimulus array regularly causes clusters to degenerate, as has been shown in several experiments. More stimuli should simply define response profiles more accurately, with no prejudice toward whether this should increase or decrease similarities among them. Perhaps if complex taste stimuli are composed of elements (sweet, salt, sour, bitter?) these are combined differently by individual cells such that these qualities would permit greater discrimination among response profiles. If this tendency persists, the existence of neuron types in a functioning system responding to hundreds of taste qualities becomes doubtful. The criterion for clustering is also crucial to answering the question of whether neuron types exist. It is clear that response profiles are not randomly distributed across tastes. However, it is difficult to demonstrate that they fall into a small number of groups (neuron types) within which they are identical.

356.15 STIMULATION OF SHAM FEEDING IN THE RAT BY SUCROSE, MALTOSE, GLUCOSE, AND FRUCTOSE. K. Joyner*, G.P. Smith, R. Shindledecker* and C. Pfaffmann. Dept. of Psychiatry, Cornell Univ. Medical College and Eating Disorders Institute and E.W. Bourne Behavioral Research Laboratory, New York Hospital, White Plains, NY 10605 and Rockefeller University, New York, NY 10021.

Sham feeding provides normal orosensory stimulation by sugars, but minimizes their postingestive negative feedback effects. Sham feeding of sucrose has been demonstrated to be a biphasic (Mook, 1963;), monotonic (Weingarten & Watson, 1982) or sigmoid function (Bernz et al, 1983) of concentration. We compared the potency of sucrose, maltose, glucose, and fructose to stimulate sham feeding in chronic gastric fistula rats (n=7) after 17 h of food deprivation and after no food deprivation. The following concentrations of all sugars were presented in ascending order: 0.1, 0.2, 0.4 and 0.8M. After 17 h of food deprivation, the rank order of potency for the stimulation of sham intake (ml-30 $min^{-1}$) was sucrose (strongest), maltose, glucose and fructose (weakest). There was one exception to this order: 0.1M maltose elicited a larger intake than 0.1M sucrose.

After no deprivation, there was a similar rank order of potency, but the curves relating sham intake to the individual sugars were shifted to the right by approximately one log concentration. In the non-deprived condition, 0.1M and 0.2M maltose elicited intakes that were equivalent to those elicited by 0.1M and 0.2M sucrose.

When the individual curves were analyzed for peak rate of change of intake per log change of sugar concentration, deprivation increased the effect of glucose ($p<.05$), but not that of the other sugars: The ratio of deprived to non-deprived peak rate of change of intake was 1.8 for glucose, 1.2 for sucrose, 1.0 for maltose, and 0.8 for fructose.

The results demonstrate (1) that deprivation increases the sensitivity of the sham feeding response to these four sugars, and increases the peak rate of change intake of glucose; and (2) that the maltose paradox (Pfaffmann, 1982) is present during sham feeding at 0.1M and 0.2M in deprived and non-deprived conditions.

356.16 CAPSAICIN SUPPRESSES DEPILATORY INDUCED IRRITATION. T.R. LAHANN* (SPON: A. SNOW). School of Pharmacy, Washington State University, Pullman, WA 99164-6510.

Capsaicin is now recognized as a relatively selective sensory neurotoxin. Injected s.c. into rodents, it produces major alterations in the neurochemistry, morphology and function of primary afferent neurons. Capsaicin also blocks some (but not all) types of cutaneous inflammation. The literature suggests that this anti-inflammatory activity may be a functional consequence of capsaicin's action on sensory neurons.

The studies reported here demonstrate that capsaicin blocks depilatory induced irritation in rats. A mild irritant response is observed after a single topical application of thioglycolate based depilatory preparations. Severe irritation develops following two or more depilations over a 4-day period. The causative factor of this irritant response appears to be the thioglycolate.

Thioglycolate (depilatory) irritation was quantitated 4 hours after the last depilation by subjectively evaluating the extent of scale and eschar formation. A 5 point grading scale was used. The observed irritation was not blocked by acetylcholine or histamine antagonists. Also, neither a topically applied nonsteroidal anti-inflammatory drug (indomethacin) nor a topical steroid (flucinolone acetonide) blocked development of the irritation. However, topical capsaicin applied in an ethanol: Tween 80:saline (48:4:48) vehicle suppressed development of the irritant response. The vehicle alone had no suppressive effect. Capsaicin's anti-irritant effect was evident when it was applied either before or after the first depilation. It was most effective, however, when applied shortly after the initial depilation. This anti-irritant action was dependent upon the amount of capsaicin applied per application, the number of capsaicin applications, and the time at which it was first applied. For example, when a 2% capsaicin solution was applied over a 6 hour period immediately following the initial depilation, the development of the irritation reaction was reduced by more than 90%.

Capsaicin's anti-irritant action does not appear to be restricted to the immediate site of its application. Even if applied to only one-quarter of the depilated area, capsaicin still effectively suppressed irritation over the entire depilated region. This expanded action does not appear to result from oral ingestion (Elizabethan collars prevented oral ingestion) or from smearing of the topical preparation, yet parenteral administration of capsaicin was only partially effective in antagonizing the depilatory induced irritation.

These data suggest that depilatory irritation is not dependent upon "classical" inflammatory mediators, but may be mediated by the peripheral nervous system. They also suggest a novel approach to the control of depilatory-induced irritation.

## LIMBIC SYSTEM AND HYPOTHALAMUS I

357.1 BASIC ORGANIZATION AND CHOLINERGIC FEATURES OF THE FELINE ISLANDS OF CALLEJA COMPLEX (ICC). K. Talbot*(1), N.J. Woolf (1) and L.L. Butcher (1,2). Psychology Dept. (1) and Brain Res. Inst.(2), UCLA, Los Angeles, CA 90024.

The granular islands of Calleja in the olfactory tubercle are accompanied by more diffusely arranged satellite neurons. This ensemble of granular and non-granular elements - the ICC of Fallon (Brain Res. Bull. 10:775, 1983) - has been described only in the rat. We report here, however, that the complex is differently and more discretely organized in the cat, where it is also more uniformly filled with an exceptionally dense cholinergic neuropil.

Unlike the case in rats, nearly all the Callejal islands in cats lie near or partially within the tubercular molecular layer. In coronal Nissl material (N = 6), these were seen to undergo progressive changes laterομedially, allowing differentiation of at least four types of islands: lateral, intermediate, medial, and tubercular-accumbal. They differ in their degree of exposure to the tubercular molecular layer, horizontal flattening, and granule cell density and cavitation. They also differ in the type and density of their satellite cells. The aggregation of these medium to large cells in hilar spaces above (and/or enclosed by) each Callejal island completes the division of the feline ICC into discrete units not commonly observed in rats or macaque monkeys.

Many satellite (but no granule) cells were found to be lightly or moderately reactive for choline acetyltransferase (ChAT) in monoclonal immunofluorescence preparations (N = 5) and for acetylcholinesterase (AChE) in pharmaco-histochemic material (N = 4). These cells were counted in 40 μm coronal sections from the rostral to the caudal pole of the olfactory tubercle, yielding 1,243 ChAT cells in 7 sections and 2,545 AChE cells in 14 sections. In both cases, over 80% of the cells were confined to hilar ICC areas (as opposed to intra-, peri-, and sub-granular ICC sectors). The vast majority were polymorphic neurons 14-28 μm in length, distinctly less voluminous than striatal ChAT or AChE cells. Their mean number rose in statistically significant ($p<.05$) increments laterομedially (e.g., from lateral to intermediate to tubercular-accumbal ICC units, the mean number of ChAT neurons increased from 4.9 to 12.8 to 29.2).

A concomitant increase in the cholinergic neuropil from lateral to medial ICC units suggested that the ChAT and AChE cells concentrated in their hilar areas are local circuit neurons. This view was reinforced, though not proved, by the observation of many descending enzyme processes from hilar areas toward a previously unreported band of intense ChAT and AChE neuropil just below most granular islands. These unusual subpial bands are virtually absent in olfactory tubercle areas between Callejal islands and appear to represent the densest cholinergic terminal fields in the forebrain.

357.2 ENTORHINAL TARGET NEURONS OF OLFACTORY BULB EFFERENT FIBERS: ANTEROGRADE DEGENERATION, GOLGI IMPREGNATION, GAD-IMMUNOCYTOCHEMISTRY AND ELECTRON MICROSCOPY COMBINED IN RAT.

F.G. Wouterlood* and E. Mugnaini. (SPON: European Neuroscience Association) Laboratory of Anatomy, Vrije Universiteit, Amsterdam, The Netherlands and Laboratory of Neuromorphology, University of Connecticut, Storrs, CT, USA.

Fibers originating in the olfactory bulb terminate superficially in layer I of the entorhinal area (EA). To identify target neurons of this projection the anterograde degeneration technique was combined with Golgi-electron microscopy of presumed projection neurons (Golgi-EM) and with immunoelectron microscopy of presumed, GABA-ergic interneurons (incubation with an antiserum against glutamic acid decarboxylase; GAD-EM). Lesion of the olfactory bulb results in electron-dense degeneration of axons and axon terminals. In early stages of degeneration the terminals remain synaptically attached to their target neurons. Two to three days following surgical removal of the olfactory bulb, young adult rats were perfused transcardially with formaldehyde/glutaraldehyde mixtures. For Golgi-EM, the dissected brains were impregnated according to Golgi-rapid and Golgi-Kopsch procedures. Twenty-five well-Golgi-impregnated EA-neurons of various classes were embedded in Epon, serially thin sectioned and screened in the EM for the presence of degenerating synaptic contacts. For GAD-EM, 40 um thick Vibratome sections were incubated with antiserum against glutamic acid decarboxylase according to an indirect procedure (Sternberger, 1979; Oertel et al, 1981). After embedding in Epon, 25 immunoreactive neurons in layer Ia of EA were serially thin sectioned and screened for the presence of degenerating axo-somatic synaptic contacts.

In the Golgi-EM material, degenerating terminals were observed forming asymmetric synaptic junctions with distal dendrites of layer II sparsely spinous pyramidal cells located in the dorsolateral subdivision (DLEA) of EA, and with distal dendrites of layers II and III spinous pyramidal cells located in the ventrolateral subdivision (VLEA) of EA. On nearly all screened GAD-immunoreactive cells, both in DLEA and in VLEA, we observed degenerating terminals, also with asymmetric synaptic junctions. These neurons are presumably small multipolar, local circuit neurons. Immunoreactive boutons form symmetric synapses in layer I both with immunoreactive neurons and with non-immunoreactive dendritic profiles. It is likely, therefore, that the GAD-immunoreactive, presumably GABA-ergic layer I neurons which receive olfactory bulb input take part in microcircuits providing feed-forward inhibition to pyramidal cells receiving olfactory bulb input.

357.3 INTERHEMISPHERIC CONNECTIONS OF THE HIPPOCAMPAL FORMATION IN THE BAT, ANTROZOUS PALLIDUS. L.J. Beasley*, G.O. Ivy, M. Leon and G. Lynch. Dept. of Psychobiology and CNLM, Univ. of Calif., Irvine, CA 92717

There have been few studies to date on the origin of hippocampal commissural projections in mammals and none in bats. Since bats are known to have a well developed hippocampus and to be adept at spatial memory tasks, it is of interest to examine one of the major projection systems of this brain region.

Four pallid bats were anesthetized and the skull overlying the hippocampus was removed unilaterally. Multiple small injections of HRP were placed along the septo-temporal extent of hippocampus. The bats were perfused the following day with a mixed aldehyde fixative. The brains were then removed and alternate sections were processed with TMB and BDHC histochemistry.

While the sizes and exact placements of the injections varied somewhat among the 4 bats, the combined results indicate that cells in every subregion along most of the septo-temporal axis of hippocampus project to the opposite hemisphere. Thus, labeled cells were found in all subregions of CA1, CA2, CA3 and CA4 as well as in prosubiculum and subiculum. No labeled granule cells were seen in the dentate gyrus. In approximately the anterior third of the hippocampus apparently all of the neurons in CA1 through CA4 were labeled. However, in more posterior regions the relative density of labeled neurons decreased in CA1 such that by approximately the middle third of hippocampus only 1/2 to 1/3 of these cells were labeled; these were located proximal to CA2. Still more posteriorly, CA1 neurons were only labeled in heavily injected cases. It appears that the CA1 projection is rather sparse, since neurons in this area were not labeled in one bat which received a smaller injection of HRP. In extreme posterior portions of hippocampus the cells of CA4 were densely labeled, while subicular neurons were lightly labeled despite dense HRP injections contralaterally.

In two of the bats there was distinct anterograde transport of HRP to the commissural zone. A fine granular reaction product covered the inner 37% of stratum moleculare of dentate gyrus and the inner 53% of this zone in CA1. Comparable figures for HRP transport in the rat are 38% and 70%, respectively (Ivy, pers. obs).

In conclusion, as is the case in other mammals,the commissural projection of hippocampus arises principally from regions CA3 and CA4 and terminates on the proximal portion of pyramidal and granule cell dendrites. However, unlike the case in the rat, all fields of Ammon's horn project to the contralateral hemisphere in the pallid bat. Further, the commissural terminal zone occupies a smaller proportion of the CA1 dendritic field in the bat than the rat. Supported by NIH NS21484 (to M.L.) and NICHD-HD06551 (L.J.B.).

357.4 A HRP STUDY OF BRAINSTEM AFFERENTS TO THE MEDIAL SEPTUM-DIAGONAL BAND NUCLEUS OF THE RAT. Robert P. Vertes. Mercer University School of Medicine, Macon, GA 31207

Cells of the medial septum-vertical limb of the diagonal band nucleus (MS-DB) have been shown to discharge synchronously in phase with hippocampal theta to pace this rhythm. Disruption of the rhythmical discharge of MS-DB neurons results in hippocampal desynchronization. It has been shown that MS-DB activity is, in turn, controlled by nuclei of the brainstem (Vertes, Prog. Neurobiol. 19: 159, 1982). In an attempt to further localize the sites of origin and trace the ascending trajectory of brainstem neurons involved in modulating the septum-hippocampus, we placed HRP injections in the MS-DB and analyzed retrograde transport to cells of the brainstem. Small WGA-HRP injections were made in 25 rats and brains were reacted using the TMB procedure of de Olmos et al. (J. Comp. Neurol. 181:23, 1978). Brainstem nuclei labeled following MS-DB injections included (from caudal to rostral): A1 noradrenergic area; cells directly adjacent to the MLF at the level of the rostral pole of the inferior olive; nucleus gigantocellularis, pars alpha (dorsal to the pyramids and ventral to NGC proper); retrofacial nucleus-C1 adrenergic area (ventrolateral medullary tegmentum directly caudal to the facial nucleus); raphe magnus; nucleus incertus (on the midline in the medullary gray at the level of the locus coeruleus); dorsolateral tegmental nucleus of Castaldi (DLT) (co-extensive and medial to LC in the pontomedullary gray); locus coeruleus, nucleus subcoeruleus; raphe pontis; medial aspect of pontis oralis; lateral parabrachial nucleus; Kolliker-Fuse nucleus; dorsal raphe; median raphe (MR); scattered cells in midbrain dopaminergic fields (retrorubral, VTA and caudal linear nuclei); prominent cell group in the mesencephalic gray directly lateral to the aqueduct; nucleus of Darkschewitsch and the supramammillary nucleus (SUM). In the hypothalamus, labeled cells were observed in the posterior, dorsal and lateral groups and in the caudal magnocellular and submammillothalmic (lateral to the mammillothalmic tract) nuclei. The most densely labeled areas were: raphe nuclei (magnus, pontis and median groups); incertus, DLT, LC, nucleus of Darkschewitsch, SUM and each of the hypothalamic nuclei.

We previously reported (J. Neurophysiol. 46:1140, 1981) that the most effective brainstem sites for producing hippocampal synchronization (theta) and desynchronization were pontis oralis and the median raphe, respectively. The present results of strong MR labeling suggests a direct influence of the median raphe on the MS-DB in the modulation of hippocampal slow-wave activity. The relatively light RPO labeling, on the other hand, suggests di- or multi-synaptic pathways from pontis oralis to MS-DB possibly through the supramammillary nucleus which was very heavily labeled in the present report.

357.5 NEOCORTICAL AFFERENTS TO THE LIMBIC CORTEX OF THE CAT. M. Pérez-Bas*, C. Cavada* and F. Reinoso-Suárez. Dept. Morfología, Fac. Medicina, Univ. Autónoma de Madrid, 28029 Madrid, Spain.

The limbic cortex (LC) is classically considered a relay station in the Papez circuit, and as such a link between the anterior thalamic nuclei and the hippocampal formation. Recently, LC has been shown to be a major source of projections to neocortical association areas, notably to the prefrontal cortex (PFC). However, little is known about the precise origin of the neural input to LC other than that arising from the thalamus. In the present study, the neocortical areas that send associational connections to LC were mapped using the retrograde transport of HRP. Single or multiple injections of the enzyme were made in each of the five subdivisions of the cat's LC, i.e., in the infralimbic (Il), prelimbic (Pl), anterior limbic (LA), cingulate (Cg) and retrosplenial (Rs) areas.

Following injections in Il and the ventral portion of Pl, labeled neurons were observed in medial and lateroventral PFC, insular cortex (IC, mainly in the agranular subdivisions), caudal half of the sylvian sulcus (SS), perirhinal cortex (PrhC), in LA, and in the portion of area 6 situated in the medial surface of the hemisphere. Injections placed in dorsal Pl labeled neurons in many of these same regions, including the PFC (with the labeling more dorsally situated than in the preceding cases), IC (mainly in the granular subdivision), SS, PrhC, LA, and medial area 6. However, dorsal Pl injections also labeled neurons in Il, cortex bordering the anterior ectosylvian sulcus (SEsA), Cg, and a few scattered cells in parieto-temporo-occipital association areas. Similar to injections in Il and Pl, injections in LA labeled neurons in PFC (especially dorsally), and in areas 6, Il, Pl and Cg. Further, low numbers of HRP-positive neurons were observed in the splenial visual area (VS), Rs, IC, SEsA, area 7, lateral suprasylvian area (LS), suprasylvian fringe (SsF), posterior ectosylvian area (Ep), posterior suprasylvian area (Ps), area 20 and PrhC. Following injections in Cg, neuronal labeling was observed in PFC, medial area 6, Pl, AL, Rs, VS, IC, SEsA, SsF, LS, areas 7, 19, 20, Ep and Ps, and in PrhC. Some of the areas containing labeled neurons and the densities of labeling varied, however, depending upon the portion of Cg injected. Following injections in Rs, labeled cells were observed in LA, Cg, ventral PFC, areas 7 and 20, and in PrhC.

These findings indicate that the largest and most consistent source of neocortical input to LC arises from the PFC and the subdivisions of LC itself. The premotor cortex, and monomodal and polymodal association cortices provide additional afferents to LC, with the Cg area being the major recipient of the connections from the association cortices. Although the various limbic areas have several common sources of neocortical afferents, the overall pattern of these connections is specific for each area.

357.6 COMPARISON OF HISTOCHEMICAL AND CYTOCHEMICAL COMPARTMENTS IN THE AMYGDALOID COMPLEX: A HUMAN AND ANIMAL STUDY. K.B. Sims*, R.S. Williams. Neuropathology, Shriver Center, Waltham, MA. 02154

The amygdala is a multimodal relay for fibers from the frontal and temporal association cortex, basal forebrain, diencephalon, striatum and brainstem. Abnormalities in the structure and function of the amygdala are known to occur in Alzheimer disease and temporal lobe epilepsy, and may be present in schizophrenia and autism. Neuropathological study of the human amygdala is hampered by the absence of a comprehensive and consensus definition of its nuclear subdivisions, and uncertainty regarding homology with anatomic subdivisions and interconnections experimentally defined in laboratory animals.

Serially adjacent sections of the human amygdala were stained with Nissl or histochemical methods for acetylcholinesterase (ACE), nicotinamide adenine dinucleotide phosphate diaphorase (NADPH-d) and cytochrome oxidase (CO). ACE and NADPH-d stained the neuropil differentially. The borders of these histochemical compartments coincided with those of the principal amygdaloid nuclei in Nissl stains. For example, the basolateral nucleus stained intensely with ACE and poorly with NADPH-d, and the central nucleus stained poorly with both methods. The relatively sharp borders of the ACE and NADPH-d compartments also facilitated confirmation of more subtle nuclear boundaries and the identification of additional nuclear subdivisions in Nissl stains. The CO method, by contrast, stained central and basal nuclei intensely, but differential staining of other nuclear boundaries was not sharp.

The NADPH-d method stained selected neurons intensely in Golgi-like fashion, and the density of stained cells varied in different nuclear subdivisions. For example, few to no NADPH-d positive cells were found in central and basal nuclei while cell density was much greater in the adjacnt lateral, medial and accesory basal nuclei. In the striatum NADPH-d positive cells are labelled with antibodies to somatostatin and neuropeptide Y (Kowall et al, unpublished), but similar data is not yet available for the amygdala.

The histochemical staining patterns in the human amygdala were compared to those of the mouse, ferret and Rhesus monkey. Differential neuropil and cell staining was the same in the principal nuclei of all species.

In summary, ACE and NADPH-d histochemical stains enhance the definition of Nissl cytoarchitectural boundaries in the amygdaloid complex, delineate nuclear subdivisions within the human amygdala and facilitate comparison of homologous subdivisions between mammallian species. They may therefore facilitate the neuropathological examination of the amygdala in human neuropsychiatric diseases. Supported by NIMH 31154.

357.7 CONNECTIONS OF THE AMYGDALA WITH THE HIPPOCAMPUS AND ENTORHINAL CORTEX IN THE MONKEY. R.C. Saunders and D.L. Rosene, Dept of Anatomy, Boston Univ Sch Med, Boston, MA, 02118.

The hippocampal formation (HF) has long been considered important in memory function and more recently, the amygdala (AMYG) has also been implicated. To the extent that both the AMYG and the HF contribute to memory function, then their interconnections either direct or via the adjacent entorhinal cortex (EC) may be of considerable functional importance. While much is known about the important afferents to the HF from the EC, much less is known of the interconnections of the AMYG with the HF and EC.

Using fluorescent retrograde tracers and tritiated amino acids, the interconnections of the AMYG, HF and EC were investigated in the rhesus monkey. In the HF, the subicular region is the major recipient of afferents originating in the lateral basal, accessory basal and medial basal nuclei of the amygdaloid complex. In turn the subiculum of the HF sends a direct projection to the medial basal and accessory basal nuclei of the AMYG. The EC receives projections from the lateral, lateral basal, accessory basal and the medial basal nuclei of the AMYG as well as from the subiculum, presubiculum and CA1 region of the HF. The adjacent prorhinal cortex receives afferents from only the lateral and lateral basal nuclei. The perirhinal cortex receives afferents from only the lateral basal and the accessory basal nuclei. The projection to the prorhinal cortex and the perirhinal cortex from the HF originates from the superficial layers prosubiculum and CA1 region. Within the EC the afferent termination from the HF and AMYG are segregated in distinct laminae. The HF fibers terminate in layers 5 and 6, while afferents from the AMYG terminate in layers 2 and 3. Prorhinal cortex receives afferent fibers from both the AMYG and the HF with overlapping termination in layers 1, 2 and 3 and additional termination in layer 5 from the subiculum. The perirhinal cortex receives afferents from the HF, which terminate in layers 2, 3 and 5 as well as from the amygdala which terminate in layer 1. In addition to the EC projections to the dentate gyrus and CA fields the perirhinal cortex (layers 4 and 5) and the prorhinal cortex (layers 2, 3 and 4) send efferents directly to the subiculum and prosubiculum, i.e., the same region as the amygdaloid projection to the HF.

It is of considerable functional interest that the major areas within the amygdala and the hippocampus which are interconnected, (the lateral basal, medial basal and accessory basal nuclei of the AMYG and the prosubiculum and subiculum of the HF) either directly or via the surrounding entorhinal cortical areas (including the prorhinal and perirhinal cortex), are also important as the sites of origin of efferent projections to subcortical nuclei which have been implicated in memory function (e.g. mammillary bodies, nucleus medialis dorsalis of the thalamus and the nucleus basalis).

357.8 VASOACTIVE INTESTINAL POLYPEPTIDE PROJECTIONS TO CENTRAL NUCLEUS OF AMYGDALA FROM SUPRACHIASMATIC NUCLEUS

C.H. Block and G.E. Hoffman-Small
Department of Anatomy, University of Rochester
Rochester, NY 14642

The central nucleus of the amygdala (CNA), a limbic structure involved in autonomic integration, contains a dense plexus of vasoactive intestinal polypeptide (VIP) immunoreactive fibers, but very few immunoreactive cell bodies (Gray, et. al., Neuroscience 11:339(1984)). In our ongoing analysis of the neuropeptidergic projection fields of CNA with other autonomic centers, we have observed that the course of VIP fibers from CNA was directed medially and rostrally toward hypothalamus. It is known that within the hypothalamus, the suprachiasmatic nucleus (SCN), a critical site for circadian regulation, contains a population of VIP cells in its ventrolateral aspect.

In an effort to determine if VIP fibers in CNA originate from cells within SCN, the retrograde tracer true blue was injected unilaterally into CNA of adult male, Wistar rats. After an appropriate survival time for transport of the tracer, the animals were treated with a 1% colchicine solution, administered intracerebroventricularly, and were sacrificed 24 hours later. Perfused brains were sectioned on a vibrating microtome at 30 μm and the tissue was processed for VIP immunofluorescence.

Injections that were localized to CNA resulted in retrograde labeling of a small population of VIP containing cells within the SCN. These double-labeled cells were distributed primarily in the ventral and lateral aspects of the ipsilateral SCN. A few cells labeled with true blue alone were also observed within dorsomedial SCN.

These data demonstrate the presence of a direct VIP projection from SCN to CNA, although contributions to this CNA plexus from other VIP cell populations are also possible. This neuropeptidergic system may provide a significant link through which circadian information can access limbic-autonomic regulatory centers within CNA.

357.9 Amygdalospinal Projections In The Cat: A Retrograde Transport Study Using Rhodamine Labeled Latex Microspheres. B.B. Sandrew*, D.L. Edwards and W.E. Foote. Departments of Neurosurgery and Psychiatry, Stanley Cobb Neuroscience Laboratory, Massachusetts General Hospital and Harvard Med. Sch., Boston, MA 01124.

There is ample evidence from retrograde transport studies in several animal species that amygdalofugal fibers arising from the central nucleus (Ce), descend the neuraxis to terminate within the mesencephalon and pontomedullary brainstem. However recent anatomical evidence based on HRP methodology has shown that the Ce of the macaque monkey contains neurons which project directly to the spinal cord (Mizuno et al, Neurosci. Lett., 53:327-330, 1985). This finding adds a new dimension to the anatomical and physiological significance of the limbic forebrain which warrants further study toward a more comprehensive understanding of amygdala function. Since a good deal of current knowledge pertaining to the amygdala has been discovered through studies of the cat we considered it especially important to confirm the presence of amygdalospinal projections in that species using a new, highly sensitive fluorescent retrograde tracer. Rhodamine labeled fluorescent latex microspheres (Beads, Katz et al, Nature, 310:498-500, 1984) were then injected below C1 into the spinal cord of 5 cats. After survival periods of 14 to 28 days animals were sacrificed coronal 40um frozen sections were cut. Spinal cord injections were found to be restricted to the needle paths with little diffusion. In all cases the injections involved dorsal and ventral quadrants of the spinal cord including the dorsal and ventral horns within C1 and C2. Bead labeled cells were concentrated within a well circumscribed area corresponding to the Ce of the amygdala. In addition, at levels in which the greatest amount of labeling was noted within the Ce distribution of fluorescent cells extended into the medial nucleus. The greatest number of Ce cells in which Beads could be detected ranged between 44 to 67/section, whereas the medial nucleus was found to have no more than 5 labeled cells within its borders in any section. In a sample of neurons (n=30) taken at various AP levels of the Ce, the dimensions of labelled soma (approximated under 25X fluorescence to be 17um +/- 5.58 s.e.m. by 29.73 um +/- 1.25 s.e.m.) indicate that amygdalospinal efferents labeled with Beads were large cells. These data show that nuclei within the cat amygdala contribute direct projections to the spinal cord. Specifically, high cervical injections resulted in retrograde labeling of a dense, well circumscribed cell group comprising the entire rostrocaudal extent of the Ce with a modest labeling in the medial nucleus. Supported by Grant NS 22549 awarded to WEF.

357.10 ORGANIZATION OF AMYGDALOID PROJECTIONS TO THE DORSOMEDIAL THALAMUS AND PREFRONTAL CORTEX IN THE RAT. A.J. McDonald. Dept. of Anatomy, Univ. of So. Car. Sch. of Med., Columbia, SC 29208.

Previous studies have shown that the amygdala projects to both the dorsomedial thalamic nucleus (DM) and its cortical projection area, the prefrontal cortex (PFC). In this investigation rats (n=28) received injections of different fluorescent retrograde tracers (true blue and diamidino yellow) into DM and either the sulcal (PFCS), polar (PFCP), or medial (PFCM) prefrontal cortex in order to examine the relationship of amygdaloid neurons with cortical and/or thalamic projections. PFC injections labeled neurons in the basolateral (BL), basomedial (BM), ventral endopiriform (Env), and rostral lateral nuclei as well as the periamygdaloid cortex (PAC) and the medial part of the amygdalo-hippocampal area (AHA). In BL, which contained the great majority of neurons projecting to PFC, most labeled cells were concentrated in particular parts of the nucleus and were topographically organized. Neurons with projections to PFCM were concentrated in dorsal and medial parts of both the anterior (BLa) and posterior (BLp) subdivisions of BL. Neurons with projections to PFCP were concentrated in the ventral part of the rostral two-thirds of BL. Neurons with projections to PFCS were concentrated in the rostral half of BLa (except its lateral edge) and the ventrolateral corner of BLp. The overwhelming majority of labeled neurons in BL were large pyramidal or piriform cells that correspond to class I neurons described in Golgi studies. Occasional small neurons with thin dendrites were also observed; these cells may be class II neurons. DM injections labeled numerous cells in the anterior division of the cortical nucleus, medial nucleus, and the adjacent caudomedial part of the central nucleus. Moderate numbers of labeled cells were found in caudal portions of BM and PAC, whereas scattered cells were observed throughout the rest of the amygdala with the exception of the lateral nucleus. In BL and AHA many DM-projecting neurons were observed along nuclear boundaries and in the adjacent white matter. Neurons in BL, BM and AHA usually had large elongated or irregular somata and 2-4 primary dendrites that branched sparingly. Other cells had smaller ovoid somata. The morphology and distribution of DM-projecting cells in the basolateral amygdala indicates that they are primarily large class II neurons. Double labeled neurons, projecting to both DM and PFC, were not observed unless the cingulate cortex dorsal to DM was inadvertently labeled by the injection needle. These findings suggest that different neuronal populations in the amygdala project to the two poles of the DM-PFC system. In BL class I neurons are the predominant cell type involved in PFC projections, whereas class II neurons, hitherto thought to be primarily local circuit neurons, project to DM. (Supported by NIH Grant NS-19733.)

357.11 BASAL FOREBRAIN EFFERENTS TO THE MEDIAL DORSAL THALAMIC NUCLEUS IN THE RHESUS MONKEY. K. K. Hreib*, D. L. Rosene and M. B. Moss. Dept. of Anatomy, Boston Univ. Sch. of Med., Boston, MA 02118.

Subcortical efferent connections of the basal forebrain (BF), [septal area (SA), diagonal band (DB), and nucleus basalis (NB)] were investigated in eight rhesus monkeys. In four animals, injections of tritiated amino acids (TAA) were placed in the BF posterior to the olfactory tubercle and below the anterior commissure. In one of the cases, the injection was centered in the anteromedial part of NB with slight involvement of the horizontal limb of the DB. In another case, the injection involved the anterolateral part of NB with no involvement of the DB. In a third case, the TAA injection was more posterior in NB beneath the anterior commissure. In all three cases extensive anterograde termination was observed in the ventral half of the magnocellular part of the medial dorsal thalamic nucleus (MD) with the heaviest termination posteriorly. In the fourth case, the TAA injection involved the ventral part of the SA as well as the vertical limb of the DB and showed extensive termination that extended more dorsally in magnocellular MD (MDmc) than the other three cases. To determine which of the diverse neuronal types in the BF give rise to these thalamic projections, in three monkeys injections of horseradish peroxidase (HRP) were placed into MD. In two cases, the injection was centered in MDmc with minimal involvement of the parvocellular part (MDpc). In a third case, the injection involved MDpc with minimal involvement of MDmc. In the cases with injections in the MDmc, labeled neurons were observed throughout the full extent of NB, DB and SA with the greatest number of cells in the DB. On the other hand, in the case with the HRP injection in MDpc, only a few scattered cells were labeled in the BF. In order to determine if the BF cells projecting to MD, were like the cortically projecting cells, acetylcholinesterase (AChE) positive, one of the MDmc cases was prepared for the simultaneous visualization of HRP and AChE. We observed that roughly 30% of the neurons in NB and DB that were HRP positive were also AChE positive, but in the SA a smaller proportion were double labeled. This double labeling was observed with a new procedure that utilized the TMB stabilization method (Rye, J Histochem Cytochem, 1984). While AChE is not an absolute marker for cholinergic neurons, studies have shown that in the BF almost 90% of the cells that are AChE positive are also positive for choline acetyltransferase (Eckenstein, J Neurosci, 1983). Hence, it is likely that the basal forebrain projection to MD is cholinergic. In order to determine if the NB projection to MD is a collateral of NB projections to cortex, a monkey was injected with fluorescent retrograde tracers in orbitofrontal cortex and MD. This case showed that approximately 50% of the BF neurons that project to orbitofrontal cortex also project to MDmc.

(Supported by NIH grants NS-19416 and AG-04321)

357.12 DIFFERENTIAL PROJECTIONS FROM CINGULATE AND RETROSPLENIAL SUBDIVISIONS OF THE POSTERIOR CINGULATE GYRUS TO THE MES- AND DIENCEPHALON OF THE RABBIT. J.L. Bassett and T.W. Berger Psychobiology Program, Center for Neuroscience, University of Pittsburgh, Pittsburgh, PA 15260

Efferent projections from the posterior cingulate gyrus to the mes- and diencephalon were studied using autoradiography. Cytoarchitectonic subdivisions of the cingulate gyrus were defined according to Rose and Woolsey (J. Comp. Neurol., 89, 1949). The present study deals with the granular (posterior) cingulate and retrosplenial subdivisions.

A series of small injections of 3H-proline (0.3ul, 75uCi/ul) into either the cingulate or retrosplenial divisions of the gyrus were made along its rostrocaudal extent. Following a 30-40 hr survival period, animals were sacrificed and their brains processed according to Cowan et al. (Brain Res., 37, 1972). Analysis of autoradiographic material revealed several differences in relative projection strengths and patterns of termination.

Terminal labeling was most dense in the anteromedial (AM) and anteroventral (AV) thalamic nuclei. Within AM, labeling was greatest after injections localized in the anterior portions of the posterior gyrus, whereas silver grain densities in AV were greatest after injections in the mid to posterior gyrus. Silver grains in lesser density also were seen in the anterodorsal nucleus and were greatest after injections in posterior cingulate and mid to posterior retrosplenial. Moderate to dense silver grain deposits were seen in the ventrolateral (VL), lateroposterior (LP) and laterodorsal (LD) nuclei. Labeling in VL was greatest after cingulate injections and was topographically organized such that rostrally placed injections resulted in the greatest densities of labeling rostrally, and more caudally located injections with densities greatest caudally. Although labeled terminals were arranged similarly within LP and LD, each cingulate subdivision contributed equally to this projection. A similar pattern of silver grains also was detected in the mediodorsal and mediodventral nuclei but was less dense. Silver grain deposits were also seen in the zona incerta and filiform nucleus. Injections in the retrosplenial subdivision yielded a greater density and longer rostrocaudal extent of silver grains in these regions than did cingulate injections.

Terminal labeling in the mesencephalon included: the pretectal area (PTA), deep layers of the superior colliculus (SP) and the central gray (CG). Although the location of silver grain deposits in the PTA and SP did not vary with differing injection locations, labeling in CG was seen only after retrosplenial injections. Label was also seen in lateral and central tegmental areas after rostral cingulate and retrosplenial injections and in the posterior thalamus after injections in the posterior portions of these subdivisions. Supported by NSF(83BNS-16464).

357.13 ADENOSINE DEAMINASE-CONTAINING PROJECTIONS FROM THE POSTERIOR HYPOTHALAMUS TO TRIGEMINAL MESENCEPHALIC PRIMARY AFFERENT NEURONS IN THE RAT. J.I. Nagy[1] and P.E. Daddona[2]* Dept. of Physiology, Univ. of Manitoba, Winnipeg, Man., Canada, R3E 0W3[1] and Dept. of Internal Medicine, Univ. of Michigan Med. Sch., Ann Arbor, 48109 MI.[2]

The mesencephalic nucleus of the trigeminal nerve (Mes V) harbors large primary afferent neurons which convey proprioceptive and mechanoreceptive input from jaw closing muscles and periodontal ligaments, respectively. It has been known for a long time that, unlike their counterparts in dorsal root ganglia, the somas of these neurons receive chemical synaptic contacts. However, the source of these synaptic terminals has not been determined. In our immunohistochemical analysis of the distribution of adenosine deaminase (ADA) in rat brain we found that, although mesencephalic neurons were themselves devoid of immunostaining for this enzyme, their surface was covered with a rich plexus of ADA-immunoreactive fiber-like structures. Occasionally, ADA-immunoreactive axons were seen travelling towards and making contact with mesencephalic neurons. The source of the ADA-containing elements surrounding neurons in Mes V was investigated using indirect immunofluorescence and peroxidase-antiperoxidase staining techniques in combination with retrograde fluorescence tracing with fast blue (FB) or lesion methods.

ADA-immunofluorescence staining was observed around mesencephalic neurons which were simultaneously retrogradely labelled with FB after injection of this dye into the masseter muscles of mastication. Injection of FB into Mes V resulted in the FB labelling of ADA-immunoreactive neurons in the posterior basal hypothalamus. Ablation of the posterior hypothalamus by radiofrequency lesions abolished ADA-immunostaining around mesencephalic neurons.

These results indicate that ADA-containing neurons in the posterior hypothalamus innervate mesencephalic primary sensory neurons which project, in part, to muscles of mastication. It is suggested that the hypothalamus, via a direct action on these sensory neurons, may exert autonomic control over jaw movements. Moreover, given their large size and accessibility, it appears that mesencephalic neurons may provide an ideal model system for electrophysiological investigations of the neurotransmitter(s) utilized by ADA-containing hypothalamic projections which are now known to include diverse areas of the brain (Nagy et al., Science 224, 166-168, 1984).

357.14 THE ANTERIOR THALAMIC NUCLEI IN ANTHROPOID PRIMATES: A GOLGI STUDY. E. Armstrong. Anatomy Department, Louisana State Univ. Med.Ctr., New Orleans, La.70112

Previous studies have shown that the human anterior principal complex (AP: anteroventral and anteromedial nuclei) contains many more neurons than expected for a nonhuman anthropoid whose brain is scaled to human dimensions. To determine whether the increase in numbers of neurons also involved changes in the size or configuration of individual neurons, the dentritic trees of AP neurons were analyzed following a Golgi impregnation of human and nonhuman anthropoid brains.

All material came from adult specimens. The perfused brains (Saimiri, number of specimens (N) =3, Aotus N=3 and Macaca N=3) were stained following the Golgi-Braittenberg method. The adult human (N=3) and chimpanzee (N=1) brains which had been routinely fixed in 10% neutral buffered formalin were impregnated with a new Golgi variant (Armstrong and Parker, in preparation). Aotus brains stained with both methods were compared and found to have no significant differences. Both methods were used and a Sholl analysis was used to quantitatively compare the dendritic sizes among the specimens.

Large multipolar neurons were observed in all the anthropoids and are the focus of this report. The dendritic trees of these anthropoids did not differ in their overall shape or appearance. No statistically significant difference in the number of primary branches was determined. The human AP neurons, however, have many more branches than those in the monkey brains and the human-monkey difference is largest at 60-80 um from the perikaryal center.

This work is supported in part by H.F. Guggenheim Foundation and N.S.F. 8204480.

357.15 THE LATERAL HYPOTHALAMIC PROJECTION TO DORSAL RAPHE IS EXCITATORY. M.R. Park, Department of Anatomy, University of Tennessee Center for the Health Sciences, Memphis, TN 38163.

The dorsal raphe nucleus receives forebrain afferents from just two sources, the lateral habenula and the hypothalamus, principally the lateral hypothalamic area. Intracellular recording experiments were undertaken in the rat to examine the input from lateral hypothalamic area, which until now has not been studied using physiological methods. Male Long-Evans rats were anesthetized with urethane (induction with a single dose of 1.0 g/kg, i.p.) and ketamine (40 g/kg., i.m., given hourly). Glass recording pipettes, filled with 4% horseradish peroxidase, for intracellular labeling, in 0.5 M Tris buffer, pH 7.6, and 0.5 M potassium methyl sulphate, were positioned in the dorsal raphe nucleus. Bipolar stimulus electrodes were placed in the lateral hypothalamic area using stereotaxic procedures.

The following observations apply to the slow firing dorsal raphe neurons with broad action potentials that are presumed to be serotonergic. Electrical stimulation of the lateral hypothalamic area, using brief (50-100 us) square wave constant current pulses 50-500uA in amplitude, produces an initial depolarizing response followed by a hyperpolarization. The depolarization is graded, can be reversed by the injection of depolarizing current, and increases in amplitude with hyperpolarization. It therefore has all the properties of an excitatory postsynaptic potential (EPSP) caused by increase in membrane ionic conductance. Similarly, the hyperpolarization is a conductance-increase inhibitory postsynaptic potential (IPSP). It is graded, increases with depolarizing current injection, and can be reversed by hyperpolarization. The IPSP most likely results from activation of the recurrent inhibitory circuit of dorsal raphe. When suprathreshold, the EPSP triggers a single action potential and after-hyperpolarization. The latter adds to the IPSP to produce a hyperpolarization that is deeper than that of the IPSP alone. The latency of the EPSP is 6-10ms. The straight line distance from stimulus to recording site, which is a good approximation of the actual axonal pathway, is approximately 4 mm, so that the fibers from lateral hypothalamus to dorsal raphe have conduction velocities in the order of 2 m/s. The EPSP latency does not change with change in stimulus strength, from which we can conclude that the response is monosynaptic.

The innervation from lateral hypothalamic area is dense and the response it evokes is correspondingly large when activated synchronously. However, even this unnatural activation of the pathway does not trigger more than a single action potential. Our data show that this is by far the major forebrain input to dorsal raphe and is the only input known to be excitatory.

357.16 HYPOTHALAMIC PROJECTION TO THE DORSAL RAPHE NUCLEUS IN THE RAT: AN ANTEROGRADE STUDY USING THE PHAL METHOD, R.L. Cowan* and M.R. Park (SPON: T. Bertorini). Department of Anatomy, University of Tennessee Center for the Health Sciences, Memphis, TN 38163.

Experiments utilizing degeneration, anterograde autoradiographic, and retrograde labeling techniques have shown a projection to the dorsal raphe nucleus from hypothalamus. We have used a new anterograde labeling technique to study the course, density, and topography of this projection.

Iontophoretic injections of phaseolus vulgaris leucoagglutinin (PHAL) were made in the lateral hypothalamic area of male Long-Evans rats. The original protocol of Gerfen and Sawchenko (Brain Res., 290:219, 1984) for injection and immunohistochemical detection of the lectin was closely followed. Survival times ranged from 7 to 14 days.

Three forms of labeling are produced. Confined to the vicinity of the injection site is a cloud of extracellular label typical of lectins. Within this cloud scattered neuronal somata and dendrites are darkly labeled. The intracellular incorporation of PHAL by these cells most likely accounts for all of the anterograde axonal labeling seen, the third form of labeling.

Terminal labeling following injections centered in lateral hypothalamic area, with some spread to anterior hypothalamus, is primarily ipsilateral and is as follows. Fibers coursing via medial forebrain bundle produce terminals in lateral and medial preoptic area, bed nucleus of the stria terminalis, ventral pallidum, substantia innominata, anterior amygdala, accumbens, septal nuclei, thalamic reticular nucleus, and zona incerta. The lateral habenula is reached via the stria terminalis and fibers passing through the fields of Forel reach periventricular grey and the dorsal raphe. Additional terminals were observed in the nucleus of the diagonal band, supraoptic, parabrachial and dorsal parabrachial nuclei, superior colliculus, thalamus, and reticular formation.

The dorsal raphe nucleus receives fibers via two different hypothalamic efferent pathways. A dorsal fiber group exits the hypothalamus and curves caudally and dorsally, entering the dorsal raphe nucleus, primarily at its rostral tip. A second, slightly smaller fiber group travels ventrally and caudally, ascends through the medial longitudinal fasciculus, pierces it perpendicularly, and enters the ventral aspect of dorsal raphe. Terminal axons having numerous varicosities are present throughout the rostral-caudal extent of dorsal raphe. A particularly dense innervation is present immediately ventral to the ependymal cell layer of the fourth ventricle. Many fibers course parallel to the rostral-caudal axis of the brain in this region.

357.17 LACK OF INHIBITORY EFFECT OF CYSTEAMINE (B-MERCAPTOETHYLAMINE,CSH) ON PITUITARY AND HYPOTHALAMIC VASOPRESSIN CONTENT WHEN ADMINISTERED CHRONICALLY. J. Haldar, I. A. Aral and G. Abram. Dept. of Biol. Sc, St. John's Univ., New York, NY 11439 and Dept. of Neurology, Columbia Univ., New york, NY 10032

Injection of Cysteamine hydrochloride (CSH) to rats decreases plasma and tissue somatostatin and prolactin. Recent work, based on $^{35}S$ Cysteine incorporation studies has suggested that CSH inhibits the biosynthesis and induces the degradation of oxytocin (OT) but not of vasopressin (VP). Work from our laboratory has demonstrated that. following an acute CSH injection during rehydration which was preceeded by dehydration, both OT, and VP levels of the hypothalamus decrease. To determine, whether chronic CSH administration would reduce the VP in the pituitary and hypothalamus content more effectively the following experiments were performed. All experiments were done on male Long Evans rats. Animals were divided into 5 groups. Control (I), 72 hrs. dehydration (II), 72 hrs. dehydration followed by 72 hrs. rehydration (III), 72 hrs. dehydration followed by 72 hrs. rehydration together with 90mg/kg/day sc CSH(IV), and the same dose of CSH in control rats (V). CSH was administered via osmotic minipumps. All rats were decapitated, the pituitary and hypothalami were isolated, homogenized in 0.1 N HCl and centrifuged. The supernatant fluid was used for the determination of VP by radioimmunoassay. Our results show (1) 72 hrs. dehydration caused 70% reduction of pituitary but not of hypothalami VP content. (2) Rehydration increased both pituitary and hypothalamic VP content, pituitaryto control level and hypothalamus to a level higher than control (3) chronic CSH administration together with rehydration did not decrease either pituitary or hypothalamic VP content. We, therefore, conclude that although acute CSH administration effectively reduces VP content of the hypothalamus, chronic CSH fails to do so. This lack of effect of CSH in the chronic experiment is perhaps due to a quicker degradation of CSH in the animals. ( Supported by NIH, HD-13147 and an Instrumental grant from NSF).

357.18 ESTROGEN TARGET NEURONS IN RAT HIPPOCAMPAL FORMATION. R. Loy and B. S. McEwen. Department of Anatomy, University of Rochester Medical Center, Rochester, NY 14642 and Department of Neurobiology, Rockefeller University, New York, NY 10021.

Many studies are finding sex differences in transmitter and receptor levels, in dendritic plasticity during development, in capacity for post-lesion axonal reorganization, and in other aspects of hippocampal function. To localize specific cell populations which may be responsible for this sexual dimorphism, we examined the dentate gyrus, Ammon's horn, subiculum, and entorhinal cortex autoradiographically in female rats following treatment with (3H)-estradiol.

Estrogen sensitive neurons are located in the deep layers of the entorhinal cortex, and in pyramidal cells of the ventral and dorsal subiculum, ventral CA1 and CA3. Within the dorsal CA1 estrogen target cells are most likely interneurons, in stratum oriens immediately subjacent to stratum pyramidale, and in stratum radiatum. Very few cells in dorsal CA3 accumulate (3H)-estradiol.

The major cell type labeled with (3H)-estradiol in the dentate gyrus is not the granule cell but hilar interneurons in the infragranular zone. As in Ammon's horn, many more cells in ventral regions than in dorsal regions accumulate estrogen.

While estrogen-sensitive neurons are not numerous in the hippocampal formation, these cells are concentrated within specific subpopulations of neurons, including pyramidal neurons in the subiculum and entorhinal cortex, and interneurons in CA1 and the dentate gyrus. We and others have found that the levels of norepinephrine and choline acetyltransferase, as well as adrenergic and cholinergic receptors, are sexually dimorphic or sensitive to estrogen levels in the hippocampus. Interneurons may be targets for both the cholinergic and adrenergic afferent systems, suggesting that transmitter activity may be regulated locally by estrogen-sensitive target neurons.

357.19 SEX DIFFERENCES IN $^{125}$I-CCK-OCTAPEPTIDE BINDING SITES IN THE VENTROMEDIAL NUCLEUS. T.R. Akesson, P.W. Mantyh, C.R. Mantyh*, D. Matt*, and P.E. Micevych. Dept. of Anatomy and Medicine and the Brain Research Institute, UCLA School of Medicine, Los Angeles, CA 90024.

Although there is a good correlation between the levels of gonadal steroids and sex differences in reproductive behavior and food intake, the neurochemical mechanisms by which gonadal steroids may regulate these behaviors remain unknown. An important central nervous system site for steroid modulation of food intake and reproduction is the ventromedial nucleus of the hypothalamus (VMN), which contains neurons that accumulate both androgens and estrogens. Recently, it has been suggested that some of the activities of the VMN are dependent on the neuroactive peptide cholecystokinin octapeptide (CCK). High levels of CCK in the VMN have been measured by radioimmunoassay, and immunohistochemical analysis has revealed a dense plexus of CCK fibers and terminals which appose and make synaptic contact with VMN neurons. A majority of the CCK fiber terminals in the VMN originate in the ipsilateral, dorsal parabrachial nucleus (PBN), a relay station in the ascending pathway of brainstem visceral and taste stimuli projecting to the VMN and rostral forebrain. The present study examines distribution of CCK binding in relation to differences in endocrine state.

Adult male and female rats as well as females on each day of the estrous cycle were sacrificed, the brains removed, and sectioned in the coronal plane. Specific high affinity $^{125}$I-CCK binding sites were then localized and quantified using the serial slide-mounted sections of VMN and PBN in conjunction with autoradiographic techniques and LKB Ultrafilm. The VMN of females contained significantly greater levels of CCK binding sites than did males of similar age whereas the levels of CCK binding sites in the cerebral cortex and striatum were similar. These data are consistent with the hypothesis that activity of CCK in the VMN is influenced by gonadal steroids. This influence could be affected by steroid hormone modulation of CCK receptors postsynaptic to cholecystokinergic imput from the PBN. These variations may provide a neurochemical basis for a number of sexually dimorphic behaviors which have been linked to the VMN.

357.20 EFFECT OF GONADAL STEROID HORMONES ON LEVELS OF CHOLECYSTOKININ IN THE HYPOTHALAMUS. P. Micevych, V.L.W. Go* and D. Matt*, Dept. of Anatomy and the Laboratory of Neuroendocrinology, Brain Research Institute, UCLA, Los Angeles, CA 90024, and the Dept. of Gastroenterology, Mayo Clinic, Rochester, MN 55905.

Sex differences in food intake (FI) and body weight are temporally correlated with levels of gonadal steroids. Male rats are hyperphagic compared to females. Body weight and FI of females increase during diestrus, when estrogen is elevated, and decrease during proestrus, when estrogen is low compared to progesterone. Although the regulation of feeding is a complex behavior involving oropharyngeal and gastric mechanisms, various CNS loci have been implicated in this regulation, including the ventromedial nucleus (VMN), paraventricular nucleus (PVN), and the lateral hypothalamic area. The VMN and PVN appear to be neural targets for the effects of gonadal steroids on FI. Recently, the neuroactive peptide cholecystokinin (CCK) has been suggested as a central satiety factor at the level of the VMN and PVN. The purpose of the present study was to determine whether variations in gonadal steroids are correlated with tissue content of CCK in specific hypothalamic regions. Because substance P and bombesin have also been linked to the control of FI, these neuropeptides were also analyzed. Normal male (220-250g) and female (200-220g) rats were decapitated, the brains removed and 500 µm coronal sections obtained through the hypothalamus. The medial preoptic nucleus, bed nucleus of the stria terminalis, PVN, VMN, lateral hypothalamic area and median eminence were microdissected and radioimmunoassayed for CCK, substance P and bombesin. Tissue levels of CCK in the medial preoptic nucleus (39.8±4.1 pmole CCK equivalents/gm) were elevated in males compared to females (30.1±5.2 pmole CCK equivalents/gm), while the VMN contained more CCK than the male (29.3±7.6 and 20.8±1.5, respectively). Moreover, CCK levels in the female varied during the estrous cycle in the VMN, bed nucleus of the stria terminalis and median eminence. CCK levels in the VMN and median eminence were highest on diestrus day one (65.8±14.6 and 35.3±2.1 pmole CCK equivalents/gm, respectively), while the CCK content in the stria terminalis, an area containing CCK cell bodies, peaked 24 hrs earlier during estrus (50.6±15.3 pmole CCK equivalents/gm). The concentration of bombesin did not vary during the estrous cycle and substance P levels changed only in the VMN where levels co-varied with CCK, highest on diestrus day one (46.0±5.6) and lowest on estrus (16.9±4.7 pmole CCK equivalents/gm). These results indicate that gonadal steroids may regulate the levels of CCK and substance P but not bombesin in specific areas of the hypothalamus. Thus steroids, especially estrogen, may facilitate the release of the satiety factor CCK in the hypothalamus which may help to explain the hypophagia observed in rats during periods of elevated estrogen.

357.21 BIDIRECTIONAL PATHWAYS BETWEEN THE MEDIAL PREOPTIC NUCLEUS AND OTHER SEXUALLY DIMORPHIC NUCLEI. R.B. Simerly and L.W. Swanson. The Salk Institute, La Jolla, CA 92037.

The medial preoptic nucleus is a sexually dimorphic complex composed of 3 distinct subdivisions (Simerly et al., '84). Although the full functional significance of this nucleus remains obscure there is general agreement that it plays a critical role in the neural control of male reproductive behavior, and perhaps participates in other sexually differentiated functions as well. While examining the neural circuitry associated with the MPN we have found that it shares bidirectional connections with several nuclei that are known to posses structural sexual dimorphisms.

Injections of the retrograde tracers true blue, SITS, or WGA into the MPN resulted in retrogradely labeled cells in many brain regions. Those containing the highest densities of labeled cells included the encapsulated part of the bed nucleus of the stria terminalis (BSTe), the medial amygdaloid nucleus (MeA), the ventrolateral septum (LSv), the anteroventral periventricular nucleus (AVPv), the ventral part of the ventromedial nucleus (VMHv), and the arcuate nucleus (ARH). Projections from each of these nuclei to the MPN were confirmed autoradiographically, or by using PHA-L as an anterogradely transported axonal tracer (Gerfen and Sawchenko, '84). Further, the projections from these regions are distributed topographically within the MPN in accordance with the cytoarchitectonically defined subdivisions.

In each region the distribution of retrogradely labeled cells showed a remarkable correspondence to the distribution of steroid concentrating cells (Pfaff and Keiner, '73; Stumpf, '79). In addition, each of these nuclei are known to posses structural sexual dimorphisms. The MPN, the MeA, BSTe and AVPv are sexually dimorphic with respect to volume (Gorski, '84 for review), and steroid sensitive sexual dimorphisms exist in the pattern of specific inputs to the LSv, ARH, MeA and AVPv; while in the VMH, sex differences in nucleolar and nuclear size of individual neurons have been found. (DeVries, '83; Arai, '81; Simerly et al., '85).

In a separate series of experiments PHA-L was iontophoretically injected into the MPN. Labeled axons (Gerfen and Sawchenko, '84) were found to project from the MPN and distribute as dense plexuses with what appear to be terminal boutons in the LSv, BSTe, MeA, AVPv, VMHv and ARH. Although the MPN projects to a great many areas, the density of projections to the above sexually dimorphic regions was markedly greater than that to presumably non-sexually dimorphic regions that do not contain a high density of steroid concentrating neurons. However, structural sexual differences may exist in other nuclei such as the ventral premammillary nucleus, which also has strong bidirectional connections with the MPN, and contains a high density of steroid concentrating cells.

Taken together, these results indicate that the MPN may be a key link in a sexually differentiated neural system that is capable of responding to fluctuating levels of endogenous steroids, and underlies reproductive function, as well as other physiological mechanisms and behaviors.

357.22 AFFERENT CONNECTIONS OF THE SEXUALLY DIMORPHIC AREA IN THE PREOPTIC REGION OF THE GERBIL BRAIN. G.J. DeVries*, C.L. Gonzales* and P. Yahr. Department of Psychobiology, University of California, Irvine, CA 92717

Various mammals, including rodents, carnivores and primates, show clear sex differences in the neural structure of the preoptic area and/or hypothalamus. Often these sex differences develop under the influence of gonadal steroids. In gerbils, the sexually dimorphic area (SDA) is affected by gonadal hormones both developmentally and in adulthood. The gerbil SDA lies on either side of the third ventricle, above the suprachiasmatic nuclei and below the anterior commissure, between the medial preoptic and anterior hypothalamic areas. In males, it is hook-shaped and contains a small, dense subgroup, the SDA pars compacta (SDApc). In females, it is ovoid and lacks an SDApc. An analysis of the hormonal inputs to the SDA showed that SDA cells accumulate both androgens and estrogens and that the pattern of hormone uptake is sexually dimorphic, following the morphology of the SDA. Now we are attempting to identify neuronal inputs to the SDA.

We searched for the SDA afferents by iontophoretically applying horseradish peroxidase, conjugated to wheatgerm agglutinin, to the male SDA and its surround. One to two days later, the males were perfused, and transverse sections of the brains were reacted for peroxidase activity using tetramethylbenzidine as the chromogen. Labelled cells were conspicuous in the medial region of the bed nucleus of the stria terminalis, in the medial amygdaloid nucleus, and in the arcuate/premammillary region of the hypothalamus. Retrogradely labelled cells were also found in the ventral part of the lateral septum, in the lateral hypothalamus, and in the ventrorostral parts of the midbrain central grey. We are now attempting to determine if these areas project differentially to the various subdivisions of the SDA, e.g., to the medial versus the lateral SDA or to the SDApc. The data already available suggest that the sites projecting to the SDA are, like the SDA itself, sites that are densely labelled by gonadal steroids.

Supported by NIMH grants R01 MH-26481 and K02 MH-00478 to P.Y.

357.23 SEROTONIN SYNAPSES IN THE MEDIAL PREOPTIC NUCLEUS (MPN) OF THE RAT: AN ULTRASTRUCTURAL STUDY. J. Larriva-Sahd*, R.A. Gorski, and P.E. Micevych (SPON: C.H. Sawyer). Dept. of Anatomy and the Laboratory of Neuroendocrinology, Brain Research Institute UCLA School of Medicine, Los Angeles, CA 90024.

There is a good correlation between the cytoarchitectonic division of the MPN and the distribution of serotonin immunoreactive fibers at the light microscopic level (Simerly et al. J. Comp. Neurol. 225:151, 1984). The lateral part of the MPN is filled with a dense plexus of serotonin immunoreactive fibers while the medial part has a low density of fibers which surround the central part of the MPN (MPNc) which is devoid of serotonin immunoreactivity. The MPNc corresponds to the sexually dimorphic nucleus of the preoptic area (SDN, Gorski et al. J. Comp. Neurol. 193:529, 1980). The sexual dimorphic distribution of serotonin immunoreactivity in the MPN may be responsible for various functions of the medial preoptic area including control of reproduction and gonadotropin release. The purpose of the present study was to examine the serotonin immunoreactivity in the MPN at the ultrastructural level. Adult male and female Sprague-Dawley rats were perfused with 4% paraformaldehyde, 0.2% glutaraldehyde in Sorensen's phosphate buffer under deep pentobarbital anesthesia. Fifty micron coronal sections obtained with a vibrating microtome were incubated with antiserum directed against serotonin (R196B, R. Elde Univ. MN), and visualized with the biotin-avidin technique using diaminobenzidine as the chromogen. The MPN was microdissected, osmicated and processed for electron microscope. Fine serotonin immunoreactive fibers (0.1-0.3 u) and boutons were localized in the MPNc as well as the medial and lateral MPN. The ratio of small (0.2-0.4 u) to large (>0.5 u) serotonin immunoreactive boutons was 10:1. The reaction product filled the dense core vesicles and was associated with the membranes of small electron lucid vesicles of the labelled terminals. The serotonin positive terminals resembled the Type I boutons of the MPNc which were classified on the basis of vesicle morphology (Larriva-Sahd and Gorski, Anat. Rec. 208:110A, 1984). These boutons are the most common type in the MPNc. The majority of the serotonin positive boutons formed symmetrical or asymmetrical junctions with varying sizes of unlabelled dentrites. These results illustrate that serotonin immunoreactive fibers and terminals are present in all three parts of the MPN although the lowest density was in the MPNc. Recently we have demonstrated that some Type I boutons contain cholecystokinin immunoreactivity, however in distinction to serotonin , cholecystokinin boutons were most dense in the MPNc. The inverse topography of the distribution of serotonin to cholecystokinin in this area may indicate a neurochemical substrate to help explain the functions of the MPN.

## LIMBIC SYSTEM AND HYPOTHALAMUS II

358.1 EPILEPTIFORM BURST RESPONSES IN VENTRAL VS DORSAL HIPPOCAMPAL SLICES. M.E. Gilbert, R.J. Racine and G.K. Smith , Department of Psychology, McMaster University, Hamilton, Ontario, Canada, L8S 4K1

Field potentials from area CA1 evoked by stimulation of the Schaffer collaterals were compared in dorsal and ventral hippocampal slices of rat brain. Eighteen male Long Evans rats were anesthetized with ether, decapitated, the brain removed and the hippocampus dissected out. Five to six 450 µm slices were cut from one pole of the hippocampus perpendicular to the longitudinal axis. The stage of the tissue chopper was then rotated 180°, and 5-6 slices taken from the other end. Slices were transferred to the recording chamber where they were perfused with warmed (34.5°), oxygenated (95% $O_2$- 5% $CO_2$) artificial cerebral spinal fluid. Single pulses were delivered to the stratum radiatum through a bipolar tungsten electrode and field potentials recorded in CA1 through a glass micropipette filled with 4M NaCl under normal (3mM KCl) and increased (6mM & 9mM KCl) K+ concentrations.

Field potentials were categorized into 5 response types on the basis of their morphology, ranging from simple (single spike component) to complex (multiple spike components). A higher percentage of ventral slices (41.2%) relative to dorsal slices (2.4%) responded with a complex morphology ($X^2$=18.51, p<.001) under normal K+ conditions. Similarly, in high K+ concentrations, 90.8% of ventral and 37.4% of dorsal slices displayed multiple spike responses ($X^2$=24.47, p<.001). Thus, there is a significantly greater tendency for ventral slices to generate burst responses.

The mean amplitude of the baseline evoked response was slightly larger in ventral ($\bar{X}$=4.9 mV) than in dorsal slices ($\bar{X}$=3.5 mV), whereas the mean intensity at which maximal responses were produced was similar in the two preparations. Spike threshold was also lower for ventral ($\bar{X}$=185 µa) than for dorsal ($\bar{X}$=283 µA) slices.

Previous results have indicated a greater propensity for the development of chronic focal epileptiform discharge in ventral as opposed to dorsal hippocampal tissue Elul, R., EEG & clin. Electrophysiol. 16: 489, 1964; Racine, R. et al, Can. J. Neurol. Sci., 4: 273, 1977). This could be due to a difference in neural connections between dorsal and ventral hippocampus and other brain sites, or it may be due to differences in the internal circuitry of the hippocampus itself. The present results provide some support for the latter.

358.2 SUSTAINED HYPEREXCITABILITY RECORDED FROM THE CA3/2 AREAS OF ORGANOTYPIC HIPPOCAMPAL EXPLANTS. J. Fowler & S.M. Crain, Dept. of Neuroscience, Albert Einstein College of Medicine, Bronx, New York.

Synchronous normal & epileptiform extracellular field potentials can be recorded from diverse areas of the CNS & are particularly prominent in the hippocampal formation (Vanderwolf '69; Dichter '69). In the rodent hippocampus, extracellular sustained potential shifts occur concomitantly with hippocampal theta activity (Gerbrandt & Fowler '80) as well as during seizure discharges (Gloor et al. '61). In acute slices from adult hippocampus, epileptiform activity resembling interictal discharges in situ can be recorded in the presence of inhibitory antagonists such as penicillin whereas more complex discharges that appear transitional between interictal & ictal states are recorded in the presence of picrotoxin (Miles et al '84). Previous studies from this laboratory demonstrated that complex, long-lasting oscillatory extracellular epileptiform discharges can be evoked in organotypic explants of neocortex (Crain & Bornstein '74), spinal cord (Crain & Peterson '63) & hippocampus (Crain & Bornstein '74; Zipser et al '73; Fowler & Crain '82, '84; Fowler et al '85; see also Gahwiler '84). In the studies reported here, organotypic mouse hippocampal explants were used for the study of sustained hyperexcitability in which complex evoked slow-wave field potentials were elicited or recorded spontaneously in the CA3/2 areas after 10 days-2 months in culture. Transverse slices (.4-.9 mm thick) of mouse hippocampus (1-2 days postnatal) were explanted onto collagen-coated coverslips & incubated at 35°C in Maximow depression slide chambers. Stimuli were single pulses (0.5 msec; 5-20 uamps) applied at 8-15 min intervals. The number of stimuli needed to elicit sustained hyperexcitability was variable & could be as few as 2, or as many as 25, but typically required 4-10. After repetitive electric stimulation of the dentate area, slow- wave discharges recorded from CA3/2 became more complex and/or self-sustaining & continued to occur spontaneously for the duration of the experiment (up to 10 hrs). In the absence of inhibitory antagonists, evoked & spontaneous oscillatory epileptiform discharges were recorded over a wide range of extracellular $K^+$ concentrations (3-9 mM). These discharge patterns were generally more complex than the interictal-like discharges recorded in the acute adult hippocampal slice in the presence of penicillin but similar to those recorded in the presence of 100 uM picrotoxin (Miles et al '84; Traub et al '84), although the interval between afterdischarges as well as the duration of the discharge sequence was often greater than reported in these studies. Continuous epileptiform discharges similar to those observed during ictal events were not elicited with this stimulation paradigm, although preliminary tests indicate that perfusion with 4-aminopyridine can more closely approximate ictal events. Supported by NIMH grant #15788. Tissue culture facilities were kindly provided by Dr. Murray B. Bornstein.

358.3 MODELS OF PROPAGATION OF SYNCHRONIZED EPILEPTIFORM EVENTS IN THE HIPPOCAMPAL SLICE. Roger D. Traub, W. Douglas Knowles, R. Miles and R.K.S. Wong. IBM T.J. Watson Research Center, Yorktown Heights, NY 10598 and Dept. of Physiology and Biophysics, University of Texas Medical Branch, Galveston, TX 77550.

We have shown (Knowles, Strowbridge and Traub, this meeting) that spontaneous epileptiform activity, as recorded by initial deflection of extracellular field potentials, propagates across the CA2-CA3 region of the convulsant-treated hippocampal slice at velocities of about 0.1 m/s. In the present study, we used computer simulations of 10x50 networks of model neurons to examine possible mechanisms underlying this propagation. We considered two different anatomical cases: (1) synaptic connections are sparse, but those connections which do exist are powerful enough to allow bursting to propagate from presynaptic cell to postsynaptic cell; (2) every cell has synaptic connections to many other cells, but synaptic connection strengths are not all identical but rather are distributed (independent of intercellular distance) so that only a minority of connections are powerful enough to allow burst propagation. We did not consider the case where each cell has a powerful connection to many other cells, since dual intracellular recordings only rarely demonstrate a functional excitatory connection between neurons. In case (1) above, random networks do not exhibit propagation of epileptiform field potentials, even when axonal conduction velocity is as slow as 0.05 m/s. For propagation to occur in this case, connections must occur preferentially to nearby cells. A time-consuming local integration process, which is slow relative to conduction time, is necessary before field potentials are generated. However, in case (2), propagation of the epileptiform activity can occur with sufficiently slow axon conduction velocity (0.2 m/s). Activity initiated in a few cells has subliminal as well as suprathreshold effects on follower cells. The subliminal fringe initially consists of nearby cells and grows with time, depending on conduction velocity. Strong connections can cause cells within the subliminal fringe to fire, generating additional subthreshold excitation. In this way, an orderly spatial recruitment of neurons arises within the network, despite a random connectivity.

358.4 INITIATION AND SPREAD OF EPILEPTIFORM BURSTING IN THE HIPPOCAMPAL SLICE. W.D. Knowles, B.W. Strowbridge* and R.D. Traub. IBM Thomas J. Watson Research Center, Yorktown Heights, NY 10598.

Convulsant treated hippocampal slices produce spontaneous, synchronized epileptiform bursts of neuronal activity which have been suggested to originate in the region of CA2 (Wong & Traub, J. Neurophysiol. 49:442-458, 1983). It is unknown whether there is a small pacemaker focus from which bursts originate or whether bursts start as a more diffuse buildup of activity over a larger population of neurons. Further, it is unknown whether subsequent spontaneous bursts originate from the same site, or from different, fluctuating sites. We addressed these questions in this study.

We measured field potentials generated by picrotoxin and penicillin induced epileptiform activity in the hippocampal slice. We used an array of 16 electrodes made from fine wires inserted through electron microscope grids in a curved pattern to match the curvature of CA2/3 stratum pyramidale.

Spontaneous epileptiform bursts from any given slice were very stereotyped; there was little variation from burst to burst in the pattern of potentials recorded. Variations from slice to slice were much larger. Penicillin and picrotoxin produced similar results. Spontaneous bursts always appeared first at electrodes near CA2, then spread smoothly and uniformly away from the site of origin. The velocity of propagation was 0.12 ± 0.05 m/sec (mean ± S.D.; n=13 slices). Occasionally, we could observe small increases in baseline noise preceding the onset of spontaneous epileptiform bursts in electrodes at which the burst first appeared. Picrotoxin induced afterdischarges originated at the same electrode site and propagated with similar velocities as the primary burst.

The pattern of origin and spread of bursts evoked by suprathreshold stimulation of mossy fibers or Schaffer collaterals was substantially different than spontaneous bursts. Mossy fiber and Schaffer collateral evoked bursts originated in CA3c and CA3a respectively, and spread two to three times faster than spontaneous bursts. The velocity of spread of stimulus evoked bursts was similar to conduction velocities of mossy fibers and Schaffer collaterals measured in normal medium using the electrode array.

These results demonstrate that spontaneous synchronized epileptiform bursts originate from a constant, well-localized focus which is near, if not identical with, CA2. The bursts spread smoothly across CA3 in a constant pattern with a velocity of about 0.1 meter/sec. This is slower than the conduction velocity of the major axons in this area. It appears that there is some low level of activity at the focus of origin immediately preceding the onset of the burst. These findings place stringent constraints on the possible patterns of local synaptic connectivities and mechanisms in this area (see accompanying paper by Traub et al.).

358.5 INHIBITION INDUCED BY ELECTRICAL STIMULATION IN SYNCHRONOUSLY FIRING HIPPOCAMPAL NEURONS IN MAN. M. Isokawa-Akesson, T.L.Babb and C.L.Wilson. Brain Research Institute and Dept. of Neurology, School of Med., UCLA, CA 90024.

A synchronized firing of neurons raises the question of how the excitability and the timing of these neurons are temporarily yoked and controlled by a mechanism different from that of independently-firing neurons. Previous findings showed that limbic neurons tend to fire synchronously, with longer inter-spike-intervals, in temporal lobe epilepsy patients (Isokawa-Akesson, et al. Neurosci. Abs. 1984.p188). The present study was designed to test durations of neuronal inhibition induced by nearby electrical stimulation. Anterior hippocampal(AHP) regions were electrically stimulated with single biphasic pulses every 10 sec (pulse duration: 100 μsec for each direction, 40 pulses, 1.5-3.0 mA). AHP neurons within 5-10 mm of the stimulation were monitored extracellularly for excitatory and inhibitory patterns. All neurons were initially tested, before the stimulation, for synchronized firings with other AHP neurons by cross-correlation analysis, with an analysis time of 50 msec before and after the expected joint firing.

Local AHP stimulation caused initial excitation in some of AHP neurons with a latency of 10.7 msec + 3.43 SEM followed by inhibition of firing. The duration of this inhibition correlated with whether or not AHP neurons had synchronized firing with other AHP neurons. In synchronously-firing AHP neurons(SAHP), stimulus-evoked inhibition averaged 412.4 + 37.81 msec. In contrast, AHP neurons that fired without synchrony to other AHP neurons(NSAHP) had average inhibitory duration of 83.0 + 18.2 msec. A second difference between SAHP and NSAHP neurons was the change in firing rate. The long recurrent inhibition induced by local AHP stimulus volleys to SAHP neurons caused a 62.4% decrease in average firing rate from its spontaneous rate. In contrast, in NSAHP neurons, stimulus volleys actually increased the average firing rate by 119.2% above the average spontaneous rate.

This finding, i.e., 1) stimulus evoked duration of inhibition in AHP neurons are longer if these neurons spontaneously fire in synchrony with other AHP neurons, and 2) the average firing rate of synchronized AHP neurons decreased when these neurons were stimulated, supports the model by Finch and Babb(Brain Res. 354. 1977) that this inhibition has a synaptic component and is determined by a local recurrent GABA-mediated inhibition. A synchronous firing of two AHP neurons may engage basket-cell-inhibition with temporal summation and produce prolonged inhibition. The functional significance of this inhibition in synchronously-firing neurons is proposed as a mechanism for setting the timing for AHP neurons to fire synchronously.

358.6 GROUP DYNAMICS OF HIPPOCAMPAL NEURONS: PATTERNS OF UNIT ACTIVITY DURING THE THETA RHYTHM. M. Kuperstein, T. VanDemark*, and H. Eichenbaum Dept. Biol. Wellesley College, Wellesley, MA 02181

Using a 24-channel microelectrode system called PRONG (Parallel Recording of Neural Groups; Neurosci. Abstr. 10:598), we have begun a study of hippocampal neural group activity by simultaneously observing the activity of several single units during theta and non-theta defined behavioral states. In several rats, up to 14 single units in the flexure of CA3 were simultaneously monitored. The hippocampal EEG was recorded across the contralateral CA1 pyramidal cell layer.

Units were analyzed by a combination of methods: inspection of spike waveform, computation of firing rate and phase relation to theta autocorrelation, and cross-correlation of spike events. Examples of correlograms are shown below (left panel synch on channel 16 at 0ms; next two panels synch on channel 21; each correlation individually normalized). Short-term firing patterns were relatively constant acro theta and non-theta states, whereas longer-term neural group patterns were selective to the theta state. At high time resolution (1ms/bin; left panel), we frequently observed bursting repetoires, as shown in their autocorrelation (e.g. channel 16), and co-activation peaks near 0ms. The degree of bursting and co-activation was similar across theta and non-theta states. At a lower time resolution (10ms/bin), cross-correlation during non-theta (second panel, power spectrum at top) indicated only broad periods of co-activation. In striking contrast, the same neurons became synchronously active during theta activity (third panel), even though these cells had different preferred phase relations to the ongoing theta cycle (right panel). The combined findings suggest that the theta rhythm signifies a powerful patterning of group activity imposed on a fixed connectivity of neighboring neurons.

358.7 MEMBRANE PROPERTIES OF AMYGDALA NEURONS AND THE EFFECT OF ESTROGEN. J. Nabekura*, Y. Oomura, Y. Mizuno* and T. Minami* (SPON: M. Tachibana). Dept. of Physiol., Fac. of Med., Kyushu Univ. 60, Fukuoka 812, Japan.

The amygdaloid body, which has many nuclei, is important in emotional behavior. The medial (MD) and basolateral (BL) nuclei affect behavior, such as feeding, aggression and sex, in opposite ways. Intracellular recordings were obtained from MD and BL neurons of rat brain slices in vitro, and effects of estrogen, which modulates feeding and sexual behavior, were examined in male and female rats.

Application of outward current pulses to the cell membrane normally induced only repetitive Na spikes in all MD neurons, but Ca spikes appeared only in TTX containing medium. These Ca spikes were blocked by external Co. Under normal condition both Na and Ca spike complexes were observed in 23% of BL neurons. The results indicate that the BL nucleus contains neurons with a type of firing which is different from that of MD neurons. The afterhyperpotentials (a.h.p.) that followed the spikes had a reversal potential of -93mV. The a.h.p. disappeared upon application of TEA and 4-aminopyridine (4-AP),($E_K$= -93mV). Delayed return of the membrane potential to resting level after cessation of an inward current pulse was blocked by 4-AP. This indicated an increase of K ($I_A$) conductance and occurred in both MD and BL neurons.

Stria terminalis stimulation elicited EPSP-IPSP sequences in 90% of the MD and 82% of the BL neurons. Application of bicuculline eliminated the IPSP with a reversal potential of -64mV ($E_{Cl}$= -64mV). External capsule stimulation elicited only EPSPs in 64% of the BL neurons.

The MD nucleus is well known to contain many estrogen receptors and differs histologically in the two sexes. Hyperpolarization of approximately 15mV accompanied by an increase in membrane conductance was induced by $10^{-8}$M 17β estradiol hemisuccinate (17β$E_2$S) in 23% of the MD neurons during normal estrous cycle or in ovariectomized estrogen-primed female rats. This effect persisted even after application of TTX and Cd. The effect of 17β$E_2$S on membrane potential and determination of the membrane I-V relationships with and without 17β$E_2$S indicated a reversal potential for the 17β$E_2$S hyperpolarization of about -90mV. This could be changed by altering K concentration in the medium, which indicates that 17β$E_2$S directly increases the K conductance of MD neurons. On the other hand, 17β$E_2$S had very little effect on male or female BL neurons, and induced responses in only 8% of male MD neurons. These sexual and regional membrane characteristics, inputs, and drug effects might be related to functional and morphological differences between MD and BL neurons, and between male and female MD neurons.

358.8 PHYSIOLOGICAL PROPERTIES OF IN-VITRO RAT MEDIAL SEPTAL NEURONS. M. Segal* (SPON: A. Mayevsky). Center for Neuroscience, The Weizmann Institute of Science, 76100 Rehovot, Israel

Medial septal neurons fire rhythmic bursts of action potentials at characteristic high rates in vivo. Activity of these neurons is associated with the generation of hippocampal theta rhythm; there is a good correlation between septal cellular activity and theta waves, stimulation of the medial septal area (MS) generates hippocampal theta and lesion of the MS abolishes it. The mechanisms underlying the rhythmic septal activity are unknown.

I have studied MS neurons in a slice taken from adult rat brain in an attempt to detect and analyze some physiological properties of these neurons that might mediate their rhythmic activity. Most MS neurons exhibit strong non-linearity in the IV relations on both the depo- and hyperpolarizing sides of the resting potential. A large proportion of MS neurons (over 1/4 of the cells) discharge spontaneously in vitro. The other neurons may discharge rhythmically upon depolarization by passage of constant current pulses across the recorded cell membrane. Rhythmicity is preserved when $Na^+$ action potentials are blocked by TTX, provided the cell is loaded with $Cs^+$ to block K currents. Rhythmicity disappears in the presence of Ca antagonists $Cd^{2+}$ or $Co^{2+}$. Also, rhythmicity disappears by hyperpolarizing the cell, indicating the absence of an underlying synaptic mechanism. Several phenomena might be related to the rhythmic activity of MS neurons: 1. a large depolarizing after potential (DAP) commonly results in firing of a second action potential at constant (4-5ms) latency after a first one. 2. a rebound depolarization seen after termination of a hyperpolarizing current pulse may occasionally fire an anodal break potential. 3. Lack of significant accomodation of the firing frequency in response to a depolarizing current pulse. MS neurons receive an inhibitory input from the lateral septal area (LS). GABA antagonists block the response to LS stimulation as well as spontaneous PSP's which share the same reversal potential as that seen in response to GABA. These results indicate that rhythmicity of in vivo MS cells is probably intrinsic and is only modulated by synaptic inputs.

358.9 STABILITY OF CORTICAL EEG ACTIVITY DURING SENSORY INTERACTION. L.C. Oatman. U.S. Army Human Engineering Lab., Aberdeen Proving Ground, MD 21005

During sensory interaction, an accessory stimulus in a second modality can have a facilitating effect upon some measurable response to a stimulus applied to a primary modality. Since sensory stimulation can elicit hippocampal rhythmic slow activity (RSA) during behavioral immobility, this study examined whether increased intensity of an accessory light stimulus increased hippocampal RSA (theta waves) during behavioral immobility in a sensory interaction paradigm.

Cortical EEG activity was recorded from six chronically implanted cats when auditory click stimuli were presented before, during, and after simultaneous accessory light stimulation of seven different intensities. Sample epochs of auditory cortex EEG activity from the three recording sessions, in the absence of bodily movement, were subjected to the fast Fourier transform, and the average power spectra were determined for the frequency bands theta (4-8 Hz), alpha (8-13 Hz), beta 1 (13-20 Hz), and beta 2 (20-40 Hz). The amount of power within the theta frequency range was not significantly different during simultaneous visual and auditory stimulation when compared with the pretest and posttest control periods of auditory stimulation, except at the most intense level of light stimulation. Simultaneous auditory and visual stimulation had no systematic effect on the amount of power occurring in the alpha, beta 1, and beta 2 frequency bands. The results suggest that sensory interaction effects do not produce hippocampal RSA (theta) during behavioral immobility when both the auditory and visual stimuli are irrelevant, except at very intense levels of stimulation.

358.10 LOCATION-SPECIFIC FIRING OF HIPPOCAMPAL THETA CELLS. J.L. Kubie, L. Kramer* and R.U. Muller*. Dept. of Physiology, Downstate Medical Center, Brooklyn, N.Y., 11203.

Complex-spike (CS) cells recorded from the hippocampus of freely moving rats fire fast only when the rat is in a delimited portion of its environment. Outside the region of rapid firing (the firing field), CS cells are virtually silent. CS cells thus have extremely clear spatial firing patterns; the in-field to out-of-field firing rate ratio is about 50:1 or more. Theta cells, which are local circuit neurons, can also be recorded from the hippocampus. They are identified by the fact that their firing rate increases 2-fold or more whenever the hippocampal EEG is in the "theta" state. Since theta cells are excited by CS cells, some degree of location-specific firing ought to be apparent in theta cells. We cannot, however, expect to see obvious firing fields, since theta cells are never silent in freely moving rats.

The techniques are the same as those previously used to study CS cells. During 16 minute sessions, rats chase food pellets dropped on the floor of a familiar cylindrical enclosure. The rat is located in a 64 by 64 matrix at 60 Hx; the number of spikes fired by the target cell during each 1/60th sec. is counted. Subsequently, color-coded firing rate maps are used to display the spatial firing pattern.

We have recorded from 9 theta cells. All showed spatial coherence of firing as judged by eye; that is, their firing rate maps were not uniform. Continuous regions of approximately constant firing rate were seen. The firing rate in "hot regions" was about twice that in slow firing regions. Such regions, whether associated with rapid or slow firing were quite large. Since the continuous regions taken together fill the apparatus, their approximate size can be estimated by noting that there were between two and 5 such regions in the maps for our sample. Crucially, the spatial firing patterns seen for individual cells were reproducible from session to session, as determined by eye and by pixel-by-pixel correlations between the spatial firing rate distributions.

Two further observations have been made about the spatial firing properties of theta cells. For three cells, we sorted samples into 4 categories according to the concurrent state of the hippocampal EEG. These categories ranged from strong theta to large, irregular activity (Vanderwolf, Electr. clin. Neuro., 1969). The spatial patterns obvserved for each category were quite similar to each other. Thus, the state of the hippocampal EEG is not the only correlate of theta cells activity. Second, on two occasions, we looked to see if spatial fring patterns differ among theta cells in the same rat. Ideally, two theta cells would be recorded simultaneously. Due to current technical limitations, we instead alternated sessions for each of two cells. The spatial firing patterns as judged by eye were very different; moreover, pixel by pixel correlations between sessions for the same cell were high, whereas similar correlations across cells were low. Thus, spatial firing patterns for theta cells are cell-specific. This reinforces our notions that theta cells are activated by particular sets of CS cells.

358.11 UNIT ACTIVITY IN THE MONKEY HIPPOCAMPAL REGION
M.W. BROWN* & F.A.W. WILSON (SPON: B. Matthews), Department of Anatomy, The Medical School, University of Bristol, Bristol BS8 1TD, U.K.

In previous experiments hippocampal unit activity has been found to be dependent on the context as defined by the behavioural task within which the stimuli were presented (1). Monkeys performed a delayed match to sample task: a trial consisted of 2 successively presented stimuli (S1 and S2) on a video monitor. Fruit juice was obtained by a right panel press when both stimuli were the same, or a left press when the stimuli differed. Standard stimuli were squares and circles. Context-dependent unit activity was selectively related to a specific stimulus (e.g. a large square) as S2 on a particular type of trial (match or non-match).

Recent experiments have examined the activity of hippocampal region units to familiar, novel and not recently seen stimuli in both the delayed matching task and in other tasks in which junk objects and foods could be viewed, or viewed and obtained by the monkey. Further examples of units with context-dependent responses and units selectively responsive to specific stimuli have been found. Units responsive in the delayed matching task were often also responsive to junk objects and foods. Some units responded maximally to novel or not recently seen stimuli, with rapid habituation to repeated stimulus presentations. These responses indicate access to both direct and stored sensory information.

Task-related unit activity often also occurred after the offset of the visual stimuli, in the interval between trials, and in some cases was dependent on the animal's motor response (right or left press). However, neuronal activity was not solely determined by mouth, arm and eye movements. Thus activity of hippocampal units codes both sensory and motor aspects of the behavioural tasks. These data support a role for the primate hippocampal region in the sensory-motor integration of learned behaviour.

358.12 EVIDENCE FOR LOCAL EXCITATORY SYNAPTIC CIRCUITS IN CA1 OF RAT HIPPOCAMPAL SLICES OBTAINED BY GLUTAMATE MICROSTIMULATION.
E.P. Christian* and F.E. Dudek (SPON: D. Holtzman). Dept. of Physiol., Tulane Univ. Sch. of Med., New Orleans, LA 70112.

Recurrent axon collaterals of hippocampal CA1 pyramidal cells, which terminate within CA1, could hypothetically subserve both excitatory and inhibitory local synaptic interactions. A direct physiological investigation with dual intracellular recordings from hippocampal slices cut in a longitudinal orientation only provided evidence for inhibitory local synaptic circuits between CA1 pyramidal cells (Knowles and Schwartzkroin, J. Neurosci., 1:318, 1981). It is possible, however, that local excitatory connections were not detected in this study because of technical problems; that is, the interactions could be rare or not oriented in a longitudinal plane. We reinvestigated this issue in hippocampal slices cut in two orientations by stimulating neuronal populations in CA1 with glutamate (Glu) microdrops. Increases in the frequency of spontaneous excitatory or inhibitory postsynaptic potentials (EPSPs or IPSPs) in a nearby CA1 pyramidal cell were used as evidence for local excitatory or inhibitory connections.

Rat hippocampal slices (450 µm thick) were cut either parallel (transverse plane) or perpendicular (longitudinal plane) to alvear fibers and maintained using standard procedures. Pyramidal cells in CA1 were recorded intracellularly while microdrops (10-50 µm dia.) of Glu (10-20 mM) or control saline were applied at several places in the CA1 stratum pyramidale at distances ranging from 0-400 µm on either side of the recording site. Spontaneous EPSPs and IPSPs (>3 mV) were counted for 10-sec periods before and after each microdrop application.

Glutamate microapplications in at least one location in CA1 consistently increased the frequency of EPSPs in 6 of 9 CA1 pyramidal cells tested in transverse slices. In longitudinal slices, glutamate microapplications did not alter the EPSP frequency in any CA1 pyramidal cells (n=10). Slow hyperpolarizations and/or increases in IPSPs were observed following glutamate applications in some cells from both transverse and longitudinal slices.

Our data support evidence from previous dual intracellular recording studies that local inhibitory circuits are present in CA1 of longitudinal hippocampal slices. They further suggest that local excitatory circuits exist in CA1, and that they are oriented predominantly in a transverse plane running parallel to the alveus. Although dual intracellular recordings will be necessary to confirm these data, the possible presence of local excitatory connections in CA1 should be considered in models of epileptiform synchronization in this hippocampal area.

Supported by NIH grant NS 16683.

358.13 SILENT HIPPOCAMPAL PYRAMIDAL CELLS IN AWAKE FREELY BEHAVING RATS.
L.T. Thompson,* J. Kapur,* P.N. Lacey,* R.A. Salerno,* & P.J. Best, University of Virginia, Charlottesville, VA 22901

Over the past 10 years, we noted many extracellularly recorded hippocampal pyramidal cells isolated in anesthetized rats either were lost or became silent when the animals recovered from anesthesia. Kubie & Ranck (1982) have reported many cells which show place field activity in one environment are silent in others. Most of our silent cells showed robust complex-spike activity when the rats were re-anesthetized. The cells were not lost, but apparently were inhibited from firing during our experiments in the awake animal.

The present study quantifies and describes the characteristics of silent cells. Ten rats were implanted with moveable bundles of ten 32 um nichrome microwire electrodes. The rats were later anesthetized with 30-40 mg/kg of pentobarbitol followed by 0.3 mg/kg of atropine sulphate, and one or more cells were isolated with 4:1 signal-to-noise ratios. Unit activity was recorded while the rats were anesthetized, after waking from anesthesia, on a radial arm maze, in a cylindrical drum, in a shock box during classical conditioning and during subsequent re-anesthetization. Automatic registration of the rat's location was combined with on-line computer analysis of cell firing to analyze place field activity.

Of 26 dorsal hippocampal cells isolated under anesthesia, 15 were silent upon awakening. The remaining 11 cells showed place field activity in at least one of the three testing environments. Five cells had active place fields in more than one environment. During final anesthetization, 10 of the 15 cells which were silent in the awake rat again showed robust activity, as did all 11 place cells.

Powerful inhibition of hippocampal pyramidal cell firing has been shown in our lab during REM sleep and upon arousal from slow wave sleep. This inhibition may enhance the processing of multisensory spatial information which occurs within the hippocampus. The rapid firing of a place cell when a rat is physically within the place field appears to be actively inhibited when the rat is outside that field. Information is thus expressed both by those cells which are active within a particular location, and by those which are silent.

358.14 DOES A REDUCTION IN RECURRENT INHIBITION CONTRIBUTE TO PAIRED PULSE POTENTIATION OF THE CA1 POPULATION SPIKE IN THE HIPPOCAMPUS?
M.W. Oliver* and J.J. Miller (SPON: J.A. Pearson), Dept. of Physiology, University of B.C., Vancouver, B.C., Canada V6T 1W5

A recent study (Oliver and Miller, Can. J. Physiol. Pharmacol., 1985) showed that repetitive stimulation of the alveus reduced the recurrent IPSP in hippocampal CA1 pyramidal cells. This effect could be observed on the second pulse of the stimulus train suggesting that the CA1 pyramidal cell's IPSP may be diminished by a paired pulse (PP) paradigm. Thus, the possibility exists that potentiation of the population spike (PS) associated with paired pulse stimulation of the stratum radiatum (SR) is in part due an increased excitability of pyramidal cells resulting from an attenuation of the IPSP. Therefore the present study was undertaken to examine the contribution which a reduction in recurrent inhibitory processes may have in the PP potentiation of the population spikes recorded from the CA1 area of rat hippocampal slices.

Paired homosynaptic stimulation of SR results in the characteristic inhibition-potentiation of the PS at condition-test (C-T) intervals < 0.04s and 0.06-8 s, respectively. In contrast to these data, paired heterosynaptic SR stimulation resulted in the inhibition of the test PS at all C-T intervals. In order to assess the effect of a SR conditioning pulse on the recurent inhibition, the alveus was stimulated 20 ms before the test SR pulse. With either homo- or heterosynaptic stimulation the magnitude of the recurrent inhibition was enhanced for C-T intervals of up to 0.1 s; however, at all other intervals tested (< 8s), the inhibition was significantly attenuated.

Intracellular recordings obtained from CA1 pyramidal cells indicate: 1) the PP inhibition observed in response to heterosynaptic stimulation correlates with the time course of the afterhyperpolarization (AHP); and 2) a significant reduction in the amplitude and conductance of the alvear-evoked IPSP occurs during the AHP.

These data support the suggestion that the PP potentiation phenomenon in CA1 not only involves perisynaptic processes but also postsynaptic mechanisms, particularly those mediating pyramidal cell inhibition.

358.15 DIFFERENTIAL SENSITIVITY OF RAT AND GUINEA PIG HIPPOCAMPAL PYRAMIDAL NEURONS TO CALCIUM-DEPENDENT PROCESSES: BIOCHEMICAL AND ELECTROPHYSIOLOGICAL EVIDENCE. P. Leung*, J.J. Miller and K.G. Baimbridge, (SPON: P.C.K. Leung), Dept. of Physiology, UBC, Vancouver, B.C., Canada. V6T 1W5

Previous immunocytochemical studies have demonstrated that the hippocampal pyramidal cells in the CA1 region and granule cells in the dentate gyrus contain calcium-binding protein (CaBP). This localization is characteristic of most species (rat, mouse and monkey), with the exception of the guinea pig in which CaBP is not present in the CA1 pyramidal cells (Baimbridge and Miller, this volume). Such a species difference for a single population of neurons suggests the possibility that these cells may also exhibit significant differences in their electrophysiological properties. We have therefore compared the responses of CA1 pyramidal neurons in the rat and guinea pig hippocampal slice preparations following perfusion with 1) low calcium medium (0.1mM $Ca^{2+}$, 2.0mM $Mg^{2+}$) to determine the sensitivity of these preparations to low calcium induced bursting; 2) pulse application of a high calcium medium (4mM $Ca^{2+}$, 1.0mM $Mg^{2+}$) which we have previously shown to induce long-term potentiation (LTP) in the rat and 3) picrotoxin (10 μM).

In the presence of a low calcium medium the CA1 pyramidal neurons of the rat exhibited the characteristic spontaneous burst activity which persisted for hours. In comparison, the onset of bursting in the guinea pig preparation was significantly delayed from that of the rat and its frequency considerably slower. Pulse application of a 4mM $Ca^{2+}$ medium (4-10 min) successfully induced LTP of the stratum radiatum (SR) evoked EPSP and population spike in the CA1 region of the rat but was ineffective in the guinea pig. In this latter preparation a subsequent tetanic stimulation of the SR induced a robust LTP. Perfusion with picrotoxin resulted in multiple population spikes evoked by stimulation of the SR in both species but was far more effective in inducing spontaneous interictal burst activity in the guinea pig than in the rat in terms of onset latency and frequency.

These observed differences of rat and guinea pig CA1 neurons to processes underlying burst discharge generation and potentiation phenomena may well be related to the presence or absence of CaBP, which has been suggested to play a role in the intracellular regulation of calcium ions. In any event these data suggest that the rat and guinea pig CA1 pyramidal cells exhibit clear differences in both biochemical and electrophysiological properties. Such differences may be important factors to take into consideration when comparing reports from different laboratories using either of these two species. In addition, a comparison of the properties of the CA1 pyramidal cells from the rat and guinea pig may help to reveal the possible function(s) of CaBP in the central nervous system.

358.16 COMPARATIVE DISTRIBUTION OF CALCIUM-BINDING PROTEIN AND PARVALBUMIN IN THE RAT, MOUSE, GUINEA PIG AND MONKEY HIPPOCAMPAL FORMATION. K.G. Baimbridge and J.J. Miller, Dept. of Physiology, UBC, Vancouver, B.C., Canada V6T 1W5

Calcium binding protein (CaBP) and parvalbumin (PV), two members of a family of proteins which bind calcium ions with high affinity, have been shown to be present throughout the cytoplasmic volume of specific neuronal populations within the central nervous system. We have previously reported that in the hippocampal formation of the rat, CaBP is present in two of the major cell types (CA1 pyramidal and dentate granule cells) but is absent from the CA3 pyramidal neurons. In the present study the distribution of this protein in the hippocampal formation of a number of different species was examined. In addition its topographical localization was compared to that of PV.

Antibodies to human cerebellar CaBP and mouse muscle PV were raised in rabbits and used to localize these proteins in cryostat sections (20 μ) of the hippocampal formation of rat, mouse, guinea pig and monkey brains fixed by formalin perfusion. The methodology has been previously described (Baimbridge and Miller 1982, Brain Res. 245, 223-229).

The marked differential distribution of CaBP previously reported for the rat was confirmed and an identical distribution was found in the hippocampal formation of the mouse and monkey. In the guinea pig, however, CaBP was found only in dentate granule cells. The absence of CaBP in the CA1 pyramidal cells may be functionally associated with electrophysiological differences observed in hippocampal slice preparations taken from either the guinea pig or rat, (see Leung, Miller and Baimbridge, this volume).

The localization of PV immunoreactivity was quite distinct from that of CaBP but was similar in all species examined. In the CA1 region a heavily stained population of small multipolar cells having short dendritic processes were present in the stratum oriens and alveus. Positively labelled neurons were also scattered throughout the stratum pyramidale of the CA1-CA4 regions and their processes extended along the cell body layer as well as into the stratum radiatum. A similar topographical localization was observed in the dentate gyrus where the stained cells were located mainly in the basal portions of the granule cell layer and their dendrites extending vertically into the stratum moleculare. Both granule and pyramidal cell layers contained a dense plexus of positively labelled fibers/terminals. While PV immunoreactive cells may represent a subpopulation of principal cells within the hippocampal formation which are distinct from those labelled by CaBP, their distribution and morphological characteristics would appear more closely associated with local circuit neurons, particularly those which have been classically identified as basket cells.

358.17 HIPPOCAMPAL CALCIUM REGULATION AS MEASURED BY KINETIC ANALYSIS OF $^{45}Ca$ UPTAKE CURVES IN THE SLICE PREPARATION. I. Mody and J.J. Miller, Dept. of Physiology, University of British Columbia, Vancouver, B.C., Canada, V6T 1W5.

Kinetic analysis of $^{45}Ca$ uptake curves has been widely used in several non-neuronal preparations to examine intracellular $Ca^{2+}$ compartmentalization. The aim of the present study was to apply this technique to the hippocampal slice preparation in view of the variety of calcium-mediated phenomena shown to exist in this CNS structure. The method consists of introducing the tracer into the extracellular medium and monitoring its uptake into the cellular network. The uptake curve is then fitted by a mathematical function and the ionic fluxes, rate constants and distributions are determined according to the principles of compartmental analysis.

The hippocampal $^{45}Ca$ uptake curves were fitted using the non-linear least squares Simplex method and were found to be best approximated by a double exponential equation. This finding indicates that the slice preparation behaves as having two exchangeable pools of $Ca^{2+}$. Both compartments are localized intracellularly since the bulk of extracellular $Ca^{2+}$ has been washed off by $La^{3+}$ following termination of the uptake.

The first compartment is characterized by a rapid rate of exchange ($T_c$=3.75 min) and its size increases linearly with alterations in $[Ca^{2+}]_o$ from 0.1-4.0 mM. Therefore it most likely represents the sum of $Ca^{2+}$ bound to the plasma membrane and free ionic intracellular $Ca^{2+}$. The second compartment has a slower exchange rate ($T_c$=33.33 min) and is readily altered by incubation of the slices with the mitochondrial uncoupler DNP and the phosphodiesterase inhibitor IBMX ($10^{-4}$M). This compartment is considered to include buffered/sequestered intracellular $Ca^{2+}$.

Contrary to expectations, the $Ca^{2+}$-channel antagonist nifedipine ($10^{-6}$M) did not block the uptake of calcium into the rapidly exchangeable pool, but instead caused an enhancement of the buffered pool. Salmon calcitonin (4 U) effectively reduced the total exchangeable $Ca^{2+}$ of the hippocampal slice through mobilization of the cation from intracellular storage sites while increasing $Ca^{2+}$ efflux.

Changes in $Ca^{2+}$-regulation as measured by the kinetic analysis were also reflected in altered electrophysiological characteristics of hippocampal neurons. It is concluded that although the hippocampal slice preparation is a heterogeneous system consisting of various types of neurons and glial cells it may nevertheless be characterized with regard to its $Ca^{2+}$-homeostasis using the kinetic analysis of $^{45}Ca$ uptake. The method provides a novel approach to investigation of CNS calcium regulation under both physiological and pathophysiological conditions.

359.1 EFFECTS OF COBALT-INDUCED CHRONIC AMYGDALOID SEIZURES UPON AFFECTIVE DEFENSE BEHAVIOR IN THE CAT. M.B, Shaikh*, M. Brutus, H. Edinger, and A. Siegel. Depts. of Neuroscience and Physiology, University of Medicine and Dentistry of New Jersey -- N.J. Medical School, Newark, N.J. 07103.

Studies conducted previously in our laboratory (Block et al, 1980, Siegel, 1984) and elsewhere (Stoddard-Apter and MacDonnell, 1980) have demonstrated that amygdaloid nuclei can differentially modulate affective defense and quiet biting attack behavior elicited from the hypothalamus of the cat. More recently, our laboratory has further demonstrated that seizures induced acutely by electrical stimulation of the amygdala and pyriform cortex can also signficantly alter thresholds for each of these responses (Brutus et al, 1984). The present study was conducted in order to identify the effects of seizures chronically induced in the amygdala by metallic cobalt powder upon affective defense behavior.

Monopolar electrodes and chemtrodes for stimulation and recording were stereotaxically implanted into the medial and lateral aspects of the hypothalamus, amygdala and pyriform cortex. Initially, stable baseline thresholds for affective defense were determined over a 1-3 week period utilizing an ascending and descending Method of Limits. Then, cobalt (approximately 50 mg.) was administered through a chemtrode into the amygdala or pyriform cortex in order to induce chronic seizures. Following administration of cobalt, baseline attack thresholds were again determined on alternate days over a 4 week period. At the completion of the experiments, animals were sacrificed and histological localization of electrode and chemtrode tracks were determined.

Our results have suggested that the effects of chronic seizures upon affective defense behavior are largely dependent upon the amygdaloid and pyriform cortical sites involved in the primary cobalt focus. In 4 cases, animals sustaining chronic seizures in which a primary focus involved the pyriform cortex showed a lowering of response thresholds over time. In contrast, animals whose primary seizure focus included the lateral and/or central nucleus displayed an increase in attack response thresholds over time. Alterations in attack thresholds also appeared to be dependent upon seizure intensity.

These findings suggest the following conclusions: (1) that chronic amygdaloid and pyriform cortical seizures can significantly modify hypothalamically-induced affective defense behavior, and (2) that the directionality of effects is specific to the location of the seizure focus.

359.2 CAT "P300": EFFECTS OF SEPTAL LESIONS. J. Harrison, J. Buchwald, K. Kaga,* N. Woolf and L. Butcher. Depts. of Physiology and Psychology, Brain Res. Ctr. Ment. Ret. Res. Inst., UCLA, Los Angeles, CA 90024.

We have previously reported on a cat model of the P300 and are now engaged in a series of studies to elucidate the generator substrates of this endogenous cognitive potential. Because the hippocampus is a postulated generator, in this study we lesioned the septal nuclei and nuclei of the diagonal band to interfere with the normal cholinergic innervation of the hippocampus. The object of this experiment was to determine whether the septal lesion depleted hippocampal acetylcholinesterase (AChE) and significantly altered the vertex recorded endogenous response. Responses were recorded for 12 pre- and 12- post-operative sessions for each cat. Acoustic stimuli included loud clicks which were rare (15%) or frequent (80%); soft clicks which were reciprocally frequent or rare, and tone pulses (5%) followed by eyelid shock which focussed the cat's attention. EEG recorded from a steel screw at the vertex was averaged separately for each of the 3 stimuli in 500-trial blocks. A "P300" was scored as present if the rare loud click response was significantly more positive in the 200-500 msec range than the frequent response. Paired t-tests of data points across the 40-1000 msec latency period showed that a "P300" was present in every cat before the lesion. The medial septal nuclei and nuclei of the diagonal band were lesioned bilaterally in 10 cats by means of a radio frequency lesion generator and then 12 more recording sessions were carried out before sacrifice and perfusion of the brain. Histological sections from the septum through the hippocampus were stained for AChE and with thionine, for lesion localization. Complete bilateral lesions of the septum resulted in dynamic changes of the "P300". For the first several days the "P300" was normal or enhanced, and , in all cases it became markedly enhanced within the first week and remained enhanced for several days. It then disappeared or decreased below its pre-lesion level. In these animals, with histologically confirmed lesions of the rostral septum and nuclei of the diagonal band, a complete bilateral depletion of AChE in the hippocampus was demonstrated. Incomplete lesion of the septal area produced varying amounts of AChE depletion and varying effects on the "P300", but never complete AChE depletion or marked enhancement of the"P300." These changes in the cat "P300" lead us to conclude that the septal nuclei and nuclei of the diagonal band may influence generation of the P300 through their cholinergic innervation of the hippocampus. (Supported by USPHS AG04088, HD05958 and NS10928).

359.3 CAT "P300": EFFECTS OF HIPPOCAMPAL LESIONS. K. Kaga,* J. Buchwald and J. Harrison. Brain Res. Inst., Ment. Ret. Res. Ctr., Dept. Physiol, UCLA Med. Ctr., Los Angeles, CA 90024.

In previous studies we have reported on a cat model of the human endogenous P300 potential. The cat "P300" is task related, appears in response to rare or omitted stimuli, shows a maximum positivity in the 200-500 msec latency range which, with principal components analysis, shows significantly different factor scores for rare versus frequent stimuli, all characteristics of the human P300. Moreover, in old cats (more than 10 years old) the cat "P300" decreases in amplitude and increases in latency, characteristics of the P300 in older human subjects. In an initial report of possible brain substrates contributing to the cat "P300", primary auditory cortex was bilaterally aspirated in a group of 4 cats. No significant effect was produced by the surgery when 12 sessions of pre-operative "P300" recordings were compared with 12 sessions of post-operative recordings, and we concluded that the cat "P300" was independent of primary auditory cortex. The present study was designed to test the hypothesis that the hippocampus is significantly involved in P300 generation. A group of 5 cats was recorded over 12 sessions pre-operatively. In each case, our typical P300 protocol was presented on a schedule of rare (15%), frequent (80%) and target (5%), and data were collected in 500 trial blocks. Four 500 trial blocks were obtained per recording session, in 2 of which the rare stimulus was a loud click and the frequent stimulus was a soft click, while on the other 2 blocks, these stimuli were reversed. In all cases, the target stimulus was a tone paired with a brief shock to the eyelid to produce a conditioned eyeblink response and focus the animal's attention. After the 12 pre-operative recording sessions were completed, the cat was anesthetized under pentobarbital and surgery was performed under aseptic conditions. Using an approach through the posterior suprasylvian cortex, a small amount of cortical and subcortical tissue was aspirated until the hippocampus could be directly visualized. The hippocampus was then aspirated both dorsally and ventrally. This procedure was carried out bilaterally. Intensive post-operative care was provided as needed, usually for no longer than 24-48 hours. Post-operative recordings commenced 48 hours after surgery and were continued on a daily basis for at least 12 sessions. The animals were then terminated with pentobarbital and the brains perfused. While data analysis is still incomplete, 4 of 5 cats showed a dynamic enhancement of the P300 postoperatively. Two of these 4 have thusfar been processed histologically and, in both, the posterior 30% of the hippocampus had been surgically aspirated bilaterally. These data indicate that partial ablation of the hippocampus results in an enhanced cat "P300" response, and thereby suggest that the hippocampus is involved in P300 generation. (Supported by USPHS grants AG04088, HD05958 and HD04612).

359.4 AN INVESTIGATION OF POSSIBLE PHYSIOLOGICAL ROLES OF THE INTERPEDUNCULAR NUCLEUS. J.R. Leu, T.J. Lynch*, L.E. Jarrard, R.A. Bauman* and J.L. Meyerhoff. Department of Medical Neurosciences, Walter Reed Army Institute of Research, Washington, DC 20307-5100.

Thyrotropin releasing hormone (TRH) has been shown to prevent pentobarbital-induced hypothermia in rats (Kalivas and Horita, Reg. Peptides, 1:335, 1981) by a mechanism apparently separate from its pituitary-thyroid action. Since the interpeduncular nucleus (IPN) is an injection site highly potent for producing this anti-hypothermic effect of TRH, we examined the effect of lesioning the IPN on core temperature responses to pentobarbital (PB) or ambient temperature challenge.

The IPN was radio-frequency (RF) lesioned in 10 rats, while in a group of 10 sham operated controls the RF electrode was lowered to the most dorsal aspect of the IPN and withdrawn. After two weeks recovery, the lesioned and sham rats plus 10 unoperated controls were exposed in separate sessions to 1 hr at 38°C, or 2 hr at 7°C. In a third experiment rats were injected with PB (35mg/kg, i.p.) 2 min following pre-treatment via i.p. injection with either saline or TRH (10mg/kg).

No differences were noted between the 3 surgical groups in baseline temperature or in response to challenge of exposure to hot or cold ambient temperatures. All 3 groups showed the same average PB-induced temperature decrease of 2°C when pre-injected with saline. Pre-treatment with TRH 2 min prior to PB significantly attenuated this hypothermia in all groups. Pretreatment with TRH attenuated PB-induced hypothermia by 93% in the controls, compared to 54% in the lesioned rats, but this difference between surgical groups was not statistically significant.

Total duration of PB-induced sleep was 46% greater in IPN-lesioned rats compared to controls ($p < 0.05$, Tukey's test). Although TRH tended to shorten sleep duration, this effect was not statistically significant in any group. The increase in PB sleep duration in IPN lesioned rats has not been previously reported. Further studies are planned to examine possible homeostatic roles of the IPN.

359.5 THE EFFECT OF FORNIX TRANSECTION ON RESPONSE TO A DISTRACTOR STIMULUS PRESENTED DURING THE FEEDING BEHAVIOR OF RATS. M. J. Epley* and B. Osborne (SPON: T. Root). Department of Psychology, Middlebury College, Middlebury, VT 05753.

The purpose of the present study was to explore the effects of distractor stimulus presentation on the feeding behavior of control and fornix transected Long Evans hooded rats. The rats were given six days of closed economy operant feeding on a continuous reinforcement schedule. The feeding behavior occurred in an environment designed to minimize sensory distraction. During the six days, both feeding and nonfeeding behaviors were recorded continuously. On the last three days a visual distractor stimulus was introduced during meals on a variable ratio three (VR-3) schedule. The study determined that rats with fornix transection did not differ from control rats in overall food consumption. However, fornix transection did result in an increased number of breaks per meal, a decreased intermeal interval, longer meals, more meal drinks and less intermeal drinks. These results were similar to those found in previous studies. Furthermore, stimulus presentation had a differential effect on control and fornix transected rats on measures of breaks per meal, meal size and pellets per meal. The results of the present experiment were interpreted as opposing neither a sensory filtering function of the hippocampus nor a behavioral sequencing function of the hippocampus in terms of feeding behavior. Rather, the hippocampus may be involved in both behavioral sequencing and sensory filtering. A subordinate influence or sensory filtering upon a primary behavioral sequencing function of the hippocampus was suggested.

359.6 SEXUAL DIMORPHISM IN THE EXPLORATORY BEHAVIOR OF RATS WITH FORNIX TRANSECTION. B. Osborne and David Dove*. Department of Psychology, Middlebury College, Middlebury, VT 05753.

The present experiment examined the behavior of male and female Long-Evans rats and sham-operated male and female control rats during the exploration of a novel environment. The rats were given a single 10 min. exposure to a novel environment equipped with environmental supports for exploratory interactions. The behavior was videotaped and analyzed for latency to initiate movement, activity levels, exploration of objects and sequential organization of behavior. Fornix transection resulted in significant changes in all measures. Rats with fornix transection in comparison to controls exhibited increased latency to initiate activity, increased frequency, but decreased duration of both activity and exploration and changes in sequential organization of behavior to a more random pattern. In comparison to males, females also exhibited patterns of exploratory behavior that differed in terms of frequency, duration and sequential organization. The differences between males and females was in the same direction as the difference between controls and fornix transected rats. Fornix transection affected both male and female exploratory behaviors but the effect was greater for males than for females. The results suggest that fornix transection does not result in hyperactivity and hypoexploration. The differences between controls and rats with fornix transection during exploration are more subtle, differing in the frequency, quality, duration and sequencing of behavior. The hippocampus may also be sexually dimorphic in function during exploratin of a novel environment.

359.7 ACTIONS OF ACETYLCHOLINE AND NICOTINE ON NEURONS IN THE RAT SUPRAOPTIC AND PARAVENTRICULAR NUCLEI. J.H. Robinson, S.A. Stwertka, E.P. Christian, V. K. Gribkoff, F.E. Dudek and S.A. Deadwyler. Dept. of Physiology, Bowman Gray Medical School and the R.J. Reynolds Tobacco Co., Winston-Salem, NC, 27103 and Dept. of Physiology, Tulane Univ. Med. Sch., Tulane University, New Orleans, LA 70112.

The supraoptic (SON) and paraventricular (PVN) nuclei of the rat hypothalamus contain magnocellular neuroendocrine cells that synthesize and release vasopressin and oxytocin. Application of acetylcholine (ACh) in the vicinity of the SON promotes vasopressin release from the neurohypophysis by a process involving nicotinic cholinergic receptors (Sladek and Joynt, Endocrinology. 105,367-371, 1979). Electrophysiological evidence also indicates that nicotinic cholinergic activation of SON neurons promotes phasic bursting (Hatton et al., J. Physiol. 345, 297-317, 1983), a firing pattern associated with enhanced hormone release by vasopressinergic neurons. The present study examined the nicotinic cholinergic activation of SON and PVN neurons in the hypothalamic slice preparation.

Nicotine (N) and ACh applied near extracellularly recorded PVN and SON neurons by microdrop (300uM-10mM) or bath delivery (100 - 200uM) increased the firing rates of some of these cells. Application of ACh or N occasionally resulted in phasic bursting in previously silent cells. Pressure application of N from the recording electrode produced systematic increases in the observed excitations with increasing ejection durations and pressures, eventually resulting in depolarization blockade. Addition of the nicotinic cholinergic antagonist d-tubocurarine (d-TC) to the bathing medium blocked or reduced the nicotine excitation in some cells but was ineffective in others. Glutamate elicited excitations were not affected by d-TC. Other neurons were unaffected or depressed by both N and ACh application. Preliminary intracellular recordings suggest that the excitatory effect of nicotine is voltage dependent and is accompanied by a decrease in membrane conductance.

Our data further support the hypothesis that a nicotinic cholinergic mechanism is important in the regulation of neuronal excitability in these hypothalamic nuclei. Although the excitatory actions of ACh and N can promote phasic firing, our studies show that these substances can have complex excitatory and inhibitory effects on PVN and SON neurons.

359.8 INFLUENCE OF ANTEROVENTRAL THIRD VENTRICLE (AV3V) STIMULATION ON THE EXCITABILITY OF HYPOTHALAMIC SUPRAOPTIC NEUROSECRETORY NEURONS. J.H. Jhamandas* and L.P. Renaud (SPON: A.T. Tan). Neurosciences Unit, Montreal General Hospital and McGill University, Montreal, Canada H3G 1A4.

Neurons in the AV3V region can be shown by anatomical and electrophysiological methods to send axons to the supraoptic nucleus, a source of vasopressinergic and oxytocinergic fibers innervating the neurohypophysis. Although the AV3V region is known to participate in the regulation of body fluid balance, the influence of structures in this area on the excitability of supraoptic neurosecretory neurons and thus the release of vasopressin and oxytocin remains uncertain. In the present study we examined supraoptic neurons for their response to electrical stimulation in the AV3V region.

Studies were conducted on pentobarbital anesthetized male Sprague-Dawley rats, using a transpharyngeal route to expose the ventral brain surface for extracellular recordings from supraoptic neurons. Neurosecretory cells were identified by antidromic activation from the neurohypophysis. These were further classified as putative vasopressin-secreting if they displayed phasic or continuous activity and a reduction in firing during peripheral baroreceptor activation induced by a transient rise in blood pressure consequent to intravenously administered metaraminol; cells with continuous activity that lacked blood pressure sensitivity were deemed to be oxytocin-secreting neurons. Monopolar cathodal stimulation (50 usec pulses, 50-150 uA) of the AV3V region was applied through glass insulated tungsten electrodes (tip exposure 50-100 um).

Post-stimulus histogram data obtained from more than 50 neurosecretory neurons revealed that AV3V stimulation could evoke a short latency (4-10 msec) reduction in excitability lasting up to 100 msec from a majority (75%) of putative vasopressin-secreting neurons. In contrast, fewer than 10% of putative oxytocin-secreting cells were responsive; some showed a low probability long duration increase in excitability.

These observations suggest that fibers arising in or passing through the AV3V region exert a selective inhibitory influence on supraoptic vasopressin-secreting neurosecretory cells and are likely to subserve a prominent role in regulating the secretion of antidiuretic hormone from the neurohypophysis (supported by MRC).

359.9 AFTERDISCHARGE IN RAT SUPRAOPTIC NEURONS FOLLOWING REPETITIVE ORTHODROMIC STIMULATION: ROLE OF SYNAPTIC AND INTRINSIC FACTORS. V.K. Gribkoff and F.E. Dudek. Dept. of Physiology, Tulane Univ. Sch. of Med., 1430 Tulane Ave., New Orleans, LA 70112.

Evidence for a projection from cholinergic neurons to magnocellular neuroendocrine cells in the rat supraoptic nucleus (SON) has previously been obtained from anatomical and in vitro electrophysiological studies (Hatton et al., J. Physiol., 345: 297-317, 1983). Single electrical stimuli, applied in the vicinity of these cholinergic neurons dorsolateral to the SON, produce EPSP's in phasically-firing (putative vasopressinergic) SON neurons; stimulus trains could produce an afterdischarge (AD). Dorsolateral stimulation either inhibited or did not affect non-phasic SON neurons. These data suggest that this pathway is important in the regulation of phasic bursting by vasopressinergic neurons. We have further examined the effects of dorsolateral stimulation on SON neurons to delineate the causal factors in the production of AD's.

Intracellular recordings were obtained from SON neurons ($R_i$>100 Mohm, AP>70 mV) of rat hypothalamic slices. We found that single electrical stimuli dorsolateral to the SON produced a short-latency EPSP in all phasic and some non-phasic neurons; repetitive stimulation produced an AD and/or promoted phasic firing in these cells. Stimulation evoked IPSP's in some non-phasic neurons.

Repetitive stimulation produced three effects that could contribute to generation of AD's in those neurons synaptically excited by dorsolateral stimulation. As previously reported by Hatton and coworkers, when neurons were hyperpolarized by intracellular current injection or were not spontaneously active, we consistently observed an increase in frequency of spontaneous PSP's that lasted between 30 sec and several minutes after train cessation. In addition, a slow depolarization followed the stimulus train in several neurons. In some of these neurons the slow depolarization probably resulted from an intrinsic mechanism, because a similar depolarization followed action potentials from intracellular depolarizing current pulses. In other SON neurons, which included phasic cells, a slow depolarization and a decrease in membrane conductance followed stimulus trains. This depolarization could occur in the absence of action potentials during the stimulus train, indicating that this event was possibly synaptic and not due to summation of depolarizing spike afterpotentials.

We have confirmed that repetitive activation of dorsolateral afferents can synaptically activate rat SON neurons, and can promote afterdischarges. Although an increase in spontaneous PSP frequency occurs after dorsolateral stimulus trains, slow depolarizations also appear to contribute to AD. Some of the slow depolarizations apparently arise from intrinsic spike afterpotentials and others may be slow PSP's.

359.10 **THE EFFECTS OF SYNAPTIC BLOCKADE ON TEMPERATURE-SENSITIVE NEURONS THROUGHOUT THE ENTIRE HYPOTHALAMUS.** J.B. Dean* and J.A. Boulant. Department of Physiology, The Ohio State University, Columbus, Ohio 43210.

Certain hypothalamic regions, such as the preoptic anterior hypothalamus (PO/AH), are known to serve in thermoregulation. Previous single unit studies have used coronal tissue slices and intact animals to study the thermoreceptive properties of PO/AH neurons. The present study used horizontal tissue slices to localize thermosensitive neurons throughout the entire hypothalamus of the rat. These horizontal slices were placed directly over 3 thermodes, which allowed independent control of temperature in the rostral, middle, and caudal regions of each slice. The effects of synaptic blockade on thermosensitive and insensitive neurons were determined by perfusion with a high $Mg^{++}$/low $Ca^{++}$ medium (11.4 mM/0.2 mM). Most of the spontaneously firing neurons were located within 1 mm of the midline and had normothermic firing rates ($FR37^{o}$) of less than 10 impulses/sec. Temperature-insensitive neurons represented the largest population. Warm-sensitive neurons were found throughout the entire hypothalamus with concentrations in the PO/AH, septum. VMH, posterior hypothalamus (PH), and mammillary body (MB). Concentrations of cold-sensitive neurons were found in the PO, PH, and MB. Warm-sensitive neurons outnumbered cold-sensitive neurons in all locations; ranging from 4:1 in the PO/AH to 9:1 in the VMH. Approximately 30% of the warm-sensitive neurons showed hysteresis during local thermal stimulation. While most warm-sensitive neurons displayed a reduced $FR37^{o}$ during synaptic blockade, other warm-sensitive neurons were unaffected. Also during blockade, warm-sensitivity either decreased slightly or remained unchanged. Temperature-insensitive neurons were primarily unaffected by synaptic blockade, but in some cases demonstrated a reduced $FR37^{o}$. This study suggests that while warm-sensitivity is inherent to many hypothalamic neurons, the activity of these neurons is influenced by local synaptic networks, as evidenced by the reduced $FR37^{o}$ and thermosensitivity during synaptic blockade. In addition, the wide distribution of thermosensitive neurons suggests that temperature can affect the hypothalamic control of a variety of regulatory systems. (Supported by NIH & Am. Heart Assoc. grants.)

359.11 A NEW, ROTATIONAL MAZE REQUIRING USE OF VESTIBULAR CUES FOR SPATIAL ORIENTATION: EFFECT OF HIPPOCAMPAL DISCONNECTION. B.L. Matthews*, W.H. Doares*, K.A. Campbell and S.A. Deadwyler. Section on Otolaryngology and Department of Physiology and Pharmacology, Bowman Gray School of Medicine, Winston-Salem, N.C. 27103.

In 1966 Douglas (J. Comp. Physiol. Psychol., 1966) proposed that spontaneous alternation in rats was susceptible to lesions of the hippocampus and that such behavior depended upon vestibular cues for its maintenance. Since that time there has been very little further investigation of the role of vestibular sensory cues in the maintenance of spatial discrimination behavior. In this study we describe a unique form of spatial learning that requires utilization of vestibular sensory inputs and that is sensitive to disconnection of the hippocampus.

A new type of maze was constructed with a short, plus-shaped alley resting on a rotating turntable in the center of an orthogonal 4-arm elevated cross maze. The central, rotating cross was completely covered and consisted of a start box and three separate alleys with curtains blocking the ends to restrict vision. The central cross could be rotated through 360 degrees so that the start box could be halted at one of four possible positions relative to the goal arm which contained a drop of water in a petri dish. Rats were required to use vestibular cues to determine spatial location of the goal on the three choice arms on any given trial. Animals were rotated in the covered cross for 1 to 10 revolutions preceding the 3-choice opportunity, with degree of rotation varying in random sequence across trials.

There were no significant differences in the performance of normal rats (n=6) and fornix-transected rats (n=9) over the first 5 days of training ($M_n$ = 52% correct; $M_{fx}$ = 45.9%, p>.1). However, normal rats improved considerably over the remaining 15-day training period, whereas fornix-cut rats did not: days 16-20 -- $M_n$ = 79.5%, $M_{fx}$ = 51.3%, p<.01). On probe trials with the cover removed, fornix-cut rats were able to use visual cues, and performed the task as effectively as normals, indicating that the impairment in fornix-cut rats was due to a specific deficit in the vestibular spatial task. When tested for ability to perform correctly on 90 degree rotations from the goal arm, fornix cut animals were deficient (20% below) with respect to normals at the beginning of each daily session but improved over the 20 day testing period such that at the end of the daily session this deficit was eliminated. The results confirm the original supposition by Douglas with regard to the role of the hippocampus as critical for processing vestibular sensory information for spatial orientation.

360.1 REGIONAL VARIATIONS IN THE CHOLINERGIC INNERVATION OF THE PRIMATE CORTICAL SURFACE. M. Mesulam, L. Volicer, J. Marquis, E. Mufson, R. Green. Harvard University and Boston University, Boston, MA

The enzyme choline acetyltransferase, a specific marker for the presynaptic component of cholinergic pathways, was measured in 33 cytoarchitectonic subregions of the Macaque cortex. As expected, the hippocampus and amygdala contained high levels of this marker. In the other parts of the cortical mantle, up to seven-fold differences were noted from one region to another. For example, the paralimbic (mesocortical) regions of the brain (e.g. parahippocampal, insular, caudal orbitofrontal and temporopolar areas) contained high levels of choline acetyltransferase. In contrast, the concentration of this cholinergic marker was the lowest within all frontal and temporo-parietal association areas. As a group, the primary sensory-motor regions contained an intermediate level of this enzyme. Choline acetyltransferase activity also showed a gradual increase from the isocortical towards the more primitive periallocortical subsectors of the paralimbic areas. Each of these differences was statistically significant ($p<.05$). The one exception to this plan of organization was presented by the cingulate cortex which - despite being a paralimbic region -contained among the lowest levels of choline acetyltransferase. Regional acetylcholinesterase activities were also assayed and showed variations which closely reflected those of choline acetyltransferase ($p<.01$, $r = .9$).

The selective concentration of cholinergic terminals within paralimbic and limbic areas may help to explain the relatively specific effects of systemically administered cholinoactive agents upon mood and memory. Although a depletion of cortical cholinergic input is an important component of Alzheimer's disease, it is interesting that the regional variations of cholinergic innervation do not help to predict the neuropathological predilection patterns that are known to exist in this condition. For example, prefrontal and temporoparietal association areas which are highly susceptible to plaque formation in Alzheimer's disease appear to have extremely low levels of natural cholinergic innervation.

This regional distribution also suggests that cortical cholinergic innervation is likely to play a pivotal role in the transmission of sensory information into the limbic system. For example, paralimbic areas which are very important in sensory limbic interactions have a high cholinergic innervation. Furthermore, in each of the three major sensory modalities, we found that the part of modality-specific association cortex which sends the most projections into the amygdala contains the highest level of cholinergic innervation. This anatomical distribution pattern suggests that cholinergic pathways may play their well known role in memory by gating motivationally relevant neural templates into and out of memory storage. 360.2 EXTRACELLULAR RECORDING FROM NUC. DIAGONAL BAND AND OTHER BASAL FOREBRAIN NEURONS IN THE RAT BRAIN SLICE. C. P. VanderMaelen, G. Gehlbach, R. C. Wilderman*, and A. S. Eison, Preclin. CNS Res., Bristol-Myers Co., Evansville, IN 47721.

Cholinergic neurons of the basal forebrain are implicated in senile dementia of the Alzheimer type. Previous extracellular recordings in vivo (Aston-Jones et al., 1983, 1984) and intracellular recordings in cell culture (Nakajima et al., 1984) from basal forebrain neurons have been made. The present study established a brain slice preparation for recording from cholinergic and non-cholinergic neurons of the rat basal forebrain. Chloral hydrate anesthetized male albino Sprague-Dawley rats, 100-150 g., were allowed to breathe 100% $O_2$ for at least 5 min. Frontal slices 400 µm in thickness were cut through the basal forebrain at the level of the anterior commissure using a Sorvall TC2 Tissue Sectioner. In 2 rats parasaggital sections were cut. Slices were incubated in a chamber containing 95% $O_2$, 5% $CO_2$ and bathed in continuously flowing artificial CSF of the following composition in mM: NaCl, 130; KCl, 5.0; $CaCl_2$, 1.25; $MgSO_4$, 1.25; $NaHCO_3$, 24.0; $NaH_2PO_4$, 1.25; D-glucose, 10.0. Extracellular single-unit recordings, usually aimed at the horizontal limb of the nucleus of the diagonal band of Broca (HDB), were made using glass micropipettes filled with 2M NaCl and 0.5% Pontamine Sky Blue. At the end of an experiment a dye spot was deposited in the slice, which was fixed in 10% formalin with 25% sucrose. 40 µm sections were cut, stained with neutral red, and locations of recorded neurons reconstructed.

Extracellular single-unit recordings were made from 98 neurons in 41 experiments. Neurons varied widely in action potential shape and spontaneous discharge rate. Action potentials were monophasic (positive or negative), biphasic (pos.-neg.) or triphasic (pos.-neg.-pos.), and were usually 0.7-2.0 msec in duration. Spontaneous discharge rates varied from 0 to 37 Hz. For 60 cells the muscarinic agonist carbachol was administered (0.1-100 µM). The vast majority (81.7%) of these cells were excited by carbachol, while 13.3% were inhibited, and 5.0% showed no response. Type of response to carbachol could not be predicted on the basis of spike shape or spontaneous discharge rate. In 77% of the experiments in which it was tried (N=13) the muscarinic antagonists atropine (0.5-100 µM) or scopolamine (0.5-1.0 µM) totally or greatly blocked the responses induced by carbachol. Histological verifications showed that most recorded neurons were located in the HDB or adjacent basal forebrain areas including substantia innominata, magnocellular preoptic nucleus, and vertical limb of the nucleus of the diagonal band. Some dye spots were located near clusters of magnocellular neurons suggesting that some recordings may have been from cholinergic neurons. Further studies will be required to determine if the cholinergic neurons can be identified by electrophysiological or pharmacological criteria.

360.3 BASAL FOREBRAIN NEURONS PROJECTING TO THE RAT CEREBRAL CORTEX: A MICROIONTOPHORETIC STUDY. P. Dutar*, O. Rascol*, A. Jobert* and Y. Lamour, INSERM U. 161, 2 rue d'Alésia, 75014 Paris (France).

The mammalian cerebral neocortex receives a diffuse cholinergic innervation from neurons located in the basal forebrain. Many of these neurons are located in the substantia innominata (SI) and in the ventral globus pallidus (GP). We recorded such basalo cortical neurons (BCNs) located in the ventro medial GP (nucleus basalis) and SI, and antidromically driven by the electrical stimulation of the frontal and parietal cortex in urethane anaesthetized rats. Conventional amplification methods were used to record neuronal activity from micropipettes filled with 1 M NaCl and 2% pontamine sky blue. These pipettes were rigidly attached to multibarreled micropipettes filled with solutions for testing by iontophoresis. The position of the BCNs was marked with a dye deposit, and the electrodes tracks subsequently reconstructed on coronal brain sections.

Sixty one BCNs were recorded from twenty eight animals. The location of the BCNs was in good agreement with previous anatomical data. BCNs were antidromically driven with latencies of 1.1 to 13.5 msec, giving conduction velocities of 0.6 to 6.8 m/s. (mean: 3.1 m/s). A majority of them was driven by the stimulation of the frontal electrodes. In some cases, evidence suggestive of axonal branching was obtained. Many BCNs had a very regular pattern of spontaneous discharge (mean spontaneous activity: 20 impulses per second). Most of the BCNs were not responsive to non-noxious peripheral somatic stimulation. BCNs were readily excited by the iontophoretic application of glutamate and strongly inhibited by GABA. Eighty-five percent of the BCNs could be excited by acetylcholine. No inhibition was observed. They could also be excited by cholinergic agonists. Muscarinic agonists excited a higher proportion of BCNs than nicotinic agonists. The most effective agonists were (ranked in order of decreasing efficacy): carbamyl methylcholine, acetyl methylcholine, muscarine, oxotremorine, carbachol, butyrylcholine, choline, TMA, DMPP. Excitatory responses to acetylcholine, carbachol and muscarinic agonists were abolished by atropine but rarely by nicotinic antagonists. It is known, on anatomical grounds, that most BCNs located on SI and GP are cholinergic neurons. Our results show that these central cholinergic neurons have relatively high spontaneous discharge rates and axonal conduction velocities. They also show that they are not inhibited but rather excited by their own transmitter, as well as by several cholinergic agonists.

360.4 CORTICALLY PROJECTING MAGNOCELLULAR BASAL FOREBRAIN NEURONS IN THE RAT. I. PHYSIOLOGY. P.B. Reiner, K. Semba, H.C. Fibiger and E.G. McGeer. Div. of Neurological Sciences, Dept. of Psychiatry, Univ. of British Columbia, Vancouver, B.C. V6T 1W5 Canada.

The magnocellular neurons of the basal forebrain provide a major extrinsic cholinergic input to the cerebral cortex. As a first step towards elucidating the functional properties of this cholinergic system, we have studied the physiological characteristics of cortically projecting magnocellular basal forebrain (CP-MBF) neurons using extra- and intracellular recordings in conjunction with morphological analyses employing intracellular HRP staining (see companion abstract).

In chloral hydrate anesthetized rats, 19 neurons satisfied criteria of constant latency and high frequency following to antidromic stimulation of cingulate (N=10) or frontal (N=9) cortices; in 4 spontaneously active neurons, collision was demonstrated as well. A sub-group of 6 CP-MBF neurons exhibited frequent loss of the somato-dendritic (SD) portion of the antidromically generated action potential. This phenomenon was clearly dependent upon stimulation frequency: in one neuron studied in detail, the initial segment spike followed faithfully at 100 Hz, while the SD segment disappeared as stimulation rates were increased from 1 to 2 Hz. SD failure was never seen during spontaneous action potentials. In contrast, the remaining CP-MBF neurons (N=13) showed no change in spike shape even at stimulus frequencies greater than 250 Hz. CP-MBF neurons exhibiting SD failures also had longer latencies to antidromic invasion (16.8 ± 6.2 vs. 3.0 ± 2.5 msec, mean ± SD, $p<0.001$) than their non-failure counterparts.

While these data demonstrate that physiological distinctions among CP-MBF neurons exist, similarities were noted as well. Although all CP-MBF neurons displaying the SD failure phenomenon had little or no spontaneous activity in these anesthetized rats, this did not serve as a distinguishing feature as 10/13 non-failure neurons were also relatively silent. Furthermore, neither the anatomical locations nor the cortical terminations (as evidenced by cortical stimulation site) of these sub-groups of CP-MBF neurons were distinct. Finally, both populations consisted of magnocellular neurons, although some morphological differences could be appreciated (see companion abstract).

In conclusion, we have identified a sub-group of CP-MBF neurons with unique and easily identifiable physiological characteristics, namely SD failure and long latency to antidromic activation. Although the majority of CP-MBF neurons can be expected to be cholinergic, the physiological heterogeneity displayed by these neurons calls for definitive characterization of the transmitter status of physiologically identified neurons.

360.5 CORTICALLY PROJECTING MAGNOCELLULAR BASAL FOREBRAIN NEURONS IN THE RAT. II. MORPHOLOGY. K. Semba, P.B. Reiner, E.G. McGeer and H.C. Fibiger. Div. of Neurological Sciences, Dept. of Psychiatry, Univ. of British Columbia, Vancouver, B.C. V6T 1W5 Canada.

In recent years, anatomical studies have revealed the existence of a topographically organized projection from the magnocellular basal forebrain to the neocortex. Several studies have shown that a majority of cortically projecting magnocellular basal forebrain (CP-MBF) neurons are cholinergic. To examine in detail the morphology of CP-MBF neurons, we injected horseradish peroxidase (HRP) intracellularly into antidromically identified cells following physiological characterization (see companion abstract).

Three CP-MBF neurons which were sufficiently well stained with HRP were reconstructed for morphological examination at the light microscopic level. The 3 cells were located, respectively, in the magnocellular preoptic area (MPA), the nucleus of the horizontal limb of the diagonal band (HLDB), and the globus pallidus-internal capsule (GP-IC) border. Physiologically, all 3 cells were driven from the cingulate cortex, and the cell in the MPA displayed the phenomenon of somato-dendritic spike failure, whereas the other two cells did not (see companion abstract).

Morphologically, all 3 CP-MBF cells had large somata (longest dimensions over 40 μm), and were isodendritic. Dendrites could be followed over 600 μm from the soma; some dendrites appeared beaded. In the MPA and GP-IC cells, the presumptive axons arose from either the soma or proximal dendrite and appeared to give off local collaterals (the axon of the HLDB cell could not be identified). Although the 3 CP-MBF cells thus showed some general similarities in morphology, some differences were noted as well. For example, the dendrites of the MPA cell ramified more frequently than did those of the other two cells. The pattern of dendritic arborization in the MPA and HLDB cells was radially oriented, while the cell located at the GP-IC border displayed a pattern extremely skewed towards the core of the GP. In addition, the dendrites of HLDB and GP-IC cells were moderately spiny distally, but relatively aspiny proximally, whereas those of the MPA cell were moderately spiny throughout.

The above observations indicate that CP-MBF cells in the rat display similar morphological features including large cell size, isodendriticity, and presence of spines. However, differences in terms of dendritic arborization patterns and distribution of spines were noted as well, which may correlate with differences in physiological characteristics. Current efforts are directed towards determining if these CP-MBF neurons are indeed cholinergic.

360.6 Cholinergic Projections from the Parabigeminal Nucleus (Ch8) to the Superior Colliculus in the Mouse. E.J. Mufson, T.L. Martin, D.C. Mash, B.H. Wainer and M-M. Mesulam, Harvard Med. Sch., Boston, MA. and University of Chicago, Chicago, IL.

Seven cholinergic cell groups extending from the basal forebrain to the mesencephalic tegmentum have been designated Ch1-Ch7 (Mesulam et al '83). The Ch1-Ch4 sectors are located within the basal forebrain and provide the primary cholinergic innervation for the telencephalon; the Ch5-Ch6 sectors are in the pontomesencephalic region and provide cholinergic projections to the thalamus; the Ch7 sector is in the habenula and projects to the interpeduncular nucleus. This study demonstrates an additional brainstem cholinergic cell group located within the parabigeminal nucleus which provides a major cholinergic projection to the superior colliculus (SC). The cholinergic cells located within this nuclear region are designated Ch8.

Peroxidase anti-peroxidase immunocytochemical staining with monoclonal antibodies to choline acetyltransferase (ChAT) in male CD-1 mice revealed intensely ChAT positive oval cell bodies (10-20 um in diameter) within the parabigeminal nucleus. ChAT processed tissue counterstained with thionin showed that approximately 80-90% of the perikarya of this region are cholinergic. Animals were also prepared for muscarine receptor autoradiography. Autoradiographic visualization of tritiated QNB binding with sufficient pirenzipine to mask $M_1$ sites revealed intense $M_2$ receptor labeling over the region corresponding to Ch8.

We injected small quantities of HRP-WGA into the SC. Retrogradely labeled neurons were observed in the contralateral and ipsilateral parabigeminal nuclei (Ch8). In tissue processed for the concurrent demonstration of ChAT and HRP, many HRP labeled neurons in the parabigeminal nucleus (Ch8) were also ChAT positive. The number of double labeled neurons was four times greater in the contralateral as compared to the ipsilateral parabigeminal nucleus (Ch8). Although no double labeled neurons were found in Ch1-Ch4 and Ch7, a few ChAT-HRP positive cells were seen in Ch5-Ch6, bilaterally. In contrast, an HRP injection into the inferior colliculus resulted in the co-localization of ChAT and HRP only in Ch5, ipsilaterally.

Tissue processed for ChAT and AChE histochemistry as well as for muscarine receptors revealed intense bands of these cholinergic markers in the superficial and deep layers of the SC. This shows that the SC receives a substantial cholinergic input and it appears that the parabigeminal nucleus (Ch8) is a major source of this cholinergic innervation. The demonstration of brainstem cholinergic neurons within Ch5 (pedunculopontine nucleus) and Ch6 (lateral dorsal tegmental nucleus) and now in Ch8 (parabigeminal nucleus) indicates the need for a more complete analysis of these regions in diseases associated with central cholinergic dysfunction. Supported by NS 20285, NS 029211, NS 17661, AG 05134, the ADRDA, and the McKnight Foundation.

360.7 MORPHOLOGIC CHARACTERISTICS OF CENTRAL CHOLINERGIC NEURONS IN THE RAT. L. L. Butcher, E. Gould* and N. J. Woolf, (SPON: R. W. Jacobs). Dept. of Psychology and Brain Research Institute, University of California, Los Angeles, CA 90024.

Morphologic assessments were performed on cholinergic neurons, specifically those that were both immunoreactive for choline acetyltransferase and stained for acetylcholinesterase. Neurons were randomly chosen from all brain regions containing cholinergic cells, and these neurons were assessed for maximal soma extent, minimal soma extent, soma shape, number of processes, degree of branching of processes, and the lengths of processes.

Intrinsically organized cholinergic neurons found in the caudate-putamen complex, nucleus accumbens, and olfactory tubercle had similar average maximal and minimal soma extents (20.9-21.5 μm and 15.0-15.6 μm, respectively). Basal forebrain cholinergic cells had maximal soma extents ranging from 19.5 μm in the lateral preoptic area to 23.4 μm in the nucleus basalis. Cholinergic cells in the pontine tegmentum were slightly larger on average (maximal soma extent in dorsolateral tegmental nucleus: 25.5 μm; pedunculopontine tegmental nucleus: 22.9 μm). In most cranial nerve nuclei the cholinergic somata were the largest found (e.g., average maximal soma extent in the motor nucleus of cranial nerve V: 32.5 μm), but cholinergic neurons found in the nucleus of cranial nerve X were considerably smaller (average maximal extent: 15.3 μm).

In general oval shapes were most common for cholinergic somata; e.g., 80% of the cholinergic cells were oval in both the caudate-putamen and the nucleus of cranial nerve X. Significant proportions of fusiform-shaped cholinergic cells were found prominently in the nucleus basalis, dorsolateral tegmental nucleus, and pedunculopontine tegmental nucleus.

Cholinergic cells in the striatum, basal forebrain, pontine tegmentum, and cranial nerve nuclei III, IV, V, and VII were observed with as many as 5-7 processes having extents up to 35-65 μm. A maximum of 2 processes having extents up to 15 μm were found for cells in the nuclei of cranial nerves X and XII.

360.8 ATTENUATION OF THE PHOTORESPONSE IN EXTRARETINAL PHOTORECEPTOR CELLS OF APLYSIA CALIFORNICA BY CHOLINESTERASE INHIBITORS. J.P. Apland. Sensory Research Division, U.S. Army Aeromedical Research Laboratory, Fort Rucker, AL 36362-5000.

Aplysia extraretinal photoreceptor (ERP) cells $R_2$, $LPl_1$, and VPN (Andresen and Brown, Experientia 38:1001, 1982) were used as models of phototransduction. The early steps of light transduction in Aplysia ERP cells are very similar to those proposed in the calcium scheme for vertebrate rod outer segments (Hagins, Ann. Rev. Biophys. Bioeng. 1:131, 1972). The effects of cholinesterase inhibitors and their antidotes on photoresponses in Aplysia ERP cells were investigated by electrophysiological methods.

Bath application of diisopropyl fluorophosphate (DFP), a potent irreversible organophosphate-type cholinesterase inhibitor, consistently decreased the maximum amplitude of the photoresponse elicited by flashing a light on Aplysia ERP cells. DFP did not change membrane resistance, nor did it change the reversal potential for the photoresponse. Physostigmine, a reversible carbamate-type cholinesterase inhibitor, depressed both photoresponse amplitude and membrane resistance. Attenuation of photoresponse was dose-dependent with both DFP and physostigmine and was completely reversed by washing out the drugs. Physostigmine was less potent. Both drugs caused depolarization of the resting membrane potential (RMP). Pyridostigmine, another reversible carbamate-type cholinesterase inhibitor, had no effect on photoresponse or membrane resistance at 5 times the concentration used for physostigmine. Bath application of carbachol, which would mimic a buildup of acetylcholine (ACh) following cholinesterase inhibition, caused a persistent hyperpolarization of the RMP. Carbachol caused attenuation of both photoresponse and membrane resistance. Jovic et. al. (Biochem Pharmacol. 20:519, 1971) have shown that DFP inhibits Na, K-ATPase. Therefore, it seemed that the depolarization caused by DFP might be caused by inhibition of the electrogenic Na pump in Aplysia ERP cells. However, superfusion with DFP still caused the usual depolarization after treatment of ERP cells with $10^{-3}$M ouabain, suggesting that the depolarization is not caused by Na pump inhibition. The muscarinic ACh receptor antagonist, atropine, blocked the photoresponse attenuation caused by DFP. Atropine did not block the attenuation of photoresponse and membrane resistance caused by physostigmine and carbachol. Calcium-free, high-magnesium sea water, which blocks release of ACh and other neurotransmitters, did not block the attenuation of photoresponse caused by DFP.

The effects of DFP are reversible, and different from those of physostigmine and carbachol. Calcium-free sea water did not block DFP's effects. These results suggest that the effects of DFP on ERP cells are not due simply to a buildup of ACh at synapses subsequent to cholinesterase inhibition. Atropine's block of DFP's effects might be caused by competition for binding sites.

360.9 EVIDENCE OF CHOLINERGIC INVOLVEMENT IN REPRODUCTIVE MECHANISMS IN NORMAL AND IN NEONATALLY ANDROGENIZED FEMALE RATS. M.V. Wagster* and N.W. Pedigo, Jr. (SPON: A.A. Gerall). Dept. of Psychology, Tulane Univ., New Orleans, LA 70118, and Dept. of Pharmacology, Louisiana State University Medical Center, New Orleans, LA 70112.

Previous research has identified the cholinergic system as a critical component for both behavioral and gonadotropic processes of the female rat. In the present study, changes in 3H-quinuclidinyl benzilate (3H-QNB) binding to CNS muscarinic receptors were compared to changes in ovulatory and behavioral mechanisms in the neonatally androgenized female rat. Sprague-Dawley females were injected with 1 ug testosterone propionate (TP), 1000 ug TP, or oil on Day 5 of life. Animals were ovariectomized at approximately 100 days of age. Injections of 3.3 ug of estradiol benzoate (EB), 72 and 48 hours before testing, and .05 mg of progesterone 2-4 hours before testing, were given and lordosis behavior was observed. Three weeks after the final behavioral test, animals were injected with either 3.3 ug of EB or oil at 72 and 48 hours before sacrifice. The incidence of regular estrous cycles and lordosis behavior decreased as a function of increasing dosage of neonatal testosterone. The ovaries from every control animal contained evidence of corpora lutea while those in 1 ug TP and 1000 ug TP had little or no evidence of corpora lutea at the time of ovariectomy. Exposure to 1000 ug TP significantly inhibited lordosis while 1 ug of TP allowed females to continue to exhibit lordosis behavior at a level only slightly below that of control females. Androgenization of the animals significantly reduced binding of 3H-QNB in the ventromedial hypothalamus (VMH). The mean levels of specific 3H-QNB binding expressed as fmol/mg protein were 800.03 for the controls, 737.17 for the 1 mg TP groups, and 583.08 for the 1000 mg TP groups. Furthermore, administration of EB prior to sacrifice significantly decreased specific 3H-QNB binding in VMH. The mean level of specific 3H-QNB binding for the groups receiving estrogen was 632.80 fmol/mg protein and for the groups receiving oil, 781.25 fmol/mg protein. Binding was not altered significantly in the medial preoptic area, the midbrain central gray, or the corpus striatum as a function of neonatal androgen treatment or estrogen administration. Conflicting results were obtained from this report in comparison to other work on the effect of estrogen on muscarinic receptor binding in the VMH. We propose that differences in the timing of EB administration, amount of EB given, and/or preparation of the tissue for the 3H-QNB assay may have been factors in the differences which were obtained. Furthermore, the decrease in muscarinic receptor binding in VMH and the trend for decreased binding in the mPOA as a result of neonatal androgenization may have important implications for the role of the cholinergic receptor in normal age-related declines in female reproductive capability.

360.10 ENHANCED $^{45}Ca$ UPTAKE AND $^{86}Rb$ RELEASE FROM RAT CEREBRAL CORTEX DURING SIMULATED HYPOGLYCEMIA. J.M.Gorell,B.Czarnecki* and S. Hubbell*.Dept.of Neurology,Henry Ford Hospital,Detroit, MI 48202.

To define some ionic mechanisms underlying reported(Gorell et al Soc.Neurosci.,1984)changes in acetylcholine(ACh) release during time- and (glucose)-graded states of simulated hypoglycemia(HG) in vitro,the uptake of $^{45}Ca$ and release of preloaded $^{86}Rb$ were studied.

In $^{45}Ca$ uptake experiments,cerebral cortex(CX) slices from adult male Sprague-Dawley rats were incubated(37°C,15min) in Krebs-$HCO_3$ (K-b) buffer containing either 0.25,0.1,0.05(HG) or 5(control)mM glucose(glc) with constant gassing(95%$O_2$:5%$CO_2$).Following 20,60 or 80 min HG induction,$^{45}Ca$ uptake(10μCi/tube) was measured during a 10 min incubation in either 3 or 60 mM KCl K-b. In $^{86}Rb$ release studies CX slices preloaded with $^{86}Rb$(60μCi/7ml)during a prior 5 mM glc incubation(37°C,45min)were superfused with K-b containing 0.05,0.1, 0.25 or 5 mM glc in 3 mM KCl for 20 or 60 min,followed by 5 min of 60 mM $K^+$-stimulation.

There was a significant increase in $^{45}Ca$ uptake in 3 mM KCl K-b vs. controls during 0.25 mM glc exposure (20 min: 132±7%, n=6,p<.01; 60 min: 177±7%,n=6,p<.001;80 min: 127±5,n=5,p<.001), with 0.1 mM glc (20 min: 134±7%,n=6,p<.001;60 min: 147±5%,n=6,p<.001;80min: 149±6%, n=5,p<.001), and with 0.05 mM glc (20 min: 149±8%,n=6,p<.001; 80 min: 138±3%,n=6,p<.001). A slight decrease in 60 mM KCl-induced $^{45}Ca$ uptake was found with 0.25 mM glc (20 min: 83±2%,n=5,p<.02;60 min: 68 ±3%,n=6,p<.001) with 0.1 mM glc (20 min: 85±2%,n=4,p<.05;60 min: 70 ±2%,n=6,p<.001;80 min: 89±3%,n=6,p<.05), and with 0.05 mM glc (20 min: 75±3%,n=6,p<.05;80 min: 88±4%,n=6,p<.01). At 20 min of HG induction, there was a slight elevation is basal (3 mM KCl) $^{86}Rb$ efflux with 0.05 mM glc (109±1%,n=12,p<.001) and no change from control with either 0.1 or 0.25 mM glc. At 60 min of HG induction, there was a significant rise in basal (3 mM KCl) $^{86}Rb$ efflux with 0.05 mM glc (130±1%,n=18,p<.001), with 0.1 mM glc (122±1%,n=24,p< .001), and with 0.25 mM glc (114±2%,n=30,p<.001). This $^{86}Rb$ release was glc-dependent (correlation coefficient -0.96). $^{86}Rb$ release during 60 mM KCl stimulation was the same in HG and control CX slices.

These observations of a HG induced increase in basal $^{86}Rb$ efflux and $^{45}Ca$ uptake strongly suggest that a state of sustained partial CX slice depolarization exists in HG, resulting in an increased ($^3H$)-ACh release under normal (3 mM KCl) conditions, as reported previously. During KCl stimulation, $^{86}Rb$ efflux and $^{45}Ca$ uptake appear to play less of a role in regulating ACh release during HG since both processes do not act at restrictive levels.

This research was supported by the Fund for Henry Ford Hospital and by the Gossett Fund.

360.11 ETHOXYCHOLINE MUSTARD: A NON-HYDROLYSABLE DERIVATIVE OF ACETYLCHOLINE MUSTARD. E.H.Colhoun*, R.Gregoire* and R.J.Rylett (SPON. C.J.Gibson). Department of Pharmacology and Department of Physiology, University of Western Ontario, London, Canada.

We have shown that the aziridinium ion species of choline mustard (ChM Az) and monoethylcholine mustard (ECM Az) are useful neurochemical probes for investigations relating to the regulation of acetylcholine (ACh) synthesis. In particular, these nitrogen mustard analogues of choline are potent inhibitors of high-affinity choline transport at cholinergic nerve terminals but weak inhibitors of choline acetyltransferase. When administered to rodents both ChM Az and ECM Az produced a hemicholinium-like toxic reaction characteristic of presynaptic cholinergic blockade. We have synthesized and studied the effects of ethoxycholine (ethylethercholine) mustard aziridinium ion (EOCM Az) which differs in chemical structure from acetylcholine insofar that the carbonyl of the ester linkage has been replaced by a methylene group but like the other choline mustards has the strained three membered ring structure with the potential to alkylate nucleophilic centers in biological macromolecules. It was predicted that this molecule could inhibit AChE but would not be a substrate for the enzyme, would be a poor inhibitor of choline transport and could be a ligand for ACh receptors. EOCM Az proved to be a weak inhibitor of synaptosomal choline uptake with a rank order of potency of the compounds tested to be : ChM Az > ECM Az > AChM Az > EOCM Az

( 1 : 2.3 : 27.8 : 400 )

EOCM Az was an agonist at both muscarinic and nicotinic ACh receptors and relative to carbachol it was found to be 13 and 40 times less potent, respectively. In other experiments, alkylation of muscarinic receptor sites in isolated guinea-pig ileum strips by EOCM Az was not detected, however, in homogenates of the strips, evidence was obtained that EOCM Az bound irreversibly to the receptor sites (using [$^3H$]QNB as the ligand). EOCM Az was also found to irreversibly inhibit AChE with evidence of alkylation of the anionic enzyme site. EOCM Az produced signs of acute cholinergic toxicity in mice, similar to that observed for AChM Az, but unlike ChM Az and ECM Az there was no evidence of hemicholinium-like toxicity. This result correlated with the evidence that EOCM Az did not produce presynaptically-mediated blockade of the twitch response in the isolated rat phrenic nerve-diaphragm preparation. Acute $LD_{50}$ values in mice were found to be 10 mg/kg and 128 mg/kg for i.v. and i.p. routes, respectively: evidence for delayed cytotoxicity was obtained at a dose of 80 mg/kg i.p.

360.12 DEPOLARIZATION ENHANCES INHIBITION OF SYNAPTOSOMAL CHOLINE ACETYLTRANSFERASE BY CHOLINE MUSTARD AZIRIDINIUM ION. R.J.Rylett and E.H.Colhoun*. Department of Physiology and Department of Pharmacology, University of Western Ontario, London, Canada.

Depolarization of synaptosomes with potassium or veratridine enhances the velocity of sodium-dependent choline transport. Although the mechanism(s) regulating the velocity of the carrier have not been elucidated, it would appear that either the cytoplasmic acetylcholine (ACh) concentration or the ACh release process may be involved. Previously, we reported (Soc.Neurosc., 10: 1180) that irreversible inhibition of high-affinity choline carriers by choline mustard aziridinium ion (ChM Az) was increased following depolarization of rat brain synaptosomes. This result would indicate that during repolarization of the nerve terminals a greater number of choline carrier binding sites were exposed at the outer membrane surface per unit time. We now report that, in addition to the enhanced inactivation of high-affinity choline carriers by ChM Az during repolarization, irreversible inhibition of synaptosomal choline acetyltransferase (ChAT) activity was increased. Rat forebrain synaptosomes were incubated in Krebs-Ringer (KR) buffer ($K^+$, 5 mM) or high $K^+$-KR ($K^+$, 40 mM) for 10 min at 37°C then exposed to ChM Az (0.9 μM) for 10 min (in regular KR) before $^3H$-choline transport activity was monitored. $^3H$-Choline uptake velocity was increased by 40% in control synaptosomes but was not enhanced in ChM Az-treated synaptosomes; inhibition of $^3H$-choline transport was increased from 46% to 61% in the previously depolarized nerve terminals. Inhibition of synaptosomal ChAT by ChM Az was increased from 17% to 26% by prior $K^+$-depolarization. The omission of sodium from the external medium abolished the depolarization-induced responses. The inactivation of synaptosomal ChAT cannot be easily explained by simple accumulation of ChM Az within the nerve terminals due to the rapid irreversible blockade of choline carrier sites. The correlation between increased inhibition of choline carriers and ChAT suggest a coupling between these two components regulated by neuronal activity.

(Supported by a grant from MRC Canada)

360.13 CHOLINERGIC NEUROPATHOLOGY FOLLOWING INTRACEREBRAL INFUSION OF ETHYLCHOLINE MUSTARD AZIRIDINIUM (AF64A). Susan R. McGurk and Larry L. Butcher. Department of Psychology and Brain Research Institute, University of California, Los Angeles, CA 90024.

Recent studies have indicated that an alkylating analog of choline, AF64A, creates a selective long-term cholinergic hypofunction. Such an effect would be invaluable in the examination of central cholinergic mechanisms. In an effort to evaluate further cytopathological effects of AF64A on cholinergic neurons, the striata or nuclei basalis of 84 adult rats (Sprague-Dawley strain) were stereotaxically and unilaterally injected with this compound. Doses were 0.02, 0.05, 0.1, 0.2, 0.25, 0.4, 0.5, 1.0, 2.0, 2.5, 5.0, 10.0, or 20.0 nmol of AF64A. The vehicle volumes included 0.5, 1.0, 2.0, 5.0, or 10.0 µl of 0.9% saline adjusted to pH 7.4 with NaOH. Control injections were 1.0, 2.0, 2.5, 5.0, or 10.0 µl of the vehicle. Subjects were sacrificed 2, 7, or 14 days post-treatment. The brains were processed subsequently for acetylcholinesterase, NADH-diaphorase, and Nissl substance as detailed in Butcher and Bilezikjian (1975, Eur. J. Pharmacol. 34, 115-125). Histological examination of both the caudate-putamen complex and nucleus basalis revealed gross non-selective tissue damage resulting from 1-20 nmol of AF64A. For the striatum, doses in the range 0.1-0.5 nmol produced minimal non-specific damage with moderate effects on cholinergic indices, while doses below 0.1 nmol did not produce significant neuronal destruction. In the nucleus basalis, doses of 0.1-0.5 nmol produced unacceptable non-selective damage, with neither non-selective tissue damage nor appreciable neuronal pathology resulting from the smallest dose range of 0.02-0.05 nmol of AF64A.

These data indicate marked differences in the cytotoxic effect of AF64A as a function of region infused. They would further suggest that careful evaluations of the parameters of dose, volume of injections, and rate of infusion, as well as of the histopathologic consequences of AF64A, must be performed before the toxin is used in behavioral and physiological studies.

[Support: NS-10928 to L.L.B]

360.14 EFFECTS OF ORGANOPHOSPHATE ANTIDOTES ON BRAIN CHOLINESTERASE ACTIVITY AND ACETYLCHOLINE LEVELS. T.-M. Shih, T. Koviak*, O. Smith*, A. Kaminiskis* and V.R. Jimmerson. Basic Pharm. Br., U.S. Army Med. Res. Inst. of Chem. Def., APG, MD 21010-5425

The toxicity of organophosphate cholinesterase (ChE) inhibitors is attributable to the inhibition of ChE activity and the subsequent elevation of acetylcholine (ACh) levels. Antidotes to these ChE inhibitors may alleviate the toxicity by reducing the degree of ChE inhibition and/or ACh elevation. We examined the effects of several antidotes, anticholinergics, anticonvulsants or oximes, to a potent organophosphate ChE inhibitor, soman, on brain ChE activity and ACh levels. Male rats were injected with atropine sulfate (16 mg/kg, i.m.), atropine methylnitrate (17 mg/kg, i.m.), aprophen (100 and 200 mg/kg, i.m.), diazepam (2.5 and 5.0 mg/kg, i.m.), 2-PAM (43 mg/kg, i.m.), or HI-6 (125 mg/kg, i.p.) in the presence or absence of soman (100 ug/kg, s.c.). Thirty min after injection, animals were killed by decapitation for ChE assay or by focused head microwave for ACh analysis, and brains were dissected into 6 parts: brainstem (B), cortex (C), hippocampus (H), midbrain (M), cerebellum (R), and striatum (S). Soman produced a 60% (S) to 80% (H, C) inhibition of ChE activity. The oximes, 2-PAM or HI-6, were unable to protect against soman-induced brain ChE inhibition, even though HI-6 treatment alone was beneficial in reversing the soman toxicity (Soc. Neurosci. Abstr. 10: 1184, 1984). Neither anticholinergics nor diazepam treatment affected ChE activity in any control brain area. Additionally, neither treatment reversed the ChE depression induced by soman. ACh levels were decreased by atropine sulfate and aprophen in all brain areas except B and R. In contrast, diazepam produced a dose-related increase of ACh in C, M and S. Therefore, the data suggest that atropine sulfate, aprophen, and diazepam changed brain ACh levels by a mechanism not related to ChE reactivation. Soman increased brain ACh levels by 6% (B) to 75% (C, H). Atropine sulfate did not reverse the soman-elevated ACh levels. Methyl atropine and oximes were not effective in modifying brain ACh levels of controls or in reversing the soman-induced ACh elevation. Although the relative ineffectiveness of these antidotes (except HI-6) in protecting rats against soman lethality may be related to their ineffectiveness in reversing the soman-induced brain ChE inhibition and ACh elevation, the observation of the effectiveness of HI-6 does not support such a relationship. Therefore, the measurement of brain regional ChE activity or ACh levels may not be useful in predicting the effectiveness of antidotes to soman poisoning. The study of other brain neurochemical functions of the cholinergic system, such as the turnover rate of ACh or the release of ACh from presynaptic terminals, may serve as a more specific indication of soman intoxication.

360.15 SIGNS OF SOMAN TOXICITY AND BRAIN REGIONAL CHOLINESTERASE ACTIVITY. V. Jimmerson, T.-M. Shih, T. Koviak*, O. Smith*, M. Pannella* and R. Mailman. USAMRICD, Aberdeen Proving Ground, MD 21010 & BSRC, Univ. N. Carolina, Chapel Hill, NC 27514

Soman, a potent organophosphate cholinesterase (ChE) inhibitor, reportedly depresses ChE activity in a dose-related manner in rat brain regions (Transact. Am. Soc. Neurochem., 14: 148, 1983). This relationship has been studied further to correlate inhibition of brain regional ChE activity (BRChE) with observable signs of organophosphate toxicity at a variety of soman doses. This correlation may prove useful in predicting BRChE in animal preparations where such activity cannot be measured directly, e.g., in brain tissue fixed by microwave irradiation. Male albino rats (200-275g) were injected with a single s.c. dose of 0.3, 0.5, 0.6, or 0.7 $LD_{50}$ of soman ($LD_{50}$=110 ug/kg) and were subsequently killed at selected time points. Animals were scored for toxic signs just prior to termination, according to the following "quality of life" (QL) categories: 0=sign free; 1=ataxia, muscle fasciculations and/or licking/chewing behavior; 2=salivation, limb weakness with hindlimb splaying, tremors, jerking and/or convulsions; and 3=moribund with loss of righting reflex. Occasionally, intermediate categories (i.e. $0^+$, $1^+$, $2^+$) were used. Toxic signs could usually be identified within 10 minutes after soman exposure. BRChE was assayed in brainstem (BST), cortex (CTX), hippocampus (HIP), midbrain (MB), cerebellum (CB) and striatum (STR) by the method of Groff et al (Clin. Toxicol., 9: 353, 1976) and is expressed as % of control activity (± standard error). At 0.3 $LD_{50}$ all animals (24/24) were free of signs of intoxication (QL=0). Similarly, at 0.5 $LD_{50}$, virtually all (28/30) animals were sign-free. At 0.3 $LD_{50}$ BRChE was minimally affected and showed 91±2%, 96±2%, 89±2%, 88±1%, 81±2%, and 103±5% of control ChE activity, whereas at 0.5 $LD_{50}$, BRChE was moderately affected and showed 70±3%, 65±3%, 59±4%, 69±3%, 62±4% and 91±2% in BST, CTX, HIP, MB, CB and STR, respectively. However, at 0.6 and 0.7 $LD_{50}$ recognizable signs of toxicity (QL=1 or above) were apparent in 52% (43/82) and 91% (29/32) of the animals, respectively. Furthermore, a correlation between QL and BRChE existed in each brain region examined. The coefficients of correlation (R) were 0.86, 0.77, 0.78, 0.87, 0.83 and 0.94 at 0.6 $LD_{50}$, and 0.70, 0.67, 0.63, 0.69, 0.65 and 0.71 at 0.7 $LD_{50}$ in BST, CTX, HIP, MB, CB and STR, respectively. Data for the 0.6 and 0.7 $LD_{50}$ doses were combined and the R for QL vs. BRChE were 0.82 (BST), 0.72 (CTX), 0.74 (HIP), 0.81 (MB), 0.78 (CB) and 0.84 (STR). Thus, we have demonstrated that in rats acutely exposed to soman at doses greater than 0.5 $LD_{50}$, various signs of intoxication may be observed and, regardless of dose, the magnitude of inhibition of BRChE correlates well with the severity of these recognizable toxic signs.

360.16 SKELETAL MUSCLE MYOPATHY FOLLOWING IN VITRO PYRIDOSTIGMINE EXPOSURE. C.S. Hudson*, D. Hinman* and M. Adler. Dept. of Pharmacol. & Exp. Thera., U of MD Sch. of Med., Balto., MD 21201 and Neurotoxicology Br., USAMRICD, APG, MD 21010.

Ultrastructural abnormalities have been reported in skeletal muscle after exposure to various carbamate and organophosphate cholinestrase inhibitors. The abnormalities appear to result from the consequences of acetylcholine accumulation, and evidence indicates that they are mediated, at least in part, by calcium influx through agonist sensitive endplate channels. The carbamate anticholinesterase agent pyridostigmine is used clinically for the treatment of myasthenia gravis and has been proposed as a pretreatment compound for protection against the toxic effects of organophosphorous cholinesterase inhibitors. Systemic administration of pyridostigmine has recently been shown to produce pathological alterations in rat skeletal muscle involving both pre- and postsynaptic components of the neuromuscular junction. Suggestions have been made that the pathology is dependent upon neurally evoked muscle activity. In order to determine the role of muscle activity on the ultrastructural lesions, we have examined the effects of pyridostigmine bromide under controlled in vitro conditions. Experiments were performed on rat phrenic nerve-diaphargm muscle preparations mounted in a twitch bath in Krebs-Ringer solution at 32°C and gassed with 95% $O_2$ - 5% $CO_2$; pH 7.4. The following stimulation paradigm was employed: (1) no stimulation; (2) indirect 20 Hz, 1 sec every 30 sec; (3) direct 20 Hz, 1 sec every 30 sec; (4) indirect 40/min. The stimulations were carried out for 2 hr in the absence or presence of 2 µM pyridostigmine. The muscles were fixed in 2.5% glutaraldehyde and processed for thin section electron microscopy. The presence of 2 µM pyridostigmine resulted in morphological alterations to the region of the neuromuscular junction regardless of the stimulation pattern employed. Presynaptic mitochondria were frequently swollen in experimental preparations. Pyridostigmine exposure also resulted in structural changes in subjunctional mitochondria ranging from rarefied areas of the matrix to extreme swelling of the organelles. Other subjunctional membrane bound organelles, including the sarcoplasmic reticulum and the nuclear envelope were usually swollen. Examination of the subjunctional sarcomeres revealed supercontraction sometimes to the point of complete disruption of myofibrillar organization. These alterations are similar to those which follow in vivo exposure to pyridostigmine. These results suggest that sustained neuronal activity is not required to produce the morphological alterations associated with pyridostigmine exposure. Supported in part by U.S. Army Contract DAMD-17-83-C-3126 to C.S.H.

360.17 ALUMINUM TOXICITY AND RAT CNS CHOLINERGIC ACTIVITY. Donald J. Connor and Richard S. Jope (Spon: John Monti), University of Alabama, Birmingham, AL 35294.

Recent reports indicate that aluminum is a neurotoxin in humans and animals. In human patients, aluminum has been implicated in the development of dialysis encephalopathy. Animal studies have shown that aluminum toxicity results in cognitive impairment and neuronal abnormalities, including neurofibrillary tangles, decreased synaptic density and dendritic debranching.

The effects of aluminum administration, especially dietary aluminum, on neurotransmission in the central nervous system are poorly understood. Since cholinergic activity is closely associated with learning and memory, we examined the effects of aluminum administration on several parameters of cholinergic function in rat brain. Three administration procedures were used:

1.) Acute dosage: aluminum lactate (600 or 1800 mg/kg body weight) via intragastric intubation.
2.) Subchronic dosage: aluminum lactate (1200 mg/kg body weight) via intragastric intubation on alternate days for a two week period.
3.) Chronic dosage: aluminum citrate ad lib in the drinking water at concentrations of 1% or 3% for 1 and 2 months. A chronic group given 2% aluminum citrate solution ad lib was injected with parathyroid hormone (i.p.) twice weekly for a one month period.

The acute and subchronic groups were sacrificed one, seven and twenty-eight days after intubation. The chronic groups were sacrificed one or twenty-eight days after the last aluminum administration. Several components of cholinergic function were measured in discrete brain regions. Choline acetyltransferase activity was determined in homogenates of striatum, hippocampus and cortex. Acetylcholine synthesis and release was measured in cortical slices using deuterium labelled choline as a tracer and quantitation by gas chromatography/mass spectrometry. The $B_{max}$ and apparent $K_D$ of muscarinic receptors were characterized by binding with tritiated 3-quinuclidinyl benzilate in homogenates of cortex, hippocampus and striatum. High affinity choline transport was measured in synaptosomes from cortex, hippocampus and striatum of chronically treated rats. Each of these processes was also measured in control tissue in the presence of aluminum added in vitro.

There were no significant effects of in vitro aluminum or acute in vivo administration of aluminum on any of these cholinergic processes. There were only minor effects of chronic treatment with aluminum on cholinergic processes.

360.18 αBUNGAROTOXIN NICOTINIC RECEPTOR AND NICOTINE-INDUCED SEIZURES. L.L. Miner*, M.J. Marks* and A.C. COLLINS*. (SPON: D.M. Gilliam). Institute for Behavioral Genetics, University of Colorado, Boulder, CO 80309.

The use of α-bungarotoxin (BTX) as a ligand to measure central nervous system nicotinic receptors has been questioned. The failure of BTX to inhibit neural function in the spinal cord and sympathetic ganglia of various species has led to questions concerning the physiological relevance of the BTX binding site in brain. Recently we have demonstrated a relationship between BTX binding in the hippocampus and sensitivity to nicotine-induced seizures in mice. In a previous study, we demonstrated that C3H/2Ibg mice are more sensitive to nicotine-induced seizures than are DBA/2Ibg mice. In addition, there are also differences in BTX binding in the hippocampus of these two strains, with C3H mice having greater binding. Utilizing a classical F2 and backcross genetic design, we demonstrated that animals which seize when given a 4.0 mg/kg dose of nicotine intraperitoneally (ip) have more BTX binding sites than those animals that do not seize. No differences were observed in $K_d$ or the displacement of BTX by L-nicotine. A genetic correlation, which indicates the extent to which two traits are influenced by the same gene or set of genes, between "seizure sensitivity" (whether an animal seizes or not) and hippocampal BTX binding was estimated (r = 0.21).

In order to obtain a quantitative measure of seizure sensitivity the following experiments were undertaken. Cannulae were implanted in the right jugular veins of 65 ± 10 day old mice from the C3H and DBA parental strains and their derived crosses (F1, F2 and backcrosses). After recovery from surgery, animals were infused with 2.0 mg/kg/min nicotine until a clonic seizure occurred. After the occurrence of a seizure, the animals were sacrificed, brains removed and dissected. Nicotinic receptors were measured with BTX as the ligand in three brain regions: cortex, midbrain and hippocampus. The pattern of inheritance for BTX binding was similar to that observed previously: C3H > F1 x C3H backcross = F2 > F1 = F1 x DBA backcross = DBA. In addition, C3H mice were more sensitive to the seizure inducing effects of nicotine than DBA mice. However, the pattern of inheritance was different from that found previously for mice given nicotine ip. The genetic correlation between hippocampal BTX binding and dose of nicotine received when a seizure occurred was greater (r = 0.32). To test further the relationship between seizure sensitivity and BTX binding in the hippocampus various other inbred strains (C57BL/6Ibg, BALB/cByL, A/Ibg, RIIIS/J, AKR/J and ISBI/Crg1) are being tested.

360.19 CHARACTERIZATION OF A MODEL OF STATUS EPILEPTICUS IN RATS. R. Morrisett, R.S. Jope and O.C. Snead. University of Alabama at Birmingham, Birmingham, AL 35294.

We examined the seizure activity produced in rats by administration of the cholinergic agonist, pilocarpine, both alone and following a low dose of lithium (Honchar et al., Science 220, 327, 1983). Adult, male Sprague-Dawley rats were stereotaxically implanted with cortical and depth electrodes in the dorsal hippocampus, caudate nucleus and basolateral amygdala while under halothane anesthesia. After one week EEG recordings were made with the rats freely moving in heated plexiglass recording chambers.

Generalized convulsive status epilepticus occurred in 100% of rats treated with pilocarpine (30 mg/kg, sc) 24 hr following administration of lithium chloride (3 mEq/kg, i.p.). Signs of peripheral cholinergic stimulation were evident within 5 min of pilocarpine administration. During the next 15-20 min the rats displayed several behavioral automatisms, including wet-dog shakes, grooming, scratching and chewing. Prominent single spike activity appeared 20.3 ± 1.3 (SEM) min after pilocarpine treatment and was always associated with staring behavior. Spike activity rapidly progressed during the next 2-3 min, with rats displaying head bobbing movements, associated with spike trains, followed by rearing and forelimb clonus. The latency to tonic clonic seizure activity and forelimb clonus was 22.4 ± 1.2 min from the time of pilocarpine administration. During a period of 1-2 min the generalized spike activity was separated by intermitant low voltage activity after which the spike trains became continuous. Generalized convulsive status epilepticus occurred in every animal treated with this combination of lithium and pilocarpine. Once status epilepticus did occur, it continued unabated for several hours and resulted in death within 24 hr in 19 out of 20 rats.

By testing the effects of high doses of pilocarpine alone we determined that lithium potentiated the convulsant effect of pilocarpine by over 13-fold. Atropine administered 15 min prior to pilocarpine in lithium treated rats effectively blocked seizure activity.

Since diazepam is considered a drug of choice for treatment of status epilepticus in human patients, we tested its effects on status epilepticus produced by the lithium-pilocarpine treatment. Pretreatment with diazepam (5 mg/kg) totally blocked the development of paroxysmal spike activity and of status epilepticus in all rats tested and all rats survived the experiment. The animal model described here should be useful for the study of the pathogenesis and treatment of generalized convulsive status epilepticus.

360.20 INDUCTION OF A DESYNCHRONIZED (D) SLEEP-LIKE STATE BY CHOLINERGIC AGONISTS DEPENDS UPON MICROINJECTION SITE WITHIN THE PONTINE RETICULAR FORMATION (PRF). H.A.Baghdoyan*, R.W.McCarley and J.A.Hobson. Lab. of Neurophysiology, Harvard Medical School, 74 Fenwood Rd., Boston, MA 02115.

Direct administration of cholinergic agonists into the PRF produces a behavioral state (D-ACh) which is similar to D sleep. The present study demonstrated that: 1) the latency to onset and the total percentage of D-ACh are dependent upon the anatomical site of drug injection within the PRF, and 2) the percentage of D-ACh is correlated with the latency to onset of D-ACh .

Twelve adult, male cats were implanted with chronically indwelling guide tubes aimed at the pontine brainstem and standard polygraphic electrodes for measuring EEG, EOG, EMG, and PGO waves. A total of 41 microinjections of either carbachol (4ug) or a mixture of ACh (5 ug) and neostigmine (20 ug) were made into 20 different pontine sites, and 21 control (saline) injections were made into 11 different sites. Regression analyses were performed using the three dimensional coordinates of each injection site (posterior, vertical and lateral) as independent variables and the percentage and latency of D-ACh as dependent variables.

Following drug administration, the posterior coordinate of the injection site accounted for 31% of the variance in D-ACh latency ($p<0.001$) and 34% of the variance in D-ACh percentage ($p<0.001$). Injections into the more rostral sites (range: 1.8P to 7.2P) produced the shortest latencies and highest percentages. The vertical coordinate of the injection site accounted for 11% of the variance in D-ACh latency ($p<0.05$) and 38% of the variance in D-ACh percentage ($p<0.001$). Injections into the more dorsal sites (range: -5.5 to -10.0) produced the shortest D-ACh latencies and the highest D-ACh percentages. The lateral coordinate of the injection site (range: 0.3 to 1.9) did not have a significant influence on latency or percentage. Following saline injections there was no significant relationship between the anatomical coordinates of the injection site and D latency or D percentage.

The highest D-ACh percentages were significantly correlated with the shortest D-ACh latencies ($r=0.62$, $p<0.001$). Ninety-two percent of drug injection trials which induced D-ACh latencies under 20 min had D-ACh percentages greater than 50%. The relationship between latency and percentage was dose dependent; with low doses it was possible to reduce the latency to onset without increasing the percentage of D-ACh. Following saline injections there was no significant relationship between latency and percentage.

These findings support the hypothesis that D sleep is generated by an anatomically distributed, cholinoceptive neuronal system within the PRF.

360.21 LESIONS OF THE NUCLEUS BASALIS MAGNOCELLULARIS (NBM). BIOCHEMICAL AND BEHAVIORAL STUDIES IN THE RAT. M. Le Moal, W. Mayo* and H. Simon* (SPON : C. Kordon). INSERM U-259 Psychobiologie des Comportements Adaptatifs, rue Camille Saint-Saëns, 33077 Bordeaux, France.

Since the demonstration of the degeneration of cholinergic cells of the NBM in patients suffering from senile dementia of Alzheimer type, these neurons have been subject of growing interest. We have studied in the rat the behavioral consequences of bilateral electrolytic (radio-frequency current) or ibotenic acid (7.5 µg) - (0.5 µl) lesions within the basal forebrain in the NBM nucleus region. Both types of lesions decreased choline acetyl transferase (CAT) activity in the anteromedial prefrontal cortex, in the sensorimotor cortex and in the amygdala. CAT activity was unchanged in the striatum and in the hippocampus. While electrolytic lesions destroyed dopaminergic and noradrenergic fibers innervating the prefrontal cortex region, the ibotenic acid injections spared these neurons and dopamine or noradrenaline were not significantly decreased in the cortex.

Electrolytic and ibotenic lesions led to profound disturbances in spontaneous and learned behaviors. Rats with lesions showed spontaneous locomotor hyperactivity, deficits in the exploratory responses, in feeding and in hoarding behaviors. These results are interpreted in terms of temporo-spatial integrative processing deficits.

Learned behaviors were also impaired as revealed by a poor performance observed in a T-maze, in a 8 arm radial maze and in a water maze. These results suggest perseverative responses and memory disorders.

Taken together, these data suggest that NBM lesions have important functional consequences similar to those generally attributed to hippocampal dysfunction. The specific involvement of cholinergic neurons in these cognitive dysfunctions remains to be elucidated.

## SPECIAL LECTURE

361 SPECIAL LECTURE. PATCH CLAMPING BEYOND NEURONS: ION CHANNELS IN LYMPHOCYTES AND OTHER NON-NEURONAL CELLS. M. Cahalan, University of California, Irvine.

The gigaohm seal patch clamp technique has allowed characterization of ion channels from diverse sources including plants, blood cells, epithelia, and glia. Distinct ion channel types from broadly divergent sources can be recognized on the basis of gating properties, ion selectivity, and pharmacological characterization. Channels that have long been associated with membrane excitability of nerve and muscle have recently been found in blood cells. Within the immune system sodium, calcium, and several types of potassium channels have been discovered. T lymphocytes express predominantly voltage-dependent potassium channels with properties very similar to delayed rectifier potassium channels in nerve cell bodies and skeletal muscle. A basophilic leukemia cell line and macrophages express inward rectifier potassium channels. Delayed rectifier and calcium-activated potassium channels can also be expressed in macrophages. Voltage-dependent sodium channels blockable by tetrodotoxin have been seen in T-lymphocytes, an erythroleukemic cell line and natural killer cells. Calcium channels have been discovered in B-cell hybridomas. In several instances the density of ion channels expressed can be modulated by varying the culture conditions or by stimulating the cells to divide. For example, the surface density of potassium channels in mouse T lymphocytes increases by more than an order of magnitude 24 hours after mitogen stimulation. Potassium channel expression within the T cell lineage also appears to change developmentally. Resting splenic or lymph node mouse T-cells express few potassium channels, while many more are expressed in thymocytes, from which mature T-cells are derived. The potassium channels are required for mitogenic activation. Blocking the channels with a variety of channel blockers inhibits protein synthesis, DNA synthesis, and secretion of T-cell growth factor, interleukin-2. The gating properties of the potassium channel are modulated immediately upon addition of mitogenic lectins, increasing the probability that potassium channels will be open. The possible functional role of channels in secretion, intracellular signalling, and cell division will be discussed.

362 WORKSHOP. ESTROGEN AND THE NIGROSTRIATAL DOPAMINE SYSTEM. J.B. Becker, The University of Michigan (Chairperson); P.J. Bedard, Hospital Enfant Jesus, Quebec City; L.A. Chiodo, Sinai Hospital, Detroit; J.H. Gordon, The Chicago Medical School; R.E. Hruska, SUNY-Buffalo; C.J. VanHartesveldt, University of Florida.

The idea that estrogen can influence neural activity in the hypothalamus and limbic system is now well accepted. In addition, considerable evidence has accumulated to indicate that estrogen modulates neural activity in other areas of the brain. Clinical reports of chorea graviderum and chorea associated with oral contraceptives suggested that neural activity in the basal ganglia could be influenced by ovarian hormones. Subsequent research in nonhuman animals has demonstrated that behavioral indices of nigrostriatal dopamine (DA) activity are profoundly influenced by the ovarian hormones, and by estrogen in particular. In this workshop we will discuss: (1) the variables that influence the effect(s) of estrogen on striatal DA activity, and (2) the mechanism(s) of estrogen's action on the striatal DA system.

Dr. Gordon will show that estrogen has a multiphasic effect on striatal DA receptor sensitivity. There is an initial hyposensitivity that is mimicked by incubating striatal tissue with estradiol, and a delayed hypersensitivity that may be induced by the formation of catechol estrogens from estradiol. Dr. Hruska will discuss the role of prolactin in the estrogen-induced hypersensitivity of postsynaptic striatal DA receptors. In addition, he will present evidence that estrogen produces behavioral effects that are not mediated by estrogen-induced changes in postsynaptic striatal DA receptors or by estrogen-induced release of prolactin.

Dr. Chiodo will describe the effect of estrogen on electrophysiological indices of nigrostriatal DA activity. Estrogen induces a rapid decrease in the spontaneous activity of substantia nigra zona compacta DA cells and this effect is blocked by DA antagonists or the inhibition of protein synthesis. Dr. Becker will present evidence that estrogen potentiates striatal DA release and amphetamine-induced rotational behavior. Dr. VanHartesveldt will present the results from behavioral studies that demonstrate that the direct application of estrogen to the striatum has rapid effects on striatal DA-mediated behaviors. Finally, Dr. Bedard will present the results of experiments investigating the effectiveness of estrogen therapy in the treatment of tardive dyskinesia. He will also discuss evidence that the dose of estrogen administered influences both the behavioral and the neurochemical consequences of estrogen treatment.

The workshop will conclude with a roundtable discussion of the information presented and recommendations for future research in the area.

363 SYMPOSIUM. SENSORY MECHANISMS IN SYMPATHETIC GANGLIA. D.L. Kreulen, Univ. of Arizona (Chairperson); J.H. Szurszewski, Mayo Foundation; M. Schultzberg*. Karolinska Institutet; Z.J. Bosnjak, Med. Col. of Wisconsin; J. Krier, Michigan State Univ.

Studies in recent years have demonstrated gastrointestinal, cardiovascular and pulmonary sensory inputs to ganglion cells in several sympathetic ganglia. Immunohistochemical studies on the localization of neuropeptides have demonstrated that both primary sensory neurons and neurons within the viscera project to some sympathetic ganglia. In this symposium we will present the evidence for the existence of sensory pathways, discuss the role of cholinergic and noncholinergic synaptic transmission in these pathways and discuss the function of peripheral ganglionic reflex arcs in the autonomic control of the viscera.

Joseph Szurszewski will describe the original discovery of peripheral mechanosensory input to abdominal sympathetic ganglia. His studies on the convergence of peripheral synaptic inputs to prevertebral ganglionic neurons revitalized the concept of sympathetic ganglia as peripheral reflex centers.

Marianne Schultzberg will describe the immunohistochemical localization of various neuropeptides in sympathetic ganglia emphasizing their localization in sensory pathways. Peptide-containing nerve fibers project to sympathetic ganglia in primary sensory pathways and in "peripheral sensory pathways" that project from the gastrointestinal tract to abdominal sympathetic ganglia.

Zeljko Bosnjak will discuss sensory mechanisms in thoracic sympathetic ganglia. Recent evidence indicates that these ganglia contain the structural and functional elements necessary for neural integration. In the stellate ganglion, efferent nerve activity can be modified by pulmonary and cardiovascular afferent input providing the substrate for peripheral reflexes in these ganglia.

Jack Krier will discuss the visceral connections of neurons in lumbar paravertebral sympathetic ganglia. Not only do these ganglia provide innervation to the abdominal viscera, but a population of the neurons in the ganglia receive synaptic input from fibers that come from the innervated organs. Synaptic inputs to the ganglia utilize both cholinergic and noncholinergic mechanisms.

David Kreulen will describe the noncholinergic or putative peptidergic sensory pathways from the gastrointestinal tract and mesenteric blood vessels to the abdominal prevertebral ganglia. Activation of mechanosensory inputs by distension of either the intestine or the blood vessels results in slow synaptic potentials. The simultaneous activation of cholinergic and noncholinergic sensory pathways suggests that acetylcholine and peptide neurotransmitters are simultaneously released on to these sympathetic neurons.

## SENSORY SYSTEMS: VISUAL CORTEX V

364.1 FLATTENING CORTEX: AN OPTIMAL COMPUTER ALGORITHM AND COMPARISONS WITH PHYSICAL FLATTENING OF THE OPERCULAR SURFACE OF STRIATE CORTEX. E. Schwartz and B. Merker. Brain Res. NYU Med. Ctr. 550 1st Ave NY NY 10016 and Courant Inst. of Math. Sciences.

Recent progress in functional mapping methods, particularly with respect to striate cortex topography, have extended the precision of measurement to the point where errors introduced by the curvature of the cortical surface should be taken into account. Furthermore, the study of any brain surface in which tangential architectural patterns are of interest would greatly benefit by the availability of workable methods of computer aided anatomical display.

We have developed an algorithm which optimally flattens brain surfaces. The geometric aspect of the 3D brain surface which is optimally preserved is its matrix of inter-point distances. We use a variational (hill-climbing) algorithm, together with an algorithm which obtains minimal geodesic distances (in the brain surface). The result is a (near) isometric mapping of the three dimensional cortical surface into the plane, together with a map of the error introduced in this process.

We illustrate this method with examples of macaque striate cortex, in the form of a three-dimensional computer graphics model reconstructed from serial sections. The 3D cortical model, and its flattened representation are used to generate a map of distance error produced by flattening. This error map will be discussed in the context of the measurements of mean and gaussian curvature of the same tissue surface (Merker and Schwartz, ARVO , 26 :164,1985).

In addition, we obtained measurements of error introduced by physically flattening similar samples of macaque striate cortex. The physical flattening was performed by squeezing unfixed, dissected opercular cortex (with pia removed) between glass slides moved in a micromanipulator assembly. The cortex was marked by a grid of india-ink dots, and movie films were taken as the cortex was pressed and relaxed. Sequential movie frames preserve the relative displacement of grid dots, allowing a map of error introduced in flat mounting to be constructed. These maps will be compared with the results of computer flattening described above.

This joint application of neuroanatomy, image processing, computer solids modeling, and differential geometry has wide applicability. Besides providing an understanding of the errors introduced in flattening cortex, it forms an essential part of the general computer aided characterization of cortical surfaces and their embedded functional architectures.

364.2 COMPUTATIONAL ALGORITHMS FOR THE PRODUCTION OF TWO DIMENSIONAL MAPS OF CEREBRAL CORTEX. G. J. Carman and D. C. Van Essen. California Institute of Technology, Pasadena, CA 91125.

In order to improve upon existing manual techniques for the construction of two dimensional, unfolded representations of the cerebral cortex (Van Essen and Maunsell, J. Comp. Neurol. 191: 255-281, 1980), we are developing a set of computational algorithms which will allow for the production of such maps by computer. Our procedures use regularly spaced histological sections to create a lattice of points which serves as a three-dimensional reference surface. For each point on this reference surface, a corresponding point is created on a two-dimensional map surface in a fashion which preserves topology. A metric of local distortion termed the energy is determined for each point from a comparison of the local geometry on the map with the corresponding geometry on the reference surface. The sum of energies of all points yields a metric of global distortion that is minimized in order to generate an optimal map of the reference surface.

To find this global energy minimum, we subject the map to simulated annealing (Kirkpatrick et al., Science 220: 671-680, 1983). In our implementation of this iterative algorithm, random displacements of points are attempted within the plane of the map. Displacements resulting in a more accurate local geometry (decrease in energy) are always accepted, while those resulting in a less accurate local geometry (increase in energy) are accepted with a probability dependent upon a control parameter termed the temperature. Initially, the temperature is set high to allow positions of points on the map to become randomized. The temperature is then gradually reduced over successive iterations, allowing the points to approach their optimal local geometries and resulting in the emergence of an optimal global conformation of the map.

These procedures have demonstrated their ability to maintain topology while generating minimally distorted two-dimensional maps of three-dimensional mathematical surfaces. We are extending these procedures to the mapping of large regions of visual cortex of the macaque monkey. Although certain aspects of the implementation remain to be developed, the results obtained thus far demonstrate that these algorithms provide a practical means for the computation of unfolded, two-dimensional maps of the cortex. (Supported by NRSA 2 T32 GM07737.)

364.3 PATCHY INTEGRATION OF GENICULATE INPUTS IN CAT LATERAL SUPRASYLVIAN VISUAL CORTEX. C. Lee, J.G. Malpeli and T.G. Weyand. Dept. of Psychology, Univ. of Illinois, Champaign, IL 61820.

We have examined the contributions of two subdivisions of the lateral geniculate body to neuronal activity in cat posteromedial lateral suprasylvian cortex (PLMS). Layer A of the dorsal lateral geniculate nucleus and the medial interlaminar nucleus (MIN) were reversibly inactivated with 115 nl injections of 4 mM cobaltous chloride and 2% lidocaine hydrochloride, respectively. For 105 histologically verified sites in the PMLS of 5 anesthetized, paralyzed cats, we determined the effect on the visually driven activity of single cells and multiple-unit clusters for inactivation of either layer A or the MIN. At 25 sites, both manipulations were done on the same cortical cells.

For inactivation of either layer A or the MIN, the effect on cortical activity was variable, ranging from total elimination of activity to slight enhancement of the visually evoked response. There was a strong tendency for the effects to occur in clusters with a reciprocal relationship between the contributions of layer A and the MIN to cortical activity. For neither layer A nor the MIN were these effects strictly related to cortical layer, suggesting that there are interdigitating columns or patches cutting across layers that are under selective control of individual geniculate subdivisions. We have begun to investigate the effects of inactivating layer C of the lateral geniculate nucleus on the PMLS, and preliminary results indicate that there are also clusters that are strongly dominated by layer C input.

The contribution of layer A to the PMLS is probably mediated by either areas 17 or 18, the main targets of layer A. The projections from areas 17 and 18 to the PMLS arise from supragranular layers (Gilbert and Kelly, J. Comp. Neurol., 163: 81, 1975). Inactivating layer A has little effect on supragranular layers in area 17 (Malpeli, J. Neurophysiol., 49: 595, 1983). On the other hand, we have observed that inactivating layer A does silence many cells in supragranular layers of area 18. Therefore, it is likely that the effects in the PMLS of inactivating layer A are mediated via area 18. We propose that the clusters of layer A dependent cells in PMLS are recipients of the patchy projections from area 18 to PMLS that have been observed anatomically (Symonds and Rosenquist, J. Comp. Neurol., 229: 1, 1984).

Previous work from this laboratory has shown that the contributions of geniculate layer A to cortical activity in area 17 are in general not horizontally clustered but are laminar specific (Malpeli, J. Neurophysiol., 49: 595, 1983). The present results indicate that different areas of visual cortex are organized in a fundamentally different way with respect to their pattern of integrating thalamic inputs. 364.4 RETINOTOPIC ORGANIZATION IN OUTLYING VISUAL AREAS OF CAT CEREBRAL CORTEX AS REVEALED BY ANALYSIS OF CORTICOTECTAL TOPOGRAPHY. C.R. Olson and T.M. Farrell*
Dept. of Psychology, Princeton Univ., Princeton, NJ 08544

The aim of these experiments was to reveal and characterize retinotopic organization in cortical areas projecting to cat superior colliculus. Our approach was to analyze the distribution of cortical cells labeled retrogradely with tracers deposited in the superior colliculus at particular retinotopic loci. We report here the results of four experiments in which one retrograde tracer (nuclear yellow; NY) was placed in medial superior colliculus (at a site representing the superior visual field) and a second tracer (bisbenzimide; Bb) was placed in lateral superior colliculus (at a site representing the inferior visual field).

Within areas 17, 18, 19, 21a, 21b, 20a and 20b, labeling patterns conformed to standard electrophysiological maps: NY and Bb labeled complementary populations of cells, with Bb concentrated in two zones known to represent the lower visual field, one spanning anterior parts of areas 17, 18, 19 and 21a and the second straddling areas 20a and 20b.

Within both banks of the middle suprasylvian sulcus, transported label was present. Cells labeled with NY and Bb formed largely nonoverlapping populations. Cells labeled with Bb (from lower-visual-field colliculus) had a generally more medial location than cells labeled with NY.

In several cortical areas not previously characterized with regard to retinotopy, cells labeled with NY and Bb were largely or partially segregated. In area 7, Bb (the lower-visual-field tracer) was concentrated in the lateral bank of the lateral sulcus and on immediately adjacent gyral cortex, whereas NY-labeling was heaviest on the crown of the suprasylvian gyrus. In the medial frontal eye field, cells labeled with Bb from the lower-field injection were concentrated in two patches on the ventral bank of the cruciate sulcus; NY-labeled cells were distributed in complementary fashion within the sulcus and appeared to extend farther onto the medial face of the frontal pole. In the ectosylvian visual area (EVA), cells labeled with Bb and NY formed a complex system of alternating patches. Segregation of cells labeled with Bb and NY was also observed in a cortical zone encompassing the entire anterior bank of the posterior suprasylvian sulcus and the immediately adjacent cortex on the posterior ectosylvian gyrus.

In summary, by analyzing corticotectal topography with multiple tracers we have revealed previously unsuspected patterns of retinotopic organization in several outlying visual areas of the cat's cerebral cortex.

364.5 VISUAL TOPOGRAPHY OF CORTICAL PROJECTIONS TO MONKEY SUPERIOR COLLICULUS. C.L. Colby and C.R. Olson
Dept. Psychology, Princeton Univ., Princeton, NJ 08544

The superior colliculus (SC) receives input from prestriate visual cortex, the intraparietal and superior temporal sulci and prefrontal cortex. We took advantage of the precise visual topography in the superior colliculus to delineate the organization of the visual field representation in these zones.

Distinguishable retrograde fluorescent tracers were injected into the upper and lower visual field representations in the SC of 3 macaques. The extent and topographic location of each injection were determined by examining the distribution of labeled cells in V1.

In prestriate cortical areas V2, V3, V3A, V4 and PO, substantial retrograde label was observed in layer V. Cells labeled from the upper and lower field colliculus injections were segregated. Within each visual area, the arrangement of labeled cells was consistent with the known retinotopic organization of that area.

In the intraparietal sulcus (IPS), moderate labeling was observed in the lateral bank and sparse labeling in the medial bank. In each bank there was clear segregation of cells labeled from the upper and lower field injections. Very few labeled cells were observed on the convexity of the inferior parietal lobule.

Substantial labeling was observed in the caudal superior temporal sulcus (STS). Area MT, identified in adjacent myelin-stained sections, was heavily labeled in a pattern concordant with its known visual topography. Outside of MT, there was clear segregation of cells labeled from the upper and lower field injections in a number of distinct regions. In the rostral half of STS, labeling was relatively sparse and cells labeled from either of the two injections were largely intermingled.

In prefrontal cortex, there was substantial labeling in a zone encompassing the frontal eye fields and the principal sulcus and extending onto the medial surface. Within the anterior bank of arcuate sulcus, cells labeled from the lower field injection were found in discrete patches confined to the inferior limb, while cells labeled from the upper field injection were distributed throughout both limbs.

These results suggest that there are additional retinotopically organized cortical regions outside of the currently known visual areas.

364.6 DIMENSIONAL ATTENTION EFFECTS IN THE RESPONSES OF V4 NEURONS OF THE MACAQUE MONKEY. Shaul Hochstein and John H.R. Maunsell.
Department of Psychology, M.I.T., Cambridge MA.
present addresses: S.H. Institute of Life Sciences, Hebrew Univ., Jerusalem, Israel; J.H.R.M. Department of Physiology, Univ. of Rochester, Rochester, NY.

When performing a matching task in which a single dimension is varied and other dimensions are fixed, attention must be paid to the variable dimension while other stimulus dimensions may, or even should, be ignored. A considerable improvement in performance is expected if irrelevant dimensions are not discriminated. On the single neuron level, this dimensional attention may correspond to a sharpening of the tuning curve to the attended dimension and a concurrent flattening out of the tuning curves of the irrelevant dimensions. We looked for such attentional effects in V4 neurons of the alert monkey trained to respond to a match in one of two stimulus dimensions: either the color or the orientation of a visual grating stimulus.

Electrophysiological recordings were made from single units in rhesus cortical area V4 during the performance of a sequential visual matching task. The monkey had to respond upon seeing a stimulus which contained the value of a dimension which was also present in a preceding cue presentation. The cue also served to inform the monkey which dimension was to be varied in the subsequent series of stimuli from which the match had to be selected. For example, if the cue was a small red patch, the series of stimulus gratings were of a single orientation but varied in color and the monkey had to respond to the red grating. If the cue was a black and white vertical grating, the series of grating stimuli were of a single color but varied in orientation and the monkey had to respond to the vertical colored grating. In this way it was possible to determine how the response of a neuron to various combinations of orientation and color depended upon the dimension to which the monkey was attending. About 1/3 of the units studied in detail showed strong dependences on dimensional attention. The changes found in the responses were consistent with the hypothesis that tuning curves are generally sharpened to the dimension being attended.

364.7 SELECTIVE ATTENTION GATES VISUAL PROCESSING IN AREA V4 AND THE INFERIOR TEMPORAL CORTEX OF THE MACAQUE. J. Moran* and R. Desimone (SPON: L. Raskin). Laboratory of Neuropsychology, NIMH, Bethesda, MD 20205.

As one moves from V1, though prestriate cortex into inferior temporal (IT) cortex, receptive fields (RFs) increase dramatically in size. Normally, many different stimuli will fall within these large extrastriate RFs, and an IT RF may even encompass an entire scene. How then does the visual system extract information about the properties of individual stimuli at specific locations? Our results indicate that when a monkey attends to a location within the RF of an extrastriate neuron, responses to stimuli at other locations within the RF are greatly attenuated, and, thus, the neuron only communicates the properties of the stimulus at the attended location. This filtering of unwanted information may also explain why we are aware of so few of the stimuli on our retinas at any one time.

The general strategy of the experiment was as follows. While the monkey held a bar and gazed at a fixation spot, a stimulus appeared briefly at one location followed shortly by a second, briefly presented stimulus at the same location. The monkey was rewarded for releasing the bar immediately if the two stimuli matched and for releasing the bar after a fixed delay if they did not match. Two other, irrelevant stimuli were also presented on each trial, each concurrent with one of the stimuli used in the task. For 8 trials the animal attended to the stimuli at one location and then, after a cue, switched its attention to the stimuli at the other location for 8 trials. The location of the animal's attention was repeatedly switched back and forth. Thus, identical sensory conditions were maintained across blocks of 8 trials but the locus of the animal's attention varied.

In two rhesus monkeys 363 cells were recorded from IT cortex, 181 from V4, and 28 from V1. When both attended and ignored stimuli were within the RF of a cell in area V4 or IT cortex, the response of the cell was determined by the attended stimulus; the influence of the unattended stimulus upon the cell was greatly attenuated. For example, if a cell was selective for red stimuli, it would respond well if a red stimulus appeared at an attended location but poorly or not at all if a red stimulus appeared at an ignored location. The RFs of cells in V1 were so small that, when relevant and irrelevant stimuli were placed within them, the monkey could not perform the task, i.e. could not ignore the irrelevant stimuli.

Cells in both V4 and V1 responded the same to a RF stimulus regardless of whether the monkey attended to it or to another stimulus outside the RF. The RFs of cells in IT cortex were too large to position a stimulus outside of them.

364.8 MECHANISMS FOR SELECTIVE ATTENTION IN AREA V4 AND INFERIOR TEMPORAL CORTEX OF THE MACAQUE. R. Desimone and J. Moran.* Laboratory of Neuropsychology, NIMH, Bethesda, MD 20205.

In a companion study we found that when a monkey selectively attends to a location within the receptive field (RF) of a V4 or IT neuron, the responses of the neuron to stimuli at unattended locations within the RF are greatly attenuated or suppressed. In the present study, we investigated the mechanism by which attention gates V4 and IT neural responses and how this mechanism interacts with other non-sensory influences on the cells.

The monkeys performed the same basic task as in the companion study. The results indicate, first, that the suppressive mechanism has a very high spatial resolution. The responses of cells to an ignored stimulus could be suppressed if the latter was separated by as little as 1/3° from the attended stimulus within the RF. Second, the suppressive mechanism does not act chronically to suppress responses to stimuli at ignored locations, but rather is driven or triggered by the onset of the attended stimulus. The visual latency of the suppressive mechanism appeared to be 100 msec in V4, since shorter latency (75-100 msec) responses in V4 to ignored stimuli were unaffected until 100 msec after stimulus onset, at which point they were sharply cut off. Furthermore, if on a given trial the normally attended stimulus was not presented, the response to the normally ignored stimulus was not suppressed. Third, novel events can also negate or switch the suppressive mechanism, as the responses to unexpected stimuli within the RF were not suppressed. Fourth, attention cannot override the silent suppressive surrounds of V4 cells. The responses of V4 cells to a RF stimulus were reduced by a large bar of the same color in the surround, even when the animal attended to the RF stimulus. Fifth, in addition to spatially directed attention, other behavior-related mechanisms influence extrastriate cells. For example, independent of the locus of the animal's attention, many cells gave a small discharge preceding the animal's motor response, even with no stimulus present, and many had reduced activity when the animal was required to delay or withhold its response. It is not yet clear if these cells are the source or recipient of this motor signal, but in either case the signal may play a role in triggering the animal's response.

We suggest that the neurons that suppress extrastriate responses to ignored stimuli are located outside of V4 and IT, that they receive visual inputs either from V4 or in parallel with V4, that it takes at least 100 msec from the onset of a stimulus to suppress extrastriate responses, and that the attention mechanism itself can be switched by novel events. Finally, this mechanism for spatial attention appears to coexist with other behavior-related mechanisms within extrastriate cortex.

364.9 VISUAL SELECTIVE ATTENTION MODIFIES SINGLE UNIT ACTIVITY IN INFERIOR TEMPORAL CORTEX. Hedva Spitzer* and Barry J. Richmond. Laboratory of Neuropsychology, NIMH, Bethesda, 20205.

In the monkey, evoked potentials from inferior temporal (IT) cortex to a particular compound visual stimulus vary in their form depending on which dimension of the stimulus, its color or its shape, is being used by the animal to discriminate that stimulus from another(1). We tested whether such selective attention would alter activity at the neuronal level(2). We recorded from single units in area TE of IT cortex from two adult monkeys while they performed discrimination tasks along two dimensions: shape and texture. In each trial, while the monkey maintained fixation on a spot of light, one of four peripherally located compound visual stimuli was randomly presented on a screen. The stimuli were either squares or circles and had textures of either dots or stripes. If shape was the relevant dimension, the monkey was rewarded for an immediate behavioral response to the onset of one shape, e.g. a circle, and with a delayed behavioral response to the onset of the other, in this case a square, regardless of the texture. Similarly, if the texture was the relevant dimension, the monkey was rewarded for an immediate behavioral response to the onset of one texture, e.g. dots, and with a delayed response to the onset of the other, in this case, stripes, regardless of the shape.

Forty-eight percent (25/52) of the IT neurons recorded thus far responded differently ($p < .05$) to the same compound visual stimulus depending on which of its dimensions the animal was attending to. For each cell, we determined which of the four compound stimuli yielded the largest difference in response between the texture and shape discrimination trials, and which of these two types of trials yielded the larger response. We then identified that feature in the relevant dimension for the compound stimulus and checked whether the second compound stimulus with this same feature also elicited a larger response when the dimension to which it belonged was relevant. Ninety-one percent of IT cells showed this phenomenon. The results demonstrate that neuronal responses of IT cortex to a stimulus are modulated by attention to different aspects of that stimulus.

364.10 TRANSMISSION OF INFORMATION BY NEURONS IN PRIMATE INFERIOR TEMPORAL CORTEX. Barry J. Richmond and Lance M. Optican* (SPON. F. Miles). National Institute of Mental Health and National Eye Institute, NIH, Bethesda, MD 20205.

Lesions of inferior temporal (IT) cortex degrade primate performance in pattern recognition tasks. Single-units in IT cortex show differential responses to various complex patterns (e.g., bars, brushes, faces), which have been characterized by univariate response measures (e.g., spike count). Often, the temporal distribution, as well as the number of spikes, varies in response to different stimuli. We asked if this temporal modulation was carrying information about stimulus parameters.

Shannon's Information Theory can quantify the amount of information transmitted through a neuron by measuring how much a response reduces the uncertainty about which stimulus was presented. We recorded single-units in IT cortex of four rhesus monkeys. To obtain a wide range of responses we presented a set of 128 stimuli based on orthogonal, two-dimensional Walsh functions. While the monkey fixated, the stimuli (each 40 degrees square and centered on the fixation point) were flashed on individually for 400 ms. The spike density, a measure of the response, was defined as the convolution of the spike train with a Gaussian pulse. Spike densities were quantified by principal component (PC) decomposition. The PC's were derived independently for each cell, yet all of the sets of PCs from 21 cells fell (about equally) into just two groups, according to whether the first PC was sustained or transient. (A cell in either group could show a sustained or transient response to an individual stimulus, so the grouping of PCs reflects the characteristics of the neuron's average response to a large number of stimuli.) The coefficients of the first three to four PCs were dependent upon the stimulus (bootstrap test, $p < 0.05$). Hence, the temporal modulation of the spike train, as well as spike count, is determined by stimulus parameters.

To quantify the information transmitted by neurons we measured the responses using either spike count alone (to form a count code), or the first three PCs together (to form a three-dimensional temporal code). Average information transmitted by the count code was $0.43 \pm 0.04$ bits (SE, $N = 21$), and by the temporal code was $0.88 \pm 0.05$ bits. Although the spike count can transmit as much as half the information in the temporal code, the spike count itself is not correlated with information ($r = 0.18 \pm 0.04$). Hence, a multidimensional spatial to temporal transform is needed to completely represent the ability of IT neurons to transmit information about stimulus parameters. Since all the sets of PCs fell into just two groups, we infer that a universal temporal code for representing stimulus features may exist.

364.11 **TWO TOPOGRAPHICALLY ORGANIZED VISUAL AREAS IN VENTRAL EXTRASTRIATE CORTEX OF THE MACAQUE MONKEY.** D. J. Felleman, E. A. DeYoe, and D. C. Van Essen. Division of Biology, California Institute of Technology, Pasadena, CA 91125.

Ventral extrastriate cortex in the macaque contains a large region of cortex sandwiched between area VP posteriorly and the posterior inferotemporal area (PIT) anteriorly. Previous work from this laboratory has shown that at least part of this region receives inputs from ventral V2, but whether it should be considered as part of V4 or as one more separate areas has remained uncertain. To address this issue, we have employed electrophysiological mapping techniques and studies of cortical connections to assess the organization of this region of cortex.

We mapped the representation of visual space in cortex anterior to VP in both the inferior occipital (IOS) and occipito-temporal (OTS) sulci in 31 microelectrode penetrations in 4 hemispheres, covering a range of eccentricities from 1-20 degrees. The results indicate that there are two topographically organized representations of the superior contralateral quadrant in the cortex anterior to VP. The first region adjoins VP along the representation of the superior vertical meridian. Provisionally, we have named this region VA, the ventral anterior area, and suggest that it is probably distinct from V4. In front of it is a second region which shares a representation of the horizontal meridian with VA and contains a representation of the superior vertical meridian at or near the posterior border of PIT. Provisionally, we have termed this region, PT, the posterior temporal visual area. PT may correspond to the region of cortex identified as TEO by von Bonin and Bailey on the basis of cortical architecture. Each region has central fields located laterally, in the IOS, and peripheral fields located medially, in the OTS.

We used a double retrograde labelling technique to study the cortical connections of VA and V4 in the same hemisphere. Both injections produced clear stripe-like labelling patterns in V2 which were generally oriented orthogonal to the V1 border. In addition to connections to several well known visual areas, these injections produced interdigitating patterns of label in the intraparietal sulcus and across large portions of posterior inferotemporal cortex. Both the VA and V4 injections produced widely separated foci of label in PIT, suggesting that it contains multiple subdivisions. Furthermore, these patches of label were almost exclusively non-overlapping, which suggests a crude topographic organization within PIT. This result contrasts with previous single unit recordings from PIT in which most receptive fields included both upper and lower fields.

Supported by NIH grant EY02091.

364.12 DIVERGENT SIGNALS ENCODED BY NEURONS IN EXTRASTRIATE AREAS MT AND MST DURING SMOOTH PURSUIT EYE MOVEMENTS. R.H. Wurtz and W.T. Newsome. Laboratory of Sensorimotor Research, National Eye Institute, Bethesda, MD, 20205, and Dept. of Neurobiology & Behavior, SUNY at Stony Brook, Stony Brook, NY 11794.

We have studied the responses of single neurons in extrastriate areas MT and MST of monkey visual cortex during smooth pursuit eye movements. Both areas contain visually responsive neurons that are selective for the direction of motion of stimuli within their receptive fields. We have previously reported that some neurons in MST also discharge during foveal pursuit of a small, moving target in an otherwise dark room. The responses of such "tracking neurons" during pursuit cannot be explained by their passive visual properties and are therefore likely to be related to some aspect of the eye movement itself. In contrast, we observed no pursuit-related responses for MT neurons with eccentric receptive fields. In recent experiments, however, we have found that neurons within the foveal representation of MT often respond during pursuit of visual targets moving in a restricted range of directions. Such responses could be due to the "slip" motion of the target on the foveal receptive field that occurs when the speed of the pursuit eye movement is imperfectly matched to the speed of the target, or the responses could be related to some aspect of the eye movement itself. To test these alternatives, we studied the responses of foveal MT neurons and of tracking cells in MST while the monkey pursued an image that had been stabilized on the retina so as to eliminate target "slip".

Rhesus monkeys were trained to pursue small foveal targets moving at $16^{o}$/sec across a tangent screen. The monkeys were rewarded for keeping their eyes within an electronically defined window centered on the target. A trial began with a 600 msec interval of normal pursuit, and the target was then stabilized on the retina by using the monkey's eye position (measured with a magnetic search coil) to drive the pursuit target. The monkey pursued the target in this "open-loop" condition for 800 msec, and then normal pursuit conditions were restored for 400 msec before the trial was terminated. We found that the large majority of neurons in foveal MT ceased responding during the open-loop interval although they gave vigorous bursts during the intervals of normal pursuit. In contrast, tracking cells in MST responded during both conditions. These results suggest that neurons in foveal MT may encode the slip of the visual target during pursuit - information that may be useful in adjusting the gain of the pursuit movement. Tracking neurons in MST, on the other hand, encode a different aspect of the pursuit eye movement, possibly providing an internal representation of eye velocity during pursuit.

364.13 REMOVAL OF STRIATE CORTEX DOES NOT ABOLISH RESPONSIVENESS OF NEURONS IN VISUAL AREA MT OF THE MACAQUE. H.R. Rodman*, C.G. Gross, and T.D. Albright. Dept. of Psychology, Princeton Univ., Princeton, NJ 08544.

Area MT receives strong projections from striate cortex and from V2, which is dependent upon striate for visual responsiveness. Thus, the visual properties of MT neurons have been thought to reflect the further processing of its striate input. However, MT also receives inputs from other visual cortical areas and from the superior colliculus via the pulvinar. We report here that striate removal or inactivation does not abolish the responsiveness, direction selectivity or binocularity of the majority of MT neurons.

The central representation in striate cortex was removed unilaterally in one animal and bilaterally in a second. Six weeks later, repeated recording sessions were begun. Animals were immobilized and anesthetized with $N_2O$. Over 200 single- and multi-units in MT were tested for responsiveness and direction selectivity using spots and slits of light and dark edges. Within the portion of MT visuotopically correspondent with the striate lesion, responses were frequently weak and single neurons difficult to isolate. Nonetheless, over two-thirds of the units gave clear responses to an optimal visual stimulus. These units showed direction preferences and binocular responses similar to those found in the normal animal. Responses in portions of MT not representing the affected part of the visual field were essentially normal.

In the unilateral case, within the region corresponding to the striate lesion, most of the MT neurons with completely normal properties had receptive fields bordering or overlapping the vertical meridian. This phenomenon was not seen in the bilaterally lesioned animal, suggesting, in the unilateral case, a functional input from the contralateral (intact) striate cortex, possibly via the contralateral MT.

In a third animal, single unit recordings were made in MT during reversible cooling of dorsolateral striate cortex. The results were in agreement with those of the lesion experiments.

In summary, MT seems to contain a heterogeneous population of cells with respect to functional dependence on striate cortex, with many MT neurons retaining their properties in the absence of striate input. Recordings made in one animal indicate that adding a superior colliculus lesion to the striate lesion eliminates the residual visual responsiveness in MT in the portion of the visual field representation covered by both lesions. These results suggest that MT, and possibly other extrastriate areas as well, operate at least partially in parallel with striate cortex.

365.1 CYTOARCHITECTURE OF THE OPOSSUM SUBSTANTIA NIGRA PARS LATERALIS. T.P. Ma and J.C. Hazlett. Department of Anatomy, Wayne State University, Detroit, MI 48201.

The pars lateralis (SNl) was examined at the light microscopic level using Nissl, Golgi, Bodian reduced-silver, and HRP-labeled material. In the adult opossum, SNl is approximately 3.5 mm in length and extends from just below the level of the oculomotor nerve to mid-mammillary levels. Caudally this sub-nucleus caps the medial aspect of the dorsolateral edge of the cerebral peduncle. Farther rostrally, SNl expands and covers the lateral third of the peduncle. It terminates as a small scattering of cells over the middle third of this fiber bundle. Throughout most of its course, SNl is separated from the pars reticulata by a cell free zone. Neurons within the SNl can be divided into three groups on the basis of cell size. Small cells (less than 18 um long axis) comprise less than 5 percent of the total population. Medium-large cells (18-35 um long axis) account for about 85%, while large cells (greater than 35 um long axis) comprise the remainder. After injections of HRP into the tectum, striatum, and thalamus, measurements of retrogradely labeled SNl cells suggest that neurons in all three size groups project to these these targets. The somata of SNl neurons vary in shape from fusiform to polygonal and most give rise to several robust dendrites. These usually divide into second order branches within 50 um of the cell body. The secondary dendrites are often quite long and are usually sparsely branched. The primary axis for the dendrites is in the dorsolateral and ventromedial direction. However, a significant number of dendrites penetrate into the underlying cerebral peduncle. A few branches are also seen extending into the overlying tegmentum. The cell bodies and dendrites of well-impregnated neurons exhibit numerous filiform and sessile spines with occassional pedunculated appendages. This latter type is more prominent distally. Although some cells have axon initial segments emerging from the soma, most arise from proximal portions of primary dendrites. Examination of Golgi-impregnated material suggests that there are two types of fibers in SNl. The first type is thin, has varicosities along its length, and usually terminates in a single swelling. The second type is thicker and gives off terminal bulbs. These bulbs are connected to the principal axon by thin stalks and often form flower spray-like terminal arborizations.

365.2 CORRELATIVE LIGHT AND ELECTRON MICROSCOPY OF HRP STAINED NIGRO-STRIATAL NEURONS LOCALIZED IN PARS RETICULATA OF THE RAT SUBSTANTIA NIGRA. I. Grofova*, B.M. Spann* and H. Kita+. Depts. of Anatomy, Michigan State Univ., E. Lansing, MI. 48824 and +Univ. of Tennessee, Memphis, TN. 38163.

Retrograde tracing studies have established that the nigrostriatal tract originates not only in pars compacta(SNC) but also in pars reticulata(SNR) of the substantia nigra. Nigrostriatal neurons are scattered throughout SNR and they are particularly numerous posteromedially. While some of these cells may give rise to non-dopaminergic nigrostriatal connection, it seems that the majority are dopaminergic(van der Kooy,D. et al.,Neuroscience,6:345-357, 1981).

In the course of experiments aiming at physiological identification and intracellular labeling of nigrostriatal neurons, two of the recovered cells were localized in SNR. One cell was antidromically activated from the striatum with a latency longer than 7ms suggesting that it was a dopaminergic neuron. The other cell was not physiologically identified but exhibited similar morphological features and was located in the posteromedial SNR. Axons of both cells were followed into the medial forebrain bundle.

The nigrostriatal SNR neurons were morphologically distinct from previously described SNR projection neurons(Grofova,I. et al., J. comp.Neurol.,208:352-368,1982). While several of the dendrites remained in SNR and made up a large dendritic field similar to that of nigrothalamic and nigrotectal cells, a thick dendritic stem coursed dorsally and contributed together with its varicose branches to the dendritic lattice of SNC. Furthermore, spines were frequent on proximal dendrites and a few were seen on the somata. The most striking difference concerned the axons which were delicate, did not collateralized and exhibited fairly regularly spaced swellings suggesting that they may establish synapses en passant. Electron microscopic examination revealed that the axons were unmyelinated during their intranigral course. Thin axonal portions averaged 0.4um in diameter and contained parallel arrays of microtubules and vesicular organelles resembling portions of SER. They were occasionally found in close apposition with large dendrites. Axonal varicosities measured up to 1.7μm in width and 3.5μm in length and contained numerous mitochondria but no accumulation of synaptic vesicles. The most common type of nigral boutons which contain densely packed large ovoid synaptic vesicles and are generally believed to represent terminals of striatal fibers were occasionally found in synaptic contacts with the distended portions of axon.

These observations offer the first positive ultrastructural identification of nigrostriatal SNR cells and axons and suggest that the axonal varicosities do not form structurally defined synapses but may be postsynaptic to presumed striatal terminals.

365.3 POSTNATAL ORGANIZATION OF THE NIGROSTRIATAL SYSTEM: ANALYSIS BY RETROGRADE TRANSPORT STUDIES AND FLUORESCENCE ACTIVATED CELL SORTING. J.J. Lopez-Lozano, D.M. Gash, J.F. Leary* and M.F.D. Notter. Departments of Anatomy and Pathology, University of Rochester, Rochester, NY 14642.

The mesostriatal system, its cells of origin and pathways, and in particular the nigrostriatal system, has been described by using anatomical and chemical techniques. However, these previous studies did not provide a complete description of the prenatal development of the system. In particular, in neonatal animals, the morpho-histochemical characteristics and distribution of its neurons, and the projections of its fibers remain partially unknown. The present experiment examines this problem by (1) retrograde tracing studies and by (2) flow cytometry and cell sorting techniques. Long-Evans rats 2-, 5-, and 8-days old received unilateral or bilateral injections into the caudate-putamen with one or two of the following markers: HRP-WGA 1% (0.2-0.6 ul), FITC-Succynil-WGA 1% (0.3-0.6 ul), PI 1% (0.3-0.5 ul), or Doxorubicin 0.5-2.5% (0.3-0.5 ul). The appropriate coordinates were calculated using a stereotaxic atlas of the neonatal animals developed by one of us (J.J.L.L.). Following a survival time of 24 hr the neonatal rats were perfused intracardially with an appropriate fixative. The study of the retrograde labelled cells, with special reference to the ventral mesencephalic region, was made by means of: using a HRP-TMB reaction, immunohistochemistry of WGA (WGA-ICC), and/or by means of fluorescence microscopy. A combination of Tyrosine Hydroxylase immunohistochemistry (TH-ICC) and WGA-ICC was used to examine the existence and percent of the retrogradely double-labelled dopamine cells in several animals. After demonstrating the localization, topographical distribution, and histochemical characteristics of the mesencephalic labelled cells, a second group of animals was bilaterally injected with FITC-SWGA into the caudate-putamen. Then, they were decapitated and the ventral mesencephalon, free of meninges, was quickly dissected out, minced and placed in a cold Ca-Mg free buffer. Tissue was dispersed providing a viability better than 89% and minimum debris. The single cell suspension was later: 1) studied by fluorescence microscopy, TH-ICC, and Neuron-Specific-Enolase-ICC (NSE-ICC); 2) cultured and examined with the cited techniques, and/or; 3) analyzed by Multiparameter Flow Cytometry and cell sorter techniques; and 4) sorted on two parameters according to specific windows determined by multiparameter data analysis as compared to a control group (single suspension of mesencephalic cells with no fluorescence tracer). NSE-ICC and TH-ICC confirmed that the sorted cells were neurons and that a high percent of them contained TH. The pattern of organization of the mesostriatal system including topographic distribution and interhemispheric projections resembled that seen in the adult animal. In addition, the procedures are presently being employed to sort select populations of mesencephalic cells for in vitro and in vivo studies.

365.4 LOCALIZATION OF GABA IMMUNOREACTIVITY IN MONKEY SUBSTANTIA NIGRA: A LIGHT AND ELECTRON MICROSCOPIC STUDY. G.R. Holstein, T. Pasik, P. Pasik and J. Hamori*. Depts. of Neurology and Anatomy, Mount Sinai Sch. Med., CUNY, New York, N.Y. 10029, and 1st Dept. of Anatomy, Semmelweis Univ. Sch. Med., 1450 Budapest, Hungary.

Histochemical, biochemical, anatomical and electrophysiological studies have suggested the presence of GABA or GAD in substantia nigra (SN), localized primarily in axon terminals, probably originating from Spiny I neostriatal neurons. Other possible sources of GABAminergic input to SN, e.g. from globus pallidus and nucleus accumbens septi, have also been described. To directly demonstrate and characterize the GABAminergic elements present in primate SN, an antiserum of known specificity (Hodgson et al., J. Histochem. Cytochem., 1985), raised against a GABA-BSA conjugate, was utilized in an immunocytochemical procedure. Vibratome 50 μm coronal sections from two adolescent monkeys (1 M. mulatta, 1 M. fascicularis and one 4-week-old monkey (M. mulatta) were incubated in 1 1:1200 dilution of antiserum and further processed with the PAP technique. No reaction product was visible in control sections.

Light microscopy revealed the presence of reaction product in fibers of both pars compacta (pc) and pars reticulata (pr). Small caliber (0.4-2.0 μm dia.) GABAminergic processes traversed the crus cerebri ventrodorsally, entered pr from the ventral aspect, and branched profusely within the nucleus. Immunoreactive fibers were seen surrounding unreacted neuronal somata. Varicosities (1.0-2.1 μm dia.) were apparent along the labeled axons, spaced 1-2μm apart. In pr, single fibers could be followed up to 45 μm through the neuropil. In contrast, the immunostained processes in pc could only be traced over shorter distances; these fibers were finer, more varicose, and formed a less dense plexus. In addition, polygonal or fusiform shaped immunoreactive neurons were observed in both regions.

Using serial section electron microscopy, small immunoreactive boutons with small dark mitochondria and densely packed vesicles (50 nm dia.) were apparent throughout pc and pr. These labeled profiles were abundantly represented, and formed synapses with large and medium size, pale dendritic elements. Such contacts were characterized by symmetrical membrane thickenings with dense projections visible in the presynaptic profile. A series of immunostained boutons could be seen arranged side-by-side, impinging on large pale dendrites visible in longitudinal and cross section.

These observations provide direct positive evidence for the presence and localization of GABAminergic fibers and terminals in monkey SN. Fibers are present in both pr and pc and, based on morphologic criteria, appear to mediate inhibition. The large pale dendritic elements observed postsynaptically may well represent the processes of dopaminergic SN neurons.

365.5 GLUTAMIC ACID DECARBOXYLASE AND ENKEPHALIN IMMUNOREACTIVE AXONS IN THE NEOSTRIATUM SYNAPSE WITH STRIATONIGRAL NEURONS. N. Aronin, K. Chase* and M. DiFiglia. Depts of Medicine, U. Mass. Med. Ctr. Worcester, MA 01605, and Neurology, Massachusetts General Hospital, Boston MA 02114.

There is evidence that neostriatal glutamic acid decarboxylase (GAD) and immunoreactive enkephalins are located in medium spiny neurons, which have long efferent axons with collaterals that terminate locally. Since numerous GAD and enkephalin-containing axons form synapses in the neostriatum, their synaptic relationship with striatofugal cells seemed likely and was examined in the present study.

Sprague-Dawley rats (n=3) were anesthetized and the substantia nigra was pressure injected with 0.5 µl of 30% WGA-HRP (Sigma). After 20 h the animals were perfused with cold buffered 4% paraformaldehyde/0.1% glutaraldehyde. To identify the retrogradely-labeled cells, tissue sections of caudate were incubated serially with $CoCl_2$ and 3',3'-diaminobenzidine containing 0.01% $H_2O_2$. Sections were immediately processed by the PAP method, using antisera directed to GAD (from J-Y Wu, Hershey, PA) and leu-enkephalin (from E. Webber, Portland, OR). Control sections, in which primary antisera were omitted or the leu-enkephalin antiserum was preabsorbed with leu-enkephalin (50 µg/ml), lacked specific staining. At the light microscopic level regions of the caudate containing a high density of retrogradely-labeled cells (marked by large reaction granules in their cytoplasm) and immunoreactive axon terminals, were selected for electron microscopic study.

At the ultrastructural level retrogradely labeled cells were of medium size with unindented nuclei and exhibited numerous electron dense bodies in their cytoplasm. Dense granules were also present in primary and secondary dendrites. Immunoreactive GAD or enkephalin containing axons terminals were identified by the presence of a dense precipitate of peroxidase reaction product in the axoplasm and on the membranes of vesicles. Many of the immunoreactive GAD and enkephalinergic boutons formed symmetric synapses with retrogradely-labeled somata and dendrites. Frequently in single sections two or three immunoreactive GAD or leu-enkephalin axon terminals synapsed with the same striatofugal projection neuron.

GABA and enkephalins are thought to have inhibitory roles in the basal ganglia and to influence neurons in the nigra directly via axon terminals of striatofugal projection cells. Present findings show that GABA and enkephalins may also affect nigral function indirectly in the neostriatum via monosynaptic contacts with striatonigral neurons. Supported by NIH grants AM-01126 (NA) and NS 16367(MD).

365.6 STRIO-NIGRAL VERSUS INTRINSIC GABA-ERGIC TERMINALS AND THEIR POSTSYNAPTIC PARTNERS IN RAT SUBSTANTIA NIGRA. C.Nitsch*, W.H.Oertel and R.Riesenberg* (SPON: European Neuroscience Association). Anatomical Institute, University of Munich, D-8000 München 2, F.R.Germany.

In an attempt to reveal the synaptic interrelation between GABAergic boutons of various origin and GABAergic neurons in rat substantia nigra (SN) pars reticulata, different forebrain lesions were performed, i.e. ibotenic acid injections in striatum, hemilesion at the level of the globus pallidus and of the frontal pole of SN. After 2 to 7 days survival, vibratome sections of SN were treated with an antiserum against glutamic acid decarboxylase (GAD) as marker for GABAergic elements. Immunoreaction was visualized with the PAP method. The sections were further processed for ultrastructural analysis.

After hemilesion at the level of the globus pallidus, degenerated boutons were found in contact with GAD-immunoreactive nerve cell bodies and their dendrites. In the same area, contacts with non-immunoreactive dendrites were also encountered. On the other hand, an appreciable number of GAD-containing boutons were preserved, in synaptic contact with both, GAD-positive and GAD-negative neuronal elements. After circumscribed lesions in the striatum, the majority of degenerated boutons contacted GAD-immunoreactive postsynaptic elements. Few degenerated boutons were found on GAD-negative dendrites, suggesting that a minority of the striatal input may terminate on dopaminergic projection neurons. However, even after complete prenigral interruption of all forebrain input, numerous GAD-immunoreactive boutons in contact with GAD-positive and GAD-negative neuronal elements were preserved. This result provides strong evidence for the existence of an elaborate GABAergic innervation intrinsic to SN.

It is concluded that the strionigral pathway communicates with the nigrostriatal projection neurons mainly via GABAergic interposal.

365.7 EVIDENCE FOR TRANSNEURONAL DEGENERATION OF DOPAMINE NEURONS IN THE SUBSTANTIA NIGRA OF THE RAT BY DESTRUCTION OF NEURONS OF CAUDATE NUCLEUS. M. Saji* and D.J. Reis (SPON: S.F. Morrison). Lab. of Neurobiology, Cornell Univ. Med. Coll., New York, NY 10021.

We sought to establish if selective destruction of intrinsic neurons of the caudate nucleus (CN), the principal target of dopaminergic (DA) neurons of the substantia nigra pars compacta (SNc) and the source of neurons of the striatonigral tract would affect the integrity of DA neurons of SNc. Ibotenic acid (IBO), an excitotoxin destroying neurons but not fibers of passage, was stereotaxically injected in three sites (4ug/0.4ul) of the head and body of CN in anesthetized rats. At various days, the rats were killed. Sections were stained with antibodies to tyrosine hydroxylase (TH) or thionine and analyzed quantitatively. IBO resulted in a 80-90% loss of neurons in CN by 10d. Associated was complete loss of anterograde transport of HRP-WGA in terminals of the striatonigral tract from CN to SN, pars reticulata (SNr). Within 10 days there was a increase (greater than 200%) in glia in the SNr peaking at 14d at 260% of the unchanged contralateral SNr. Gliosis of the SNc increased very modestly beginning by 21d to maximum (150%) at 30d control. Shrinkage of some DA dendrites in SNr appeared between 5-10d with a progressive reduction in size of DA neurons in SN. The volume of SNr was reduced to 73% by d10 and to 51% between d30-60. Despite atrophy the number of SNc neurons which could still retrogradely transport HRP-WGA injected into CN was unchanged. Between d30-60 16% of the DA neurons in SNc died.

We compared the IBO-initiated changes to those of the retrograde reaction elicited by axotomy of DA neurons produced by microinjection of 6-OHDA into three sites of the CN (4 ug/0.4 ul). Axotomy resulted in a rapid loss of TH immunoreactivity in CN by 75-90% by 7d indicating axonal degeneration. The numbers of CN neurons was unchanged. Seventy percent of DA neurons in SNc began to die by 7d postlesion. By d21 70% of DA neurons were dead. Retrograde transport of HRP-WGA from CN to SNc was almost eliminated but anterograde transport to SNr was unchanged. A modest gliosis was greater in SNc than in SNr (maximal SNc 190 vs. 160% in SNr) between 14 and 21d. The volume of SNr was unchanged until 60d postlesion. We conclude: destruction of neurons in CN by IBO results in rapid dendritic shrinkage, reduction in the volume of SNr and delayed loss of DA neurons in SN associated with marked gliosis in SNr with little in SNc. Such changes differ qualitatively and quantitatively from retrograde cell loss produced by axotomy. It is most probable that the loss of TH neurons represents anterograde transneuronal degeneration of DA neurons produced by loss of striatonigral projection.

365.8 NEUROCHEMICAL CORRELATES OF TRANSNEURONAL CELL LOSS OF DOPAMINERGIC NEURONS OF SUBSTANTIA NIGRA. J.I. Woo*, M. Saji*, S.P. Arneric and D.J. Reis (SPON: A.B. Judd). Lab. of Neurobiology, Cornell Univ. Med. Coll., New York, NY 10021.

It has been proposed that destruction of intrinsic neurons of the caudate nucleus (CN) by neurotoxins such as ibotenic acid (IBO) destroys local neurons while preserving innervating fibers of dopamine (DA), neurons of the substantia nigra (SN). We have recently found that such treatment results, after a delay of about 1 m, in progressive shrinkage of dendrites, neuronal atrophy and death of some DA neurons in the SN. Such changes contrast with the rapid and more extensive loss of DA neurons produced by axotomy (Saji et al., this volume), and have been interpreted as reflecting anterograde transneuronal degeneration of DA neurons by lesions of striato-nigral projection. We sought to characterize the associated biochemical changes in CN and SN produced by microinjection of IBO into the CN and to contrast these with changes produced by axotomy elicited by local injection of 6-OHDA into the CN.

The activities of glutamic acid decarboxylase (GAD), choline acetyltransferase (CAT) and tyrosine hydroxylase (TH), markers of GABAergic, cholinergic and dopaminergic neurons, respectively, were measured in CN and SN at various days after lesions. The sodium-dependent uptake of $^3$H-DA into terminals of the CN was also measured. IBO was microinjected into three sites of the head and body of the CN (3.0ug/0.3ul). Groups of 5-8 rats were killed at various days thereafter and CN and SN removed by micropunches. CN. In the ipsilateral CN, IBO produced a rapid reduction to 35% (n=5-8, $p \leq 0.01$) of CAT activity by 48 hrs with a more gradual decline in GAD activity (to 34%, n=5-8, $p < 0.001$) by 8d. TH acitivity increased transiently by 72h and recovered by 4d. However, between 21-50d it progressively declined to 60-75% of control. $^3$H-DA uptake, unchanged at first, gradually declined after d21 reaching 34% of control by d56 (n=5, $p < 0.001$). SN. In ipsilateral SN, GAD activity declined to 56% by d14. TH activity was unchanged.

In comparison, axotomy of DA neurons produced by 6-OHDA differed: CN. By 8d in pisilateral CN, TH was reduced to 15%, CAT increased by 34% and GAD was unchanged ($p < 0.001$). At 4w, TH remained reduced while CAT and GAD returned to control. SN. The enzymes were unchanged by 8d in SN. By 4w, TH activity was reduced to 54% of control.

These results, taken with the morphological data (see Saji et al., this volume) indicate that destruction of intrinsic neurons of the CN by IBO acutely produces rapid loss of intrinsic GABAergic and cholinergic neurons, with the projections of the GABA neurons degenerating at a slower rate, and with preservation of DA terminals in CN. However, after a delay of many weeks, there is a gradual loss of DA terminals in the CN reflecting the delayed atrophy and death of DA neurons of SN. The delayed degeneration differs qualitatively and quantitatively from that of the retrograde reaction and are consistent with an anterograde transneuronal degeneration of DA neurons consequent to loss of innervation from the striato-nigral tract.

365.9 LOCALIZATION OF CALCIUM BINDING PROTEIN IN STRIATONIGRAL AND NIGROSTRIATAL SYSTEMS IN THE RAT AND MONKEY.
C.R. Gerfen, K.G. Baimbridge† and J.J. Miller†, Laboratory of Neurophysiology, NIMH, Bethesda, MD and †Dept. of Physiology, University of British Columbia, Vancouver, BC, Canada.

Two distinct striatonigral projection systems originate from the "patch" and "matrix" compartments of the striatum (Gerfen, Nature 311:461,1984). The striatal patches project to dopaminergic neurons in the substantia nigra whereas the matrix projection is distributed to nondopaminergic nigral neurons. The present study shows that antisera to calcium binding protein (CaBP) isolated from human brain specifically labels the striatonigral neurons in the matrix compartment and is nearly absent in the opiate receptor-rich patches in the brains of both monkeys and rats. Nearly all projection neurons in the ventromedial three-fourths of the striatal matrix are labeled for CaBP, as are fibers and terminals that correspond to the known distribution of striatal efferents. Thus, CaBP marks nearly the entire projection system from the striatal matrix and shows that such nigral afferents are densely distributed in the pars reticulata and avoid areas that contain dopaminergic cells labeled for tyrosine hydroxylase-immunoreactivity (TH). This pattern is particularly striking in the monkey substantia nigra in which there are many areas of the pars reticulata containing dopaminergic cells that show a clear absence of CaBP terminal labeling. The localization of CaBP to the matrix-striatonigral projection system is in marked contrast to the distribution of peptide markers of the patch-striatonigral systems that target nigral dopaminergic cells.

The nigrostriatal system has also been shown to be organized in terms of the striatal compartments (Gerfen, Neurosci. Abstr. 10:9, 1984). Dopaminergic projections from the ventral tegmental area (VTA) selectively innervate the striatal matrix. The subtantia nigra contains mixed types of nigrostriatal neurons, some dopaminergic neurons project to the matrix whereas others project to the patches, and nearly all nondopaminergic nigrostriatal neurons project to the matrix. CaBP is localized to most VTA and to a subset of substantia nigra dopaminergic cells (co-localized with TH) and to a small number of nondopaminergic pars compacta cells. This pattern of distribution and the absence of CaBP in terminals in the striatal patches suggest the preferential distribution of this protein to midbrain cells projecting to the striatal matrix.

In both rat and monkey CaBP labels nearly the entire matrix-striatonigral system and the nigrostriatal system to the matrix. Whereas each of these systems are composed of mixed types of neurons, with individual neurons containing different transmitter(s), CaBP provides a common marker of each entire system, in addition to their connections, which may be related to the functional significance of the compartmental organization of the basal ganglia.

365.10 THE DOPAMINE-CONTAINING INNERVATION OF STRIOSOMES: NIGRAL SUBSYSTEMS AND THEIR STRIATAL CORRESPONDENTS. J. Jimenez-Castellanos* and A.M. Graybiel. Whitaker College, MIT, Cambridge, MA 02139.

Specialized relations between the substantia nigra pars compacta (SNpc) and striosomal compartments of the striatum are suggested by two types of experimental finding. First, the dopamine-containing fibers forming the "dopamine islands" during development innervate striatal compartments that are the forerunners of striosomes (Graybiel'84). Second, striatal projection neurons lying in striosomes are labeled by retrograde tracer injections centered in the medial SN or SNpc (Fishell & van der Kooy,'84; Gerfen'84), whereas there is predominant labeling of extrastriosomal matrix neurons following injections centered either in the pars reticulata of the SN (SNpr)(rat, Gerfen'84) or in the pallidum (Graybiel et al'79). In an effort to determine the origin of the dopamine island fibers, and to compare directly nigrostriatal and striatonigral compartmentalization in the striatum, we labeled nigrostriatal afferent fibers and striatonigral projection neurons in 15 cats by placing bilateral deposits of wheatgerm-horseradish peroxidase agglutinate and/or $^{35}S$ methionine into the SN and adjoining cell groups. Tyrosine hydroxylase (TH)-positive subdivisions in the midbrain were identified by reference to sections stained for TH. Those injected included A8 and, in the SNpc, two zones: (1) a caudal, medial and ventral zone with densely packed TH-positive cells probably including the ventrally-extending TH-positive cell nests farther rostrally and laterally, and (2) a dorsal, rostral and lateral zone with diffusely distributed cells continuing into SN pars lateralis (SNpl). In the caudate nucleus there was preferential labeling of fibers (F) innervating dorsal striosomes with deposits centered in caudal zone 1 of SNpc. A lateral component of striosomal innervation appeared with deposits probably affecting lateral zone 1 as well as lateral zone 2 and SNpl. Labeling of cell bodies (CB) in the striosomal system was ordered. A caudal zone 1 injection labeled CB in dorsal striosomes. More dorsal deposits in medial zone 2/A8 labeled CB in ventral striosomes. A deposit centered in SNpl labeled CB in caudoventral striosomes of the caudate nucleus as well as putamenal CB. Labeling of CB in the matrix occurred with deposits centered in SNpr. CB-poor striosomes were present and, evidently depending on the involvement of SNpc/A8, also CB-rich striosomes.

These findings suggest differential origins for the nigrostriatal innervations of striosomes and matrix. The cell-dense zone 1 of SNpc and probably also A8 appear to innervate striosomes. Zone 2 of SNpc may contribute to the innervation of the matrix. The fact that deposits in zone 1 label both fibers and cell bodies in dorsal striosomes indicates further that the dorsal island system may be part of a nigrostriatonigral loop. Finally, in the cat, as in the rat (Gerfen'84), medial SNpc/A8 (or at least medial SN/A8) receives an input from striosomes, whereas many matrix neurons project to lateral SN, apparently to SNpr. Funded by NSF BNS83-19547.

365.11 BEHAVIORAL SENSITIZATION TO DOPAMINE STIMULANTS INDUCED BY CHRONIC NEUROLEPTIC AND CHRONIC COCAINE TREATMENT: ROLE OF NIGRAL GABA RECEPTORS. S.E. Bachus & K. Gale. Dept. Pharmacology, Georgetown Univ. Sch. Medicine & Dentistry, Washington D.C., 20007.

Stimulation of GABA receptors in substantia nigra elicits stereotyped behaviors resembling those elicited by systemic dopaminergic (DA) stimulants (Scheel-Kruger et al., Neurosci. Lett. 4:351, 1977), and may, in response to striatonigral transmission, mediate DA stimulant-induced stereotypies. Consistent with this idea, chronic blockade of DA receptors by neuroleptic drugs, which enhances behavioral responses to dopamine agonists (Tarsy & Baldessarini, Nature New Biol. 245:262, 1973), also increases GABA receptor binding in nigra (Gale, Nature 283: 569, 1980). Thus, changes in nigral GABA function may contribute to altered response to DA stimulants. Stereotypies are also augmented by repeated exposure to the DA stimulant cocaine (COC). The mechanism of this effect is not well understood, nor is it clear whether it involves the neural changes which mediate neuroleptic-induced sensitization. To approach this question we examined functional changes in nigral GABA transmission following chronic treatment with chlorpromazine (CPZ) or cocaine (COC). As an index of nigral GABA receptor sensitivity, we evaluated the behavioral response to intranigral muscimol.

Adult male Sprague-Dawley rats received either CPZ (20 mg/kg) or vehicle daily for 8 wks, or COC (cumulative dose of 120 mg/kg/day) or vehicle for 6 days. Both drugs caused marked behavioral sensitization to DA stimulants. Three to 5 days after cessation of chronic treatment, rats were tested for behavioral responses to 2.5-5 ng muscimol infused bilaterally into substantia nigra.

Consistent with the results of GABA binding studies, CPZ-treated rats showed a significantly more intense behavioral response to intranigral muscimol than did controls. Gnawing and repetitive restricted head movements and forelimb alternation or flexing were exhibited by these rats following a dose of muscimol which produced only sniffing and locomotion in controls. In contrast, rats exposed to chronic COC did not show enhanced stereotypy in response to intranigral muscimol, despite the fact that they exhibited sensitization to COC-induced stereotypy.

The neural mechanisms responsible for COC-induced sensitization to DA stimulants are therefore dissociable from those underlying neuroleptic-induced DA sensitization. In the latter case, our data indicate an involvement of nigral GABA receptor supersensitivity, which develops secondary to chronic blockade of striatal DA receptors. On the other hand, it appears that changes in nigral outflow are not involved in the sensitization produced by chronic COC. While we have implicated nigral outflow in the expression of COC stereotypies (Bachus & Gale, Soc. Neurosci. Abst. 10: 114, 1984), changes in these behaviors consequent to chronic COC exposure must depend upon alterations in other pathways. Supported by HHS grants DA02206 & NS07453

365.12 THE CO-OCCURRENCE OF SUBSTANCE P-LIKE IMMUNOREACTIVITY AND DYNORPHIN-LIKE IMMUNOREACTIVITY IN STRIATOPALLIDAL AND STRIATONIGRAL PROJECTION NEURONS. A. Reiner. Department of Anatomy and Cell Biology, The University of Michigan, Ann Arbor, MI 48109.

Substance P-like immunoreactivity (SPLI) has been observed in striatopallidal projection neurons and in striatonigral projection neurons in the basal ganglia of all avian, reptilian and mammalian species studied. Recent studies have shown that dynorphin-like immunoreactivity (DLI) is also present in striatopallidal and striatonigral projection neurons in members of each amniote class. The present studies were carried out to determine whether SPLI and DLI are found in two different populations of striatal neurons that have parallel projections or whether they are found in the same striatal neurons.

An immunofluorescence double-labeling procedure (Erichsen et al., Nature, 295, 1982) was used to determine whether SPLI and DLI co-occur in individual striatal neurons and in individual pallidal and nigral fibers in pigeons and turtles. A rat monoclonal antibody against substance P (Accurate Chemical) was used in conjunction with a TRITC-conjugated secondary antiserum (goat anti-rat IgG) to label SPLI-containing neurons and fibers. To label DLI-containing neurons and fibers in SPLI-labeled tissue, a rabbit antiserum specific for the C-terminus of Dynorphin A (1-17) (provided by L. Terenius) was used in conjunction with an FITC-conjugated secondary antiserum (goat anti-rabbit IgG). The dynorphin antiserum was blocked with 100μM leucine-enkephalin to prevent any crossreactive labeling of enkephalinergic neurons.

In colchicine-treated pigeons and turtles, both the medial striatum (the source of projections to the substantia nigra and the ventral tegmental area) and the lateral striatum (the source of projections to the globus pallidus) contained numerous SPLI-containing neurons and numerous DLI-containing neurons. Within the medial striatum, nearly all of these neurons contained both SPLI and DLI. The co-occurrence of SPLI and DLI was also very extensive in the lateral striatum, but not as extensive as in the medial striatum. Although nearly all of the DLI-containing neurons in the lateral striatum were found to contain SPLI, a significant percentage of the SPLI-containing neurons (approximately 10-25%) did not contain observable DLI. Within the globus pallidus, substantia nigra and ventral tegmental area, SPLI and DLI were observed to co-occur extensively in fibers and boutons.

The present results indicate that the co-occurrence of SPLI and DLI in striatopallidal and striatonigral projection neurons in pigeons and turtles is highly extensive. Since striatal organization is generally similar among the members of the various amniote groups, it seems likely that SPLI and DLI co-occur extensively in striatal neurons in all amniotes. This research was supported by NS-19620.

366.1 MATERNAL NACL INTAKE AND OFFSPRINGS' FOOD CHOICES. E. Bird and R.J. Contreras, Dept. of Psychology, Yale Univ., New Haven, CT 06520.

Experimental evidence suggests that the food choices of weanling rats are influenced by maternal diet during gestation and/or lactation. Our interest is in determining whether differences in early dietary NaCl intake modify the salt intake of rats later in life. The present study was designed to assess the influence of maternal dietary salt levels on offsprings' voluntary consumption of salt in the diet at weaning.

Prior to breeding and during gestation and lactation adult female rats were fed a diet either low (.08%), mid (1%), or high (4%) in sodium chloride. Litters were culled to nine pups on postnatal day one. The pups were weaned on day 21 and randomly assigned to one of two experiments assessing voluntary NaCl intake. In one experiment, the rats were fed a sodium-free diet and their elective consumptions of 1.8% saline and water were measured every 24-hr for five days. In the other experiment, salt was presented in food rather than in solution; the rats were given deionized-distilled water to drink and their intakes of no-salt diet and 1.8% NaCl diet were measured every 24-hr for five days.

In the solution choice experiment, there were significant differences between the groups in saline preference, which is defined as saline intake/total fluid intake ($F(2,9)=6.35$, $p<.05$). The mean NaCl preference of the low salt pups (.19) was lower and that of the high salt pups (.42) was higher than that of the mid salt animals (.38). The differences in preference are attributable to significant effects of dietary group on saline intake and water intake ($F(2,9)=4.27$, $p<.05$; $F(2,9)=6.99$, $p<.05$). Compared to the mid salt group, the low salt animals drank less saline and more water and the high salt animals drank more saline and less water. There were no differences between the groups in total fluid intake (saline+water) or food intake.

Preliminary results from the food choice experiment suggest a similar effect; the low salt pups tend to ingest less salt and the high salt pups more than the mid salt group. It is interesting to note that, in the food choice tests, rats from all groups chose a diet whose effective salt level was less than 0.6%. This suggests that, contrary to earlier findings, weanling rats do not choose the maternal diet (or, by extrapolation, its nutrient levels) over alternatives. This observation also calls into question the common practice of maintaining rats on lab chow containing 1% NaCl.

These data indicate that maternal dietary salt levels affect offsprings' elective salt consumption in the diet at weaning.

E.B. was supported by an NSF Predoctoral Fellowship, and the research was supported by NIH Grant HL-28952.

366.2 LONG-TERM NEUROCHEMICAL CHANGES AFTER PRENATAL EXPOSURE TO MONOSODIUM GLUTAMATE. B. Frieder and V.E. Grimm*. Center of Neurosciences and Behavioural Research, The Weizmann Institute of Science, 76100 Rehovot, Israel.

Exposure of rats to monosodium glutamate in the mother's diet throughout gestation has been found to result in a later learning deficit and juvenile obesity. The deficit was observed only in a complex black and white discrimination maze where two stimuli were presented simultaneously but not in two other mazes were stimuli were presented separately.

In the present study neurochemical changes resulting from the same prenatal exposure to monosodium glutamate were investigated in the brains of both juvenile and adult rats. Uptake of choline, norepinephrine (NE) and GABA were studied in the cortex and hippocampus of 15, 30 and 60 days old rats. Choline uptake was reduced to 20% at 15 days of age, remained still low (60% of control) at 30 days but was elevated by 32% in the adults. Choline uptake in the hippocampus was also elevated in the adults (by 24%). Norepinephrine uptake in the frontal cortex was reduced by 25% only in adulthood while NE uptake in the hypothalamus was reduced only at 30 days of age. The results indicate that prenatal monosodium glutamate exposure results in long term neurochemical changes. The possible relationship between the behavioural and the neurochemical changes will be discussed.

366.3 THE EFFECT OF PRENATAL ETHANOL EXPOSURE ON INTRAVENOUS ETHANOL SELF-ADMINISTRATION BY THE ADULT BEAGLE. J.M. Johnson*, M.B. Waller*, J.R. Pick* and J.H. Wilson* (SPON: M.J.W. Chang). Div. of Lab. Animal Med., Univ. of North Carolina, Chapel Hill, NC 27514.

Pregnant beagle dogs were intubated twice daily with 1.8 g/kg ethanol (25% w/v in water) throughout gestation. Control bitches received isocaloric sucrose. All bitches received a formulated diet containing 16.5% lactalbumin protein. Ethanol treated animals consumed more food than controls and were therefore pair-fed to controls. Following normal delivery, litters were culled to a maximum of 4. The offspring were weaned at 5 weeks and raised to adulthood. Starting at approximately 20 months of age, permanent indwelling jugular catheters were surgically implanted in offspring from each maternal treatment group (Control = CONT, Ethanol Treated = ETOH). Following recovery from surgery, each animal was placed in a sound attenuated operant chamber and, upon pressing a lever (FR-1), received 0.100 g/kg ethanol (15% w/v in saline) via an infusion pump. When responding stabilized, daily sessions of 2 hr duration were conducted at injection doses ranging from 0.025 to 0.100 g/kg. CONT offspring, at an injection dose of 0.075 g/kg, self-administered ethanol in amounts ranging from 0.8 to 2.9 g/kg/session ($N = 4$) resulting in end-session blood ethanol concentrations (BEC) of 81 to 268 mg/dl. ETOH offspring ($N = 4$) administered ethanol in amounts ranging from 2.9 to 3.4 g/kg/session (BEC: 280-338 mg/dl). Since it was observed that most self-administration responding occurred during the initial 20 min of a 2 hr session and declined rapidly thereafter, a second study was conducted in which representative animals were subjected to sessions of 20 min duration. Total amounts of ethanol administered ranged from 0.8 to 1.6 g/kg (BEC: 110 to 203 mg/dl) for the CONT animals ($N = 3$) and from 2.4 to 2.7 g/kg (BEC: 293 and 294 mg/dl) for the ETOH animals ($N = 2$). Although the number of offspring tested was small, the data suggest increased ethanol self-administration by beagles that were exposed prenatally to ethanol. (This work was supported by N.I.A.A.A. Grant No. 5-R01-AA03123-06)

366.4 THE DEVELOPMENT OF HUMORAL AND CELLULAR IMMUNE COMPONENTS FOLLOWING EXPOSURE TO PRENATAL MATERNAL SOUND STRESS IN RATS. S.K. Sobrian, V.T. Vaughn*, L. Crane* and E.F. Bloch*. Dept. of Pharmacology, Howard Univ. Col. of Med., Washington, D.C. 20059.

Last year, we reported that exposure of pregnant rats to environmental stress (electric foot shock) during the last week of gestation significantly reduced IgG levels in the offspring at birth and 4 weeks of age. This deficiency could be eliminated by exposure of pups to mild or moderate postnatal stress. We now report the effects of prenatal exposure to loud noise on the maturation of both humoral and cellular immune responses in the preweanling offspring.

Ten pregnant Sprague-Dawley rats were exposed daily for 60 min on gestational days 15-21 to an 85dB bell that was programed to ring on a variable interval schedule of 30 times during a 60 min period; the duration of each ring was 5 seconds. As females remained in their individual maternity cages during the stress procedure, handling of the pregnant animal was not necessary; 10 control females were left undisturbed. Females delivered naturally and litters were raised by their biological mothers. Total serum IgG and spleen lymphocyte proliferation following mitogenic stimulation with pokeweed (PWM:20ug), phytohemagglutinin (PHA:20ug) or concanavalin A (ConA:20ug) were determined every 7 days from birth to weaning at postnatal day (PND) 21.

Prenatal maternal sound stress (PSS) significantly shortened the gestational period. Birth weights were unaffected but litter size was larger in the PSS females and significantly more female pups were born to PSS mothers than to controls. However, indices of maternal-pup interaction, i.e., latency to nest build and retrieve pups, nursing and grooming, were not significantly different between the groups. Pinna elevation and the development of several reflexes (i.e., surface righting, cliff avoidance and auditory startle) were delayed in PSS offspring; incisor eruption, eyelid dysjunction and free-full righting were unaffected. These difference were unrelated to nutritional factors as body weights and organ/body weight ratios of spleen, thymus and adrenal glands were not significantly different at PNDs 0,7,14 and 21.

The development of the humoral immune response was unaltered by PSS; IgG levels increased during the first 2 postnatal weeks, peaked at PND 14 and then declined. Despite the similar developmental pattern, IgG was consistently lower in PSS offspring; this difference reached significance at PND 21. In constrast to the decrease in humoral immunity, cellular immunity, as measured by lymphocyte stimulation, was enhanced to the T-and B-cell mitogen, PWM, on PND 0 in PSS offspring. An increased proliferation to the T-cell mitogens, ConA and PHA were observed on PND 7 and PND 21, respectively. These data indicate that prenatal sound stress has a differential effect on components of the immune system; humoral components (i.e., B-cell mediated responses) appear to be suppressed by PSS, while T-mediated cellular responses are enhanced.

366.5 PRENATAL STRESS, EMOTIONALITY AND ASYMMETRY IN NEONATAL TAIL POSTURE. Ester Fride* and Marta Weinstock*. (SPON: European Neuroscience Association). Dept. of Pharmacology, Hebrew University-Hadassah Medical School, Jerusalem, Israel.

It has been suggested that the two hemispheres of the brain process emotional responses differently (Flor-Henry, Integr. Psychiat., 1:46, 1983) and that the influence of early experiences on emotionality is unequally distributed in the two hemispheres (Denenberg et al., Science 201:1150, 1978). Behavioural and neurochemical left-right asymmetries can be produced in rats by neonatal handling, a procedure known to reduce emotionality (Sherman et al., Brain Res., 192:61, 1980; Camp et al., Physiol. Behav. 33: 433, 1984). It is therefore possible that prenatal stress, which has been shown to increase emotionality in the offspring (Fride et al., Life Sci. in press; Fride et al., in preparation), may also alter their behavioural asymmetry. This possibility was investigated by determining tail posture in the newborn rat, which is said to predict asymmetry of dopamine pathways at adulthood (Rosen et al., Brain Res., 297: 305, 1984).

We exposed 30 pregnant rats to 3 randomly distributed (unpredictable) sessions of 4 hours of noise (95 db SPL) and flashing lights (20 fc) each week throughout gestation. Thirty pregnant controls were left undisturbed. Mothers were removed from their litters for 3 min. and tail position of the pups was scored for left-, right- or no-preference, within 24 hrs after birth (day 0) and on days 1 and 2.

On day 0, there was no side preference in control rats, whereas prenatally stressed pups showed a shift to the right ($X^2$= 11,3; p<0.001). There were no sex differences on this day. On day 1, controls had developed a leftward bias (p<0.001) which was significant only for males. By day 2, the female control pups had also developed a leftward bias (p<0.1), while the prenatally stressed pups still showed a deviation to the right, although somewhat reduced (p<0.01).

These results demonstrate that unpredictable prenatal stress causes a shift in neonatal tail posture, which may be indicative of asymmetry at adulthood. We suggest therefore, that a prenatally induced change in brain lateralisation may underly our previous findings that mature animals which had experienced prenatal stress, showed an increase in emotionality and a reduction in the ability to cope with stressful situations.

366.6 ONTOGENY OF SEIZURE INCIDENCE, LATENCY AND SEVERITY IN GENETICALLY EPILEPSY PRONE RATS. D.L. Amend, J.E. Franck* and D.L. Hjeresen*. Departments of Psychology and Neurological Surgery, University of Washington, Seattle, WA 98195.

The Genetically Epilepsy Prone Rat (GEPR) has been extensively studied as an animal model of epileptiform disorders (Jobe and Laird, Biochem. Pharm. 30:3137-3144,1981). When tested as adults the GEPR is susceptible to audiogenic, visual, chemical and temperature induced seizures. However, the possibility that seizure susceptibility may be the result of developmenal changes in the central nervous system has not been addressed. The results of the present study indicate that GEPR pups are insensitive to audiogenically-induced seizures through 27 days of age and that seizure incidence, latency and severity increase significantly when rats are retested at 60 days of age.

Eighty GEPR pups from 8 different dams were tested for incidence, latency and severity of an audiogenically induced seizure at 6,9,12,15,18,21,24,27,28,29 or 30 days of age (one test per pup). Seizure testing was conducted in an enclosed cylindrical metal container (40.6 cm dia. X 50.8 cm deep) equipped with an alarm bell with a measured output of 110 db(a). Pups were placed in the chamber and the bell was activated for 60 s or until the onset of a seizure. Seizure severity was quantified on the 9 pt. scale of Jobe, et al. (J. Pharmacol. Exp. Ther. 184:1-10,1973a). At 60 days of age all pups were retested. Results were evaluated by analyses-of variance and by a paired-T test between the initial and 60 day seizure test. Results indicate that sensitivity to audiogenic seizures begins at day 27 post-partum. Prior to Day 27 a brief running fit was noted in a single 18 day old rat. Seizure incidence, latency and severity were significantly greater on days 27, 28, 29 and 30 than all previous days (F's=2.17, 2.21, and 4.71 respectively). When retested at Day 60, seizure incidence, latency and severity were significantly greater than on initial tests regardless of of whether rats had seized during their initial test or not.

The results suggest that seizure sensitivity in the GEPR rat occurs as the result of developmental events in the CNS occuring on or shortly after Day 27 post-partum. These behavioral results are paralleled by the additional finding from our laboratories that benzodiazepine binding in the medial geniculate nucleus declines with age in the GEPR. This suggests that inhibitory mechanisms in the GEPR may decline with age.

366.7 INCREASED CELL DENSITY OCCURS IN THE INFERIOR COLLICULUS OF THE YOUNG GENETICALLY EPILEPSY PRONE RAT. R. C. Roberts*, H. L. Kim* and C. E. Ribak (SPON: D. D. Williams). Dept. of Anatomy, Univ. of Calif., Irvine, Irvine, CA 92717.

Previous work from our laboratory has shown an increase in the number of total neurons as determined by counts of Nissl stained cells and an increase in the number of GABAergic neurons in the inferior colliculus (IC) of the genetically epilepsy prone rat (GEPR) as compared to Sprague-Dawley rats. To determine whether this increase in cell number was present in young GEPRs prior to seizures the brains of GEPRs and Sprague-Dawley rats, 4-10 days of age, were studied. The brains were embedded in paraffin, sectioned in the coronal plane at a thickness of 10 um and stained with cresyl violet. A representative 62,500 $um^2$ grid in the ventral lateral portion of the central nucleus was examined from eight to ten sections across the rostrocaudal extent of the IC; neurons were classified as small, medium and large and counted. In addition, the area of the IC in these sections was determined by a digitizing morphometry computer program.

A statistically significant increase occurred in the numbers of small neurons in the IC of the young GEPR. At 4 days of age there were 116±24 small ,30 ±14 medium and 1±1 large neurons per analyzed grid in the SD rat. In contrast, age matched GEPRs displayed 180±50 small, 18±14 medium and 1±0.3 large neurons in the same area in the GEPR. This is a 55% increase in the numbers of small neurons in the GEPR as compared to the SD rat. At 10 days of age there were 67±22 small, 57±31 medium and 2.5±2.8 large neurons in the SD rat. In contrast, there were 138±48 small, 60±21 medium and 5±5 large neurons in the GEPR. This represents a 105% increase in the numbers of small neurons in the GEPR as compared to the SD rat. However, the numbers of the medium and large neurons were similar in both groups of rats and no significant difference occurred between the areas of the IC.

These data suggest that there is a developmental defect in the generation of small size neurons resulting in an increase in the number of this size neuron in the GEPR IC that is present prior to the seizure state. Since there are similar numbers of medium sized neurons in the 10 day old rats but an increase in numbers of medium sized neurons in the adult, there may be a developmental lag in the growth of this size neuron in the GEPR.

366.8 EFFECTS OF EXPERIMENTAL HYDROCEPHALUS ON THE MORPHOLOGY OF CORTICAL NEURONS. J.P.McAllister II, T.A.Maugans*, M.V.Shah*, A. Norelle* and R.C.Truex, Jr*. Depts. of Anatomy and Neurosurgery, Temple University School of Medicine, Philadelphia, PA 19140.

Obstructive hydrocephalus produces gliosis and damage to periventricular white matter in the cerebral cortex, and results in severe neurological deficits. However, the changes in neuronal morphology that accompany this disorder are relatively unknown. Recently, we utilized an animal model of hydrocephalus to characterize the dendritic morphology of cortical pyramidal neurons from the most severely affected rats (McAllister,J.P. et al., J. Neurosurg., in press). The present report describes both the cytological and dendritic changes observed throughout the sequence of this disorder. Newborn rats received kaolin injections in the 4th ventricle. These animals were sacrificed at 3,6,7,10 and 12 days post-injection and their brains processed by Nissl and Rapid Golgi methods. Since the parieto-occipital region was the most severely affected portion of the cortex, well impregnated neurons from this area were selected for microscopic analysis and compared to age-matched litter-mate controls. Grossly, ventriculomegaly and cortical thinning were not evident at 3 days post-kaolin injection, but were at 6-7 and 10-12 days. Cellular changes were first seen in experimental animals at 3 days and became progressively more severe. Nissl preparations revealed intense gliosis in the external capsule and absence of neuropil by 10-12 days. Dark shrunken neurons and gliosis were also evident in deep portions of layer V, but not in any other laminae. Golgi impregnation demonstrates that during normal postnatal development, dendrites of pyramidal neurons lose their bead-like swellings (varicosities) and produce dendritic spines. In all cortical layers, pyramidal neurons exhibited progressive increases in dendritic varicosities and decreases in dendritic spines. These changes were variable, however, such that some dendritic segments were smooth with normal complements of spines. Spine reduction and varicosity formation were most notable on distal portions of individual branches and within regions of the dendritic tree closest to the ventricular and meningeal surfaces. Furthermore, the basal dendrites of pyramidal neurons had fewer branches and those that remained were shorter. We conclude that experimental hydrocephalus (1) alters the morphology of cortical neurons and (2) dendritic changes precede gross tissue changes. The dendritic alterations are consistent with other reports of dendritic changes that accompany aging, mental retardation and alcohol exposure. Thus, our observations suggest that hydrocephalus causes deterioration or retardation of somatic and dendritic maturation. The fact that neuronal morphology was not more severely affected may indicate that these effects are reversible. (Supported by BRSG #S07RR05417)

367.1 **EVIDENCE THAT A NERVE INJURY INDUCED, 37K PROTEIN IS A FORM OF APOLIPOPROTEIN E.** M.J. Ignatius, P.J. Gebicke-Harter*, J. Shilling* J.H.P. Skene and E.M. Shooter. Dept. of Neurobiology, Stanford Univ. Med Center, Stanford, CA. 94305.

Upon injury of both peripheral and central nervous system tissue, the synthesis and secretion of a 37K protein is markedly increased (Skene and Shooter, PNAS 80:4169, 1983). This soluble, slightly acidic protein has been shown by a variety of studies to correlate with events of nerve axon growth during development and regeneration. In this report we present evidence that this protein bears striking homology to a well studied serum protein, apolipoprotein E, that is known to be involved in both transport and metabolism of lipids and cholesterol.

In a previous abstract we described the purification of the 37K protein and subsequent production of mono-specific rabbit antisera. In the present study, using this antisera, we examined the cellular origin of the 37K protein in enriched cultures of new born rat oligodendroglia and astroglia. After 7 days in culture the most prominent staining was confined to a population of small (10um) cells, which were generally associated with cellular debris and which contained large inclusion bodies. That these are macrophages or a form of microglia seems likely. Other lines of evidence suggest that glia, rather than these small round cells, are the primary source of the 37K protein in vivo. However, our evidence for 37K protein in macrophage-like cells in vitro raised the possibility that the 37K protein might be similiar to a 35K glycoprotein, apolipoprotein E, that has been shown to be secreted by rat macrophages.

By two criteria, immuno-cross reactivity and amino acid sequence we tested the degree of homology between these two proteins. First in immuno-blots, comparing cross reactivity of both anti-apo E and anti-37K for the two proteins, we found that both antisera recognized each of the denatured proteins. Secondly, we derived a partial amino acid sequence of the 37K protein, for comparison to the complete sequence of rat apo E. Two fragments from the 37K protein of 12 amino acids each, one from the N-terminus and one from an internal region were found to match at all but one position with the known sequence of similiar regions of rat apo E.

The homology of the nerve sheath derived 37K protein to serum apo E suggests that the 37K protein may be involved in similiar events ascribed to apo E, for example in lipid transport and metabolism, yet confined to the nervous system. The presence of the 37K protein during development and its induction after injury indicates that it may play a role in both assembly and maintenance of myelin or axonal membranes during development and regeneration via the mobilization of lipid rich precusors, or in degenerative events whereby lipid rich debris is absorbed and cleared from the site of injury.

367.2 SUBSTANCES ORIGINATING FROM GROWING NERVES INDUCE MORPHOLOGICAL RESPONSES CHARACTERISTIC OF REGENERATION IN INJURED OPTIC NERVE OF ADULT RABBIT. V. Lavie*, S. Sharma, A. Harel*, D. Lobel*, A. Solomon*, A. Doron*, M. Belkin* and M. Schwartz. Dept. of Neurobiology, The Weizmann Institute of Science, Rehovot, Israel.

We have demonstrated that the adult rabbit visual system can express regeneration-associated characteristics after injury if subjected to appropriate growth-associated triggering factors (GATFs). Active GATFs are found in media conditioned by regenerating fish optic nerves or by optic nerves of neonatal rabbit (Schwartz et al., Science, 228:600, 1985; Hadani et al., Proc. Natl. Acad. Sci. USA 81:7965, 1984). The implantation-induced response was manifested by a general increase in protein synthesis in the retina, changes in synthesis of specific polypeptides, and sprouting of new fibers in culture.

The present work provides evidence for the morphological changes following implantation of GATFs in adult rabbits. Axonal fibers and corresponding retinal ganglion cells were retrogradely labelled with horseradish peroxidase (HRP) at various times after optic nerve crush and GATF implantation. Forty-eight hours following HRP application, flat-mounted retinae were processed using DAB as a chromagen. One week following optic nerve injury, light microscopic analysis revealed labelled fibers and ganglion cells in both the implanted and control (injured only or injured and implanted with silicone tubes coated with collagen but free of GATFs) preparations. In control preparations, no staining of fibers or ganglion cells could be detected. In contrast, two weeks or one month after the injury, the GATF implanted preparation showed a high degree of viable ganglion cells with dendritic arborizations and abundant stained fibers, some with growth cones.

Electron microscopic analysis revealed unmyelinated nerve fibers with growth cones embedded in the scaffold formed by glial cells only in the implanted injured nerve.

These results emphasize that GATFs implanted around the injured optic nerve of an adult rabbit induce a morphological response in addition to the biochemical response previously reported. Whether this response leads to complete anatomical recovery or only to abortive growth warrants further investigation.

367.3 MOLECULAR ASPECTS OF OPTIC NERVE REGENERATION IN REGENERATIVE AND NON-REGENERATIVE SYSTEMS. C. Stein-Izsak, A. Harel*, A. Solomon*, D. Neumann*, M. Belkin*, M. Rubinstein * and M. Schwartz. Dept. of Neurobiology, The Weizmann Institute of Science, Rehovot, Israel, 76100.

The induction of regeneration-associated changes following neuronal injury to a non-regenerative adult mammalian CNS has been achieved in our laboratory (Schwartz et al., Science, in press). Application of growth associated triggering factors (GATFs), from non-neuronal cells of regenerating or growing nerves, as an implant around the injured optic nerve of an adult rabbit resulted in a general increase in retinal protein synthesis, changes in synthesis of specific polypeptides and sprouting of new fibers from the retina in vitro (Hadani et al., Proc. Natl. Acad. Sci. USA. 81: 7965, 1984). These changes are characteristic of regeneration in goldfish and other lower vertebrate CNS having a high regenerative capacity. To gain an understanding of the mechanism underlying the action of the GATFs and the resultant changes in the retina, mRNA translation products from retinas of goldfish and rabbit were analyzed under various experimental conditions. The purification and characterization of GATFs from non-neuronal cells of regenerating fish optic nerves was also undertaken.

Poly $(A)^+$ RNA was extracted from retinas of goldfish 2, 4, 8 and 35 days following crush injury to the optic nerve. The contralateral uninjured retina served as control. The mRNA was translated in a reticulocyte lysate cell free system and the translated polypeptides were examined by 2-dimensional gel electrophoresis. Translation products from retinas of regenerating goldfish optic nerves included polypeptides barely detectable in the controls. Among these polypeptides, those of apparent molecular weight 24-28 kDa; 43-49 kDa; 60 kDa; and 65 kDa may be analogous to the growth associated polypeptides described in other regenerative or developing systems. The induction of regeneration-associated characteristics in the retina of the injured rabbit optic nerve implanted with GATFs was reflected by changes in mRNA translation products of molecular weight 16-18 kDa; 28 kDa; 32-35 kDa; 43-47 kDa; 56-60 kDa and some higher molecular weight species.

Thus, in visual systems of both the goldfish (representing a regenerative CNS) and the rabbit (representing a non-regenerative mammalian CNS), regenerative responses in the retina are associated with alterations in mRNA expression.

To isolate and identify the molecule(s) which trigger the regenerative response in the rabbit retina, GATFs from non-neuronal cells of regenerating fish optic nerves were fractionated by Sephadex G-25 chromatography. The active moiety, as assessed by bioassay, resided in a peak of molecular weight less than 5 kDa. This fraction, when further purified by reverse-phase HPLC, yielded several peaks, only one of which was active.The apparent molecular weight of this peak is 3 kDa. We have previously shown that non-neuronal cells of regenerating fish optic nerves display changes in their pattern of pulse-labelled polypeptides and mRNA translation products (Rachailovich et al., Proc. 14th Meet. Soc. Neurosci. 10: 1031, 1984). In addition, GATFs derived from these cells have greater biological activity than GATFs from control nerves. The amino acid sequence of the purified GATF will be used to study the regulation of its expression in regenerating and non-regenerating CNS.

367.4 EXPRESSION OF SPECIFIC NON-NEURONAL PROTEINS DEFINES DISTINCT "GROWTH-STATES" OF REGENERATING AND NON-REGENERATING NERVES IN MAMMALS. H.W.Müller, M.J.Ignatius, P.Gebicke-Härter*, D.H.Hangen* and E.M.Shooter. Dept. of Neurology (H.W.M.), University of Düsseldorf, F.R.Germany and Dept. of Neurobiology, Stanford Univ. Med. Sch. Stanford, CA 94305.

Protein synthesis in non-neuronal (sheath) cells of injured as well as intact mature and developing sciatic nerves and optic nerves from rat was investigated by incubating segments of nerve with ($^{35}S$)-methionine in vitro. The composition of radioactively labeled proteins released into the incubation medium was analyzed by two-dimensional gel electrophoresis and fluorography.

The expression of 4 proteins in sciatic nerve with the apparent molecular masses of 70kDa, 54kDa, 51kDa and 37kDa was of particular interest because of the correlation of their synthesis and secretion with nerve growth and regeneration. The 37kDa protein was synthesized at a significant rate during neonatal development as well as during Wallerian degeneration and axon regeneration following a crush lesion but not in the intact mature nerve. The synthesis of the 37kDa protein was inhibited when proper innervation was established. In contrast, the synthesis remained at almost maximal rates following permanent denervation. The 70kDa protein was synthesized at a significant rate only in response to axotomy thus confining its role to some aspect(s) of nerve repair. On the other hand, the 54kDa and 51kDa proteins were expressed in the intact mature nerve sheath. Their synthesis and release was rapidly inhibited upon axotomy but returned to normal or higher levels within 3-4 weeks post-injury suggesting a function in the maintenance of the integrity of the mature (non-growing) sciatic nerve. Particular growth states (i.e. developing, intact mature, regenerating, permanently denervated) of rat sciatic nerve can thus be identified by the differential expression of specific proteins in non-neuronal (sheath) cells.

A protein which is homologous to the 37kDa protein in peripheral nerve was synthesized at significantly higher rates in optic nerve of neonatal rats than in adult animals. As a specific response to denervation the synthesis of this protein was stimulated approximately 100-fold in the mature optic nerve. However, in contrast to sciatic nerve, the 37kDa protein did not accumulate in the optic nerve. The differences in accumulation of the 37kDa protein correlate with the apparent differences in the ability of peripheral and central axons to regenerate.

367.5 **SEM VISUALIZATION OF EARLY EVENTS IN PNS NERVE REGENERATION WITHIN A TUBULAR PROSTHESIS: EFFECTS OF DIFFERENT PROTEIN ADDITIVES.** L. Kljavin-, R. Madison, C. F. Da Silva, and R. L. Sidman. Departments of Neuropathology and Neuroscience, Harvard Medical School and Children's Hospital, Boston, Ma. 02115.

The present experiments were undertaken to gain insight into the 3-dimensional aspects of the early events of nerve regeneration within tubular prostheses. Twenty adult male C57BL/6J mice received sciatic nerve transections at mid-thigh level and both proximal and distal nerve stumps were sutured into a 6 mm long polyethylene tube, ID 0.76 mm (Clay Adams) to give a final nerve gap distance of 4 mm. The tubes contained either a laminin-containing gel (gift of Drs. Kleinman and Martin, NIH) or a collagen matrix (Vitrogen, Flow laboratories) at the time of implantation. Two animals from each group were sacrificed at 1, 2, 4, 7, 11, or 15 days after surgery, and the tissue cable within the tube processed for SEM analysis.

At day 1 and 2 the laminin gel appears very globular with some smaller collagen fibers, probably Type IV, apparent. There is no overall orientation to either the collagen or the globular masses within the cable. Many presumptive macrophages and red blood cells are present within and on the surface of the cable. By day five the cable is markedly less globular in appearance and more collagen is seen around the periphery of the cable while large channel like openings are seen within the cable itself, suggesting a reworking of the matrix components into a more longitudinally oriented arrangement. By day 7 many more channel like openings are seen in the cable, and a distinct epineurium with much collagen surrounds the boundaries of the cable. Fewer cells are evident within the cable at this time point, and some presumptive unmyelinated axons can be seen. By 11 and 15 days, the cable is begining to look more normal with a distinct epineurium, bundles of unmyelinated axons can be seen surrounded by perineurium, and individual myelinated axons can be seen.

The appearance of the collagen filled tubes is quite different. At days 1 and 2 there is only collagen present in the cable arranged in a random fashion. Some presumptive fibroblasts can be seen migrating on the surface of the cable. By day five the collagen is begining to appear less random and many more presumptive fibroblasts are seen on the surface of the cable and some within the cable itself. By days 7-15 the collagen becomes much more ordered into longitudinal arrays, macrophages are seen, and at the later time point presumptive unmyelinated and a few potentially myelinated axons can be distinguished.

The remaining 8 animals were sacrificed at two weeks for retrograde cell labeling and these animals also suggest a more rapid growth of axons across the nerve gap in the group that received the laminin-containing gel. Animals in this group displayed more labeled sensory and motor cells and more myelinated axons compared to the group that received collagen in the inside of the tube (see also, Da Silva et. al.; and Madison et. al., this volume.) Supported by NIH grants EY05317 (RM), NS20820, NS20822, HD18655 (RLS).

367.6 **QUANTITATIVE EFFECTS OF A LAMININ-CONTAINING GEL, COLLAGEN, OR EMPTY POLYETHYLENE TUBE ON PERIPHERAL NERVE REGENERATION IN VIVO.** C. F. Da Silva, R. Madison, D. Greatorex*, P. Dikkes*, & R.L. Sidman. Departments of Neuroscience, Children's Hospital & Neuropathology, Harvard Medical School, Boston, Ma. 02115

We recently reported an in vivo model to quantify the number of primary motor and sensory cells that send an axon across a 4 mm nerve gap in the mouse sciatic nerve using entubulation repair (Da Silva et. al., Brain Res, in press). **The present studies utilized this model system of PNS regeneration to quantify the effects of different protein additives to the lumen of the tube on the rate and extent of axonal regeneration.**

The sciatic nerve of adult C57BL/6J mice was transected at mid-thigh and proximal and distal stumps were sutured into a polyethylene tube (PT) 6 mm long (0.76 mm I.D.), to give a final gap distance of 4 mm. Animals were divided into three groups of 16 animals each. The first group received an implantation of a PT alone, the second group a PT filled with a laminin-enriched gel (Kleiman, H.K. et al, Biochem.,21:6188-6193, 1982) and the third group a PT filled with a purified preparation of collagen (vitrogen, Flow Labs. Inc.). Four animals in each group were sacrificed following survival times of 2, 4, 6 and 12 weeks, and the distal nerve stump was cut and exposed to an HRP solution. After an additional three days, animals were perfused with fixative. The L3-L5 dorsal root ganglia (DRG) and the lumbar spinal cord were processed for HRP-TMB histochemistry; labelled cells were counted in 40 um serial sections. The polyethylene tubes with the regenerating nerve cables were processed for plastic embedding; the number of myelinated axons in 1 um sections at the mid-point of the cables was determined with a computer-controlled system. The values (mean±SEM) obtained are (*=significant differences between groups):

**These results suggest that specific protein additives have differential effects on the rate and extent of PNS regeneration in the mouse, and demonstrate the usefulness of this model system to test manipulations of the microenvironment of regenerating axons.** Supported by NIH grants EY05317 (RM), NS20820, NS20822, HD18655 (RLS).

367.7 **MODIFICATION OF THE MICROENVIRONMENT ALLOWS AXONAL REGENERATION ACROSS A 20 mm NERVE GAP USING ENTUBULATION REPAIR.** R. Madison, C.F. Da Silva., and P. Dikkes*. Departments of Neuropathology and Neuroscience, Harvard Medical School and Children's Hospital, Boston, Ma. 02115

We have recently developed a model to quantify the number of primary motor and sensory neurons that send axons across a nerve gap (Da Silva et. al., Brain Res., in press), and have shown that axonal regeneration is significantly enhanced if a laminin-containing gel is added to the inside of the tube at the time of implantation (Madison et. al., Exp. Neurol.; 88 (3), 767-772, 1985). The present experiments were undertaken to determine if similar modifications to the internal environment of the tube would increase the maximum distance that PNS axons will elongate within a tubular prosthesis. Two different laboratories have reported that the sciatic nerve of rats will not regenerate a nerve cable within a tubular environment if the nerve gap distance is more than 10 mm in length (Seckel et. al., J. Plast. Reconstr. Surg.; 74, 173-181; Lundborg et. al., Exp. Neurol. 76, 361-375).

Eight adult male Sprague-Dawley rats received sciatic nerve transections at mid-thigh level and both nerve stumps sutured into a silicone tube (Cole Parmer, ID-1/16 inch) to bridge a nerve gap of either 15 or 20 mm. The tube was either left empty (N=2), filled with a laminin-containing gel (N=3, gift of Drs. Kleinman and Martin, NIH), or a collagen matrix ( N=3, Vitrogen, Flow Labs). After 4-12 weeks, the distal stump was resectioned 5 mm beyond the end of the tube and sealed into a polyethylene tube filled with an HRP solution. Three days later animals were perfused with fixative and the L3-L5 dorsal root ganglia and lumbar enlargement of the spinal cord processed for HRP histochemistry using TMB as the substrate. The regenerated nerve cable was processed for plastic embedding. All of the animals with laminin-gel(N=2 at 4 wks., 15 mm gap; N=1 at 5 wks., 20 mm gap) or collagen (N=3 at 6-12 wks., 20 mm gap) added to the interior of the tube displayed labeled cells in both the DRG and spinal cord, and a tissue cable connecting proximal and distal nerve stumps. Myelinated axons could be seen in the light microscope to extend as far as 10 mm into the tube. Electron microscopic analysis revealed the tissue cable to be composed of fibroblasts, schwann cells, macrophages, abundant collagen, many unmyelinated axons and numerous small myelinated axons. Neither of the two control animals (empty tube) displayed either a nerve cable in the tube or labeled cells in the DRG and spinal cord when sacrificed at 12 weeks.

**These results suggest that the maximum distance that PNS axons will elongate within a tubular prosthesis can be dramatically increased, at least by a factor of two, by additives to the interior of tube.** Supported by NIH grant EY05317(RM).

367.8 NERVE REGENERATION THROUGH HOLEY SILICONE TUBES. R.E. Coggeshall and C.-B. Jenq. Marine Biomedical Institute and Depts. of Anatomy and of Physiology & Biophysics, University of Texas Medical Branch, Galveston, TX 77550.

Recently a number of laboratories have studied various parameters of peripheral nerve regeneration after the nerve is transected and the stumps placed in an impermeable silicone tube. A reasonable hypothesis is that the tube, being impermeable, is beneficial because it holds various growth factors in a pool around the axons that regenerate from the proximal stump. One way to test this hypothesis is to drill macroscopic holes in the tube so that the general extracellular fluid has free access to the regrowing axons.

To do this, we removed an 8mm segment of adult rat sciatic nerve and the resulting stumps were placed in a silicone tube which had 2 rectangular holes, (0.6 x 25 mm) in its walls. Axons were counted in the distal stump, in the sural nerve and in the medial gastrocnemius nerve 8 weeks following surgery.

The normal rat sciatic nerve contains approximately 8,000 myelinated and 15,000 unmyelinated axons, the normal sural nerve contains approximately 1,000 myelinated and 3,500 unmyelinated axons and the normal nerve to the medial gastrocnemius muscle contains approximately 300 myelinated and 450 unmyelinated axons. After the above surgery, the distal stump for sciatic nerve contains approximately 8,000 myelinated and 16,000 unmyelinated axons, the sural nerve contains approximately 800 myelinated and 2,000 unmyelinated axons and the nerve to the medial gastrocnemius muscle contains approximately 250 myelinated and 500 unmyelinated axons. These numbers are in general closer to the normal numbers than after similar regeneration through an impermeable tube. Controls assured that not enough axons entered or left the holes in the tube to influence the counts. Thus, if a silicone tube is made permeable by putting large holes in its wall, the regeneration that results may be superior at least in terms of the parameters measured in the present study.

367.9 SCIATIC NERVE, MUSCLE OR COLLAGEN MATRIX FOR TRANSECTED SPINAL CORD REPAIR. J.C. de la Torre, M.T. Richard*, and L.P. Ivan*. (SPON: J. Metuzals). Division of Neurosurgery, Univ. of Ottawa, Health Sciences and Ottawa General Hospital, Ottawa, Ont. K1H 8M5.

One the critical problems in mammalian spinal cord reconstruction following a severe injury that results in permanent paralysis, is choosing a material to replace the defect produced by the lesion. In our continuing attempt to collate the optimum factors that may promote regeneration of severed neuronal processes, we examined tissue matrices composed of autologous sciatic nerve, skeletal muscle and cell-free bovine collagen and used these to bridge the transected gap in rat spinal cord. Rats were divided into 4 groups: sciatic nerve implant (N), muscle implant (M), collagen implant (C) and gelfoam controls (G). All rats underwent a 200 gram/centimeter force dorsal cord injury at $T_{10}$. Rats were allowed to recover for 14 days then were transected at $T_{10}$ and 2-2.5 mm of cord tissue was removed by trimming the proximal-distal cord stumps using a Codman ML-10 $CO_2$ laser. Each group received their respective implant which completely filled the space left by the laser trimmed proximal-distal cord stumps.

After 2 weeks, rats underwent somatosensory evoked potentials (SEP) and neurological evaluation. Rats were killed for light microscopic examination of cord tissue using conventional stains and SPG histofluorescence for catecholamines. Results indicate that the interfaces of proximal cord tissue with C and to a lesser extent M, contained catecholamine varicosities when examined 15 days following implantation of these bridge matrices. There were no catecholamine varicosities visible in the proximal cord tissue interface with S or G matrices. The intraaxonal catecholaminergic density in the proximal host tissue near the lesion was the same in all groups. Only 1 rat in group C showed catecholamine varicosities in the distal cord after 2 weeks. At the time of sacrifice, all SEP's and the neurological evaluation were negative for all rats.

We conclude from this data that the cell-free collagen matrix implant is superior to muscle, sciatic nerve and gelfoam bridges with respect to supporting axonal catecholaminergic proliferation ostensibly growing from proximal host tissue regeneration.

367.10 EXOGENOUS MATRIX PRECURSORS STIMULATE THE TEMPORAL PROGRESS IN A SILICONE NERVE REGENERATION CHAMBER. L.R. Williams and S. Varon (Spon: E. Keithley). Dept. of Biology, Sch. of Med., Univ. Calif. San Diego, La Jolla, CA 92093.

Successful peripheral axonal regeneration across a 10 mm gap within a silicone chamber is dependent on at least two sequential events: 1) a fibrin matrix must form and connect the proximal and distal nerve stumps; and 2) nonneuronal cells that possess properties supportive of axonal elongation must migrate into and replace the matrix (Williams and Varon, J. Comp. Neurol., 1985). When chambers are implanted empty or prefilled with saline, cell migration and axonal regeneration are delayed by the 5-7 days required for formation of a complete matrix bridge in situ. We now report that the temporal progress of cell migration and axonal regeneration can be stimulated by prefilling the chamber with a solution of fibrin matrix precursors. Proximal and distal stumps of a transected rat sciatic nerve were sutured into the ends of a silicone chamber (1.8 mm I.D.) leaving a 10 mm gap between the stumps. Control chambers were prefilled with phosphate-buffered saline (PBS). Experimental chambers were prefilled with a solution of citrated rat plasma obtained via cardiac puncture that was dialyzed against PBS to remove calcium-citrate chelates (dialyzed plasma, DP). Fibrinogen (Fg) content was measured and solutions diluted with PBS. Fibrin polymerization in chambers prefilled with DP occurred between 2 hr and 24 hr, presumably triggered by calcium supplied by the exudate from the nerve stumps. The matrix within the DP chambers was longitudinally oriented and had an apparent density proportional to the Fg concentration in the DP solution used to prefill the chamber. At all later time periods examined (i.e., 14, 16 and 18 days postimplantation - PI) a stimulation in the progress of regeneration was observed in chambers prefilled with DP containing 2.5 mg/ml Fg. For example, at 16 days PI, Schwann cell migration and the extent of axonal regeneration were 1-3 mm more advanced in the DP chambers. At 18 days PI, the process of remyelination was 3 mm more advanced and 2.5-fold more axons were present at S5 in the DP chambers. The temporal stimulation observed in chambers prefilled with DP containing 2.5 mg/ml Fg was not observed if the Fg was diluted below 2.0 mg/ml. Nor was the effect observed when chambers were prefilled with 90%, non-citrated, "intrinsically clottable" plasma which generated a randomly oriented fibrin matrix.

Supported by NSF Grant No. BNS-81-8847.

367.11 AN ANTIGENIC DETERMINANT INDUCED IN THE DISTAL STUMP OF SEVERED RAT PERIPHERAL NERVE INFLUENCES AXONAL REGENERATION. W. D. Matthew and A. W. Sandrock* (SPON: R. Nishi) Dept. of Neurobiology, Harvard Medical School, Boston, MA 02115

The distal stump of severed mammalian peripheral nerves reacts to the lesion by undergoing a series of events known as Wallerian degeneration. In the aftermath of injury, axonal and myelin debris are removed by phagocytosis and Schwann cells proliferate. Regenerating axons grow toward their target regions within the confines of the persistent Schwann cell basal laminal tubes of the distal stump. The effectiveness of axonal regeneration within this environment implies that it is particularly hospitable for regenerating axon sprouts. Richardson and Ebendal (Brain Res. 246: 57, 1982) have provided evidence that the secretion of soluble nerve growth factors is elevated in the distal stump of previously severed rat peripheral nerve. We wondered whether modifications are also made in the extracellular matrix (ECM) of peripheral nerves undergoing Wallerian degeneration so as to provide the ideal terrain for regrowing axons.

As stated in another abstract of this issue (Sandrock and Matthew), we are now able to analyze the neurite-promoting activities of rat peripheral nerve extracellular matrix components by measuring the rate of axonal regeneration from superior cervical ganglia that have been explanted onto longitudinal sections of fresh-frozen sciatic nerve. Although there is rapid axonal regrowth over sections of normal sciatic nerve, we have found that the rate of elongation is significantly greater over sections of the distal stump of peripheral nerves that had been cut four to seven days before removal (henceforth termed "reactive nerve"). In an effort to investigate the molecular basis of this phenomenon, we immunized mice with a crude membrane preparation of normal sciatic nerve, suppressed the immune response to this tissue with the anti-mitotic agent, cyclophosphamide, re-immunized with a crude membrane preparation of reactive sciatic nerve, and fused the spleen cells with a myeloma cell line. Some of the hybridomas generated by this fusion secrete monoclonal antibodies that recognize ECM determinants which are highly induced in reactive nerve, as visualized by immunofluorescence. Many of these determinants appear to be localized to the Schwann cell basal lamina. Curiously, a large number of antibodies recognizing epitopes in the ECM of sciatic nerve also stain the cell surfaces of certain CNS glial cells. One of the antibodies that binds to an inducible determinant in peripheral nerve inhibits the rate of axonal regeneration over sections of reactive nerve. We are presently characterizing the biochemical identity of this antigen, quantitating its level of induction in reactive nerve by RIA, and surveying its tissue distribution.

367.12 DYNAMICS OF INDUCTION OF AXONAL REGENERATION IN RAT OPTIC NERVE. M.J. Politis, Department of Anatomy, College of Medicine, University of Saskatchewan, Saskatoon, Canada S7N 0W0

Little or no axonal regeneration normally occurs distal to site of injury in the adult mammalian CNS. It is widely believed that this is due to creation of a millieu which is not conducive for axonal regeneration. In the present study, attempts were made to transform the matrix of traumatized rat optic nerve into a millieu which supports axonal regeneration. Specific interventions were designed to, inhibit reactive gliosis and/or, introduce exogenous tropic factor. Nerves were crushed directly behind the eyeball and a longitudinal dural slit made distally. An Elvax pellet containing homogenate obtained from distal stump of previously-transected sciatic nerve (shown in previous studies to support PNS axonal regeneration in Silastic tubes), or homogenate-free Elvax pellets were inserted into the dural slit. Reactive gliosis was regulated by systemic administration of mitotic inhibitor (Ara C, cytosine arabinofuranoside, shown in previous studies to inhibit biochemical and morphological expressions of reactive gliosis) via interperitoneal injection for the first 8 post-operative days. Axonal regeneration was assessed 2.5 mm distal to the site of optic nerve crush by, a) electron-microscopic examination, b) silver staining, and c) immunohistochemical studies using antibody neurofilament protein. Additional experiments were conducted to determine the presence of laminin in these regions.

Results in homogenate-free pellet preparations showed no evidence of axonal regeneration. In contrast, marked alterations in optic nerve were observed when homogenatecontaining pellets were employed. Approximately 50% of the otherwise reactive-glial matrix was replaced by tissue which contained large numbers of regenerating axons. EM examination showed these axons to be organized in bundles surrounded by basal laminae. These regions stained positively with silver and with antibody to neurofilament protein. This effect was dependent on the concentration of PNS homogenate in Elvax pellets, and required systemic administration of AraC. Laminin antibody staining was evident in regions associated with regenerating axons. Results suggest that CNS tissue distal to site of injury can be transformed into a millieu which will avidly support axonal regeneration by systemic administration of mitotic inhibitor and localized infusion of exogenous tropic factors/substrate molecules. Experiments are in progress to determine if exogenous laminin is sufficient or necessary for this effect and to determine if this paradym is effective in traumatized spinal cord. Supported by the MRC Grant MA-8893.

367.13 ANTISERUM DIRECTED AGAINST WHITE MATTER INDUCES THE FORMATION OF CELLULAR BRIDGES AND THE GROWTH OF AXONS WITHIN LESIONS OF THE ADULT RAT CENTRAL NERVOUS SYSTEM. E.E. Geisert, T. Darongsuwan* and C.D. Alley*. Department of Cell Biology and Anatomy, University of Alabama at Birmingham, Birmingham, AL 35294.

In previous studies (Alley and Geisert, Neurosci. Abs. 10; Geisert and Alley, Neurosci. Abs. 10), we have demonstrated that when lesions of the adult mammalian central nervous system are bathed in pepsin-digested antiserum directed against damaged brain, cellular bridges are formed that span the lesion and axons grow across the lesion in these bridges. In an initial effort to define the antibodies responsible for the bridge formation and axonal growth, different antisera were made: antiserum against white matter (made by inoculating rabbits with dissected optic nerve and fornix); antiserum directed against gray matter (made by inoculating rabbits with whole brain then absorbing with white matter); and, antiserum against scar (made by inoculating rabbits with damaged brain and absorbing with normal brain). Thus, the original antiserum was divided into three subpopulations. Rats (270 to 350g) were anesthetized, large lesions were made, a cannula was lowered into the lesion and cemented to the skull. The treatment was delivered by a mini-osmotic pump (0.5µl/hour for 14 days). The rats were assigned to treatment groups; 4 rats, normal saline; 6 rats, normal rabbit serum F(ab')2 fragments; 5 rats, anti-gray matter F(ab')2 fragments; 6 rats, anti-scar F(ab')2 fragments; and 5 rats, anti-white matter F(ab')2 fragments. Following a 20 day survival period the animals were deeply anesthetized and perfused through the heart. Three series of 40µm sections were stained by a different method: the Nissl method, a silver technique for axons, and an indirect immunoperoxidase method with the primary antibody directed against neurofilaments. The lesion area in each of the brains was reconstructed and the percentage of the lesion that was cavity, scar, or dense cellular bridge was calculated. The formation of dense cellular bridges and axonal growth was only seen in rats that were treated with the anti-white matter F(ab')2 fragments. The percentage of the lesioned occupied by dense cellular bridge in each of the anti-white matter animals was: 0%, 3.0%, 3.2%, 4.7%, and 9.9%. The response to treatment in anti-white matter animals was robust when compared to the rats from earlier studies treated with antiserum against damaged brain (in the best case only 1.6% of the lesion was bridge). The epitopes that are necessary to develop an antiserum capable of inducing bridge formation and axonal growth are found in white matter. These data demonstrate that the formation of dense cellular bridges and the axonal growth seen in this study is antibody specific, for it did not occur in rats treated with normal rabbit serum, anti-gray matter antiserum, or the anti-scar antiserum. This work was supported by the Spinal Cord Society grant number G-A UAI.

367.14 THE EFFECT OF $GM_1$, THYROXINE AND HYDROCORTISONE ON FETAL CATECHOLAMINERGIC NUCLEI TRANSPLANTED INTO THE TRANSECTED SPINAL CORD OF THE ADULT RAT. John W. Commissiong and G. Toffano. Dept. of Physiol., McGill Univ., Montreal, Canada H3G 1Y6 and Dept. of Biochem., Fidia Res. Lab., 35031 Abano Terme, Italy.

Fetal locus coeruleus (LC) of rat has previously been successfully transplanted into the transected spinal cord of the young adult rat (Commissiong, 1983). In the present experiments, the ganglioside $GM_1$, thyroxine (T4) and hydrocortisone (HC) were tested for their ability to promote the survival, growth and development of fetal day (FD) 16 LC and substantia nigra (SN) tissue after their transplantation into the transected spinal cord of the adult rat. Female Sprague Dawley rats of 150 g were anaesthetized with Brietal (60 mg/kg i.p.). A laminectomy was done, following which the cord was completely transected subpially at T8, creating a spinal cavity about one-half of a segment long. Another cavity was made at L2, in the dorsolateral intumescence. Fetal LC or SN was implanted into both cavities, and the pia over the implants sutured. The implanted animals and their appropriate controls were treated with $GM_1$ (30 mg/kg i.p.), or T4 (50-100 µmol/kg s.c.) or HC (40 mg/kg i.p.) daily for the first 21 days after surgery, and thereafter every other day until sacrificed.

As reported previously, the survival rate of the animals is 95%. The rate of fusion of the fetal implants with the spinal cord is 40%. The solid implants subdivided into smaller cell clusters which became lodged in the host tissue away from the site of implantation. Neurite and axonal growth occurred in excess of 15 mm away from the cell bodies. Growth of sympathetic noradrenergic fibres normally associated with blood vessels within the cord was again observed in the caudal region of the transected cord. Neither $GM_1$, T4 nor HC exerted any beneficial effect on any of the above parameters. However, $GM_1$ and T4 exerted a marked enhancement of the fluorescent intensity of the noradrenergic cells in the subcoeruleus which normally project to the spinal cord. The somatic dendrites of these cells were also longer, and morphologically more robust. $GM_1$ also caused an increased sprouting of the descending monoaminergic (catecholaminergic and serotonergic) damaged axons in the rostral region of the transected cord. These axotomized neurons originate in the brainstem. HC had no marked effect on any of these parameters. The results demonstrate that $GM_1$, and to a lesser degree T4 are capable of enhancing the regeneration of the chemically defined subset of neurons in the central nervous system of the adult rat. The observed effects of $GM_1$ on both the cell body and axon terminal regions of the axotomized neuron suggest that it may have a more general effect on the regenerating neuron, versus T4 for example, whose effect was restricted to the cell body region only.

Commissiong, J.W. Brain Res. 271, 174, 1983.

## SEROTONIN

368.1 Serotonin (5-HT) in the squid nervous system. Susan C. Feldman and Jean Muldur*, Dept. of Anatomy, New Jersey Medical School, Newark, N.J. 07103 and Marine Biological Laboratory, Woods Hole, MA. 02543.

As part of an ongoing inquiry into the functional, anatomical and comparative relationships of transmitter systems we describe the immunohistochemical localization of 5-HT containing neurons and processes in the nervous system of the cephalopod mollusk, the squid Loligo pealei: The nervous system of cephalopods is highly complex with separate lobes important in vision, learning and motor behavior. In addition, squid neurons range in shape from true multipolar to amacrine and the uni- and bi-polar neurons common in most invertebrates.

For this study, squid nervous system - optic lobes, circumesophageal ganglia and stellate ganglion - were dissected and fixed by immersion in Bouin's solution. Prior to sacrifice, several animals were injected with the MAO inhibitor pargyline (10mg/squid, 20 min) into the coelomic cavity. This increased 5-HT immunoreactivity primarily in fibers but did not alter the distribution of 5-HT neurons or fibers from that seen in untreated animals. 5-HT was localized in both paraffin-embedded and vibratome sections using an antiserum to 5-HT (Immunomuclear Corp.) and the standard PAP technique.

The distribution of 5-HT was extremely widespread. 5-HT neurons were confined to a small number of areas-the medulla of the optic lobe, several supraesophageal lobes, and two lobes of the subesophageal complex. In the optic lobe medulla axons of 5-HT neurons contributed to the formation of the optic tract. These could be followed into the supraesophageal ganglia where they branched extensively. In the supraesophageal complex, 5-HT neurons were found in the peduncle lobe, the frontal lobe and the anterior division of the basal lobe. In this latter lobe every cell contained 5-HT; this was in marked contrast to the other lobes in which 5-HT neurons were not clustered. In the subesophageal complex, or motor centers, 5-HT was present in a small number of cells and in fibers surrounding nonimmunoreactive neurons and in large nerves emanating from this region. In the stellate ganglion, 5-HT was limited to a small number of cells.

In summary, the squid nervous system was characterized by a widespread distribution of 5-HT fibers and a more restricted distribution of 5-HT containing neurons, an arrangement somewhat reminiscent of the mammalian situation.

368.2 STRESS AND ACTIVITY RELATED CHANGES OF HYDROXYLASE COFACTOR CONCENTRATIONS IN BRAIN TISSUES AND BLOOD. E.H.Y. Lee. Inst. of Biomed. Sci. Academia Sinica, Taipei, Taiwan, Republic of China.

Tetrahydrobiopterin ($BH_4$) functions as a cofactor for phenylalanine hydroxylase (Kaufman 1959,1963). It also serves as a cosubstrate for brain tyrosine hydroxylase (Nagatsu et al.,1964) and tryptophan hydroxylase (Lovenberg et al., 1967) in regulation of catecholamine and serotonin biosynthesis. Previous reports have shown that amphetamine, which elevated locomotor activity, decreased striatal $BH_4$ level in rats (Lee & Mandell, 1985). Furthermore, diurnal rhythm study of rat striatal biopterin, the oxidized form of $BH_4$, indicated a high biopterin level in the light phase when activity is low and low biopterin level in the dark phase while the activity is high in these nocturnal animals (Lee & Mandell, 1985). The purposes of the present study were to examine whether there is an inverse relationship between activity level and biopterin concentration in brain and to examine the effects of electric shock stress on biopterin in different brain tissues and blood.

Thirty-three male Sprague-Dawley rats (150-225 g) were used. Twenty-one of them were used for activity and biopterin correlation study. Biopterin concentrations in the caudate nucleus and nucleus accumbens were measured in each animal. The other twelve rats were used for stress study. After 15 min of foot shock stress (2mA, 300 msec duration, 5 sec ISI on the average), animals were sacrificed immediately. Caudate, hypothalamus, hippocampus, raphe nuclei and blood were collected for biopterin assay. The method used for biopterin assay was HPLC with fluorescence detection.

Results indicate that there is a significant inverse relationship between activity and cofactor concentration in the striatum ($r=0.446, p<0.05$) but not in the nucleus accumbens ($r=0.054, p>0.05$). Foot shock stress significantly elevated cofactor levels in the hypothalamus and plasma, and decreased the same measure in the raphe nuclei without significantly changing it in the caudate nucleus and hippocampus. The above results are consistent with the finding that amphetamine reduced striatal $BH_4$ while it increased locomotor activity in animals. It also suggests that endogenous striatal $BH_4$ is an important factor regulating animal's locomotor activity in general. Alterations of $BH_4$ levels in specific brain regions and blood may also be a new indicator of stress situations. Change of $BH_4$ in the hypothalamus may be associated with the neurotransmitter-hormonal interrelationships along the adenohypophyseal axis which regulates the release of stress hormones. This work was supported by the research fund of the Inst. of Biomed. Sci., Academia Sinica, Taiwan, R.O.C.

368.3 SPIROXATRINE: A SELECTIVE ANTAGONIST OF SEROTONIN-1A RECEPTORS. D.L. Nelson and E.W. Taylor*. Dept. of Pharmacol. & Toxicol, Col. of Pharmacy, Univ. of Arizona, Tucson, AZ 85721.

The characterization of the properties and functional significance of the putative subtypes of serotonin (5-hydroxytryptamine, 5HT) receptors has often been impeded by the lack of selective pharmacologic agents, especially selective antagonists for the 5HT-1 receptors. Since the neuroleptic spiperone has relatively high-affinity for the 5HT-1A subtype of sites (in addition to its high affinity for 5HT-2 sites), we have examined several analogs of this compound in an attempt to find a structure that would retain the high affinity for the 5HT-1A site, but which would have lowered affinity for the 5HT-2 site. The relative potencies of the compounds at the different 5HT binding sites were assessed by comparing the inhibition curves generated against the binding of [$^3$H]5HT (which labels both 5HT-1A and 5HT-1B sites), [$^3$H]8-hydroxy-N,N-dipropyl-2-aminotetralin (PAT, which labels 5HT-1A sites), and [$^3$H]ketanserin (KET, which labels 5HT-2 sites). The binding was carried out using membranes prepared from the rat cerebral cortex. The concentrations of the [$^3$H]ligands were approximately equal to their reported $K_d$ values (1.8 nM, 1.0 nM, and 0.5 nM for [$^3$H]5HT, [$^3$H]PAT, and [$^3$H]ketanserin respectively). Of the compounds tested only one, spiroxatrine (Janssen Pharmaceutica, Beerse , Belgium), showed selectivity. The $IC_{50}$ values (nM) for this compound compared to spiperone were as follows:

| | [$^3$H]PAT | [$^3$H]5HT | [$^3$H]KET |
|---|---|---|---|
| Spiperone: | 137.6 | 4038 | 0.68 |
| Spiroxatrine: | 5.04 | 1211 | 226.2 |

These data showed that spiroxatrine, unlike spiperone, was much more potent at 5HT-1A than 5HT-2 sites. In addition, its low $IC_{50}$ at [$^3$H]5HT compared to [$^3$H]PAT binding suggested a very low affinity for the 5HT-1B site. When spiroxatrine was examined in an in vitro preparation of the canine basilar artery, which has been proposed to contain 5HT-1 receptors, it produced no contractions up to the highest concentration used ($10^{-5}$ M). However, when 5HT was used as the agonist (in the presence of 100 nM KET to eliminate the possibility of 5HT-2 receptors contributing to the contraction), spiroxatrine antagonized the contractions with a $K_B$ value of 25 ± 8 nM. Arterial contractions produced by low concentrations (<$10^{-6}$ M) of PAT were also blocked by spiroxatrine (100 nM). The data, therefore, suggest that spiroxatrine is a selective 5HT-1A antagonist. Because of its high affinity this compound may have significant potential as a tool for studying these sites. (Supported by NIH grant NS16605 and a predoctoral fellowship from the PMA Foundation).

368.4 MCPP, A 5HT IB AGONIST, PRODUCES PROLACTIN, CORTISOL AND GROWTH HORMONE RELEASE AND BIPHASIC BEHAVIORAL CHANGES IN HEALTHY HUMAN SUBJECTS. G. R. HENINGER and D. S. CHARNEY*, Dept. of Psychiatry, Yale Univ. Med. Sch., New Haven, CT 06508.

Recent biochemical and physiologic investigations have provided evidence of two different serotonin (5HT) type I receptors. 5HT Ia receptors preferentially respond to indole agonists, and 5HT Ib receptors to piperazine agonists. In order to assess the effects of 5HT Ib stimulation in humans, the specific 5HT Ib agonist MCPP (1-(3-chlorophenyl) piperazine) and the 5HT precursor tryptophan (TRYP) were administered intravenously to healthy subjects. This allowed a comparison of the effects of specific 5HT Ib stimulation by MCPP to the relatively less specific 5HT stimulation resulting from the tryptophan infusion.

METHODS: Thirteen subjects (5 males) between the ages of 18 and 47 gave informed written voluntary consent and received placebo, .025, .05, .1, and .2 mg/kg of MCPP and 100 mg/kg L-tryptophan on 6 separate test days. Subjects slept at home, fasted overnight and reported to the laboratory at 8:30 A.M. where they had a catheter inserted, then a 90 min. adaptation period, and then were administered one of the infusions. Repeated blood sampling and subjective and objective assessment of behavior were carried out before and after the infusion. Plasma prolactin (PRL), cortisol (CORT) & growth hormone (GH) were assayed with standard RIA methods.

RESULTS: MCPP produced a significant dose response curve for all three hormones. At the .1 mg/kg dose the average maximal effect (peak minus base) was 12 ng/ml, 10 ug/dl, and 8 ng/ml for PRL, CORT and, GH, respectively. The TRYP infusion produced a corresponding maximal effect of 18 ng/ml, ~2 ug/dl and 7 ng/ml for PRL, CORT and GH respectively. MCPP produced increased feelings of mellow, high, happy and calm at the .05 mg/kg dose and several subjects had increased sexual desire. At .1 and .2 mg/kg of MCPP, many subjects had increased dysphoric feelings of anxious, nervous, irritable and drowsy and somatic symptoms of nausea, dizziness, blurred vision, tremulousness, piloerection, hot and cold flashes, feelings of unreality and headache. This prevented use of the .2 mg/kg dose in 6 subjects. TRYP produced mild increases in feelingcs of drowsy, high and mellow without the somatic symptoms seen with MCPP. Blood pressure, pulse rate and oral temperature demonstrated little change with either MCPP or TRYP.

DISCUSSION: MCPP and TRYP both stimulated PRL and GH release; while only MCPP stimulated CORT release. MCPP had a biphasic effect on mood, producing positive feelings at low doses and negative feelings at higher doses. TRYP did not produce negative feelings. This data suggests that the neuroendocrine and behavioral response to MCPP will be a useful test of the 5HT Ib receptor system for the study of neurologic and psychiatric conditions. Supported by USPHS MH36229, MH25642, and MH30929.

368.5 SOLUBILIZATION OF SEROTONIN 5-HT1c SITES FROM PIG CHOROID PLEXUS. P.R. Hartig, and K.A. Yagaloff*, Department of Biology, The Johns Hopkins University, Baltimore, MD 21218.

We have previously reported the localization of a unique serotonergic binding site in the rat choroid plexus and have characterized the binding of $^{125}$I-LSD to rat choroid plexus homogenates (Yagaloff and Hartig, J. Neuroscience (1985)). In addition, Pazos et al. (Eur. J. Pharmacol. 106, 539 (1984)) have characterized a very similar serotonergic binding site (termed 5-HT1c) in pig choroid plexus homogenates. We report here the solubilization of 5-HT1c serotonergic binding sites from pig choroid plexus membranes using ionic and nonionic detergents.

Pig choroid plexus membrane preparations were solubilized with various detergents and centrifuged at 100,000 x g for 1 hour. Approximately 40% of the membrane sites were recovered in the soluble supernatant using a postlabelling methodology (reversible labelling after solubilization). Specific binding was typically 70-80% of total labelling in the solubilized supernatant. Binding to the solubilized site was reversible, stereospecific, and both heat and protease sensitive. The solubilized sites were not retained by a 0.22 micron Millipore filter and were exluded from the void volume of a Sepharose CL-6B column.

Scatchard analyses of binding to the membrane preparation and to the solubilized supernatant indicated that radioligand binding affinities were the same in both preparations. The pharmacological profile of binding to the choroid plexus site revealed an identical rank order of potency for 12 compounds binding to both solubilized and membrane sites. In addition, nearly all of the compounds were equipotent or more potent in binding to the solubilized site in comparison to the membrane site.

The yield and stability of the solubilized 5-HT1c site are superior to those obtained for other solubilized serotonergic sites in the brain, indicating that the choroid plexus 5-HT1c site is a promising system for the purification and biochemical characterization of mammalian brain serotonergic sites.

368.6 COVALENT LABELING OF PUTATIVE SEROTONIN RECEPTOR IN APLYSIA NEURONS. J.C. Shih, T. Saitoh, R.W. Ransom* and J.H. Schwartz (Spon. S. Eiduson ), Institute for Toxicology, School of Pharmacy University of Southern California, Los Angeles, CA 90033, and Howard Hughes Medical Institute, Columbia University, College of Physicians and Surgeons, New York, NY 10032.

We have previously shown that 1-(2-4-aminophenyl)ethyl)-4-(3-trifluoromethyl phenyl) piperazine (p-$NH_2$-PE-TFMPP) selectively binds to 5-HT-1A receptor in rat brain (Asarch, Ransom and Shih, Life Sci. 36:1265-73, 1985). The accompanying abstracts show that $^3$H-p$NH_2$-PE-TFMPP binds selectively with high affinity to 5-$HT_{1A}$ receptor sites in rat brain. Furthermore, the azido derivative of $^3$H-p-$NH_2$-PE-TFMPP ($^3$H-p-azido-PE-TFMPP) photolabels one 5-HT-1A receptor protein in rat brain. This report demonstrates the covalent labeling of serotonin receptor in Aplysia neurons by $^3$H-p-azido-PE-TFMPP.

Serotonin increases the synthesis of c-AMP in Aplysia neurons and stimulates the adenylate cyclase in membranes isolated from nervous tissue with a Kact of 0.8 uM. Under the same conditions, p-$NH_2$-PE-TFMPP stimulates adenylate cyclase with a Kact of 20 uM. p-azido-PE-TFMPP also stimulates the cyclase in the dark, however, with much less efficiency (Kact = 200 uM). Irradiation of the membrane with 50 uM of p-azido-PET abolished 75% of the cyclase activity stimulated by 50 uM serotonin suggesting that this compound may occupy the receptor binding site, and thus may be suitable for labeling the receptor protein. $^3$H-azido-PE-TFMPP (50 uM) was incubated with membranes from Aplysia neurons for 5 min at 25° C, washed once, and irradiated on ice. A fluorogram of SDS-gels shows that there are many proteins labeled under this condition, however, only one polypeptide with a molecular weight of 63,000, whose labeling was protected by the presence of 0.2 uM serotonin during incubation and photolysis. None of the protein labeled by $^3$H-azido-PE-TFMPP in Aplysia muscle could be protected by serotonin. This result suggests that the protein with M.W. of 63,000 may be related to serotonin receptors. (Supported in part by grant from NIMH, MH 37020.)

368.7 IDENTIFICATION OF A 5-$HT_{1A}$ RECEPTOR POLYPEPTIDE IN RAT BRAIN BY PHOTOAFFINITY LABELING. R.W. Ransom*, K.B. Asarch*, J.C. Shih (Spon. S. Chen), Institute for Toxicology, School of Pharmacy, University of Southern California, Los Angeles, CA 90033.

The reversible and irreversible binding of 1-(2-(4-azidophenyl) ethyl)-4-(3-trifluoromethylphenyl) piperazine (pAzido-PE-TFMPP) and ($^3$H)pAzido-PE-TFMPP to rat brain 5-$HT_{1A}$ receptors is presented. The inhibition of ($^3$H)5-HT binding in cortex and hippocampus by pAzido-PE-TFMPP was best fit by a two site model. The computer generated dissociation constants for the azide's high and low affinity sites were 0.4 nM and 200 nM, respectively. The fraction of high affinity sites (40% in cortex, 60% in hippocampus) for the azide corresponded to the number of 5-$HT_{1A}$ sites in these tissues as determined by spiperone displacement of ($^3$H) 5-HT binding. pAzido-PE-TFMPP inhibition of ($^3$H)5-HT binding in the presence of 1 uM spiperone was consistent with displacement from a single site having a Kd of 200 nM for the azide. These results demonstrate that pAzido-PE-TFMPP and spiperone recognize the same two subpopulations of 5-$HT_1$ sites and it is the 5-$HT_{1A}$ subtype for which pAzido-PE-TFMPP has high affinity.

Using 10 uM 5-HT to define nonspecific binding, ($^3$H)pAzido-PE-TFMPP labeled a single site in membranes prepared from cortex and hippocampus with a Kd of 1 nM. The ability of 5-HT, LSD, 8-hydroxy-2-(di-n-proplyamino)tetralin (PAT), and spiperone to displace specific ($^3$H)pAzido-PE-TFMPP binding corresponded to their high affinity for 5-$HT_{1A}$ sites. In photolysis experiments, hippocampal membranes were incubated with 6 nM ($^3$H)pAzido-PE-TFMPP, washed twice, and irradiated. SDS-PAGE of these membranes showed that radioactivity was primarily incorporated into a polypeptide with a molecular weight of 54,000. The labeling of this polypeptide was completely inhibited when membranes were incubated with the tritiated azide in the presence of 1 uM 5-HT, PAT, LSD, or spiperone. The labeling was unaffected by the presence of 1 uM ketanserin. These results indicate that the labeled polypeptide represents the 5-$HT_{1A}$ receptor or a subunit of the receptor. (Supported by NIMH Grant No. MH 37020.)

368.8 [$^3$H]-1-(2-(4-aminophenyl)ethyl)-4-(3-trifluoromethylphenyl) Piperazine: A Selective Radioligand for 5-$HT_{1a}$ Receptors in Rat Brain. K.B. Asarch*, R.W. Ransom*, and J.C. Shih. Institute for Toxicology, School of Pharmacy, University of Southern California, Los Angeles, California 90033.

We have synthesized a new serotonergic radioligand which has high selectivity for 5-$HT_{1a}$ sites in rat brain. 1-(2-(4-amino-phenyl)ethyl)-4-(3-trifluoromethylphenyl)piperazine ($pNH_2$-PE-TFMPP) inhibits [$^3$H]5-hydroxytryptamine binding to 5-$HT_{1a}$ and 5-$HT_{1b}$ sites in rat brain with apparent equilibrium dissociation constants ($K_d$) of 2.9 nM and 328 nM, respectively. $pNH_2$-PE-TFMPP was tritiated by catalytic reduction of a ring brominated analogue of $pNH_2$-PE-TFMPP under tritiated hydrogen gas. Using either 10 μM serotonin or 1 μM 8-hydroxy-2-(di-n-propylamino)tetralin (DPAT) to define nonspecific binding, [$^3$H]$pNH_2$-PE-TFMPP bound to a single class of sites in rat cortical membranes with a $K_d$ of 1.8 nM and a maximal binding density ($B_{max}$) of 222 fmol/mg protein. This affinity very closely matched the affinity obtained by displacement with the unlabeled $pNH_2$-PE-TFMPP (2.9 nM). d-Lysergic acid diethylamide and serotonin, two nonselective inhibitors of [$^3$H]5-HT binding, displaced 1 nM [$^3$H]$pNH_2$-PE-TFMPP with $K_i$ values (2.5 nM and 18 nM, respectively) that are consistent with their affinities for 5-$HT_1$ receptors. Spiperone and DPAT, two compounds that discriminate [$^3$H]5-HT binding to 5-$HT_{1a}$ and 5-$HT_{1b}$ sites, inhibited [$^3$H]$pNH_2$-PE-TFMPP binding with $K_i$ values (40 nM and 2.8 nM, respectively) in accordance with their much higher affinities for the 5-$HT_{1a}$ receptor subtype. Furthermore, the ability of (m-trifluoromethylphenyl) piperazine and ketanserin to inhibit [$^3$H]$pNH_2$-PE-TFMPP binding ($K_i$ values 233 nM and 1000 nM, respectively) reflected their low affinities for the 5-$HT_{1a}$ receptor. The regional distribution of serotonin sensitive [$^3$H]$pNH_2$-PE-TFMPP sites also correlated with the relative densities of 5-$HT_{1a}$ receptors in the rat brain: hippocampus > cortex > corpus striatum > cerebellum). These results indicate that [$^3$H]$pNH_2$-PE-TFMPP binds selectively and with high affinity to 5-$HT_{1a}$ receptor sites in the rat brain.

In the rat hippocampus the divalent cations magnesium, calcium, and manganese at 5 mM all significantly increase the amount of specific [$^3$H]$pNH_2$-PE-TFMPP binding (66 to 99%) as has been observed for [$^3$H]5-HT binding. In contrast, GTP decreases the specific binding of both [$^3$H]$pNH_2$-PE-TFMPP and [$^3$H]5-HT specific binding in the rat hippocampus with similar potencies ($IC_{50}$ = 30 μM). Preliminarily, we observe a stimulation of adenylate cyclase activity by $pNH_2$-PE-TFMPP in synaptic membranes prepared from hippocampi from adult rats of about two-thirds the magnitude of the 5-HT stimulation with an $EC_{50}$ (100 nM) similar to 5-HT. (Supported by NIMH Grant No. RO1-MH 37020).

368.9 DIRECT LABELING OF 5-$HT_{1A}$ AND 5-$HT_{1B}$ BINDING SITES WITH $^3$H-OH-DPAT AND $^3$H-5HT IN BOVINE BRAIN. S. J. Peroutka, P. J. Ison* and J. R. Schlegel*. Department of Neurology, Stanford University Medical Center, Stanford, CA 94305.

The interactions of 12 serotonergic agents with both $^3$H-8-OH-DPAT binding in bovine hippocampal membranes and $^3$H-5-HT binding in striatal membranes were analyzed. 8-OH-DPAT is the most potent inhibitor of $^3$H-8-OH-DPAT binding. 5-HT, bufotenine, 5-MeDMT, RU 24969 and TVX Q 7821 also have nanomolar affinity for the $^3$H-8-OH-DPAT binding site. DMT, TFMPP, spiperone and pizotifen have $IC_{50}$ values ranging from 190 - 750 nM. Quipazine is the weakest agent at the $^3$H-8-OH-DPAT binding site with an $IC_{50}$ value of 4,500 ± 1,000 nM. These values correlate well with drug affinities for $^3$H-8-OH-DPAT binding sites in rat brain membranes.

A strikingly different pharmacological profile is observed at the $^3$H-5-HT binding site in bovine striatal membranes. 5-HT ($IC_{50}$ = 7.5 ± 2 nM) and bufotenine ($IC_{50}$ = 13 ± 3 nM) are the only agents which display less than 100 nanomolar affinity for these binding sites. These drugs, in addition to DMT, TFMPP and quipazine, have similar affinity for both hippocampal $^3$H-8-OH-DPAT and striatal $^3$H-5-HT binding sites. All other agents are markedly less potent at $^3$H-5-HT striatal binding sites than $^3$H-8-OH-DPAT hippocampal binding sites. Drugs such as pizotifen, spiperone and RU 24969 are 19 - 86-fold less potent at $^3$H-5-HT striatal binding sites. For example, spiperone is 86-fold less potent at $^3$H-5-HT ($IC_{50}$ = 18,000 ± 2,000 nM) binding sites than $^3$H-8-OH-DPAT sites. TVX Q 7821 and buspirone are more than 1,000-fold less potent at these binding sites. 8-OH-DPAT is the most selective agent, being 18,000-fold weaker ($IC_{50}$ = 31,000 ± 6,000 nM) at $^3$H-5-HT binding sites in the striatum than at $^3$H-8-OH-DPAT binding sites in the hippocampus.

The major finding of the present study is that 5-$HT_{1A}$ and 5-$HT_{1B}$ binding sites can be selectively labeled using specific ligands in appropriate brain regions. $^3$H-8-OH-DPAT can be used to directly label the 5-$HT_{1A}$ binding site in hippocampal membranes. Although no specific label exists for the 5-$HT_{1B}$ binding site, Nelson and co-workers have defined the site as $^3$H-5-HT sites which are insensitive to low concentrations of spiperone. In addition, lack of sensitivity to 8-OH-DPAT is also a characteristic of the 5-$HT_{1B}$ binding site (Middlemiss and Fozard, 1983). According to these criteria, 85 - 90% of the $^3$H-5-HT labeled sites in bovine striatal membranes can be classified as 5-$HT_{1B}$ binding sites. Therefore, analysis of $^3$H-5-HT binding in this tissue represents the most direct method to characterize the 5-$HT_{1B}$ site.

368.10 NUCLEOTIDE INTERACTIONS WITH 5-$HT_{1A}$ AND 5-$HT_{1B}$ BINDING SITES. J. R. Schlegel* and S. J. Peroutka. (SPON: R. Angel). Department of Neurology, Stanford University Medical Center, Stanford, California 94305.

Nucleotide interactions have been extensively evaluated at 5-$HT_1$ binding sites. However, $^3$H-5-HT binding sites have been recently subdivided into 5-$HT_{1A}$ and 5-$HT_{1B}$ binding site subtypes. Using $^3$H-8-OH-DPAT to directly label 5-$HT_{1A}$ binding sites and $^3$H-5-HT in the presence of $10^{-7}$M 8-OH-DPAT to label 5-$HT_{1B}$ binding sites in rat cortex, we have evaluated the interactions of guanine and adenine nucleotides with 5-$HT_1$ binding site subtypes.

Guanosine triphosphate (GTP) and guanosine diphosphate (GDP) decrease the specific binding of $^3$H-8-OH-DPAT to 5-$HT_{1A}$ binding sites. At a concentration of $10^{-5}$M, GTP and GDP reduce specific $^3$H-8-OH-DPAT binding to 83 ± 2% and 88 ± 5% of control values, respectively. At $10^{-4}$M, GTP and GDP reduce specific $^3$H-8-OH-DPAT binding to 49 ± 4% and 50 ± 3%. At $10^{-3}$M, they reduce specific binding to 21 ± 2% and 35 ± 3%. By contrast, guanosine monophosphate (GMP) and the adenine nucleotides have little effect, reducing specific $^3$H-8-OH-DPAT binding to 85 - 92% of control values at concentrations of $10^{-4}$M.

At $^3$H-8-OH-DPAT binding sites, the affinity of both classical and novel serotonergic agonists (5-HT, 5-MT, 5MeODMT, LSD, TFMPP, 8-OH-DPAT, RU24969, buspirone, and TVX Q 7821) is decreased in the presence of $10^{-4}$M GTP, with $IC_{50}$ values shifted two to four fold. No significant shift in displacement curves or $IC_{50}$ values is observed in the presence of GTP when serotonergic antagonists (spiperone, metergoline, and pirenperone) compete for 5-$HT_{1A}$ binding sites. Saturation experiments using $^3$H-8-OH-DPAT in the absence or presence of $10^{-3}$ and $10^{-4}$M GTP demonstrates a decrease in the affinity of $^3$H-8-OH-DPAT for 5-$HT_{1A}$ binding sites in rat cortex without affecting the total number of binding sites.

By contrast, less pronounced effects of GTP and GDP are observed with $^3$H-5-HT binding to 5-$HT_{1B}$ binding sites. In rat cortex, $^3$H-5-HT binding in the presence of $10^{-7}$M 8-OH-DPAT is reduced to 80 ± 4% and 81 ± 4% by $10^{-4}$M GTP and $10^{-4}$M GDP, respectively. GMP and the adenine nucleotides have little effect at 5-$HT_{1B}$ binding sites, with specific $^3$H-5-HT binding ranging from 89 - 100% in the presence of $10^{-4}$ nucleotide.

The major finding of the present study is that guanine nucleotides differentially affect radioligand binding to 5-$HT_1$ binding site subtypes. Although GTP and GDP versus other nucleotides selectively inhibit agonist binding to both 5-$HT_{1A}$ and 5-$HT_{1B}$ sites, the effect is significantly more pronounced at the 5-$HT_{1A}$ binding site.

369.1 CAN TRIGEMINAL CHEMORECEPTORS DISCRIMINATE ODORANTS? W.L. Silver, J.R. Mason*, and A.H. Arzt*, Monell Center, Phila., PA 19104

Trigeminal chemoreceptors can respond to a wide variety of odorants. However, it is not known whether these chemoreceptors can discriminate between odorants matched for equal intensity. We addressed this issue using both electrophysiological and behavioral techniques with the tiger salamander.

For the electrophysiological experiments, integrated multiunit responses were obtained from the trigeminal nerve as it passed through the orbit of the eye. An air-dilution olfactometer (as was also used in the behavioral experiments) delivered the stimuli to the animals. Concentration-response curves were obtained for amyl acetate (AMA) and cyclohexanone (CH). The concentration of both compounds necessary to produce an equivalent response (150% of CH std., ~1100 ppm) was then used in cross-adaptation experiments. A background stream of ~1700 ppm CH or ~ 2800 ppm AMA severely reduced the responses to both AMA and CH. Only concentrations above background elicited increases in response magnitude.

For the behavioral experiments, six salamanders were randomly assigned to two groups. Group 1 was trained to avoid CH (S+: ~ 900 ppm) and not to respond to AMA (S-: ~1100 ppm). Group 2 received opposite training. When criterion was achieved (> 90% S+ responding, <20% S- responding), both groups were given varied concentrations of their respective S+ odorant. S+ concentrations (CH:~ 325 ppm; AMA: ~200 ppm) that elicited 80% avoidance were used in subsequent discrimination tests. Both groups discriminated CH from AMA.

Following discrimination trials, all animals were given bilateral olfactory nerve cuts, and additional presentations of varied S+ concentrations. Higher concentrations of odorant were necessary to elicit 80% avoidance in nerve cut animals. Discrimination tests between behaviorally equivalent odorant concentrations (CH: ~1000 ppm; AMA ~1250 ppm) revealed that neither group was able to discriminate CH from AMA. Additional discrimination trials with concentrations that elicited 95% avoidance produced similar results. However, both groups discriminated an S+ concentration that elicited 95% avoidance from an S- concentration that elicited 80% avoidance (for the opposite group). When concentrations were switched (i.e., 80% S+, and 95% S-), all animals avoided S- (and not S+) presentations.

On the basis of these electrophysiological and behavioral findings, we speculate that trigeminal chemoreceptors are unable to discriminate between odorants matched for equal intensity. Thus, these chemoreceptors discriminate odorant quantity, not quality.

369.2 THE PHEROMONAL RELEASE OF NIPPLE-SEARCH BEHAVIOR IN NEWBORN RABBITS DOES NOT DEPEND ON THE VOMERONASAL ORGAN R. Hudson* and H. Distel* (SPON: A. Hofbauer). Inst. Med. Psychol., Univ. München, D-8000 München, Germany.

Rabbit pups are only nursed for about 3 minutes once a day. To locate nipples in this short time they are totally dependent on a short-ranging pheromone on the mother's belly which releases and guides the stereotyped nipple-search behavior. This is the case even for pups delivered preterm, and thus without postnatal experience of the pheromone. However, newborn pups can be rapidly conditioned to respond to artificial odors with nipple-search behavior when these are paired with suckling (Hudson, Dev.Psychobiol., in press). As it has long been known that bilateral olfactory bulbectomy completely disrupts suckling behavior in rabbits (v. Gudden, Arch. Psychiat. 2:693, 1870), the relative role of the main and accessory olfactory systems in mediating inborn and acquired responsiveness to nipple-search odors was investigated.

Irrigating the nasal mucosa of 3-day-old pups (n=5) with a 2% zinc sulfate solution eliminated responsiveness to the pheromone, and hence suckling, on the subsequent days. Similarly, pups conditioned to the odor of citral (n=6) no longer responded to it with nipple-search behavior after the ZnSO4 treatment. While histological verification of these cases showed the olfactory epithelium to be completely destroyd, the epithelium of the vomeronasal organ appeared virtually intact.

In contrast, completely removing the vomeronasal organ of normal (n=4) and citral-conditioned (n=3) pups on day 3 had little effect on their ability to respond to the pheromone, or to the learned odor, with nipple-search behavior. Even pups delivered 1 day preterm by injecting the doe with oxytocin (n=5), and lesioned before their first suckling experience, responded as vigorously to the pheromone as unlesioned control pups.

These findings suggest that both inborn and postnatally acquired responsiveness to odors releasing nipple-search behavior in newborn rabbits are mediated by the main olfactory system. This is of particular interest given the important role attributed to the accessory olfactory system in pheromonal perception. However, it might be necessary to distinguish between pheromones associated with suckling and therefore peculiar to mammals, and other pheromones.

(Supported by the Deutsche Forschungsgemeinschaft: Di 212/3-1).

369.3 **CYTOARCHITECTURE AND PROJECTION SITES OF SOME RETROBULBAR CORTICES IN THE RAT BRAIN.** C.K.H. REYHER and W.K. SCHWERDTFEGER. Dept. Neuroanatomy, Freie Universität Berlin, D - 1000 Berlin 33, FRG Max-Planck-Institut für Hirnforschung, Frankfurt. (SPON: European Neuroscience Association).

The organization of the central connectivity of individual olfactory-related retrobulbar structures with the primary and higher olfactory brain was investigated by means of highly sensitive tracing methods. To characterize the afferent and efferent olfactory connections of the retrobulbar cortices wheat germ agglutinin conjugated to horseradish peroxidase (Sigma) was injected stereotaxically into the main and accessory olfactory bulb, into the anterior piriform and dorsal peduncular cortex, and into several subdivisions of the anterior olfactory nucleus. After a 1-day survival time the animals were transcardially perfused with a 1% paraformaldehyde/ 1% glutaraldehyde - solution. Frozen sections were reacted with tetramethylbenz - idine as chromogen.

Neurons projecting to individual retrobulbar cortices were found to arise in the subiculum, the ventral limb of the precommissural hippocampus, the lateral entorhinal cortex, the anterior and posterior parts of the piriform cortex, the tuberculum olfactorium, the entire main olfactory bulb, as well as the mesencephalic raphe nuclei and the locus coeruleus. Some of these tracts were topographically mapped by a computerized morphometric unit to define localization and arborization of individual neurons; this allowed comparison of HRP-labeled cells with corresponding ones obtained by using Golgi impregnation techniques. Thus, we determined e.g. that the majority of output neurons of the lamina externa of the anterior olfactory nucleus which project exclusively to the opposite olfactory bulb are characterized by a lack of basal dendrites.

These results offer evidence that retrobulbar cortices are involved in a highly organized controlling system which may exert influences onto the parallel processing of olfactory information related to the two hemispheres.

369.4 TASTE BUD DENSITY ON THE HUMAN TONGUE. Inglis J. Miller, Jr. Dept. of Anatomy, Bowman Gray Sch. Med., Winston-Salem, NC 27103.

The density and regional distribution of human fungiform taste buds are important factors in the diagnosis of taste disorders and the study of taste perception. While such information is available for several species of animals, equivalent observations for human tongues is lacking. Preliminary studies are underway on tongues from 37 human cadavers as follows: 5 infants, 4 aged 20-39 yrs, 7 aged 40-59 yrs,8 between 60-75 yrs,10 from 75 to 95 yrs and 3 of unknown origin. Photography was used to document morphological features of the surface. Areas of the tongue tip and midregion measuring about 1-2 cm sqr were sectioned serially, mounted on slides, stained with H & E, and examined by light microscopy. Preliminary results are available for males from 5 adult and one infant subject aged 79, 53, 29, 22, 22 yrs and 2 mo., respectively. The number of papillae containing taste buds from adults varied from 0 in the midregion of one specimen to 55 in the tip region of another. The tip contained an average of 18.2 gustatory papillae per cm sqr of surface, while the midregion contained only about 6.8 gustatory papillae per cm sqr of surface. Taste buds were observed on eminences which differed from classical fungiform papillae, so there was no effort to count the number of "papillae" which lacked taste buds. From 1 to 18 taste buds were found on each gustatory papilla for an average of 4.8 taste buds/papilla on the tip and 3.8 taste buds per papilla on the midregion. The density of taste buds per cm sqr of surface on the tip ranged from 3.6 to 170.8 with a mean of 100.5. The density in the midregion ranged from 0 to 68.7 taste buds per cm sqr with a mean of 27.0 across subjects. The infant tongue contained 157 gustatory papillae on an area of 0.8 cm sqr on the tip for a density of 196 papillae/cm sqr. These papillae contained 328 taste buds (410 taste buds/cm sqr) for an average of 2.09 taste buds/papilla with a range from 1-6. The midregion contained 68 gustatory papillae on a surface of 1.08 cm sqr for a density of 63 papillae per cm sqr. There were 152 taste buds for an average of 2.2 (s.d. 1.3, range 1-7) taste buds per papilla. Thus, the average number of taste buds per papilla was higher for the adults than the infant, but the density of taste buds was higher on the tongue of the child which contained only about 1/3 as much surface area. The two youngest adults (both 22 yrs) had lower taste bud densities than the three older ones and the infant. Both died unexpectedly of acute trauma. We plan to examine gender and race in subsequent studies as well as to document relevant findings from autopsy and medical history. Our objective is to determine taste bud density in a population of human subjects and to identify sources of variation within the population.(This work is supported by grant NS 20101 from NINCDS and by donations of anatomical gifts.)

369.5 CONVERGENCE OF SYNAPTIC INPUT IN MOUSE TASTE BUDS. J.C. Kinnamon and T. Sherman*. Rocky Mountain Taste and Smell Center, Univ. of Colorado Medical School and Dept. MCD Biology, Univ. of Colorado, Boulder, CO 80309.

We have previously demonstrated that both light cells and dark cells synapse onto sensory nerve fibers in murine taste buds. In order to determine the patterns of synaptic connectivity, we have been using the combination of high voltage electron microscopy and three-dimensional computer reconstructions from serial thick sections to study sensory nerve arborizations and synaptic connections in murine vallate taste buds. Nerve fiber contours and the locations of taste cell-sensory nerve synapses have been digitized into a microcomputer using software developed by Dr. Stephen Young (Univ. of CA, San Diego) and Mr. Timothy Edwards (CO State Univ., Fort Collins). To date we have reconstructed 5 nerve fibers and their synaptic connections.

Nerve fibers enter the taste bud at its base and course tortuously up to within 6 um of the taste pore. Some nerve fibers have no branches while others form complex branching patterns extending from one side of the taste bud to the other. A single nerve fiber may have up to 7 synapses with taste bud cells. In all instances the taste bud cells are the presynaptic elements. We have observed two instances where a taste cell has had 3 synapses onto the same nerve fiber.

Some nerve fibers receive synaptic input from light cells or light cells and intermediate cells. Other nerve fibers receive input from dark cells or dark cells and intermediate cells. In no case does a nerve fiber receive input from both dark and light cells.

We are currently in the process of reconstructing more nerve fibers. Although our sample size is small, we speculate that some form of recognition exists, wherein nerve fibers form synapses with specific taste cell types. The basis for this specificity is unknown, but the functional implications are apparent: Separate pathways for dark cells and light cells support the notion that these different cell types may respond differentially to the various types of gustatory stimuli. Hence, some form of range fractionation may exist among the gustatory receptor cells in taste buds.

This work was supported in part by a grant from the Procter & Gamble Co. and NIH grant RR-00592.

369.6 THE GUSTATORY RECIPIENT ZONE OF THE NUCLEUS OF THE SOLITARY TRACT IN THE HAMSTER. B.J. Davis and T. Jang*. Department of Cell Biology and Anatomy, University of Alabama at Birmingham, AL 35294.

A series of correlative light and electron microscopic studies have revealed the gustatory zone of the hamster's nucleus of the solitary tract (NST), and have characterized its major peripheral inputs and neuronal types. Our previous work has quantified the axonal constituencies of the chorda tympani (CT) (Jang and Davis, Chem. Sen. Abs., '85). The IXth nerve contains about 1600 fibers and averages 96μm in diameter. The cross-sectional area of the IXth nerve is at least twice that of the CT. 80% of the IXth nerve fibers are unmyelinated and average 0.6μm in diameter; the remaining myelinated fibers average 1.8μm. Our quantitative light morphometric and accompanying EM studies find four common and morphologically distinct classes of neurons in the gustatory NST based on either differences in cross-sectional somal areas (and major and minor diameters), their general appearances and ultrastructural features. X1 neurons represent 52% of our sample (N=866), possess deeply invaginated nuclei and have somal areas that average 187 μm2; X3 neurons appear similar to the X1 group, are encountered only 22% of the time and have smaller somal areas of 99 μm2. In contrast, 12% of our sample are X2 neurons which do not possess invaginated nuclei, have relatively large somal areas averaging 201 μm2, and possess an unusual amount of perinuclear cytoplasm and membraneous organelles. The smallest class of gustatory NST neurons are the X4 group; this group also has non-invaginated nuclei, has somal areas of only 82 μm2 and almost no perinuclear cytoplasm, are comparable in size to olfactory bulb granule cells, and are good candidates for interneurons. Output neurons have been identified at the EM level following HRP injections into the pontine taste area, the rostral projection target of the gustatory NST. These HRP-positive neurons are most often large and possess invaginated nuclei and are classified as X1 neurons, although invaginated HRP-positive neurons comparable in size to X3 neurons are also observed. Larger non-invaginated X2 neurons represent about 21% of the HRP-positive neurons observed. HRP-positive X4 neurons have not been seen. Our previously described light microscopic morphometric and ultrastructural studies of the gustatory NST, together with the above comparison of the morphologically distinct neurons of the gustatory NST at both the light and EM microscopic levels contribute to our understanding of the intrinsic organization of a major relay nucleus in gustation.

369.7 PROJECTIONS TO THE GUSTATORY THALAMUS OF NEW WORLD PRIMATES. R.B. Hamilton, T.C. Pritchard, and R. Norgren. Dept. Behavioral Science, Col. of Medicine, Penn. St. Univ., Hershey, PA 17033.

The central organization of the gustatory system differs between rodents and lagomorphs, on the one hand, and non-human primates, on the other. In rodents, gustatory neurons in the nucleus of the solitary tract (NST) project rostrally to the pontine parabrachial nuclei (PBN), which in turn, project to both the thalamic gustatory relay (VPMpc) and the ventral forebrain. In primates, gustatory neurons in NST bypass PBN and project monosynaptically to VPMpc. The primate PBN receives axons from neurons in the visceral afferent areas of medial NST and projects to ventral forebrain. The primate PBN projections to VPMpc, however, are almost non-existent. The differences between rodents and primates are substantial, but the primate data derive only from Old World monkeys (Cercopithecidae, Macaca). In order to examine the central gustatory system in New World monkeys (Ceboidea), horseradish peroxidase conjugated to wheat germ agluttinin (HRP-WGA) was injected into the electrophysiologically identified thalamic taste relay (VPMpc) in 2 marmoset (Callitrix nystax) and 1 squirrel monkey (Saimiri sciureus). An additional squirrel monkey received a similar HRP-WGA injection into the thalamic trigeminal sensory relay (VPM). The VPMpc injections labeled some neurons both in the parabrachial nuclei and in the nucleus of the solitary tract caudal to the entry of the intermediate (facial) nerve. The major concentrations of retrogradely labeled cells, however, connected these 2 cell groups. Unlike rodents, the neurons labeled in the marmoset PBN were concentrated rostrolaterally and were primarily located contralateral to the thalamic injection site. In the squirrel monkey, only a few PBN neurons were labeled on either side. In both New World primate species, neurons were labeled in NST caudal to the intermediate nerve, but compared with Old World monkeys, the distributions were more restricted. At this level, only neurons in the most lateral aspect of the solitary nucleus projected to VPMpc. In addition, a few labeled cells were situated near the anterior 1.5 mm of the solitary tract. In both Old and New World primates species, NST extends rostrally from the level of the intermediate nerve. Dorsal to the oral spinal trigeminal nucleus this anterior extention of NST contained a few labeled neurons. At the caudal border of the principal trigeminal nucleus (PV), the anterior extension expanded into a globular form and was filled with retrogradely labeled neurons. The cytoachitecturally distinct NST extension ended, but labeled neurons continued dorsomedially into the vicinity of the medial parabrachial nucleus. In addition, labeled neurons were evident dorsally and laterally in PV itself. Taken with earlier results in rodents and Old World monkeys, these data imply substantial heterogeneity in the central organization of the gustatory system.

369.8 CENTRAL GUSTATORY LESIONS I: INTAKE AND TASTE REACTIVITY TESTS. R.Norgren, F.W.Flynn, H.J.Grill, and G.Schwartz.* Dept. Behavioral Science, Col. Medicine, Penn. St. Univ., Hershey and Dept. Psychology, Univ. of Penn., Phila. PA.

In rodents, the gustatory system ascends through three nuclei before reaching its neocortical representation. These areas, the nucleus of the solitary tract (NST), the pontine parabrachial nuclei (PBN), and the parvicellular division of the ventral posteromedial thalamic nulceus (VPMpc), however, each have connections other than those relaying to the next higher level. To begin assessing the functions of these areas, separate groups of rats were prepared with bilateral lesions at each level, and then all the rats were tested for their capacity to exhibit a variety of behaviors guided by gustatory stimuli. Under barbiturate anesthesia, the gustatory nuclei were localized electrophysiologically using tactile, thermal, and sapid tongue stimulation, and cathodal lesions made through the recording electrode (60-80 uA/30 s, N=6 each for NST, PBN, & VPMpc). Full surgical and unoperated control animals (N=4 each) were run in tandem. After a minimum 2 wk recovery, all rats were placed on an 18 h. water deprivation schedule, and given a daily 15 m., 1 bottle consumption test with water and 3 concentrations each of sucrose, NaCl, HCl, and quinine HCl (QHCl). After 2 repetitions of this test, all rats were re-anesthetized and implanted with bilateral intraoral cannulas. After recovery, they were re-tested with the same sapid stimuli infused via the cannulas (1.0 ml in 1.0 m.) and their oro-motor responses recorded on videotape. After the taste reactivity testing, the rats were tested further for sodium appetite, taste aversion conditioning, and a variety of metabolic challenges. The results of these later tests are summarized in accompanying abstracts (Schulkin et al.; Grill et al., this vol.). Although the lesions in each group destroyed much or all of the intended gustatory relay nuclei, neither the thalamic nor medullary damage produced consistent effects in the 15 m., 1 bottle tests. The pontine lesions, however, did significantly lessen the aversion exhibited to the highest concentration of sucrose (1.0 M), NaCl (1.0 M), and QHCl (0.003 M), as well as to the middle concentration of HCl (0.003 M). The taste reactivity test, on the other hand, revealed that NST lesions resulted in significant changes in response to high concentrations of both QHCl and NaCl. Sucrose data remains to be analyzed. Rats with NST lesions exhibited significantly fewer aversive responses than did the control groups or the other rats with lesions. Similar effects were observed with 0.5 M NaCl. Aversive responses to this stimulus were observed in 4/5 PBN, 4/5 VPMpc, and 5/5 control rats, but in none of the 5 NST lesioned animals. The NaCl stimulus also elicited fewer ingestive taste reactivity responses in the NST group. Supported by NIH NS-20397 & AM-21397.

369.9 CENTRAL GUSTATORY LESIONS II: EFFECTS ON SALT APPETITE AND TASTE AVERSION LEARNING. J. Schulkin*, F.W. Flynn, H.J. Grill, & R. Norgren (SPON. L. Hurvich). University of Pennsylvania, & College of Medicine, Pennsylvania State University.

Large central gustatory lesions apparently impair salt appetite as well as conditioned taste aversion. Nevertheless no systematic study has determined the precise gustatory regions that account for these deficits. We tested both of these taste-related behaviors in groups of rats with bilateral lesions in the thalamic taste area (VPMpc, N=6), parabrachial nuclei (PBN, N=5), and nucleus of the solitary tract (NST, N=5), as well as 5 control animals (see Norgren, et al., this vol.). Methods. On day 1, rats were placed on a low NaCl diet and given access to 0.5 M NaCl and distilled water in graduated tubes. On day 2 (when sodium replete) 24 h. fluid intakes were measured and the NaCl solution removed from the home cage. Subsequently, the oro-motor activity of the rats was videotaped while 0.5 M NaCl was infused via an intraoral cannula (2 ml/2 M). Immediately following this taste reactivity test the rats were injected SC with 5 mg of DOCA and 7.5 mg of furosemide. Two h. later an additional SC injection of furosemide was administered to promote additional urinary sodium loss. On day 3 (sodium deplete) the rats were run again in the taste reactivity test using 0.5 M NaCl. Rats were then returned to their home cages and given access to the hypertonic saline for 24 h. On day 4 their 24 h. NaCl intake was measured. Approximately 1 mo. later these groups were examined for their capacity to form a conditioned taste aversion to a novel stimulus (CS=0.3 M L-alanine; US=1.5 mEq LiCl IP) using the taste reactivity protocol. Results. While Na replete, intraoral infusions of 0.5 M elicited fewer aversive responses from the 3 lesion groups than from the controls, although only the NST group reached statistical significance; there were also no differences in their NaCl home cage ingestion. When tested following salt appetite arousal, both control and VPMpc groups produced significantly greater ingestive responses in the taste reactivity test than when they were Na replete and increased their home cage intake of NaCl ($p's < .05$). The PBN and NST groups neither changed their taste reactivity response nor their 24 h. NaCl ingestion. In the taste aversion conditioning test, VPMpc and NTS groups were similar to control rats in significantly decreasing their ingestive responses and increasing their aversive responses as a function of the number of daily taste-LiCl pairings. The PBN group was significantly different from the other groups; 2 of the 4 PBN rats tested failed to display taste aversion learning. The salt appetite results suggest that first and second order brainstem gustatory regions contribute to the neural processing of salt appetite. Future research will specify the nature of the deficits in salt appetite in the NTS and PBN groups. Supported by NIH AM-21397, NS-20397, NS-21833 & MacArthur Postdoc.

369.10 CENTRAL GUSTATORY LESIONS: III. REGULATION OF ENERGY BALANCE. H.J. Grill, F.W. Flynn and R. Norgren. Dept. Psychol., & Inst. Neurol. Sci., Univ. of Pennsylvania, Philadelphia and Dept. Behav. Sci., College of Med., Penn. State Univ., Hershey, PA

Behavioral and autonomic responses act in concert to control energy balance. The experiments reported here examine the effects of central gustatory lesions on these energy balance responses. The lesion procedure is described in the accompanying abstract (Norgren et al). Rats had bilateral lesions in the nucleus of the solitary tract (NST, n=5), parabrachial nuclei (PBN, n=4), or gustatory thalamic area (VPMpc, n=5). Seven control rats were tested as well. Rats had ad libitum access to powdered chow and water. The following sequence of tests occurred approximately 2 mo. post-lesion; a minimum of 3 days separated each test. Method (a) 2DG and insulin-elicited feeding. Chow was removed at 0800 h. and 1 h. later rats were given IP injections of either saline (0.15M), 250 mg/kg 2DG, or 2 U/kg regular insulin. Food dishes were then filled with fresh chow, weighed, and returned to the rats' cages. Four hours later, the dishes (corrected for spillage) were re-weighed. (b) Intragastric loads. Rats were food deprived for 24 h. Prior to the return of the chow, rats were intubated 20 ml/kg saline (0.15M) or sweetened condensed milk/water solution (2 kcal/ml). Food dishes were reweighed 1 and 3 h. later. (c) Hyperglycemic response. Food was removed and 1 h. later a blood sample taken. The rats were then injected IP 250 mg/kg 2DG, and blood samples taken 1 and 4 h. later. Results All 4 groups consumed significantly more chow following 2DG or insulin than following saline injection ($p's<.05$). In response to saline intubation, rats of the control, NTS, PBN, and VPMpc groups consumed similar amounts of chow. Food intake was significantly reduced in control rats and rats with NTS and VPMpc lesions at 1 h. (median 85%) and 3 hr (median 60%) following the diet intubation. Diet significantly reduced chow intake by rats with PBN lesions, but the suppression at 1 h. (73%) and 3 h. (34%) was significantly less than that seen in control rats. Plasma analysis revealed that glucose levels of the 4 groups were similar prior to the 2DG injection. The hyperglycemic response elicited by 2DG was of comparable magnitude in the groups at 1h. (240-300 mg/dl) and 4 By 4 h., plasma glucose levels had decreased, but remained significantly greater than pre-injection levels for the 4 group In summary, gustatory nuclei lesions did not affect the ingesti of a familiar food source following the metabolic challenge pos by 2DG and insulin treatments. The stomach load test, however, indicated that the PBN is involved in the caudal brainstem circuitry mediating the effects of energy repletion signals generated by stomach loads on food intake. Whether this effect i due to the damage of ascending vagal projections or the integrat of taste and postingestional feedback remains to be determined. Supported by NIH AM 21397 & NS 20397

## BRAIN METABOLISM IV

370.1 PHYSOSTIGMINE-INDUCED ALTERATIONS OF LOCAL CEREBRAL GLUCOSE UTILIZATION IN AWAKE RATS. H.W. Holloway*, T.T. Soncrant*, D.M. Larson* and S.I. Rapoport (Spon: P. Newhouse). Laboratory of Neurosciences, National Institute on Aging, National Institutes of Health, Bethesda, MD 20205.

Physostigmine (PHYSO) is a drug that enhances cholinergic neurotransmission in the central nervous system and the periphery by inhibiting the acetylcholine-degrading enzyme, acetylcholinesterase. PHYSO reportedly improves short-term memory in experimental animals (Cox et al., Neuropharmacol., 13: 205, 1975) and in human subjects (Christie et al., J. Psychiat., 138: 46, 1981). This action has been ascribed to an increased effect of acetylcholine at CNS sites, and suggested a potential therapeutic role for PHYSO in Alzheimer's disease, in which large cholinergic deficits occur. We wished to elucidate the regional CNS metabolic changes produced by PHYSO and to relate them to the patterns of metabolic change that we have reported after arecoline, a muscarinic agonist (Soncrant et al., Brain Research, in press) and nicotine (McNamara et al., Trans. Am. Soc. Neurochem., 16:149, 1985).

Groups of 5-6 male, 3 mo old, awake Fischer-344 rats received physostigmine sulfate 2 mg/kg or vehicle i.p. To reduce autonomic effects of PHYSO, all rats, except those of one control group, were pretreated with methylatropine and hexamethonium, muscarinic and nicotinic antagonists, respectively, that do not enter the brain. The behavioral effects of PHYSO were scored periodically on a scale of 0 (no behavioral change) to 4 (extreme tremor) for 2 h after its administration. Local cerebral glucose utilization (LCGU) was measured by the quantitative, autoradiographic [14C]-deoxyglucose method (Sokoloff et al., J. Neurochem. 28: 897, 1977), beginning at 10, 30, or 60 min after PHYSO administration.

Tremor was observed in all animals that received PHYSO. It peaked at 10 min, and largely subsided by 30 min. LCGU measured during peak tremor activity (10 min) was increased significantly ($p < 0.05$) in 68 of the 86 brain areas examined. No areas of decreased LCGU were found. LCGU effects of PHYSO were smaller at later time points and were related to the intensity of behavior observed. The pattern of the brain metabolic response to PHYSO is a composite of those produced by arecoline and nicotine. Increased LCGU was observed in neocortical layers IV and V and in the hippocampus, where arecoline, but not nicotine, elevated LCGU. PHYSO also increased LCGU in the subiculum, terminal nucleus of the optic tract, and the substantia nigra, in which LCGU rose after nicotine, but not after arecoline.

These preliminary findings demonstrate that PHYSO increases regional CNS metabolic activity by enhancing cholinergic neurotransmission at both muscarinic and nicotinic receptors.

370.2 ALTERATIONS IN REGIONAL BRAIN METABOLISM FOLLOWING CHRONIC HALOPERIDOL TREATMENT IN RATS DETERMINED BY THE $C^{14}$-DEOXYGLUCOSE METHOD. J.M. FREY, R.D. HUFFMAN, R.D. BELL*. Dept. of Pharmacology, Div. of Neuropharmacology, and Dept. of Medicine, Div. of Neurology, Univ. of Texas Health Science Center, San Antonio, Texas 78284.

Acute administration of the dopamine receptor antagonist haloperidol has previously been reported to produce regional changes in glucose utilization (ℓ-CMRg) within extrapyramidal, mesolimbic and cortical areas (McCulloch et al., Brain Res., 243:81-90, 1982). Since it has also been reported that the cataleptogenic action of haloperidol is attenuated upon repeated administration in rats and that tolerance develops to the extrapyramidal side-effects but not the neuroleptic action of haloperidol in humans (Lloyd & Worms, Adv. Biochem. Psychopharmacol., 24:253-258, 1980; Ayd, F.J. Intern. Drug. Ther. Newslett., 6:33-56, 1971) we thought it would be of interest to see whether the acute effects of haloperidol on regional brain metabolism persisted after prolonged administration.

Male Sprague Dawley rats were administered haloperidol (0.01-.02%) in their feed for at least 30 days. Control rats received plain chow. Under ketamine anesthesia, these animals were instrumented with femoral arterial and venous catheters and allowed to recover a minimum of 3 hours, after which a quantitative 2-deoxyglucose (2-DG) study was performed as described by Sokaloff et al, J. Neurochem., 28:897-916, 1977). Each animal was injected with an intravenous bolus of $^{14}$C-2-DG (8 µci/100gms). Arterial blood samples (0.2cc) were drawn at timed intervals up to 45 minutes to determine arterial 2-DG and glucose concentration curves. At 45 minutes, animals were sacrificed, the brain removed and frozen in liquid nitrogen. The tissue was then cut into 20µm sections and exposed to x-ray film (Kodak, SB-5) for 2 weeks. $^{14}$C tissue concentrations in structures of interest were obtained with the use of a Gamma Scientific microdensitometer. Significant decreases in glucose utilization ($p<.01$) were found within cortex, thalamus (VL,VM,DM), entopeduncular nucleus, hippocampus, amygdala, and superior colliculus as well as in the caudate-putamen and subthalamic nucleus ($p<.05$). Increases in glucose metabolism were detected within the nucleus accumbens ($p<.01$) and the nucleus pedunculopontis ($p<.05$). Whereas McCulloch et al., 1982 reported dose-related changes in glucose utilization within substantia nigra and globus pallidus after acute haloperidol, we found no alterations in ℓ-CMRg within those structures after 30 days of chronic treatment.

370.3 THE EFFECT OF TYPICAL AND ATYPICAL NEUROLEPTIC AGENTS ON REGIONAL CEREBRAL GLUCOSE METABOLISM IN THE RAT. P.M. Garvey, A. Braun*, L.C. Kao and H.L. Klawans.* Dept. of Neurological Sciences, Rush-Presbyterian St. Lukes Med. Ctr., Chicago, Il. 60612.

Exposure to typical neuroleptic agents such as haloperidol (Hal), chlorpromazine (Cpz) or fluphenazine (Flu) produces a number of acute side effects such as parkinsonian symptoms and dystonias commonly referred to as extrapyramidal side effects (EPSE). Neuroleptic agents such as thioridazine (Thio) or clozapine (Cloz) possess antimuscarinic activity in addition to their action at DA receptors and are less associated with these effects. As such, they are referred to as atypical. We examined the effect these agents have on glucose metabolism in the freely responding rat utilizing the 2 deoxyglucose method.

All neuroleptics studied reduced metabolic activity in the anteromedial frontal cortex and the cingulate cortex while increasing activity in the lateral habenula. Typical neuroleptics however were least effective in reducing anteromedial frontal activity and most effective in elevating activity in the lat. habenula. Typical neuroleptics elevated activity in the caudal regions of the striatum as well as the globus pallidum whereas Thio and Cloz had no affect or actually reduced activity respectively. A similar trend was also observed in the ventral tier of the thalamus. On the other hand atypical neuroleptics increased activity in all regions of the CNS known to possess choline acetyl transferase activity such as the hippocampus, the septal region, the amygdala, n. diagonal band, the lateral preoptic area and especially the ventral pallidum. These data suggest that although there are common effects, typical and atypical neuroleptics can influence metabolic activity differentially which may explain their propensity to induce EPSE's. In this regard, discriminant analysis performed on both neuroleptic groups and saline treated controls demonstrated that the anteromedial frontal, the cingulate and the suprarhinal cortices as well as the caudal striatum, the ventral thalamus and the superior colliculus could segregate neuroleptic effects with high confidence. This would suggest that the 2 deoxyglucose method could model and potentially predict neuroleptic activity.

370.4 THE EFFECTS OF SEROTONERGIC AGENTS QUIPAZINE AND METHIOTHEPIN ON LOCAL CEREBRAL GLUCOSE UTILIZATION IN THE RAT. G.L. Ricchieri*, T. T. Soncrant*, S.I. Rapoport (SPON: C. Grady). Laboratory of Neurosciences, National Institute on Aging, National Institutes of Health, 10/6C103, Bethesda, MD 20205.

Quipazine (QUIP) is a relatively specific agonist at serotonin (5-hydroxytryptamine, 5-HT) receptors. QUIP produces stereotyped behavior in rats similar to that seen after the administration of L-tryptophan or of 5-hydroxytryptophan (5-HT precursors). This behavioral "5-HT syndrome" includes hyperactivity, tremor, head shaking and weaving, hindlimb abduction, backing, circling and shivering. Methiothepin (METH), a 5-HT receptor antagonist, causes catalepsy characterized by reduced motor activity in rats.

We measured local cerebral glucose utilization (LCGU), using the quantitative [14C]-2-deoxy-D-glucose method, in awake 3 mo Fischer rats at 1 h after administration of QUIP maleate 20 mg/kg or saline i.p., and at 1, 2, 3 or 4 h after METH maleate 0.1 mg/kg or vehicle, i.p. Behaviors were rated subjectively at fixed time intervals after QUIP and METH.

Intense behavior (5-HT syndrome) was seen in all animals at 1 h after QUIP. METH produced catalepsy that peaked at 3 h after drug treatment. LCGU was increased significantly ($p<0.05$) at 1 h after QUIP in 48% of the 92 brain regions examined. The mean increase in LCGU was 20-25%. LCGU rose in olfactory regions, limbic areas (dentate gyrus of ventral hippocampus, mammillary nuclei, medial amygdala), in most thalamic and subthalamic nuclei examined, raphe nuclei, and in regions without a blood-brain barrier (area postrema, subfornical organ). QUIP increased LCGU also in several extrapyramidal motor regions (caudate n., globus pallidus, substantia nigra, subthalamic n., inferior olive, cerebellum) which were metabolically activated also during stereotypic behavior produced by bromocriptine, a dopamine agonist (Pizzolato et al., Brain Res., in press). In contrast, LCGU was reduced in 35% of regions examined at 3 h after METH administration. The basal ganglia and cortical, hippocampal, and thalamic regions were affected by METH.

These results indicate that pharmacological activation of central 5-HT pathways can produce widespread increases in brain functional activity, by direct or indirect mechanisms, and cast doubt upon a net inhibitory role for 5-HT in the CNS. Activation of a behavior-related motor pathway by both QUIP and bromocriptine suggests that the functional effects of 5-HT activity can be mediated via dopamine pathways, in accord with biochemical findings (Chase, 1974; Dray, 1980). Finally, reductions in LCGU after METH are inconsistent with the notion that METH primarily antagonizes presynaptic 5-HT receptors (Pettibone, 1984). Instead, they suggest an important role for METH at postsynaptic 5-HT receptors.

370.5 REGIONAL CEREBRAL GLUCOSE UTILIZATION DURING KETAMINE ANESTHESIA. D.W. Davis*, A.M. Mans*, J.F. Biebuyck* and R.A. Hawkins (SPON: W.P. Graham). Departments of Anesthesia and Physiology, M.S. Hershey Medical Center, The Pennsylvania State University College of Medicine, Hershey, PA 17033

The anesthetic ketamine appears to produce both excitatory and depressant effects in the brain. Reports on its effects on cerebral glucose use ($CMR_{Glc}$) are not clear (1,2,3). We measured regional $CMR_{Glc}$ in unrestrained rats given 2 different doses of ketamine. The rats had catheters placed in the right atrium 2 days before the experiment, and were housed in chambers insulated against outside stimuli until completion of the experiment. This technique enabled infusion and blood withdrawal without apparent awareness by the rat. Ketamine was given as an initial bolus followed by a 20-minute infusion to saturate all compartments. This ensured a steady level of ketamine throughout the 5-minute experimental period, following the infusion. A total of either 5 mg/kg or 30 mg/kg was given. Regional $CMR_{Glc}$ was measured using $^{14}$C-glucose and autoradiography. Rats given ketamine were compared to saline-infused rats. The 2 doses of ketamine produced strikingly different behavior. Rats given 30 mg/kg remained motionless throughout the entire period whereas those given 5 mg/kg moved continuously about the cage. Cerebral metabolism was likewise affected differently by the 2 doses of ketamine. Rats receiving 5 mg/kg showed elevated rates of $CMR_{Glc}$ (13-43%) in many (26 of 43) brain areas, compared to control. The greatest increases were seen in several cortical areas, the posterior hippocampus and white matter areas. In rats receiving 30 mg/kg a different pattern was observed; 3 areas, the inferior colliculus, vestibular nucleus and inferior olive showed significant decreases of 14 to 29%. No other areas were affected at this dose. These results may explain the conflicting earlier reports on the effects of ketamine. Hawkins et al. (1), using $^{14}$C-glucose after a bolus of 35 mg/kg ketamine, found essentially no change in $CMR_{Glc}$. In contrast, others report increases in some areas and decreases in others (2,3). In the latter two studies $CMR_{Glc}$ was measured using the deoxyglucose method which requires an experimental period of 45 minutes. During this time the ketamine concentrations and therefore the state of anesthesia would be expected to change; the results would reflect a combination of anesthetic and recovery states. Our results obtained during 5 minutes under steady-state conditions show that the effect of ketamine on both behavior and cerebral metabolism is dose-dependent, and that specific brain areas are affected differently.

370.6 EFFECT OF CHRONIC NALTREXONE ON REGIONAL CEREBRAL OXYGEN CONSUMPTION IN THE CAT. E. Buchweitz* and H.R. Weiss*, (SPON. B. Hine) UMDNJ-Rutgers Medical School, Heart and Brain Circulation Laboratory, Department of Physiology and Biophysics, Piscataway, NJ 08854

The purpose of this investigation was to correlate the effects of up-regulation of opiate receptors by chronic naltrexone administration on average and regional cerebral blood flow, oxygen extraction and oxygen consumption. Fourteen adult mongrel cats were administered subcutaneous injections of 1 mg/kg naltrexone HCl or 1 ml 0.9% saline twice daily for 21 days. Two days later, regional cerebral blood flow was monitored using radioactively tagged microspheres. The animals were sacrificed and prepared for microspectrophotometric analysis of regional cerebral venous and arterial oxygen saturation. Cerebral oxygen consumption was calculated as the product of cerebral blood flow and oxygen extraction. Chronic naltrexone did not significantly alter blood pressure, heart rate or blood gas parameters. Average cerebral blood flow increased significantly from 47.9±3.4 (mean±S.E.M.) ml/min/100g to 80.3±6.5 ml/min/100g in the chronic naltrexone treated group. Flow was significantly increased in the cortex, lenticulate nuclei, cerebellum, thalamus and pons. Average oxygen consumption was not significantly altered by treatment. The distribution of flow and oxygen consumption among the examined regions was significantly altered in the animals receiving chronic naltrexone injections. Flow was significantly higher in the lenticulate nuclei, and significantly lower in the hypothalamus of the treated group. Chronic opiate receptor blockade significantly increased average cerebral blood flow, while not altering average cerebral oxygen consumption. These changes were not restricted to brain regions dense in neuronal opiate receptors. Since cerebral blood flow was significantly increased without a concommittant change in oxygen consumption, chronic naltrexone administration may have a direct effect on the cerebral vasculature.

370.7 REGIONAL CEREBRAL BLOOD FLOW FOLLOWING INTRAVENOUS HEROIN IN RATS. T.C. Trusk and E.A. Stein. Department of Biology, Marquette University, Milwaukee, WI 53233.

Morphine and other opiates are known to generally decrease cerebral use of oxygen and glucose in a naloxone-reversible manner. The purpose of this work is to observe the effects of heroin on blood flow in discrete areas of the rat brain. A bolus of 0.2 mg/kg heroin or saline vehicle was injected into the femoral vein of conscious, restrained rats. One minute later iodo($^{14}$C)antipyrine in saline (6 µCi/100 g) was infused for 30 seconds into the same femoral vein. Femoral artery blood was sampled every 5 seconds during the infusion. The rat was then immediately decapitated, the brain rapidly removed and frozen in isopentane. Each brain was cut into 20 µm sections which were dried onto glass slides and exposed to x-ray film for 5 days. The optical density of selected brain regions was determined with a Spatial Data Image Analyzer and converted to regional cerebral blood flow (RCBF) by means of the Kety-Schmidt equation. Heroin produced differential effects on RCBF in relation to saline-injected rats. Significant increases in blood flow (15-40%) were observed in somatomotor cortex, dorsal and ventral striatum, hippocampus, and corpus callosum. RCBF significantly decreased 15-20% in frontal cortex, globus pallidus, and the lateral hypothalamus. RCBF remained unchanged in the other brain regions studied. It has been suggested that RCBF varies directly to the local metabolic demands of functional activity. Previous observation of local cerebral glucose utilization 30-45 minutes following morphine or opioid peptide injection reported global decreases in brain activity. The present results suggest that heroin may not only decrease brain activity but may also increase functional activity in selected regions shortly after systemic injection. These changes may represent a neural substrate of the behaviorally-excitant effects observed immediately after opiate injections. Supported in part by NIDA grant #DA02234 to EAS.

370.8 THE EFFECTS OF CHRONIC DIPHENYLHYDANTOIN ADMINISTRATION ON CEREBRAL METABOLISM IN THE ADULT RAT. J.W. Melisi*, D.L. Dow-Edwards, R. Barbour* and T.H. Milhorat. Laboratory of Cerebral Metabolism, Department of Neurosurgery, SUNY Downstate Medical Center, Brooklyn, N.Y. 11203.

Diphenylhydantoin (DPH) is one of the most widely used anticonvulsant agents in humans. In the central nervous system, it exerts a protective effect by altering the seizure threshold. Presumably, then, a drug such as this should have profound effects on cerebral metabolic activity. To test this, we employed the quantitative autoradiographic $^{14}$C deoxyglucose method to measure rates of in vivo glucose utilization in the rat brain (Sokoloff et al, J Neurochemistry 28:897-916,1977). We analyzed 31 structures in the adult rat brain to determine if DPH has global or site-specific effects on cerebral metabolism.

Male Sprague-Dawley rats (350-400g) were divided into two groups. The experimental group received a loading dose of 100 mg/kg DPH ip (Dilantin, Parke-Davis) in two doses given eight hours apart. For the next five days, 50 mg/kg DPH ip per day was administered. Control animals received equivalent volumes of vehicle kindly supplied by Parke-Davis. On the seventh day, the rats were anesthetized with Halothane and arterial and venous femoral catheters were placed. The rats were allowed to recover over the next two hours. Thirty minutes prior to deoxyglucose administration, the final dose of drug or vehicle was given. $^{14}$C labeled deoxyglucose (125 uCi/kg) was then given as a bolus through the venous catheter. Timed arterial samples were taken over the next 45 minutes and analyzed for glucose and $^{14}$C deoxyglucose concentrations. The animals were sacrificed after 45 minutes, the brains rapidly removed and frozen in isopentane chilled to -35°C. The brains were sectioned for autoradiography as described by Sokoloff et al(1977).

Blood samples taken during the deoxyglucose procedure were analyzed for levels of Dilantin using flourometric methods. Experimental animals had average plasma drug levels of 10.7ug/ml, similar to that found to be therapeutic in humans. Significant differences in local cerebral glucose utilization were found in 21 of 31 structures studied. All of the differences represented decreases in glucose utilization in treated animals compared to controls. The largest changes were noted in the auditory pathways, hippocampus, thalamus, basal ganglia, fastigial and lateral septal nuclei and throughout the cortex. These data support previous studies that show DPH affects multiple sites in brain. It also indicates that an increase in seizure threshold, reported by others to be due to an increased duration and decreased amplitude of the action potential, results in a decrease in metabolic rate.

370.9 CHANGES IN BRAIN $pO_2$ DURING SOMAN-INDUCED SEIZURES IN THE RAT. T.J. Lynch*[1], C.S. Stratton*[2] and J.F. Glenn[2]. [1]Dept. of Medical Neurosciences, Walter Reed Army Institute of Research, Washington, D.C., 20307-5100, and [2]Neurotoxicology Branch, US Army Medical Research Institute of Chemical Defense, APG, MD 21010-5425.

CNS neuropathies and axonopathies have been demonstrated in animals exposed to either convulsive (McLeod et al., Neurotoxicol. 5:53, '84) or subconvulsive (Petras, Fundam. Appl. Toxicol., 1:242, '81) doses of the irreversible anticholinesterase soman. Since brain $pO_2$ has been shown to drop repeatedly during seizures induced by the bicyclic organophosphates (Lynch et al., Neurosci. Abs., 10:123.10, '84), the potential role of hypoxia as an etiological factor in development of soman-induced brain damage was investigated in free-ranging rats. Following injection of a convulsive dose of soman (100-120 mcg/Kg, s.c.), brain $pO_2$ levels were measured polarographically from platinum electrodes implanted in various limbic sites, with concurrent monitoring of behavioral signs and neocortical EEG.

Brain $pO_2$ was found to increase by as much as 100% during the early ictal stages. Behavioral signs during this period included forelimb clonus, excessive grooming, postural abnormalities and intermittent myoclonus. The development of typical physiological signs of anticholinesterase toxicity, such as excessive salivation, paralleled increases in paroxysmal EEG activity. As the EEG and behavioral signs of seizure intensified, the $pO_2$ levels were maintained above control except for transient sharp drops by as much as 56% during periods when whole body tonus prevented adequate ventilation. An increase in the variability of the normal $pO_2$ oscillations from 2-7% to 9-24% of baseline was associated with increased fluid secretions. Fluid asphyxiation appeared to be the proximate cause of a final slow decline in $pO_2$ since respiratory frequency was increased during all but the immediate pre-mortem period. No $pO_2$ decline occurred in the absence of marked secretions.

Hypoxia does not appear to be a major cause of soman-induced brain damage. Rather than a lack of adequate tissue oxygenation, excitotoxicity or mismatches between increased metabolic demand during soman-induced seizures (McDonough et al., Neurotoxicol., 4:203,'84) and metabolic capacity would appear to be more likely contributing factors to the neuronal damage observed by others.

370.10 DIFFERENCES AMONG METABOLIC CONVULSANTS. J. Wright*, D. Martin*, Y. Walker*, A. Borders*, L. Watson*, P. Rauch*, M. Liveriatos*, L. DiCarlo*, D. Ryan*, J.A. Brown* and Mary Ann Marrazzi (SPON: J.A. Benjamins). Dept. Pharmacology, Wayne State University School of Medicine, Detroit, Mich. 48201

Insulin hypoglycemia, fluoroacetate and 2-deoxyglucose (2DG) all induce metabolic convulsions, presumably due to a fuel shortage. Insulin hypoglycemia decreases overall glucose metabolism by decreasing the glucose available to brain. Fluoroacetate blocks the Krebs cycle, by being converted to fluorocitrate which blocks the citrate to isocitrate step. 2DG blocks glycolysis at the hexose isomerase step immediately after hexokinase. These three metabolic convulsants can be quantitatively differentiated on the basis of the effects of gold thioglucose (GTG) and 5-thioglucose (5TG) on the convulsive sensitivity in female CBA/J mice. A single IP injection of GTG causes a cytotoxic lesion focused in the ventromedial-arcuate hypothalamus (VMH) and a biphasic change in the sensitivity to insulin hypoglycemic convulsions. The percent convulsions in a population is decreased at early times (16-24 hours) and increased at later times (1-2 weeks) after GTG. Blood glucose measurements indicate that both changes are differences in the convulsive response to equal hypoglycemia, rather than the hypoglycemic response to insulin. Non-metabolic Metrazol induced convulsions are not affected, indicating that the generalized brain excitability is not altered. 5TG simulates the early component of the GTG effect on insulin hypoglycemic convulsions, but has no effect at 1 week. It also does so without causing the VMH lesion. In contrast to insulin hypoglycemic convulsions, the sensitivity to either fluoroacetate or 2DG induced convulsions is not affected by GTG or 5TG. Therefore, these three metabolic convulsants are qualitatively, as well as quantitatively, different. The GTG phenomenon also suggests a regulatory center involved in adjusting the brain's convulsive response to insulin hypoglycemia - a "GTG lesioned glucostat" (J. Pharmacol. Exper. Therap. 219:258, 1981). The 2DG and fluoroacetate data suggest that the portions of glucose metabolism blocked by these convulsants are not necessary for the operation of the proposed "GTG lesioned glucostat".

370.11 DIAZEPAM PREVENTS ORGANOPHOSPHATE-INDUCED INCREASES IN BRAIN CHOLINE LEVELS. C. J. Flynn and L. Wecker. Louisiana State University Medical Center, New Orleans, LA 70112.

The organophosphate cholinesterase inhibitors sarin and soman induce convulsions in rats when administered at doses that inhibit acetylcholinesterase activity by 90-100%. When measured 1-2 hours after the onset of convulsions, levels of free choline in brain are significantly increased. Since this increase in free choline may result from phospholipid breakdown, which has been shown to occur during convulsions induced by other agents, it was of interest to determine whether pretreatment of rats with diazepam would prevent the convulsions and concomitant increase in choline levels. Male Sprague-Dawley rats were injected with either saline or diazepam (4 mg/kg, i.p.) 30 minutes prior to the administration of saline, soman (57-64 ug/kg, s.c.), or sarin (95-100 ug/kg, s.c.), doses of the organophosphates that inhibit acetylcholinesterase activity in striatum and hippocampus by 90-100%. Animals were killed two hours after the second injection by head-focused microwave irradiation and the levels of choline in striatum and hippocampus were quantified by pyrolysis gas chromatography. When rats were injected with diazepam prior to the administration of sarin or soman, no seizures were evident, whereas in rats injected with saline prior to sarin or soman, seizures were exhibited by all rats. Two hours after the administration of sarin or soman, choline levels in striatum increased significantly from control values of 33 nmoles/g to 46 nmoles/g and 54 nmoles/g, respectively. Diazepam pretreatment completely prevented the organophosphate induced increase, and choline levels after the combined injections were not different from control values. In the hippocampus, choline levels increased from 23 nmoles/g to 62 nmoles/g and 68 nmoles/g following the administration of sarin and soman, respectively. Diazepam pretreatment partially prevented this increase and levels of choline were only 38 nmoles/g and 42 nmoles/g following the administration of sarin and soman, respectively. Diazepam by itself had no effect on free choline levels in either area. These results indicate that the convulsions induced by these two organophosphates cause elevations in the levels of free choline in brain which are prevented by pretreatment with diazepam. It is likely that soman and sarin enhance the release of choline from phospholipids, a finding consistent with studies indicating a relationship between seizure activity and phospholipid hydrolysis. 370.12 2-(1-$^{14}$C)-DEOXY-D-GLUCOSE UPTAKE IN DISCRETE AREAS OF BRAIN IN DIFFERENTIALLY HOUSED MICE. S. McCall, C. VanderWende, and M.T. Spoerlein. Rutgers University, P.O. Box 789, Piscataway, New Jersey 08854.

2-(1-$^{14}$C)-deoxy-D-glucose (2-d-g) has been shown to be transported by the glucose transport system into neurons where it is phosphorylated and accumulates because it can not be further metabolized. This property of 2-d-g has served as a means of measuring neuronal activity since an increase or decrease of neuronal activity will lead to a respective increase or decrease of 2-d-g uptake and accumulation.

Individual housing (social isolation) of male mice produces marked behavioral and neurochemical changes. Some of the most prominent behavioral changes are the development of fighting between conspecific males and a hyperactivity syndrome. We were interested in determining whether there is an increase of activity in certain areas of the brain related to motor and behavioral function using the accumulation of 2-d-g.

Group housed CF-1 male mice, 35 days of age, served as the zero time control animals. Other animals were either group housed or individually housed for 1, 2, 3, or 4 weeks. On the day of the test, 150 uCi were administered i.v. and the mice sacrificed by decapitation 45 minutes later. The brains were rapidly removed, weighed, and dissected over ice to remove the striatum, hippocampus, hypothalamus and frontal cortex. Each area was dissolved in 0.4 ml Protosol to which was added 4 ml of Aquasol II. Radioactivity was measured in a liquid scintillation spectrometer and the results expressed as DPM/mg of tissue. Results show in all areas studied an increased accumulation of 2-d-g with increasing time of isolation.

370.13 **THE EFFECTS OF OCTANOIC ACID ON DOPAMINE, SEROTONIN AND THEIR METABOLITES IN THE CAUDATE NUCLEUS AND HYPOTHALAMUS.** **C.S. Kim*, C.R. Roe*, J.D. Mann and G.R. Breese. Dept. of Neurology, Psychiatry, Biol. Sci. Res. Ctr., Univ. of North Carolina Sch. of Med., Chapel Hill, NC 27514 and Dept. of Pediatrics, Duke Univ. Med. Ctr., Durham, NC 27709.**

**The relationship between the encephalopathy of medium-chain acyl-CoA dehydrogenase deficiency (MCAD) and elevation in serum octanoic acid is not well understood. Accumulation of endogenously produced organic acids in CSF and brain, secondary to reduced clearance by choroid plexus (CP), could be a contributing factor in the development of encephalopathy. The present in vivo study was undertaken to determine whether organic acid metabolites of monoamines are accumulated in the brain after treatment of octanoic acid. Male Sprague-Dawley rats (100-150g) were injected i.p. with either saline or octanoic acid (500 or 1000 mg/kg). Two hours later, rats were sacrificed by decapitation and their brains rapidly removed. The caudate nucleus (CN) and hypothalamus (H) were dissected and immediately frozen. Dopamine, 3,4-dihydroxyphenylacetic acid (DOPAC), 3-methoxy-4-hydroxyphenylacetic acid (HVA), serotonin and 5-hydroxy-indoleacetic acid (HIAA) were determined in these tissues by HPLC. In the controls, the concentrations in CN and H for HVA were 6.47 + 0.51 and 0.13 + 0.06 ng/mg protein and for HIAA were 4.59 + 0.17 and 7.03 + 0.24 ng/mg protein, respectively. Octanoic acid (1000 mg/kg) elevated HVA by 54% ($p < 0.05$) in CN and 338% ($p < 0.05$) in H, while increasing HIAA in both CN and H by approximately 50% ($p < 0.05$) compared to control. A lower dose (500 mg/kg) increased HIAA by 29% in CN ($p < 0.05$) and 20% in H ($p < 0.05$). Treatment with octanoic acid failed to change the level of dopamine, serotonin and DOPAC in CN and H.**

**The present study demonstrates that octanoic acid produces major changes in the level of endogenous organic acid metabolites of HVA and HIAA in CN and H. We have previously shown that octanoic acid disrupts the mitochondrial ultrastructure in CP and inhibits the organic anion transport system (Kim et. al., Brain Res. 310:149-153, 1984). Since this transport system in the CP is responsible for the excretion of monoamines metabolites from brain to plasma, the present study provides further evidence that octanoic acid disrupts transport of acid compounds. Failure to clear organic acid metabolites from CSF by CP could contribute to the development of encephalopathy in children with MCAD who have elevated levels of octanoic acid systemically.** **This study was supported in part by NIH grants: HD-03110 and ES-03458.**

370.14 BRAIN GLUCOSE USE, MONOAMINES AND AMINO ACIDS AFTER NUTRITIONAL THERAPY OF HEPATIC ENCEPHALOPATHY. A.M. Mans*, D.W. Davis*, J.F. Biebuyck* and R.A. Hawkins. Departments of Anesthesia* and Physiology, M.S. Hershey Medical Center, The Pennsylvania State University College of Medicine, Hershey, PA 17033

Portacaval shunting in rats produces several metabolic abnormalities, including a 25-30% depression of brain glucose use. Plasma and brain amino acid concentrations are altered and there may be an imbalance in brain monoamine neurotransmitters. With the idea that the latter may promote encephalopathy, treatments have been devised to try to normalize the brain amino acids which are precursors for monoamine synthesis. Thus, amino acid mixtures rich in branched chain amino acids, which compete with the precursor amino acids for transport into brain, have been infused into patients with hepatic encephalopathy. In this study we gave oral glucose or glucose with valine, leucine and isoleucine for two weeks to shunted rats. The diet was made up in agar blocks containing a salt mixture to prevent mineral loss. No other food was provided; the rats had free access to water. Treated rats were compared with normally fed rats. Brain glucose use was measured using $^{14}$C-glucose and autoradiography in 8-minute experiments. One brain hemisphere was used for autoradiography and the other for measurement of amino acids and the monoamines norepinephrine, dopamine, serotonin, and 5-hydroxyindoleacetic acid (5-HIAA). Shunting produced the typical pattern in plasma of raised glutamine, phenylalanine, tyrosine and histidine, and lowered branched chain amino acids and threonine. The elevated amino acids were lowered by both types of treatment; the branched chain amino acids were further depressed by glucose alone but in the normal range in the group given amino acids. In brain, the monoamine precursor amino acids tryptophan, tyrosine and phenylalanine were increased after shunting. Both treatments lowered phenylalanine and tyrosine; glucose alone normalized tryptophan. The high glutamine was normalized by both treatments. Norepinephrine was significantly higher after shunting and unaffected by treatment, even though both plasma and brain phenylalanine and tyrosine were lowered. Dopamine was normal in all groups. Brain serotonin and 5-HIAA were significantly raised after shunting. The glucose diet brought both into the normal range but glucose with amino acids had less effect. Thus, several metabolic abnormalities believed to be important in the development of hepatic encephalopathy were reversed by nutritional therapy. In contrast, neither treatment had any effect on brain glucose use, which remained depressed in all 40 brain areas examined. Therefore, since function appeared unimproved, these results raise the question of whether changes in brain amino acids and monoamines are of etiologic significance in hepatic encephalopathy.

Supported in part by National Institutes of Health NS 16389.

370.15 ALTERED CEREBRAL AND HEPATIC PROTEIN AND AMINO ACID METABOLISM IN AN ANIMAL MODEL OF A REYE-LIKE SYNDROME. P.H. Schwartz, C.G. Wasterlain, B.E. Dwyer, and E.L. Arcinue Dept. Neuroscience, U.C.L.A. Sch. of Med., Los Angeles, CA 90024

Margosa oil (MO, an extract of the seeds of the neem tree in Indomalaysia) has been shown to give rise to a Reye-like syndrome (RLS) in human children. The purified oil has been used as a panacea for millenia but the crude oil has been shown to be toxic. Using the toxic oil we have developed an animal model of this RLS and now report the results of a dose-response study of the effects of MO on cerebral and hepatic protein and amino acid metabolism. The data show that early abnormalities in hepatic protein synthesis and mitochondrial function occur and suggest that these may be responsible for the hepatopathy seen in this model and may thus contribute to the encephalopathy. Eight-day old rat pups were injected subcutaneously with a "flooding" dose of 3,4-$^3$H-valine (VAL) five minutes after intraperitoneal administration of varying doses of MO or saline. Two hours after VAL injection the animals were sacrificed by decapitation, blood was collected, and brains and livers were removed and frozen at -70°C. VAL and its metabolites in the sulfosalicylic acid soluble fraction of the tissues were assayed by LC, HPLC, TLC and LSS. The acid precipitable fractions obtained from liver and brain were washed, delipidated, and assayed for rates of incorporation of VAL into protein. The results show that MO administration caused a biphasic, dose-dependent decrease in accumulation of total VAL metabolites in blood (to 45% of control), brain (45%), and liver (52%), a decrease in protein synthesis in the liver but not the brain (unless the animals were moribund), and an increase in VAL concentration in the liver (123%, paralleling plasma levels) but not the brain. The concentration of nonvolatile metabolites remained unchanged in all groups while the concentration of volatile metabolites (i.e., primarily $^3H_2O$ resulting from mitochondrial oxidation) decreased in a biphasic, dose-dependent manner both in brain and in liver. The depression of VAL metabolism may reflect a mitochondrial insult since volatile metabolite production was primarily affected. The decreased hepatic protein synthesis may reflect an indirect effect resulting from a decrease in mitochondrial energy output. These results contribute to our understanding of the mechanisms of this RLS and indicate that deranged mitochondrial metabolism occurs early in the development of the syndrome and may give rise to both the subcellular and gross pathology of the liver. This may, in turn, contribute to the encephalopathy seen in children suffering from MO toxicity.

This work was supported in part by the Division of Pediatric Intensive Care of Childrens Hospital of Los Angeles, Research Grant NS13515 from NINCDS, and the United Cerebral Palsy Research and Education Foundation.

370.16 $^3$H-GLYCOGENOLYSIS IN THE CEREBRAL CORTEX : CONCENTRATION-DEPENDENT EFFECT OF $K^+$ AND ADENOSINE IN NORMAL MICE AND REDUCED EFFECT OF NOREPINEPHRINE (NE) IN THE TOTTERING MOUSE, A SPONTANEOUSLY EPILEPTIC MUTANT. P.J. Magistretti, P. Hof*, J.-L. Martin* and M. Celio+. Dept. of Pharmacology, University of Geneva, 1211 Geneva, and Anatomisches Institut+, University of Zürich, Switzerland.

$^3$H-glycogen is synthesized in a time-dependent manner from $^3$H-glucose by mouse cerebral cortical slices maintained at 37° in Krebs-Ringer bicarbonate buffer. Neurotransmitters such as VIP and NE promote a concentration-dependent hydrolysis of the newly synthesized $^3$H-glycogen. We have now examined the effects, on $^3$H-glycogen levels, of factors such as $K^+$ and adenosine that are released in the extracellular space during neuronal activity. By increasing extracellular $K^+$ between 5 mM and 53 mM a concentration-dependent $^3$H-glycogenolysis is observed, with an $EC_{50}$ of 10 mM. Significant (15-47 %) glycogenolysis is observed when $K^+$ is increased between 5 mM and 10 mM. These are concentrations of the ion that are reached in the extracellular space upon electrically-induced depolarization. Adenosine promotes a concentration-dependent $^3$H-glycogenolysis with an $EC_{50}$ of 10 µM. Previous investigations have indicated that adenosine concentration in the extracellular space raises, upon electrical stimulation, to 150-400 µM. The rank-order of potency of adenosine agonists indicates that the glycogenolytic effect of adenosine is mediated by receptors of the $A_2$ subtype. These results suggest that $K^+$- and adenosine-mediated glycogenolysis may constitute a mechanism aimed at restoring the energy balance, in rodent cerebral cortex, which would follow an increase in neuronal activity. This mechanism could be contrasted with neurotransmitter-mediated glycogenolysis presumed to constitute an anticipatory mechanism for the local regulation of energy metabolism.

In another set of experiments we have examined the glycogenolytic effect of NE in cerebral cortical slices prepared from the spontaneously epileptic mouse mutant tottering (tg/tg). In this mutant, a selective increase in the number of noradrenergic axons in the terminal fields innervated by the n. locus coeruleus, including the cerebral cortex, has been demonstrated. We have observed that, when compared to wild type (+/+), the concentration-response curve of the glycogenolytic effect of NE is shifted to the right, with a 50-fold increase in the threshold-concentration required to elicit glycogenolysis (+/+ : 10 nm; tg/tg : 500 nM) and in the $EC_{50}$ (+/+ : 100 nM; tg/tg : 5 µM, N=9). Thus a sub-sensitive response of a cellular action of NE can be demonstrated in vitro in the cerebral cortex of tg/tg mice; the metabolic nature of this adaptive change suggests that an impaired capacity of the coeruleo-cortical noradrenergic system in increasing the availability of energy substrates may be related to the expression of the epileptic symptomatology in this mutant.

370.17 MATURATIONAL CHANGES IN ARTERIAL VERSUS BRAIN OXYGENATION IN THE RAT. D.S. Horne, N.R. Krelsman, J.E. Olson, D. Holtzman. Depts. of Pharm., Physiol., Psychiatry/Neurol., Tulane Univ., New Orleans, LA 70112.

Cerebral tissue $Po_2$, cytochrome $aa_3$ ($aa_3$) oxidation, and hemoglobin (Hb) saturation were compared with systemic arterial $Po_2$ and Hb saturation in 10 and 20 day old Sprague-Dawley rats. Animals were anesthetized with 40 mg/kg pentobarbital and either the skull or the femoral artery was exposed. Variations in systemic and cerebral oxygenation were achieved by having the rats respire gas mixtures containing between 0 and 100% $O_2$ (balance $N_2$) via a face mask. Cerebral $Po_2$ was measured polarographically and relative changes in $aa_3$ oxidation or Hb saturation were monitored spectrophotometrically. Tissue $Po_2$, $aa_3$ oxidation, and Hb saturation were expressed as a percentage of full scale signals, defined as the difference between maximum and minimum signals obtained with the various inspired gas mixtures. Arterial blood gas levels were measured in 100 µl samples taken from the abdominal aorta. For both ages, curves relating inspired $O_2$ to cerebral $Po_2$, oxidation of $aa_3$, or Hb saturation were sigmoidal. At inspired $O_2$ concentrations between 5 and 50%, all indices of cerebral oxygenation were greater for 20 day old than for 10 day old rats. For example, at 21% inspired $O_2$, percentages of the full scale signals (mean ± SEM) were:

| AGE | CEREBRAL $Po_2$ | OXIDATION OF $aa_3$ | Hb SATURATION |
|---|---|---|---|
| 10 | 21±9 (n=2) | 47±5 (n=10) | 40±3 (n=6) |
| 20 | 54±2 (n=4) | 73±3 (n= 9) | 68±2 (n=5) |

In contrast, relationships between inspired $O_2$ concentration and systemic arterial $Po_2$ or Hb saturation were the same at both ages. We conclude that age-related differences in cerebral $O_2$ consumption, blood $O_2$ content, or blood flow are responsible for the differences in brain oxygenation. However, cerebral $O_2$ consumption has been shown to increase with development. Therefore, we suggest that either: 1) the ratio of $O_2$ delivery to consumption may change with maturation; or 2) cerebral $O_2$ consumption may be a function of cerebral $O_2$ supply, with the dependence possibly differing with age. Determination of the pertinent mechanisms will be important in the evaluation and treatment of neonatal hypoxia and seizures. (Supported by NS 17443 to NRK, LA Heart Assn. grant to DSH, and NS 20029 and the Psychiatry and Neurology Development Fund to DH and JEO.)

370.18 DIFFERENTIAL DISTRIBUTION OF OXIDATIVE ENZYMES WITHIN SUBNUCLEI OF THE RAT INTERPEDUNCULAR NUCLEUS. G.S. Hamill and B. Fass. Dept. of Anatomy, Hershey Med. Ctr., Penn State University, Hershey, PA 17033, and Dept. of Psychology, Brain Res. Lab., Clark University, Worcester, MA 01610.

Glucose-6-phosphate dehydrogenase (G6-PDH) and succinate dehydrogenase (SDH) are cellular enzymes which catalyze the oxidation of substrates entering the pentose phosphate shunt and citric acid cycle, respectively. These enzymes are differentially distributed throughout the brain within both neurons and neuropil, in amounts which closely correlate with the level of cellular metabolism (Mellgren & Blackstad, 1967).

In this study, histochemical staining for G6-PDH and SDH within individual subnuclei of the interpeduncular nucleus (IPN) was evaluated in adult male rats (300-400 gms). Fresh-frozen cryostat sections (30µ) cut coronally through the IPN were incubated in medium containing polyvinyl pyrrolidone to limit diffusion, and subsequently processed using a standard procedure for demonstrating dehydrogenases (Troyer, 1980). The intensities of G6-PDH and SDH staining within individual IPN subnuclei (Hamill and Lenn, 1983) were quantified by optical densitometry (Nikon Magiscan Image Analysis System).

Optical density (O.D.) scores reveal that G6-PDH and SDH enzymes are differentially distributed within IPN subnuclei, in patterns very different from one another. G6-PDH is most intensely concentrated within the rostral subnucleus, especially within the caudal ovoid regions, followed in order of decreasing intensity by central, intermediate and lateral subnuclei. SDH is most intensely concentrated within the central subnucleus, followed in order of decreasing density by intermediate, rostral, and lateral subnuclei. Control sections incubated without substrate and coenzyme revealed no staining.

The localizations of G6-PDH and SDH in different patterns within individual subnuclei of IPN are nearly identical to the distributions of specific neuropeptide transmitters. The ovoid regions of rostral subnucleus are remarkable for substance P and vasoactive intestinal peptide immunoreactive processes. G6-PDH and SDH staining within the central and intermediate subnuclei indicate possible localizations within horizontal laminations of neuropil, a pattern which precisely overlaps the established distribution of medial habenular axons (Cajal, 1909). Ultrastructural studies are needed in order to determine the precise subcellular localizations of these enzymes within IPN subnuclei.

We thank R.J. O'Connell for use of the densitometer (NS #14453), and Donald Stein for support (FIDIA Contract # CS-185-84).

370.19 AUTORADIOGRAPHIC VISUALIZATION AND CHARACTERIZATION OF [$^3$H]-OUABAIN BINDING TO THE ($Na^+ + K^+$)-ATPase OF RAT BRAIN AND PINEAL GLAND. Mary Lou Caspers*, Rochelle D. Schwartz, Rodrigo Labarca* and Steven M. Paul* (SPON: R.L. Hauger). Clinical Neuroscience Branch, NIMH, Bethesda, MD 20205.

Ouabain binds to the catalytic subunit of ($Na^+ + K^+$)-ATPase and [$^3$H]-ouabain binding can be used as a measure of the number of enzyme molecules present in a given tissue. Previous studies in our laboratory have characterized a "high affinity" population of [$^3$H]-ouabain binding sites in rat and human brain and lesion studies with kainic acid suggest that these binding sites reflect the neuronal form of ($Na^+ + K^+$)-ATPase (Hauger et al., J. Neurochem., in press). In the present study the autoradiographic visualization of [$^3$H]-ouabain binding was determined by incubating 24 µm sections of rat brain in 100 mM Tris buffer (pH 7.4) containing $Na^+$ (10 mM), $Mg^{2+}$ (10 mM), ATP(2 - 10 mM) and [$^3$H]-ouabain (0.02 - 15 µM). In the absence of ATP or in the presence of unlabeled ouabain (50 µM), [$^3$H]-ouabain binding was reduced by 98%. Addition of 30 mM $K^+$ or omission of $Mg^{2+}$ resulted in a 78% and 93% decrease in specific binding, resp. Strophanthidin, digoxin and digoxigenin displaced [$^3$H]-ouabain binding with $IC_{50}$ values of 0.73, 0.48 and 1.4 µM, resp. Scatchard analysis showed a single class of binding sites with an apparent $K_D$ of 339 nM and a Bmax of 34.9 pmol/mg protein. [$^3$H]-Ouabain binding was unevenly distributed throughout the brain with white matter having virtually no specific binding. Using computer assisted densitometry, grain densities in several brain regions were compared to those in white matter. Values reported represent the ratio of grain density of the region to that of white matter. The olfactory nuclei (3.05 ± 0.16), superior colliculus (2.94 ± 0.17), inferior colliculus (2.43 ± 0.10) and dentate gyrus (2.81 ± 0.07) had relatively high densities of [$^3$H]-ouabain binding sites. The pineal gland (2.52 ± 0.12) also had a high density of sites, whereas the caudate/putamen (1.73 ± 0.06) and hypothalamus (2.05 ± 0.24) had lower levels of specific binding. Outer layers of the frontoparietal cortex showed greater specific binding (1.97 ± 0.03) than the inner cortical layers (1.77 ± 0.04). The effect(s) of kainic acid lesions on the autoradiographic visualization of [$^3$H]-ouabain binding in the caudate will be presented. Finally, the binding of [$^3$H]-ouabain in the pineal gland was characterized. Although technically a peripheral tissue, the pineal possessed a high affinity binding site for [$^3$H]-ouabain suggesting a similarity to the CNS (neuronal) binding site.

## STRESS, HORMONES AND AUTONOMIC NERVOUS SYSTEM I

371.1 MECHANISMS OF STRESS-INDUCED GASTRIC ULCERATION IN RAT. Bernt T. Walther and Hans K. Bakke *, Depts. of Biochemistry and Physiological Psychology, Univ. of Bergen, Bergen, N-5000 NORWAY.

Rats maintained in darkness and without food for 23 hours, develop gastric erosions and ulcerations when subjected to forced immobilization. We have found that such stress-induced ulceration depend on a central nervous mechanism since ulcerations are abolished by the central nervous neurotoxin DSP-4 ( N-2-chloroethyl-N-ethyl-2bromobenzylamine).This finding is consistent with numerous reports implicating noradrenalinergic pathways in the central nervous system in stress-caused gastric ulcerations. -In further experiments we have assessed the biochemical changes of the stomach during the ulcerogenic process. No detectable changes could be found in the proteins and glycoproteins of the sub-mucosal layers of the stomach, while the mucosal layer of the stomach corpus exhibited selective depletion in its contents of glycoproteins. In the stomachjuice we found small but significant reductions in the level of pepsin-activity. In trying to reconcile theexperimental findings we have assayed the contents of unsecreted pepsinogens in the gastric walls, after pH-inactivation of activated pepsins present. Stressed animals have 3.2 fold higher contents of pepsinogens in their corpal stomachs than control animals. This situation pertains to stomachs not yet exhibiting massive gastric erosions. Our data suggest that such stomachs are highly susceptible to gastric erosions both because of their diminished protection from mucosal glycoproteins, but also due to the impact of a potential release of an excessive dose of proteolyttic enzymes.However, as DSP-4 treated animals exhibit lowered glycoprotein contents and lowered susceptibility to stress-induced ulceration, the contents of the stomach in terms of pepsinogens and glycoproteins may be necessary but not sufficient for ulceration to occur. Since we have found elevated levels of circulating corticosterone in only stressed control and not in stressed DSP-4 animals, our data suggest that a second central nervous mechanism mediates stress-signals to elicit ulcerations in stress sensitized rat stomachs.

371.2 LATERAL HYPOTHALAMIC LESIONS DIFFERENTIALLY AFFECT THE GASTRIC MUCOSA OF MALE AND FEMALE ALBINO RATS. C.V. Grijalva and B. Roland*. Department of Psychology and Brain Research Institute, UCLA, Los Angeles, CA 90024.

Changes in gastric secretory responses and the production of gastric erosions and ulcers can be induced by various manipulations of certain hypothalamic and limbic system structures and/or their interconnecting pathways. For example, electrolytic lesions of the lateral hypothalamic (LH) area in male rats are immediately followed by vagally-mediated increases in gastric acid secretion and a breakdown of gastric mucosal barrier properties which, in turn, contribute to the formation of stomach ulceration (Grijalva, C.V. et al., Brain Res. Bull. 5, Suppl 1: 19, 1980; Grijalva, C.V., Western J. Med., in press). Invariably, male rats of various strains have been used in previous studies investigating the role of the brain in gastric functions. In the present study the effects of LH lesions in female rats on the stomach were examined.

Three groups of rats were deprived of food overnight. In two groups, one comprised of males and the other of females, animals were anesthetized with sodium pentobarbital (50 mg/kg, ip) and then given bilateral electrolytic LH lesions by passing a 1.2 ma anodal current for 10 sec. Animals were placed in their home cages postoperatively and then sacrificed 24 h later. No food or water was consumed during the 24 h postoperative period. The stomachs were removed, opened along the greater curvature, visually inspected and then analyzed for total area of gastric pathology under a dissection microscope. The third group comprised of female rats served as an unoperated control (2 anesthetized, 3 not) and were similarly food and water deprived.

| Group | N | Total Area of Gastric Pathology ($mm^2$) Glandular | Rumenal |
|---|---|---|---|
| LH Male | 5 | 3.5±0.8* | 0.2±0.2 |
| LH Female | 7 | 0.8±0.5 | 4.7±1.9* |
| C Female | 5 | 0.6±0.3 | 0 |

Male rats with LH lesions primarly displayed hemorrhagic erosions of the glandular mucosa whereas lesioned female rats exhibited edema and crater-like erosions of the rumenal mucosa. Despite the lack of hemorrhagic ulceration to the glandular mucosa in lesioned female rats, the mucosa appeared pathologic and strikingly different from that of the males. The glandular mucosa appeared blanched and sloughing of the superficial lining as well as adherent mucus was notable in 6 of the LH female rats. These results suggest that there may be important dimorphic characteristics involved in the pathophysiology of the gut.

371.3 LACK OF NEUROENDOCRINE RESPONSES TO A MANIPULATION PROCEDURE IN NORMAL VOLUNTEERS. John E. Thornburg, Sheila Barnes*, Myron C. Beal* and Keith T. Demarest. Depts. of Pharmacology and Toxicology, and Family Medicine, Michigan State University, East Lansing, MI 48824.

The objective of this study was to determine if application of a manipulation procedure used commonly in manual medicine causes perturbations in the hypothalamic-pituitary-adrenal axis or sympathetic nervous system as reflected by plasma levels of norepinephrine, cortisol, glucose and β-endorphin. For comparison, the effects of a 1 minute cold pressor test and orthostasis on these neuroendocrine parameters were also determined.

Ten healthy volunteers ranging in age from 20-27 years and who gave informed consent were tested as follows: A heparin lock was established in an antecubital vein. Following 45 minutes in a supine position, baseline blood samples were obtained. A manipulation procedure consisting primarily of stretching of the left and right thoracic paravertebral muscles was applied by one of the investigators (MCB) for 4 minutes. Blood samples were obtained after 1, 5 and 30 minutes. Subjects then stood erect for 10 minutes to determine the effects of orthostasis and blood samples were obtained at 5 and 10 minutes. Subjects were then in a sitting position for 30 minutes before placing a hand (opposite to the i.v.) in ice water (0°-4°C) for 1 minute. Blood samples were obtained at 0, 1 and 5 or 10 minutes. Plasma norepinephrine were determined using a catechol-o-methyltransferase radioenzymatic procedure. Plasma cortisol and β-endorphin were measured using radioimmunoassay kits from Immuno-Nuclear Corp. (Stillwater, MN).

The manipulation procedure did not alter any of the neuroendocrine parameters measured using within subjects comparisons. In contrast, the cold pressor test caused significant increases in plasma levels of cortisol and norepinephrine. Orthostasis increased only plasma levels of norepinephrine.

In conclusion, application of a manipulation procedure to young pain-free individuals did not alter indices of pituitary-adrenal or sympathetic nervous system activity. (Supported by a Biomedical Research Grant from the College of Osteopathic Medicine, Michigan State University.)

371.4 NEUROENDOCRINE RESPONSE TO MAXIMAL TREADMILL EXERCISE. M.A. Oleshansky, R.H. Herman*, J. Zoltick*, P. Kluge*, E.H. Mougey* and J.L. Meyerhoff. Dept. of Medical Neurosciences, Div. of NP, Walter Reed Army Institute of Research and Cardiology Div., Dept. of Medicine, Walter Reed Army Medical Center, Washington, D.C. 20307-5100.

Plasma norepinephrine (NE), epinephrine (EPI), β-lipotropin (β-LPH), β-endorphin (β-END), adrenocorticotropin (ACTH), cortisol and cAMP levels were measured in healthy volunteers before, during and after maximal treadmill exercise to characterize the extent and duration of neuroendocrine and neurochemical responses to physical stress. Since previous studies have noted an effect of prior physical training on β-END responses, a range of highly fit to non-fit subjects was studied.

A maximal exercise treadmill test (ETT) was performed on twenty healthy male subjects, age 41±2.2 years (mean±S.E.M., range 20-61 years). The exercise was performed until exhaustion on a treadmill at a constant rate of 3.3 mile/hr with a 5% increase in grade every three min. Maximal ETT time provided an index of fitness. Plasma was collected: (A) thirty minutes after resting supine; (B) fifteen min after standing, just prior to exercise; (C) upon exercising to a heart rate of 140 beats/min; (D) immediately following maximal exercise; and (E) fifteen min after exercise. NE and E were extracted from 1 ml of plasma and assayed by HPLC. β-LPH and β-END were extracted from 1 ml of plasma and assayed by RIA. ACTH, cortisol and cyclic AMP were assayed by RIA.

Mean ETT time to heart rate 140 was 9.0±0.6 (range 3.0-13.0) and mean maximal ETT time was 15.0±0.6 min (range 8.9-19 min). Values for plasma catecholamines, proopiomelanocortin-derived peptides, cortisol and cyclic AMP (mean ± S.E.M.) at the various time points are given below.

| | A | B | C | D | E |
|---|---|---|---|---|---|
| NE(pg/ml) | 279±32 | 567±54 | 1270±129 | 1929±194 | 600±60 |
| EPI(pg/ml) | 85±9 | 120±15 | 239±32 | 285±42 | 136±20 |
| β-LPH(pg/ml) | 56±4 | 60±5 | 74±5 | 219±26 | 198±30 |
| β-END(pg/ml) | 3.4±0.4 | 4.3±0.6 | 6.6±0.9 | 33.0±5.0 | 26.1±5.1 |
| ACTH(pg/ml) | 22±8 | 28±9 | 36±9 | 68±10 | 68±15 |
| CORTISOL(ug%) | 6.4±0.7 | 6.3±0.5 | 7.5±0.7 | 6.6±0.8 | 10.0±0.9 |
| cAMP(pg/ml) | 28±2 | 31±3 | 42±5 | 47±5 | 37±3 |

Plasma values were poorly correlated with exercise time to heart rate 140 or maximal ETT time with the exception of NE at time C which correlated strongly with exercise time to heart rate 140; R value of 0.60 ($p<0.02$). The mean changes of plasma β-LPH and β-END and ACTH levels from maximal exercise (D) to recovery (E) were -20.7±22.6 (range -136 to +243), -7.0±4.6 (range -33 to +37) and -7.5±7.6 (range -42 to 70) pg/ml respectively. The change of plasma β-LPH, β-END and ACTH levels from maximal exercise to recovery were inversely correlated with maximal ETT time with R values of -0.48 ($p<0.05$), -0.44 ($p<0.07$) and -0.52 ($p<0.03$).

We find that changes in the plasma levels of the major proopiomelanocortin-derived peptides during a brief recovery period after exercise are inversely correlated with fitness as expressed by maximal ETT time.

371.5 NEUROENDOCRINE RESPONSE TO STRESS IN SYRIAN GOLDEN HAMSTERS. B.N. BUNNELL, K.M. LEVY*, S.M. GILCHRIST*, A.A. GRANBERRY*, E.H. MOUGEY*, W.L. GAMBLE* AND J.L. MEYERHOFF. Dept. Psychology, U. Georgia, Athens, GA 30602 and Dept. Med. Neurosciences, Walter Reed Army Institute of Research, Washington, DC 20307-5100.

Despite the widespread use of Syrian golden hamsters as subjects for research on a large number of neuroscience problems, little is known about the neuroendocrine response to stress in this species. The data that are available indicate that cortisol is the primary glucocorticoid secreted by hamsters, that hamsters have the lowest adrenal corticoid secretion rate of any laboratory animal studied, and that cold stress produces significant increases in corticoid secretion (Schindler, W.J. and Knigge, K.K., Endocrinology, 65:739, 1959; Frenkel, J.K., et al., Lab. Invest., 14:142, 1965).

The present study investigated changes in plasma cortisol, ACTH, and β-endorphin levels in male and female hamsters in response to stress induced via footshock. Sixteen male and 16 female adult golden hamsters were handled daily for 14 days prior to the experiment. In the stress condition, 8 males and 8 females were subjected for 20 min to intermittent 5 sec, 1 mA footshock delivered on a 60 sec variable time schedule in sound attenuated shock chambers. The remaining animals served as home cage controls. Animals were sacrificed by decapitation and trunk blood was collected in heparinized tubes. After centrifugation, plasma was stored at -18°C in tubes containing 50 µg trasylol until radioimmunoassays for plasma hormones were carried out. The experiment was conducted over two days, with 8 males and 8 females used each day. The schedule was arranged such that animals were sacrificed between 9:00 and 11:00 AM; they were housed under a 12:12 LD cycle with lights on at 6:00 AM.

Plasma corticosterone levels were extremely low, and did not increase in response to footshock. Plasma cortisol levels were low in male controls, but were significantly elevated in response to the stressor. Cortisol responses in females paralleled those of males on day 1. On day 2, however, females in the control group had high levels of cortisol. This may have been an effect of endogenous estrogen.

| | PLASMA CORTISOL (µg/100ml) | | | |
|---|---|---|---|---|
| | Male | | Female | |
| | Day 1 | Day 2 | Day 1 | Day 2 |
| Shock | 4.78 ± 1.36 | 4.76 ± 0.36 | 3.74 ± 0.42 | 2.29 ± 0.46 |
| Control | 0.58 ± 0.21 | 0.21 ± 0.27 | 0.21 ± 0.08 | 3.88 ± 1.09 |

There were significant positive correlations between cortisol levels and ACTH (+.72) and β-endorphin (+.71). ACTH and β-endorphin levels had a correlation of +.77.

371.6 EFFECT OF DISHABITUATION AFTER INTERRUPTION OF REGULARLY REPEATED COLD EXPOSURE IN C57BL/6J MICE. M.I.Talan and B.T.Engel*. Lab. of Behavioral Sciences, Gerontology Research Center, National Institute on Aging, NIH, Baltimore, MD 21224.

We defined cold tolerance as the rate of decline of colonic temperature per min during a 3-hr period of restraint in an ambient temperature of 10°C (Talan, M.I. and Engel, B.T., Exp. Gerontol., 19:79, 1984). In Experiment 1, two groups of male C57BL/6J mice, 10 animals each, aged 12 mo at the beginning of the study were exposed to repeated cold stress tests with 2-wk intervals over 4-6 mo (Talan, M.I., Engel, B.T. and Whitaker, J.R., J. Gerontol., 40:8, 1985). In group 1 tests number 4 and 8, were omitted so there was a 4-wk interval preceding tests 5 and 9, whereas group 2 was always tested at 2-wk intervals. Cold tolerance was not different between groups for any test, $F_{(1,17)}=1.24$, $p=0.28$, except 5 and 9, where cold tolerance was significantly worse for group 1 ($p's<0.05$). This effect was limited to cold tolerance and did not include baseline colonic temperature. Furthermore, cold tolerance returned to previous levels in subsequent tests following restoration of the 2-wk testing cycle. In Experiment 2, mice, which participated in Experiment 1, underwent stereotaxic implantation of concentric electrodes in "rewarding" areas of the lateral hypothalamus. Previously, we had shown that electrical stimulation in these areas could retard age-related deterioration of cold tolerance in 30-mo old C57BL/6J mice (Talan, M.I., Engel, B.T. and Whitaker, J.R., Physiol. Behav., 33:969, 1984). Seven animals in group 1 and seven in group 2 were presented the schedule of cold exposure as in Experiment 1; test 5 was skipped in group 1 and test 8 was skipped in both groups. During 4-wk interval between tests 4 and 6, group 1 received 30 min daily sessions of brain stimulation. Both groups demonstrated a decline of cold tolerance on test 9; however, test 6 was not different between groups. Therefore, electrical stimulation of a "rewarding" area of the hypothalamus seems to supress the effect of dishabituation following interruption of regular cold exposures.

371.7 ADRENAL CATECHOLAMINE SECRETION ASSOCIATED WITH NATURAL AGGRESSIVE BEHAVIOR IN THE CAT. S.L. Stoddard-Apter, V. Bergdall* and B.E. Levin. Dept. of Anatomy, Indiana Univ. Sch. of Med., Ft. Wayne, IN 46805 and Dept. of Neurosci., N.J. Med. Sch., Newark, NJ 07103.

This study was designed to evaluate the contribution of the adrenal medulla to the sympatho-adrenal (SA) response during naturally elicited aggressive behavior in the cat. An arterial cannula was placed in the aortic arch through the left internal carotid for the continuous monitoring of heart rate and blood pressure. Two cannulae were placed in the inferior vena cava (IVC) through the left external jugular vein for the withdrawal of venous blood samples. Within the IVC, the tips of the two cannulae were placed 8-10 cm apart, with the proximal line positioned to collect blood from the effluent of the left adrenal vein. The sympatho-adrenal response was determined following both offensive and defensive forms of aggressive behavior. Offense (pure attack) was observed in trained, adult male cats, while defense was evoked by exposure to either a large, barking dog or a hypothalamically stimulated cat. Blood samples were withdrawn simultaneously from both venous cannulae during two baseline periods prior to aggressive behavior, and 0.25, 0.5, 0.75, 1 and 3 min following the behavior. Levels of plasma norepinephrine (NE) and epinephrine (E) were determined by radioenzymatic assay. The difference in the levels of catecholamines (CAs) in plasma samples collected proximal and distal to the output of the left adrenal vein served as an index of the activity of the adrenal medulla. Initial studies of defense behavior found that both NE and E increased following the behavior. Two observations implicated the adrenal medulla as the source of both CAs: the peak increases in these CAs were concomitant, and they occurred first in the plasma sample collected from the proximal cannula. Furthermore, plasma CA levels reached a peak immediately following the behavior. The subsequent decrease in CA levels in the plasma was similar to a half-life curve, suggesting that activation of the adrenal medulla was restricted to the period of the behavioral stimulus. These preliminary data support a previous observation that, in the cat, hypothalamically mediated aggressive behavior may involve adrenal medullary release of levels of NE equal to, or greater than, the levels of E.

[Supported by a grant from the Harry Frank Guggenheim Foundation (SLS-A) and the Research Service of the Veterans Administration (BEL).]

371.8 DIETARY CALCIUM, BEHAVIORAL STRESS, AND HYPERTENSION IN THE SPONTANEOUSLY HYPERTENSIVE RAT. M.S. Muntzel*, P.E. Huie,* D.C. Hatton*, J.A. Metz*, & D.A. McCarron* (SPON: D. Trune), Depts of Medical Psychology & Nephrology, Oregon Health Sciences University, Portland, OR 97201.

The interaction of dietary calcium with both chronic and acute stress was studied in two experiments. In the first, 50 6-week-old male spontaneously hypertensive rats (SHRs) were randomly assigned to one of 3 diet conditions: Normal (1.0% Ca, .25% Na); High (2.0% Ca, 1.0% Na); Low (.10% Ca, .25% Na); and to either a Social Stress (SS) or Control (C) condition, thus making a 2 x 3 factorial design. Chronic stress was produced by housing the 8 male subjects with 8 female SHRs in a cage consisting of a 1m square central arena with two smaller cages on each side. Control subjects were housed in groups of 3 and 4 in standard lab cages. Tail-cuff systolic BP measurements were taken biweekly for 13 weeks. Over the last 4 measurements mean BP (mmHg) was significantly higher ($p < .01$) in L diet rats (SS=215, C=200) than in N (SS=190, C=183) or H diet rats (SS=184, C=183) in both SS and C groups, while N and H rats did not differ from each other at either stress level. BP change scores computed relative to the week 1 baseline showed a significantly larger stress effect ($p < .01$) in L diet rats relative to that effect in N and H diet rats. Moreover, between-groups t-tests revealed that S rats had lower serum ionized $Ca^{+2}$ (mMol/l: S=1.10; C=1.18; $p < .01$) than controls.

These results suggested a synergistic interaction between dietary Ca and chronic stress in augmenting the development of elevated pressure in the SHR. Since it is suspected that the development of hypertension in SHRs is partly due to their exaggerated SNS responses to environmental stimuli, such as would be afforded by the frequent conspecific encounters in the social stress situation, it was hypothesized that the observed interaction between diet and chronic stress might in fact reflect an effect on acute CV responsivity to environmental stressors. To test this hypothesis, a second experiment was performed in which 30 6-week-old male SHRs were randomly assigned to the N, H, or L diets as above. After 11 weeks on the diet all rats were classically conditioned with 24 trials of a 20 sec tone followed by a 500 msec electric shock. Mean arterial pressure (MAP) was measured by femoral catheter during baseline (10 sec pre CS) and during successive 2 sec periods of the CS. Change scores were computed for each counting period by subtracting MAP for that period from the baseline score. While all groups showed pressor responses to the CS, t-tests showed the diet groups to be different from one another ($p < .05$) at all counting periods except the first, with the Ca deprived, L diet rats having the greatest responses and the H diet rats the smallest.

371.9 PSYCHOSOCIAL STRESS ALTERS MAMMARY TUMOR GROWTH IN MICE. J. Weinberg, A. Scarth* and J.T. Emerman*. Dept. of Anatomy, Faculty of Medicine, University of British Columbia, Vancouver, B.C. V6T 1W5.

The influence of psychosocial stress on mammary tumor incidence and growth was studied. Tumor cells were obtained from the transplantable androgen-responsive Shionogi mouse mammary carcinoma. Male mice (DD-S) were injected (s.c.) in the interscapular region with 4 x $10^6$ cells in 0.2 ml medium. Four groups (n = 10-12 per group) were formed immediately following injection: 1) Isolate to Group (IG) - males raised singly housed from 30 days of age were moved to non-sib groups of 4-5 males; 2) Isolate to Male-Female Pair (IP) - males raised singly housed were caged with a female; 3) Group to Isolate (GI) - males raised in sibling groups of 2-3 were separated and housed singly; 4) Group to Group (GG) - males raised in sibling groups of 2-3 remained in their groups. In addition, half the animals in each of the 4 housing groups were subjected daily to the acute stress of placement into a novel environment (15 min/day, 5 days/week). Mice were palpated twice weekly and time until appearance of palpable tumors was recorded. Once palpable, tumors were measured using calipers and tumor weight calculated. Observations were continued for 23-24 days following injection of cells. On the day of termination, animals were decapitated and trunk blood collected for determination of plasma levels of corticosterone. Tumors and spleens were then removed and frozen.

Tumor growth was significantly altered both by housing condition and by the acute stress of daily exposure to novel environments. Tumor growth was most rapid in GI animals and least rapid in IG animals. By the day of termination animals in each of the 4 housing conditions differed significantly from each other in mean tumor weights (GI>GG>IP>IG, ps <.05).
In addition, animals subjected to daily novelty stress developed larger tumors than animals in the unstressed group ($p < .05$), with the greatest effect appearing in singly housed animals. There was no chronic change in basal levels of corticosterone due to housing condition. However, animals subjected to novelty stress showed significant corticoid elevations, even following the 16th exposure.

Thus both housing condition and novelty stress significantly affected rate of tumor growth. Pituitary-adrenal activation may have some role in mediating the effects of exposure to novel environments. The immunocompetence of these animals is currently being investigated. In addition, we are examining the role of androgens in differential tumor growth.

371.10 **MODIFICATION OF PITUITARY-ADRENOCORTICAL RESPONDING TO STRESS BY CHOLINERGIC BLOCKADE.** **M. Alharbi* and R.P. Maickel** (SPON: G.K.W. Yim). Dept. of Pharmacology and Toxicology, School of Pharmacy and Pharmacal Sciences, Purdue University, West Lafayette, IN 47907.

**A previous report from this laboratory (Odio and Maickel, Fed. Proc. 42: 726, 1983) had shown that pretreatment of rats with a cholinergic blocking agent (atropine) potentiated the response of the pituitary-adrenocortical system to acute exposure to stressful stimuli such as immobilization, cold exposure, or inescapable random foot shock. This increased response was manifested by increases in magnitude and duration of elevated levels of plasma corticosterone (PCS) during 1 to 4 hours of exposure to the stressful stimuli. The present paper describes studies of the effects of cholinergic blockade on the responses of PCS, plasma fatty acids (PFA) and plasma glucose (PGL) in rats exposed to repetitive periods of stressful stimuli on an irregular/unpredictable schedule for 16 days. Two stressful stimuli were used: isolation in a novel environment (ISOL) and immobilization (IMMB). In addition, two control groups were used: no drug (NODR) and placebo injected (INJC). The first studies used atropine (5.0 mg/kg, i.p.) as the cholinergic blocker; it was administered 15 minutes prior to the start of a stress session. Blood samples were obtained by orbital sinus puncture immediately before and at the termination of the stress session. At least 72 hours separated repeated tests in the same animal. Atropine pretreatment significantly increased the response of PCS to IMMB and INJC, but did not produce a significant change in the response to ISOL. These results suggest that there may be a differential role of cholinergic systems related to either type or severity of stress. With regard to the PFA response, atropine had no significant effects on animals exposed to either ISOL or IMMB. In contrast, atropine pretreatment significantly increased the PGL response to INJC and ISOL, but had no significant actions on the response to IMMB. Thus, cholinergic blockade appears to have stress-specific and response-specific actions; whether this involves effects on specific neuronal pathways remains the subject of future study. (Supported in part by the Saudi Arabian Educational Mission and by American Cancer Society CH194A).**

371.11 ATROPINE SULFATE AND 2-PYRIDINE ALDOXIME METHYLCHLORIDE ELICIT STRESS-INDUCED CONVULSIONS AND LETHALITY IN MICE. B.A. Donzanti, M.D. Green*, E.I. Shores* and C.K. Burdick*. U.S. Army Medical Research Institute of Chemical Defense, Aberdeen Proving Ground, MD 21010-5425.

Atropine sulfate and 2-pyridine aldoxime methylchloride (2-PAM) are currently the treatments of choice for organophosphate chemical warfare agent intoxication. These drugs appear to be relatively nontoxic even after repeated administration of high doses. However, most toxicological studies have been performed under nonstressful environmental conditions which may not always be applicable to the soldier in the field. It is more likely that the use of these compounds will occur under stressful situations. Since stress has been shown to modify the pharmacological actions of some drugs, it was the intent of this study to investigate changes in the behavioral toxicity of atropine and 2-PAM induced by physical stress.

Male ICR Swiss mice were injected intramuscularly (i.m.) with either vehicle or drug and placed individually in beakers filled with cold water (16°C) from which there was no escape. Control animals receiving sterile water showed no adverse behavioral signs other than fatigue. Similarly, the administration of low doses of atropine (0.1, 5.6 and 11.2 mg/kg) or 2-PAM (5, 12.5 and 25 mg/kg) prior to the stress did not produce any adverse behavioral effects. In contrast, higher doses of atropine (80.6 and 150 mg/kg) or 2-PAM (50 and 100 mg/kg) precipitated violent tonic-clonic convulsions and death within 15-20 minutes while being stressed. Moreover, dose combinations of atropine and 2-PAM, as low as 0.1 and 12.5 mg/kg, respectively, elicited convulsions. Similar results were observed when N-methyl atropine was substituted for atropine. Pretreatment with an alpha-adrenergic blocking agent, phenoxybenzamine (6 mg/kg, i.p.), completely blocked stress-induced convulsions and death elicited by dose combinations of atropine (11.2 mg/kg) and 2-PAM (25 mg/kg); however, a beta-adrenergic blocking agent, propranolol (20 mg/kg, i.p.), was totally ineffective. The cholinomimetic, pilocarpine (5 mg/kg, i.m.), did not alter the incidence of atropine and 2-PAM stress-induced convulsions but did provide significant protection ($p < 0.05$) against the ensuing lethality. Diazepam (1.25 mg/kg, i.m.) showed significant protection ($p < 0.05$) against both the precipitation of convulsions and lethality. Changes in plasma glucose levels and rectal body temperature did not appear to account for the precipitation of convulsions.

The above results suggest that alpha-noradrenergic mechanisms are involved in the precipitation of atropine and 2-PAM stress-induced convulsions and that cholinergic mechanisms may be involved in the lethality following convulsions.

371.12 BLOOD GLUCOSE REGULATION DURING STRESS IN STREPTOZOTOCIN TREATED MICE. L.J. Leedom*, W.P. Meehan*, T. Nagayama*, and A. Zeidler* (SPON: R. Binggeli). USC Sch. of Med., Los Angeles, Calif. 90033.

Previously we have shown that the resident-intruder paradigm may be used to demonstrate altered social behavior in diabetic mice. In this study we used this experimental design to investigate the effects of psychosocial stress on blood glucose regulation in male diabetic mice.

69 adult male Swiss Webster mice were used in this study. Diabetes mellitus was induced with the diabetogenic drug streptozotocin (SZ). To obtain varying degrees of diabetes, several doses of I.P. SZ were given: single dose 140mg/kg (n=18) and 200mg/kg (n=18) and multiple dose 200 mg/kg over 5 days (40mg/kg/day) (n=9). 25 mice received vehicle and served as controls. SZ treated mice were used 14-28 days after injection. Experiments were done on fed animals between 10 A.M. and 2 P.M. Mice were bled by retro-orbital puncture to obtain baseline glucose values, and introduced singly into the home cages of individually housed, aggression trained, resident males. The behaviors of the mice were videotaped while they were allowed to interact for 10 minutes. After the 10 min. stress period the test animal was removed and immediately bled to obtain a post stress blood sample. To control for bleeding effects, mice (n=55) were also bled, returned to their home cages for 10 minutes, and bled again. Glucose was analyzed using a Beckman Glucose Analyzer.

Fed baseline blood glucose of the control mice was 177±24 mg/dl s.d. In these mice bleeding alone without psychosocial stress increased blood glucose from 177±25 to 197±41 mg/dl with an average increase of 20±40 mg/dl ($p<0.05$ paired t test). In controls post-stress mean blood glucose was increased from pre-stress (179±21 to 246±41 mg/dl). The average stress glucose increase was significant (66±44 mg/dl $p<0.0005$).

In SZ treated mice with baseline glucose 120-250 mg/dl (n=11) bleeding alone produced an increase in blood glucose from 202±25 to 243±51 mg/dl, the mean increase of 47±37 mg/dl was significant ($p<0.0005$). Following psychosocial stress an even greater increase in blood glucose 218±55 (pre-stress) to 320±71 mg/dl (post stress) was seen. The mean rise was 102±42 mg/dl ($p<0.0005$). Mice which were both bled and stressed (n=8) were examined to see how well bleeding trial glucose changes correlated to stress trial glucose changes. There was a 0.97 correlation between increases from bleeding and increases from stress ($p<0.001$). In SZ treated mice with baseline blood glucose 251 to 699 mg/dl (n=19), bleeding produced an increase from 524±94 to 567±107 mg/dl, with an average increase of 44±38 mg/dl ($p<0.0005$). Stress increased blood glucose from 487±123 to 585±139 mg/dl, with an average increase of 98±61 mg/dl ($p<0.0005$). In mice which were both bled and stressed there was a positive correlation between increases in glucose from bleeding alone and increases due to stress ($r=0.35$). In SZ treated mice with baseline blood glucose >700 (n=14), neither bleeding alone nor stress increased blood glucose significantly: bleeding alone: 783±36 to 771±78 mg/dl, and stress: 763±37 to 782±49 mg/dl.

In summary, 1) In control mice blood glucose increased significantly to psychosocial stress and to bleeding alone. 2) Mildly or moderately diabetic mice sustained a significant rise in blood glucose from bleeding alone, and a 2x greater increase from psychosocial stress. 3) In severely diabetic mice, significant increases in blood glucose did not occur with bleeding alone or psychosocial stress.

In conclusion, the degree of change in blood glucose during stress in mice was shown to be related to both 1) the severity of the stress and 2) the baseline diabetic state.

371.13 CORTICOSTERONE, NOVELTY-INDUCED HYPERGLYCEMIA AND AND CHLORDIAZEPOXIDE. C.F. Flaherty, G.A. Rowan*, and L. Pohorecky.* Psychology Dept. and Center for Alcohol Studies, Rutgers University, New Brunswick, N.J. 08903.

Previous studies have shown contradictory results when exogenous insulin is administered as a US in studies of glycemic conditioning. Some have found a hypoglycemic CR on test trials for conditioning (e.g. Woods, S., Am.J. Physiology, 223:1424, 1972), whereas others have obtained a hyperglycemic CR (Siegel, S., J.Comp. Physiol. Psych., 89:189, 1975). The hyperglycemic CR has been interpreted as a conditioned compensatory response, a learned response which functions to oppose the effects of the US.

We have previously obtained both hyperglycemic and hypoglycemic CR patterns when different environmental contexts are used as the CS. Our interpretation that the hyperglycemic CR represented a conditioned stress response was supported by the finding that chlordiazepoxide (CDP) administration as a pretreatment resulted in a hypoglycemic CR in the environment previously shown to elicit hyperglycemic CRs (Flaherty, et.al., Physiol. & Behav., 33:595, 1984).

In the present experiment we show that different degrees of environmental novelty, relative to the animals' housing conditions, lead to graduated increases in corticosterone secretion and plasma glucose levels. The largest increase in both occurred when the rats were moved to the context in which a hyperglycemic CR was obtained in prior experiments. The context in which hypoglycemic CRs were previously obtained led to a significantly smaller rise in plasma glucose and corticosterone. CDP (5 and 10 mg/kg) decreased the degree of hyperglycemia elicited by environmental novelty. The results are taken to support the hypothesis that the conditioned hyperglycemic CR is a conditioned stress response related, in part, to degree of environmental novelty.

371.14 ADRENAL DEMEDULATION ATTENUATES AND CORTICOSTERONE SYNTHESIS INHIBITION ENHANCES THE GLYCEMIC RESPONSE TO BRIEF FOOTSHOCK STRESS. R.J. Bialik and D.C.S. Roberts. Dept. of Psychology, Carleton Univ., Ottawa, Canada, K1S 5B6.

Many labs have reported that manipulation of adrenal hormones can impair performance in learning situations involving stress. It is possible that these deficits are due to an alteration in hormonally mediated blood glucose responses. Studies on isolated hepatic tissue have suggested that both epinephrine (E) and corticosterone (CORT) promote glycogenolysis in the liver which would lead to an increase in blood glucose levels. The present study investigated the roles of these two hormones in the blood glucose response to a stressfull situation similar to that found in some learning tasks.

Blood glucose was measured in a small sample of blood taken from the tail before and at various intervals after a series of footshocks (15 X 0.5 mA shocks over a 5 min period). Sham operated rats displayed a 40% increase in blood glucose levels 10-20 min following footshock. In contrast, adrenalectomized rats failed to show an increase in blood glucose levels. This blockade was also observed in the adrenal demedulated rats, although they showing a CORT response similar to control animals (300% increase following stress). These data indicate that, in the paradigm used here, E is necessary for the stress-induced blood glucose response.

In a second experiment, rats were treated with an inhibitor of CORT synthesis (Metopirone, 50 mg/kg ip) 2 hours before subjecting them to footshock stress. We found that this drug treatment enhanced the blood glucose response to footshock stress compared to vehicle treated rats (75% vs 40% increase). These data indicate that CORT may function to attenuate the blood glucose surge in response to a mild stressor. This suggestion is consistent with recent views that CORT may function in a general manner to dampen adaptive responses to stress.

We conclude that the increase in blood glucose caused by mild footshock stress is mediated by release of E from the adrenal medulla. Furthermore, in our paradigm, CORT functions to dampen this hyperglycemic response to footshock stress. Since the number and intensity of footshocks in this experiment are similar to those used in behavioral studies, these hormonal alterations in the blood glucose response to mild stress may explain deficits in aversive conditioning caused by manipulation of these hormones (eg. Bialik, Pappas & Roberts, Behavioral Neuroscience, 98 (1984) 847). (Supported by the Medical Research Council and an Ontario Mental Health Foundation Studentship to RJB).

372.1 STRESS-LIKE NEUROCHEMICAL AND BEHAVIORAL EFFECTS OF CORTICOTROPIN-RELEASING FACTOR (CRF) A.J. Dunn and C.W. Berridge*. Dept of Neuroscience, Univ. of Florida Coll. of Med., Gainesville, FL 32610.

A primary function of CRF is to mediate the physiological release of ACTH from the anterior pituitary. However, CRF-containing neurons in the hypothalamus project to other brain regions, and intracerebrally injected CRF has distinct behavioral effects, so that CRF may act directly on brain cells. We have studied the behavioral and neurochemical responses of mice to both central (lateral ventricle) and peripheral (SC) administration of CRF. ICV injection of 1 µg (but not 0.2 µg) CRF induced abrupt brief bouts of hyperactivaty, resembling that reported in rats (Sutton et al., Nature 297:331, 1982). By contrast, SC CRF (1 or 10 µg) caused hypoactivity and periods of inactivity.

The behavioral response to ICV CRF resembles that which occurs in novel situations, so we tested whether CRF produces a response of cerebral catecholamine systems like that of stress. Using HPLC with electrochemical detection we measured the cerebral content of dopamine (DA) and norepinephrine (NE), and their respective major catabolites, dihydroxyphenylacetic acid (DOPAC), and 3-methoxy,4-hydroxyphenylethyleneglycol (MHPG), 30 minutes after CRF. ICV CRF (0.2 or 1 µg) significantly increased DOPAC and DOPAC/DA ratios in prefrontal cortex, caudate-putamen, septum, hypothalamus, and brain stem relative to animals injected with saline. MHPG and MHPG/NE ratios were also increased in the hypothalamus, hippocampus, and brain stem. By contrast, SC CRF (1 or 10 µg) markedly increased MHPG and MHPG/NE ratios in all brain regions, but DOPAC/ DA only in the frontal cortex. These results bear a close resemblance to those observed following stressors such as footshock. At low shock intensities, DOPAC/DA is selectively elevated in frontal cortex, hypothalamus, and brain stem; whereas higher intensities or restraint treatment causes widespread increases in DOPAC/DA. MHPG and MHPG/NE is increased in most brain regions by any stressor.

Plasma corticosterone was not significantly altered by ICV CRF relative to saline, but was markedly elevated by SC CRF.

These results suggest that CRF administered by either route activates CNS DA and NE systems, and that the responses resemble those in stress. However, the effects of ICV CRF on noradrenergic systems are less marked (relative to saline) than those of stress. It is possible that intracerebral CRF mediates the CNS activation of catecholamines, and that these changes underlie the behavioral responses. However, ICV CRF cannot be considered a stressor because it fails to activate the hypothalamic-pituitary-adrenal (HPA) axis. In fact, it fractionates the normal stress response. Peripherally administered CRF may trigger a global stress response because it stimulates the CNS DA and NE systems and the HPA axis.

372.2 STRESS-INDUCED ALTERATIONS IN CORTICOTROPIN RELEASING FACTOR-LIKE IMMUNOREACTIVITY (CRF-LI) IN RAT BRAIN. M. A. Smith, P. B. Chappell*, G. Bissette, J. Ritchie, C. D. Kilts, and C. B. Nemeroff. Department of Psychiatry, Duke University Medical Center, Durham, N.C. 27710.

Corticotropin releasing factor (CRF) is believed to play a crucial role in regulating endocrine, autonomic and behavioral responses to stress. Recent evidence indicates that CRF-like immunoreactivity is widely distributed throughout the CNS. In the current study, we investigated the effect of acute and chronic stress on CRF-LI concentrations in 36 different rat brain regions.

A control group of 10 male rats was handled daily for 2 weeks. The acute stress group was subjected to 3 hrs of immobilization stress at 4°C; the chronic stress group was exposed to a series of stressors (overcrowding, cold, forced swimming etc.) for 2 weeks prior to decapitation. Brains were frozen, 300 um coronal sections were cut on a cryostat, and 36 brain regions were microdissected by the technique of Palkovits. The brain samples were sonicated in 1 N HCL, centrifuged, and the supernatants lyophilized and assayed for CRF-LI by radioimmunoassay, using a specific antiserum to ovine CRF.

Measurable CRF-LI (pg/mg protein ± SEM) was found in most of the 36 regions. Acute stress reduced CRF-LI in the median eminence/arcuate nucleus from 5050 ± 670 to 2420 ± 530 ($p < .01$) and in the medial preoptic nucleus from 143 ± 11 to 97 ± 5 ($p < .01$). In contrast, acute stress produced a significant increase in CRF-LI in the locus ceruleus from 147 ± 9 to 306 ± 50 ($p < .001$). In chronically stressed animals, CRF-LI was elevated not only in the locus ceruleus but also in the anterior hypothalamus and periventricular nucleus. Reduced concentrations were found in the dorsal vagal nucleus from 194 ± 15 to 128 ± 11 ($p < .025$). The median eminence of chronically stressed rats had similar reductions of CRF-LI as in the acutely stressed animals. Other areas which contained relatively high concentrations of CRF, such as the amygdala and raphe nuclei, were unaffected by either acute or chronic stress. Plasma corticosterone and ACTH were significantly elevated during acute stress while only corticosterone and adrenal weights were elevated following chronic stress.

These results suggest that stress may alter concentrations of CRF-LI in various brain nuclei. In addition to the hypothalamus, stress-induced changes in CRF-LI were observed in the locus ceruleus and the dorsal vagal nucleus, and these areas may play a role in mediating the central nervous system response to stress. (Supported by NIMH MH-39415)

372.3 PLASMA NOREPINEPHRINE, EPINEPHRINE AND CORTICOSTERONE STRESS RESPONSES TO RESTRAINT IN INDIVIDUAL MALE AND FEMALE RATS, AND THEIR CORRELATIONS. G.T. Livezey, J.M. Miller and W.H. Vogel, Dept. Pharmacology, Thomas Jefferson Univ., Phila. PA 19107

Many studies have shown that the plasma levels of norepinephrine (NE), epinephrine (E), and corticosterone (C) rise markedly during exposure to stress. Most frequently, NE and E, and C levels were measured in seperate studies and reported only as group means of unstressed and stressed animals. However, more recently it has become evident that rats from the same strain and reared almost identically show marked, but individually constant, differences in the NE, E, and C responses to stress (Pharmacol.Biochem.Behav. 13:129-131, 1980). We examined the stress response of NE, E and C in the same individuals and compared these values within and among themselves, as well as correlations within and among E, NE, and C. Male and female Sprague Dawley rats were fitted with chronic jugular catheters and individually housed with ad lib food and water. After 24 hours recovery, blood samples (0.3ml) were taken before (time 0) and during 30 minutes of restraint (times 5, 15 and 30 min.) with equal volumes of heperinized saline reinfused. The plasma levels of NE and E were determined by radio-enzymatic analysis and plasma C by radioimmunoassay. Some animals were selected for blood sampling through the catheter and by decapitation to compare C values. The concentrations of NE, E, C, and the area under the curve ( AUC ) for the stress response time course were compared using a two-tailed student's t-test ($P<.05$). The levels of NE, E, and C at 5, 15, and 30 min. were compared to baseline, and catheter vs. decapitated C levels, by the paired t-test ($P<.05$). The correlation coefficients for all parameter pairings were calculated and since this was a large number of pairings only those reaching $P<.001$ were considered significant.

C levels were lower in blood obtained by catheter as compared to decapitation. Individual rats responded differently to immobilization and females usually showed higher stress values. NE and E levels rose smoothly and simultaneously in all animals and peaked early. The early (5 min) NE and E levels, but not the baseline (0 min), predicted ($P<.001$) the total extent of NE and E stress responses. C levels were independent of NE and E, dropping initially (5 min) in most animals and rising to peak at the end of immobilization (30 min). Supported by United States Public Health Service Grant AA 06017.

372.4 BIOGENIC AMINES IN BRAIN AND ADRENALS OF RATS WHICH CAN OR CANNOT COPE WITH STRESSFUL FOOTSHOCK. M. Graffy Sparrow* and W.H. Vogel. Department of Pharmacology, Thomas Jefferson Univ., Philadelphia, PA 19107.

It is generally accepted that stressful events cause stress which can manifest itself as changes in various biochemical measures, such as central and peripheral biogenic amine levels and turnover. Recent studies from this and other laboratories seem to indicate that it is not the exposure to a stressor, but the ability or inability of the animal to control the stressor, which causes most of these changes. To explore the effects of coping and noncoping on the stress response, we exposed pairs of rats to identical footshock (FS) for either a single one hour trial or for one hour on each of days 1 and 3. One animal was given the ability to terminate the shock (coping) while the yoked animal had no control over the shock (noncoping). A third rat remained unstressed in the home cage. Biogenic amine profiles of adrenals and various brain areas were studied. Although adrenal weights decreased significantly in noncoping rats exposed to one hour of FS, no changes in norepinephrine (NE), epinephrine, or dopamine (DA) were seen in adrenals in either study. Significantly lower NE levels were measured in the frontal cortex (FC) of noncoping rats in both groups and in the thalamus of coping rats only after two FS trials. DA levels rose significantly in the pons-medulla (PM) of noncoping animals after one trial and of coping rats after both single and double trials, and in the hypothalamus (HT) of coping and the striatum of coping and noncoping rats after one hour FS. Furthermore, the ratios of DA to its metabolite dihydroxyphenylacetic acid were significantly lower in the FC of noncoping animals of both exposure groups and of coping animals after one trial. 5-hydroxyindole acetic acid (5-HIAA) levels increased significantly after one hour FS in the FC of both coping and noncoping animals and in the FC and PM of noncoping animals after two exposures. Serotonin/5-HIAA ratios were significantly higher in the HT of coping rats and significantly lower in the PM of noncoping rats after two exposures. These results clearly show that the biochemical events detected are not only due to the FS schedule but also to the ability or inability of animals to cope with a stressor.

372.5 DEPENDENCE OF GLUCOCORTICOID ACTIONS IN HIPPOCAMPUS MODULATING VIP-STIMULATED CYCLIC AMP FORMATION ON IN VIVO PRESENCE OF ACTH. Allan Harrelson* and Bruce S. McEwen. Laboratory of Neuroendocrinology, Rockefeller University, New York, NY 10021

Glucocorticoids (GC's) are known to exert effects on a variety of brain functions and biochemical mechanisms. In particular, it has been reported by Mobley and Sulser (Nature 286:608 (1980)) that GC's inhibit norepinephrine (NE)-stimulated cyclic AMP (cAMP) formation in slices from rat frontal cortex. Subsequent studies from the same laboratory (J. Pharm. Exp. Therap. 226:71 (1983)) showed that this GC action was equally effective in adrenalectomized (ADX) and hypophysectomized (HYPOX) rats, implying that GC's act directly on the brain, without the mediation of pituitary hormones such as adrenocorticotropic hormone (ACTH). We have recently discovered that ADX increases, and in vivo GC replacement suppresses, the stimulation of cAMP in hippocampal (HIPP) slices by vasoactive intestinal peptide (VIP) in ADX rats (cf Harrelson et al, Neurosci. Abstr. 9:26.13 (1983)). The time course is approximately two days and is consistent with a genomic mechanism of GC action on some component of adenylate cyclase (AC) activation. In the present study, we investigated whether GC regulation of AC in the HIPP was also independent of the pituitary. In our first experiment, we gave implants of the synthetic GC, dexamethasone (DEX), to HYPOX rats and measured VIP-stimulated cAMP accumulation in HIPP slices relative to stimulation in HYPOX controls. The DEX replacement was ineffective, implying that pituitary hormones, and not GC's, might be regulating AC. A similar result was obtained for NE-stimulated cAMP formation in HIPP from HYPOX rats, contrasting with the suppression obtained with DEX in ADX rat HIPP. In the second experiment, VIP-stimulated cAMP accumulation was found to be increased by HYPOX, just as by ADX. Administration of ACTH to HYPOX animals reduced VIP-stimulated cAMP levels, just as DEX treatment had done in ADX rats. However, when we gave ACTH to HYPOX rats which had been ADX, we found that there was no response, implying that the presence of adrenal gland is necessary for ACTH to have its effect. Taken together with other findings that gonadal hormone and mineralocorticoid treatments have no effect, these results suggest that GC's are the primary modulators of VIP-stimulated AC in the HIPP, but that ACTH may be permissive for such regulation. Such an interpretation is consistent with other studies which have indicated that ACTH may have specific effects on HIPP electrophysiology and biochemistry.

372.6 EARLY, ENVIRONMENTAL FACTORS MODIFY THE DEVELOPMENT OF HIPPOCAMPAL GLUCOCORTICOID RECEPTORS AND THE ADRENOCORTICAL STRESS RESPONSE. M.J. Meaney, D.H. Aitken*, S. Bhatnagar*, S.R. Bodnoff* and L.J. Iny*. Center for Studies in Behavioral Neurobiology, Concordia University, Montreal, Canada H3G 1M8.

In previous work (Behav. Neurosci., in press) we reported that early, postnatal handling alters the development of the glucocorticoid receptor (Gr) system in selected brain regions. The handling procedure involves the daily separation of pups from the nest and their mother for 15 min. As adults, animals handled from Days 1 to 21 showed significantly higher (≈35 to 40%) Gr levels (Bmax) in hippocampus and frontal cortex than did nonhandled animals (measured using an in vitro receptor binding assay with (3H)dexamethasone as ligand). There were no differences found in the hypothalamus, pituitary, amygdala, or septum, nor were there any differences in the affinity (Kd) for (3H)dexamethasone. In the work reported here we have found that the handling effect on Gr development is apparent by Day 7 of life, and that the magnitude of the effect at that time is indistinguishable from that seen in adult animals. Moreover, when examined as adults, animals handled from Days 1 to 7 or from Days 8 to 14 did not differ from animals handled from Days 1 to 21 in hippocampal Gr levels and each of these three groups differed significantly from animals handled from Days 15 to 21 and nonhandled animals. Thus, the sensitivity of the Gr system to the effects of handling wanes between the second and third weeks of life, a period that corresponds to the development of adult Gr levels in the hippocampus (Meaney, Sapolsky & McEwen, Dev. Brain Res., 18:165, 1985). In subsequent work we found that, compared to handled animals, nonhandled animals as adults hypersecrete corticosterone following the termination of a stressor (i.e., exhibit a significantly longer period of elevated corticosterone following stress) suggesting a less efficient adrenocortical negative-feedback system in the nonhandled animals. Sapolsky, Krey and McEwen (Proc. Nat. Acad. Sci. USA, 81:6174, 1984) have presented strong evidence for a relationship between hippocampal Gr levels and adrenocortical negative-feedback and our findings are consistent with their results. Taken together, these findings suggest that early, environmental factors may permanently modify the adrenocortical stress response and that this effect appears to be mediated through the development of the hippocampal Gr system.

372.7 FEAR INDUCED CARDIAC ARRHYTHMIAS IN THE DIGITALIS PREDISPOSED RABBIT: AMYGDALOID CENTRAL NUCLEUS CONTRIBUTIONS. C.G. Markgraf,* B.S. Kapp and C.D. Khazam.* (SPON. J. van Houten). Dept. of Psychology, Univ. of Vermont, Burlington, Vt. 05405.

Clinical observations suggest that intense emotional states such as fear can induce potentially lethal ventricular arrhythmias, particularly in a diseased myocardium inclined to electrical instability (Natelson, 1979). Accordingly, animal models have been developed to more accurately define the conditions under which such emotional states generate these arrhythmias (Lown & Verrier, 1978; Natelson et al., 1978; Skinner et al., 1975). Lacking, however, is the application of an appropriate animal model to the identification of the central nervous system (CNS) circuitry participating in emotionally induced arrhythmias. The present study was therefore designed to establish such an appropriate model, and to apply it to an identification of the CNS circuitry contributing to the production of emotionally induced arrhythmias.

In Experiment I, 18 New Zealand rabbits received Pavlovian fear conditioning trials in which a tone conditioned stimulus (CS) was paired with a shock unconditioned stimulus (US). A retention test was given 24 hours later during which ouabain, a digitalis glycoside, was infused i.v. (110 µg/kg) over a 50 min period to predispose the heart to electrical instability. Presentations of the CS alone during infusion resulted in a significant increase in arrhythmic episodes when compared to the pre-CS baseline periods ($p < .05$). These CS-induced arrhythmias were preceded by bradycardia and included ventricular premature contractions, ventricular tachycardia, and complex ventricular ectopic beats, as well as idiojunctional rhythms and various types of heart block. An additional experiment demonstrated that they were significantly reduced by atropine methylnitrate ($p < .01$), thereby indicating a parasympathetic involvement in their generation.

Previous research (Kapp et al., 1984) has suggested that the amygdaloid central nucleus (ACE) contributes to the expression of bradycardia to a CS during Pavlovian fear conditioning. Experiment II was therefore conducted to determine if electrical stimulation of the ACE, which produces bradycardia, would induce arrhythmias in the digitalis-predisposed rabbit. Four rabbits received Pavlovian fear conditioning followed 24 hours later by ouabain infusion and random presentations of either the tone CS or electrical stimulation of the ACE (60-80 µA), both 5.0 sec in duration. Both CS presentation and stimulation produced arrhythmias of similar topography, and in both cases they were preceded by bradycardia and blocked by atropine methylnitrate.

The results demonstrate an animal model with which to investigate emotionally induced arrhythmias, and suggest a contribution for the ACE in the generation of parasympathetically-mediated arrhythmias. Supported by the American Heart Association.

372.8 ROLE OF ALPHA1- AND BETA-ADRENERGIC RECEPTORS IN THE CARDIOVASCULAR RESPONSES SHOWN TO CLASSICALLY CONDITIONED DEFENSE REACTION IN THE RAT. M.F. Callahan, R.F. Kirby, M.J. Brody and A.K. Johnson. Depts. of Pharmacology and Psychology and The Cardiovascular Center. The University of Iowa, Iowa City, IA 52242.

The current studies examined the role of the sympathetic nervous system mechanisms mediating the hemodynamic responses to conditioned aversive environmental stimuli. Male Sprague-Dawley rats received miniaturized pulsed Doppler flow probes on the left renal (REN) and superior mesenteric (MES) arteries and the lower abdominal aorta (Hq) for the determination of blood flow and carotid and jugular catheters for the determination of blood pressure and drug infusions, respectively. Following a recovery period, rats received 30 conditioning trials/day. The conditioned stimulus (CS) consisted of a light/tone (15 sec), the termination of which initiated an unconditioned stimulus of intermittent foot shock (1mA, 15 sec). On successive days, animals received pharmacological antagonism of adrenergic systems between trials 10 and 11 and the responses of these trials were compared. The hemodynamic responses to the CS consisted of a primary pressor response occurring at approximately 1 sec (~13 mmHg) followed by a smaller secondary pressor response (~7 mmHg) for the duration of the CS. At 1 sec post CS onset, there was a significant MES vasoconstriction with no change in the other beds. At 8 sec post CS onset, MES resistance reached a peak while the Hq bed showed a significant decrease. Following $alpha_1$-adrenergic receptor blockade with prazosin (0.5 mg/kg, i.v.), the pressor response and the MES vasoconstriction were attenuated. In addition, the Hq vasodilation appeared to be attenuated. Beta-adrenergic receptor blockade with dl-propranolol (0.1 mg/kg, i.v.) blocked the Hq vasodilation seen at the 8 sec time point, leading to a larger pressor response (7 mmHg before-vs-13 mmHg after propranolol). The results of these studies demonstrate that the cardiovascular response to a conditioned aversive stimulus consists of a complex hemodynamic pattern. The primary pressor response at 1 sec post CS onset is mediated by increased sympathetic drive, reflected in part by increased mesenteric vasoconstriction. The secondary pressor response is mediated in large part by the interaction of mesenteric vasoconstriction and skeletal muscle vasodilation. These mesenteric and skeletal musle responses are mediated by $alpha_1$- and beta-adrenergic receptors respectively.

Supported in part by NHLBI fellowship 1F32 HL07265

372.9 COMPARISON OF THE ACTIONS OF REPEATED STRESS AND REPEATED ANTIDEPRESSANT TREATMENT ON RAT BRAIN NORADRENERGIC RECEPTORS AS ASSESSED BY CATECHOLAMINE-STIMULATED cAMP FORMATION IN BRAIN SLICES. E.A. STONE, J.E. PLATT and A.S. HERRERA*. Dept. Psychiatry, New York Univ. Sch. of Med., New York, NY 10016.

Previous studies have shown that repeated stress and repeated antidepressant treatment both reduce the function of postsynaptic noradrenergic receptors in the rat brain as evidenced by a reduced cAMP response to NE in brain slices. The latter response is known to be mediated by a beta adrenergic receptor which is directly linked to adenylate cyclase and an alpha adrenergic receptor which modulates the size of the beta response. The present studies were undertaken to determine which of these receptors is affected by stress and antidepressants.

Restraint stress was administered repeatedly to rats twice daily for 10 days. The antidepressant drug, desmethylimipramine, (DMI) was injected 10 mg/kg, ip, twice daily for 10 days. Animals were killed 24 hrs after treatment. Cerebral cortical slices were incubated with catecholamine agonists and antagonists and assayed for cAMP accumulation by published methods. In order to selectively activate alpha adrenergic receptors, slices were incubated either with 6-fluoro-NE (6-FNE) alone or NE in the presence of timolol. To selectively activate beta receptors either isoproterenol (ISO) alone or NE plus phentolamine or prazosin was employed. To activate alpha and beta receptors either NE alone or 6-FNE plus ISO was used.

Restraint stress was found to have no effect on the cAMP response to either pure alpha or pure beta adrenergic stimulation but to significantly reduce the response to combined alpha and beta stimulation. DMI was found to have no effect on the response to alpha stimulation but to reduce significantly the responses to both beta and alpha plus beta stimulation. The decrease in the alpha plus beta response after DMI was attributable entirely to the reduction of the beta component of the response.

The results suggest that restraint stress and DMI affect the brain catecholamine cAMP generating system at two different loci. DMI acts selectively to reduce the function of beta receptors whereas stress acts selectively to reduce the synergistic interaction between alpha and beta stimulation. Since stress has been previously reported to alter some properties of brain beta adrenergic receptors however it is possible that the reduced alpha-beta interaction results from some change in the beta receptor which is not manifested in the ISO-cAMP response.

Since they appear to act at different sites, antidepressants and stress may be capable of enhancing the subsensitivity to NE caused by each other. If confirmed this may constitute a mechanism by which antidepressants could enhance adaptation to stress by magnifying the latter's effect on the reduction of the NE-cAMP response. (Supported by grants MH22768 and MH08618).

372.10 AN ESTRADIOL-INDUCED PROTEIN SYNTHESIZED IN THE VENTRAL MEDIAL HYPOTHALAMUS (VMH) AND TRANSPORTED TO THE MIDBRAIN CENTRAL GRAY (MCG). C.V. Mobbs, R.E. Harlan, and D. W. Pfaff (SPON: Z.M. Wenzel). The Rockefeller University, New York, NY 10021.

Several lines of evidence suggest that the estradiol (E2)-dependent female sexual behavior, lordosis, is regulated in part by the synthesis of proteins in the VMH which are transported to the MCG. We developed a strategy involving microinfusion of radioactive amino acids, followed by 2-dimensional gel electrophoresis, to identify proteins which may be involved in this system. A mixture of 35-S-methionine and 35-S-cysteine (2:1, total 500-1000 uCi), suspended in 1 uL phosphate buffered saline, is infused bilaterally into the VMH over a period of 2 hours into female rats which have been ovariectomized at least one week and given silastic implants containing E2 at the beginning of infusion. The rats are sacrificed either 6 or 14 hours after receiving E2, and 16 brain regions are obtained by microdissection. Samples are analyzed by 2-dimensional gel electrophoresis, entailing isolectric focusing in the first dimension and SDS-polyacrylamide electrophoresis (molecular weight separation) in the second dimension, followed by visualization by fluorography, routinely separating at least 250 spots. The infusion procedure results in the incorporation of at least 4 million cpm into TCA-precipitable protein in the VMH; about 5% of this amount is usually found in the MCG samples. In turn, the MCG routinely contains 5-10 times more cpm than regions immediately adjacent, which have fewer projections from the hypothalamus. We consistently find a protein spot with MWr of 70 kilodaltons, migrating on the basic side of the gel, which appears very rarely in VMH samples from ovariectomized rats given no E2 replacement, but almost always in rats given E2 replacement. This protein spot is similarly induced in the MCG samples. Three lines of evidence suggest that the labelled protein in the MCG is due to transport from the VMH and not local synthesis: (1) radioactivity after infusion is much higher in regions with hypothalamic projections than other regions; (2) tubulin, which is synthesized at high levels in the VMH but is transported slowly, is much less abundant in the MCG samples; (3) previous studies using a similar infusion procedure followed by autoradiography have directly visualized radioactivity in axonal projections to the MCG but not in cell bodies in the MCG. It is not clear if the protein is synthesized de novo in response to E2, or is the result of a modification of another protein. In any case, these studies suggest that E2 causes the appearance of this protein in the VMH, from whence it is transported to the MCG. The possible roles this protein may play in mediating functional effects of E2 remain to be established. (Supported by NIH grants AG05326 and HD05751).

372.11 STRESSOR CONTROLLABILITY AND PITUITARY-ADRENAL ACTIVITY. N. H. Kalin*, C. M. Barksdale*, S. M. Ryan and S. F. Maier. W. S. Middleton Memorial V.A. Hospital, Dept. of Psychiatry, Univ. of Wisconsin, Madison, WI 57305, and Dept. of Psychology, Univ. of Colorado, Boulder, CO 80309.

The degree of behavioral control which an organism has over a stressor can modulate the behavioral and physiological impact of that stressor. Rats exposed to a single session of 80 inescapable and unavoidable (uncontrollable) shocks reveal a variety of subsequent behavioral and physiological changes not seen following exposure to a series of physically identical escapable (controllable) shocks. It has often been argued that uncontrollable aversive events are more "stressful" than controllable aversive events and that some component of the stress response might mediate many or all of the behavioral and physiological changes. Virtually all of these changes are influenced by pituitary-adrenal hormones, and differential release of these hormones might be intimately involved in the mediation of these stressor controllability effects. However, pituitary-adrenal hormones have not been measured in controllability experiments which use the same species and shock parameters as those used to demonstrate the differential behavioral and physiological outcomes. Thus here we measured plasma ACTH and corticosterone levels after shock conditions identical to those used in the behavioral controllability experiments. Rats were given either 80 escapable, yoked inescapable, or no shocks. Plasma ACTH and corticosterone were measured by radioimmunoassay either immediately, 30 min, 60 min, 150 min, or 24 hr following the shock treatment. There were no differences in either the ACTH or corticosterone response to the escapable and inescapable shock. Many of the effects of controllability are typically assessed 24 hr following shock treatment and involve reexposure to the stressor. It is still possible that the pituitary-adrenal response of escapably and inescapably shocked subjects to subsequently occurring stressors might differ. We thus exposed escapably shocked, inescapably shocked, or non-shocked subjects to 5 footshocks 24 hr after initial treatment. ACTH and corticosterone were measured immediately, 30 min, and 60 min after the shock reexposure. Again, there were no differences between escapably and inescapably shocked subjects. Thus differential levels of ACTH and corticosterone cannot be used to explain behavioral and physiological differences produced by these shock treatments.

372.12 INESCAPABLE TAILSHOCK STRESS POTENTIATES THE INHIBITORY EFFECTS OF MUSCIMOL ON NEURONAL FIRING IN RATS SUBSTANTIA NIGRA PARS RETICULATA. Daniel W. Hommer, Robert C. Drugan, Gene R. Stoner*, Jacqueline N. Crawley, and Steven M. Paul*. Clinical Neuroscience Branch, NIMH, NIH, Bethesda, MD 20205.

Stress may affect neuronal inhibitory systems which employ gamma-aminobutyric acid (GABA) as a neurotransmitter. Inescabable tailshock stress has been reported to facilitiate bicuculline-induced seizures 2 hours after the stress (Drugan et al., 1985, Brain Research, in press). This facilitatory effect of inescapable shock on seizures can be prevented by pretreatment with aminooxyacetic acid, an agent which elevates GABA levels. (McIntyre et al., 1984, Neurosci. Abst.). Enhancement of the effects of the GABA agonist muscimol on GABA release in striatal slices following cold and immobilization stresss also has been reported (Kuriyama et al., J. Neurochem 42: 943-950, 1984). These findings suggest that stress may potentiate the actions of GABAergic agents.

The substantia nigra pars reticulata (SNR) is heavily innervated by GABAergic fibers and may be involved in the GABAergic modulation of seizure activity. We investigated the effect of inescapable shock stress on the ability of muscimol to inhibit neuronal firing in the SNR.

Male Sprague-Dawley rats were pretreated with either no shock, or 80 five second tailshocks (increment from 1-2 mA) at a rate of 2 per minute. Two hours after the last shock rats were anesthetized with chloral hydrate and mounted in a stereotaxic apparatus. A burr hole was drilled over the SNR and a single barrel microelectrode lowered into the brain until a unit which had extracellularly recorded characteristics matching those previously identified with SNR neurons was found. After a five minute baseline was recorded muscimol was administered at two minute intervals in doses of 1, 1, 2, 4 and 8 mg/kg i.v.

Muscimol produced a significant, dose dependent decrease in the activity of SNR neurons both in the shock-stressed (n=13) well as in the unstressed animals (n=13). However, the stressed animals were significantly more sensitive to muscimol-induced inhibition than control animals (3-way ANOVA with repeated measures on the dose; $F(1, 24) = 5.1$, $p < .03$).

This data suggest that stress may produce a functional neuronal supersensitivity to GABAergic agents. The precise nature of this supersensitivity remains to be elucidated.

372.PO *PSEUDOCHOLINESTERASE ACTIVITY IN PATIENTS WITH MITRAL VALVE PROLAPSE, W.A. Price, A.J. Giannini, D.A. Hoffman, R.H. Loiselle. Northeastern Ohio Universities College of Medicine, Rootstown, OH 44272.

Both elevated pseudocholinesterase (PC) levels and mitral valve prolapse (MVP) are known to occur with increased frequency in patients with anxiety disorders, panic attacks and agoraphobia. Pseudocholinesterase is felt to be a biological marker for trait anxiety, while MVP is thought to be associated with hypernoradrenergic tone. To date no relationship is known to exist between PC and MVP. PC levels were obtained, using the Dupont (ACA) clinical analyzer method, from 15 patients (10 women, 5 men; ages 22-65) with the Axis I diagnosis of anxiety disorder, panic attacks or agoraphobia, as determined using DSM-III criteria. These patients additionally had confirmed MVP as determined by both cardiac ausculatory findings and echocardiogram. These levels were compared against 15 similar sex and age matched controls who had MVP, but no associated psychiatric diagnosis. Results revealed that only 2 of the 15 patients with some form of anxiety disorder and MVP had elevated PC levels, which compared exactly to the number encountered in the control group. There therefore does not seem to be a relationship between MVP and trait anxiety as measured by elevated PC levels.

## MOTOR SYSTEMS AND SENSORIMOTOR INTEGRATION: CORTEX

373.1 INTERCONNECTIONS AMONG CORTICAL MOTOR OUTPUT REGIONS (CMORs) CONTROLLING THE FACIAL MUSCULATURE OF CAT. R.S. Waters, D.P. Friedman, M. Bornschlegl. The Rockefeller University, Laboratory of Neurophysiology, New York, N.Y. 10021 and Neurosciences Research Branch, NIDA and Laboratory of Neuropsychology, NIMH, Bethesda, MD 20205.

We previously investigated the pattern of brainstem projections to the facial musculature of cat from independent low threshold cortical motor output regions (CMORs) in the border between motor and premotor cortex (areas 4,6), suprasylvian gyrus (SII), parietal cortex (SIII), and cortex along the medial bank of the anterior ectosylvian sulcus (SIV). While the CMORs do not project directly to the motor neurons of the facial nucleus (FN), they do project to several intermediate relay sites in the brainstem where facial motor integration may occur prior to reaching FN. While the motor output from each CMOR appears to be independent of the other CMORs, available physiological evidence suggests that at least some of the CMORs may be interconnected at the cortical level and may thus serve to modulate motor output. In order, therefore, to understand the pattern of connectivity among these regions we examined connections in the CMORs using a combination of electrophysiological mapping and anatomical tracing techniques. Injections of tritiated amino acids or HRP were made into physiological identified sites in each CMOR which yielded contractions of facial muscles with low current microstimulation. The following results were obtained:

Injection of tritiated leucine-proline into area 4-6 border resulted in terminal labeling in SII, SIII, and SIV. Isotope injection into SII produced labeling in area 4-6, SIII and SIV, whereas SIII injections yielded labeling only in area 4-6 and SIV. SIV injections produced labeled cells in area 4-6, SII and SIII although the possibility exists that isotope may have spread into SII. These results demonstrate the existence of reciprocal connections between all pairs of related fields except between SII and SIII, where a projection to SII could not be positively identified. Labeling appeared densest and most extensive in layer I.

The results demonstrate the existence of extensive interconnections among the CMORs. Each CMOR in itself exerts independent motor control over facial musculature and yet has access to a variety of thalamo-cortical and cortico-cortical input which may serve as a closed loop system to modulate or update its own motor output. The CMORs represent an interactive set of independent parallel descending motor systems that may form the anatomical substrate for voluntary control of complex facial movements.

373.2 THALAMO-CORTICAL INPUT TO A PHYSIOLOGICALLY IDENTIFIED CORTICAL MOTOR OUTPUT REGION (CMOR) IN PARIETAL CORTEX, AREA 5, CONTROLLING THE FACIAL MUSCULATURE OF CAT. M. Bornschlegl* and R.S. Waters (SPON: D. Dahl) The Rockefeller University, Laboratory of Neurophysiology, New York, NY 10021.

The cortical area in cats immediately posterior to the ansate sulcus, area 5, is described as the third somatosensory cortex. Neurons in this area receive somatotopically organized input from the contralateral side of the body. This region contains a relatively large face representation in its most lateral part. Intracortical microstimulation (ICMS) delivered into the lateral part of area 5 elicits contraction of facial muscles with stimulating currents as low as 2-3 uA. In addition, the motor effect from this cortical motor output region (CMOR) is independent of the integrity of the motor cortex. In this study, by using a combination of electrophysiological and anatomical techniques we investigated the thalamo-cortical projection to area 5 to determine whether, this CMOR receives thalamic input characteristic of other known cortical motor regions.

Cats were anesthetized with Halothane gas, and a chamber was installed over the parietal cortex. Following surgery cats were maintained on low doses of Ketamine (1-2mg/kg) throughout the experiments. A tungsten-in-glass microelectrode was inserted into area 5, and the face region was identified using the microstimulation technique (trains of 10-12 cathodal pulses, 0.2ms duration, 300 Hz, 30uA maximum intensity). A micropipette filled with a 20% HRP solution in 0.2M KCl was then driven into the center of the physiologically identified facial motor region, and HRP was iontophoresed. After a 48 hr survival time, the cat was sacrificed and the tissue was processed according to the TMB method.

Examination of tissue sectioned frontally through the thalamus revealed two locations of heavy retrograde labeling. One was found in the medial part of the posterior nuclear complex (POm), where it forms a shell dorsally over the ventrobasal complex. This labeling in POm was continuous with labeling in the caudal parts of VL, where it borders on VB. The other location was found in the rostro lateral parts of the VA-VL complex. Only occasionally did labeled cells appear in VB and in the small-celled part of CL and LP. While the thalamocortical projection from POm may mediate a variety of sensory input to area 5, the connections between area 5 and the lateral parts of VA-VL, known as thalamic relay for cerebello-cortical projections, give further support to the interpretation of area 5 as a sensorimotor area.

373.3 RELATIONS BETWEEN DIRECTION OF 3-DIMENSIONAL ARM MOVEMENTS AND SINGLE CELL DISCHARGE IN PRIMATE MOTOR CORTEX. A.B. Schwartz, R. Kettner, and A.P. Georgopoulos. Bard Laboratories of Neurophysiology, Department of Neuroscience, The Johns Hopkins University, School of Medicine, Baltimore, MD 21205.

How is the discharge of single cells in the motor cortex related to the direction of 3-D arm movements? Previous studies using 2-D arm movements coupled to an articulated manipulandum have shown that the activity of single motor cortical cells is broadly tuned to the direction of movement (Georgopoulos et al., J. Neurosci. 2:1527, 1982). Can this finding be generalized to 3-D, unconstrained arm movements? We studied this problem by recording the activity of single cells in the motor cortex while monkeys moved their arm and touched lighted targets in a 3-D space in front of them in a reaction time task. The targets were arranged as the corners of a cube with 15cm edges. Movements were made in 8 directions from the center of the cube to each of the targets. Thus, the spherical extrapersonal space was sampled at equal angular intervals. The center of the cube was 22 cm in front of the midline of the animal's body and at shoulder level. The trajectories of the movements were monitored using a 3-D ultrasonic tracking system (J.G. Chubbuck and A.P. Georgopoulos, Soc. Neurosci. Abst. 10:337, 1984). We found that motor cortical cells related to arm movements are, indeed, broadly tuned to the direction of movement in 3-D space. For a particular cell, the frequency of discharge is highest in association with movements in a certain direction (preferred direction) and decreases in an orderly fashion with movements made farther away from the preferred direction. Preferred directions differ among different cells. Preliminary analyses suggest that the cell's 3-D "tuning volume" can be described by Fisher's distribution on the sphere.

These results indicate that the directional tuning is a general property of cells in the motor cortex. The presence of a preferred direction and broad tuning suggest that the coding of the direction of movement may rely on the neuronal population, along the lines suggested previously ("vector hypothesis", Georgopoulos et al., Exp. Brain Res. Suppl. 7:327, 1983). (Supported by USPHS Grants NS17413, NS07226, MH18030.)

373.4 RESPONSE OF NEURONS IN MONKEY MOTOR CORTEX TO STOPPING LIMB MOVEMENTS. E. V. Evarts, V. A. Jennings* and S. P. Wise. Laboratory of Neurophysiology, NIMH, Bethesda, MD 20205

If, as Phillips hypothesized in 1969, certain somatosensory inputs to the primary motor cortex (MI) during active movements signal deviations from an intended movement, then the magnitude of MI neuronal responses should be graded according to the degree of mismatch between actual and intended displacement. This possibility was examined by recording the response of MI neurons to stopping wrist movements in two operantly conditioned rhesus monkeys. The monkeys made wrist flexion-extension movements of 15° in the paradigm described elsewhere (Jennings, this volume). In task A, stops always occurred at the same angular position (the "stop position"), but the angular distance to the target (the "remaining distance") varied. In task B, the remaining distance was held constant at 12°, but the stop position was varied.

Neurons over a wide area of the forelimb region of MI responded to stopping movements with increases or decreases in activity at latencies of 20 ms to 65 ms. The present analysis focuses on neurons in rostral regions of MI that showed phasic bursts of activity before the onset of movement in one (the "preferred") direction. These neurons responded to stops of movements in the preferred direction with sustained increases in activity. In general, neurons with the largest stop responses also had the largest premovement phasic burst of activity. In task A, these MI neurons showed a graded stop response that was proportional to the magnitude of the remaining distance. The neuronal stop response increased by approximately 11 IPS/deg as the remaining distance increased from 1.5° to 13.5°. At the maximum remaining distance tested (13.5°), i.e., when the stop position was closest to the start zone, the magnitude of the stop response was similar to the magnitude of the phasic burst of premovement activity. In task B, when the stop position was shifted in the preferred movement direction with the remaining distance held constant, the stop response increased by about 3 IPS/deg.

It is concluded that the stop response of these MI neurons depends on the distance remaining to be moved and the joint position at which the stop occurred. The graded nature of this response and its resemblance to the muscle stop response (see Jennings, this volume) support the hypothesis that MI neurons contribute to mechanisms that act to compensate for deviations from an intended movement. Further, the similarity of the stop response (at the maximum remaining distance) to the premovement activity burst suggests that MI makes a comparable contribution to motor activity at the beginning of movement and the resumption of a stopped movement.

373.5 REPRESENTATION OF MOVEMENT DIRECTION IN PRIMATE MOTOR CORTEX IN THE ABSENCE OF IMMEDIATE MOVEMENT. M.D. Crutcher, A.B. Schwartz, and A.P. Georgopoulos. Bard Laboratories of Neurophysiology, Department of Neuroscience, The Johns Hopkins University, School of Medicine, Baltimore, MD 21205.

Visual targets were presented to monkeys who were trained to withhold their movement toward the target. A two-dimensional working surface and an articulated manipulandum were used. The animals grasped the manipulandum and captured first a light at the center of the plane. After a variable period of time, the center light was turned off and another light was turned on at one of several positions on a circle of 8 cm radius. A variable delay (range = 0.5-3.2s) was then imposed during which the animals did not move but waited holding the manipulandum at the center of the plane. At the end of the delay period the target light dimmed. This served as a "go" signal to capture the target. Thus movements of different directions were generated after the delay, but the information about target location and upcoming movement direction was present with the first appearance of the target.

The activity of 120 motor cortical cells that were related to contralateral arm movements and to task performance was recorded in 3 hemispheres of 2 monkeys. Data were analyzed for 6 different target locations for each cell (N = 6x120 = 720). Statistically significant changes in neuronal activity during 0.5s following the initial presentation of the target were detected in 476/720 (66%) of the cases. Increases in activity were observed twice as frequently as decreases. The shortest latency changes were observed at the 40-60ms bin, and 50% of them had occurred by 100ms following target onset. Many cells showed changes in activity that extended throughout the delay period. These changes usually differred according to the direction of the upcoming movement. Similar findings were obtained when the initial position of the hand was at the periphery and the final point at the center of the plane. Does this early recruitment of motor cortical cells result in a substantial change of firing in the neuronal population? Population histograms were constructed for each direction of the upcoming movement after the spike trains of single trials were aligned to target onset. A significant increase (3 to 4 fold) in the population activity was observed 80ms after the target onset. Do these changes predict what the upcoming direction of movement will be? A directional analysis of the population changes was performed, according to the "vector hypothesis" (Georgopoulos et al., Exp. Brain Res. Suppl. 7:327, 1983). We found that indeed the direction of the population vector during the delay period was close to the direction of the movement that was to be made 0.5-3.2s later. These results suggest that the motor cortex might be involved in early processing of the upcoming movement direction, even in the absence of immediate motor output. (Supported by USPHS Grants NS17413, MH15330, NS07226).

373.6 DIFFERENCES IN THE SPATIAL RELATION BETWEEN MOVEMENT DIRECTION-DEPENDENT AND LOAD DIRECTION-DEPENDENT ACTIVITY CHANGES IN PRIMATE CORTEX AREAS 4 & 5. J.F.Kalaska, D.A.D.Cohen* and M.L.Hyde*. Centre de recherche en sciences neurologiques, Faculté de médecine, Université de Montréal, Québec, Canada, H3C 3J7.

We reported previously (Neurosci.Abstr.10:738) that the activity of motor cortex area 4 cells in a 2-dimensional reaching task shows large continuously-graded changes for both the direction of arm movement and the direction of external loads applied to the arm. We also reported that only the first parameter produces large changes in the activity of parietal area 5 neurons. Area 5 cells show much smaller changes in their movement-related activity than do area 4 cells while a monkey compensates for loads applied in different directions. Thus, the activity of single area 5 cells during motor behavior does not reflect the muscle contractile activity to the same degree as does that of area 4 cells.

In both regions, the changes in a cell's activity related to different directions of movement were centred on one direction, its "preferred direction" for movement. Similarly, changes in activity caused by loads applied to the limb in different directions were centred on one direction, or "load axis". We describe here an important difference in the spatial relationship between these two properties of each cell for the two cortical regions.

In area 4, the preferred direction and the load axis for each cell tended to be opposite (mean difference 179° ± 49°). A cell's activity in this task may be represented by a vector oriented along its preferred direction (Exp.Br.Res.Suppl.7:327). We will show that the vectorial sum of the load direction-dependent changes in the activity of the area 4 cells in our sample is a vector oriented in a direction approximately opposite to that of the applied load. Thus, the net area 4 population response to an applied load is a signal to apply a force in a direction opposing the load. These data for shoulder-related cells is consistent with previous experiments for cells related to more distal arm movements.

In contrast, there does not appear to be a fixed relationship between the preferred direction and the load axis for cells in area 5. As a result, the small load-dependent activity changes seen at the single-cell level in our area 5 sample are apparently further reduced at the population level, because these variations tend to cancel out when the cell activities are added vectorially. This implies that the overall pattern of activity of the area 5 population should provide a rather reliable and unambiguous signal about the posture and movement of the limb in space, that does not vary with changes in the relative degree of contractile activity of the muscles involved, unlike area 4. The data suggest that this feature of area 5 activity results from mechanisms that opperate at both the single-cell and population levels. (Supported by an MRC Scholarship and MRC grant M-7693).

373.7 GABA-ERGIC INHIBITION IN THE PRIMATE MOTOR CORTEX AND THE CONTROL OF VOLUNTARY MOVEMENT. M.Matsumura*, T. Sawaguchi* and K.Kubota. Dept. of Neurophysiology, Primate Res. Inst., Kyoto Univ., Inuyama, Aichi 484, Japan.

Effects of intra-cortical injection of GABA, its agonist (Muscimol) and antagonist (Bicuculline) into the hand motor area were studied, at behavioral and single neuron levels, while the monkeys were performing a visual reaction time task. Monkeys pressed or released the lever by hand in response to a visual cue.

After injection of Muscimol (2 -6 μg), using Hamilton syringe, into the hand motor area, identified by intra-cortical micro-stimulation, the reaction time for lever release became significantly longer, and the amount of task-related EMG activities of the forearm and upper arms decreased. These effects began to appear 5 min. after the injection and lasted for more than 30 min.. After a similar injection of Bicuculline (10 -20 μg), the variability of the reaction time increased, (S.D. more than two times greater than control condition), and EMG durations became longer. Further, EMG activities, which showed reciprocal patterns under the control condition, became bi-directionally active. In later stages after injection, twitching appeared in muscles during inactive phases in the control, and finally convulsion occurred.

GABA, Mucimol and Bicuculline were iontophoretically applied to isolated single neurons, of which activities were related to lever press and/or lever release. Ninety-seven neurons, including 14 PTNs, of the hand area of the contralateral motor cortex in four macaque monkeys, were related uni- or bi-directionally to the lever press or release movement. In 90% of 45 neurons showed an activity decrease to GABA and/or Muscimol applications (current<30nA), and in 90% of 85 neurons Bicuculline showed an activity increase at lever release or lever press phases without any changes in background activity. In seven neurons, Bicuculline induced uni-directional discharge patterns into bi-directional ones. These results suggest that GABAergic inhibitory neurons play a role in forming spatially and temporally organized reciprocal discharge patterns in the motor cortex neurons and that their activities, in turn, lead to reciprocally organized hand movement.

373.8 CORTICO-CORTICAL INPUTS TO IDENTIFIED MOTOR CORTEX NEURONS. P. Zarzecki. Department of Physiology, Queen's University, Kingston, Ontario, Canada, K7L 3N6.

Cortico-cortical neurons synapse upon pyramidally-shaped neurons. However, the cells of origin of many corticofugal pathways are pyramidally-shaped, so that this does not specify which of these receive cortico-cortical contacts. Electrophysiological studies have revealed cortico-cortical inputs to pyramidal tract neurons (Blum et al. 1968, Exp. Neurol.), but the occurrence of monosynaptic cortico-cortical epsps outside of layer V of cortex (Herman et al. 1985, Exp. Brain Res.) indicates that cortico-cortical effects are not restricted to PT neurons. Accordingly, in this study we tested a variety of antidromically identified cortical neurons for cortico-cortical inputs. In barbiturate anaesthetized cats, electrodes were stereotactically placed to antidromically activate cortical neurons projecting to the striatum, thalamus, red nucleus, and through the cerebral peduncle. Optimum placement of stimulating electrodes was aided by depth-threshold analyses and confirmed histologically. This report is based upon 70 antidromically identified neurons of the motor cortex. Current spread calculations and branching analyses confirmed that projections to separate subcortical targets usually originate from separate cortical neurons. Cortico-cortical effects were evoked by surface stimulation of area 3a of primary somatosensory cortex and were detected by collision-extinction techniques and, when subthreshold or inhibitory, by the facilitation or retardation of antidromic invasion which they cause.

Excitatory cortico-cortical effects have been detected upon cortico-thalamic, cortico-rubral, and cortico-peduncular neurons. The latency of cortico-cortical excitation ranged from 0.9 to 4.1 ms. Inhibition was always later. In recording tracts where cortico-cortical excitation has been observed, it has never appeared upon all corticofugal neurons. The strongest evidence for this apparent selectivity in the distribution of cortico-cortical excitation was obtained when several neurons of the same corticofugal class were recorded and studied simultaneously. In all 8 instances, cortico-cortical effects could be detected for only some of the nearby neurons projecting to the same sub-cortical target. Furthermore, thalamo-cortical effects were distributed mostly, but not exclusively, to neurons without detectable cortico-cortical input. In conclusion, excitation from somatosensory cortex to motor cortex reaches cortico-thalamic and cortico-rubral neurons, in addition to pyramidal tract neurons, but it seems not to be distributed equally to all members within a class of corticofugal neuron.
Supported by the MRC of Canada.

373.9 THE ORGANIZATION OF INTERCONNECTIONS BETWEEN THE PREMOTOR AREAS IN THE PRIMATE FRONTAL LOBE AND THE ARM AREA OF PRIMARY MOTOR CORTEX. D.C. Primrose* and P.L. Strick. V.A. Med. Ctr. and Depts. of Neurosurg. and Physiol., SUNY-Upstate, Syracuse, NY 13210.

In macaques, the premotor areas which project most densely to the arm area of the primary motor cortex are: 1) the arcuate premotor area (APA), located in and around the caudal bank of the arcuate sulcus and 2) the supplementary motor area (SMA), located on the medial wall of the hemisphere (Muakkassa and Strick, Brain Res. '79). In the present experiments we examined the topographic distribution, laminar origin and laminar termination of projections from the premotor areas to the arm area of the primate motor cortex using amino acid and WGA-HRP transport.

The "arm areas" of the APA and SMA have substantial interconnections with one another and with "arm" regions of the primary motor cortex on the precentral gyrus. On the other hand, the two premotor areas do not have significant interconnections with more caudal regions of motor cortex in the deeper two-thirds of the central sulcus. This topographic pattern suggests that the APA and SMA are functionally related to the "rostral zone" of arm representation in primary motor cortex, but not to the "caudal zone".

Interconnections between primary motor cortex, APA and SMA originate from cells located in the same cortical layers: largely layer III, but also layers II and V. However, the laminar patterns of termination in the 3 cortical areas differ. Efferents from the primary motor cortex terminate in a trilaminar pattern in the premotor areas. One band of labeling is located in layer I, another in layer III and a third in layer V. The most dense terminations in the premotor areas are located in layer III. In contrast, efferents from the premotor areas terminate in a bilaminar pattern in the motor cortex. One band of labeling is located in layers I, II and the outer one half of layer III, and the other band is in layer VI. The most dense terminations in the motor cortex are located in layer I. Based on these patterns of termination, the projections from the motor cortex to the premotor areas are similar to the "forward" cortico-cortical connections of sensory systems, while the projections from the premotor areas to the motor cortex are similar to the "backward" connections (e.g., Maunsell and Van Essen, J. Neurosci. '83). These observations raise significant questions about the classical schemes of hierarchical organization proposed for frontal motor areas.

373.10 MULTIPLE AND DIFFERENTIAL PROJECTIONS FROM THE PARIETAL LOBE TO THE PREMOTOR AREAS OF THE PRIMATE. D.D. Galyon* and P.L. Strick (SPON: D.Hoffman). V.A. Med. Ctr. and Depts. of Neurosurg. and Physiol., SUNY-Upstate, Syracuse, NY 13210.

There is extensive clinical and experimental evidence for the involvement of the parietal lobe in the generation and control of voluntary movement. Classically, the influence of the parietal lobe has been thought to be mediated via its projections to "premotor areas" in the frontal lobe. Using retrograde transport of WGA-HRP, we have examined the connections of the parietal lobe with each of the "arm areas" in the two premotor areas which project most heavily upon the macaque motor cortex, i.e., the arcuate premotor area (APA) and the supplementary motor area (SMA) (Muakkassa and Strick, Brain Res.'79).

The arm areas of both the APA and the SMA receive substantial projections from regions considered to be part of the classical somatosensory areas (SI, SII, and SIII). The APA receives projections only from part of the SII arm representation within the lateral fissure. In contrast, the SMA receives projections from part of the SI arm representation in area 2 just lateral to the postcentral sulcus and from part of SIII in area 5 on the medial wall of the hemisphere.

The intraparietal sulcus is the source of substantial projections to the arm areas of the APA and SMA. The APA receives projections from a part of area 5 located deeply in the sulcus, from part of area 2 located laterally in the sulcus and from part of area 7 located laterally in the sulcus and extending onto the adjacent cortical surface. In contrast, the SMA receives projections from separate medial and lateral regions of area 5 located superficially in the sulcus and extending onto the cortical surface.

The arm areas of the APA and SMA also receive projections from different parts of lateral area 7. The APA receives a projection from more rostral parts of area 7 located just dorsal to SII on the cortical surface. The SMA receives projections from caudal parts of area 7B located in the lateral fissure and on the adjacent cortical surface.

In total, there are 12 spatially separate cortical regions in the parietal lobe which project to the "arm areas" of the APA and SMA. Five of these parietal regions project to the APA and 7 to the SMA. Surprisingly, none of the parietal regions project to both premotor areas. These findings suggest that there are multiple parietal regions concerned with the control of arm movement and that these parietal regions distinguish between the APA and SMA.

Supported by funds from the VA Medical Research Service, USPHS-NS 02957, and the Dept. of Neurosurgery.

373.11 SINGLE UNIT ACTIVITY IN THE PARIETAL CORTEX OF THE PRIMATE DURING A HAPTIC DELAYED MATCHING-TO-SAMPLE TASK. Kevin W. Koch and Joaquin M. Fuster. Neuroscience Interdepartmental Ph.D. Program, Brain Research Institute and Dept. of Psychiatry, University of California, Los Angeles, CA 90024.

Anatomical and physiological data suggest that the parietal association cortex serves in the complex somesthetic discriminations that take place during the manual exploration of the environment. In order to test this idea, the present study analyzes neuronal activity in the parietal lobe of behaving monkeys during a task requiring the perception and temporary retention of haptic (stereognostic) information. Extracellular records of 300 single units in parietal cortex of 2 rhesus monkeys were taken during a haptic delayed matching-to-sample (DMS) task. In a task trial the monkey, sitting in a dimly lit and sound attenuated chamber, first hears a warning click, indicating that the sample object, either a cube or a sphere (26 mm diameter/side), is in position to be manipulated. The animal then reaches through an opening to where he has learned he will find the object, which is attached to the upper end of a vertical rod and in a central position (the same for all trials) in front of the animal. After the animal has felt and pulled it, the sample object is withdrawn and an 18-sec delay period initiated. At the end of the delay, another click signals the presentation of the choice objects: a cube and a sphere, 10 cm apart. The animal has 3 sec to feel both objects and choose the correct one (matching the sample) by giving it a slight pull, for which he is rewarded with a squirt of fruit juice. The sample object and the side (right or left) of the correct choice are varied randomly from trial to trial. Preliminary data analysis indicates the following: (1) the majority of cells in all areas examined underwent significant changes in firing during the presentation of the sample object; those changes were usually related to the arm projection and/or the manipulation of the object, more rarely to the warning click; (2) in anterior areas, firing changes were generally excitatory, while in posterior areas most of the cells were inhibited during sample presentation; (3) cells in posterior areas were likely to show changes during the delay and those changes were usually inhibitory; (4) fewer delay-related cells were found in anterior positions, although their delay changes were excitatory; (5) a small proportion of the cells showing increased activity during the haptic manipulation or delay period were differentially activated by the cube and the sphere. The results indicate that neurons in parietal cortex participate in the sensory-motor processes of manual exploration and perception of objects. Some neurons in anterior parietal cortex appear involved in the discrimination and short-term retention of haptic sensory attributes. (Supported by NSF Grant BNS-8213806)

373.12 EFFERENT TOPOGRAPHY OF THE MACAQUE SUPPLEMENTARY MOTOR AREA: DEMONSTRATION WITH INTRACORTICAL STIMULATION. A. R. Mitz. Laboratory of Neurophysiology, NIMH, Bethesda, MD 20205.

The supplementary motor area (SMA), like the primary motor cortex (PMC), has a direct corticospinal projection (Murray and Coulter, J. Comp. Neurol., 195:339, 1981). However, examination of SMA efferent organization with standard microstimulation has been hampered by the paucity of evoked movements, contributing to the recent suggestion that the SMA may lack a topographic organization (Macpherson et al., Exp. Brain Res., 45:410, 1982).

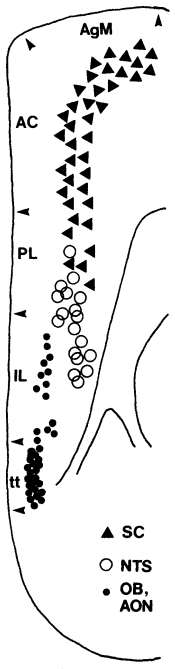
Two rhesus monkeys were implanted with chronic recording chambers over the left SMA and glass-coated platinum-iridium electrodes were inserted into the SMA through the dura. Three methodological changes greatly increased the number of movements evoked from the SMA: (1) The electrode-tip surface area was increased from 100-250 $um^2$ to approximately 1000 $um^2$. (2) 100 ms pulse trains were used because they were significantly more effective than pulse trains under 50 ms. (Other stimulation parameters were: 0.2 ms/phase biphasic pulses, 330 pulses/second, currents usually below 60 ua.) (3) Because SMA responses were more labile than PMC responses, and apparently more easily masked by an uncooperative animal, the number of responses was increased by delivering stimuli at nonuniform intervals or by sedating the animal with 1.3 mg/kg of ketamine.

Orofacial movements, including movements of the pinnae, lips, tongue, and jaw, and conjugate eye movements to the contralateral visual hemifield, were observed most rostrally. Contralateral forelimb movements, including movements of the digits, wrist, forearm, elbow, and shoulder, were evoked from sites immediately caudal to the face area. Hindlimb and tail movement sites were caudal to the forelimb representation, however, preliminary analysis was unable to establish a clear boundary between hindlimb sites of the primary motor cortex and hindlimb sites of the SMA. The orofacial, forelimb, and hindlimb representations each spanned from the dorsal bank of the cingulate sulcus, to the medial surface of the hemisphere and at least 2 mm onto the hemispheric convexity. Movements of the neck and trunk were evoked from 3 or 4 apparently separate areas in the convexity and medial wall of the hemisphere. The overall rostrocaudal extent of the SMA covered 12-14 mm.

373.13 EFFERENT PROJECTIONS FROM THE MEDIAL FRONTAL CORTEX TO THE NUCLEUS TRACTUS SOLITARIUS, SUPERIOR COLLICULUS AND OLFACTORY BULB. E.J. Neafsey, Karen Hurley-Gius* and Dimitrios Arvanitis*. Departments of Anatomy and Pathology, Loyola University Medical Center, Maywood, IL 60153.

The rat medial frontal cortex (MFC) projects to the nucleus tractus solitarius (NTS; Terreberry and Neafsey, BR:278, 1983), the superior colliculus (SC; Wyss and Sripanidkulchai, BR:293, 1984), and the olfactory bulb (OB; Haberly and Price, JCN:181, 1978). Using double retrograde labeling methods we have attempted to determine the topography and amount of overlap between the MFC cell populations projecting to these targets.

Thirteen male rats (350-580g) were utilized in these experiments. Each animal was anesthetized with ketamine HCl (100mg/kg, IP) and had his cisterna magna opened to permit access to the NTS. All animals received an injection (0.4ul, 2%) of fluorescent tracer (Fast Blue, Diamadino Yellow or Rhodamine microspheres) just lateral to the obex into the region of the NTS and a second injection of a different tracer into either the ipsilateral OB (n=9) or the ipsilateral SC (n=4). All animals were recovered from surgery and the OB/NTS group was allowed to survive 4-5 days, while the SC/NTS group survived 7-8 days. Each animal was then sacrificed, and the tissue processed for visualizing fluorescent labeling.



As the figure to the right illustrates, the pattern of retrograde labeling is topographic. Cells projecting to the OB and anterior olfactory nucleus (filled circles) are located most ventrally in the taenia tecta (tt) and in the more superficial layers of the infralimbic cortex (IL). Cells projecting to the NTS (open circles) are located in the deep layers of IL and in prelimbic cortex (PL), with the most ventral of these being overlapped by more superficially located OB projecting cells. Interspersed among the NTS cells in PL are cells which project to the SC. These cells continue dorsally thru the anterior cingulate (AC) into medial agranular cortex (AgM).

This anatomical arrangement of the efferents from the MFC is consistent with the functional division of the MFC into a ventral "visceral motor" cortex and a more dorsal frontal eye field area. Since behaviors such as feeding, reproduction, foraging and territorial marking require the integration of olfactory, gustatory, visceral and visual information, it is likely that the MFC is part of the cortical sensorimotor apparatus involved in these behaviors.

373.14 CHANGES IN CORTICOMOTONEURONAL (CM) POSTSPIKE FACILITATION OF EMG ACTIVITY ASSOCIATED WITH LOGARITHMIC AND SQUARE TRANSFORMATION OF THE EMG SIGNAL. P.D. Cheney and K. Mewes*. Dept. of Physiol., Univ. of Kansas Med. Ctr., Kansas City, KS 66103.

Although spike-triggered averaging of EMG activity is a powerful method of establishing causal relations between cortical cell discharge and muscle activity in awake monkeys, it suffers from the low yield of cells that produce clear postspike facilitation (PSF) (Fetz, E.E. and Cheney, P.D., J. Neurophysiol. 44:751, 1980). One factor that could contribute to the low yield of clear PSF is the possibility that some cortical cells preferentially facilitate only a fraction of the recorded motor units, for example, only the small or large units (Clough, J.F.M., et al., J. Physiol. 198:145, 1968). We therefore, attempted to enhance PSF by selectively increasing the amplitude of small motor unit potentials relative to large ones using a logarithmic (log) amplifier and large potentials relative to small ones using an amplifier which squared the EMG signal. Multichannel, spike-triggered averages of the simple rectified EMG signal as well as log and square transformed versions of the same rectified EMG signal were computed simultaneously. We tested a sample of 10 CM cells yielding a total of 67 spike-triggered averages, 42 of which showed PSF. We used two types of measures to quantitatively compare the magnitude of PSF in averages of different versions of the EMG signal. With one measure, the mean increase of PSF above baseline was expressed as a percent of baseline. The averages of percent mean PSF in the simple rectified, log and square versions of the EMG signal from 42 facilitated muscles were 4.7%, 2.8% and 9.6%, respectively. From these results, squaring the EMG signal seems to produce a marked enhancement of PSF and the log transformed EMG, a marked reduction in PSF. However, these changes were due largely to changes in the average baseline EMG signal rather than to genuine effects on the strength of PSF. To avoid this problem, we quantified PSF with a signal-to-noise measure in which the increase above baseline of the mean PSF was divided by the standard deviation of the baseline points. Based on this mean-to-noise measure, 15 of 42 PSFs were enhanced an average of 20% in the log transformed signal and 11 of 42 PSFs were enhanced an average of 25.3% in the squared EMG signal. However, log or square transformation revealed no PSF from CM cells that was not evident in the average of simple rectified EMG signals nor did it identify any additional CM cells. We conclude that log and square transformation of EMG signals can yield modest improvement of PSF, although generally not sufficient in magnitude to warrant routine use of these procedures. The results also emphasize the limitations of expressing the magnitude of postspike effects as a percent of baseline. We suggest that a more consistent and accurate indicator of the strength of postspike effects is provided by signal-to-noise measures. Supported by NSF grant BNS 82-16608.

373.15 MOTOR CORTEX RESPONSES TO CEREBELLAR STIMULATION IN THE MONKEY. S. Pullman, R. L. Watts and E. V. Evarts. Laboratory of Neurophysiology, NIMH, Bethesda, MD 20205

Neuronal responses to electrical stimulation of the brachium conjunctivum were recorded in primary motor cortex of monkeys in which pyramidal tract neurons (PTNs) were identified by their antidromic responses to electrical stimulation of the medullary pyramid. The major goals of the study were to determine (1) the responsiveness of motor cortex PTNs as compared to more superficially situated motor cortex neurons and (2) the responsiveness of PTNs as a function of axonal conduction velocity. Recordings were obtained from awake, chronically prepared monkeys that sat relaxed during recordings and that had not been trained to execute specific movements.

Data were obtained on 494 non-PTNs and 158 PTNs in the primary motor cortex. With 200 usec stimuli of 0.3 to 0.5 mA, 141 (29%) of the non-PTNs were activated, with the response commonly being a single spike with a latency of about 3 msec. Increasing the stimulus to 1.0 or 1.5 mA sometimes evoked two successive spikes with latencies of 3 and 6-8 msec. The shortest response latency was 2.5 msec. The cerebellar-evoked cortical field potential had a latency of 1.6 msec, and showed a sign reversal at about 1.5 mm below the cortical surface, the same depth at which non-PTN cerebellar responses were most prominent. Marking lesions made via the microelectrodes during recording of the most prominent responses were found to be in cortical layer III upon subsequent histological analysis.

Of the 158 PTNs that were recorded, 5 (3.2%) showed responses to cerebellar stimulation. Even in these 5 PTNs the average numbers of spikes per stimulus were less than in non-PTNs; latencies ranged from 3 to 10 msec. Because only 5 PTNs were activated, these data could not answer the question as to the correlation between PTN axonal conduction velocity and responsivesness to cerebellar inputs.

In conclusion, it was found that reponses to stimulation of the brachium conjunctivum were approximately ten times more prominent in cells of cortical layer III than in PTNs. The greater prevalence of cerebellar-evoked unit responses in layer III is consistent with anatomic data showing a concentration of thalamic terminal arborizations in layer III. While this does not contradict previous anatomic and physiologic evidence as to the existence of monosynaptic thalamic inputs to PTNs (all of which are in layer V), the present results show the relatively greater strength of the inputs to layer III neurons under the conditions of relaxed immobility that prevailed in the present study.

373.16 CONTRASTING FEATURES OF SOMATOSENSORY RESPONSES IN PYRAMIDAL TRACT NEURONS (PTNs) AND NON-PTNs IN SENSORIMOTOR CORTEX OF THE MONKEY. R. L. Watts, S. Pullman, and E. V. Evarts. Laboratory of Neurophysiology, NIMH, Bethesda, MD 20205.

Previous studies contrasting the responses of pyramidal tract neurons (PTNs) and non-PTNs in precentral and postcentral sensorimotor cortex of monkeys have been carried out during volitional movements and actively maintained postures. In such studies the relatively small numbers of PTNs that were systematically investigated made it difficult to compare quantitative features of sensory responses in PTNs (all of which are located in layer V) and more superficial neurons. This study, which was carried out in awake monkeys that had not been trained to perform movements and that sat quietly during recordings, allowed collection of larger samples of neurons and revealed significant differences in the somatosensory responses of PTNs and more superficial cells in both primary motor (MI) and in primary sensory (SI) cortex.

Recordings were concentrated in a rostral region of MI that received deep inputs generated by wrist displacement and in a region of area 2 in SI that was likewise activated by wrist displacement. Ramp flexor and extensor displacements of up to 15° and of 50 msec duration were produced by a DC torque motor. In both MI and SI, responses were more prominent in superficial neurons than in PTNs. Of a total of 226 non-PTNs recorded in MI, 78 (35%) were activated by wrist displacement whereas only 7 (12%) of 56 PTNs in MI were responsive to wrist displacement. In SI, 260 (74%) of 352 non-PTNs were responsive to wrist displacement and 9 (40%) of 22 PTNs responded.

For the 78 responsive MI non-PTNs, 74 of the responses were of the phasic or mixed phasic/tonic type (median response latency (MRL) 16 msec) and 4 responses were of the purely tonic type (MRL 87.5 msec). For the 7 responsive MI PTNs, 5 responses were of the phasic or mixed type (MRL 26 msec) and 2 were of the tonic type (MRL 64 msec). In SI, the responses of the 260 non-PTNs consisted of 239 that were phasic or mixed (MRL 16 msec) and 21 that were tonic (MRL 60 msec). Of the 9 SI PTN responses, 8 were phasic or mixed (MRL 20 msec) and 1 was tonic (latency 100 msec).

These findings parallel results on differences between cerebellar-evoked responses in PTNs as compared to more superficial MI neurons and show that PTNs are relatively less responsive to somatosensory as well as to cerebellar inputs, at least under conditions of relaxed immobility.

373.17 COURSE AND TERMINATIONS OF THE RODENT CORTICOSPINAL TRACT FROM PHYSIOLOGICALLY IDENTIFIED AREAS OF SENSORY AND MOTOR CORTEX. C.F. SIEVERT AND E.J. NEAFSEY. Dept. of Anat., Loyola Univ. Med. Cntr., Maywood, Il 60153.

Using WGA-HRP as an anterograde tracer, the course and termination of the rodent corticospinal tract (CST) from various physiologically identified areas of sensory and motor cortex were studied in twenty-eight male Long Evans rats (300-500 grams). Animals were anesthetized with Ketamine HCL (100 mg/kg IM) and placed in a stereotaxic apparatus. The cisterna magna was opened to prevent cortical swelling, and a craniotomy performed over the left frontal and parietal cortex. Forelimb primary and secondary somatosensory areas were delineated by recording evoked multiunit activity during peripheral stimulation. Motor areas were identified and mapped by intracortical microstimulation with a glass insulated tungsten electrode. Stimulation parameters were 0.25 msec pulses, 350 hz, 300 msec trains; currents were limited to 50 uamps. After mapping, small injections (one per animal) of wheat germ agglutinin-HRP were made in the rostral forelimb motor area, caudal forelimb motor area, forelimb primary sensory area, hindlimb sensory-motor area and the secondary somatosensory area. Animals were perfused and the tissue processed for HRP histochemistry using TMB. Spinal cord sections were cut in the coronal plane to best visualize terminal labeling, and in the horizontal plane to best demonstrate fibers. Corticospinal fibers were found in five areas of the cord, including both dorsal funiculi, both lateral funiculi and the ipsilateral ventral funiculus. All five paths could be found as low as the lumbar enlargement in animals which received injections in the hindlimb area. The heaviest "terminal labeling" was found contralaterally but there was also some ipsilaterally in most animals. The forelimb primary sensory cortex had heavy terminations to the medial portions of lamina III-VI in the dorsal horn. Secondary somatosensory cortex had terminations similar to but lighter than the forelimb primary sensory cortex, the major difference being the lack of ipsilateral terminations. Hindlimb sensory-motor cortex had terminations at lumbar levels in lamina II-VII with sparse terminations in lamina VII. The caudal forelimb motor cortex had terminations more ventrally in lamina IV-IX with very sparse terminations in lamina VIII. Finally, the rostral forelimb area had terminations similar to the caudal forelimb motor area, except that lamina VIII in the medial ventral horn appeared to contain significant terminal labeling.

(Supported by NIH grant NS 16146).

373.18 AN ULTRASTRUCTURAL AND MORPHOMETRIC STUDY OF UNMYELINATED AXONS IN THE PYRAMIDAL TRACT OF MONKEYS. A.P. Thomas* (SPON: K. Chan). Dept of Anatomy, School of Medicine, Univ. of Puerto Rico, San Juan, P.R. 00936

The pyramidal tracts of fascicularis and rhesus monkeys were used in this study. The pyramidal tracts (PT) were prepared for light and electron microscopy (Langford and Coggeshall, Anat. Rec. 197: 297, 1980). 1mm-thick cross-sectional areas from the medullary pyramid were divided into three or four small blocks. One-half micron thick sections from each of the blocks were studied with the light microscope. The total cross-sectional area of the PT was obtained from thick sections. Ultrathin sections (70 nm thick) cut from each of the blocks were double stained with uranyl acetate and lead citrate. These sections were scanned and systematically examined with a transmission electron microscope. Photographs were taken at regular intervals.

Unmyelinated axons were identified based on the presence of microtubules, neurofilaments, and mitochondria that differentiated them from glial processes. Unmyelinated axons were observed to be scattered among the myelinated axons. Unmyelinated axons occurred: singly; in small groups of two or six; or in large groups of twenty to twenty-five. Diameters of unmyelinated axons were measured; 200 randomly-selected axons were categorized as small, medium, or large in diameter and the various diameters within each group were averaged. Small-diameter axons ranged from 0.1 to 0.224 μm; mediums ranged from 0.225 to 0.424 μm; and large diameters ranged from 0.425 to 0.9 μm. Unmyelinated axons made up about 13% of the total population of PT axons. Components of unmyelinated axons observed among the young, were also observed in mature adult fascicularis and rhesus monkeys. The number of myelinated axons per PT ranged from 490163 to 583920. Thus, electron microscopy has demonstrated the occurrence of a significant number of unmyelinated axons in the PT of fascicularis and rhesus monkeys. (SUPPORTED by NIH grants RR00166 and NS16934).

373.19 ORIGINS OF THE CORTICOSPINAL TRACT. R. J. Nudo* and R. B. MASTERTON. Department of Psychology, Florida State University, Tallahassee, FL 32306. (SPON: John A. Jane).

To visualize the cells of origin of the corticospinal tract, a hemisection of the spinal cord was performed just above C2 and flakes of HRP placed in the cut. A very high degree, if not complete backfilling of the corticospinal tract was obtained by this procedure in 22 selected species of mammals: The vividness of the pyramidal decussation, the number of labeled cells in the brainstem tegmentum, red nucleus, etc., each provide independent assurance that few descending fibers might have escaped labeling. At neocortex, Golgi-like labeling of neuronal somata was invariably obtained.

Although a full comparative analysis is still underway, certain generalizations can already be made. First, the CST in many mammals takes origin in a much wider area of neocortex than previously supposed. Second, all corticospinal neurons originate in layer V. No exception to this generalization has yet been found. Third, the total number of CST cells in neocortex rises sharply across phyletic grades based on the animal's propinquity with mankind. This marked increase in number is attained first by a stacking of the CST cells, then by a reduction in the stacking but a concurrent expansion of the total area containing CST cells and an increase in their average size. Fourth, animals at higher levels of the sequence show an increasing number of "new" areas of neocortex containing concentrations of CST cells.

This acquisition of what might be considered "new" corticospinal tracts, together with the cytoarchitectural changes in the number, size, distribution, density and arrangement of cells within each cortical field, each independent of more general morphological features such as body size, would seem to be of physiological as well as evolutionary significance. (Supported by NINCDS NS07726.)

## BEHAVIORAL PHARMACOLOGY: PHENCYCLIDINE AND OPIATES

374.1 BEHAVIORAL AND BIOCHEMICAL EFFECTS OF PHENCYCLIDINE IN DIFFERENTIALLY HOUSED MICE. C.A. Wilmot, C. VanderWende and M.T. Spoerlein. Rutgers University, Dept. Pharmacology, PO Box 789, Piscataway NJ 08854

The abuse of phencyclidine (PCP) is noted for producing psychoses and unpredictable episodes of violent behavior. The following studies were conducted to determine (1) whether acute or chronic treatment with PCP would modify the fighting behavior of grouped (GH) or individually housed (IH) mice, (2) the relationship between the effects of PCP on motor activity and fighting and (3) the effects of PCP on the accumulations of 5-HTP and DOPA after decarboxylase inhibition in GH and IH mice.

PCP, 0.625-2.50 mg/kg, produced a dose-dependent increase in the total time spent fighting in mice individually housed from 10 to 45 days, but did not increase the percentage of mice fighting at any time. These doses did not increase motor activity, suggesting some behavioral selectivity of low doses for fighting behavior. The effects of PCP on fighting were dependent on the condition of IH, as neither acute nor chronic treatments of PCP to GH mice produced fighting. IH mice had significantly greater accumulations of DOPA and higher levels of tyrosine in the striatum and frontal cortex compared to GH mice. Significant effects of PCP treatment on 5-HTP and DOPA accumulations were seen in the striatum and frontal cortex of IH mice only.

In conclusion, PCP facilitated the expression of fighting behavior in IH but not GH mice at doses that did not stimulate motor activity. A difference in the functional activity of monoaminergic systems may be the basis of the increased sensitivity of IH mice to the behavioral effects of PCP.

Supported by Predoctoral Fellowship MH08873-01 from NIMH to C. Wilmot and by grant G-82-84-718-NB-30 from the Charles and Johanna Busch Foundation to C. VanderWende

374.2 THE EFFECTS OF DSP-4 ADMINISTRATION ON PHENCYCLIDINE-INDUCED LOCOMOTOR AND EATING BEHAVIORS IN THE RAT. P.A. Seymour and R.G. Browne, Central Research Division, Pfizer Inc., Groton, CT 06340.

A large body of evidence implicates a role for norepinephrine (NE) in locomotor and consummatory behaviors in the rat. Administration of the psychotomimetic agent, phencyclidine (PCP), has been shown to induce pronounced increases in horizontal locomotor activity (Castellani and Adams, Eur. J. Pharmacol., 73:143, 1981) and eating (unpublished observations). It has been suggested that PCP acts, in part, by a presynaptic mechanism involving the release of norepinephrine from noradrenergic terminals (Marwaha et al., J. Pharmacol. Exp. Ther., 215:3, 606, 1980), and by enhancing the release of dopamine from terminals in the striatum (Vickroy and Johnson, J. Pharmacol. Exp. Ther., 223:669, 1982). The noradrenergic-selective neurotoxin, DSP-4, has been shown to markedly deplete NE in the CNS, with maximal reductions occurring within 6 hours after administration (Jonsson et al., Eur. J. Pharmacol., 72:173, 1981). To examine the effect of acute NE depletion on PCP-induced locomotor and eating behaviors, male CD rats were injected with DSP-4 (50 mg/kg, i.p.) or vehicle and 6 hours later were placed into computer-monitored behavioral chambers for the assessment of baseline behavior. Twenty-four hours later PCP (3.2 mg/kg, s.c.) was administered and data were collected for an additional 24 hours. DSP-4 administration severely reduced baseline eating and locomotor activity, as measured by both horizontal (crossovers) and vertical (rearing) data. Pretreatment with DSP-4 significantly attenuated the PCP-induced increases in crossovers and eating, although significant increases in these behaviors were observed. It was concluded, therefore, that NE plays a major role in normal locomotor activity and eating, but may only play a minor role in the PCP-induced manifestations of these same behaviors.

374.3 EFFECTS OF CALCIUM ANTAGONISTS ON PCP AND AMPHETAMINE-INDUCED LOCOMOTOR STIMULATION IN MICE. Ronald G. Browne and Patricia A. Seymour. Pfizer Inc., Central Research, Groton, CT 06340.

Several lines of recent evidence suggest that calcium channel blockers might be useful as psychotherapeutic drugs. In animals, calcium antagonists displace PCP from high affinity binding sites (Eldefrawi et al. Biochem. Pharmacol., 31:2549, 1982.), and, at high doses, antagonize PCP-induced stereotyped behavior in rats (Shah et al., Pharmacologist, 24:160, 1982). A more recent link between calcium and antipsychotic drugs was the demonstration (Proc. Natl. Acad. Sci. 80:5122, 1983) that some antipsychotic drugs act as calcium channel antagonists. In order to explore the possibility that various calcium channel blockers might be active in tests predictive of antipsychotic activity, we examined the effects of these agents on amphetamine- or PCP-induced locomotor stimulation in mice. Male CD1 mice (at least 8/group) were injected with vehicle or test compound 15 min before receiving 3.2 mg/kg of d-amphetamine or 3.2 mg/kg of PCP. Fifteen min after the challenge drug, the mice were placed into individual chambers designed to record locomotor activity. The effect of various calcium blockers on amphetamine-induced locomotor stimulation revealed that at least 10 mg/kg of drug was necessary to reduce amphetamine's effect. However, at these doses, the drugs alone frequently produced a sedative effect. Neither Bepridil nor Lidoflazine had a significant effect on amphetamine hyperactivity even at 100 mg/kg. PCP at 3.2 mg/kg also increased locomotor activity. Verapamil dose-relatedly reduced PCP hyperactivity, but the dose necessary to produce this effect was no different from that required to reduce amphetamine-induced activity. Consistent with the effects seen with amphetamine, neither bepridil nor lidoflazine antagonized PCP. However, low doses (3.2 mg/kg) of nitrendipine, nimodipine or nifedipine significantly reduced PCP-induced stimulation, in contrast to the lack of effect at this dose against amphetamine-induced hyperactivity. Furthermore, a dose of 3.2 mg/kg of these calcium blockers given alone did not significantly reduce locomotor activity. Therefore, the observed anti-PCP activity cannot be explained as a superimposed sedative effect. Furthermore, pharmacokinetic studies indicate that the calcium antagonists do not produce their effects by altering the disposition of PCP. The results of these experiments showing that various calcium channel blockers antagonize PCP-induce hyperactivity at doses which, by themselves, are non-sedating, suggests that these agents may be selective PCP antagonists.

374.4 EFFECT OF DOSE OF CYCLAZOCINE ON PHENCYCLIDINE-INDUCED LOCOMOTOR AND STEREOTYPED BEHAVIOR IN MICE. M.E. Nevins. Dept. of Biological Research, G.D. Searle & Co., Skokie, Ill. 60077

The behavioral effects of and the interaction between two drugs that bind with high affinity to the phencyclidine receptor, phencyclidine HCl(PCP) and the opiate mixed agonist-antagonist cyclazocine, were studied. The effects of i.p. administration of PCP and cyclazocine on locomotor and stereotyped activity of mice were studied both alone and in combination. Locomotor activity and stereotyped activity were assessed by the use of microprocessor-based infra-red photocell activity monitors. Locomotor activity is expressed as the accumulated distance the mouse travels. Stereotypy is defined here as any repetitive movements that interrupt any photocell beam repeatedly and is expressed as accumulated time spent in repetitive behaviors.

PCP doses of 5, 10 and 20 mg/kg increased both locomotor and stereotyped activity. Evidence of ataxia was seen in the dose-related delay of peak locomotor and stereotypic effects at the two higher doses. Cyclazocine doses of 0.5 and 2 mg/kg had no significant effect on either total locomotor or total stereotyped activity accumulated over the 60 minute test. At 10 mg/kg cyclazocine significantly increased both locomotor activity ($p<.05$) and stereotypy ($p<.05$).

The effects of the interaction of cyclazocine and PCP on locomotor and stereotyped activity were studied by pretreating mice with either 0, 0.5, 2, 10 or 25 mg/kg of cyclazocine 20 minutes prior to administration of PCP 5 mg/kg. Pretreatment with 0.5 mg/kg of cyclazocine significantly reduced the total locomotor ($p<.05$) and the peak (20-40 minutes post PCP injection) stereotypy ($p<.05$) effects of PCP. Pretreatment with 2 mg/kg of cyclazocine had no effect on PCP-induced locomotion or stereotypy. The two higher doses of cyclazocine, 10 and 25 mg/kg, both significantly delayed the peak locomotor ($p<.05$) and the peak stereotypic ($p<.05$) effects of PCP. This delay in peak effect is similar to that induced by higher doses of PCP. The results are discussed in terms of a possible dose-related effect of cyclazocine on PCP with low doses of cyclazocine partially antagonizing PCP effects and higher doses adding to PCP effects.

374.5 STRONG ABSOLUTE CONDITIONED PLACE PREFERENCE IS OBTAINED WHEN MORPHINE IS PAIRED EXCLUSIVELY WITH TACTILE STIMULI IN AN OPEN FIELD. P. Vezina and J. Stewart. Center for Studies in Behavioral Neurobiology, Concordia University, Montreal, Quebec, Canada H3G 1M8.

Despite the widespread use of conditioned place preference techniques (CPP) to assess the reinforcing properties of drugs of abuse little is known about the basis of this effect. Although it has generally been assumed that stimuli associated with morphine come to elicit approach and continue to do so in the absence of the drug empirical support for this view has been equivocal prompting some to question the validity of the technique.

Three groups of rats were trained and tested in an open field (68x68 cm). The conditioned stimuli (CS) used were entirely tactile (since these require an animal to make direct contact with them in order to experience them) and consisted of different floor textures in the open field. Care was taken to minimize the influence of other stimulus modalities. The open field floor was divided into four quadrants. For conditioning, all four quadrants were of the same texture (either wire screen or steel rod). For testing, the number of quadrants having the floor texture previously paired with morphine (CS+ quadrant) was reduced and combined with quadrants of the texture previously paired with saline (CS- quadrant).

During conditioning, one group received morphine (10 mg/kg, i.p.) paired with the wire screen floor on one day and saline paired with the steel rod floor on the following day. A second group received the opposite pairings and a third control group received saline with both floor textures. This procedure was repeated four times. Conditioning sessions lasted 30 min. On three subsequent test days all animals were administered saline and placed in the open field with different numbers of CS+ quadrants available (1, 2 or 4 quadrants). Time spent on the CS+ quadrant as well as horizontal locomotion throughout the open field were measured for 30 min.

Both conditioning groups spent from 66-85% of their time on the CS+ when two CS+ quadrants were present. When only one CS+ quadrant was present, animals still demonstrated a CPP for the CS+ of 64-74% (chance on this test was 25%). This preference was observed through out the test sessions. No preference for any particular quadrant was evident when all four quadrants were CS+. Control group animals demonstrated a slight preference for the screen floor. It was also found that animals from conditioning groups were least active when only one CS+ quadrant was present, intermediately active when only two CS+ quadrants were present, and most active when all four quadrants were CS+. Thus, the fewer the number of CS+ quadrants, the lower the activity. Hence, once an animal made contact with the CS+ it maintained contact with the stimulus and reduced its approach to and contact with other stimuli. These CPP and locomotion data clearly demonstrate that stimuli previously associated with morphine subsequently elicit approach and contact in the absence of the drug.

374.6 MAGNETIC FIELD INHIBITION OF MORPHINE-INDUCED ANALGESIA: POSSIBLE INVOLVEMENT OF CALCIUM AND OTHER DIVALENT IONS. M. Kavaliers and K.-P. Ossenkopp (SPON: R. Shivers). Depts. of Zoology and Psychology, University of Western Ontario, London, Ontario, Canada N6A 5B7.

It is increasingly apparent that magnetic fields can influence biological systems. Of particular interest is the extremely low frequency band in the range of 50-60 HZ, this being the frequency of alternating currents used as sources of electrical energy by man. One of the more consistent and dramatic effects of exposure to magnetic fields is the attenuation of morphine-induced analgesia. Calcium ($Ca^{++}$) and other divalent ions are considered to be involved in the control of the actions of opiates, while it has been hypothesized that magnetic fields alter neuronal $Ca^{++}$ binding. We report here that acute (1 h) exposure to 0.5 Hz magnetic fields reduces morphine-induced analgesia in a manner consistent with effects on $Ca^{++}$ ions.

In experiment 1 the effects of $Ca^{++}$ on morphine-induced analgesia in male CF-1 mice was examined. Intracereboventricular (i.c.v.) injections of low doses of $Ca^{++}$ antagonized morphine sulfate (10 mg/kg)-induced analgesia, while $Ba^{++}$ was without effect. The chelator, EGTA, given i.c.v., blocked this inhibitory effect of $Ca^{++}$, while the ionophore, A21387, potentiated the antagonistic effects of $Ca^{++}$. EGTA, A21387, or saline, given i.c.v., had no effects on morphine-induced analgesia. These results confirm previous findings of $Ca^{++}$ involvement in the actions of opiates. In experiment 2 exposure of mice for 1 h to a 0.5 Hz rotating magnetic field (RF, 3-90 gauss) reduced morphine-induced analgesia. This inhibitory effect of the RF was blocked by the chelator, EGTA, and augmented by i.c.v. administration of the ionophore A21387.

The results of these experiments show that exposure to magnetic fields alters morphine-induced analgesia in mice in a manner compatible and consistent, with effects on $Ca^{++}$ (and possibly other divalent ions) that are involved in the actions of opiates.

374.7 DIFFERENTIAL HOUSING IN MICE: EFFECTS ON BEHAVIORAL RESPONSES TO OPIATE AGONISTS, ANTAGONISTS AND ETHANOL. G.C. Teskey, R. Book, and M. Kavaliers. Department of Zoology, University of Western Ontario, London, Ontario, N6A 5B7.

Social housing conditions (grouped/isolated) have been shown to affect the behavioral and physiological responses of many species of animals. These socially related behavioral modifications have been attributed to changes in monoaminergic activity. Endogenous opioid systems, which have a major role in the mediation of emotional and stress responses, have also been proposed to be affected by, and be involved in, the determination of behavioral responses to social housing conditions. We describe here the effects of short (1 week) and longer term differential housing conditions on the nociceptive responses of mice to various opiate agonists, antagonists, and doses of ethanol.

Male CF-1 mice of two size classes (20-25 or 30-40 gms) were housed either singly or in groups of 5 for designated time periods. Mice were peripherally injected with either the mu opiate agonists levorphanol, the kappa opiate agonist U-50,488, the sigma opiate agonist SKF-10,047, the mu opiate antagonist naloxone, the delta opiate antagonist ICI-154,129, saline (control) or ethanol (0.5, 1.0, 2.0 g/Kg). Nociceptive responses of the mice, as determined by the hot-plate test, were measured 30 minutes following injection.

There were significant differences in response latencies between the grouped and singly housed mice to various opiate agonists, antagonists and ethanol. Differences were evident after both short (1 week) and longer differential housing. These differences in responses may be attributed to changes in both specific opioid systems and dopaminergic and other monoaminergic neurotransmitters.

374.8 DECREASED SENSITIVITY OF ISOLATION-REARED RATS TO MORPHINE AS MEASURED IN THE CONDITIONED TASTE AVERSION PARADIGM. S. Schenk*, T. Hunt*, G. Klukowski* and Z. Amit (SPON: Z.W. Brown). Center for Studies in Behavioral Neurobiology, Concordia University, 1455 de Maisonneuve Blvd. W., Montreal, Quebec H3G 1M8.

Isolation rearing has been shown to alter the sensitivity of mature rats to dependence-inducing drugs. In the present study, we compared the sensitivity of differentially reared rats to various doses of morphine in a conditioned taste aversion (CTA) paradigm.

Rats were obtained immediately post-weaning (21 days) and housed either singly or in groups of 4 per cage for 6 weeks. They were then placed on a deprivation schedule, allowing them access to fluids for a 20 min. period per day. Following 7 days habituation to this schedule, the CTA experiment began. The deprivation schedule was maintained throughout the 30 day experiment.

Every 6th day, the rats were presented with a solution of 0.1% Na Saccharin for 20 min. Immediately following the presentation, they were given an injection of morphine (0, 2.5, 5.0, 10.0 or 20.0 mg/kg, i.p.). Saccharin consumption was recorded. In all, 5 such pairings of saccharin and morphine were made. In the intervening days, the rats were presented with water for the daily 20 min. period.

The rats that received saline injections following the presentation of the novel tasting solution steadily increased their consumption of saccharin over the 5 pairing days. For both housing conditions, the rats that received a dose of 2.5 mg/kg failed to show such an increase (prolonged neophobia) although they also failed to decrease their consumption of saccharin across pairings. ANOVAs were performed on the change in saccharin consumption from the first pairing day to subsequent pairings for each dosage group. There was a significant interaction between the early housing environment and the pairing days for the rats that received 5.0 mg/kg and 10.0 mg/kg. The group housed rats showed a larger magnitude of CTA than did the isolation housed rats. These findings support the notion that drug sensitivity in the adult can be influenced by environmental conditions.

374.9 DIFFERENTIAL EFFECTS OF GONADAL HORMONES ON MORPHINE-INDUCED ANALGESIA IN MALE AND FEMALE MICE. J. F. DeBold and K. A. Miczek. Department of Psychology, Tufts University, Medford, MA 02155.

In a pilot study we observed that pregnant and lactating female mice were less sensitive than males to the analgesic properties of morphine. The present experiment investigated this apparent sex difference by manipulating testosterone and estradiol levels in both male and female mice and then assessing the animals' response to a wide range of morphine doses.

Adult male and female mice were gonadectomized and then 2 weeks later implanted s.c. with a silastic capsule. The silastic capsules contained one of 6 hormone treatments: 100% testosterone in a 7.5 mm capsule, 10% testosterone (7.5 mm), cholesterol (7.5 mm), 100% estradiol (2.5 mm), 10% estradiol (2.5 mm), or cholesterol (2.5 mm). There were 8 males and 8 females in each hormone group. Testing for morphine response began 1 week after hormone implantation. Baseline levels of the tail flick response and rectal temperature were established in each animal 15 minutes prior to an i.p. injection of morphine (0, 3.0, 6.0, 10.0, 17.0, or 30.0 g/kg morphine sulphate in saline). Animal temperature and tail flick response were again recorded at 15, 30, 60, 90, 120 and 180 minutes after injection.

Estradiol treatment inhibited morphine-induced analgesia in ovariectomized females but not in castrated males. 10 mg/kg morphine induced analgesia in ovariectomized cholesterol implanted mice, but 17 mg/kg morphine was required in estradiol implanted females. In addition, at each morphine dose the estradiol females were less analgesic than cholesterol females. The testosterone capsules had relatively little effect on the response to morphine in ovariectomized females. Males, however, showed a very different steroid-morphine interaction. Castrated male mice with cholesterol implants were somewhat less sensitive to morphine than the testosterone or estradiol implanted castrated males. Testosterone and estradiol treated males were significantly analgesic with 10 mg/kg morphine but 17 mg/kg morphine was required in the cholesterol treated castrated males.

These results demonstrate that sex differences in morphine-induced analgesia can be altered by gonadal steroids, but that males and females are differentially responsive to the effects of estradiol and testosterone on morphine sensitivity. This difference in response to estradiol and testosterone may be the result of hormone effects during sexual differentiation.

374.10 **EFFECTS OF ETHYLKETOCYCLAZOCINE ALONE AND IN COMBINATION WITH TRIPELENNAMINE ON REWARDING BRAIN STIMULATION.** **E.M. Unterwald and C. Kornetsky. Laboratory of Behavioral Pharmacology, Boston University School of Medicine, Boston, MA 02118**

**An increased sensitivity to rewarding brain stimulation has been used as an animal model of drug-induced euphoria. Previous studies have shown that the opiates, morphine and heroin, and to a lesser extent the mixed agonist/antagonist opioids, pentazocine and nalbuphine, lower the threshold for brain-stimulation reward. The euphoria produced by opiates is believed to be mediated by mu opiate receptors. In addition, tripelennamine, an antihistamine, significantly potentiates the modest lowering effect produced by pentazocine or nalbuphine. The present study evaluates the effects of ethylketocyclazocine (EKC), a putative kappa opiate receptor agonist, alone and in combination with tripelennamine on the threshold for rewarding intracranial stimulation. Bipolar electrodes were stereotaxically implanted into the medial forebrain bundle - lateral hypothalamic area of male CDF rats. Thresholds for rewarding brain stimulation to this site were determined by using a modification of the psychophysical method of limits. EKC (.004-.125 mg/kg) administered subcutaneously failed to produce a significant change in reward threshold in any animal. Higher doses incapacitated the animals to the extent that they could no longer perform the task. A dose of 2.5 mg/kg of tripelennamine, which did not cause a significant change in reward threshold, was then administered concomitantly with the various doses of EKC. These combinations produced a dose-dependent lowering of reward threshold which was not seen when EKC was administered alone. The results of this study support the contention that EKC not only has kappa agonist properties but also has some activity at mu receptors. This activity appears to be low but is significantly potentiated by the addition of tripelennamine.**

374.11 LOW INTENSITY 60-HZ MAGNETIC FIELDS AND EPILEPSY: REDUCED INCIDENCE OF LETHAL PENTYLENETETRAZOL INDUCED SEIZURES IN RATS PREEXPOSED TO MAGNETIC FIELDS. K.-P. Ossenkopp, D.P. Cain and S.M. Smith. Dept. of Psychology, Univ. Western Ontario, London, Ontario, Canada N6A 5C2.

A growing body of evidence indicates that magnetic fields can influence a number of biological processes. Of special concern is the possibility that natural and man made sources of low intensity magnetic fields, especially those in the 50 to 60-Hz frequency range, can affect the electrical activity of the brain. For example, a significant correlation between seizures in humans and geomagnetic field changes has been noted (Neurosci. Lett., 24:187-191, 1981). In the present series of experiments we examined the effect of brief (1 hr) pre-exposure to 60-Hz low intensity (1 gauss) magnetic fields on pentylenetetrazol (PTZ) induced seizures in male hooded rats. The magnetic fields were produced by two large (100 cm diameter) Helmholtz coils. In Experiment 1 the rats were pre-exposed to the 60-Hz field or to a sham exposure condition (the coils were not energized) and then given an intraperitoneal (i.p.) injection of 55 mg/kg PTZ. Pre-exposure to the magnetic field resulted in a significant reduction in the frequency of lethal seizures ($p < .05$) and in significantly shorter total durations of seizures ($p < .02$). Experiment 2 examined the effects of pre-exposure to the magnetic fields on seizures induced by different doses of PTZ. Animals were pre-exposed to the field or to sham conditions and then injected i.p. with 45, 60, or 75 mg/kg PTZ. Analysis of the data revealed a significant drug dose effect on mortality and on seizure duration ($ps < .01$), but only a nonsignificant trend for reduced mortality in the magnetic field pre-exposed rats at all drug dose levels. In the last experiment rats were again pre-exposed to the magnetic field or sham exposure condition and then injected with 60 mg/kg PTZ. Data analysis indicated a significant reduction in mortality for the magnetic field exposed animals ($p < .05$) and a nonsignificant trend for shorter total seizure duration. When data for those rats injected with 55 or 60 mg/kg PTZ from all three experiments were combined, a highly significant reduction in mortality ($p = .001$) was apparent in those animals pre-exposed to the 60-Hz magnetic field (Magnetic field = 8.3% mortality; Sham exposed = 36.2% mortality). Clearly, the experimental manipulation protected against the lethal effects of PTZ induced seizures.

374.12 MAGNETIC RESONANCE IMAGING AND MORPHINE-INDUCED ANALGESIA: SOME TEMPORAL EFFECTS OF THE TIME VARYING MAGNETIC FIELD. F.S. Prato*, K.-P. Ossenkopp, M. Kavaliers and E. Sestini* (SPON: T.E. Feasby). Research Institute, St. Joseph's Hospital and Depts. Psychology and Zoology, University of Western Ontario, London, Ontario, Canada N6A 5C2.

A large body of research has shown that magnetic fields can influence a number of biological processes. Of special interest are the recent demonstrations that the magnetic and radio-frequency fields associated with Magnetic Resonance Imaging (MRI) can alter murine morphine-induced analgesia. Both day- and nighttime exposure results in strong inhibition of the analgesic effect with stronger inhibition at night. In the present experiments we exposed adult male CF-1 mice to the time varying magnetic field (TVMF) component of the MRI procedure during the mid-dark period since this component was shown previously to produce the greatest inhibitory effect. The mice were injected intraperitoneally with 10 mg/kg morphine sulfate and tested 30 min later for nociceptive reaction to a thermal stimulus (hot plate) to assess analgesia levels. In Experiment 1 exposure of the mice to the TVMF for 4.86, 11.6 and 22.5 min prior to drug injection (during the mid-dark phase) resulted in increasing inhibition of the morphine-induced analgesia levels as a function of exposure length ($p < .001$). In Experiment 2 mice were exposed to the TVMF for 45 min and tested for morphine-induced analgesia either immediately or 24 hr later. The mice tested immediately showed complete inhibition of the analgesic effect ($p < .01$), whereas the mice tested 24 hr later had normal levels of analgesia. Thus, the effects of the TVMF had dissipated by 24 hr post-exposure. In the last experiment we examined the effects of exposing the mice to the TVMF before or after the morphine injection. Exposure to the TVMF for 22.5 min resulted in an equivalent and significant ($p < .01$) degree of inhibition of the pre- and post-injection exposed animals. These experiments show that the TVMF from MRI can alter the behavioral effects of morphine in a systematic manner and that these effects dissipate within 24 hr.

374.13 SINGLE-TRIAL CONDITIONED PLACE PREFERENCE USING INTRAVENOUS MORPHINE. M. T. Bardo and J. L. Neisewander.* Dept. of Psychology, University of Kentucky, Lexington, KY 40506.

In three experiments, we assessed the reinforcing effect of acute intravenous morphine. Adult male rats were implanted with a jugular cannula made of Clay Adams polyethylene tubing (PE 50). At 2 or 3 days after surgery, single-trial place conditioning was conducted in a 3-compartment rectangular apparatus with one white and one black end compartment, and a small center gray compartment separated from the end compartments by guillotine doors. Animals were conditioned by pairing morphine with the white compartment for 30 minutes. On an alternate day, animals were exposed to the black compartment for 30 minutes without drug. Following conditioning, animals were given access to all 3 compartments for 15 minutes. Conditioned place preference (CPP) was defined as a significant increase in duration spent in the white compartment relative to saline-injected controls.

In Experiment 1, each animal was injected i.v. with either 0, 4 or 8 mg/kg morphine sulfate immediately after being placed into the white compartment. In Experiment 2, each animal received 2 i.v. injections, one 15 minutes after and one 25 minutes after being placed into the white compartment; the injection sequence was either 8 mg/kg morphine-saline, sal-morph, or sal-sal. In Experiment 3, each animal received 3 i.v. injections, one immediately after, one 15 minutes after, and one 30 minutes after being placed into the white compartment; the injection sequence was either 8 mg/kg morph-sal-sal, morph-sal-2 mg/kg naloxone, morph-nalox-sal, nalox-sal-sal, or sal-sal-sal.

Single trial CPP was dose-dependent when morphine was given immediately after placement into the white compartment (Experiment 1). No CPP was obtained when morphine was delayed 15 or 25 minutes after placement into white (Experiment 2). Naloxone blocked single-trial CPP when given 15 minutes, but not 30 minutes, after morphine, although naloxone did not alter preference when given alone (Experiment 3).

(Supported by USPHS grant DA03487).

374.14 ENDOGENOUS OPIATE INVOLVEMENT IN LEARNED HELPLESSNESS AND ASSOCIATED CHANGES IN BRAIN NOREPINEPHRINE METABOLISM. R. B. Hemingway* and T. G. Reigle. Dept. of Pharmacology & Toxicology, Univ. of Georgia, College of Pharmacy, Athens, GA 30602.

Naloxone (3 mg/kg, i.p.) was administered either 10 min before or 48 hr after exposure of male Sprague-Dawley rats to an uncontrollable footshock stress in order to evaluate the contribution of endogenous opiate systems to the induction and expression of learned helplessness (LH). Escape latencies in a two-way shuttlebox task served to demonstrate the development of LH when compared to latencies obtained with paired animals exposed to escapable footshock and non-shocked controls. The shuttlebox escape deficit (LH) elicited by uncontrollable footshock was prevented by the administration of naloxone prior to the initial stress. However, naloxone given immediately prior to the shuttlebox test, 48 hr after the initial footshock, had no effect on LH. Thus, while endogenous opiate systems appear to be involved in the initial induction of LH, the ultimate expression of this behavioral deficit does not seem to be opiate dependent.

Immediately after shuttlebox testing, rats were sacrificed and the brain was removed and dissected. The brainstem and hippocampus were assayed for two norepinephrine (NE) metabolites, 3,4-dihydroxyphenylethylene glycol (DOPEG) and 3-methoxy-4-hydroxyphenylethylene glycol (MOPEG), by HPLC with electrochemical detection. Since DOPEG is mainly formed by presynaptic monoamine oxidase, while MOPEG can be formed by both pre- and postsynaptic metabolic pathways, the MOPEG/DOPEG ratio was used as a qualitative index of NE activity. In both the hippocampus and brainstem, the MOPEG/DOPEG ratio in animals exhibiting LH was significantly ($p<0.01$) lower than the ratio observed in animals exposed to escapable footshock or non-shocked controls. In animals which received naloxone 48 hr. after uncontrollable footshock (LH not affected), the MOPEG/DOPEG ratio remained significantly ($p<0.01$) decreased. However, when naloxone was given prior to the initial footshock stress (LH prevented), no significant difference in the MOPEG/DOPEG ratio was observed among the three experimental groups. Thus, although LH appears to require an endogenous opiate mechanism for induction, its expression is associated with a decrease in brainstem and hippocampal NE activity. This is in agreement with the biogenic amine hypothesis of depression and serves to enhance the acceptance of LH as an animal model for this disorder.

374.15 DISSOCIATION OF FUNCTIONAL TOLERANCE FROM OTHER TYPES OF TOLERANCE TO THE EFFECTS OF MORPHINE ON SCHEDULE-CONTROLLED BEHAVIOR. R.E. Solomon*, E.A. Wasserman* and G.F. Gebhart. Departments of Pharmacology (College of Medicine) and Psychology, University of Iowa, Iowa City, IA 52242.

Following the original reports by Schuster et al. (J. Exp. Anal. Behav., 4: 327; Psychopharm., 9: 170), there have been numerous demonstrations of tolerance to the behavioral actions of a variety of drugs which is not entirely accounted for by traditional theories of tolerance. The term functional (or behavioral) tolerance has been used to describe mechanisms which, in addition to pharmacokinetic and pharmacodynamic changes, contribute to the development of tolerance. An experiment was designed to determine whether functional mechanisms alone may account for decreases in the initial behavioral effects produced by morphine. Eight rats were trained daily to respond on a two lever, multiple trial, multiple differential-reinforcement-of-low-rate fixed-ratio (mult DRL FR) schedule of food reinforcement. Reliable stimulus control was maintained when sessions were conducted just twice per week. Following saline injections, there was a greater than 7-fold inter-component difference in response rates, but the rates of reinforcement in the two components were not significantly different. The effects of cumulative doses of morphine or chlordiazepoxide were tested once per week; saline injections were given in the intervening sessions. Initially, both morphine (1.0 - 8.0 mg/kg) and chlordiazepoxide (4.0 - 32.0 mg/kg) produced dose-related decreases in response rates and reinforcement rates in both the DRL and FR components. The effects of morphine were similar in the two components; chlordiazepoxide produced greater decreases in FR than in DRL response rates, but similar effects on rates of reinforcement in the two components. The same doses of morphine were then evaluated weekly until it was evident that their initial effects had diminished. As an independent measure of tolerance development via traditional mechanisms, hot plate tests were conducted in the same animals 15 minutes after the initial and final morphine sessions. The selective development of tolerance to the effects of morphine administered once weekly on schedule-controlled behavior, but not, in the same animals, to its antinociceptive effects, would appear to constitute evidence that functional mechanisms alone may be responsible for the development of tolerance to the behavioral effects of morphine. Lack of cross-tolerance to chlordiazepoxide would demonstrate the pharmacological specificity of this effect, and would suggest the interpretation of these data with regard to a state-dependent learning hypothesis or a habituation model of tolerance. Supported by DA 02879 and T32 GM 07337.

374.16 A COMPARISON OF THE RELATIVE POTENCY OF HEROIN AND MORPHINE ON BRAIN-STIMULATION ESCAPE AND REWARD. C.B. Hubner and C. Kornetsky Laboratory of Behavioral Pharmacology, Boston University School of Medicine, Boston, MA 02118.

Previously we reported (Hubner and Kornetsky, Soc. Neurosci. Abst., 10(2):1106, 1984) that heroin (diacetylmorphine) is approximately thirty times more potent than morphine sulfate in lowering the threshold for rewarding brain stimulation. Although reports in the literature suggest that it is only 2-10 times more potent than morphine as an analgesic, we felt it was important to determine the relative analgesic potency of heroin to morphine in our laboratory. In the present study, we compared the analgesic effects of heroin to our previous findings with morphine using a model that makes use of aversive electrical stimulation to the mesencephalic reticular formation (MRF) (Marcus and Kornetsky, Psychopharmacologia, 38:1-13, 1974).

Bipolar stainless steel electrodes aimed at the MRF were stereotaxically implanted in male albino rats (CDF - Charles River Laboratories). Animals were trained to turn a wheel manipulandum to escape from aversive electrical stimulation to this brain site. Determination of the brain-stimulation escape thresholds was accomplished by using a modification of the psychophysical method of limits. The results indicate that heroin, subcutaneously administered, caused a dose-related increase in the threshold, with the minimally effective dose being approximately 0.50 mg/kg. In this paradigm the minimum threshold raising dose of morphine is approximately 5.0 mg/kg. Morphine, unlike heroin, is only slightly more potent in lowering the threshold for rewarding stimulation than in raising the escape threshold. Since the active metabolites of heroin are 6-acetylmorphine and morphine, this increased effect on rewarding brain stimulation suggests a more selective effect of 6-acetylmorphine on those receptors mediating the rewarding rather than the analgesic effects. (Supported in part by NIDA grant DA 02326 and NIDA Research Scientist Award (CK) K05 DA 00099).

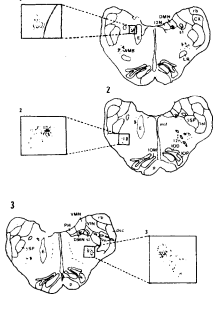
## SLEEP

375.1 CHOLINE ACETYLTRANSFERASE CONTAINING CELLS IN THE BRAINSTEM: RELATIONSHIP TO CARBACHOL MICROINFUSION SITES. P. Shiromani, E. Sutin*, D. A. Armstrong and J. C. Gillin. Department of Psychiatry, UCSD and VA Medical Center, San Diego.

Evidence from brainstem cholinergic infusion studies supports a cholinergic-REM sleep link. Anatomical evidence, however, indicates that in the pontine regions where carbachol readily evokes REM sleep, there are very few muscarinic receptors and even fewer cholinergic cells. In this study we investigated the location of choline acetyltransferase (ChAT) containing cells in relationship to carbachol microinfusion sites.

Two cats were implanted, under Nembutal anesthesia, with sleep recording electrodes and two cannulas in the brainstem. Initially, carbachol (4 ug/0.5 ul Ringers) was infused into each site to determine the REM sleep response. Two weeks after the end of the carbachol test period, one infusion each of GABA (4 ug/0.5 ul Ringers), VIP (100 ng/0.5 ul Ringers) or Ringers (0.5 ul) was made in each site and sleep recordings obtained for at least 6 hours. The order of the infusions were randomized and at least 48 hrs were allowed between infusions.

Compared to Ringers, GABA (n=2) and VIP (n=2) produced a slight decrease in REM sleep (Mean Ringers=20 %; GABA=16%; VIP=14%). The latency to REM sleep was increased considerably (Mean REM latency Ringers=75 mins; GABA=150 mins; VIP=170 min). Carbachol infusions produced either dissociated REM sleep components (see figure legend) or complete REM sleep within 10 mins of infusion (n=2).



Localization of ChAT labeled perikarya (each dot represents one labeled cell) in medulla of one cat. Note relative position of immunolabeled neurons to cannula tract (E). Cholinergic cells are observed in the dorsal motor nucleus of the vagus (insert 1) and nucleus ambiguus (inserts 2 and 3). Carbachol infusion at this site produced increased clusters of PGO waves coupled to nystagmus. This may have occurred as a result of vestibular stimulation. While we did not find any dark staining ChAT neurons in the vestibular nuclei, others have reported high levels of ChAT (Burke and Fahn, Brain Res,328:, 1985) and muscarinic receptors (Wamsley etal, J Neurosci,1:, 1981) in the vestibular complex.

375.2 REM SLEEP AND MUSCARINIC RECEPTOR BINDING IN RATS ARE AUGMENTED DURING WITHDRAWAL FOLLOWING CHRONIC SCOPOLAMINE TREATMENT. E.L. Sutin*, P. Shiromani, J.R. Kelsoe Jr.*, F.I. Storch*, and J.C. Gillin. University of California, San Diego and VA Medical Center, La Jolla, California, 92161

Much evidence suggests that REM sleep is regulated by pontine muscarinic receptors. In cats, rats, and humans cholinomimetics readily evoke REM sleep. In normal humans, a 3-day chronic treatment in the morning with scopolamine decreases the latency to REM sleep during the night. This suggests that chronic scopolamine treatment upregulates muscarinic receptors which might then influence REM sleep. We sought to determine, in rats, whether during withdrawal from chronic scopolamine there is a REM increase correlated with brainstem muscarinic receptor upregulation.

21 male Sprague-Dawley rats (200-550 gm) were implanted with chronic indwelling EEG and EMG sleep recording electrodes. After a recovery week and two adaptation days, two 6 hour baseline sleep recordings were obtained starting at 9 AM. A randomly assigned experimental group received an injection of scopolamine (10 mg/kg, IP) every morning for 7 consecutive days, while the control group received saline injections only. A 6 hour sleep recording was obtained after the first and last injections and on the subsequent two withdrawal days After the second withdrawal day the animals were decapitated, their brains rapidly removed, and several brain areas were grossly dissected and frozen.

Muscarinic receptor binding was determined by incubating crude membrane preparations of the brain areas (1 mg tissue/ml) with 1 nM 3H-QNB for 90 minutes at 37°C in 2 ml Na-K phosphate buffer. Incubation was terminiated by filtration and 3 quick 5 ml washes. Specific binding was defined as the total binding minus binding in the presence of 0.01 mM atropine.

Preliminary data indicate that scopolamine treated animals showed a significant increase in REM sleep during the first (+29%; $t=5.18$; $df=6$; $p<.05$) and second (+40%; $t=4.56$; $df=6$; $p<.05$) withdrawal days compared to baseline. There were no significant changes in total sleep time or non-REM sleep. No changes in REM sleep were observed in the control group.

Scopolamine produced significant increases in binding in the caudate (+32.0%, $t=5.03$, $df=8$, $p<.01$) and hippocampus (+24.6%, $t=3.24$, $df=16$, $p<.01$). There was no significant change in cortex (+7.3%), brainstem (+1.0%) or cerebellum (+19.8%). Subsequent scatchard analysis revealed an increase in Bmax and not Kd.

These preliminary findings indicate that there is a significant REM augmentation during withdrawal from scopolamine. Contrary to our prediction, there was no increased binding of muscarinic receptors in the brainstem, an area which is implicated in REM generation. Possible explanations for this are discussed.

375.3 EXOGENOUS AMINOACIDS, SLEEP SPINDLES AND DREAMS. J. GARCIA-RAMOS Dept. of Physiology, Biophysics and Neurosciences. Centro de Investigación y de Estudios Avanzados del I.P.N. México 14, D.F. MEXICO.

Considering a possible role of aminoacids in the production of dreams, several aminoacids were topically applied over the exposed cortex of barbiturate anesthetized cats. It was found that most of them, putative excitatory or inhibitory, favored the production of sleep spindles although reducing the surface negative waves. Looking for the possible mechanisms involved, observations were made on isolated islands of the same cerebral cortex and on the terrapin turtle cortex. The results showed that all the aminoacids tested depress the surface negative component of the direct cortical responses, the evoked potentials and particularly that of the strychnine spikes. At the same time they facilitate the appearance of oscillatory responses. Since the cortical excitability did not seem to be increased some other change was thought to be implicated. The possibility of a functional opening of low-resistance junctions is suggested by the light increase in the electrical impedance of the tissue after the local application of the aminoacid. The magnitude of the effects were greater for glycine, followed by GABA, alanine, glutamate and aspartate. The present results showed that in order to initiate an oscillatory response it is necessary the presence of a synchronous activation of a relatively large group of dendrites and it is postulated that by electrical coupling another dendritic cluster would be later activated via low resistance junctions and this in turn would activate the first one by the same route to establish a circus movement. The cortical oscillations would trigger the pyramidal neurons which would start the activation of the neural circuits involved in the imagery of dreams.

375.4 SLEEP STRUCTURE AND ITS PARAMETERS IN RELATION TO PARADOXICAL SLEEP DEPRIVATION AND PENICILLIN INDUCED PETIT MAL-LIKE EPILEPSY IN CATS. S. Janković*, R. Veskov*, V. Šušić* and J. Ivanuš*, Inst. for Biological Res., Beograd, 29. Novembra 142, Yugoslavia (SPON: European Neuroscience Association)

Five adult male cats were implanted under Nembutal anesthesia with cortical and subcortical electrodes and prepared for polygraphic recording of sleep. We examined the effects of intramuscular Crystalline Penicillin (P) injections on the parameters of sleep and sleep structure prior to and after the 72 hours of paradoxical sleep (PS) deprivation (SD) as well as the influence of different phases of wakefulness-sleep cycle on P generalized petit mal-like epileptiform discharges.

P prolongs the duration of total sleep time (TST) while SD prolongs it even more. P and SD together render TST shortened. P prolongs the duration of slow wave sleep (SWS) while SD shortens this effect. The number of changes of sleep phases after P administration is significantly higher (leading to a frequently interrupted sleep pattern) as compared to control and postdeprivation sleep. SD antagonize this P effect. SD increases the frequency of PS phases while P, alone or with SD, has no significant effect. In any of these situations mean duration of PS phases is not substantially affected. SD shortens the latency of PS onset while P, either alone or with SD, has no significant effect.

Wakefulness after sleep onset (WASO) is shortened after P but not significantly. SD significantly shortens WASO as compared to control and P. P with SD render WASO prolonged in respect to the effect of SD alone. Thus P, having no effect by itself, partly antagonize the shortening effect of SD. Total number of awakenings (TNAw) is significantly higher after P and lower after SD, as compared to control. After simultaneous application of P and SD, TNAw is significantly decreased in respect to the effects of P. It follows that the SD effect oppose the intensity of P effect.

Since P and SD have the influence on sleep in the same direction when they act separately and when applied at the same time they counteract each other we are postulating that P and SD interaction is antagonistic.

P induced epileptiform discharges are more frequent and characteristically modified during SWS as compared to discharges during awake (Aw) and PS. Correlation of brain epileptiform activity and periferal, muscle, component during SWS approaches zero, while during Aw equals one. During PS the discharges are significantly reduced; when they appear they are much alike the discharges during Aw, but they differ in having no electromyographic correlates.

375.5 PINEALECTOMY INCREASES REM SLEEP DURING THE EARLY LIGHT PHASE OF THE DIURNAL CYCLE OF RATS. J. V. Martin,* R. J. Salin-Pascual,* L. Tamarkin* and W. B. Mendelson* (SPON: P. Skolnick). National Institute of Mental Health, 9000 Rockville Pike, Bethesda, Maryland 20205, USA

In order to clarify the role of the pineal gland in the regulation of sleep, the effects of pinealectomy and injection of melatonin on electroencephalographic (EEG) sleep stages were studied in 300-350 g male rats.

One group of rats was pinealectomized 30 days prior to implantation of cortical and electromyographic electrodes. A second group of rats was simply implanted with the electrodes. All animals were then allowed to recover for two additional weeks before testing. During the first week of testing, each animal was injected either with 250 μg/kg of melatonin or vehicle at 10:00 AM and the EEG was recorded for two hours. A second two hours of EEG was recorded beginning at 2:30 PM that afternoon. In the second week of the experiment, the animals were given the drug treatment not received the first week and the EEG was recorded as before.

No significant effects on sleep latency or duration were observed in this study. However, analysis of variance showed a highly significant effect of pinealectomy ($p<0.0001$) on total time in REM sleep during the two-hour test period.

Minutes of REM Sleep During 2-Hour Recording

| | Pinealectomized | Control |
|---|---|---|
| AM | | |
| Melatonin | 13.0±2.3 | 3.2±1.0 |
| Vehicle | 16.2±2.5 | 2.2±0.6 |
| PM | | |
| Melatonin | 12.8±2.8 | 5.4±0.6 |
| Vehicle | 7.1±1.2 | 7.1±1.5 |

In the morning REM sleep time in pinealectomized rats injected with vehicle was increased approximately seven-fold over that of intact control rats. During the afternoon intact control rats showed a significant increase in amounts of REM sleep and pinealectomized vehicle-injected rats showed a significant reduction in REM sleep as compared to in the morning (Least Significant Difference Post Hoc Tests; $p<0.05$). These findings need not imply that the effect of pinealectomy is simply an advance of the sleep phase, since amounts of REM sleep in the afternoon were the same in vehicle-injected pinealectomized rats and in intact controls. Further, pinealectomized rats injected with melatonin did not show a significant change in REM sleep with time of day. These data appear to implicate the pineal gland as a possible modulator of REM sleep.

375.6 RELATIONSHIP BETWEEN SLEEP PATTERNS AND HYPOTHALAMIC TEMPERATURE CHANGES DURING NORMAL AND BY CHRONIC BARBITURATE TREATMENT. M. Okamoto and V. Adamson. Dept. of Pharmacology, Cornell University Medical College, New York, NY 10021

An abrupt withdrawal from chronic barbiturate treatment often produces insomnia. Duration of insomnia is dependent on intensity of the drug treatment. Hypothalamic thermoregulatory structure has been reported to be intimately involved in the regulation of normal sleep processes. Accordingly, sleep-wake cycles and hypothalamic temperature were continuously monitored in freely moving animals during the control and the barbiturate withdrawal periods through chronically implanted electrodes. Body core temperature was also monitored in order to establish relationship with hypothalamic temperature. During the control period (4 days), 94% of REM sleep incidence was associated with an increase in hypothalamic temperature (Av. +0.207°C) while 69% of SW sleep was associated with a decrease (Av. -0.134°C). Onset of these temperature changes preceded the onset of each comparable sleep stage. Furthermore these hypothalamic temperature fluctuations were less than that of body core temperature. Chronic barbiturate treatment (1 x day, 4 weeks, Na pentobarbital, intragastrically) while the drug was on board, suppressed these temperature fluctuations and also mean hypothalamic temperature. During the withdrawal and during the insomnic period, the fluctuations in temperature were continuously dumped; the degree of rise in hypothalamic temperature was dependent on the intensity of withdrawal. (Supported by the grant DA-00591 from NIDA.)

375.7 THE MORPHOLOGY AND TOPOGRAPHY OF SCALP POTENTIALS RELATED TO PHASIC MEMA IN HUMAN REM SLEEP. M.Fazen*, G.Gerken*, P.Hilton*, D.Slegel*, and H.Roffwarg. Dept. of Psychiatry, Univ. of Texas Health Science Center, Dallas, TX 75235.

We investigated the morphology and scalp distribution of a unique EEG potential that is time-locked to phasic middle ear muscle activity (MEMA) in REM sleep. EEG was recorded at Fz, Cz, Pz, Oz, C5, C6, T3, and T4 in 5 subjects for 3 nights. Bilateral MEMA, EOG, and facial and laryngeal EMG were also recorded. The computer-identified onset of episodic MEMA functioned as a triggering signal ("time-zero") for collection of an EEG epoch about the MEMA trigger ( $\pm$ 750 msec.). Following data acquisition, an averaging program computed the mean, the +/- reference, and a random average for each recording site.

RESULTS: In all 5 subjects, we found an event-related potential (ERP) that begins prior to the initiation of MEMA. It has at least 3 distinct components: a small positive wave, 65-100 msec. before MEMA onset; a prominent negative wave that peaks at or near time-zero; and a large positive component, which reaches its maximum within 260 msec. after MEMA onset. The ERP is stable and synchronous across the 8 recording sites. It is maximal at Cz, and decreases with increasing distance from the vertex. Additionally, an asymmetric increase in positivity on the right side of the skull was noted in the 250 msec. preceding the ERP. The ERP was not observed in either the +/- reference or the random average, both of which emphasize the character of background EEG activity.

The characteristic atonia of the head and neck muscles in REM sleep, the minuteness of the middle ear muscles, the small size of the temporal lobe area ERP, and the fact that the ERP precedes the initiation of MEMA, render it unlikely that this time-locked potential originates in the middle ear muscles. Nor is it likely that EOG contributes artifact to the ERP, since EEG epochs were averaged together without regard to direction of any concurrent saccades. It is possible that brain activity related to eye movements may influence MEMA-related EEG activity, though the ERP scalp distribution suggests otherwise. Also, when only eye movement-free epochs of EEG were averaged, a similar ERP was observed. Though its generating sources cannot be specifically determined from our data, enough similarities exist between the ERP and the auditory evoked potential to suggest that the ERP is cortical rather than sub-cortical in origin and is probably generated in or near the primary auditory projection cortex. Our data, combined with a growing body of work from animal research on the neural pathways transmitting central phasic discharges in REM sleep, allow continuing consideration that the MEMA-related scalp potential reflects, at least in part, an afferent input to the upper brain.

375.8 INTERFERON ALPHA-2 ENHANCES SLOW-WAVE SLEEP IN RABBITS. J.M. Krueger, J. Walter, D. Davenne, S. Shoham and C.A. Dinarello*. The Chicago Med. Sch., North Chicago, IL 60064 and *Tufts Univ. Sch. of Med., Boston, MA 02111

Subjective feelings of sleepiness often occur during the course of infectious disease. The immune response to infectious agents includes increased synthesis and release of interleukin-1 (IL1) and interferon (IFN); both are endogenous pyrogens (1). Prevously we showed that IL1 induces excess slow-wave sleep (SWS) independently from fever induction (2). IFN induces subjective drowsiness in human patients (3) but its effects on SWS are unknown. We now report that IFN induces excess SWS in rabbits. Rabbits were implanted with EEG electrodes, ventricular guide tubes and brain thermistors (2). IFN was human recombinant and provided by Shering Inc.; it contained less that 50 pgm endotoxin per $10^7$ units IFN. IFN was administered either into a lateral cerebral ventricle (ICV) or by intravenous (IV) injection. EEG was recorded for 6 hr after ICV and 5 hr after IV administration of IFN. ICV infusion of $0.2x10^6$ units of IFN failed to affect duration of SWS or body temperature (Table). Significant increases in duration of SWS and body temperatures were observed following ICV infusion of $1-2x10^6$ IFN units and after IV injection of $15x10^6$ units. IFN-induced excess SWS appeared normal in the sense that sleep remained episodic and abnormal behavior was not observed. Pretreatment of IFN with polymyxin B failed to alter IFN-induced sleep responses thus suggesting that responses were not the result of contaminating endotoxin. It is also unlikely that excess SWS was caused by IFN- induced fever; IL1-induced fever and sleep responses could be separated (2) and other substances can induce fever without increasing sleep (4). That IFN and IL1 can modulate sleep may indicate that sleep plays an important role in recuperative processes whether it is recovery from a day's activity or from disease states.

INTRAVENTRICULAR INFUSION

375.9 RELATIVE CONTRIBUTIONS OF RESPIRATORY AND CARDIAC RATE AND VARIABILITY MEASURES TO MACHINE DETERMINATION OF SLEEP STATE IN INFANTS. R.M. Harper, Z. Frostig*, T. Hoppenbrouwers*, R.C. Frysinger. Brain Research Institute and Department of Anatomy, UCLA, Los Angeles, CA 90024.

Determination of sleep state in developing infants typically requires human assessment of EEG, eye movement, and body movement criteria. We have previously described utilization of machine-determined cardiac and respiratory measures that classify sleep states with an agreement with human observers that approximates interobserver repeatability.

We have extended these procedures to incorporate additional features of respiratory and cardiac rate variability. These additional features incorporate assessment of frequency and amplitude characteristics of low-frequency variation in heart rate, together with determination of higher-frequency, respiratory-related variation in cardiac R-R intervals.

Twenty-five neurologically normal infants were polygraphically recorded for a 12-hour period (1900-0700 hours) at 1 week and at 1, 2, 3, 4, and 6 months of age. EEG, eye movement, facial muscle, body movement, respiratory, and ECG measures were obtained, and minute-by-minute sleep classifications for all 25 infants were determined from polygraphic tracings by observers trained to a worst-case accuracy of 80% agreement. Twelve infants were used to derive cardiac and respiratory parameters for testing of 13 remaining infants using discriminant analysis (BMDP7M). The minute-by-minute measures included heart and respiratory rate and variability, together with determination of amplitude of respiratory-related variation of cardiac R-R intervals, and amplitude and frequency of long-term variation in R-R intervals. State classifications were made into waking (AW), quiet sleep (QS), and active sleep (REM) only.

A subset of parameters was found useful for state classification across all ages. Additional parameters were useful for classifying state at particular ages. The hierarchy of parameters useful for classification was respiratory variability, followed by heart rate, heart rate variability, respiratory rate, amplitude of respiratory-related variation of R-R intervals, and amplitude of low-frequency R-R intervals. The order of most frequently correctly classified was QS, REM, and AW.

We conclude that machine assessment of periodic motor activity, such as respiration, combined with assessment of autonomic measures, such as heart rate variability, can provide adequate indicators for state classification in normal infants. Variability in these parameters plays a major role in machine decision-making.

375.10 THE DECREASE OF REM SLEEP BY ATROPINE IS REVERSED BY AUDITORY STIMULATION. G. Arankowsky, R. Aguilar-Roblero*, O. Prospéro* and R. Drucker-Colín. (Spon: Rocío Salceda) Departamento de Fisiología, Centro de Investigaciones en Fisiología Celular, UNAM, México 04510, D.F.

In previous work (Drucker-Colín et. al., Brain Res. 278:308-312, 1983), it was shown that an auditory stimulus given before the appearance of Rapid Eye Movement sleep (REM) increases the duration of this period. On the other hand some pilot experiments suggested that Atropine decreases REM sleep duration.

The present study attempts to determine whether the auditory stimulus is capable of protecting the animal from the effects of atropine on REM sleep.

A group of cats were implanted under pentobarbital anesthesia with electrodes for conventional polysomnographic recording. The cats were divided in four groups, receiving different treatment: Group 1 received 0.2 mg/kg of Atropine I.M., Group 2 was acoustically stimulated during the REM period. Group 3 received both treatments. Group 4 was used as a control.

The sleep-waking cycle of the animals was recorded during an eight hour period. When appropriate according to group 2, a 2 kHz 90 dB auditory stimulus in the form of a beep of 20 ms duration was applied every 20 ms just prior to a REM sleep period and throughout its duration.

The results of these experiments showed that atropine reduced the duration of REM sleep from 7.0 $\pm$ 3.3 to 4.3 $\pm$ 2.2 ($p<.05$). On the other hand the auditory stimulus protected the animals from the effects of atropine, since the mean duration of REM sleep in atropine pre-treated animals given the auditory stimulus was 7.3 $\pm$ 3.8, as compared to 7.0 $\pm$ 3.3 for untreated controls. In addition, the auditory stimulation (Group 2) had a mean duration of 10.0 $\pm$ 3.4, which was significantly different ($p<.01$) from Group 4 duration which was 7.0 $\pm$ 3.3, thus confirming the previously reported increase of REM due to acoustic stimulation. Since both atropine and auditory stimulation have been suggested to impinge upon PGO spike density it is possible that the changes in REM duration are the result of changes in PGO density.

375.11 A COMPARISON OF TWENTY-FOUR HOUR SLEEP RECORDINGS IN GENETICALLY NARCOLEPTIC AND CONTROL DOGS. K.I. Kaitin, T.S. Kilduff and W.C. Dement. Sleep Research Center, Stanford Univ. Medical Center, Stanford, CA 94305.

Two previous studies (1,2) done in this laboratory reported no significant differences in total amounts of wakefulness (W) and slow-wave sleep (SWS) between small-breed narcoleptic dogs and control dogs. It had been our impression from behavioral observation, however, that large-breed, genetically narcoleptic dogs in our colony appeared excessively sleepy. Because excessive daytime sleepiness is a consistent and debilitating symptom of human narcolepsy, we examined whether genetically narcoleptic dogs in fact show evidence of excessive sleepiness.

Three genetically narcoleptic and three control dogs from each of two affected breeds (Labrador retrievers and Doberman pinschers) whelped and reared in our animal breeding facility, were surgically implanted at seven weeks of age with electrodes for recording standard sleep parameters. Dogs were adapted to a 12 hour light/dark cycle and to the recording chamber prior to the first recording which occurred two weeks after surgery. Two continuous 24 hour recordings were made from each animal one week apart. Polygraph records were scored in 30-sec epochs for W, drowsy (D), light sleep (S1), deep SWS (S2), REM sleep (R), and cataplexy (C). Statistical comparisons between narcoleptics and controls of the same breed were made with a two-tailed t-test.

Genetically narcoleptic dogs showed significantly less W than controls of the same breed (27% vs 41% and 26% vs 32% for Labradors and Dobermans, respectively). Moreover, there was an increase in D in the narcoleptic dogs that was statistically significant in the Labrador group (7% vs. 5%). Narcoleptic dogs displayed greater amounts of S2 than controls (18% vs 14% and 20% vs 17% for Labradors and Dobermans, respectively), but S1 was less in the narcoleptic Dobermans (25%) than controls (28%). Although amounts of R were generally less in the narcoleptic dogs, R and C together were significantly greater than R alone in the controls (26% vs 15% and 23% vs 17% for Labradors and Dobermans, respectively).

The results indicate that, whereas genetically narcoleptic dogs show less W than controls, they are not hypersomnolent. However, the high levels of D in the affected Labradors suggest that they are "sleepier" than controls and may be a useful animal model for studying excessive sleepiness.

375.12 NEUROLEPTIC WITHDRAWAL INDUCED CHANGES IN SLEEP EEG, PROLACTIN AND OTHER CLINICAL PARAMETERS, G. Thaker*, A. Wagman, C. Tamminga, Maryland Psychiatric Research Center, University of Maryland, Baltimore, Maryland 21228

Chronic neuroleptic treatment induces a variety of neuronal changes in brain dopamine (DA) systems which manifest themselves clinically as withdrawal or tardive phenomenona. In order to evaluate the effect of chronic neuroleptic treatment on central dopaminergic systems, the biologic sequelae of antipsychotic drug withdrawal are being studied. Preliminary results are reported here. Seven schizophrenic inpatients, (four with tardive dyskinesia, three without) each treated for at least 4 weeks with haloperidol (40 mg/day) or RO221319, a $D_2$ antagonist (120 mg/day) participated in the study. Four patients also received benztropin (up to 4 mg/ day) for parkinsonian side-effects. Sleep studies were initiated while the patients were on neuroleptics and were continued for seven more days following abrupt drug withdrawal. No medication changes were made during the final week of treatment; in patients already receiving benztropin, it was continued through the seven neuroleptic withdrawal nights. Subsequently, patients were kept drug free for at least four weeks and another set of sleep EEG recordings were obtained. In some patients, twice weekly psychosis and tardive dyskinesia (TD) ratings were obtained; also, hormonal (prolactin and growth hormone) measurements were carried out during chronic antipsychotic drug treatment, first week of withdrawal and at the end of 4-week drug-free period.

Results: A consistent REM suppression was observed in all patients during the first week of drug withdrawal. This effect was short lasting (2-4 days) and occurred on different withdrawal nights in each patient. A peak withdrawal night was determined in each patient when there was maximum change in REM sleep; the mean of 3 consecutive nights, including the night of peak withdrawal effect and nights preceding and following was used in calculations. REM sleep in minutes was significantly decreased during peak withdrawal period (46 $\pm$ 22 min.) when compared to both chronic treatment (85 $\pm$ 17 min.) and 4-week drug-free (79 $\pm$ 15 minutes) periods (Freidman's test, =11.1, df=2, p=0.0038 and post hoc Wilcoxin signed rank test p 0.02) Patients with tardive dyskinesia had a more marked response to neuroleptic withdrawal in that their mean REM reduction was 59 $\pm$ 21% compared to 34 $\pm$ 15% in non-TD patients. In the whole group total sleep and NREM time remained unchanged. Neuroleptic withdrawal effect on other clinical and hormonal parameters will also be discussed. We propose that sleep EEG may provide a sensitive measure of post-neuroleptic DA-receptor hypersensitivity in man.

375.13 EFFECT OF A SEROTONIN AGONIST AND A SEROTONIN REUPTAKE INHIBITOR ON SLEEP IN NORMAL AND REM-DEPRIVED RATS. Ross H. Pastel and John D. Fernstrom. Department of Psychiatry and the Center for Neuroscience, University of Pittsburgh, Pittsburgh, PA 15213.

Serotonin neurons are thought to be involved in the mechanisms which control REM sleep. Previous experiments in our laboratory have shown that fluoxetine, a selective serotonin reuptake inhibitor, has a selective suppressive effect on REM sleep in rats while having no significant effect on non-REM (NREM) sleep. The selective REM effect is seen in the dose range 0.94-2.5 mg/kg. At higher doses, fluoxetine also increases sleep latency. In the present set of experiments, we compared the effects of fluoxetine with those of trifluoromethylphenylpiperazine (TFMPP). TFMPP is a selective serotonin agonist which does not induce the serotonin motor syndrome [Lucki I, Frazer A. Soc Neurosci Abstr 8:101, 1982]. To test their potency in suppressing REM, each drug was studied under two conditions: administration at the normal onset of the daily light period, and after a three hour period of REM deprivation. Rats were REM deprived by tapping on their cages whenever the EEG showed signs of REM sleep. Each rat served as his own control, receiving i.p. saline and either fluoxetine (2.5 mg/kg) or TFMPP (2.5 mg/kg).

Both drugs had strong REM suppressive effects. TFMPP suppressed REM for over 4 hours when administered at lights on or after REM deprivation. When given at lights on, fluoxetine suppressed REM sleep for three hours. The REM suppressive effect was shorter when fluoxetine was administered after REM deprivation, the effect lasting approximately two hours. In comparing the REM suppressive effects of TFMPP versus the effects of fluoxetine, TFMPP had a longer time course of action and a more complete suppression of REM. Neither drug induced an abnormal EEG at any time. NREM sleep was not significantly different after injection of either drug at lights on. When administered after REM deprivation, fluoxetine again had no effect on NREM sleep, while TFMPP increased wakefulness in the first hour after injection.

Fluoxetine and TFMPP each enhance serotonin transmission, although by different mechanisms, and each drug suppresses REM. This fact suggests that the effects seen on REM are due to the action of these drugs on serotonin neurons. Since fluoxetine was less effective when administered after REM deprivation than at light onset, the findings also suggest that serotonin neurons may be less active when a strong REM pressure is present. The results thus provide additional support for the hypothesis that serotonin neurons are involved in the mechanisms of REM sleep.

375.14 CHARACTERIZATION OF CARDIAC BEAT-TO-BEAT PERIODICITIES WITHIN SLEEP-WAKING STATES UTILIZING TIME DOMAIN PROCEDURES. Z. Frostig*, R.D. Frostig, and R.M. Harper (SPON: H. Lesse). Brain Research Institute and Department of Anatomy, UCLA, Los Angeles, CA 90024.

Plots of successive cardiac beat-to-beat intervals against time demonstrate at least two prominent periodicities: a high-frequency variation with a period related to respiratory activity (sinus arrhythmia), and low-frequency variation with a period of 10 seconds or more. Amplitude and frequency characteristics of both high- and low-frequency variation provide useful indices of hemodynamic and respiratory action, and may be useful in sleep-state assessment, particularly in infants.

The classic manner of describing these variability changes has been spectral analysis calculated after Fourier transforms. However, frequency domain procedures that average over relatively long time periods are extremely sensitive to occasional artifacts, such as missed beats or very short intervals resulting from double triggering of the cardiac R wave. This study utilized a robust analytical method to characterize periodic variation in R-R data.

"Peaks" and "troughs" in the R-R interval plots are noted when successive R-R interval differences become negative or positive. These points describe high-frequency aspects of the R-R curve. Values for low-frequency variations are derivatives of changes in the high-frequency values. Thus, low-frequency peaks are defined as peaks of the curve formed by high-frequency peaks, and its troughs as the troughs formed by the curve of high-frequency troughs. Relative rise times are used to discriminate aberrant points, which result from artifacts. Median values, being a robust measure relative to the mean, are used to characterize periodicity within each minute, and the following parameters are typically measured: amplitude, period in time, and period in number of intervals for high-frequency changes, and corresponding characteristics of the low-frequency periodicity.

The procedure has been successfully applied to studies quantifying high- and low-frequency variation in heart rate over the first 6 months of life (Schechtman et al., Soc. Neurosci. Abs., 1985) and for infant sleep-state classification using cardiac rate variation as state classification parameters (Harper et al., Soc. Neurosci. Abs., 1985). ANOVA assessment on cardiac rate variation, for example, demonstrates that all parameters listed above can be used to discriminate infant sleep-waking states. Relative to spectral procedures, a much larger data sample is available for analysis using this procedure, since errors introduced by artifacts are very much reduced.

375.15 THE EFFECTS OF PARADOXICAL SLEEP DEPRIVATION ON EEG POWER DENSITY IN THE RABBIT. R.T. Pivik, F.W. Bylsma* and P. Cooper*. Lab. of Neurophysiology, University of Ottawa, Ottawa, Ontario K1H 8L6

It has been suggested that the pervasive increase in low frequency EEG power density across all sleep stages following total sleep deprivation in man reflects the presence of a unitary sleep-intensity process (Borbely et al., Electroencephalogr. Clin. Neurophysiol., 5:483, 1981). The present investigation was conducted to determine if similar effects would be present following selective deprivation of paradoxical sleep (PS) in the rabbit.

Standard EEG (postcentral cortex), EOG and nuchal EMG activity were continuously monitored for 5 consecutive days (2 days baseline, 1 day PS deprivation, 2 days recovery) in adult New Zealand White male rabbits (n=5). Animals were maintained on 12 hour light-dark cycles with food and water continuously available. PS deprivation was effected by auditory stimuli (900-1000 Hz, 84-87 db tone bursts) delivered at PS onset via speakers mounted in the recording chamber. One minute tape-recorded samples of postcentral EEG activity were digitized (200 samples/sec) and power density was determined for the following frequency bands: 0-2, 2.1-8, 8.1-12, 12.1-15, 15.1-20 and 20.1-50 Hz during wakefulness (W), drowsy (D), slow wave (SW) sleep, and PS. Data were statistically analyzed using analysis of variance procedures with post hoc tests when appropriate.

PS time was significantly reduced during deprivation ($p<.01$) and significantly enhanced (rebound, $p<.05$) during recovery relative to baseline values. Neither total sleep time nor total amount of slow wave sleep was significantly affected by the deprivation procedure.

Post-deprivation recordings did not differ from baseline values in total power. Furthermore, no frequency band showed consistent power density changes either across sleep-wakefulness states or across sleep stages only. However, significant post-deprivation power variations did occur within conditions and included: increased high frequency beta (20.1-50 Hz) during W, $p<.07$; decreased beta (15.1-20 Hz) during D, $p<.02$; increased theta (2.1-8 Hz) and sigma (8.1-12 Hz) during PS, $p<.01$ and $p<.09$, respectively; and, decreased high frequency beta ($p<.02$) during PS.

The absence of significant increases in power density in delta activity (0-2 Hz) and the concentration of effects in PS following PS deprivation (a) suggest that selective sleep deprivation has relatively selective state EEG power density effects; and, (b) do not support the notion of a unitary sleep process indexed by low frequency activity.

## DEVELOPMENT AND PLASTICITY: MOTOR SYSTEMS

376.1 THE DEVELOPMENT OF RUBROSPINAL PROJECTIONS IN THE NORTH AMERICAN OPOSSUM. T. Cabana* and G.F. Martin (SPON: R.H. Ho). Dept. of Anatomy, The Ohio State University, Columbus, Ohio 43210.

In experiments using retrograde tracing techniques, we defined a developmental sequence as to the origin of descending projections to the spinal cord of the opossum (Cabana and Martin, Devel. Brain Res., 15 (1984) 247-263). Axons from the vestibular nuclei, reticular formation raphe and coeruleus complex reach the cord very early in development; those from other brainstem areas, such as the red nucleus, reach the cord somewhat later, and those from the cerebral cortex reach the cord last. With orthograde tracing, we were then able to describe a sequential innervation of the spinal cord by cortical axons (Cabana and Martin, Soc. Neurosc. Abst., 10 (1984) 321). We are now seeking to describe the intraspinal growth of rubral axons in developing opossums.

Horseradish peroxidase conjugated to wheat germ agglutinin was injected into the red nucleus of 26 pouch young opossums, Didelphis virginiana, and in areas surrounding the red nucleus or in the subarachnoid space of 45 control pups. By postnatal day (PD) 7, a few labeled rubral axons were present in the external part of the contralateral dorsolateral funiculus at all spinal levels. Injections in younger pups labeled rubral axons at the medullo-spinal junction, but not in the cord. We interpret the latter data with caution, however, since injections in the younger animals included only a small rostral portion of the red nucleus. At PD 7, rubral axons did not enter the gray matter except, maybe, at rostral cervical levels. By estimated PD (EPD) 15, the rubrospinal tract was more densely labeled at all spinal levels. Rubral axons arborized in the lateral half of laminae V-VII at upper cervical levels, began to penetrate lamina VI at the cervical and lumbosacral enlargements, but only approached, without entering, the gray matter at thoracic levels. At EPD 17, rubral axons at upper cervical levels were present throughout the lateromedial extent of laminae V-VI, although denser laterally, and in laminae IV and VII. They were restricted mainly to the lateral border of lamina VI at the enlargements and the lateral border of lamina V at thoracic levels. By EPD 25, rubral axons were more densely labeled in laminae IV-VII at all spinal levels and were seen for the first time in lamina III at cervical and lumbosacral levels

These observations suggest that: 1) rubral axons do not innervate the gray matter of a given segment until some time after they have reached that segment, 2) rubral innervation of the spinal gray does not follow an absolute rostral-to-caudal gradient, 3) innervation of each segment occurs in a similar sequence and 4) rubral innervation of the cord is completed prior to cortical innervation of either the cord or the red nucleus (Cabana and Martin, Am. Assoc. Anat. Abst., 1985). Supported by BNS-8309245 and NS-10165.

376.2 MAINTENANCE OF TRANSIENT OCCIPITOSPINAL AXONS IN THE RAT. M.A. Sharkey, R.D. Lund, R.M. Dom*. Department of Anatomy, Medical University of South Carolina, Charleston, SC.

Early in development the pyramidal tract originates from the entire extent of cortical Layer V including the occipital cortex (Stanfield et al., Nature, 298:371-373, 1982). These occipital corticospinal fibers disappear during the first three postnatal weeks, but the cells of origin persist and have been shown to sustain projections to the pons and/or superior colliculus (Stanfield et al., Neurosci., 9:375, 1983).

In this study, embryonic day 15 tectum was transplanted into the pyramidal tract of the cervical spinal cord in newborn Long Evans hooded rats. The tectal transplants were prepared and maintained in a sterile dish containing Ham's F10 culture medium. The newborn rats were anesthetized by cooling with ice. Then superficial layers of the superior colliculi were extirpated, a laminectomy performed on cervical vertebrae 2 and 3, the dura opened longitudinally, and the pia reflected prior to creating a small midline cavity in the dorsal columns. Following this, the fetal tectal tissue was transplanted into this midline cavity, the vertebral bodies reapproximated, and the muscle and fat layers repositioned and sutured. As controls, fourteen newborn rats received superficial tectal ablations without transplants. This control group was allowed to survive for a time period identical to that of the experimental animals that received transplants.

Four to five weeks after transplantation, the animals were anesthetized with tribromoethanol, reopened as above, and the transplant visualized. Using a pipette secured to a Hamilton syringe, horseradish peroxidase, HRP (0.2-0.4 $\mu$l), was injected into either the transplant and surrounding cervical cord or into the corticospinal tract at the C2-C3 level of the spinal cord in the control group; forty-eight hours later the animals were perfused transcardially with phosphate-buffered solutions of 0.5% glutaraldehyde followed by 0.2% glutaraldehyde. The brains and cervical spinal cord were removed, frozen sectioned at 40 $\mu$m, and alternate sections processed with the chromagens diaminobenzidine tetrahydrochloride and tetramethylbenzidine.

HRP labelled cells were demonstrated in visual association areas 18a and 18b at four to five weeks postnatally in the animals receiving tectal transplants. The control animals which received HRP injections into the spinal cord at cervical levels showed no HRP positive cells in the occipital cortex. Thus, the aberrantly placed tectum influences the survival of occipitospinal axons which are normally eliminated during the third week of postnatal life.

376.3 ANALYSIS OF CORTICOSPINAL PLASTICITY USING RETROGRADE FLUORESCENT TRACERS IN RATS. B.S. Reinoso* and A.J. Castro (SPON: T. Khan), Dept. of Anat., Loyola Univ. Stritch Sch. of Med., Maywood, IL 60153.

The rodent corticospinal tract (CST) is predominantly a crossed pathway. However, after unilateral cortical lesions in neonatal rats, a marked increase in ipsilateral CST fibers, originating from the unablated cortex, has been reported. The present study was undertaken to determine whether these fibers represent axonal collaterals of normal crossed projections or whether they arise from a separate population of cortical neurons.

Large lesions of the right cerebral hemisphere of 1-2 day old Long Evans rats (n=9) were made by aspiration. Control animals (n=4) did not receive lesions. At 2-8 months and using sodium pentobarbital anesthesia, laminectomy of 1-2 vertebrae at cervical enlargement levels was performed. Spinal columns were secured with a vertebral clamp and five 0.01 ul injections of 2% fast blue and 0.06 ul of 2% diamidino yellow were spaced 1-2 mm apart rostral caudally and 1 mm deep on the left and right (or vice-versa) side of the spinal cord. After 6 days animals were transcardially perfused with 10% buffered formalin. Fifty um horizontal sections through the cervical enlargement and 40 um sagittal sections through the brain were cut frozen, mounted from water and viewed using an epifluorescent Leitz microscope.

Histological analysis indicated that injection sites in 10 animals were restricted to one side of the cord. The presence of only FB or DY labeled neurons within either of the red nuclei further verified the placement of spinal cord injections. In control animals, numerous FB and DY single-labeled neurons were found predominately contralateral to injections. No doubled labeled cells were found in these animals. In experimental animals, numerous FB and DY singled labeled neurons were found within the unablated hemisphere; no double-labeled cells were found.

The absence of double-labeled cells in the unablated cortex of animals that sustained unilateral cortical lesions indicates that anomalous ipsilateral CST fibers are primarily not collaterals of normal crossed CST fibers. Accordingly, the ipsilateral CST fibers described after neonatal cortical lesions may represent (1) normal fibers that failed to decussate, (2) the development of fibers from neurons that normally do not project to the spinal cord or (3) the abnormal persistence of developmentally transient fibers. (Supported by NIH Grant NS 13230.)

376.4 CORTICALLY-EVOKED HINDLIMB MOVEMENTS IN RATS THAT SUSTAINED NEONATAL SPINAL CORD LESIONS. M.F. Dauzvardis*, G. Kartje-Tillotson and A.J. Castro. Dept. of Anat., Loyola Univ. Stritch Sch. of Med., Maywood, IL 60153.

Corticospinal fibers have previously been reported to grow around partial spinal cord lesions made in neonatal animals (Schreyer and Jones, Neurosci. 9:31, 1983; Bregman and Goldberger, Develop. Brain Res. 9:137, 1983). In view of these findings, the present study examined limb movements evoked by intracortical microstimulation in adult animals that sustained partial mid-thoracic spinal cord lesions at birth or at maturity. Using a sharpened no. 11 scalpel blade, lesions intending to transect the dorsal funiculus, and therefore the path of the corticospinal tract, were made in hypothermic-anesthetized 1-2 day old rats (n=4) and adult rats (n=6) anesthetized with sodium pentobarbital (40mg/kg). Animals without neonatal (n=4) or adult (n=4) lesions served as controls.

Thirty days postoperatively and using Ketamine anesthesia (100mg/kg), intracortical microstimulation (0.25 msec pulses; 350 hz, 300 msec trains, at 5-100 uamps) was applied at a depth of 1.7mm in the forelimb (FL) and hindlimb (HL) motor areas of the right cortex of each amimal. Mean threshold values (i.e., the minimal current needed to evoke movements) for contralateral FL and HL movements in control animals equaled 12 and 25 uamps, respectively. Mean threshold values for FL movements in animals that sustained adult or neonatal spinal cord lesions approximated control values whereas HL movements could not be evoked at current intensities under 100uamps in the adult lesion group. In contrast, evoked HL movements at mean threshold values of 52uamps were observed in the neonatal lesion group. Histological analysis (50um frozen sections, cresyl violet) demonstrated comparable lesions in both experimental groups.

The evoked HL movements observed in mature animals that sustained neonatal spinal cord lesions suggest that the previously described rerouting of corticospinal fibers around neonatal spinal cord lesions may be functional (Supported by NIH Grant NS 13230.)

376.5 DEVELOPMENT OF HINDLIMB STEPPING BEHAVIORS: NEUROMUSCULAR PATTERNS IN NORMAL AND SPINAL NEONATAL KITTENS. N.S. Bradley and J.L. Smith. Dept. Kinesiology, UCLA, CA 90024.

Limited EMG data in neonatal kittens suggest that antagonist hindlimb muscles are not reciprocally activated during stepping prior to onset of weight-supported locomotion at 2-3 wks of age (Scheibel & Scheibel, Exp. Neurol. 29:1970). It has also been suggested that spinalization in the neonate can hasten maturation of hindlimb stepping (Robinson & Goldberger, Neurosci Abst. 8:1982). We examined these notions, using EMG synchronized with video records during airstepping (ASTP), treadmill locomotion, and overground stepping in normal and spinal kittens.

To examine intra- and interlimb coordination during the stepping behaviors, the lateral gastrocnemius (LG), tibialis anterior (TA), and vastus lateralis (VL) were implanted in 12 kittens at 1 day of age. Normal animals (n=4) and those spinalized (T12) at 1 day (n=4) or 14 days of age (n=4) were tested 3 times/wk from 3 to 32 days of age. To elicit stepping motions, each kitten was: held under the chest with hindlimbs pendent (ASTP), held above a treadmill with hindpaws contacting the moving (≤0.2m/s) belt, and encourgaged to step overground while supporting its own weight.

Normals. At 3 days of age, 3-11 consecutive steps with minimal weight support were recorded in all animals on the treadmill with cycle periods (interval between LG burst onsets) of 1067-5169 ms. VL onset (±2% cycle) and duration (60-80% cycle) were tightly coupled with LG. TA onset was variable, often occurring during LG activity and/or LG silence. Contralateral LG onset was synchronous (±10% cycle) or alternating (30-40% cycle). During ASTP, 2-19 steps/bout were recorded at 3-7 days, with similar cycle characteristics. Overground, 1-3 steps/bout were taken, with only one TA burst per cycle (onset 80%, duration 20% cycle). Development of stepping 3-32 days of age was characterized by increases in cycles/bout and decreases in cycle period.

Spinals. Treadmill locomotion and ASTP in spinals 3-32 days old differed from normals: cycle periods were shorter (680-2478 ms), extensor burst durations less (30-50% cycle), and a single, prolonged TA burst began at 30-50% cycle. ASTP persisted the 1st mo in spinals, but seldom occurred in normals after 1-2 wk. During best steps on the treadmill, weight support did not appear to differ between normals and spinals.

Our data show that stepping occurs in the hindlimbs of normal neonatal kittens under several conditions with a tight synergy between extensors, while phasing of flexors is variable, particularly during treadmill locomotion. Shorter cycle periods during stepping behaviors in spinal neonates suggest spinalization removes inhibition by rostral centers, but whether or not it hastens maturation warrants further study. Supported by NS 19864.

376.6 SOMATOTOPIC ORGANIZATION OF IPSILATERALLY PROJECTING CORTICOSPINAL NEURONS IN RATS SUBJECTED NEONATALLY TO ABLATION OF ONE MOTOR CORTEX. W.F. Nation*, M. Cox* and D.R. Humphrey. Lab. of Neurophysiology, Emory Sch. of Med., Atlanta, GA 30322.

If one motor cortex is ablated in the rat on postnatal days (PND) 1-4, the surviving motor cortex develops an 'aberrant', ipsilateral corticospinal projection, in addition to its normal contralateral projection (Hicks and D'Amato, Exp. Neurol., 29: 416). It is not known at present, however, how this ipsilateral system is organized somatotopically within the surviving motor cortex, nor how its development alters the somatotopic organization of the cells origin of the normal contralateral projection. To examine this and related questions, we used the technique of intracortical microstimulation (ICMS) to study the somatotopic organization of the surviving motor cortex, in adult rats subjected on PND 1 to ablation of one motor cortex (N=4); experiments were also performed in normal control animals (N=4). Anterogradely transported HRP was also used to study the course and terminal distributions of normal (N=4) and aberrant (N=4) corticospinal pathways. Finally, pyramidotomies were performed in normal (N=3) and in neonatally ablated adult animals (N=3), to establish that novel motor responses seen ipsilaterally were indeed mediated by fibers traversing the medullary pyramid. Our major findings were as follows.

(1) ICMS (0.2 msec cathodal or biphasic pulses, 100 msec train, 300 pps, 2-120 μA intensities) in the ketamine-sedated (50 mg/Kg) normal animal evoked only contralateral movements, at thresholds ranging from 4-60 μA. Ipsilateral responses could be evoked, but only with macroelectrodes (0.5 mm exposed tip) and at high thresholds (25-150 μA). (2) In the neonatally ablated animal, however, ipsilateral responses were evoked with ICMS at thresholds comparable to those for evoking contralateral movements (4-60 μA). In none of these animals, however, were movements of the digits evoked on either side. (3) The motor cortex map for contralateral responses was basically similar in normal and ablated animals, but the anterior and posterior forelimb zones were less distinctly separated in the latter. (4) For any given joint or body part, the map for ipsilateral responses in the ablated animals was roughly isomorphic with that for contralateral responses, raising the possibility that single neurons may project to similar regions on both sides of the cord. (5) Ipsilaterally terminating corticospinal fibers traveled in both the dorsal and anteromedial columns, with re-decussation occurring at both medullary and spinal levels. (6) Pyramidotomy abolished both ipsi- and contralaterally evoked responses, indicating that the fibers responsible for the former are either corticospinal, or part of a cortico-reticulo-spinal pathway; experiments are currently underway to resolve this point. (Supported by NIH Grant NS 20146).

376.7 CONTRACTILE PROPERTIES OF MOTOR UNITS IN DEVELOPING RAT SOLEUS MUSCLE. H. Lee Sweeney* and Wesley J. Thompson, Depts. of Physical and Health Education and Zoology, University of Texas, Austin, TX 78712.

We are currently investigating the contractile properties of motor units in developing rat soleus muscles. Soleus muscles were dissected in contiguity with the ventral roots L4 and L5 from 8 day and 16-17 day old animals and examined in vitro. Single motor units were isolated by teasing and stimulating ventral root filaments. Previous histochemistry of glycogen depleted units at these ages had suggested that there were two types of units present: those comprised primarily (>70%) of nominally slow fibers and those comprised primarily (>90%) of nominally fast fibers. To ascertain if these two histochemical types of units give rise to two populations of units distinct in their mechanical properties, we measured the twitch kinetics as well as the velocity of unloaded shortening of isolated motor units. At both ages, time to peak tensions were not obviously bimodally distributed. Rather, there seemed to be a continuum of twitch rise times, with the range being greater in the 16-17 day old muscles than in the 8 day muscles. The distribution of the velocities of unloaded shortening is uncertain due to the present small sample size. However, it is clear that the range of unloaded shortening velocities is greater in the older animals. In experiments where the units were first activated separately and then combined, the time to peak tension of the combined units was a weighted mean of the individual units, whereas the unloaded shortening velocity was determined by the speed of the fastest unit.

Thus, the two types of motor units revealed by histochemistry do not clearly translate into a bimodal distribution of the contractile properties of the units. This could be due to factors other than the myosin contained in the fibers. Certainly, in the case of the twitch kinetics, changes in the rate of SR calcium release and uptake could be deterministic. However, in the steady state conditions (i.e. tetanus) during which the velocity of unloaded shortening was measured, it is likely that the velocity differences we see are indicative of contractile protein differences. Thus, it is possible that a broad distribution of myosin isozymes is contained within motor units of developing animals. The conclusions previously drawn from histochemistry could be too simplistic, due to the inability of the ATPase staining to detect subpopulations of fibers within the two broad histochemical classifications. We are continuing to address this issue via simultaneous contractile measurements and glycogen depletion studies.

376.8 NEUROMUSCULAR JUNCTIONS ON EMPTY MUSCLE BASAL LAMINAE IN METAMORPHIC FROG MUSCLE. K. Lynch* (SPON: R. Cowie), Dept. of Anatomy, Uniformed Services University of the Health Sciences, Bethesda, MD 20814-4799.

During and shortly after metamorphosis, a contingent of muscle fibers in the rectus abdominis muscle of Rana pipiens undergoes degeneration (Lynch, K., J. Morphol. 182:317, 1984). Phagocytes fragment the muscle fibers within the basal laminae and phagocytose the fragments. The empty basal laminae persist for days to weeks, compressed between the remaining muscle fibers. We have observed presynaptic elements on such empty basal laminae in a number of muscles from metamorphic and early postmetamorphic animals. Ultrastructurally, these are indistinguishable from the presynaptic elements of normal neuromuscular junctions. The nerve terminals are overlain by Schwann cells and contain the normal assortment of organelles, including synaptic vesicles clustered over active zones. Often there are small, membrane-bounded profiles adherent to the postsynaptic surface of the basal laminae. Some of these have no stainable content; others appear to contain cytoplasm. In the rare instances in which neuromuscular junctions were seen on degenerating muscle fibers, a fragment of muscle which included the postsynaptic specialization was invariably bound to the presynaptic elements by synaptic basal laminae; that is, phagocyte processes did not separate the pre- and postsynaptic elements. Adherent postsynaptic fragments of muscle are thus the likely origin of the small postsynaptic profiles left by phagocytes within otherwise empty basal laminae.

The persistence of structurally normal nerve terminals on empty basal laminae is evidence that the synaptic basal lamina alone is sufficient to induce the axon to maintain its presynaptic specialization. This is consistent with the discoveries of Marshall, Sanes, McMahan and colleagues (reviewed by Sanes, J.R., Ann. Rev. Physiol. 45:581, 1983). The "unilateral" neuromuscular junctions also suggest that denervation plays no role in the selective loss of muscle fibers during metamorphic remodeling.

This research was supported by USUHS and by NIH grant NS17417.

376.9 DIFFERENT PROGRAMS OF SYNAPSE DEVELOPMENT IN TWO MUSCLES OF XENOPUS LAEVIS. J.L. Owens and R. Kullberg. Biology Dept., University of Alaska, Anchorage, AK 99508.

A comparative study was made of the development of synaptic currents in the superior oblique and interhyoideus muscles of Xenopus laevis. The superior oblique is an extraocular muscle which produces rapid saccadic movements of the tadpole eye. The interhyoideus is a broad, flat muscle which elevates the floor of the mouth. In order to assay the development of acetylcholinesterase (AChE) activity and acetylcholine receptor (AChR) gating kinetics, we examined the developmental change in miniature endplate current (MEPC) decay constants at endplates in each muscle. The earliest stage at which we were able to detect synaptic activity in these muscles was stage 41 (3 days old). The following developmental changes in MEPC decays were observed. Interhyoideus: MEPC decay constants were initially 5-6 msec. They decreased within 16 hours to 2-3 msec. There was no further change in decay constant until late metamorphosis, approximately 7 weeks later, after which the decay constants underwent a further decrease to about 1 msec. Superior oblique: MEPC decay constants were initially 3-4 msec. They decreased within 11 hours to about 1 msec and remained about that value for the following 4 weeks. They then gradually became longer, reaching values of 1.5-2.0 msec at mid-metamorphosis to adulthood.

Two points of interest emerge from these data: (1) Different muscles within a species may vary markedly in their programs of synapse development, and (2) within a given muscle, there may be more than one distinct phase in the development of synaptic function. The initial rapid decline in MEPC decay in both muscles may be due in part to the development of AChE. Karnovsky stain revealed no localized accumulations of AChE in stage 41 muscle, while such accumulations were apparent 16 hours later in stage 44 muscle. After the development of AChE, subsequent differences in MEPC time course between the two muscles probably represent different relative numbers of slow and fast AChR channels. The longest and briefest MEPC decay constants, recorded in either muscle, were equivalent to the estimated open times of the slow and fast AChR channels known to be present in Xenopus muscle. Some MEPCs in both muscles had biphasic exponential decays, and in such cases the decay constants were comparable to the mean channel open times of the two classes of AChRs. In interhyoideus muscle, the shift to fast MEPC decay constants can be induced at early developmental stages by treatment with thyroid hormones. Having observed these contrasting programs of synapse development in two muscles of Xenopus laevis, it will be of interest to relate them to possible differences in the development of muscle function.

376.10 **Development of Command System Function During Transformation in the Sea Lamprey.** L. Margolin*, D. Kaufman* and J. Ayers. Marine Science Center, Northeastern University, East Point, Nahant, MA 01908

Although much is known about the fictive patterns elicited by electrical stimulation of brain command centers in lampreys, the behavioral significance of these motor patterns has received less attention. We have developed a preparation which allows quantitative analysis of movement parameters in response to command tract stimulation. We find, that although the command systems can evoke undulatory behaviors within the range of normal swimming, the descending control of the motor output in larvae differs quantitatively from that observed in recently transformed adults. Specimens were prepared for brain stimulation by a ventral longitudinal slit through the gill chamber which allowed the specimen to be pinned out by its gill arches. The head and brain case was then dissected away to expose the brain for focal extracellular stimulation (Brain Res 279: 238-240). Biphasic stimuli (ammocoetes, 5-50 hz, 7-46 μa; transformers, 5-20 hz, 20-35 μa) were delivered through double barreled glass microelectrodes inserted into the bilateral command tracts in the rhombencephalon.

In both larvae and transformed adults, the stimulation of this tract could evoke front to rear undulations within the range which characterizes normal swimming movements (Science 221: 1312-1314). In adults, high currents could sometimes evoke behavior similar in timing to other undulatory behaviors, but curvature was always much lower. In larvae, the motor output was typically (>60%) bilaterally symmetrical in curvature; whereas, in transformed adults, the motor output was typically (>90%) assymmetrical in curvature. In ammocoetes, increases in the stimulus current caused the period, intersegmental delay and intersegmental phase lag to decrease with no effect on curvature. Variation in the stimulus frequency was for the most part without effect. In contrast, in adult specimens, increases in stimulus current caused increases in period and delay with little effect on intersegmental phase lag and curvature. Increases in frequency caused decreases in period, intersegmental delay and curvature. We conclude that transformation induces developmental alterations in the efferent effects of this descending command system.

376.11 LONG-TERM ADAPTATION OF CRAYFISH NEUROMUSCULAR SYNAPSES DOES NOT REQUIRE AN INCREASE IN THE ACTIVITY OF THE ALTERED SYNAPSES. G.A. Lnenicka and H.L. Atwood, Dept. of Physiology, University of Toronto, Toronto, Ontario, Canada M5S 1A8

We have previously reported that direct in vivo stimulation of a relatively inactive crayfish phasic motoneuron (the fast excitor to the claw closer muscle) results in greater fatigue-resistance of its neuromuscular synapses as well as a reduction in the initial transmitter release (Lnenicka & Atwood, 1985, J. Neurosci. 5:459-467). This effect, called long-term adaptation (LTA), requires 2h of stimulation per day for at least 3 days, lasts for at least 1 week, and cannot be produced in decentralized motor terminals (Lnenicka & Atwood, 1985, J. Neurobiol. 16 (2): 97-110). The ultrastructure of the motor terminals become more similar to tonic axon terminals as a result of chronic stimulation. We report here that increased activity of the altered synapses is not required for establishment of LTA.

To determine whether an increase in synaptic input to the central processes of the fast excitor is sufficient to produce LTA of peripheral synapses, tactile receptors on the biting surface of the claw which reflexively drive the fast and slow excitors were electrically stimulated in vivo. Although the slow excitor can be reflexively driven for hours in vivo, the fast excitor fails to spike after only a few trials, due to the high threshold for impulse production in this neuron (Wiens, 1976, J. Comp. Physiol. 112:213-233). The tactile receptors in one of the paired claws were electrically stimulated at 12 Hz in .75sec trains delivered every 2sec, 2h/day, for 1 week. Since the fast and slow excitors receive parallel sensory input (Wiens, ibid.), the effectiveness of the sensory stimulation was monitored by chronically recording the reflexively evoked myogram of the slow excitor. One day after the final stimulation period, fast excitor EPSP amplitudes were measured in experimental and contralateral control claws. Initial fast axon EPSP amplitudes in the experimental claw were significantly smaller and showed significantly less depression during 5 Hz stimulation, compared to the contralateral control claw - an effect similar to that produced by direct stimulation of the fast axon. These results suggest that depolarization of motoneuron's central processes can affect the properties of the neuromuscular synapses in the absence of motor action potentials. However, since the activity of the slow axon was increased during sensory stimulation, we presently cannot rule out the possibility that the increase in muscle fiber activity plays a role in initiating these synaptic changes in the fast excitor. The fact that the muscle fibers in which fast excitor EPSPs were measured are very weakly innervated by the slow excitor argues against this possibility. (Supported by NSERC and MRC of Canada).

376.12 CHANGES IN THE ORGANIZATION AND DENSITY OF SYNAPTIC CONTACTS IN MOTOR CORTEX DURING PRE- AND POSTNATAL LIFE OF RHESUS MONKEYS. N. Zecevic and P. Rakic. Section of Neuroanatomy, Yale University. School of Medicine, New Haven, CT 06510

We have studied the development of synapses in the motor cortex (Brodmann's area 4) of 16 rhesus monkeys at various embryonic (E) and postnatal ages. Two to four vertical EM probes consisting of 100-250 overlapping micrographs (14,000X) that spanned the thickness of the cortex were prepared for each animal. Synaptic density was calculated per unit volume of neuropil (excluding neuronal and glia cell bodies, blood vessels and extracellular space), and the synapses were categorized according to their morphology (symmetrical or asymmetrical) and location (on spines or on shafts). The length of synaptic contacts and the ratio of different types of synapses were recorded on each probe using an image analyzer. From the total of 115,000 synapses recorded, a sample of 11,000 were classified and analyzed statistically.

The first synapses to appear in the prospective motor cortex are observed at about E55 in the marginal zone (prospective layer I) and in the subplate zone situated beneath the developing cortical plate. Around midgestation synapses appear within the cortical plate itself. By E89 synaptic density is about 5/100um$^3$ and increases 8-fold during the last two months of gestation to reach 40/100um$^3$ at the time of birth. This period of rapid synaptogenesis continues until the 4th postnatal month when a peak density of 56/100um$^3$ is attained. Thereafter synaptic density declines gradually to a level of about 33/100um$^3$ in mature animals (3-5 years), and by the end of the second decade of life it diminishes even further to a level of about 20/100um$^3$. The decline in synaptic density is caused to a large extent by the loss of synaptic terminals rather than by the dilution of a constant synapse population due to growth in neuropil volume. Futhermore, the drop in absolute synaptic density can be attributed mainly to the elimination of synapses on dendritic spines: the population of synapses on dendritic shafts remains relatively constant. The predominant loss of axo-spinous synapses is reflected in a change in the ratio between asymmetrical and symmetrical synapses. This ratio is 4:1 at E112, 7:1 at birth, 24:1 during the 4th postnatal month, and again 7:1 in the oldest animals. While the mean length of synaptic junctions does not change significantly during development, the number of complex synapses - with multiple junctions - shows an overall increase from about 1% at E112 to about 10% during the second decade. Thus, the development of the complex synaptic architecture of the primate motor cortex involves overproduction, elimination, and rearrangement of synaptic junctions. These changes occur nearly simultaneously with similar events in visual, somatosensory, limbic, and association cortices (Bourgeois and Rakic, '83,'85; Rakic et al., '85).

376.13 REORGANIZATION OF THE SOMATIC REPRESENTATION IN MOTOR CORTEX FOLLOWING FORELIMB AMPUTATION IN NEWBORN RATS J.P. Donoghue, B.Z. Berger*, S. Ryan*, and J. Sanes. Center for Neural Science, Brown University, Providence, RI and Lab. Neurophysiology, NIMH, Bethesda MD.

Previous studies have found that damage to sensory receptors modifies the topographic organization of somatic representations in cerebral neocortex. However, the degree to which sensory reorganization is accompanied by corresponding modification of the cortical motor output is unknown. Accordingly, we examined the somatic representation in rat primary motor cortex (MI) subsequent to forelimb (FL) amputation. The FL was amputated at the shoulder joint on postnatal day 1. After a 1-6 month survival period, the organization of MI was mapped during ketamine anesthesia (100mg/Kg, i.p.), using intracortical microstimulation techniques (30msec trains of 200usec long pulses, 333Hz). Microelectrode penetrations were spaced from 100-500 um apart throughout the presumptive MI FL and adjacent areas. Current intensities up to 100uA were delivered 1.8 mm below the pial surface. Control maps were obtained from normal adult rats, normal littermates, or from MI ipsilateral to the amputation.

The size and location of the MI FL representation in controls generally agreed with previous studies in rat. Stimulation at less than 30 uA over a rostrocaudally elongated strip (mean area=4.7±1.2 mm$^2$; N=3) of frontal cortex elicited distal FL movements, most commonly, wrist extension and/or elbow flexion. Proximal (shoulder) movements were only observed by increasing levels of stimulation at distal FL sites in the caudal 2/3 of MI. In all 6 amputated rats, stimulation in the region of the presumptive FL representation produced discrete movements of muscles about the shoulder stump or scapula. Thresholds for proximal movements in amputated rats were less than 30uA (mean=19±6uA) at 37% of these sites, compared with 9% less than 30uA in controls. This proximal region overlapped the caudal region of the normal FL representation, but occupied a territory smaller than the usual FL area (mean area 2.7±1.1mm$^2$, N=5). In 5 of the 6 amputated rats, vibrissae movements were evoked by stimulation in rostral parts of MI that are normally occupied by the FL representation. Vibrissae movements were never observed in this same area in control animals. From these data we conclude that forelimb amputation in the newborn induces reorganization of MI so that part of MI normally influencing distal forelimb musculature is "redirected" to control novel muscle groups. Ongoing experiments will identify the extent of cortical and subcortical reorganization in these animals.

377.1 EFFECT OF GABAERGIC DRUGS ON THE YAWNING BEHAVIOUR OF THE RAT. E. Doger *, R. Urbá-Holmgren * and B. Holmgren * ( SPON: J.A. Roig ) Departamento de Ciencias Fisiológicas, Instituto de - Ciencias. Universidad Autónoma de Puebla, Pue., México.

It has been shown that cholinergic and dopaminergic mechanisms are involved in the genesis and regulation of yawning behaviour in mammals. An increment of the central cholinergic activity induces yawning behaviour, and an increment of the dopaminergic activity decreases its frequency. (Holmgren B., Urbá-Holmgren R., Acta Neurobiol. Exp., 40: 633-642, 1980). On the other hand, regulatory mechanisms between gabaergic and dopaminergic systems have already been described in some structures of the basal ganglia, (Mc Geer, et al., Canadian J. of Neurol.Sciences 11:89-99,1984).

Experiments were performed with the purpose of providing a first approach to the possible participation of gabaergic mechanisms in the regulation of this behaviour. The following drugs were used: gamma-acetilenic-gaba, progabide, bicuculline, methiodide; all drugs were injected i.p.

The behavioral observations were carried out in Sprague-Dawley male rats, 2-3 months old (n=10-12 per group) from a selectively bred subline to get spontaneus, highly yawning-rats. The results were analyzed with the U-Mann Whitney Test.

The dose-response curve of gamma-acetilenic-gaba shows an increase of yawning at 7 mg/kg ($p < 0.05$), other doses being ineffective. With progabide an increase in yawning behaviour was also obtained at 25 mg/kg ($p < 0.04$). Quite different results were obtained with bicuculline, which produced an inhibition of the yawning behaviour 3mg/kg ( $p < 0.007$), other doses being ineffective.

These results show that moderate increases of the gabaergic activity obtained by gamma-acetilenic-gaba and progabide produce an increment of yawning, while a gaba antagonist reduces yawning frequency. These data are consistent with the hypothesis that gaba inhibits the activity of dopaminergic neurons. Further studies are needed in order to obtain more information about the role of gaba, and the type of receptors involved in the modulation of yawning behaviour .

377.2 **EFFECT OF 1,4-BENZODIAZEPINES AND OTHER ANXIOLYTICS ON HARMALINE-INDUCED TREMOR.** W. J. Millard, Barbara R. Keith*, and Kristen C. Hughes*. Laboratory of Psychobiology, Mount Holyoke College, South Hadley, Massachusetts 01075-1462.

Harmaline is a ß-carboline that has established hallucinogenic and tremorgenic properties (Fuentes, J.A., & Longo, M.V.G., Neuropharmacol, 10:15, 1971.). Several ß-carbolines have been found to antagonize the spectrum of pharmacological effects of the 1,4-benzodiazepines, e.g., diazepam and chlordiazepoxide (Braestrup, C,, & Neilsen, M., Beta-carbolines and Tetrahydroisoquinolines, 227, 1982).

The objective of the present experiments was the characterization of the dose-response relationship for tremor induced by the acute administration of harmaline. The mechanism of action of harmaline was further studied in a second procedure in which the antagonism of harmaline-induced tremor by a chlordiazepoxide, Na pentobarbital, and Ro 15-1788, a 1,4-benzodiazepine antagonist.

The tremor induced by the acute administration of harmaline (1.0-100.0 mg $kg^{-1}$) was dose-dependent in C57BL/6J mice. The results of a second procedure indicated harmaline-induced tremor was antagonized by a 1,4-benzodiazepine, chlordiazepoxide (10.0-40.0 mg $kg^{-1}$).

The nature of the antagonism was specific as indicated by the absence of antagonism by chlordiazepoxide on tremor induced by oxotremorine (0.25 mg $kg^{-1}$), a compound having a cholinergic site of action.

377.3 **CENTRAL NICOTINIC BLOCKADE OF DIAZEPAM'S ANTICONFLICT EFFECTS IN THE RAT.** Gregory F. Heath* & Joseph H. Porter(SPON:M.L. Fine). Dept. of Psychology, VA Commonwealth Univ., Richmond, VA 23284.

Diazepam produces an increase in punished responding in conflict procedures in rats and other species that is predictive of its antianxiety activity. Heath and Porter (Eastern Psychological Assoc., 1985) reported that nicotine blocks the anticonflict effects of diazepam in rats tested in a modified Geller-Seifter conflict procedure(Psychopharmacologia, 1:482,1960). However, the muscarinic agonist, arecoline, did not block diazepam's anticonflict effects. These data suggest that this cholinergic antagonism of diazepam's anticonflict effects involves nicotinic, but not muscarinic, receptors. The present study examined the role of central versus peripheral nicotinic receptors in this blockade of diazepam's anticonflict effects.

Adult male rats (N=17) were maintained at 80% body weight and tested daily on a modified Geller-Seifter conflict procedure with a multiple fixed interval 1-min (food reward only) fixed ratio 1 (food plus scrambled foot shock) schedule. All rats were tested with the following drug conditions both alone and in combination: 0 and 4 mg/kg diazepam ; 0 and 1.4 mg/kg (-)-nicotine; 0 and 1 mg/kg mecamylamine (central nicotinic antagonist); and 0 and 1 mg/kg hexamethonium (peripheral nicotinic antagonist). Data on test days were converted to percent of the preceding control (non-drug) day. Separate Dunnett's tests were performed on conflict data (i.e., punished responding during FR components) for all drug conditions with 0 mg/kg diazepam and for all drug conditions with 4 mg/kg diazepam.

The increase in punished responding produced by diazepam (mean = 2034.6%) was significantly suppressed by nicotine (mean = 1181.9%). This effect of nicotine on diazepam was blocked by mecamylamine (mean = 2272.5%), but not by hexamethonium (mean = 635.8%). Mecamylamine in combination with diazepam resulted in a significantly greater increase in punished responding than diazepam alone (3399.5% vs. 2034.6%). Hexamethonium in combination with diazepam was not significantly different from diazepam alone (1663.3% vs. 2034.6%). In the absence of diazepam, mecamylamine produced a significant increase in punished responding as compared to vehicle (365.1% vs. 224.2%).

These data support our previous findings that nicotine blocks the anticonflict effects of diazepam. Further, it was demonstrated that this nicotinic blockade of diazepam's anticonflict effects appears to be mediated by central nicotinic receptors and that peripheral nicotinic receptors do not appear to be involved in this effect. One intriguing result was the synergistic effect of mecamylamine with diazepam, and the significant increase in punished responding produced by mecamylamine alone. These data suggest that mecamylamine may possess anxiolytic activity.

377.4 DOSE-RELATED EFFECTS OF DIAZEPAM ON NOISE-INDUCED POTENTIATION OF THE ACOUSTIC STARTLE REFLEX: DISCLOSURE OF SEVERAL UNDERLYING MECHANISMS. A. T. Sullivan* and C. K. Kellogg. Dept. of Psychology, University of Rochester, Rochester, NY 14627.

The noise potentiated acoustic startle reflex (ASR) has been utilized to elucidate the effects of prenatal and adult exposure to diazepam (DZ). The ASR was induced by a 120 dB tone burst against a background noise (centered about 1 kHz) of 30, 50, 70, or 90 dB. In the prenatal study, pregnant dams (Long Evans strain) were administered DZ at doses of 1.0, 2.5, or 10 mg/kg per day during gestational days 13-20. Previous work indicated that prenatally exposed rats had a reduced ASR and background noise did not facilitate the ASR (Sci., 207:205, 1980). In the present prenatal study, exposed offspring were tested in adulthood (70-90 days), and all animals (exposed and uninjected controls) demonstrated similar amounts of potentiation of the ASR. However, significant differences in the baseline ASR were apparent. Rats exposed to DZ at 2.5 mg/kg were hyperresponsive to the startle stimulus, rats exposed to DZ at 10.0 mg/kg were hyporesponsive, and rats exposed to DZ at 1.0 mg/kg showed no differences as compared to uninjected controls. Furthermore, combined exposure to DZ (2.5 mg/kg) and the benzodiazepine antagonist RO 15-1788 (10 mg/kg) prenatally did not prevent the hypersensitivity to the ASR observed in rats exposed to 2.5 mg/kg DZ alone. These observations suggested that DZ given prenatally may intereact with multiple receptor subtypes.

Administration of DZ to normal adults in cumulative doses of .25, .75, and 2.25 mg/kg induced a dose-related decrease in noise potentiation of the ASR with no effect on basal ASR. If RO 15-1788 was given concurrently with DZ, the inhibition by DZ was enhanced. Further study demonstrated that a single dose of DZ (2.5 mg/kg) induced a 73% inhibition of noise potentiated ASR. This effect was reversed by a subsequent injection of RO 15-1788 but not by vehicle. However, a single dose of DZ at .25 mg/kg induced only a 16% reduction in potentiation which was enhanaced to 73% and 72% when animals were given either RO 15-1788 or vehicle. Basal ASR increased in the last test. The low dose of DZ may engage mechanisms which are not sensitive to the central antagonist. Initial studies have shown that neither the triazolopyridizine CL 218-872 nor methyl-betacarboline-3-carboxylate alter potentiation or basal ASR; hence, analysis of noise potentiated ASR may elucidate mechanisms of action of DZ and related compounds not disclosed by other paradigms. Supported in part by grant MH 31850.

377.5 ALCOHOL AND AGGRESSIVE BEHAVIOR IN RATS: INTERACTION WITH BENZODIAZEPINES. K.A. Miczek. Dept. of Psychology, Tufts Univ., Medford, MA 02155.

The discovery of benzodiazepine receptors and the development of drugs that selectively and specifically interact with these receptors provides new avenues to investigate the mechanisms by which alcohol alters behavior. (1) The behavioral profiles of alcohol and diazepam are similar; particularly intriguing are the dose-dependent bidirectional effects of both drugs on aggressive behavior. (2) Moreover, alcohol and diazepam appear to add to each other's aggression-enhancing and -suppressing effects, when given concurrently. (3) Whether or not specific benzodiazepine receptor blockade may alter alcohol's effects on aggression remains unresolved.

In several series of experiments pharmacological manipulations of benzodiazepine receptors were performed in order to study their role in alcohol effects on aggressive behavior in rats. The resident males of 12 independent rat colonies were confronted twice weekly with an intruder male. The resident's attack, threat, pursuit behavior, aggressive postures and grooming as well as nonaggressive rearing, walking and grooming were encoded into computer files while viewing the videorecords of the resident-intruder encounters. In addition, the intruder's defensive, submissive and escape reactions were measured.

The frequency of attack bites and the display duration for aggressive posture was significantly increased by either a low diazepam (0.3, 1.0 mg/kg, i.p.) or a low alcohol dose (0.3 g/kg, p.o.). In the presence of a fixed low alcohol dose, either 0.1 or 0.3 g/kg, the dose-effect curve for diazepam on the resident's aggressive behavior was shifted to the left, indicating additive effects on both the aggression-enhancing and -decreasing effects of the two compounds. It will be important to determine how concurrent administration of the specific benzodiazepine receptor blocker Ro15-1788 modulates the aggression-enhancing and -suppressing effects as well as the sedative effects. At present, it remains unclear at what level alcohol and diazepam in their respective mechanisms of action interact in order to produce not only similar, but also additive effects on aggressive behavior.

377.6 PUNISHMENT ATTENUATING EFFECTS OF PENTOBARBITAL ARE NOT RATE-DEPENDENT. S.I. Dworkin, T. Miyauchi* and C. Bimle*. Psychiatry Research Unit, Departments of Psychiatry and Pharmacology, Louisiana State University Medical Center, Shreveport, LA 71130.

Drugs used clinically for their anxiolitic or sedative properties typically increase punished responding. These drugs, however, also increase low rates of responding that are not suppressed by punishment. Therefore, comparable rates of punished and unpunished responding are necessary to investigate potential specific punishment-attenuating effects of these agents. This study investigated the effects of pentabarbital on such a baseline.

Five pairs of littermate rats were trained on either a random-ratio 50 or a yoked random-interval food presentation schedule. The random-ratio subject received a food pellet after completing a randomly select number of responses (average 50). A reinforcer was presented to the yoked random-interval subject for each response that immediately followed a reinforcer delivery to the subject on the ratio schedule.

This procedure resulted in high rates of responding maintained by the subject on the ratio contingency and low rates by the subject on the interval schedule. However, the reinforcer density was the same for both subjects. A random ratio schedule of electric footshock presentation was then added to the random-ratio food presentation schedule. The intensity of the shock was adjusted to suppress responding to rates comparable to those maintained by the yoked-interval contingency. This additional contingent resulted in similar rates of punished and unpunished responding and nearly equivalent reinforcement density. Moderate doses of pentobarbital (10 mg/kg) increased the low rates of punished responding but did not increase similar rates of unpunished responding. Larger doses (17 mg/kg) decreased responding maintained by both contingencies. These data demonstrated that pentobarbital selectively increased punished responding.

377.7 DOES DIAZEPAM CAUSE SEIZURES IN INFANT RATS? J.W. Smythe,* C.L. Ryan* and B.A. Pappas* (SPON: T. Tombaugh). Unit for Behav. Med. & Pharmacol., Carleton Univ., Ottawa, Ont., K1S 5B6.

This laboratory has previously shown (Pappas & Walsh, Pharmacol. Biochem. & Behav., 1983) that benzodiazepines (BZs) produce a behavioural syndrome in infant rats characterized by leg paddling and wall progression. Barr and Lithgow (Nature, 1983) also demonstrated this syndrome, which they suggest may indicate "behavioural convulsions." If BZs have intrinsic convulsogenic activity in rat pups, they would not block the effects of a known chemical convulsant. The following study investigated this hypothesis by determining if diazepam (DZP) blocks pentylenetetrazol- (PTZ) induced seizures in rat pups.

Four groups of seven-day-old Wistar rat pups were used to examine the putative convulsogenic activity of DZP. The first group was injected subcutaneously with 0.5 mg/kg DZP while a second group received 65 mg/kg PTZ. A third group was administered a pretreatment of 0.5 mg/kg DZP, followed 30 minutes later by an injection of PTZ. A fourth group received only saline, and served as the controls. The groups were assessed for the overt behavioural manifestation of paddling and wall progression, head tremor, and body tremor.

DZP alone elevated paddling and wall progression scores, but did not alter head and body temor scores. PTZ alone did not affect paddling and wall progression, but significantly elevated head and body tremor scores. The combined DZP + PTZ treatment produced the same elevated paddling and wall progression as did DZP alone. Head tremor scores were significantly reduced, however, while body tremor scores were reduced, but not significantly.

These results indicate that DZP reduces the effect of PTZ and thus seems to be an anticonvulsant in young pups. If BZ-induced paddling and wall progression are behavioural manifestations of brain seizures, then at the very least these seizures are markedly different than those produced by PTZ. Alternatively, these behaviours do not reflect brain seizures. Confirmation of one or the other of these alternatives requires analysis of EEG activity after BZ administration. Preliminary investigations indicate that DZP may flatten the EEG and cause interspersed spike activity in rat pups. In contrast, PTZ causes marked and virtually continuous spiking. Further EEG data will be presented at the meeting. (Supported by NSERC)

377.8 EFFECTS OF PSYCHOACTIVE DRUGS ON A DRL TASK IN CATS. M. Curtis*, P. Saxton, J. Siegel. (Spon: A. M. Granda). Institute for Neuroscience, University of Delaware, Newark, DE, 19716.

In the first phase of a series of experiments designed to study central nervous system inhibitory mechanisms, the effects of psychoactive drugs on a differential reinforcement of low rate of response (DRL) operant task was determined in cats. Six cats were trained to perform on a DRL food-motivated bar-press schedule which involves an active behavioral inhibitory process. DRL cats served as their own drug injection controls. Drug effects were also contrasted with two cats trained on a fixed interval (FI) operant schedule, which uses the same motor patterns but does not involve an active inhibitory mechanism.

Using a blind procedure, fasted animals were dosed once a week with one of three drugs. Imipramine at 6.0 - 9.5 mg/kg was given i.p. 45 min before testing, chlordiazepoxide at 4.0 mg/kg i.p. 15 min before testing, and haloperidol at 0.2 mg/kg i.m. 2 hrs before testing. Minimal CNS side effects noted such as slight ataxia were recorded up to 3 hrs after dosing. Performance indices (errors, reinforcements, inter-response times, and perseveration) were tabulated for each 5 min period in a 30 min test session by a computer. Errors on a DRL schedule were made when the animal failed to withold a bar press for a specified period of time (e.g. 15 sec). Reinforcements (liquid mash reward) were received when the animal bar-pressed at the correct time.

All three drugs impaired performance using the DRL paradigm. Imipramine, a tricyclic antidepressant, increased DRL errors without significantly altering number of reinforcements but decreased FI extra presses. Haloperidol, a butyrophenone neuroleptic, increased DRL errors, decreased FI extra presses, and caused pausing in bar-pressing activity which resulted in decreased reinforcements. Chlordiazepoxide, a benzodiazepine anxiolytic, dramatically increased both DRL errors and FI extra presses. Disinhibition that resulted from chlordiazepoxide treatment could not be attributed to a response rate-dependent effect since both DRL and FI response rates were accelerated. The differential effects of these drugs provide clues about the interaction of neurotransmitter systems involved in inhibition on a DRL task, and serve as the basis for direct brain infusions of more selectively acting agents.

377.9 DISCRIMINATIVE STIMULUS PROPERTIES OF CENTRALLY APPLIED MIDAZOLAM: GENERALIZATION FROM PERIPHERAL TRAINING CONDITIONS. R.R. Griffiths*, M.J. Kuhar and N.E. Goeders (SPON: S. Lukas). Departments of Neuroscience and Behavioral Biology, Johns Hopkins University School of Medicine and Laboratory of Neuroscience, NIDA Addiction Research Center, Baltimore, MD 21205.

The discriminability of a number of benzodiazepines (BZD) has been demonstrated in studies in which rats were trained to discriminate the peripheral administration of a BZD from vehicle. The autoradiographic visualization of BZD receptors has demonstrated an uneven distribution of these receptors in the rat brain, with high densities localized in the cortex, amygdala, hypothalamus and cerebellum (Young and Kuhar, J. Pharm. Exp. Ther., 212, 337, 1980). This investigation was designed to determine whether the central application of a BZD into discrete brain regions would occasion drug-appropriate responding in rats trained to discriminate peripherally administered BZD.

Male Long Evans hooded rats were trained to discriminate the triazolobenzodiazepine, midazolam (1.0 mg/kg, i.p.) in a two-lever drug discrimination procedure (Ator and Griffiths, J. Pharm. Exp. Ther., 226, 776, 1983). Food delivery depended on 10 consecutive responses on one lever in sessions preceded by an injection of the training dose of midazolam and on 10 consecutive responses on the other lever after no drug. All rats reliably completed 96-100% of total session responses on the appropriate lever with no response runs of the length required for reinforcement on the incorrect lever prior to the first pellet delivery. Following the completion of dose-response curves with i.p. drug delivery, the rats were stereotaxically implanted with unilateral guide cannulae into either the medial prefrontal cortex or posterior division of the basolateral amygdaloid nucleus and were allowed two weeks to recover. The surgical procedures did not affect response rates or i.p. midazolam discrimination. Intracranial microinjections of low doses of midazolam (0.1 to 10 nmol) did not occasion drug-lever responding in animals with cannulae implanted into either brain area. However, rats responded on the drug lever (>96%) when microinjected with higher concentrations (50 to 200 nmol) into the medial prefrontal cortex. Microinjections of similar doses of midazolam into the amygdala did not occasion consistent drug-lever responding. Injections of higher doses (>400 nmol) into either brain locus resulted in pronounced ataxia and little or no responding on either lever.

The results of this investigation suggest that neuronal systems associated with the discriminative stimulus properties of peripherally administered midazolam can be activated directly through the discrete application of the drug into the medial prefrontal cortex. 377.10 DIAZEPAM DISRUPTS SEXUAL, AGGRESSIVE AND GROOMING BEHAVIORS IN THE RAT. N. Shanks* and T.B. Wishart, Department of Psychology, University of Saskatchewan, Saskatoon, Saskatchewan, Canada, S7N 0W0.

The behavioral effects of diazepam on normal rats in a naturalistic environment were studied during acute and chronic administration of the drug and during withdrawal. An ethological rating technique (modified from Silverman, A.P., Brit. J. Pharm., 24:579, 1965) consisting of 29 distinct behavioral components was used to analyze the behavior of male rats treated chronically (28 days) with diazepam (2 mg/kg) when housed continuously with a female conspecific, or when combined with a novel female.

When housed continuously with a female rat, diazepam treated males were observed to sleep more, explore less, and engage in fewer types of behaviors generally during the first few days of treatment. As treatment progressed, tolerance developed to these sedative effects of diazepam. Treated animals initiated fewer sexual behaviors, but were both more aggressive and more submissive than controls. Grooming behaviors were virtually absent in the drugged animals throughout the 28 day treatment phase.

When paired with a novel, sexually receptive female, males treated with diazepam were again found to be both more aggressive and submissive. They also displayed qualitatively different sexual behaviors in that the copulatory sequence occurred less frequently, lasted longer, and was incomplete on many occasions. Once again, diazepam completely blocked the occurrence of grooming.

Most of the behavioral differences between controls and experimental animals had disappeared by the end of the two-week withdrawal period.

The results indicate that diazepam has effects on a wide spectrum of behaviors in the normal animal; this has implications for the possible side effects of this drug in man.

377.11 ELECTROACUPUNCTURE INDUCED ANALGESIA AND GAMA - AMINO-BUTYRIC ACID (GABA) IN MAMMALIAN CENTRAL NERVOUS SYSTEM. Sumita Chakraborty¶ A. Ganguly*and M.K.Poddar. Department of Biochemistry, University of Calcutta, 35 B. C. Road, Calcutta-700 019, INDIA.

Acupuncture, the ancient Chinese medical treatment is being widely used for curing various diseases. It is also known that acupuncture or electroacupuncture developes analgesia. In the present investigation, the effect of electroacupuncture(EA) induced analgesia on GABA system of rat central nervous system(CNS) have been studied. Adult male albino rats(120 - 140g) exposed to EA(Frequency, 10 Hz/sec; Intensity, 1 volt) were sacrificed by cervical dislocation at different time periods (2, 10 and 15 min.) during EA induced analgesia(onset, optimum and duration respectively) and at its post periods(10 and 30 min.). GABA level was increased during post acupuncture analgesia in thalamic(63.5%-101.3%) and hypothalamic(100.8%-77.9%) region of the brain. No significant change in GABA level was observed in pons-medulla, cerebral cortex and spinal cord during and after EA. Glutamic acid decarboxylase(GAD) activity was increased at optimum period of EA(10 min.)induced analgesia in only thalamus(29.3%) and at post EA induced analgesia both in thalamus(10-41.3%) and hypothalamus(17.5%-65.0%) No significant change was observed in other regions of CNS during or after EA. GABA-transaminase(GABA-T) activity was increased at the time of onset(116.3%), optimum (81.6%) and at 30 min after EA induced analgesia(263.2%) in pons-medulla. In thalamus GABA-T activity was increased at the optimum(78.3%) and at 30 min after EA induced analgesia(23.5%). No appreciable change in GABA-T activity was found in other regions of the CNS(hypothalamus, cerebral cortex and spinal cord) during and after EA. These results suggest that the GABAergic system in pons-medulla and thalamic regions of the brain is involved during EA induced analgesia; whereas in post period of the EA induced analgesia the GABAergic system of the thalamic and hypothalamic regions are affected. (Supported by Indian Council of Medical Research, New Delhi, India).

377.12 COMPARISON OF DRUG VS. DRUG DISCRIMINATION PARADIGMS USING CHLORDIAZEPOXIDE VS. CAFFEINE AND CHLORDIAZEPOXIDE VS. PENTYLENETETRAZOL. F.A. Holloway, R.C. Michaelis, A.M. Holohean*, and G.A. Hunter*. Dept. of Psychiatry and Behavioral Sciences, Univ. of Oklahoma Health Sciences Center., Oklahoma City, OK 73190.

Two drug vs. drug discriminations were trained in two separate groups of rats, pitting chlordiazepoxide (CDP) versus caffeine (CAF) or pentylenetetrazol (PTZ). Subjects were trained under a VR 10 schedule of reinforcement. Tests consisted of two minute sessions under extinction conditions, during which the total number of responses and the percent of responses emitted on each lever were monitored. Acquisition of both discriminations proceeded more quickly than acquisition of the respective drug vs. saline discriminations. In addition, compared to drug vs. saline discriminations, drug vs. drug training produced a greater percentage of responses on the drug-appropriate lever when subjects were tested after low doses of the training drugs.

Testing subjects in the undrugged (saline) state revealed interesting differences between the two paradigms. After several days of no drug exposure, saline produced approximately equivalent responding on both levers in both groups. However, response rates were drastically reduced in the CDP/CAF discriminators only. In CDP/PTZ discriminators, saline tests at various times after large doses of CDP produced a predominance of CDP lever responding for approximately 12 hours, followed by a predominance of PTZ lever responding. The period of predominantly PTZ lever responding could also be precipitated at shorter postinjection intervals by injection of RO 15-1788. A similar temporal pattern of change in response distribution was not seen in the CAF/CDP discriminators.

These findings suggest that the CDP/CAF discrimination represents two orthogonal stimuli, and that testing under saline presents a third orthogonal stimulus which is not perceived as being similar to either of the training stimuli. In contrast, the discriminative stimuli generated by CDP and PTZ appear to lie at opposite ends of an affective continuum, with the undrugged (saline) state capable of illustrating the dynamic biphasic changes in subjective stimulus state which follow injection of large doses of these training drugs.

377.13 CHLORDIAZEPOXIDE VS. CAFFEINE DRUG DISCRIMINATION IN THE RAT. A.M. Holohean*, F.A. Holloway, R.C. Michaelis, and G.A. Hunter*. Dept. of Psychiatry and Behavioral Sciences, Univ. of Oklahoma Health Science Center, Oklahoma City, OK 73190.

Drug. vs. drug (DD) discriminations have most frequently employed drugs whose stimulus properties have at least one aspect in common. Little parametric data is available concerning DD discrimination using contrasting drugs. In this study, a discrimination was trained between caffeine (CAF) and chlordiazepoxide (CDP), which produce different discriminative stimuli and interact antagonistically in several behavioral and biochemical tests. Rats were trained to discrminate 32.0 mg/kg CAF from 5.0 mg/kg CDP (i.p. 30 min prior to session) using a VR 10 schedule of food reinforcement. Tests consisted of two minute sessions under extinction conditions. The percent of responses made on each lever and the total number of responses made in the two minute session were monitored.

The CAF/CDP discrimination was acquired more quickly than the corresponding drug vs. saline discriminations. In addition, subjects showed higher percentages of drug-appropriate lever pressing at low doses of the training drugs than are seen in drug vs. saline paradigms. Subjects showed significant ( > 80%) generalization to the training cues after only 8.0 mg/kg CAF and 0.625 mg/kg CDP, respectively. Response rates were minimal after injection of saline or low doses of the training drugs.

Both accuracy and response rate varied in some tests depending upon whether the previous day's training session had involved CAF or CDP injection. In those subjects who maintained responding at low doses, greater percentages of CAF lever presses were seen after low doses of CAF when tests were run following a CDP injection day versus a CAF injection day. In addition, overall response rates during some CAF tests were higher following a CDP injection day versus a CAF injection day. When training drugs were administered together, a significant percentage of CDP lever responding ( > 77%) was seen after 32 mg/kg CAF plus doses as low as 1.25 mg/kg CDP.

The dramatic decrease in response rates during saline tests suggests that CAF and CDP produce orthogonal discriminative stimuli, and that the saline stimulus is a third orthogonal stimulus which does not generalize to either. In addition, results showed that training drug injections could influence performance on tests for a period of time which far exceeded the expected presence of the drug in the brain. These data suggest that contrasting DD discrimination produce quantitatively and qualitatively different generalization curves for the training drugs than that seen wth the corresponding drug-saline procedures.

377.14 RECOVERY OF FUNCTION AFTER BRAIN DAMAGE: SEVERE AND CHRONIC DISRUPTION BY DIAZEPAM. T. D. Hernandez*, T. Barth* and T. Schallert. Dept. of Psychology, Univ. of Texas at Austin, TX 78712.

Unilateral damage to anteromedial cortex (AMC) in rats causes a somatosensory asymmetry that is readily quantified using tactile extinction tests (originally designed to assess sensory function after damage to nigrostriatal dopaminergic neurons: Schallert et al., *Pharm. Biochem. Behav. 19*: 753, 1983; Schallert & Whishaw, *Behav. Neurosci. 98*: 518, 1984; Barth et. al., *Neurosci. Abstr. 10*: 1146, 1984). Recovery (a gradual reduction in the magnitude of sensory asymmetry) occurs consistently by about a week after surgery. The present study was conducted to determine whether daily postoperative exposure to diazepam interferes with this recovery. So that sedation would not be a factor, all behavioral tests were conducted *before* daily drug treatment. The dose used (5 mg/kg) was well below that necessary to affect sensorimotor behavior in control animals at the time of testing.

The results were that diazepam completely blocked recovery in all animals. Even following discontinuation of diazepam (after 22 days), the sensory asymmetry continued unabated. Up to 3 months after surgery (the duration of our observations), the magnitude of the asymmetry remained just as severe as it was on the first postoperative day. In contrast, undrugged (vehicle-treated) animals with AMC lesions recovered by 8 days. Apparently, the recovery process failed to occur in the drugged animals. Sham operated animals given diazepam or vehicle showed no postoperative asymmetry.

In a second experiment, rats with AMC lesions were given their first dose of diazepam at least three weeks *after* they had recovered from sensory asymmetry. A mild asymmetry was reinstated in a few of the animals, but only transiently (1-2 days) despite continuous drug treatment.

The data indicate that there may be a critical period after brain damage in which the recovery process is particularly vulnerable to diazepam. The effects of other agents on recovery are currently being evaluated, including drugs with anti-convulsant properties commonly used clinically to prevent seizures following brain damage.

377.15 INFLUENCE OF TESTING CONDITIONS ON THE ASSESSMENT OF DRUG EFFECTS IN A RAT OPEN FIELD TEST. F.O. Risinger*, W.M. Bourn, and R.L. Garrett*. Northeast Louisiana University, Division of Pharmacology and Toxicology, Monroe, LA 71209.

The characteristics of the testing environment have been shown to influence open field behavior. The purpose of this study was to examine the effects of different levels of illumination and sound on a multivariate assessment of drug effects in a rat open field test.

Adult female Sprague-Dawley rats were randomly assigned to 1 of 4 experimental conditions and 1 of 3 drug treatment groups (N = 20 per group). They were observed in an open field chamber (90 x 90cm) 20 minutes after dosing (i.p.). The open field observations lasted 15 minutes with ambulation, rearing, defecation, inner square penetration, and grooming recorded. The testing conditions consisted of either high (70fc) or low (.5fc) illumination with either high (100db tone) or low (5db background noise) sound. Drug treatment consisted of either chlordiazepoxide (3 mg/kg), pentylenetetrazol (20mg/kg), or saline. As a further characterization of locomotor effects, an additional experiment was conducted using activity cages. Large and small movements were measured under the same drug treatments as previously stated.

Multiple discriminant analysis of the open field data indicated that the greatest separation of drug treatment groups occurred in the low illumination conditions. For each of the low illumination conditions, two significant ($p < .01$) discriminant functions were derived. Within group classification was 83% for either low illumination condition. For both of the high illumination conditions, only one significant discriminant function was derived. Under the high illumination-high sound condition, 72% of the animals were correctly classified while under the high illumination-low sound condition, 68% of the animals were correctly classified. In the activity cages, both drug treatments produced a decrease ($p < .01$) in small movements while chlordiazepoxide produced a decrease ($p < .05$) in large movements.

These results indicate that testing conditions are a factor in the relative sensitivity of open field procedures when used to identify drug effects. Also, the locomotor effects of a drug are partially dependent on the experimental situation and instrument.

378.1 ATROPINE POTENTLY INHIBITS THE ONSET BUT NOT THE REEMERGENCE OF OVARIAN STEROID-INDUCED MATERNAL BEHAVIOR. C.A. Pedersen, J.D. Caldwell*, P.J. Brooks* and A.J. Prange, Jr. (SPON: R.L. Glasser) Department of Psychiatry, Biological Sciences Research Center and the Neurobiology Curriculum, University of North Carolina, Chapel Hill, NC 27514

The role of classical neurotransmitter systems in MB has been little studied. In this investigation we examined the effect of muscarinic and nicotinic antagonists on the onset and reemergence of MB.

Nulliparous Sprague Dawley rats were ovariectomized under ether anesthesia and treated with 17-β estradiol (E) and progesterone (P) for a two week period. Thirty minutes prior to introduction of three 1-5 day old rat pups some nullipara received ICV various doses of atropine sulfate (AS) or hexamethonium bromide (HB) in normal saline (NS) or NS vehicle alone. Nullipara receiving no ICV treatment before introduction of pups and primipara were allowed 4-5 days of mothering experience before being separated from pups for 24 hrs. Thirty minutes prior to reintroduction of three 1-5 day old pups primipara and nullipara received ICV various doses of AS or NS vehicle alone. Behavioral responses were recorded during each of the first six hrs and the twenty-fifth hr after introduction of test pups.

In naive nullipara, all doses of AS (0.75, 1.5, 3.0, 6.0, 12.5 and 25 µg) significantly lowered the incidence of full maternal behavior (FMB) in the first hr of pup contact compared to NS. AS doses of 6.0, 12.5 and 25 µg significantly lowered the cumulative incidence of FMB in each of the first 3-6 hrs of pup contact. In contrast, a dose of HB equimolar to 12.5 µg AS had no significant effect on the cumulative incidence of FMB in any hr of observation. In nullipara and primipara allowed 4-5 days of MB experience 12.5 µg of AS did not significantly lower cumulative incidences of FMB in any hr of observation while 25.0 µg of AS significantly lowered the incidence of FMB compared to NS in the first hr of pup contact alone. AS doses of 12.5 and 25.0 µg produced significantly lower cumulative incidences of FMB in E + P treated nullipara with no prior pup contact compared to nullipara and primipara with prior MB experience over the first three hrs (12.5 µg AS) or two hrs hrs (25.0 µg AS) of pup contact.

We conclude that muscarinic but not nicotinic cholinergic neurotransmission plays a critical role in the ovarian steroid-induced onset of FMB but not in the reemergence of established FMB.

378.2 COCAINE EXPOSURE INCREASES SUBSEQUENT BEHAVIORAL RESPONSE TO NICOTINE. R.L. Hakan* and C. Ksir. Dept. of Psychology, University of Wyoming, Laramie, WY 82071.

Rats given daily injections of nicotine develop an increased stimulant response to nicotine which is concomitant with an increase in the number of CNS nicotinic cholinergic receptor sites (Ksir, Hakan, Hall & Kellar, Neuropharmacology, 1985). Amphetamine, cocaine and morphine have each been reported to produce a similar type of behavioral sensitization. We now report that in three separate experiments, rats preexposed to cocaine for five days showed an increased behavioral activation to a test dose of nicotine given on day 6.

In one experiment, 12 rats were placed in the photocell test cages each day for a 1-hour adaptation period. Then six rats received saline and six received 5 mg/kg cocaine (i.p), after which activity was monitored for another hour. This was repeated for five days. On the sixth day all rats received a test dose of 0.2 mg/kg nicotine (s.c.). The rats that had been exposed to cocaine showed greater activity during the first ten min after nicotine than the rats previously given saline ($t$=4.08, df=10, $p<.01$).

Experiments in which rats were exposed to daily doses of morphine (5 mg/kg) or d-amphetamine (0.5 or 1.0 mg/kg) found no differences in nicotine effects on the test day. Thus, this effect is not common to all drugs that might produce behavioral sensitization.

In another experiment, rats were given preexposure injections of cocaine or saline in their home cages. Again there was significantly greater activity during the first ten minutes after nicotine in the group preexposed to cocaine ($t$=2.9, df=10, $p<.01$). In a third cocaine experiment, rats were given either saline or 10 mg/kg cocaine each day for five days in their home cages. Again the cocaine preexposure group showed more activity following nicotine ($t$=2.69, df=9, $p<.025$).

Another group of rats was given an initial test dose of 5 mg/kg cocaine in the test cages, after which they received five once-daily injections of 0.2 mg/kg nicotine followed by a second test dose of cocaine. The response to cocaine on the post-nicotine test was not significantly greater than the response on the pretest (in fact the trend was for a reduced effect). This indicates that the cocaine-nicotine interaction is a one-way preexposure effect.

The mechanism by which cocaine preexposure alters subsequent nicotine response is unclear. Preliminary binding results indicate that cocaine does not bind to nicotinic sites nor does cocaine preexposure increase nicotinic receptor numbers.

378.3 NICOTINE BEHAVIORAL EFFECTS IN A FISH, PIMEPHALES PROMELAS (fathead minnow). D.A. Scratchley*, R.L. Hakan* and C. Ksir (SPON: M. Renner). Dept. of Psychology, University of Wyoming, Laramie, WY 82071.

Nicotine has been shown to produce increased locomotor activity in rats, as measured in photocell activity cages (Ksir, Hakan, Hall & Kellar, Neuropharmacology, 1985). In the current experiments minnows were placed in 20 x 20 cm testing containers. The floor of each container was marked so that 4 equal quadrants were defined. Twelve of these containers were simultaneously monitored from above by a video camera. Each tank contained 1500 ml of dechlorinated tap water at room temperature. After a 10 min drug-free adaptation period, nicotine (1 mg/l), mecamylamine (5 mg/l) or hexamethonium (10 mg/l) was added to some of the containers. Behavior was then recorded for ten minutes on a videocassette. Subsequently, the activity of each fish was indidivually scored in terms of quadrant entries.

Fish exposed to no drug made an average of 28.8 quadrant entries (+/- 3.9) in the 10-minute test period. Fish exposed to nicotine made almost ten times as many quadrant entries (247.5, +/- 11.8). The fish given mecamylamine and nicotine showed no significant increase in activity relative to controls, whereas fish given hexamethonium plus nicotine showed a large increase in activity similar to that seen with nicotine alone. Mecamylamine and hexamethonium are both classical nicotinic antagonists, but hexamethonium does not readily cross the mammalian blood-brain barrier. The current results imply that the minnow's blood-brain barrier also limits uptake of hexamethonium, and that this dramatic behavioral effect of nicotine is mediated by drug action within the central nervous system.

378.4 CHOLINERGIC INVOLVEMENT IN THE BEHAVIORAL ACTIONS OF FORMETANATE, A FORMAMIDINE PESTICIDE. V.C. Moser and R.C. MacPhail*. Neurotoxicology Division, U.S. Environmental Protection Agency, Research Triangle Park, NC 27711.

Formetanate (FMT) is a formamidine acaricide/insecticide which also has a carbamate moiety in its molecular structure. FMT-induced lethality is reportedly due to an inhibitory action on acetylcholinesterase (AChE, EC 3.1.1.7; see Knowles and Ahmad, Pest. Biochem. Physiol. 1:445-452, 1972). We set out to determine its monoamine oxidase (MAO; EC 1.4.3.4) inhibitory properties (a common feature of formamidines) as well as its AChE inhibitory actions and to examine in rats the neurochemical basis for the sublethal, behavioral effects of FMT.

In rat brain homogenates, FMT inhibited AChE at concentrations $\geq$0.03 µM, with a IC50 of 0.14 µM. FMT also inhibited MAO in vitro, and was selective for type A MAO. Inhibitory concentrations were $\geq$10 µM with an IC50 of 86.2 µM. Type B MAO was slightly inhibited only at higher concentrations (>1 mM). Thus, FMT was a more potent inhibitor of AChE in vitro, even though it did efficaciously inhibit MAO-A.

For in vivo measurements, rats were dosed i.p. either with FMT (1 mg/kg) and sacrificed 0.5-24 hr post-injection (N=5/time point), or with FMT (0.03-5.6 mg/kg; N=5/dose) and sacrificed 1 hr later. AChE activity was inhibited maximally at 0.5-1 hr post-injection and had returned to control levels at 3 or more hr post-injection. The ED50 for AChE inhibition was 0.9 mg/kg. MAO-A and MAO-B activities were not inhibited by FMT in vivo.

Horizontally- and vertically-directed motor activity were decreased in rats (N=12) receiving $\geq$1 mg/kg FMT 20 min before testing. In rats (N=7) trained using milk reinforcement to lever-press under a multiple fixed-interval 1-min fixed-interval 5-min schedule, FMT 0.56 mg/kg (5 min before the 55 min session) produced a pronounced suppression of response rates. Injections of scopolamine (0.1 mg/kg) and methyl-scopolamine (0.1 mg/kg) 15 min before the FMT dose blocked the response rate suppression, whereas neither mecamylamine (2 mg/kg) nor hexamethonium (2 mg/kg) did. These data indicate that the behavioral effects of FMT on schedule-controlled responding are primarily mediated by central and peripheral muscarinic receptors. The similarity in the dose ranges for AChE inhibition and for disruption of both motor activity and operant responding, along with the ability of muscarinic antagonists to block the effects of FMT on operant responding, suggest that the behavioral effects of FMT are closely associated with inhibition of AChE.

378.5 EFFECTS OF INTRACRANIAL APPLICATION OF VARIOUS CHOLINERGIC DRUGS AND ESTROGEN ON LORDOTIC BEHAVIOR IN LONG EVANS RATS. L.S.Kaufman, D.W. Pfaff and B.S. McEwen. Labs of Neuroendocrinology and Neurobiology and Behavior, The Rockefeller University, New York 10021

Previous experiments have demonstrated that lordotic behavior in albino rats is mediated, in part, by cholinergic mechanisms (Clemens et al., Pharm. Biochem. Behav. 13:81, 1980; Kaufman et al., Neurosci. Abstr. 10, 1984). The goal of the present investigation was to study cholinergic mechanisms of lordotic behavior in the basomedial hypothalamus. Eighteen Long Evans female rats were ovariectomized and implanted under anaesthesia with bilateral cannulae that were stereotaxically placed in the basal hypothalamus; 5 days later, daily systemic injections of estradiol benzoate (EB) commenced. The females were then brought into sexual receptivity every third day with systemic injections of 500 ug progesterone (P) mixed in propylene glycol, and behavioral tests with sexually vigorous Long Evans males were conducted. During each test, lordosis quotients (LQs) were measured prior to drug administration and hourly for 4 hrs after. The order of drugs tested was varied for each rat. Additionally, the females' weights and gross startle responses were monitored approximately once a week. This procedure enabled us to study the effects of cholinergic antagonists scopolamine methyl bromide (S), atropine sulfate (A) and pirenzepine (P, an M1 blocker); the cholinergic agonist, carbachol (C); the nicotinic ganglionic blocker, hexamethonium (H); and different dilutions of E in cholesterol (1:75, 1:150, 1:250) on the lordotic behavior of exogeneously-primed female rats. The findings were: 1) S inhibited lordosis (L) in 13 rats ($\bar{X}$% inhibition = 71) and had no effect in 7 rats; 2) A inhibited L in 11 rats ($\bar{X}$% inhibition = 91) and had no effect in 1 rat; 3) C facilitated L in all 5 rats tested (maximal facilitation was from a baseline LQ of 0 to 100); 4) P had no effect on L in 5 rats tested; 5) H did not affect L in 4 rats, but had a slight inhibitory effect in 1; 6) 1:75 E + systemic P produced L in 10 out of 13 rats tested ($\bar{X}$LQ = 90); 7) 1:150 E + P produced L in 3 out of 10 rats ($\bar{X}$LQ = 80); 8) 1:250 E + P did not produce lordotic behavior in any of 7 rats tested. Additionally there were no significant changes observed in the weight and startle responses of the female rats. The latency to the onset of behavioral effects after drug application occurred within 1 hr. In 3 rats, the effects of S, A and P were tested in each animal. In 3 other rats, the effects of C, A and S were tested in each animal. Carbachol facilitated L while A and S inhibited it in the same rats. The latencies to the onset of both behavioral effects were similar. (<1hr). These data demonstrate robust cholinergic effects on L in the basomedial hypothalamus of rats.

Supported by HDO6425 and NSO7080. We would like to thank the Boehringer-Ingelheim pharmaceutical co. for generously supplying us with pirenzepine.

378.6 INTRAHIPPOCAMPAL INJECTIONS OF PIRENZEPINE SELECTIVELY IMPAIR REPRESENTATIONAL MEMORY. W.S. Messer, Jr., W.P. Hoss and G.J. Thomas. Center for Brain Research, University of Rochester School of Medicine and Dentistry, Rochester, N.Y. 14642.

Pirenzepine, a novel muscarinic antagonist, distinguishes subtypes of muscarinic receptors within the rat brain on the basis of affinity. High affinity pirenzepine sites (termed $M_1$) are found in highest concentrations in the forebrain, while low affinity sites ($M_2$) predominate in the brainstem. The distribution of pirenzepine binding sites appears quite distinct from the binding profile for muscarinic agonists such as carbamylcholine. The functional significance of the selectivity of pirenzepine for lower affinity agonist sites is not well understood.

In an earlier study (Messer et al., Soc. Neurosci., 1983), we measured the effects of intracranial and intraperitoneal injections of scopolamine (a classical muscarinic antagonist) on the performance of a representational memory task (a kind of alternation). Although systemic injections of scopolamine decreased the percentage of correct responses, running times were also affected and the deficit could not be classified purely as a representational memory impairment. Hippocampal injections of the drug were more effective in selectively producing representational memory deficits, although some animals still showed marked increases in response times, perhaps due to diffusion of the drug to surrounding areas. The present study measures the effects of pirenzepine on the performance of the representational memory task to determine if a ligand with higher selectivity for the hippocampus would be more effective in producing representational memory deficits.

Rats were trained to perform a representational memory task in a T-maze. Repeated exposures to the maze and the food habituated the animals to the test environment. Once the animals demonstrated proficiency in the maze, they were anesthetized and implanted stereotaxically with cannulae aimed at left and right hippocampi. Animals were given one week to recover from surgery before being injected with saline bilaterally to provide a control from which to compare the effects of pirenzepine injections. While injections of saline failed to produce an impairment of performance on the representational memory task, bilateral injections of pirenzepine (0.5 µl of 69.1 mg/ml pirenzepine in saline in each injection) into both hippocampi caused a significant ($p < .001$) reduction in the percentage of correct responses (71%). Rats also were impaired (73%) following an injection of saline on the subsequent day. Running times were not affected on either day, indicating that the deficit was due to an impairment of representational memory processing. Tolerance developed rapidly as shown by the failure of subsequent injections of either pirenzepine or saline to impair performance. The data indicate that pirenzepine acts selectively on hippocampal muscarinic receptors involved in representational memory processing, as was predicted from examination of high affinity binding sites in the rat brain.

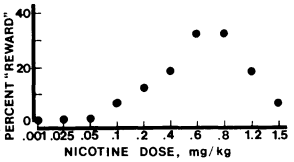
378.7 THE MOUSE PORSOLT BEHAVIORAL DESPAIR TEST: ACTIVITY OF CHOLINERGIC AGONISTS AND ANTAGONISTS. R.E. Chipkin* and B.A. Marasca* (Spon: N. Eisenstein). Schering Corp., 60 Orange St., Bloomfield, NJ 07003.

The Porsolt swim test uses drug-induced decreases in an animal's immobility as a measure of antidepressant (AD) activity and has been proposed as a potential screening procedure for these drugs. In this lab, the test is conducted in the following manner: mice are injected with either vehicle or drug and 60 min later placed in a circular tank (diameter = 14.5 cm) filled with water to a depth of 11 cm. The mouse is permitted to swim for 2 min and then the total time spent immobile during the following 4 min is measured. Typical ADs like desipramine (DMI) and MAO inhibitors reduce immobility times (ITs) in this test relative to vehicle-treated control animals, e.g., the minimal effective dose (MED) to produce a significant ($P<.05$) decrease in ITs for DMI is 30 mg/kg ip and for tranylcypramine is 15 mg/kg ip. However, atypical ADs such as trazodone and mianserin are inactive in this test and at high doses (MED > 10 mg/kg ip) increase ITs. The test might still be useful for screening if it only missed these "true positives". Unfortunately, a variety of agents from diverse pharmacological classes without clinical AD activity can also reduce ITs and as such are false positives. For example, it is well known that muscarinic antagonists are active in this test (atropine's MED = 0.3 mg/kg ip). Unexpectedly, muscarinic agonists such as pilocarpine and oxotremorine are also active (MED = 0.1 and 0.03 mg/kg ip, respectively). Further, both nicotinic agonists (e.g., nicotine) and antagonists (e.g., mecamylamine) reduced ITs (MED = 0.1 and 1 mg/kg ip, respectively) as did cholinesterase inhibitors such as physostigmine (MED = 0.1 mg/kg ip). In general, a screening procedure that fails to identify known true positives has limited utility. Furthermore, a test that consistently targets false positives and cannot discriminate agonists from antagonists within the same class has the additional limitation of requiring multiple secondary tests to separate out drugs with the desired profile. In summary, these results suggest that the Porsolt swim test in mice should only be used as a broad, primary screen and by itself has little predictive power for identifying clinically useful ADs.

378.8 NICOTINE(NIC)-INDUCED CONDITIONED PLACE PREFERENCE (CPP): DOSE-RESPONSE, TEMPORAL REQUIREMENTS AND LACK OF TOLERANCE DEVELOPMENT. P.J. Fudala* and Edgar T. Iwamoto, Department of Pharmacology and Tobacco and Health Research Institute, Univ. of Kentucky, Lexington, KY 40536.

In order to substantiate our previous findings (PBB 22:237, 1985) that NIC causes "reward" and "aversion" in rats, experiments were designed to evaluate the dose-response and time-response of NIC, and the effects of repeated nicotine conditioning and testing in the CPP paradigm.

Methods. On alternate days for 6 da, adult male Sprague-Dawley rats were subcutaneously injected with either saline (SAL, 1 ml/kg) and placed in the preferred compartment, or injected with NIC (0.001-1.5 mg/kg) and placed in the non-preferred compartment of a 3-compartment CPP apparatus. Conditioning sessions were 20 min. On test day, rats ambulated between a central compartment and the two conditioning compartments for 15 min. The durations spent in the saline-paired (S) and drug-paired (D) compartments determined a "residence ratio", RR=(S-D)/(S+D), for each animal. After calculating 1 SD from the control group, drug-paired rats were categorized as exhibiting "reward" if their RR was 2 SD < the mean RR of saline controls. If RR (drug) > [2 SD+$\overline{RR}$ (control)], rats were categorized as exhibiting "aversion". The temporal relationship of NIC-induced CPP was examined by injecting rats with NIC 0.8 mg/kg or SAL at 0, 60 or 120 min prior to conditioning. To ascertain development of tolerance to NIC-induced reward, groups of rats were conditioned with NIC 0.8 mg/kg or SAL over the usual 7 da conditioning and testing period. After 2 da, this sequence was repeated, and after 2 more da, repeated a third time.



Results. Within the dose range of 0.2 to 0.8 mg/kg, NIC reward was positively correlated with dose. In contrast to our previous interpretations, no dose-relation was found for aversion. NIC reward diminished at the 1.2 and 1.5 mg/kg treatment levels. The time-response experiments indicated that animals administered NIC 60 or 120 min prior to conditioning exhibited neither reward nor aversion. The proportion of animals categorized as exhibiting "reward" and "no effect" did not change over the 3 testing sessions: proportion "reward" = 6/16, 6/16 and 9/16; proportion "no effect" = 9/16, 8/16 and 6/16. The data suggest that NIC is rewarding in the CPP paradigm, that the NIC reward cue occurs within 60 min of injection, and that tolerance apparently does not develop to NIC-induced reward. (Supported by the Kentucky Tobacco Research Board).

379.1 INFLUENCE OF $A_1$ NORADRENERGIC REGION STIMULATION ON THE NEURONAL EXCITABILITY OF THE MEDIAL PREOPTIC AREA (mPOA). Y.I. Kim*, C.A. Dudley and R.L. Moss. Dept. of Physiology, Univ. Texas Hlth. Sci. Ctr., Dallas, TX 75235.

Norepinephrine (NE) in mPOA has been implicated in the control of several physiological functions including gonadotropin secretion. One of the major noradrenergic inputs to mPOA has been shown to be the $A_1$ noradrenergic cell group of the caudal medulla. The role of the $A_1$ cell group in controlling the excitability of mPOA and septal neurons was studied with electrophysiological methods in urethane (1.3 mg/kg, IP) anesthetized, ovariectomized female Sasco rats (240-340 g). A multi-barrelled glass microelectrode was used for extracellular recording of single units and iontophoretic application of drugs. Peri-stimulus histograms were generated to evaluate the effect on cell firing of paired cathodal monophasic pulses (50-120μA, 0.1-0.2 msec duration, 20 msec intrapair interval) delivered to the $A_1$ region through a stainless steel bipolar electrode (0.2-1.0 Hz frequency range). For antidromic identification of mPOA-septal cells projecting to median eminence (ME) biphasic pulses (1-2 mA, 0.2 msec duration) were applied to ME. At the end of each experiment histological verification of stimulating and recording sites was performed.

Of 71 cells recorded, stimulation of the $A_1$ region evoked orthodromic responses from 22 cells. Nineteen cells (86%) were excited whereas 3 cells (14%) were inhibited. These 3 inhibited cells were not further analyzed. Of the 19 excited cells one was activated antidromically from ME stimulation. Excited cells displayed a short latency (46.2±8.7 msec, mean±S.E.M.) and a relatively long duration ($\bar{x}$=300.7±54.0 msec) response. Effects of sotalol (β-noradrenergic antagonist) on these stimulus-bound excitations were assessed in 13 excited cells by applying the drug iontophoretically during generation of a "sotalol" histogram. The ratio between firing rates during the response epoch and during the period of spontaneous discharge was calculated from the "sotalol" histogram and compared to that of its control histogram. Sotalol decreased the ratio in 7 cells and increased it in 1 cell. Iontophoresed NE effects on spontaneous firing rate were also tested in 6 of these excited cells and, additionally, in 5 cells unresponsive to $A_1$ region stimulation. In the excited cell group, spontaneous firing rate was affected by NE in two neurons (one increased, one decreased), whereas in the unresponsive cell group, only one neuron was affected (decreased).

The results suggest that the predominant effect of $A_1$ noradrenergic input on the mPOA-septal cells is excitatory, that mPOA-septal cell(s) projecting to ME can be influenced by $A_1$ region stimulation, and that sotalol may block the stimulus-bound response by acting on the noradrenergic receptors. Studies involving α-noradrenergic antagonist are presently in progress to further characterize the noradrenergic receptors. Supported by NIH grant NS-10434.

379.2 Effects of Ventral Medial Preoptic Nucleus (vMPN) and Suprachiasmatic Nucleus (SCN) Lesions on the LHRH Neuronal System of the Female Rat. O.K. Ronnekleiv, M.J. Kelly and B.R. Naylor*, Dept. of Physiology, Oregon Health Sciences University and Oregon Regional Primate Research Center, Portland, OR 97201.

Lesions of the SCN or vMPN disrupt the estrous cycle of the female rat and prevent the preovulatory surge of LH and PRL. It is not known whether these lesions affect both the synthesis and/or release of brain peptides (e.g. LHRH) that control the preovulatory surge of the pituitary hormones. We designed the present study to determine the effects of discrete lesions of the SCN or vMPN on LHRH neurons of the female rat. We made bilateral electrolytic lesions by passing 1-5 μA current for 3 min. through Wood's metal electrodes (70μm tip; 2-10 MΩ). Vaginal cytology and hormonal profiles of LH, PRL, estrogen and progesterone were assessed for each individual animal (see Dykshoorn et al., Soc. Neurosci. Abstr., Vol. XI, 1985). Two to three months following the lesions, control (N = 8) and lesioned-animals (N = 8) were perfused intracardially with 500-600 ml of 4% paraformaldehyde in phosphate buffer. We cut the brain into 50 μm coronal sections on a vibratome and processed the tissue for LHRH-immunocytochemical staining using the PAP method and a high titer, conformational antiserum (EL-14) which recognizes the mature decapeptide (Ellinwood et al., Peptides 6:45-52, 1985). The number of LHRH neurons between the septal area (Konig and Klippel:A9410) and caudal medial basal hypothalamus (MBH; K&K:A3750) were counted in alternate sections and extrapolated to the total number of neurons for all sections. Other sections were used for immunocytochemical controls. Faintly stained LHRH neurons were observed in both the POA and MBH in all animals at all stages of the cycle. The number of immunoreactive cell bodies varied from a high of 595 in animals sacrificed on the morning of proestrus, to a low of 41 in animals sacrificed on estrus ($\bar{x}$ = 279 ± 84; N = 8). In contrast, the constant estrous animals with lesions showed an increased density of LHRH neurons rostral, lateral, and caudal to the lesion. Qualitatively, the intensity of staining was more dense in neurons throughout the POA-MBH, and quantitatively the numbers ranged from 575 to 980 cells per animal ($\bar{x}$ = 779 ± 41, N = 8; $p<.001$ vs. control). Moreover, all lesioned animals exhibited intense fiber stain in the median eminence region. Together, these data indicate that the lesion-induced constant estrous female rat is capable of synthesizing LHRH, but the neural signal for its release is disrupted. 379.3 STIMULATORY EFFECT OF GABA AND A GABA AGONIST ON LUTEINIZING HORMONE-RELEASING HORMONE (LHRH) RELEASE FROM HYPOTHALAMIC FRAGMENTS IN VITRO. C. Masotto* and A. Negro-Vilar (SPON: N. Kreisman). Reproductive Neuroendocrinology Section, Lab. Reprod. Dev. Tox., NIEHS, NIH, Research Triangle Park, NC 27709.

The neurotransmitter γ-aminobutyric acid (GABA) is found in high concentration in the hypothalamus and has been reported to be involved in the control of anterior pituitary hormone secretion. The role of GABA and its analogs in the regulation of gonadotropin secretion has not yet been fully clarified, with some studies suggesting a stimulatory effect of GABA on LH secretion, while others favoring an inhibitory role. In terms of the site of action, however, the scant evidence available seems to indicate a central (hypothalamic) site. In order to explore in more detail these issues, we performed experiments to evaluate the direct effect of GABA and its specific agonist, muscimol, on LHRH release in vitro. Adult intact male Sprague-Dawley rats served as tissue donors. A hypothalamic fragment consisting of the intact arcuate nucleus-median eminence region (ARC-ME) and surrounding structures was dissected and incubated in vitro in a Krebs buffer. LHRH release was evaluated during a 30-minute incubation period following a 30-minute preincubation. GABA and muscimol at the concentration of $10^{-4}$M significantly increased LHRH release. Different concentrations of muscimol ($10^{-6}$ to $10^{-4}$M) produced graded increases in LHRH release. In addition, the effects of muscimol were completely blocked in the presence of the specific GABA receptor antagonist, bicuculline. Addition of bicuculline to the incubates in the absence of the agonist did not affect basal release of LHRH. These results provide evidence supporting a stimulatory role of GABA on LHRH release and, indirectly on gonadotropin secretion. Further, the results also suggest that GABA-ergic receptors located within the arcuate-median eminence region are stimulatory to LHRH release. Since GABA is in general an inhibitory neurotransmitter, the data may indicate that its effects are possibly mediated by interacting with another inhibitory neuron located within this region. Recent studies from our laboratory indicate that blockade of opiate receptors in ARC-ME fragments in vitro results in a stimulation of LHRH release. Therefore, we hypothesize that GABA may interact with this or other inhibitory systems within this region to modulate LHRH secretion.

379.4 GNRH SECRETION IN VITRO: INTERACTIONS BETWEEN ESTROGEN AND NOREPINEPHRINE DURING DEVELOPMENT. R.W. Clough, C.D. Sladek and G.E. Hoffman. Dept. of Anatomy and Neurology, University of Rochester School of Medicine and Dentistry, Rochester, NY 14642.

Evidence from both in vivo and in vitro studies suggest that secretion of gonadotropin releasing hormone (GNRH) is controlled by a catecholaminergic system. It is also recognized that estrogen plays a major role in control of anterior pituitary gland gonadotropin secretion in females. In addition, catecholamine neurons have been found to sequester tritiated estrodiol while GNRH neurons have not. Our present studies are designed to investigate the complex interactions between estrogen, catecholamines and GNRH release from preoptic area-mediobasal-median eminence (POA-MBH-ME) explants in an in vitro perifusion system. Series one: Adult female rats were ovariectomized (ovx'ed) two weeks prior to receiving a subcutaneous injection of estradiol benzoate (EB, 10 ug/rat) or an oil vehicle. At 1100 hours, two days following EB, rats were decapitated, brains were excised and the POA-MBH-ME explants were placed into individual 500 ul incubation chambers. Six microchambers were perifused simulataneously with tissue culture media (Gibco, F12) at a flow rate of 20 ul/minute. Effluents of the chambers were collected in 15 minute fractions and GNRH concentration was measured by specific radioimmunoassay. The POA-MBH-ME explants were exposed to norepinephrine (NE) pulses of known concentration and duration. Near completion of each series, the explants were perifused with a pulse of 57 mM potassium chloride to assess their viability. NE induced a significant increase in GNRH release from explants taken from ovx'ed animals both with and without EB replacement ($p$ .05). However, following termination of the NE pulse, the oil treated group did not return to the prestimulus baseline while the EB treated explants showed an immediate return to baseline. Series two: Prepuberal female rats were administered EB or oil vehicle on day 25 after birth in order to induce a proestrus-like gonadotropin surge on the afternoon of day 27. Prior to the expected gonadotropin surge, the POA-MBH-ME explants were excised as previously and placed into the multiple microchamber perifusion system described. NE was pulsed over the explants as in the previous series of experiments. In this series, NE induced a significant elevation in GNRH release from explants of EB-treated prepuberal females but had no effect on GNRH release from the non-EB treated prepuberal rat explants. These studies indicate that catecholamine mediated GNRH secretion is activated by prior exposure to estrogen; however, continued exposure to estrogen may not be required to maintain at least the stimulatory effect of NE on GNRH release. This interaction between EB, NE and GNRH release may be one of the mechanisms underlying the estrogen dependence of puberal activation of phasic pituitary gland gonadotropin secretion in females.

379.5 HYPERPROLACTINEMIA ATTENUATES OVARIAN STEROID INDUCED INCREASES IN SERUM LH LEVELS AND REGION-SPECIFIC SEROTONIN SYNTHESIS IN OVARIECTOMIZED RATS. ARE THESE EFFECTS RELATED? T. S. King, A. J. Carrillo and W. W. Morgan. Dept. Cellular Structural Biology, Univ. Texas Hlth. Sci. Ctr., San Antonio, TX 78284.

Hyperprolactinemia adversely affects reproductive function, presumably through an effect at the hypothalamic level (del Pozo et al., Obstet. Gynecol. 46: 539, 1975). Given the numerous published reports linking hypothalamic serotonin (5-hydroxytryptamine: 5HT) mechanisms to the regulation of gonadotrophin secretion (see: Kalra and Kalra, Endocr. Rev. 4:311, 1983), we sought to determine the effects of experimentally-induced hyperprolactinemia on ovarian steroid-induced increases in serum LH levels and region-specific hypothalamic 5HT synthesis in ovariectomized rats. In the first study, bilaterally ovariectomized Sprague-Dawley rats either received two pituitary homografts implanted beneath the left kidney capsule or were sham-grafted. Both groups of rats were injected s.c. with 5µg · $100g^{-1}$ of estradiol benzoate ($E_2$) in corn oil vehicle at 0800h, one and two days before serum collection and 5 $mg \cdot 100g^{-1}$ of progesterone (P) in corn oil vehicle at 0700h on the day of serum collection. Blood samples were collected via chronic jugular cannula from each rat at 1000h, 1200h, 1300h, 1400h, 1600h and 1800h. A statistically significant elevation in serum LH levels was detected at 1300h, 1400h and 1600h. This increase in serum LH levels was significantly attenuated in rats bearing pituitary-homografts, an effect attributed to the high serum PRL levels measured in these animals. In the second study, bilaterally ovariectomized Sprague-Dawley rats were divided into three experimental groups: (1) rats bearing two pituitary homografts and injected with $E_2$ and P on the schedule and at the dosages previously described, (2) sham-grafted rats injected with $E_2$ and P on the schedule and at the dosages previously described and (3) sham-grafted rats injected with corn oil vehicle only. The rats were then injected i.v. with 100 $mg \cdot kg^{-1}$ of NSD-1015 six hours after P injection and 30 min prior to killing the rats. Accumulation of 5-hydroxytryptophan in various hypothalamic areas was then assayed by LCED as a relative index for the level of 5HT synthesis. Administration of these ovarian steroids produced an increase in estimated 5HT synthesis in the preoptic area-anterior hypothalamus (POA-AH) but not in the median eminence or mediobasal hypothalamus. The $E_2$ + P induced increase in 5HT synthesis in the POA-AH was significantly blunted in rats with pituitary homografts. Considering the postulated role a 5HT mechanism within the POA-AH plays to facilitate ovarian steroid-mediated surges in LH secretion, hyperprolactinemia may inhibit LH secretion through its attenuation of ovarian steroid stimulation of 5HT synthesis in the POA-AH. 379.6 ROLE OF CATECHOLAMINES AND OPIATES IN STIMULATION OF LH RELEASE BY NEUROPEPTIDE Y (NPY). L.G. Allen*, W.R. Crowley* and S.P. Kalra, (SPON. B. Cooper) Dept. OB-Gyn, Univ. Fla. Col. Med., Gainesville, FL 32610 and Dept. of Pharmacol., Univ. Tenn. Col. Med., Memphis, TN 38163

We have shown that intraventricular NPY (0.5-10 µg/rat) stimulated LH release in estradiol benzoate, progesterone (EBP)-primed ovariectomized rats in a manner similar to that reported for norepinephrine (NE) and epinephrine (E). Because of the neuronal coexistence of NE, E and NPY and the close anatomical relationships between NPY, opioids and LHRH neurons in the hypothalamus, we investigated the involvement of catecholamines and opiates in the NPY-induced LH response. Twelve days after ovariectomy and placement of permanent cannulae in the third ventricles, rats received EB (30 µg/rat) and P (15 mg/rat). Two days later, catecholamine receptor antagonists or synthesis inhibitors were administered prior to Ivt NPY injection. Blood samples were withdrawn through indwelling atrial catheters prior to and at 10, 20, 30 and 60 min after Ivt NPY. NPY (2 µg, previously shown to evoke maximal LH response) significantly stimulated LH release in the EBP rats; peak levels at 10 min and significantly high LH levels were evident at 20 and 30 min. $\alpha_1$-adrenergic receptor antagonist, prazosin (1 or 3 mg/kg), ß-adrenergic receptor antagonist, propranolol (10 mg/kg) or dopamine receptor antagonist, pimozide (0.63 mg/kg) failed to block the NPY-induced stimulation of LH release. In fact, the high dose of prazosin potentiated the NPY-induced LH response. Rats pretreated with phentolamine (10 mg/kg) failed to show LH stimulation after NPY administration, but a subsequent study revealed that phentolamine on its own stimulated LH release. Prior suppression of hypothalamic E stores with a PNMT inhibitor LY 78335, 2,3-dichloro-methyl-α-benzylamine (50 mg/kg), delayed the NPY-induced LH response; a significant LH rise was evident only at 20 min. However, suppression of NE and E levels by a DBH inhibitor, diethyldithiocarbamate (550 mg/kg), suppressed LH release elicited by NPY. Stimulation of opiate receptors with morphine (20 mg/kg, s.c.) failed to block the NPY-induced LH response. These studies show that stimulation of LH release by NPY may occur independently of postsynaptic adrenergic or opiate receptor mediation. However, the findings that NPY stimulation of LH release was delayed or interrupted by catecholamine synthesis inhibitors, suggest that a complex interaction between hypothalamic NPY and adrenergic neurons may be involved in the regulation of LH release. (Supported by NIH HD 08634).

379.7 ROLE OF CENTRAL SEROTONIN SYSTEMS IN THE STIMULATORY EFFECTS OF OVARIAN HORMONES AND NALOXONE ON LH RELEASE IN FEMALE RATS. M.D. Johnson* and W.R. Crowley. Dept. of Pharmacology, University of Tennessee, Memphis, TN 38163

The present experiments tested whether serotonergic neurons that innervate discrete areas of the hypothalamus are involved in the stimulation of LH release by ovarian hormones or by the opiate antagonist, naloxone. Two weeks after ovariectomy, rats received either oil vehicle or estradiol benzoate (EB). Forty eight hours later, one group of EB-treated rats was decapitated; the remainder received either oil vehicle or progesterone (P) and were decapitated three or six hours later. Thirty minutes prior to sacrifice, half the animals in each hormone treatment group received saline, while the other half received the monoamine oxidase inhibitor, pargyline HCl. LH was measured in serum by radioimmunoassay. Discrete hypothalamic nuclei were removed by the microdissection technique, and serotonin (5-HT) was measured by liquid chromatography with electrochemical detection. Two days after EB, LH concentrations were reduced in the morning, but rose by late afternoon. Administration of P to EB-primed rats stimulated an afternoon LH surge. EB plus P treatment also enhanced the pargyline-induced accumulation of 5-HT, suggesting increased 5-HT activity, in the medial preoptic nucleus and interstitial nucleus of the stria terminalis. EB plus P treatment decreased 5-HT accumulation in the ventromedial nucleus, suggesting decreased serotonergic activity. 5-HT levels or accumulation after pargyline were unchanged after EB alone. Ovarian hormones did not affect 5-HT in the arcuate - median eminence region. The administration of naloxone (10 mg/kg) to EB-primed rats also stimulated LH release one hour later, but did not affect 5-HT concentrations or the pargyline-induced accumulation of 5-HT in any of the nuclei dissected. To test the relationship of the ovarian hormone-induced changes in 5-HT activity to the stimulation of LH release, the indoleamine neurotoxin, 5,7-dihydroxytryptamine (5,7 DHT) was microinjected into the preoptic area to deplete 5-HT locally. Such treatment blocked the LH surge induced by EB plus P, in association with decreased 5-HT and unchanged catecholamine levels in the preoptic area.

The present results suggest that 1) central 5-HT neurons innervating the preoptic area are important for the estradiol/progesterone-induced LH surge, 2) changes in 5-HT activity may not mediate the inhibitory or stimulatory effects of estradiol alone on LH release, and 3) endogenous opioids may not affect LH secretion via an interaction with central 5-HT systems.

379.8 CHRONIC MORPHINE TREATMENT ENHANCES THE POSITIVE AND NEGATIVE FEEDBACK EFFECTS OF ESTRADIOL ON GONADOTROPIN SECRETION IN OVARIECTOMIZED RATS. S.M. Gabriel, L.A. Berglund* and J.W. Simpkins, Dept. of Pharmacodynamics, College of Pharmacy, University of Florida, Gainseville, FL 32610.

The influence of endogenous opioid containing neurons on the feedback regulation of gonadotropin secretion was evaluated using female rats. Rats, ovariectomized for 2 weeks, were chronically exposed to morphine (75 mg freebase, s.c. implants, plus 2 additional implants every 2 days) or placebo treatments. After 2 days of morphine exposure, rats were given silastic implants containing 17-ß-estradiol (E2). The silastic implants were 10 mm E2, 5 mm E2 or 5 mm tubes filled with E2 which had been first diluted in half with cholesterol. Serum LH concentrations were determined in blood samples taken in the morning (1000h) and afternoon (1600h) at 2 days after the E2 treatment. E2 implants alone caused a dose-dependent decline in serum LH concentrations at 1000h and each dose caused a midafternoon surge in LH. Chronic morphine treatment alone was ineffective in altering morning levels of LH but it further reduced morning levels of LH when combined with each of the 3 doses of E2. Similarly the midafternoon surge in LH was enhanced by the combination of morphine plus each dose of E2. A detailed time course revealed that chronic morphine exposure advanced the time of onset and increased the magnitude of the E2-induced LH surge. After 4 days of exposure to E2, chronic morphine treatment continued to enhance the inhibitory, but not the stimulatory, effects of E2 on LH secretion. Similar, albeit less pronounced, effects of chronic morphine treatment on the inhibitory and stimulatory action of E2 on FSH secretion were observed. These results indicate that morphine enhances both the negative and positive feedback effects of E2 on gonadotropin secretion in the female rat and suggest that endogenous opioid peptides may play a role in altering the set point of the brain gonadostat. Supported by NIH grants AG02021 and HD14075 to JWS and AM7561 to SMG.

379.9 A SEX DIFFERENCE IN NEUROENDOCRINE MECHANISMS REGULATING THE ACUTE PITUITARY FOLLICLE-STIMULATING HORMONE RESPONSE TO CASTRATION. P.V. Berardo* and L.V. De Paolo* (SPON:A. Carrillo). Dept. of Physiol., Univ. Tx. Hlth. Sci. Ctr., San Antonio, TX 78284.

It is well known that acute pituitary gonadotropin responses to castration differ between male and female rats. Whereas increases in plasma levels of LH and FSH levels occur within 12h after orchidectomy (ORDX), only FSH levels are increased immediately after ovariectomy (OVX). Therefore, the following experiment was conducted to ascertain the role of the central nervous system in mediating pituitary FSH responses to ORDX and OVX in hopes of identifying a possible sex difference in central mechanisms controlling these responses. Adult male rats and 4-day cycling female rats on diestrus-1 were injected i.p. with either phenobarbital sodium (Pb, 80 mg/kg BW) or vehicle at 0800h. Following a blood collection at 1000h, rats given barbiturate or vehicle were either sham-castrated or castrated under ether. Additional blood samples were obtained at 3,8,13,18 and 24h after castration. Supplemental injections of Pb or vehicle were given at these times. Plasma levels of LH and FSH were measured by RIA. Compared to sham-castrated rats, plasma LH and FSH levels were elevated by 13h after ORDX. Increases in plasma levels of both gonadotropins after ORDX were completely prevented by Pb. In female rats, initial increments in plasma FSH levels occurred between 3 and 8h after OVX. However, in contrast to ORDX, Pb treatment did not prevent initial rises in plasma FSH levels at 8h after OVX and only partially suppressed elevated OVX-induced increases in plasma FSH levels between 13 and 24h. Plasma LH levels were not elevated by 24h after OVX.

In order to specifically evaluate the role of luteinizing hormone-releasing hormone (LHRH) in mediating the Pb-sensitive rises in gonadotropins after castration, groups of male rats and female rats on estrus were injected s.c. with 400 µg of a potent LHRH antagonist (ALHRH) or oil at 1200h. At 1000h on the next morning, an initial blood sample was taken and all rats were castrated under ether. Additional blood samples were taken as described in the previous experiment. Similar to Pb, ALHRH completely abolished ORDX-induced increases in circulating LH and FSH levels. In contrast to Pb, ALHRH partially suppressed increases in plasma FSH levels 8h after OVX, but like Pb, ALHRH partially suppressed FSH levels between 13 and 24h. The difference in results obtained in female rats using Pb vs. ALHRH may be attributed to an incomplete suppression of LHRH release by Pb.

These results clearly demonstrate that acute increases in plasma LH and FSH levels after ORDX are totally mediated by LHRH. In contrast, acute increases in plasma FSH levels after OVX are due to both an LHRH-dependent and LHRH-independent mechanism (i.e. increase in basal FSH secretion). (Supported by NIH grant HD-17807).

379.10 PHASE SPECIFIC STARVATION DURING THE ESTROUS CYCLE BLOCKS HAMSTER OVULATION. L.P. Morin. Dept. Psychiatry, SUNY, Stony Brook, NY 11794.

Reproductive capacity of female hamsters, as estimated by the ovulatory response, is particularly susceptible to interference by food deprivation. Previous studies (Printz & Greenwald, Neuroendocrinology 7:171, 1971; Morin, Biol. Reprod. 13:99, 1975) showed that hamsters generally fail to ovulate if deprived of food for one or two estrous cycles. The present studies demonstrate that starvation which is specific to the two days immediately following ovulation will block the next expected ovulation in about 80% of the animals.

When placed with vigorous males, food deprived animals which subsequently failed to ovulate also failed to show lordosis behavior at the expected estrous cycle time. With exogenous estradiol benzoate provided, animals showed short latency lordosis despite food deprivation. This suggests that endogenous estradiol levels are insufficient for behavior change. Starvation also resulted in significantly smaller ovarian follicle sizes. The preovulatory gonadotropin release pattern was altered by phasic food deprivation with the afternoon proestrous surge of LH apparently eliminated. FSH levels on the morning of proestrous were elevated compared to control levels. Efforts to facilitate ovulation with prolactin or gonadotropins given at several different estrous cycle times were not successful.

The results suggested that phasic food deprivation blocks a rather specific set of neuroendocrine events which retard follicular development. As a consequence, estradiol release is inadequate to prime the neuro-endocrine system for lordosis behavior and the ovulatory release of LH.

379.11 EVIDENCE FOR ALPHA$_2$ ADRENERGIC MEDIATION OF THE STIMULATORY EFFECTS OF ANGIOTENSIN II (AII) AND NOREPINEPHRINE (NE) ON LUTIENIZING HORMONE (LH) RELEASE IN FEMALE RATS. M.K. Steele and W.F. Ganong, Department of Physiology, University of California, San Francisco, 94143.

We have hypothesized that intraventricular (IVT) infusion of AII affects LH secretion by altering brain NE release (Steele, et al, Neuroendocrinology 40:210, 1985). We have tested this hypothesis by observing the effects of AII on LH release in animals treated with either the alpha$_1$ adrenergic antagonist, prazosin (1.0 mg/kg, i.p.) or the alpha$_2$ adrenergic blocker, yohimbine (3.5 mg/kg, i.p.). Animals infused IVT with NE were also tested.

Ovariectomized rats, implanted with a cannula aimed at the third cerebral ventricle, were treated s.c. with estradiol benzoate (50 ug) and progesterone (25 mg) 72 h prior to use in experiments. A jugular cannula was inserted 24 h prior to blood collection. On the day of the experiment, a "basal" blood sample (100 µl whole blood) was withdrawn, followed immediately by injection of prazosin, yohimbine or saline vehicle. Continuous whole blood samples (100 µl/15 min) were withdrawn via peristaltic pumps for 1.5 h, at which time a 30 min infusion of artificial cerebrospinal fluid (aCSF, 25 µl/h), AII (600 ng/25 µl/h) or NE (15 ug free base/ 25 µl/h) was begun. Blood withdrawal continued during and for 1.0 h following the IVT infusion. Whole blood concentrations of LH were determined by RIA. Water intake was also monitored in these experiments.

Both prazosin and yohimbine produced moderate increases in blood LH levels at 30 and 60 min, which returned to baseline by the start of the IVT infusions. Prazosin administration did not affect either the AII- or NE-induced increase in blood LH levels. Yohimbine treatment, on the other hand, prevented the rise in blood LH produced by AII and by NE infusion.

Infusion of AII increased water intake compared to aCSF or NE administration. Neither prazosin nor yohimbine treatment modified water ingestion due to AII. During the 1.5h preinfusion time period, yohimbine alone increased water intake compared to treatment with prazosin alone.

These data suggest that the stimulation of LH release induced by AII and by NE in steroid-treated female rats is mediated by an alpha$_2$ adrenergic mechanism.

(Supported by USPHS grants HD18020 and HL29714).

379.12 EVIDENCE THAT VASOACTIVE INTESTINAL PEPTIDE IS SYNTHESIZED IN ANTERIOR PITUITARY TISSUE. M.A. Arnaout,* D.R. Martinson,* T.C. Hagen,* T.L. Garthwaite. VA Medical Center and the Medical College of Wisconsin, Milwaukee, WI 53193.

Vasoactive intestinal peptide (VIP) is a putative hypothalamic prolactin (PRL) releasing factor based on its presence in the hypothalamus, its release into hypophysial portal blood, and its ability to release prolactin from anterior pituitary tissue in vitro. Although several studies have demonstrated that VIP is also present in the anterior pituitary, the origin and functional role of pituitary VIP are unknown. Our observation that anti-VIP antiserum attenuates the basal release of PRL from cultured anterior pituitary cells suggests that VIP may be synthesized in the pituitary and may exert local effects on PRL release. We report here evidence for intrapituitary synthesis of VIP.

Quartered anterior pituitaries from male rats were washed with Medium 199 and incubated in leucine-free Eagle's media containing 14 µCi/ml $^3$H-leucine for 2 hours. These labeled pituitaries were studied further by a combination of gel chromatography, immunoprecipitation with anti-VIP antiserum, or perifusion.

The incorporation of the $^3$H-leucine label into cell proteins was assessed using Sephadex G-50F gel exclusion chromatography of pituitary homogenates. The majority of the label was found in or near the void volume fractions with a smaller peak of activity coeluting with synthetic porcine VIP. Immunoprecipitation of labeled pituitary homogenates revealed significantly ($p < 0.025$) greater precipitation of the label with anti-VIP antiserum than with non-immune rabbit serum.

Incorporation of $^3$H-leucine into releasable products was assessed by perifusion of labeled pituitaries for 2 hours with Medium 199 at a rate of 2 ml/15 min. followed by a 1 hour perifusion with Medium 199 containing 56 mM KCl. Immunoprecipitation of the KCl-stimulated perifusate fractions obtained significantly greater radioactivity with anti-VIP than with non-immune rabbit serum ($p < 0.025$). Gel chromatography of the KCl-stimulated perifusate revealed two peaks of activity. One peak coeluted with synthetic VIP and contained VIP immunoreactivity by RIA.

Conclusions: VIP appears to be synthesized in anterior pituitary tissue as suggested by a) coelution of labeled peptides from pituitary homogenates and KCl-stimulated perifusates with synthetic VIP, b) immunoprecipitation of labeled peptides from homogenates and perifusates by specific anti-VIP antisera, and c) release of immunoassayable VIP in response to KCl-induced depolarization.

379.13 HYPOTHALAMIC PROLACTIN- AND TYROSINE HYDROXYLASE-IMMUNOREACTIVE NEURONS IN PITUITARY PROLACTIN-DEFICIENT DWARF MICE. C.J. Phelps. Department of Anatomy, University of Rochester Medical Center, Rochester, New York 14642.

Prolactin (PRL)-immunoreactive cells have been described in the hypothalamus of rats (Toubeau et al., J. Endocrinol. 83:261, 1979): these neurons have extensive projections both rostrally and caudally (Shivers et al., SN Abs. 9:108, 1983). CNS production of prolactin implies a genetic question regarding differentiation of pituitary and brain hormone expression. Snell dwarf mice are hypopituitary homozygous recessive mutants which neither translate nor transcribe pituitary PRL, although the PRL gene is intact (Slabaugh et al., Mol. Cell. Endocrinol. 28:289, 1982). Tuberoinfundibular dopamine (DA) is also severely deficient (Morgan et al., Endocrinol 109:2069, 1981; Phelps et al., Cell Tiss. Res., 1985). The present study was undertaken to determine whether hypothalamic PRL or tyrosine hydroxylase (TH) immunoreactivity exist in dwarf (dw/dw) and normal (DW/?) mice of the same strain (DW/J). Brains of young adult mice were processed by intracerebroventricular colchicine pretreatment and vascular perfusion with Zamboni's fixative. Coronal sections (30 um) were processed for PRL immunocytochemistry (ICC) using NIADDK anti-mouse PRL, 1:2000. Specific staining was abrogated by 1) substitution of non-immune serum for PRL antiserum, and 2) pre-absorption of the antiserum with 1.0, but not 0.1, $\mu$M mouse PRL (AFP-4111-E). The PRL antiserum has <1% crossreactivity with other mouse pituitary hormones (A.F. Parlow). TH ICC was performed on adjacent sections, using Eugenetech anti-TH serum, 1:3000.

In the brains of DW/? and dw/dw littermates, PRL-immunoreactive fine-sized varicose fibres were particularly numerous throughout periventricular regions, reached rostrally to medial basal olfactory cortex and to lateral septum, ramified through the supraoptic commissure, to suprachiasmatic and supraoptic nuclei, and were extensive in paraventricular nuclei and in medial basal hypothalamus, extending to internal median eminence and proximal pituitary stalk. No differences in fibre pattern were observed between sexes or between DW/? and dw/dw mice. PRL-immunoreactive perikarya (up to 60 per section) were identified in hypothalamus, primarily in, and extending laterally from, ventral arcuate nucleus, but occasionally in PVN and SON. Cell bodies were less numerous and faintly stained in dwarfs, perhaps due to difficulty in effective colchicine treatment. TH immunoreactivity in cells and fibres of dwarf brains was similar to that in normal mice, except in the tuberoinfundibular DA (A12) region: fewer perikarya were stained, and axons at the ventrolateral border of the arcuate nucleus appeared tortuous and swollen.

These observations indicate that the PRL deficiency in Snell dwarf mouse pituitary does not affect CNS PRL expression, but that the morphology, as well as transmitter content, of tuberoinfundibular DA neurons is adversely affected in the condition.

379.14 EFFECT OF CYSTEAMINE (CSH) ON SUCKLING-INDUCED PROLACTIN (PRL) SECRETION IN THE RAT. Peter N. Riskind, William J. Millard, and Joseph B. Martin, Department of Neurology, Mass Gen Hosp, Boston, MA 02114.

We have previously reported that CSH administration severely attenuates basal and pharmacologically-induced PRL secretion in the rat. The present experiments investigated the effect of CSH on suckling-induced PRL release, to determine whether CSH also blocks physiologically-induced PRL secretion. Sprague-Dawley rats were implanted with Silastic right atrial catheters on days 14-17 of pregnancy. On the second day postpartum the mothers and their pups (6 pups/litter) were transferred to isolation/blood sampling cages. Blood sampling from the freely-moving unanesthetized rats was done as previously described (Endocrinology 114:1232, 1984) between days 13-16 postpartum. Suckling activity was confirmed by observation of the animals through a small viewing window. The first experiment determined the dose-response of CSH on suckling-induced PRL release. On the day of experimentation pups were removed from their mothers at 0:800 h (lights on from 0:800-20:00 h). At 10:00 h mothers were administered either CSH at doses of 30, 90, or 300 mg/kg, sc or ethanolamine (300 mg/kg, sc) as a control injection. Blood sampling was initiated at 11:30 h with samples taken every 15 min throughout the study. The pups were returned to their mothers at 12:00 h and sampling was continued for another 2 h. In both control animals and those receiving 30 mg/kg CSH, suckling caused a rapid elevation of plasma PRL with peak responses occurring at 60-75 min after returning the pups. No elevation of plasma PRL was found in animals which were administered either the 90 or 300 mg/kg doses of CSH, despite normal nursing behavior by the CSH-treated rats. Moreover, CSH did not acutely affect the amount of milk obtained by the pups, as determined by their weights before and after suckling. The second experiment investigated whether prior suckling, which reportedly causes "depletion-transformation" of pituitary PRL stores, prevents a subsequent inhibitory effect of CSH. Pups were removed from their mothers at 08:30 h, and returned for a 30-min suckling period beginning at 14:30. CSH 90 mg/kg, sc, was given immediately after the pups were removed, and 60 min later the pups were returned for a second 90-min suckling period. Despite previous suckling stimulation, CSH completely inhibited the PRL rise during the second nursing period. These results indicate that CSH administration inhibits physiologically-induced PRL secretion with similar potency and efficacy as previously reported for CSH effects on basal and drug-induced PRL secretion. Furthermore, the effect of CSH is not obviated by a previous suckling stimulus, suggesting that "depletion-transformation" (which presumably occurred) does not protect against the effect of CSH. Supported by grants HD-17364 and AM-32711.

379.15 INTRAVENTRICULAR CHOLECYSTOKININ OCTAPEPTIDE ELEVATES PLASMA PROLACTIN K. Tanimoto*, C.A. Tamminga, M. Knight and T.N. Chase, Experimental Therapeutics Branch, NINCDS, NIH, Bethesda, MD 20205 and Maryland Psychiatric Research Center, Baltimore, MD 21228

Cholecystokinin is found throughout brain, in the hypothalamus and brain stem as well as cortex and basal ganglia. Although its precise physiologic functions remain elusive, many central actions of the peptide have been elucidated. Because CCK-8 is colocalized with dopamine (DA) in certain mesencephalic neurons, the role this peptide might play in CNS DA-modulated functions like prolactin (PRL) secretion is of interest. Prolactin (PRL) release is regulated by a hypothalamic releasing factor and an inhibiting factor. Much evidence indicates that the PRL-inhibiting factor is dopamine. Although the identity of the PRL-releasing factor is uncertain, VIP and PHI are currently thought to be candidates. Therefore, we investigated the effect of CCK-8 on plasma PRL levels in freely moving rats which were implanted with chronic indwelling right atrial catheters.

Intravenous (iv) injections of CCK-8 (4 and 40 ng/rat, and 1 ug/rat) in the chronically cannulated rats did not alter plasma PRL levels. However, plasma PRL levels were significantly elevated following intracerebroventricular (icv) injection of CCK-8 @ 40 ng/rat and 400 ng/rat. Proglumide (0.2 mg/kg,iv) and benzotript (0.2 mg/kg,iv), specific antagonists of cholecystokinin, completely blocked the PRL release induced by CCK-8 (40 ng, icv). The CCK-8 induced rise in PRL was not apparent with haloperidol (0.2 mg/kg,iv), sulpiride (0.1 mg/kg, iv), domperidone (0.1 mg/kg,iv) or RO 22-1319 (0.1 mg/kg,iv). However, the inhibition of PRL secretion by apomorphine (0.1 mg/kg,iv) was significantly antagonized by CCK-8 (40 ng and 400 ng, icv). These results indicate that icv, but not intravenous administration of CCK-8 modifies PRL levels in plasma through its action on a central receptor, possibly by modifying the activity of hypothalamic PRL-releasing and/or inhibiting factor. Our data lead us to speculate that CCK-8 alters plasma PRL levels at a cholecystokinin receptor in the hypothalamus which regulates the PRL-releasing factor.

379.16 NEUROHORMONES INVOLVED IN PHOTOPERIOD- AND OPIATE-INDUCED PROLACTIN SECRETION. L. S. Leshin*, D. Kuehl*, K. K. Schillo*, and G. L. Jackson* (spon: E. J. Roy), Department of Veterinary Biosciences, University of Illinois, Urbana, IL 61801

In many species circulating prolactin concentrations can be elevated or depressed by exposure to long or short daily photoperiods, respectively. The purpose of this study was to determine which neurohormones mediate photoperiod-induced changes in prolactin secretion. Two groups of mature ovariectomized ewes were kept in photochambers under either short (8L:16D) or long (16L:8D) photoperiods for 60 to 90 days. Push-pull cannulae were stereotaxically positioned into the hypothalamic median eminence. After a 6- to 10-day recovery period, the ewes were subjected to hypothalamic perfusion and blood was collected from the jugular vein. Perfusate (21 µl/min) was collected continuously and divided into 15-minute fractions. Blood was collected from the jugular vein at 15-minute intervals starting 7.5 minutes after onset of perfusion. Perfusates were assayed for thyrotropin-releasing hormone (TRH) by radioimmunoassay and biogenic amines by HPLC-EC. Blood samples were assayed for prolactin. The first 1-2 hours of perfusion was a stabilization period. During the next 2 hours, saline was infused into one jugular vein. This was followed by a 2-hour infusion of morphine (1 mg/kg/hr) to acutely stimulate prolactin secretion and to determine if the hypothalamic factors measured during basal secretion also were affected. Location of cannulae tips was verified by histologic procedures. Data from 12 animals in which either the cannulae clogged during perfusion or TRH was undetectable in over 50% of samples were excluded from analysis. Data from 5 ewes kept under each photoperiod were analyzed. Long photoperiods significantly ($P < 0.01$) increased prolactin concentrations. Morphine significantly increased ($P < 0.01$) prolactin concentrations in sheep exposed to both short and long photoperiods (8L-Saline 51 ± 6 vs 8L-Morphine 175 ± 12 ng/ml; 16L-Saline 149 ± 13 vs 16L-Morphine 648 ± 71 ng/ml). TRH concentrations varied greatly among animals and may in part reflect cannulae location. Mean TRH levels tended to be higher under long photoperiods and during morphine treatment ($P < .10$) under both short and long photoperiods (8L-Saline 5.8 ± 0.7 vs 8L-Morphine 7.9 ± 0.9 pg/15 min; 16L-Saline 8.7 ± 1.3 vs 16L-Morphine 11.3 ± 2.1 pg/15 min). Detection of biogenic amines was quite variable and insufficient for pooled analysis. The metabolites DOPAC, HVA, and 5 HIAA were most commonly detected. Dopamine was rarely detected in samples that also contained TRH. The data suggest that neither photoperiod-induced nor opiate-induced increases of PRL are readily explained by enhanced TRH secretion from the median eminence. (USPHS Grant HD13037)

379.17 TIME DEPENDENT EFFECTS OF URETHANE ANAESTHESIA ON MILK EJECTION AND PLASMA PROLACTIN CONCENTRATIONS IN LACTATING RATS. D.W. McKay and K. Brown-Grant*. Fac. of Med., Memorial University of Nfld., St. John's, Newfoundland, Canada A1B 3V6.

Lactating rats anaesthetized with urethane (U) 180 minutes prior to pup application milk eject at regular intervals and show modest increases in plasma prolactin (PRL) concentrations over the next two hours. Similar rats anaesthetized with U plus xylazine (X) and suckled 30 minutes later exhibit milk ejections at rates double that observed in rats treated with U alone (McKay & Brown-Grant, Neurosci. Abstr. 9: 707, 1983). Despite the persistence of milk ejections and a continuous suckling stimulus over 120 minutes, concentrations of plasma PRL decreased rapidly.

The present study was performed to compare the effects of U alone and U plus X on the occurrence of milk ejection when pups were applied 30 minutes after the induction of anaesthesia. We also hoped to determine the effects of U and X on plasma PRL concentrations before and during suckling.

Long-Evans rats were anaesthetized with either 1.2g U/kg i.p. or 0.8g U/kg i.p. plus 10 mg X/kg i.m. on day 14 of lactation, and 10 hungry pups were applied to the nipples 30 minutes later and allowed to suckle for 120 minutes. Episodic release of oxytocin and the subsequent milk ejection (ME) were monitored by observing the synchronized stretch reactions of the suckling pups. In some animals, blood samples were taken through an intracardiac catheter which had been implanted on day 8 of lactation.

With U + X, all rats (n=10) had repeated milk ejections and the onset of ME occurred on average 2.4 minutes after pup application with an average incidence of 16 ME's for the 120 minute period of suckling. Of the animals treated with U alone, 8 of 11 had no ME's at all and the others had 1,1 and 2 respectively. There was no initial rise in PRL nor did PRL increase during suckling. Doses of 0.8g U/kg alone or 10 mg X/kg alone were not sufficient to anaesthetize lactating rats and we could not examine the ME reflex. X treatment led to elevated plasma PRL concentrations 15 minutes later (18 vs. 62 ng RP2/ml). Saline had no effect.

These findings suggest that timing may be a critical factor in studies on lactating rats under urethane anaesthesia. Milk ejections occur and PRL concentrations increase in rats suckled beginning 180 min after injection. When pups are applied at 30 minutes after induction of anaesthesia, ME's are rare and plasma PRL concentrations do not increase. The reasons for these differences or for the apparent facilitatory effect of X are at present unknown. The lack of ME does not appear to be due to a peripheral insensitivity to oxytocin. A bolus injection of 0.5 mU of oxytocin i.v. consistently induced stretch reactions in pups suckling either a U or U + X treated mother.

379.18 CIRCULATING GROWTH HORMONE (GH) LEVELS AND THE THYROTROPIN (TSH) RESPONSE TO THYROTROPIN-RELEASING HORMONE (TRH) IN DEPRESSED MEN. V.S.Wahby,M.D.,Ph.D., F.Saddik*, M.D., E.L.Giller,M.D.,Ph.D. and J.W.Mason,M.D.* VA Medical Center and Yale University, West Haven, CT 06516

PURPOSE: To find out whether circulating GH levels are related to a blunted TSH response to TRH in depressed men.

BACKGROUND: GH, via a short-loop feedback, may increase central somatostatin release, which may cause blunting of TSH response to TRH. Also, depression may be associated with blunting of that TSH response. It would be interesting to find out whether GH is implicated in this phenomenon of blunting of TSH response in depressed subjects. An initial step to evaluate this possibility is to see if there is a relationship between circulating GH levels and TSH response to TRH in this clinical condition.

METHODS: Fasting a.m. blood GH levels were determined and TRH tests (500 ug IV) were performed on 26 euthyroid men with major depressive disorder. None of the patients were diabetic, acromegalic, alcoholic, cirrhrotic or with other systemic illnesses. The incidence of depression was diagnosed by the Research Diagnostic Criteria (RDC) and its severity measured by the Hamilton Depression Scale (HDS). GH, TSH and thyroid hormones were measured by radioimmunoassay.

RESULTS: $\Delta$ TSH Maximal was 5.9 $\pm$ 0.4 uU/ml (mean $\pm$ SE) and mean basal GH level was 0.9 $\pm$ 0.2 ng/ml. No significant correlation was found between these 2 parameters, nor between GH levels and HDS ratings.

CONCLUSIONS: Basal circulating GH levels did not correlate with TSH response to TRH in depressed men. It is tempting to speculate that GH does not play a role in influencing TSH response to TRH in depression. However, it is not known whether basal serum GH levels accurately reflect its secretory rates in this clinical condition. Further work is needed to assess this finding as well as GH secretory rates in larger groups of depressed patients.

379.19 EFFECTS OF SHORT-TERM EXPOSURE TO GONADAL STEROIDS ON GROWTH HORMONE (GH) SECRETORY PATTERNS IN ADULT MALE AND FEMALE RATS. W.J. Millard, T.M. Badger*, T.O. Fox and J.B. Martin. Departments of Neurology and Gynecology, Mass. Gen. Hosp., Boston, MA 02114.

The pattern of GH secretion in the rat is sex-dependent. Males display a low-frequency, high-amplitude GH secretory pattern with bursts of GH occurring every 3-4 hrs and separated by prolonged GH trough periods where GH levels are very low or undetectable. Females show a high-frequency, low-amplitude pattern of GH secretion with pulses of GH occurring every 1-2 hrs. Individual peak amplitudes are lower and GH trough values higher and of shorter duration than those of male rats. We have previously found that long-term exposure (6-8 weeks) to gonadal steroids can alter GH secretory patterns in adult animals. In the present study we investigated whether short-term exposure to gonadal steroids can also modulate the expression of the GH secretory pattern. Adult intact or castrate male and female rats were bled via an indwelling atrial catheter for 8 hr (900-1600 hr). Immediately following the first sampling period males were given a subcutaneous 5 mm estrogen (E)-filled Silastic implant mixed 1:1 with cholesterol and females received a 15 mm testosterone (T) implant. Animals were sampled weekly for two weeks, steroid-filled capsules were removed; and then animals were sampled weekly for an additional two weeks. Although E exposure did not alter the periodicity of the GH secretory pattern in intact males, it consistently elevated GH trough levels. The effect on GH peak amplitudes was variable, with some animals showing reduced peak amplitudes. In intact females, exposure to T transformed their GH patterns into male-like GH secretory patterns. This occurred within 1 week. One week after removal of the steroid implants the homotypic GH secretory patterns again were observed in both intact male and female animals. Castration did not alter the pulse frequency of respective GH secretory patterns but did elevate GH trough levels in males and lowered trough levels in females. Within 2 weeks of E exposure the male GH secretory pattern was transformed to a female-like secretory pattern in castrate males. Like intact females, castrate females exposed to T displayed GH secretory patterns typical of males. However, unlike that of intact males and females, the GH secretory patterns in castrate animals did not revert back to their preexisting GH secretory patterns. Instead, the female GH secretory pattern persisted in castrate males given E and the male pattern persisted in castrate females given T for at least 2 weeks after removal of the steroid capsules. The contrasting data between intact and castrate animals suggest that the effects of T override those of E. T most likely acts within the hypothalamus to modulate the phasic release of somatostatin and/or GH-releasing factor. E effects both the pituitary and the hypothalamus, however, the central effects of E are apparent only in the absence of T. Supported by PHS grants AM26252, HD18656 and HD17364.

379.20 HYPOTHALAMIC SOMATOSTATIN IN GENETICALLY OBESE ZUCKER RATS. J.A. Finkelstein, L.Murray*, C.Centers* and M.Berelowitz. Dept. of Anatomy, Northeastern Ohio Univ. Col. Med., Rootstown, OH 44272 and Div. of Endocrinology/Metabolism, Univ. of Cincinnati Col. Med., Cincinnati, OH 45267.

The role of somatostatin (SOM) in the decreased growth hormone levels observed in genetically obese Zucker rats has been investigated in a series of experiments. In a previous study (DonCarlos et al, Neurosci. Abst., 1983) it was found that the number of SOM-immunoreactive hypothalamic cell bodies is similar in obese and lean rats, and that the level of SOM immunoreactivity in hypothalamic blocks from obese and non-obese rats is not different when measured by radioimmunoassay (RIA). Our first experiment was designed to investigate the possibility of subtle SOM differences in discrete hypothalamic regions. Eleven nuclear groups as well as the median eminence were micro-punched from 300u sections of hypothalamus from five obese and five lean Zucker rats. There was no difference in SOM concentration in any area studied. In a second experiment, in vitro dynamic SOM release from blocks of hypothalamic tissue was measured (six obese and six lean rats). After preincubation to achieve stable basal SOM release, the incubation medium (Krebs ringer bicarbonate buffer) was changed every six minutes for a total incubation time of 36 minutes. The protocol included one basal period followed by a period of stimulation, then four recovery periods. Basal SOM release was greater from hypothalami of obese (32.5pg/M) than from hypothalami of non-obese rats (26.7). Stimulation by 60 mM potassium led to increases in SOM release from hypothalamic blocks of both obese and non-obese rats, but the increase was greater from obese hypothalami (225.7) versus non-obese hypothalami (162). During the subsequent recovery periods SOM release decreased in both groups, with release from obese hypothalami remaining elevated above lean hypothalami until the final period. ANOVA showed significant differences between obese and non-obese rats. These in vitro data suggest that in vivo SOM release from the hypothalamus of obese rats may be chronically elevated. In such a situation, a change in the level of SOM receptors in the pituitary would be hypothesized. In a preliminary experiment, SOM pituitary receptor concentration in obese rats was about one-third of that seen in the lean animals, with no concomitant change in receptor affinity. Downregulation of SOM pituitary receptors, resulting from a chronically elevated hypothalamic SOM release, could be compatible with our failure to observe significant differences in SOM concentration in the hypothalamus of obese vs. non-obese rats, if accompanied by increased hypothalamic SOM synthesis. Chronically elevated SOM tone could also explain previous findings of decreased pituitary resposiveness to growth hormone releasing factor and SOM in obese Zucker rats (Berelowitz et al, Endocrine Soc. Abst.,1983) and obese human subjects (Williams et al, NEJM, 311,1984). Supported by NIH grants RR05806 and AM30686.

380.1 UPTAKE OF PROLINE AND PIPECOLIC ACID BY CULTURED NEURAL CELLS. J. G. Ortiz, Dept. of Pharmacology, School of Medicine, Univ. of Puerto Rico. 00936

Proline and pipecolic acid are normal constituents of the mammalian brain (Giacobini 1983). These imino acids have been shown to have properties, such as high affinity synaptosomal uptake, which are consistent with their possible role as neurotransmitters/neuromodulators (Giacobini 1983). However, it still remains to be shown whether they represent two independent neuromodulatory systems.

The uptake of $^3$H-proline (Pro) and $^3$H-pipecolic acid (PA) has been examined in three neural cell lines; N-18 (mouse neuroblastoma) PC-12 (rat pheochromocytoma) and rat glioma (C-6) in order to characterize the uptake (and transport) mechanism(s). Confluent cultures were washed with and preincubated for 1 hr. in Earle's Balanced Salts Solution, after which labelled imino acid was added. At different times thereafter, cultures were washed twice with ice-cold phosphate buffered saline (PBS). Radioactivity was determined in 0.5 M NaOH cell extracts after neutralization with glacial acetic acid.

The uptake of proline and pipecolic acid by these cell lines, is linear for at least 25 min. Experiments with a wide range of concentrations ($10^{-6}$ - $10^{-3}$ M) suggest the presence of one uptake system. The uptake of these imino acids appears to require $Na^+$ and is ouabain-sensitive. Detailed kinetic analysis shows that N-18 cells are capable of taking up both proline and pipecolic acid with similar affinities (1.4 mM and 6.0 mM respectively). On the other hand, PC-12 and C-6 cells have higher affinity for proline than for pipecolic acid. The different characteristics of the proline and pipecolic acid uptake system by these cell lines may be useful in the understanding of the possible role(s) of these imino acids in the Central Nervous System.

380.2 CYTOCHEMICAL VISUALIZATION OF FREE RADICAL FORMATION IN SYMPATHETIC NEURONS EXPOSED TO A BRIEF PERIOD OF STARVATION. J.C. Saez*, J.A. Kessler+, M.V.L. Bennett and D.C. Spray. Depts. of Neuroscience and Neurology+, Albert Einstein College of Medicine, Bronx, N.Y. 10461.

Substrate deprivation occurs during pathological conditions such as ischemia, perhaps leading to tissue injury as a consequence of free radical (FR) generation. Involvement of FR generation in ischemia of the nervous system has been difficult to prove; FRs are extremely reactive and have such short lifetimes (<1 s) that they are difficult to detect, and substrate deprivation (starvation) in ischemia is complicated by hypoxia. Starvation is easily produced in superior cervical ganglion cells maintained in culture (Saez et al., Soc. Neuroscience Abstr. 10: 887, 1984). A 10 min exposure to glucose free saline kills 45% of the cells. We now report that certain chromophores that are reduced or oxidized by FRs (depending on their redox potentials) permit the visualization of FR generation in single neurons during and after starvation. In one procedure cells were incubated for 10 min in glucose free saline with nitro blue tetrazolium (NBT). During starvation many cells turned blue due to reduction of NBT which is pale yellow in its oxidized state. Intracellular superoxide anions were involved, since the color change was blocked by intracellular superoxide dismutase, internalized by presoaking along with 50 mM $K^+$. A second approach was to load cells with the nonfluorescent indicator 2', 7'-dichlorofluorescin ($Cl_2FH$) by soaking in its diacetate ester. The ester enters the cells and $Cl_2FH$ is then released by action of intracellular esterases and retained because of its polar nature. In starved cells $Cl_2FH$ is oxidized to the highly fluorescent 2', 7'-dichlorofluorescein ($Cl_2F$), indicating that oxidants are generated intracellularly. The number of cells showing reduction of NBT correlated with the mortality rate determined by trypan blue incorporation in parallel experiments. Cells showing $Cl_2F$ fluorescence subsequently lost their fluorescence and incorporated trypan blue, indicating loss of the surface permeability barrier and death. Since generation of FRs and other oxidants is oxygen dependent, it is unlikely that they are generated during hypoxia (another consequence of ischemia). Indeed both reactions were substantially less frequent when cells were maintained in a $N_2$ environment for 10 min, consistent with the lower mortality rate following $N_2$ treatment (7%). Based upon our separation of starvation and hypoxic aspects of ischemia and cytochemical techniques that allow indirect visualization of FRs during these insults, we propose that FR generation is at least partially responsible for the deleterious changes induced by substrate deprivation.

380.3 MACROPHAGES ENHANCE THE PROBABILITY OF NEURONAL SURVIVAL AFTER AMPUTATION OF DENDRITES. C.R. Gardner* and G.W. Gross (SPON: D.J. Eder). Department of Biology, Texas Woman's University, Denton, TX 76204.

We have previously reported that elicited peritoneal macrophages (MPs) cocultured with neurons were attracted to lesions along neurites. The lesions were performed with laser microbeam cell surgery at a wavelength of 337nm and constituted both complete neurite transections as well as localized neurite damage resulting only in cytoplasmic pinching at the 2.2μm diameter irradiation site (Gardner and Gross, Soc. Neurosci. Abstr. 9:594, 1983). Complete neurite transections usually triggered phagocytic activity at the lesion suggesting that MPs might interfere with neuronal recovery. However, contrary to expectations, the presence of MPs significantly enhanced the survival of neurons after surgery. At a lesion distance of 50μm from the soma, the percent cell survival increased from 31±3% (SEM) in normal MEM with 10% horse serum (MEM 10), to 64±5% in MEM 10 supplemented an average of 7 days earlier with $2x10^6$ MPs per 4ml medium (28cm$^2$ culture area). At a lesion distance 100μm from the soma, survival increased from 53±6% to 88±5%. These highly significant increases in percent cell survival are based on a total of 120 neurite amputations at each lesion distance.

At the present time, it is unclear whether macrophage contact with the lesion is essential for enhancing neuronal survival. Some preliminary experiments have indicated that we may be dealing with a soluble but labile factor secreted by MPs.

380.4 ETHANOL-INDUCED LIPID PEROXIDATION IN BRAIN MEMBRANES. F. Ahmad,* D-Z. Lee,* D. Cowan* and A.Y. Sun. Sinclair Comparative Medicine Research Farm, Biochem. Dept. and Dept. of Phys., Univ. of Missouri, Columbia, MO 65203.

Brain membranes contain a high proportion of polyunsaturated fatty acids and are more susceptible to free radical attack. We have shown that ethanol enhanced lipid peroxidation in brain microsomal membranes in vitro (Ahmad et al., Trans. Am. Neurochem. Soc. 15, 1985). By using N-t-butyl-2-phenyl-nitrone (PBN) to trap the free radicals formed and examining the spin signal with an electron spin resonance (ESR) spectrometer, we found that brain microsomes are active in generating free radicals in the presence of $Fe^{++}$. Ethanol (0.5 M) added to the incubation medium containing microsomes and $Fe^{++}$ greatly enhanced the free radical formation. When animals were treated with an acute dose of ethanol (6 g/kg) and sacrificed at 3 or 24 hr after ethanol administration, no spin signals were detected in either liver or brain of control and alcohol-treated animals. However, by employing a free radical-generating agent, $CCl_4$, we were able to detect free radical formation in both brain and liver using PBN as trapping agent. An acute dose of ethanol enhanced the $CCl_4$-induced free radical formation in liver and brain at 3 or 24 hr after alcohol administration. The results indicate that ethanol per se may not stimulate free radical formation. However, ethanol may enhance free radical formation by perturbing the membrane acyl groups, thus exposing viable membrane sites for free radical attack. An increase in the level of intracellular lipofuscin in brain has been reported in the chronic alcoholic patients. It is possible that alcohol drinking may enhance age pigment formation and accelerate aging through elevated lipid peroxidation and other pro-oxidation reactions due to free radical attack. (Supported in part by grant No. AA02054 from DHHS.)

380.5 INTERRELATION OF BICARBONATE & AMMONIA CHANGES IN SPREADING DEPRESSION. R.P. Kraig & A.J.L. Cooper*. Department of Neurology, Cornell University Medical College, New York, New York 10021.

Spreading depression (SD) is a reproducible and transient perturbation of brain characterized by biochemical and biophysical changes similar to those of ischemia. Hence, SD may be a useful pathophysiologic event through which to study the mechanisms by which brain regulates $[H^+]$ in compromised states such as ischemia. SD is associated with an alkaline, then acid going shift in $[H^+]_o$ (Kraig et al., J Neurophysiol 49:831, 1983). In neocortex, lactate accumulates to 7 mmol/kg during SD (Mutch & Hansen, JCBF & Met 4:17 1984). How volatile $H^+$ buffers (i.e. $HCO_3^-$ & $NH_3$) respond to this acid load is unknown.

Rats were anesthetized with halothane and spontaneously ventilated; warmed to 37°C; and an artery cannulated. Parietal cortex was exposed and superfused with Ringer. Arterial pressure, pH, $PCO_2$, $PO_2$, and glucose were stabilized. SD was elicited by a 1-3 sec, 100 Hz stimulus to nearby cortex. $[H^+]_o$ and either $PtCO_2$ or $[NH_3]$ were monitored in pairs. $H^+$ microelectrodes (tridodecylamine) were placed 300 µm below and $PtCO_2$ or $NH_3$ electrodes at the pial surface. To compare volatile $H^+$ buffer changes to $[H^+]_o$, we improved the response time (95%) of the $PtCO_2$ and $NH_3$ electrodes from 40 & 50 sec to 5 & 10 sec, respectively. In addition electrodes responded linearly between 1-760 mm Hg and 1 µM-1 mM, respectively.

Temporal changes were compared to the negative dc shift of SD. $[H^+]_o$ changes began simultaneously with the dc shift and consisted of a brief alkaline, then acid shift. $[H^+]_o$ was 7.30±0.01 pH (n=33) before SD and became more acid in 9±1 sec to reach a peak of 6.93± 0.02 pH (36±1 sec) before returning to baseline 11.9±0.8 min later. $PtCO_2$ changes began 11±2 sec (n=12) after the dc shift started; reached a peak in 37±2 sec; and returned to baseline in 6.6±1.3 min. $[HCO_3^-]_o$ changes were calculated from these measured variables and showed that $[HCO_3^-]_o$ first rose with the alkaline spike and then reached a low of 13.6±0.6 mM (between 9-37 sec after the dc shift) and returned to baseline in 11.9±0.8 min. $[NH_3]$ changes were more delayed and prolonged. SD initiation produced a small rise in $[NH_3]$ from 2.3±0.1 µM (n=20) but with SD $[NH_3]$ rose rapidly to reach a peak of 4.4±0.3 µM 1.8±0.1 min after the dc shift. Furthermore, 20.8±2.1 min elapsed before $[NH_3]$ returned to baseline.

These results show that during SD rapid and focal changes in $[HCO_3^-]_o$ and $[NH_3]$ can occur in brain. The delayed changes in $[NH_3]$ imply that they are a response to the rise in $[H^+]$ and $PtCO_2$. If so, the $[NH_3]$ changes during SD could influence brain acid-base homeostasis directly through physicochemical $H^+$ buffering of $NH_3$ and indirectly by $HCO_3^-$ production from glutamine metabolism. 380.6 APOLIPOPROTEINS SERVE AS MARKERS IN THE CSF FOR DEMYELINATING NEUROPATHY. S. S. Bock*, G. J. Snipes, J. J. Norden, & J. A. Freeman (SPON: A. Burt) Dept. of Anatomy, Vanderbilt University, Nashville, TN 37232.

In demyelinating conditions produced by stroke, trauma, and various progressive neurological diseases, myelin lipids must be removed from the site of demyelination and redistributed. We have recently discovered that part of this lipid shuttling mechanism involves the induction and secretion of apolipoproteins by non-neuronal cells within the central nervous system (Snipes et al., PNAS, 1985). We have obtained direct evidence, by immunohistochemistry, that apolipoprotein E (Apo E) accumulates around degenerating fiber tracts in the rat brain. As a result of CNS injury apolipoproteins and lipids form large macromolecular lipoprotein complexes which we have isolated by density gradient ultracentrifugation. While characterizing these brain derived lipoprotein complexes, we have identified an additional apolipoprotein, Apo Al, produced by non-neuronal cells in response to injury (Snipes et al., this volume). Similar lipoprotein complexes exist in serum. An interesting property of these serum lipoproteins is that systemic lipid dynamics are reflected in the quantity and composition of individual apolipoproteins. Therefore, since we now know that the brain responds to injury by the secretion of apolipoproteins, we tested whether demyelinating CNS neuropathies might be reflected in the amount and composition of apolipoproteins found in cerebrospinal fluid (CSF). To do this, we used anti-Apo E and anti-Apo Al antibodies to quantitate, by western blot analysis, the levels of these apolipoproteins in the CSF of brains of normal rats and of rats that have received different injuries. In preliminary experiments, we found that CSF Apo E levels were unchanged, but that Apo Al levels underwent a significant increase during demyelination following traumatic injury to the CNS. These findings raise the possibility that specific neurological diseases may be diagnosed and the extent of active degenerative neuropathy associated with such conditions as demyelinating disease, stroke, and trauma can be detected and quantitated by monitoring the level of apolipoproteins in the CSF. This would provide a valuable clinical tool. (Supported by NIH Grant NS18103 and NEI Grant EY01117 to J.A.F.)

380.7 RELATIONSHIP BETWEEN AXONAL AND MYELIN SHEATH PARAMETERS FOLLOWING AXONAL ATROPHY PRODUCED BY ACRYLAMIDE INTOXICATION. B. G. Gold*†, J. W. Griffin§ and D. L. Price§. †The Johns Hopkins University School of Hygiene and Public Health, §The Johns Hopkins University School of Medicine, Baltimore, MD 21205

Myelin sheath thickness is, in general, closely related to axonal caliber and internodal distance. However, it is not clear which axonal parameters are the most significant determinants of sheath thickness. In the present study, we have used a model of proximal axonal atrophy produced by repeated acrylamide (AC) administration to separate the effects of axonal area (AA) and axonal perimeter (AP) on the thickness of the myelin sheath.

Three-week old Sprague-Dawely male rats received daily intraperitoneal injections of AC (30 mg/kg) for 24 days. At seven weeks of age, animals were perfused, along with age-matched controls, with 5% glutaraldehyde in 0.1 M sodium phosphate buffer (pH 7.3). Morphometric analysis of the L5 dorsal root ganglia was performed using light microscopic prints (200-300 fibers/section) to determine axonal diameters and areas. Histograms of axonal diameter and area were constructed and mean values determined for the largest 25% of fibers. Electron microscopic prints of randomly photographed fibers (4-5 fibers/grid) were used to determine the AP, as well as the numbers of neurofilaments (NF) and myelin lamellae. From this data, we calculated AA, NF density, and the length of the "unrolled" sheath, or myelin spiral length (MSL) for each fiber. Osmium-postfixed sciatic nerves were teased in glycerol for measurement of internodal distances.

Histograms of axonal diameters were significantly ($p < 0.05$; Mann-Whitney U-test) shifted to the left in AC-intoxicated animals with little or no apparent loss of fibers at this level. Mean axonal diameters and areas for the largest 25% of fibers were 23% and 41%, respectively, of control values. In intoxicated animals, NF density was increased (120 vs. 175 NF/$\mu m^2$) to levels comparable to those observed in AC-induced proximal swellings, and myelin sheaths appeared relatively thick for axonal caliber. In normal rats, MSL was linearly ($r=0.94$) related to AP; a less significant ($r=0.87$) correlation was obtained between MSL and AA. AC-intoxicated rats also demonstrated a significant ($r=0.91$) relationship between MSL and AP but no relationship between MSL and AA ($r=0.14$). In AC-intoxicated rats, the slope of the relationship between MSL and AP was significantly ($p < 0.05$) less (135 vs. 99; control and AC-intoxicated, respectively), and teased fibers had shorter internodal lengths.

The results demonstrate that MSL remains linearly correlated with AP in an experimental model where AA is severely reduced. It is suggested that the reduced relationship, i.e., slope, between MSL and AP is a result of a failure of longitudinal and radial growth of fibers in these young AC-intoxicated animals.

380.8 HUMAN GLIOMA- AND CNS METASTASIS-DERIVED TUMOR CELL GROWTH REGULATION AND INTERACTIONS WITH NORMAL CELL POPULATIONS. B.H. Smith, D. Parker*, J. Galicich*. Dreyfus Medical Foundation and Memorial Sloan-Kettering Cancer Center, New York, NY 10022.

The established human glioma-derived cell line U251, new cell lines derived from metastatic brain tumors, as well as human dural-derived fibroblast lines and a bovine endothelial cell line have been utilized to compare neoplastic glial cell growth regulation, as well as the interactions between these tumor cells and normal vascular cells and fibroblasts. Initial cultures were established from surgical explants in MEM with NEAA supplemented with 10% fetal calf serum (GIBCO) in a 3.5-5.0% CO2 atmosphere at 37C. Routine mycoplasma screening is carried out. Passage numbers for U251 were P16-35 and for the other lines P1-6. Feeder layers were dural fibroblasts irradiated with 3000 rads. Standard growth curves were established for each cell line.

Growth regulatory effects of feeder layers, collagen, epidermal growth factor (EGF), dibutyryl cAMP (10-3,-4M), dimethylformamide (DMF) (up to 1.5%), phenytoin (PHT) (1-100mcg/ml), as well as extracellular K+, Na+, and Ca2+ have been evaluated in all lines. DBcAMP produced growth retardation (up to 70% at 10-3M) in all lines tested, although the effect was more marked in the tumor lines (U251, other gliomas, and lung carcinoma). PHT (50-100mcg/ml) had a tumor line effects (70 and 50%) at 7-10 days. DMF had a striking inhibitory effect (90%) by day 7 in U251 and induced morphological changes as well. EGF has been without effect on the glioma-derived lines, but does enhace fibroblast growth. Fibroblast feeder layers appear to inhibit U251 to a modest degree, but may accelerate the lung cell growth. The inhibitory effects of both DBcAMP and PHT are consistent with alterations in ionic flux, in particular Na+ and Ca2+ influx for PHT.

The availability of both normal and neoplastic cell lines provides a useful in vitro model for the study of primary and secondary tumor cell growth regulation normal -tumor cell interactions and differing invasive potentials in the CNS.

380.9 NEURAL CELL ADHESION MOLECULE (N-CAM) ACCUMULATES IN DISEASED (DENERVATED) HUMAN MUSCLE FIBERS. N.R. Cashman[1], J. Covault[2], R.L. Wollman[1], and J.R. Sanes[2], [1]Dept. of Neurology, Univ. of Chicago, Chicago, IL 60637, and [2]Dept. of Anatomy and Neurobiology, Washington Univ. School of Medicine, St. Louis, MO 63110.

N-CAM, a glycoprotein present on neuronal surfaces, is thought to mediate a variety of intercellular adhesive interactions in the nervous system (Rutishauser, Nature 310, 549, 1984). While most intensively studied as a neuronal protein, N-CAM is also transiently expressed in muscle: it is present on embryonic myotubes, but is lost during development and is virtually absent from adult muscle fibers. However, denervation of adult rat, mouse, or chicken muscle leads to the reappearance of N-CAM on the surface and within the cytoplasm of denervated fibers (Covault and Sanes, PNAS, 1985). We report here that N-CAM also appears in muscle fibers of patients with denervating diseases.

Biopsies of deltoid and gastrocnemius muscles, obtained for clinical diagnostic purposes, were frozen and cross-sectioned in a cryostat. Sections were stained with affinity-purified antibody to chicken N-CAM (known to cross-react with mammalian N-CAM; Covault and Sanes, op cit.) and fluorescein-second antibody, then examined with epifluorescent illumination. N-CAM immunoreactive fibers were observed in muscles from patients with several diseases known to involve denervation: amyotrophic lateral sclerosis (ALS), infantile spinal muscular atrophy (Werdnig-Hoffman disease), sensory-motor neuropathy, and progressive denervating post-polio syndrome. In each case, most of the stained fibers were likely to have been denervated, as judged by their small diameter. However, not all small fibers were stained, nor were all stained fibers small. In particular, a histologically normal biopsy from an ALS patient displayed scattered N-CAM positive fibers, suggesting that N-CAM-staining may detect recently denervated fibers that have not yet atrophied. N-CAM-positive fibers were rarely detected in normal muscle or in muscles from patients with disorders that are thought not to involve denervation (rheumatologic type II fiber atrophy, and myotonia). No fibers were stained when normal rabbit Ig was substituted for anti-N-CAM. Thus, N-CAM accumulates selectively (although perhaps not exclusively) in denervated human muscle fibers. N-CAM immunohistochemistry may therefore be a useful technique in the differential diagnosis of diseases of the motor units. Furthermore, in that some synaptogenetically important nerve-muscle interactions may be mediated by N-CAM (Rutishauser et al., J. Cell Biol. 97, 145, 1983; Covault and Sanes, op. cit.), it will be interesting to seek diseases in which disorders of innervation are not accompanied by accumulation of N-CAM. (Supported by NIH and MDA).

380.10 PRELIMINARY EVIDENCE OF MAGNESIUM DEPLETION AND EXCESSIVE CALCIUM ACCUMULATION IN HUMAN MYOBLASTS OF DYSTROPHIC ORIGIN. Syamal K. Bhattacharya and Alice J. Crawford. Surgical Research Laboratory, University of Tennessee Medical Center, Memphis, Tennessee 38163.

Duchenne muscular dystrophy (DMD) is a progressively crippling X-linked disease characterized by biochemical, histological, and cardiac abnormalities which result in severe muscle degeneration. The membrane hypothesis suggests a generalized functional defect in the cellular plasma membranes of DMD patients which stimulates an increased cellular ingress of $Ca^{2+}$ and $Na^{+}$ and a leakage of intracellular constituents such as $K^{+}$, CK, and LDH to the extracellular environment. In previous studies, we have demonstrated that muscle Ca content is increased by 300% and muscle Mg content is depleted by 45% in patients with DMD (Neurology,32:1088,1982). Serum Ca and Mg concentrations, however, are normal in human and animal forms of muscular dystrophy (MD) while the serum CK level is extremely elevated. These biochemical abnormalities also occur to a lesser extent in patients with other neuromuscular disorders such as congenital myopathies, polymyositis, and fascioscapulohumeral and limb girdle MD. We have demonstrated that older non-ambulatory DMD patients reveal a significantly lower ($p<0.001$) muscle Mg content compared to younger ambulatory patients whose muscles are also Mg deficient. We have recently reported excessive intracellular calcium accumulation (EICA), in the absence of cellular necrosis, in the biceps and quadriceps of human fetuses at risk of DMD, with no apparent muscle Mg depletion (Neurology,34:1436,1984). This evidence indicates that muscle Mg deficiency is present in the early stages of DMD and becomes progressively severe as the disease advances, whereas EICA occurs in utero and does not change with time. Since we hypothesize that muscle Mg may have an antagonistic effect on EICA in MD, we studied the Ca and Mg contents of myoblasts, grown in vitro, collected from apparently normal human fetuses and those at risk of DMD. Myoblasts were grown in 80% Dubelco media, fortified with 10% horse serum and 10% fetal calf serum, harvested at equivalent stages of maturation, and washed twice with Ca and Mg free normal saline. Minerals were measured in the myoblasts and growth media before and after cell growth, and in the saline-wash before and after myoblast washings, to ensure an accurate comparison between normal and dystrophic myoblasts and to test for contamination or mineral uptake by the growth media or saline wash. We found a decreased Mg content and an elevated Ca content in the myoblasts of dystrophic origin as compared to the controls. To overcome possible cell counting errors, we calculated the Mg:Ca ratio and found it to be severely depressed in dystrophic myoblasts. This observation correlated well with our previous Mg:Ca ratio results in DMD patients and fetuses at risk of DMD. We conclude that in DMD: 1) EICA represents one of the earliest detectable biochemical changes 2) Muscle Mg depletion is progressive, whereas EICA does not change with disease advancement 3) Mg depletion and EICA also occur in human myoblasts of dystrophic origin.

380.11 CELL TRANSPLANT TREATMENT FOR MUSCLE DISEASES. P.K. Law and T.G. Goodwin*, Depts. of Neurol., Physiol./Biophys., Univ. of Tennessee, Memphis, TN 38163

Muscle development and complementation mechanisms were studied after genetically normal myoblasts were injected into growing and regenerating dystrophic muscles. Applicability of this new technique to alleviate muscle weakness in hereditary myopathies was tested in dystrophic mice. We showed that the procedure significantly improved the structure and function of dystrophic muscles.

Dystrophic cells degenerated because of the lack of the normal genome. The normal genome might become incorporated when normal donor myoblasts fused with satellite cells of the dystrophic hosts to form mosaic myofibers. In myopathies of recessive inheritance, gene products from the normal nuclei might restore the phenotype of these heterokaryotes to normal. Furthermore, surviving donor cells would develop and replace the myopathic tissue. These two mechanisms of genetic complementation were demonstrated in this study.

About $10^6$ cultured myoblasts from genetically normal mouse embryos were injected into the right soleus of 20-day-old normal or dystrophic mice. Hosts and donors were of C57BL/6J background, and were immunocompatible. Test and control muscles were compared at 6 months after injection. Survival and development of donor myoblasts in host muscles were analyzed with electrophoresis of muscle isozymes of glucose phosphate isomerase (GPI). Donor cells produced GPI-1C. Host cells produced GPI-1B. Presence of both isozymes and/or GPI-1BC substantiated genetic mosaicism in the test dystrophy solei.

Table 1 shows that the test dystrophic soleus generated significant greater twitch (Pt) and tetanus (Po) tensions than the contralateral, unoperated muscle. The test dystrophic soleus also showed a reduction in half-relaxation time (1/2 RT) towards normal. It had more fibers with high resting potentials (74.6 ± 6.2 SD (48)) than its control (68.2 ± 6.0 (48)). It showed significant improvement over its control histologically.

TABLE 1

| | Normal | | Dystrophic | |
|---|---|---|---|---|
| | Test | Control | Test | Control |
| Pt (gm) | 3.2 ± 0.3 | 3.0 ± 0.5 | 2.8 ± 0.5 | 2.1 ± 0.6* |
| Po (gm) | 18.5 ± 3.1 | 14.2 ± 3.2* | 13.1 ± 2.6 | 9.0 ± 2.7* |
| 1/2RT(msec) | 16.8 ± 3.8 | 15.9 ± 3.0 | 19.8 ± 3.5 | 24.9 ± 3.5* |

Mean ± SD of 5 normal and 4 dystrophic mice studies at 37°C in vivo with nerve stimulation. Paired t-test was used. *, significant at P 0.01 level.

We have hereto demonstrated the beneficial effects and the genetic complementation mechanisms of injecting normal myoblasts into dystrophic muscles. (Supported by USPHS NS-20251 and MDA)

381.1 WHEAT GERM AGGLUTININ-RICIN A-CHAIN CONJUGATE IS A POTENT CYTOTOXIN IN VITRO BUT IS LESS ACTIVE AS A SUICIDE TRANSPORT AGENT IN THE CNS T.N. Oeltmann & R.G. Wiley. Medicine and Neurology Depts., Vanderbilt Univ. Med Sch and VAMC, Nashville, TN, 37203.

The disulfide conjugate of wheat germ agglutinin to ricin A-chain (WGA-SS-RTA) is active as a suicide transport agent when injected into the vagus nerve of a rat. It is retrogradely transported to vagal sensory and motor neuron cell bodies and destroys these neurons (Abstracts Soc.Neurosci., 10:352,1984). In the present study, we sought to determine if WGA-SS-RTA was an effective suicide transport agent in the CNS. WGA-SS-RTA was synthesized and purified as previously described (above). The hybrid toxin was dissolved in PBS containing $NaN_3$ and N-acetylglucosamine and pressure microinjected (0.5-1 ul containing 2-10 ug toxin) into the caudate nucleus of anesthetized adult male rats using stereotaxic technique. After 2 days-2 weeks survival, rats were reanesthetized and transcardially perfused with phosphate buffered aldehyde fixative. Brain sections were cut out of 30% sucrose in a cryostat and processed for indirect peroxidase immunohistochemistry using the Vectastain (Vector Labs, Burlingame, CA). Rabbit primary antiserum to ricin A-chain was raised in our lab; anti-WGA was purchased (Vector). This same immunohistochemical procedure demonstrates retrograde transport WGA-SS-RTA by vagal neurons. Alternate sections were stained with cresyl violet (Nissl stain), and 4 rats were processed for combined cresyl violet and catecholamine histofluorescence using the formaldehyde-aqueous glutaraldehyde (FAGLU) technique. Cresyl violet and histofluorescence sections demonstrated definite but incomplete cell loss in the substantia nigra pars compacta (SN) ipsilateral to the caudate injection in 6 of 10 rats; 4 showed equivocal cell loss. Immunohistochemical staining was positive for WGA in 4 of 4 rats but negative for ricin A-chain in 4 of 4. In order to understand why WGA-SS-RTA was not more effective as a suicide transport agent, the toxin was tested for its ability to inhibit protein synthesis in vitro. Neuroblastoma cells (2A) in monolayer culture or hematopoietic stem cell line (K-562) in suspension culture were incubated at 37°C for 18 hrs with WGA-SS-RTA and then pulse labelled with a radioactive amino acid mixture for 2 hrs. Radioactivity incorporated into TCA precipitable material was quantitated by liquid scintillation counting. WGA-SS-RTA was highly effective in blocking protein synthesis in both cell lines ($LD_{50}$=0.2 nM for K-562). These results indicate that WGA can function effectively as a carrier under certain conditions (in vitro) but WGA-SS-RTA is not efficient in delivering ricin A-chain to neuron cell bodies in vivo presumably due to premature dissociation of the hybrid toxin. (Supported by VA Merit Review Award.)

381.2 GLYCOSIDASE ENZYME DIGESTION AND LECTIN CYTOCHEMICAL STUDIES OF AXONALLY TRANSPORTED GLYCOCONJUGATES. C.E. Hart* and J.G. Wood* (SPON: M. Tigges). Dept. of Anatomy, Emory Univ. Sch. of Med., Atlanta, GA 30322

The carbohydrate composition of axonally transported glycoproteins in sciatic nerve of rat was studied by post-embedding lectin cytochemistry in combination with glycosidase enzyme digestions. A cold block procedure for the interruption of axonal transport was employed to selectively increase the population of anterograde moving components on the proximal side of the transport block. Electron microscopic observations revealed that a cold block applied for 6 hours to the sciatic nerve of an anesthetized rat produced an increase in axonal smooth membrane vesicles at a site directly proximal to the cold block. Axon profiles greater than 0.5 mm proximal to the cold block or axons from control nerves showed a normal distribution and density of smooth membrane vesicles. Post-embedding lectin cytochemistry of the sciatic nerve demonstrated a substantial increase in Concanavalin A (Con A), wheat germ agglutinin (WGA), and succinylated WGA binding sites in axons directly proximal to the cold block. Axons outside the cold block area or in the control nerve had very few lectin binding sites observable by light microscopy. Endoglycosidase H (endo H) digestion prior to lectin cytochemistry characterized a large population of the axonally transported Con A binding sites as polymannose and/or hybrid N-linked oligosaccharides (endo H susceptible). Also, a distinct population of neuraminidase resistant WGA binding sites was found in axons directly proximal to the transport block. The increase in smooth membrane vesicles observed at the ultrastructural level and the increase of lectin binding sites in axons proximal to the transport block support the hypothesis that a system(s) of smooth membrane inside the axon is involved in the transport of axolemmal and synaptic terminal glycoproteins from the cell soma to their cell surface destinations. Results of glycosidase enzyme digestions and lectin cytochemistry experiments suggest that many of the axonally transported glycoprotein carbohydrates are polymannose and/or hybrid N-linked oligosaccharides. This observation is especially interesting in relation to our previous reports which indicate that most lectin binding sites on the neuronal cell surface are composed of complex oligosaccharides. Supported by USPHS grant NS-17731.

381.3 SYNAPTOGENESIS AND EYE-OPENING PRECEDE ANTEROGRADE TRANSSYNAPTIC TRANSPORT OF WHEAT GERM AGGLUTININ-HORSERADISH PEROXIDASE (WGA-HRP) IN THE DEVELOPING RAT RETINO-TECTO-PARABIGEMINAL PATHWAY. S.K. Itaya Dept. of Anatomy, Univ. of Illinois at Chicago, Chicago, IL 60680.

In previous studies we have found that the lectin conjugate, WGA-HRP, undergoes anterograde transsynaptic transport in several sensory pathways in the central nervous system of both rats and monkeys. Two characteristics suggest that a highly specific neuronal mechanism is involved: 1) anterograde transsynaptic transport of WGA-HRP occurs in some, but not all, pathways, and 2) anterograde transsynaptic transport is neuron-specific, directionally-specific, and limited to synaptically connected neurons. Based on these findings, we hypothesized that the transport of WGA-HRP actually demonstrates a pre-existing, interneuronal route normally taken by an endogenous, WGA-HRP-like molecule. Such a molecule could function as a recognition signal prior to synaptogenesis, and/or as a trophic factor in the mature nervous system. In order to test this hypothesis, we have studied transport of WGA-HRP in a developing pathway, using the rat retino-tecto-parabigeminal pathway as a model. In adult experiments, intravitreal injections of WGA-HRP consistently label retino-tecto-parabigeminal terminals, thus demonstrating anterograde transsynaptic transport. Much of the rat visual system develops postnatally, so anterograde transsynaptic transport can be correlated with developmental events, e.g., eye-opening at 16 days and retino-tectal synaptogenesis, which begins at birth (Lund, R.D. & Lund, J.S., Brain Res. 41:1, 1972). Neonatal rats at 7, 16, and 22 days of age were studied. Rat pups were anesthetized and 1% WGA-HRP (Sigma) was injected into the vitreous. After 1-2 days, the animals were reanesthetized, perfused, and brain sections were processed for the TMB procedure (Mesulam, M.-M., J. Histochem. Cytochem. 26:106. 1978). In all cases there was heavy labeling of the primary visual pathways, especially in the contralateral superior colliculus. Terminal labeling in the parabigeminal nucleus, however, was not present in the 7 or 16 day old cases, but appeared only in the 22 day old. Thus, we conclude that while anterograde transport of WGA-HRP occurred in all age groups, anterograde transsynaptic transport of WGA-HRP took place only in the 22 day old rat. Our results indicate that anterograde transsynaptic transport does not occur during synaptogenesis, nor does it occur prior to eye-opening, even though the axons and synapses of the retino-tecto-parabigeminal pathway are in place (Linden, R. & Perry, V.H., J. Comp. Neur. 218:270, 1983). The results suggest that anterograde transsynaptic transport occurs only at a physiologically functioning synapse, and therefore probably has a role related to synaptic transmission. Thus, the hypothetical, endogenous WGA-HRP-like trophic factor may act as a signal indicating that a synaptic connection is intact. Supported by NIH NS21021, BRSG 5369 & 8309.

381.4 AXONAL TRANSPORT OF MONOCLONAL ANTIBODIES. T.C. Ritchie, R.H. Fabian*, J.V.A. Choate* and J.D. Coulter. Marine Biomedical Institute and Dept. of Neurology, Univ. Texas Medical Branch, Galveston, Texas.

Three monoclonal antibodies against rat brain synaptosomes, produced by conventional hybridoma techniques, were screened for their ability to undergo uptake and axonal transport in vivo. Injections of ascitic fluid or of purified IgG were made into the vitreal chamber of the eye in anesthetized rats to test for anterograde transport in retinal afferents to the contralateral superior colliculus. Retrograde transport by facial nucleus motoneurons was evaluated after injections of antibody into the mystatial vibrissal skin and musculature. Transported immunoglobulins were localized in tissue sections using a modification of the peroxidase anti-peroxidase technique. One monoclonal antibody, S-2C10, was found to undergo fast anterograde transport in retinal ganglion cells and retrograde axonal transport in facial motoneurons. The anterograde transport rate was determined to be at least 100 mm/day. Transported immunoglobulins were detectable even after injection of dilute antibody solution (0.01%), and the uptake-transport process for this antibody appears saturable. The antigen recognized by S-2C10 was shown to accumulate proximal and, to a lesser degree, distal to ligations of the sciatic nerve, suggesting that the antigen is synthesized and transported by motoneurons and/or sensory ganglion cells. Preliminary studies indicate the antigen is likely to be an intrinsic membrane protein or proteoglycan. Two other antibodies tested, S-4E9 and S-1G10, exhibited the ability to undergo retrograde transport, but only after injections at relatively high antibody concentrations ($\geq$ 1.0%). Neither of these antibodies was shown to undergo anterograde transport. The retrograde labeling produced by injections of S-4E9 and S-1G10 consisted of punctate reaction granules within the motoneuron somata. In contrast, S-2C10 was localized in neuronal perikarya, proximal dendrites and in the adjacent neuropil of the facial nucleus after retrograde transport. The uptake of both S-4E9 and S-1G10 antibodies appears to involve non-specific, fluid phase endocytosis. Uptake-transport of the S-2C10 antibody, however, appears to be mediated by specific, adsorptive endocytosis after binding of the antibody to a plasma membrane component (or components) present on both soma-dendritic and nerve terminal membranes. These results indicate that monoclonal antibodies will be useful as in vivo and in vitro probes for characterizing neuronal plasma membranes, and the composition and intracellular processing of internalized macromolecules.

Supported by NIH grants NS 07185 and NS 12481.

381.5 UPTAKE AND TRANSPORT OF ANTIBODIES TO WHEAT GERM AGGLUTININ BINDING GLYCOCONJUGATES. J.V.A. Choate*, T.C. Ritchie, R.H. Fabian* and J.D. Coulter. Marine Biomedical Institute, Depts. of Physiol. & Biophys., Psychiat. & Behav. Sci. and of Neurology, Univ. of Texas Medical Branch, Galveston, TX 77550.

Previous experiments have shown that the lectin wheat germ agglutinin (WGA) and antibodies to wheat germ agglutinin binding glycoconjugates (antiWGA-GC) are transported retrogradely by rat facial motoneurons. In addition, the transport of antiWGA-GC can be inhibited by incubation of antiWGA-GC with its immunogen. Since it is well established that the uptake of WGA is via adsorptive endocytosis mediated by binding to membrane "receptors," competition between WGA and antiWGA-GC would suggest that a similar process underlies uptake of the antibodies.

Polyspecific antibodies were generated in rabbits against wheat germ agglutinin binding glycoconjugates, isolated by lectin affinity chromatography from Triton X-100 solubilized rat brain synaptosomes. The antiserum (50% sol) or preimmune serum containing different concentrations of WGA was injected into the vibrissal musculature of anesthetized rats. Controls consisted of injections of antiserum, preimmune serum or WGA alone into the contralateral side. After 24 hours, the rats were anesthetized and perfused with 3.5% paraformaldehyde. Retrogradely transported antibody or WGA was localized in the facial nucleus. Retrograde transport of the antibody was blocked by WGA concentrations of 100 μM or greater. Transport of the antibody was not blocked by other lectins, including peanut agglutinin and Lens culinaris agglutinin. Retrograde transport of WGA was not blocked by the antiserum. That WGA transport is not detectably effected by the antiserum seems likely to be due to the antiserum being directed to a subset of the WGA "receptors." Comparison of the staining patterns of the antiserum and the lectin on Western blots of electrophoresed WGA binding proteins supports this conclusion. To control for the possibility that the WGA lectin blocks the antiserum transport by cross-linking the carbohydrate-rich Fc portion of the immunoglobulin, $F(ab)_1$ fragments were prepared. The $F(ab)_1$ fragments transported as well as the whole antibody. When tested in competition with WGA, the transport of the $F(ab)_1$ was blocked, as before. This suggests that the lectin competes directly for the antibody binding sites. These studies indicate that the uptake and transport of the antibody is mediated by a subset of the wheat germ agglutinin binding glycoconjugates.

381.6 PHOSPHORYLATION AND CALCIUM-ACTIVATED PROTEOLYSIS OF NEUROFILAMENT PROTEINS IN THE SQUID GIANT NEURON

Paul E. Gallant, Harish C. Pant, Rebecca Pruss*, and Harold Gainer. Laboratory of Preclinical Studies, National Institute on Alcohol Abuse and Alcoholism, Rockville, Maryland 20852 and The Marine Biological Laboratory, Woods Hole, Massachusetts 02543.

The posttranslational modifications of neurofilament proteins were studied in the squid giant neuron. The ability of endogenous phosphorylation and calcium activated proteolysis to modify neurofilament proteins was studied by 1.) identifying the products formed after endogenous phosphorylation and calcium activated proteolysis of the neurofilament proteins and 2.) by examining the cell bodies and axoplasm for modified neurofilament proteins. Phosphorylation was initiated by adding 10-20 μCi ($\gamma^{32}P$) ATP to homogenized axoplasm or cell bodies. The proteins were separated by polyacrylamide gel electrophoresis (PAGE). Gels were then dried and autoradiographed. To study calcium activated proteolysis 6 mM CaCl was added to homogenized axoplasm or cell bodies. The reaction was stopped with 2% SDS, 5% BME and the proteins were separated by PAGE and then stained with Coomassie Blue or silver.

When axoplasm is incubated in the presence of ($\gamma^{32}P$) ATP most of the phosphate is incorporated into two neurofilament proteins: one at 220 kilodaltons (K) (NF-220), and a high molecular weight neurofilament protein (NF-HMW). Endogenous calcium activated proteolysis cleaves the NF-220 more rapidly than the NF-HMW. The initial proteolysis of the NF-220 produces a pelletable fragment at 100 K and two soluble fragments: one at 160 K and a second at 110 K. The latter contains most of the $^{32}P$. The cell bodies of the giant neuron, unlike the axoplasm, contain no detectable NF-220. The cell bodies do, however, contain a number of proteins that both bind to a monoclonal anti-intermediate filament (IF) antibody, and are sensitive to endogenous calcium activated proteolysis. This IF antibody detects all the axoplasmic proteins that copurify with neurofilaments, i.e., in the order of their IF staining intensity: a 60 K, 65 K, 220 K, and a 74 K protein. In the cell bodies the IF antibody labels, in order of their staining intensity: a 65 K, 60 K, 74 K and a 180 K protein. The presence of different major (65 K instead of 60 K) and minor (an unphosphorylated 180 K instead of a phosphorylated 220 K) intermediate filament proteins in the cell bodies versus the axoplasm suggest that the intermediate filament (neurofilament) proteins synthesized in the cell bodies may be enzymatically modified before being transported into the axon.

381.7 DIFFERENCES IN THE AXONAL TRANSPORT OF CYTOPLASMIC MATRIX PROTEINS IN THE SOMATIC-MOTOR AND PARASYMPATHETIC OCULOMOTOR AXONS. P. Paggi and R.J. Lasek. Dept. of Cell. and Dev. Biol., University "La Sapienza", 00185 Rome, Italy, and Dept. of Dev. Genetics and Anatomy, C.W.R. University, Cleveland, Ohio 44106, U.S.A.

Studies of the axonal transport of radiolabelled cytoskeletal proteins can provide information about the transport characteristics of the cytoskeleton in axons (Lasek, R.J., J. Cell Biol. 99:212s, 1984). We compared the kinetics of transport of the cytoplasmic matrix proteins in the two functionally distinct axon populations that are part of the oculomotor system in chickens. The oculomotor nerve contains two populations of axons: somatic-motor (M) axons and parasympathetic (P) axons.

Three-old-week chickens received injections of $^{35}S$-methionine in the cerebral aqueduct and were sacrificed from 1 to 93 days after injection. Labeled proteins were analyzed in segments of the oculomotor nerve, which contains the M and P fibres; in the ciliary ganglion, where the P terminals are located; and in the somatic-motor branches of the oculomotor nerve where M axons course. The radiolabeled proteins were subjected to one and two-dimensional SDS-PAGE and fluorography, and were quantified by counting the excised bands.

As in other neurons, the cytoplasmic matrix proteins were transported at two different rates corresponding either to the slow component (SCa) which is defined by the neurofilament proteins (NFP) and tubulin or to the slow component (SCb) which is defined by actin, clathrin and other matrix proteins. The rate of the SCa proteins differed in M and P axons. NFP moved three times faster in M axons than in P axons. In M axons most of the tubulin moved coherently with the NFP and only a small fraction of the tubulin moved ahead of the neurofilaments. In P axons tubulin moved with NFP in SCa but a large fraction of the tubulin also moved with the proteins of SCb. These results suggest that the dynamic structural relationships between microtubules and neurofilaments in somatic-motor axons differ from those in the parasympathetic neurons of the oculomotor system.

381.8 RETROGRADE AXONAL TRANSPORT IN MOTOR AND SENSORY AXONS OF RAT SCIATIC NERVE. D.J. Fink, D. Purkiss,* and M. Mata. Neurology Research Laboratory, University of Michigan and VA Medical Center, Ann Arbor, MI 48105

We have previously used $^{3}H$ N-succinimidyl propionate ($^{3}H$ N-SP), an in-vivo acylating agent, to label endogenous axonal proteins within the nerve in order to study their subsequent bidirectional transport. In sciatic nerve slow anterograde and slow retrograde transport were labeled, but rapid transport in either direction was not seen. In the neurosecretory neurons of the neurohypophysis however, accumulation of rapidly transported components could be detected in the nerve terminals at the pituitary. We undertook the current study to determine whether accumulation of rapidly retrogradely transported $^{3}H$ N-SP labeled proteins could be detected at the cell bodies of sensory and motor axons.

One microliter containing 67 microCuries of $^{3}H$ N-SP (50Ci/mmol) was injected subepineurially in the sciatic nerve of 200-225 gram Sprague Dawley rats. At times ranging from 6 hours to 28 days after injection the animals were sacrificed by intracardiac perfusion and the sciatic nerve and dorsal root ganglia processed for total and TCA precipitable counts. The spinal cord was sectioned in a cryostat and the ipsilateral and contralateral lumbar ventral horns sampled using the Palkovitz punch technique and processed for both total and TCA precipitable radioactivity.

The amount of counts appearing in the sensory neurons and motor neurons respectively were expressed relative to the total amount of counts remaining in the nerve. DRG neurons showed a biphasic accumulation of radioactivity, with early accumulation peaking at 24 hours after injection and a larger accumulation occurring over the subsequent week. Motor neurons showed the first accumulation over 7 days, and a second larger accumulation by 2 weeks after injection. The difference in time of accumulation corresponds to the difference in distance from the injection site to the cell body of the sensory and motor neurons respectively, suggesting that rapid and slow retrograde transport of endogenous proteins occurs in both neurons, at equivalent rates, and that each contains roughly the same proportion of transported material. Control nerves, ligated between the injection site the DRG, showed no accumulation of radioactivity in the DRG or the spinal cord.

Light microscopic autoradiography of both DRG and spinal cord at 1 day and 5 days after injection showed grains localized specifically within the neurons in both the DRG and the spinal cord. Samples of both the DRG and the spinal cord neurons were separated by SDS gradient gel electrophoresis and fluorographed.

381.9 **AXONAL TRANSPORT AND COMPOSITION OF GANGLIOSIDES IN SENSORY AXONS OF RAT SCIATIC NERVE.** G.J. Harry,*, A.D Toews* and P. Morell. Biol. Sci. Res. Ctr. & Dept. of Biochem., Univ. of N.C., Chapel Hill, NC 27514.

**The synthesis and axonal transport of gangliosides and glycoproteins in sensory neurons of rat sciatic nerve were examined at various times following injection of [$^3$H]glucosamine into the L5 dorsal root ganglion. Incorporation of labeled precursor into these glycoconjugates at the ganglion continued for 6-12 hours following injection. Outflow patterns for labeled gangliosides were compared to those for glycoproteins at times from 3 to 24 hrs after precursor injection. The crest of transported radioactivity for both of these classes of glycoconjugates moved down the sciatic nerve at a rapid rate of approximately 360 mm/day. Although radioactivity in glycoproteins in the ganglion was 15-20 fold greater than that in gangliosides, levels of transported glycoprotein radioactivity in the nerve was only about 10 fold greater than gangliosides. This suggests a possible preferential commitment to transport for gangliosides, relative to glycoproteins.**

**The composition of gangliosides transported down the axons (radioactive gangliosides accumulating at a ligature on the nerve) differed somewhat from that synthesized in the ganglion. $GM_3$ was preferentially retained in the ganglion (presumably in the neuronal perikarya), while the tri- and tetrasialogangliosides were preferentially exported. The distribution of radioactivity among individual ganglioside species synthesized locally in the nerve (following intraneural injection of [$^3$H]glucosamine) differed substantially from the pattern of gangliosides synthesized in the ganglion and from that committed to transport.** **This work was supported by USPHS grants NS11615 and ES01104.**

381.10 EXAMINATION OF THE REDISTRIBUTION OF LYSOSOMES AND LIPOFUSCIN GRANULES FOLLOWING DISRUPTION OF NORMAL MICROTUBULE FUNCTION. V.J. Roberts, M.C. Bundman, G.O. Ivy, C. Gorenstein. Department of Pharmacology and Center for the Neurobiology of Learning and Memory, University of California, Irvine 92717.

Under normal conditions, lysosomes and lipofuscin granules are localized in neuronal cell bodies. We have previously shown that injections of a mitotic inhibitor, colchicine, into the lateral cerebral ventricle of the rat induced a paradoxical translocation of these organelles from the cell somata of neurons into the dendrites (Gorenstein et al., J. Neurosci., in press; Gorenstein and Ribak, J. Neurosci., in press).

The thiol proteinase inhibitor, leupeptin, has been shown to cause an increased concentration of neuronal lipofuscin-like granules (Ivy et al., Science 226 1984), a condition resembling the aged brain. Colchicine treatment (100 µg i.c.v) caused a redistribution of these granules similar to that seen with lysosomes. In order to characterize this modulation further, the time course of the redistribution of lysosomes and lipofuscin granules following colchicine treatment was examined quantitatively at the electron microscope level.

Microtubules must be able to polymerize and depolymerize for normal cellular function. The effect of taxol (a mitotic inhibitor with microtubule stabilizing properties) on the distribution of lysosomes was also examined. Taxol (90ug) was injected into the lateral cerebral ventricle of rats. Cellular death occurred in parts of the cerebellum 5 days following treatment. However, while both taxol and colchicine disrupt normal microtubule function, only colchicine affected the normal cellular distribution of lysosomes. We speculate that this redistribution may be due to a disruption of microtubules which normally sequester lysosomes within the cell body. To account for the specific movement of lysosomes into dendrites once microtubules are disrupted, we also propose that lysosomes are coupled to a unique transport system which specifically directs these organelles into dendrites.

381.11 A METHOD FOR THE ELECTROPHYSIOLOGIC STUDY OF ENZYME DISSOCIATED AXONS IN THE RAT SCIATIC NERVE. R. Rumpf, T. Spagnolia, W.J. Levy, D.H. York. University of Missouri Health Science Center, Columbia, Missouri 65212

Existing methods for studying axons have involved whole nerve preparations, axons teased from excised nerves, or tissue culture. To complement these it would be advantageous to study the normal and pathologic function of isolated, separate axons in vivo, still in continuity with the CNS and end organ. To achieve this the surgically isolated sciatic nerves of pentobarbital anesthetized, adult male rats were passed through a glass-bottom Silastic$^R$ chamber designed for controlled temperature, pH and flow rate superfusion with physiologic saline solutions and enzyme dissociation solutions. This chamber was mounted on the stage of an inverted phase contrast microscope. The process of axon dissociation by superfusion with $Ca^{++}$-free Hank's Balanced Salt Solution (HBSS) followed by 1% Collagenase in full complement HBSS was monitored and photographed with the high-power inverted microscope. This process was enhanced by dissecting the epineurium off before dissociation, and by including thrombin (100 units/ml) and vasopressin ($1 \times 10^{-8}$ M) in the dissociation solutions to reduce bleeding. Using this technique 1 cm of sciatic nerve could be reliably dissociated into free, separate axons substantially free of extracellular matrix in 2 to 4 hours at 37° C. EMG recordings from the lumbrical muscles of the foot and peripheral nerve recordings from the tibial nerve obtained before and after enzyme dissociation were not dramatically different. Osmium tetroxide (2% in phosphate buffer) staining of dissociated axons showed no obvious morphologic damage. Single axon action potentials were recorded with extracellular pipette microelectrodes (2 M NaCl, tip resistance 2 - 10 Mega Ohms) under mineral oil. Action potential propagation was thus studied under conditions of reversible cold and lidocaine blocks, selective cation exclusion and anoxia. Axons separated by this technique were also found to maintain axoplasmic transport (Spagnolia, Rumpf, Levy and York, NEUROSCIENCE ABSTRACT, October, 1985). With this model action potential properties were studied up to 12 hours. This model provides a large percentage of usable axons which do not show observable damage and may be useful for the study of normal and pathologic peripheral nerve function.

381.12 THE MAUTHNER NEURON AS AN IN VITRO VERTEBRATE MODEL TO STUDY AXOPLASMIC TRANSPORT. Edward Koenig, Div. of Neurobioilogy, Dept. of Physiology, SUNY at Buffalo, Buffalo, NY 14214.

The two principal in vitro models that have been used to study organelle movement in axons are from invertebrates; namely, the giant axons of the squid (Allen, et al., 1982, Science 218:1127), and of the lobster (Forman, et al., 1982, Soc. Neurosci. Abstr. 8:827). The squid preparation consists of expressed axoplasm, lacking its rim of ectoplasm, while the lobster preparation includes its sheath and is permeabilized by a detergent. A potentially good vertebrate model is the large axon of the Mauthner cell (M-cell) from goldfish, which ranges from 40-80 µm in diameter (Funch, et al., 1981, Neurosci. Lett. 27:159).

The M-cell axon in a native state can be translated out of its myelin sheath with a pair of microtweezers under Fluorinert, a fluorinated aliphatic liquid. Movements of organelles can be visualized with time-lapse video phase-contrast microscopy. However, organelle movement activity is critically dependent on the composition of the solution in which the brain and spinal cord are suspended before axons are exteriorized. This is apparently due to the fact that some extracellular fluid "coats" the axon when it is translated out of its in situ location. Neither a standard fish physiological salt solution (e.g., Cortland), nor a number of potassium-containing artificial "internal" media yields discernible movement activity in isolated axoplasm. However, a betaine based medium (0.28M) with Mg (2mM), EGTA (1mM), glucose (5mM), Mes (20mM), beta-alanine (50mM) and spermidine (1mM) yields a preparation with spontaneous movements of organelles that continue for 30-45 minutes. Axons isolated in this medium with reduced spermidine (0.1mM) also reveal spontaneous organelle movements when supplemented with ATP (2mM), dithiothreitol (0.2mM), polyvinylpyrrolidone (3%) and sodium pyrophosphate (5mM); however, the level of movement activity is reduced compared to those isolated under Fluorinert. The basis for cessation of movement activity after a period of in vitro isolation has not been investigated, and it is not clear whether the basis is the same when axons are isolated under Fluorinert or bathed by an artificial medium. Preliminary measurements of saltation rates of several classes of organelles range from 0.07 to 1.58 µm/sec. at 20 degrees C.

381.13 FAST AXONAL TRANSPORT IN SQUID AXOPLASM IS MEDIATED BY CROSS BRIDGES BETWEEN MICROTUBULES AND VESICLES. R.H. MILLER* and R.J. LASEK. Dept. of Anatomy, Case Western Reserve Univ., Cleveland, Oh. 44106.

The recent demonstration that individual microtubules at the periphery of axoplasm extruded from the squid giant axon will support vesicle transport clearly demonstrates that microtubules can provide the linear substrate for vesicle transport in axons (Schnapp, et.al. Cell 40:455,1985).

We have examined the detailed morphological relationships between actively moving vesicles and their substrate microtubules at the periphery of extruded axoplasm, using thin sections and transmission electron microscopy. Vesicle transport was focally interrupted by the application of a short term cold block, and anterogradely and retrogradely moving vesicles collected on either side of the block. This approach increased the number of vesicles available for analysis. When the cold block was released by rewarming the preparation, the accumulated vesicles began moving again in their former direction, as shown by AVEC-DIC microscopy. The region of axoplasm containing large numbers of actively moving vesicles was then fixed and processed for TEM.

Longitudinal sections through the axoplasm showed that at the periphery the axoplasm expanded and individual microtubules became separated from the other cytomatrix components, allowing detailed analysis of the vesicle-microtuble interactions. In this region, both the anterogradely and retrogradely moving vesicles were preferentially associated with the individual microtubules, indicating that the actively moving vesicles have a higher affinity for the microtubules than for other cytomatrix components, (i.e.the neurofilaments). Detailed analyses show that both the anterogradely and the retrogradely moving vesicles were attached to their substrate microtuble by 16-18nM crossbridges.

This observation supports the crossbridge model for vesicle transport. We propose that the 16-18nM crossbridges connecting the vesicles to microtubules are the ATPase bearing structures that generate the force for vesicle translocation.

381.14 INFLUENCE OF TRANSLOCATION TRACK ON THE MOTION OF INTRA-AXONALLY TRANSPORTED ORGANELLES IN HUMAN NERVE. M.P. Lynn,* A.C. Breuer and M.B. Atkinson.* Cleveland Clinic Foundation, Cleveland, OH 44106.

The mechanism by which organelles are transported bidirectionally in axoplasm is still unknown; however, evidence of a key role for microtubules has been mounting. We have observed common or shared tracks within the axoplasm of human nerves along which multiple organelles of varying size and shape are bidirectionally transported. To investigate this phenomenon, we obtained human nerves from patients undergoing limb amputation or en-block resection for tumor removal. The motion of organelles traveling anterogradely and retrogradely was visualized by video-enhanced differential interference contrast optics and analyzed with the aid of computer image processing techniques.

Speeds of translocating organelles were determined at eight to 16 translocation points along a path or "track". Each translocation speed was then plotted against its corresponding position on the tract to develop a "speed/position diagram". In axonal regions containing more than one common tract some tracks exhibited greater activity (number of organelles/unit time) than others. However, the average mean translocation speed of organelles on a common track was not related to the activity of the track.

A range of mean translocation speeds was evident on each common track in an axon. Regardless of mean organelle speed or direction of motion, organelles sharing a common track exhibited similar patterns of "speeding up" and "slowing down" relative to position along the track. Speed/position data for organelles translocating in the local axonal region of a common track showed no unique patterns (not different from a uniform distribution, $p < 0.05$). The unique speed/position patterns exhibited by common tracks were not necessarily related to the patterns of other tracks in the immediate vicinity (distance between tracks $< 0.50$ μm). These findings suggest that 1) there are "common tracks" shared by organelles moving retrogradely and anterogradely; 2) both the organelles and the "track" associated with its translocation play a role in the resultant motion of that organelle; 3) the influence exerted by a common track on the motion of an organelle results in a pattern of speed changes related to position along the track.

381.15 ANTEROGRADE AND RETROGRADE AXOPLASMIC TRANSPORT HAVE THE SAME VELOCITY. E.J. Muñoz-Martínez & W. Ejido* (SPON: E. Stefani). Dept. Physiology, Biophysics and Neurosciences, CINVESTAV. A.P. 14-740. 07000-México, D.F.

Previous determinations of the retrograde velocity of endogenous proteins intraaxonally transported involves considerable uncertainties. In general, it has been estimated that the velocity of retrograde transport is about half of that for anterogradely transported proteins. The experiments reported here indicate that the velocity of fast axonal transport is unique independently of the transport direction. Cats were anaesthetized (pentobarbitone 35 mg/Kg I.P.) to expose the seventh lumbar spinal ganglia bilaterally. Each ganglia received 10 μl of $^{3}$H-Leucine and anterograde transport was allowed to proceede for 10 hs after injection. Thereafter, two ligations were made in the sciatic nerves at 3.5 and 7 cm from the ganglia and transport was allowed to proceed in the isolated portion of the nerve for variable intervals (0.5-10 hs) before killing the animals.
The isolated portions of the sciatic nerves were removed and sectioned in 5 mm long pieces to determine radioactivity by scintillation counting. It was found that in the 5 mm segment just distal to the proximal ligation, the radioactive label initially decreased indicating deplection due to anterograde transport, but subsequently increased indicating proximal accumulation of proteins previously accumulated in the most distal 5 mm segment of the isolated portion of the nerves. Accumulation in the proximal segments started 2-2.5 hs after the simultaneous ligations. Thus, assuming that retrograde transport started immediately after ligation, the velocity of this transport was 14 to 17.7 mm/h which closely coincide to that found for anterograde transport. It is concluded that both anterograde and retrograde transport may use the same transport system.

382.1 TOPOGRAPHICAL ORGANIZATION OF THE FACIAL NUCLEUS IN THE RABBIT. Ronald H. Baisden, Michael L. Woodruff, Duane C. Baker*, Dennis L. Whittington and Amy E. Benson*. Department of Anatomy, Laboratory for Neurobehavioral Science, Quillen-Dishner College of Medicine, East Tennessee State University, Johnson City, TN 37614.

The topographical representation of the branches of the facial nerve in the motor nucleus of CN VII was studied in 33 rabbits following retrograde transport of HRP. In cross section, the facial nuclear complex appears to be formed from a series of four subnuclei. A large medial subnucleus (MSN) is separated from a slightly smaller lateral subnucleus (LSN) by a slender intermediate subnucleus (ISN). A small accumulation of cells composing the superior subnucleus (SSN) is found dorsal to the LSN. Cells which give rise to the various branches, however, are not confined to a particular subnucleus but appear to be distributed in topographical fashion throughout the complex. The cells which give rise to the mandibular branch are located predominately in the LSN and ISN, however some cells are found in the SSN. The buccal branch innervating the anterior muscles of the face and lips split into a superior and inferior division. They both arise from a common population of cells located in the LSN and ISN. The zygomatic branch to the upper face below the orbit is derived from cells which cap the facial nuclear complex with the majority found in the SSN, but which extend over and into the medial aspect of the MSN. In contrast, the auriculopalpebral branch to the eyelids comes from a large mass of cells in the MSN as well as a dorsal group that extends over into the SSN. This same pattern is observed in the organization of the cells that give rise to the rostral auricular branch to the anterior ear. The posterior auricular branch arises exclusively from cells of the MSN, as does the cervical branch, although in this case labeled cells are confined to the ventrolateral portion of the MSN. The nerves to the stylohyoid, the platysma and the digastric are all derived from cells which primarily reside in the ISN, although the digastric, which in the rabbit consists only of an anterior belly, also receives a substantial innervation from cells located in the posterior medial portion of the trigeminal motor nucleus as well as a string of cells which connect with a cluster of cells found outside of, and dorsal to, the facial complex proper. No attempt was made in the present study to determine the origin of the nerve to the stapedius muscle. These studies demonstrate that the facial nucleus is organized in a topographic pattern reflecting the anatomy of the facial musculature. The results are consistent with reports of facial nucleus organization in other mammalian species.

382.2 SYMPATHETIC INNERVATION OF THE TYMPANIC PLEXUS IN MACACA FASCICULARIS. PJ Gannon* and AR Eden. Dept of Otolaryngology, Mt. Sinai School of Medicine of the City University of New York, NY 10029.

The extent of the sympathetic innervation to the tympanic plexus is largely unknown. This study was designed to analyze the number of fibers in the tympanic plexus originating from the superior cervical ganglion (SCG) using an E.M. ultrastructural degeneration procedure. In humans, the tympanic plexus consists of efferent and afferent nerve fibers from the tympanic branch of the glossopharyngeal nerve, the auricular branch of the vagus, and sympathetic fibers from the external carotid nerve plexus via the caroticotympanic nerves. A similar arrangement is found in old world monkeys such as macaques.

Animals were unilaterally sympathectomized by surgical excision of the SCG and 2-3mm of the superior nerve trunk to ensure removal of all ganglion cells. The distal stump was cauterized and the animals allowed to survive 20 and 40 days. Excised SCG were wax embedded and sectioned to observe the extent of the ganglion cells. Animals were fixed transcardially, then the middle ear entered and the nerves postfixed in situ with osium tetroxide. The nerves were dissected out from various points in the tympanic plexus and processed for E.M. whole nerve transverse sectioning. Total counts (in duplicate) of degenerating myelinated and unmyelinated fibers were made from electron micrograph photomontages at a magnification of 3000x.

Analysis of Nissl-stained 5um sections of excised SCG indicated that the sympathectomy was complete and that all ascending fibers had been transected. Quantitation of degenerating fibers in tympanic plexus nerves showed a consistent pattern. Caroticotympanic nerves entering the plexus showed 35-44% myelinated and 17-20% unmyelinated nerve fiber degeneration, while the tympanic nerve showed 34-46% myelinated and 18-28% unmyelinated fiber degeneration. A hypotympanic branch of the tympanic nerve was present in one animal and was analyzed separately.

Future studies will determine the specific innervation of organs such as the parotid gland and inner ear via the tympanic plexus.

382.3 FLUORESCEIN PENETRATES MIDLINE BRAIN STRUCTURES OF FEMALE RAT BRAINS TO A GREATER EXTENT THAN MALE BRAINS. Leonard Koda, Joe L. Martinez, Jr.*, and Floyd Bloom. Scripps Clinic and Research Foundation, La Jolla, CA 92037 and *Dept of Psychology, Univ of California, Berkeley, CA 94720.

Hormonal substances likely access the brain through the blood brain barrier, through the CSF via the choroid plexus, or through the circumventricular organs. In our attempt to identify entrance sites of peptides into brain we noticed greater penetration of fluorecein into female as compared to male rats.

In this study female and male (150-200 g) Charles River rats were anesthetized with pentobarbital. The abdominal cavity was opened below the diaphragm. A 22 ga needle was placed into the heart through the diaphragm and the rat was injected with 2% sodium fluorescein solution (.4ml/100g). Five m later the descending aorta was clamped and the rats were transcardially perfused with sal. For fluorescence photomicroscopy, 4% depolymerized paraformaldehyde in phosphate buffer was substitute for sal. Brain parts (frontal cortex, cerebellar cortex, rest of brain) were homogenized in 5 vol phosphate buffer. Samples were microcentriguted (Eppendorf) for 1 m. A 0.15 aliquot of supernatent was diluted with 1.35 ml phosphate buffer and measured in a fluorometer. There were no differences between the amount of fluorescein measured between males and females in cortex or cerebellum. However, females had significantly ($p = .002$) more fluorescein (1.73 + .14 nm/wet wt) than males (1.07 + nm/wet wt) measured in the rest of brain. This same relationship was observed when ovariectomized and castrated rats were examined. Photomicroscopy revealed intense fluorescence in the circumventricular organs and adjacent areas. Both the area postrema and nucleus tractus solitarius were fluorescent as well as the median eminence, paraventricular and arcuate nucleus, and the organum vasculosum and the suprachiasmatic area. The choroid plexus was fluorescent, but in contrast to the circumventricular organs, the adjacent areas did not fluoresce.

We conclude the fluorescein enters the female rat brain more readily than the male brain. This increased penetration is not associated with the blood brain barrier as cortex and cerebellum did not increased fluorescence. Rather it appears that the circumventricular organs and associated brain nuclei are primary sites of uptake. Further this sex difference is not maintained by sex hormones as gonadectomy did not alter fluorescein penetration. (Supported by ONR N00014-83-K-0408 and NIAAA 06420).

382.4 DESCENDING PROJECTIONS FROM THE MEDIAL VERSUS LATERAL PREFRONTAL CORTICES OF THE RAT. S.G.P. Hardy. Dept. of Anat., Univ. of Miss. Med. Ctr., Jackson, MS 39216.

In recent years there has been a resurgence of interest in the prefrontal cortex (PFC) and its connectivity. In the rat, the PFC is parcellated into medial and lateral subdivisions. Few attempts have been made to compare the connectivity of these subdivisions throughout the brainstem. In this study, using a variety of HRP techniques, it was determined that there are considerable differences in the trajectory of descending axons originating from these cortical subdivisions. Some of these differences are as follows:

From the medial PFC: Axonal labeling in the THALAMUS was heaviest in the dorsolateral part of the mediodorsal (MD) nucleus, medial aspect of the ventral thalamic nucleus and in the parafascicular nucleus. In the MIDBRAIN, labeling was most pronounced in the deep layers of the superior colliculus and dorsolateral periaqueductal gray. In the PONS, labeling was primarily in the parabrachial nuclei and lateral pontine tegmentum, although some labeling was also observed in the paramedian pontine reticular formation. No labeled axons were observed descending into the medulla.

From the lateral PFC: Axonal labeling in the THALAMUS was heaviest in the medial part of the MD nucleus, lateral aspect of the ventral thalamic nucleus, nucleus reticularis and zona inserta. In the MIDBRAIN, labeling was heaviest in the nucleus cuneiformis, nucleus of Darkschewitsch, medial accessory nucleus of Bechterew and substantia nigra. In the PONS, labeling was present in the parabrachial nuclei and lateral pontine tegmentum. At more caudal levels of the pons, labeled axons were observed to pass ventrally through the lateral tegmentum. In the MEDULLA, the labeled axons passed into the vicinity of the facial nucleus, then decussated in the region of the nucleus raphe magnus. The axons then assumed a position in the dorsal lateral tegmentum, lying medial to the spinal trigeminal nucleus. At caudal levels of the medulla, labeled axons passed medially to the dorsal column nuclei, hypoglossal nuclei and vestibular nuclei. There was also slight labeling of the nucleus of the solitary tract.

Additional studies were performed, in which HRP was placed into various brainstem sites. The resulting retrograde cortical labeling supported the findings of this study.

In this study it has been demonstrated that the descending projections from the medial versus lateral PFC are distinctive throughout their course in the brainstem. (Generally, the projections from the medial PFC were to dorsomedial brainstem sites, whereas projections from the lateral PFC were to lateral brainstem sites.) This suggests that these PFC subdivisions may be functionally distinct. (Supported by NIH grant BRS2S07-RR05386).

382.5 THE SO-CALLED "INITIAL" TYPE OF THE NEOCORTEX: RELATION TO CETACEAN BRAIN ORGANIZATION. I. Glezer*, M.S. Jacobs and P.J. Morgane (SPON: F.M. Liebman). CUNY Medical School, New York, NY 10031; Dept. Pathobiology, NYU Dental Center, New York, NY 10010; Worcester Foundation for Experimental Biology, Shrewsbury, MA 01545.

The idea of the existence of the "archetypal" neocortical plate originates not in the field of neuroanatomy, but in comparative anatomy. All paleontological and comparative anatomical data confirm that the most primitive of extant living placental mammals are the Insectivora. Ancient Paleocenic representatives of this group are considered as ancestral to all placental mammals. From this notion evolved a concept that was intensively developed by Filimonoff and his school (Preobrashenskaja, N. et al., Z. Mikr.-Anat. Forsch., 87:490, 1973). This concept reiterates that if insectivores are the most primitive and closest to the ancestral stock then their brain and, especially, cortex may represent the "archetype" that then developed into specialized cortical types in different Orders of mammals. The main features of the archetypal neocortex are: (1) absence or weak representation of layer IV, (2) intense staining of densely packed cells in layer II, (3)hypertrophy of layer I which is extremely wide and contains abundant tangential axon branches as well as ramifications of apical dendrites of pyramidal cells of layers II, V and VI, and (4) overall slight development of the associative zones of the neocortex and predominance of the primary functional zones. This kind of cortex was found in some of the basal Insectivora (Valverde, F., Ch. 13, In: Ramon y Cajal's Contribution to Neuroscience. Elsevier, 1983). More recently in the dolphin brain (Morgane, P.J. et al., Evolutionary morphology of the dolphin brain, In: Conference on Dolphin..., Erlbaum, In press, 1985), many features have been found resembling those present in the hedgehog brain. Comparative anatomical classification of Cetacea disconnect this group from Insectivora at the time whales went to water. Hence, it is uncertain whether the so-called primitive features of the cetacean cortex are ancestral or originated as a result of the highly specialized aquatic evolution. We can contemplate two types of brain phylogeny. In the first or terrestrial type the emphasis was on diversity of the primary neocortical areas and on the prevalent growth of the non-specific (associative) zones between the primary zones. In the second type of evolution, as may be represented by purely aquatic Cetacea, the emphasis was on the unification of what might be initially diverse modules of the neocortex. The main direction of this type of evolution was in multiplication of the unified module which may have resulted in the expanded but architectonically "monotonous" cortex of dolphins. (Supported by NSF Grant BNS 84-14523).

382.6 A GOLGI STUDY OF NEURONAL COMPONENTS IN CONVEXITY NEOCORTEX OF DOLPHIN BRAIN. P.J. Morgane, M.S. Jacobs, I. Glezer* and A. Galaburda. Worcester Foundation for Expt. Biol., Shrewsbury, MA 01545; New York University Dental Center, New York, NY 10010; City College, New York, NY 10031 and Dept. of Neurol., Harvard Med. School, Boston, MA 02215.

Among extant insectivores, the hedgehog (Erinaceus europaeus) is regarded as perhaps the most direct modern descendant of the primitive placentals (Romer, 1974). It has been termed a "survivor of the Paleocene" (Romer, 1949). It has retained, apparently with minor variations, basic characteristics of its primitive insectivore ancestors. Hence, it is a reference for the study of what might be considered a prototype of neocortical organization and a valid, though not unique, model of neocortical phylogenetic development. In the present study we have compared some cytoarchitectural and morphological details in the hedgehog's auditory and visual neocortical areas with those in the cerebral cortex of the bottlenose dolphin. The aim is to define types of neurons that might be present in these cortices in relation to homologous types described in other species. Neurons showing a predominantly subpial dendritic arborization, i.e., "extraverted neurons" dominate in layer II of dolphin cortex and are mostly medium sized pyramids and polymorphous neurons. They occur over the entire convexity cortex in both dolphin and hedgehog brains. Since the extraverted neurons resemble closely those of the superficial cell condensations of the first and second growth rings of the neocortex, i.e., periallocortex and proisocortex, they are considered to represent an ancient type of cortical neuron. In most mammalian cerebral cortices this type is preserved only in the primitive allocortices. In dolphin layer II we see a range of neurons from moderately extraverted to well-balanced (approximately equal apical/basal dendritic systems) small pyramids. The functional significance of dendritic extraversion is that this type of protoneocortical organization represents axodendritic contact through the zonal layer which is a feature of organization in the allocortices. Golgi material in the dolphin shows the presence of long radiator (reticular) type stellate cells at many levels in the cortex and several varieties of giant stellate cells similar to those described in the hedgehog brain by Sanides (1972). There is no trace of a hypergranular cortex anywhere in the dolphin convexity cerebral cortex, with layer IV being absent. Convexity cortex in dolphin is dominated by transitional forms of neurons varying between pyramids, spindles and stars. Study of the dolphin cortex as compared to that of the hedgehog cortex reveals many striking similarities. At the level of resolution provided by the Golgi method, our findings suggest in both species a stage of cortical evolution in which a general allocortical plan of neuronal organization is dominant (Supported by NSF Grant BNS 84-14523).

382.7 HIPPOCAMPAL FORMATION OF DOLPHIN: A MORPHOMETRIC GOLGI STUDY. M.S. Jacobs, I. Glezer* and P.J. Morgane. Dept. Pathobiology, NYU Dental Center, New York, NY 10010; CUNY Medical School, New York, NY 10031; Worcester Foundation Exp. Biology, Shrewsbury, MA 01545.

Since describing the cytoarchitectonic features of the archicortex in Tursiops truncatus (Jacobs et al., Brain Res. Bull., 4:Suppl.1, 1979), we have recently applied a modified Golgi-Kopsch method to a study of the cellular morphology of the hippocampal formation (HF). Well impregnated cells in the dentate gyrus (DG), hippocampal fields CA4, CA3, CA2, CA1 as well as the subiculum (Sb) have been examined morphometrically. In the paucicellular molecular layer (ML) of the DG are found cells resembling displaced granule cells (GC) as well as stellate neurons. The densely packed granular layer (GL) contains predominantly small (16.1um x 12.3um) oval GC with moderately spined apical dendritic branches extending well into the ML. In addition, basket cells are found intermixed with typical GC in the layer. The hilar region contains scattered medium sized polymorphic basket cells (21.0um x 14.3um) as well as medium sized non-aligned pyramidal cells (21.9um x 13.6um), the latter having dendrites that are more densely spined than GC. The pyramids of CA4 are scattered, small (18.0um x 12.0um) and have well developed apical and moderately developed basal dendrites. Continuous with the pyramids of CA4 appears the narrow cell band of the stratum pyramidale (SP) of CA3. Most CA3 pyramids lack a typical pyramidal shape, are medium to large sized (28.6um x 15.4um) and have moderately spined apical and basal dendrites. Cells from the SP scatter into the stratum oriens (SO). In counterstained Golgi material there is a progressive widening and increase in density of the SP from CA3 to CA1. In CA2 the SP separates into a denser, patchy superficial sublayer and a less dense, more homogeneous deep sublayer. The pyramids of CA2 are smaller (21.2um x 14.9um) than in CA3 and do not scatter as much into the SO. In CA1 the pyramidal cells are medium in size (25.7um x 13.7um) and are characterized by more densely spined and more heavily branched apical and basal dendrites than in other hippocampal fields. In counterstained Golgi sections the SP is more densely cellular than CA2 and continues to show the same sublamination seen in CA2. Extending from CA1 to Sb the SP widens but becomes less dense. The Sb is characterized by distinctly different populations of pyramids at different levels of the cortex. The contrast is sharp between club shaped deep pyramids with long apical dendrites branching near the plexiform layer and basal dendrites contributing to a horizontal plexus, and more typical superficial pyramids with short, widely branching apical dendrites and obliquely oriented basal dendrites. This Golgi pattern enables the border between the Sb and CA1 to be identified. Overall, the HF of the dolphin has many features similar to those in other species, including primitive extant insectivores. This reflects the generally conservative character of the HF throughout phylogeny. (Supported by NSF Grant BNS 84-14523).

382.8 ABSENCE OF SEXUAL DIMORPHISM OF THE CORPUS CALLOSUM IN SCHIZOPHRENIA: A MAGNETIC RESONANCE IMAGING STUDY. H.A. Nasrallah, N.C. Andreasen, S.C. Olson*, J.A. Coffman*, C.E. Coffman*, V.D. Dunn*, J.C. Ehrhardt*. Departments of Psychiatry and Radiology, Ohio State University, Columbus, OH and The University of Iowa, Iowa City, IA.

A post-mortem study (DeLacoste-Utamsing and Holloway, 1982) reported that right handed (RH) males and females show gender-related morphological differences in the corpus callosum, with a larger splenium in females. This difference was attributed to the developmental differentiation of the right cerebral hemisphere in males for visuo-spatial tasks, and the reduction in posterior (splenial) interhemispheric callosal fibers. We present the first in vivo study of callosal sexual dimorphism in both normal subjects and schizophrenic patients, using magnetic resonance imaging (MRI).

Volunteer RH males (N=11), RH females (N=10), LH males (N=10) and LH females (N=10) were recruited into a MRI brain study of callosal morphology. In addition, RH male schizophrenics (N=23), RH female schizophrenics (N=10) and LH male schizophrenics N=5) consented to participate in the protocol. Several studies have suggested abnormalities in callosal structure and function in schizophrenia (Nasrallah et al, 1982).

MRI scans were obtained with a Picker .5 Tesla superconducting magnet. The midline saggital (inversion-recovery) view was used for this study. The corpus callosum was divided into four quartiles. The percentage area of the posterior quartile relative to the entire corpus callosum area was measured in all subjects and the means of the groups (by gender, handedness and diagnosis) were statistically compared.

The posterior quartile proportion of the callosal area was significantly larger in normal RH females (36.3%) compared to normal RH males (33.4%) but no difference emerged between schizophrenic RH females (32.8%) and schizophrenic RH males (34.4%). In fact, a trend for the opposite pattern was noted in the schizophrenic group. Finally, LH males did not differ from females regardless of handedness and female schizophrenics had a significantly smaller posterior quartile than female controls.

The results replicate the post-mortem findings of sexual dimorphism in the corpus callosum, and suggest that this sexual dimorphism is absent in schizophrenic patients. The significant decrease of the posterior callosal quartile in female schizophrenics is suggestive of a possible "masculinization" in the brain of female schizophrenics, and perhaps a different pattern of cerebral hemisphere organization compared to normal females.

382.9 CONVERGENCE, DIVERGENCE AND NEURONAL NUMBER IN PERIPHERAL SYMPATHETIC PATHWAYS OF MAMMALS OF VARYING SIZE. W. Snider*, D. Purves, E. Rubin, and J. Lichtman. Departments of Neurology and Anatomy and Neurobiology, Washington University School of Medicine, 660 S. Euclid Ave., St. Louis, MO 63110.

The largest mammalian species are at least 10 million times the size of the smallest. This enormous range in animal size raises a fundamental problem for nervous system function: how do larger animals maintain adequate control of peripheral structures that are many times more massive and extensive than the homologous structures in smaller animals? In order to study this question we have explored several quantitative aspects of the organization of the peripheral sympathetic nervous system of five mammals (mouse, hamster, rat, guinea pig, and rabbit). We have chosen the superior cervical ganglion and its pre-ganglionic supply in the spinal cord as a relatively simple neural pathway in which the numbers of pre- and post-synaptic neurons, the numbers of axons innervating each ganglion cell (convergence), and the number of ganglion cells innervated by each axon (divergence) can be assessed with reasonable accuracy.

The average adult weights of these species vary over approximately a 65-fold range. However, the number of superior cervical ganglion cells increases by only a factor of 4 between the smallest of these animals (mice; about 25 grams) and the largest rabbits; about 1700 grams); the number of spinal pre-ganglionic neurons that innervate the ganglion increases by only a factor of 2. Thus, the numbers of nerve cells in the sympathetic system do not increase in proportion to animal size.

It is obviously of interest to ask how larger animals might compensate for this relative deficiency in numbers of neurons. Several differences in the organization of this peripheral sympathetic pathway are apparent across these species. Ganglion cells increase in size from the smaller of these species to the larger and bear progressively more complex dendritic arbors. In addition, there is a progressive increase in the number of axons contacting each ganglion cell. The number of ganglion cells innervated by each pre-ganglionic neuron can be estimated by multiplying the degree of convergence by the ratio of ganglion cells to pre-ganglionic neurons. This estimate of preganglionic divergence also increases progressively across these species from approximately 60 in the mouse to approximately 400 in the rabbit.

We suggest that modulation of convergence and divergence in sympathetic ganglia allows this part of the nervous system to effectively activate homologous peripheral targets over a wide range of animal size. Preliminary results in a parasympathetic ganglion (the submandibular) suggest that some of these relationships hold for the autonomic nervous system in general.

382.10 THE CYTOARCHITECTURE OF THE CERVICAL AND THORACIC SPINAL CORD OF THE RABBIT. P.L. Vera*, T.W. Jarrell*, H.H. Ellenberger*, J.R. Haselton*, C.L. Haselton* and N. Schneiderman (SPON: W.H. Evoy). Psych. Dept., University of Miami, Coral Gables, Fl. 33124.

The cervical and thoracic cords of 5 adult and 2 neonatal rabbits were examined using the laminar scheme presented by Rexed (J. Comp. Neurol., 1954, 100, 297-380) for the spinal cord of the cat. Serial transverse or horizontal frozen sections (40, 60 or 80 um) were stained with cresyl violet, thionin or a modified Weil stain for myelin. Lightfield and darkfield illumination were used to examine the sections. Darkfield illumination was found to be particularly useful in determining the layers of the dorsal horn.

All ten laminae proposed by Rexed were identified in the spinal cord of the adult rabbit although they were easier to identify in the neonatal cord. Layers I through IV were similar to the cat, with the exception that layer IV appeared to extend down the medial border of the dorsal horn to a greater extent. The reticulation of layer V appeared to be more extensive than was reported for cats. It occupied a larger area dorsoventrally, and mediolaterally it extended for 1/2 to 2/3 of the dorsal horn.

Within layer VII, at the level of the second thoracic segment, the lateral horn (LH) appeared for the first time. The area of the LH was greatest at this level (11096 square microns) and it decreased caudally until the level of T6 (5396 square microns). Beyond T6, the LH became even further reduced and started disappearing so that it was not present in every section. Also, at the levels where LH was present (T2-T6), it appeared to be separated from the intermediate grey matter of lamina VII by intervening white matter. The separation was rarely complete so that often the top and bottom of the LH were connected with the intermediate grey matter. The separation was greatest at T2 (69 um) and it decreased caudally until it disappeared at T7, with the disappearance of the LH.

In the ventral horn, the cervical enlargement started at the caudal level of the third cervical segment, with the appearance of the phrenic nucleus, and it extended into the first thoracic segment.

Outside of the grey matter, a number of cells were found lateral to the lateral border of the dorsal horn in the area that Rexed called the lateral cervical nucleus. This aggregation of cells was more prominent in cervical segments 1-3. However, a number of scattered cells were present in the same location throughout the rest of the cervical and thoracic cord. Therefore, it might represent a similar nucleus to the lateral spinal nucleus described in the rat (Molander et al, 1984, J. Comp. Neurol., 1984, 230, 133-141).

382.11 CONNECTIONS OF THE NUCLEUS OF THE SOLITARY TRACT (nTS) IN THE PIGEON. J.M. Wild, J.J.A. Arends* and H.P. Zeigler, Dept. of Anatomy, School of Medicine, University of Auckland, Auckland, New Zealand, and Biopsychology Program, Hunter College, CUNY, New York, N.Y. 10021.

A combination of autoradiographic and histochemical tracing procedures was used to identify the connections of the avian nTS. Evoked potentials to cervical vagal nerve stimulation were used to control the stereotaxic placement of large pressure injections of tritiated amino acids (proline/leucine) into nTS at various rostrocaudal levels. Confirming previous reports in mammals, terminal labelling was seen in the subjacent reticular formation, in the parabrachial nuclear complex (nPB), and in a periventricular region of the posterior hypothalamus. In contrast to mammalian findings no terminations were seen at telencephalic levels.

Iontophoretic and pressure injections of wheat germ agglutinin-horseradish peroxidase (WGA-HRP) into nTS provided anterograde data confirming these projections and produced retrograde labelling of neurons within nPB and the nucleus periventricularis magnocellularis (PVM) and the stratum cellulare externum of the hypothalamus. WGA-HRP injections into the hypothalamus or nPB produced retrograde labelling of nTS neurons, particularly those within subnuclei known to receive a projection specifically from PVM (Berk, M.L. and J.A. Finkelstein, J. Comp. Neurol., 220: 127, 1983).

These data indicate some basic similarities in the central connections of nTS at brainstem levels in birds and mammals. However, in the pigeon the nuclear origin of hypothalamic projections to nTS is not the same as the hypothalamic region receiving projections from nTS. In addition, it appears that the organization of visceral connections with more rostral forebrain levels may differ in birds and mammals.

382.12 THALAMIC PROJECTIONS TO THE NONCORTICAL TELENCEPHALON IN A REPTILE. M.B. Pritz and M.E. Stritzel*. Div. Neurol. Surg. Univ. of California Irvine Med. Ctr., Orange, CA 93668

Orthograde degeneration experiments in Caiman crocodilus have identified specific portions of the dorsal ventricular ridge (dorsolateral area) that receive auditory, visual, and spinal, somatosensory input. The present study examined total thalamic projections to noncortical areas of the telencephalon and then focused on thalamic connections with the central portions of the dorsolateral area where thalamic afferents are less well characterized.

Horseradish peroxidase (HRP) injections were placed in noncortical telencephalic areas of 8 juvenile Caiman crocodilus under cold narcosis. After survival periods of 2 to 7 days at water temperatures of 23 to 30°C, animals were given a lethal overdose of sodium pentobarbital and processed for HRP histochemistry with tetramethylbenzidine as the chromogen.

Following large injections of HRP that involved nearly the entire dorsolateral and ventrolateral area, retrogradely labelled neurons were found ipsilaterally in the following thalamic sites: nucleus dorsolateralis anterior, nucleus dorsomedialis anterior, nucleus rotundus, nucleus reuniens, the medialis complex, nucleus diagonalis, and nucleus posterocentralis. Smaller injections restricted to a central portion of the dorsolateral area resulted in intensely labelled cells primarily in the medialis complex and nucleus posterocentralis. Marked filling of neurons in these nuclei enabled visualization of soma shape and pattern of primary dendritic branches.

The number of retrogradely labelled and unlabelled neurons seen after large injections of the dorsolateral and ventrolateral area were further examined in nuclei whose boundaries were easily recognized in neutral red counterstained sections. The cell groups studied were nucleus rotundus and nucleus reuniens pars centralis which receive visual and auditory input respectively from the midbrain, and nucleus dorsolateralis anterior whose afferents are incompletely known. Very few unlabelled cells were present in nucleus rotundus or nucleus reuniens pars centralis. Similarly, few unlabelled cells were seen in nucleus dorsolateralis anterior. However, the unlabelled neurons in nucleus dorsolateralis anterior were somewhat more numerous than those present in nucleus rotundus or nucleus reuniens pars centralis. Although preliminary, these findings of nearly complete retrograde labelling of specific sensory (nucleus rotundus and nucleus reuniens pars centralis) and presumed non-sensory (nucleus dorsolateralis anterior) thalamic nuclei suggest that most of the neurons in these nuclear groups are projection cells and that few exclusively intrinsic neurons are present. If the observations described here are confirmed in other thalamic nuclei in Caiman and in other reptiles, then the development of intrinsic neurons may be an important feature in the evolution of the thalamus.

Supported by Grant 1R01-NS-20120 to MBP from NINCDS.

382.13 AFFERENT CONNECTIONS OF THE CEREBRAL CORTEX OF THE TURTLE (PSEUDEMYS SCRIPTA ELEGANS). P.H. Desan, Dept. Psych., Univ. of Colorado, Boulder, CO 80309.

The cerebral cortex of the turtle consists of five areas: from lateral to medial, areas L, D2, D1, DM, and M. Their afferent connections were studied with retrograde tracers (HRP, HRP conjugated to lectins, fluorescent beads), and the results suggest homologies between the cortical areas of turtles and mammals.

Injection of retrograde tracers into area D2 labels cells in the anterior nucleus and lateral geniculate nucleus of the thalamus (the latter has been shown to receive optic input: Hall, Foster, Ebner, and Hall, Brain Res. 130:197, 1977), while injections in areas D1, DM, or M label cells in the dorsolateral anterior nucleus of the thalamus. These injections also label cells in thalamic areas which primarily project to the striatum and perhaps resemble the intralaminar nuclei of mammals. Injection of tracer into area L labels cells in the olfactory bulb as well as scattered cells in the dorsolateral anterior nucleus.

Injections in the cortex also label cells in the partly cholinergic nuclei of the basal forebrain (Mufson, Desan, Mesulam, Wainer, and Levey, Brain Res. 323:103, 1984): within the cortex, the nucleus basalis principally projects to area D2, the medial septum to areas DM and M, and the nucleus of the diagonal band to area L.

Finally, area D2 receives projections from the dorsal ventricular ridge, dorsal sector, and area D1 from all of the sectors (these sectors are known to receive projections from thalamic sensory nuclei: Balaban and Ulinski, J. Comp. Neurol. 201:95, 1981). Areas DM and M receive input from the medialmost strip of area L and from area D1.

Thus, both areas D2 and L receive primary sensory input from the visual thalamus and the olfactory bulb, respectively: Area D2 may be homologous to mammalian primary visual neocortex and area L to mammalian primary olfactory cortex. Area D1 receives its main input from area D2 and other thalamorecipient sensory areas: it is perhaps homologous to mammalian polysensory association cortex. Areas DM and M receive convergent olfactory information via a medial part of area L and thalamic sensory information via area D1: areas DM and M are thus similar to the mammalian hippocampus. Indeed, the projections from areas L and D1 resemble the mammalian lateral and medial perforant paths (Desan, Soc. Neurosci. Abstr., 1981), suggesting that these areas correspond to the lateral and medial entorhinal areas of mammals. The differential projections of the cholinergic basal forebrain nuclei are consistent with this division of the turtle cerebral cortex into "paleocortical," "neocortical," and "archicortical" zones.

## COMPARATIVE NEUROANATOMY II

383.1 AN IMMUNOHISTOCHEMICAL STUDY OF THE TELENCEPHALON OF THE AFRICAN LUNGFISH. R.G. Northcutt and A. Reiner. Division of Biological Sciences and Department of Anatomy and Cell Biology, The University of Michigan, Ann Arbor, MI 48109.

Lungfish are among the last living members of the group of bony fish that gave rise to terrestrial vertebrates. Studies of lungfish can thus shed light on the evolution of the brain during the vertebrate transition to land. In this immunohistochemical study, antisera against the following neuroactive substances were used to study the telencephalon of the African lungfish, Protopterus: 1) serotonin (5HT, Immunonuclear Corp.); 2) tyrosine hydroxylase (TH), a marker for catecholamines (T. Joh); 3) substance P (SP, Accurate Chemical); 4) leucine-enkephalin (LENK, Immunonuclear Corp.); 5) avian pancreatic polypeptide (APP, J. R. Kimmel); and 6) LANT6 (R. E. Carraway).

In lungfish, the ventrolateral telencephalic wall, like that of amniotes, possesses 1) a "striatal" region rich in SP+ and LENK+ neurons and fibers and appears to give rise to a descending SP+ pathway that terminates on tegmental TH+ neurons that appear to have a reciprocal projection to the "striatum", and 2) a caudally situated "pallidal" field of large LANT6+ neurons. The ventromedial wall of the telencephalon contains a more ventral region that is rich in SP+, LENK+ and LANT6+ neurons and in TH+, 5HT+ and APP+ fibers, and a more dorsal region rich in SP+, LENK+, LANT6+, 5HT+, TH+ and APP+ fibers. In these characteristics, these regions are comparable to the nucleus accumbens septi and the septal nuclei, respectively, in amniotes.

The dorsomedial wall of the telencephalon (termed the medial pallium) comprises three immunohistochemically distinct cell groups: 1) a dorsal cell group distinctively rich in SP+ and LENK+ fibers; 2) an intermediate cell group distinctively rich in APP+, 5HT+ and TH+ fibers and APP+ neurons; and 3) a ventral cell group with a moderate number of 5HT+, TH+, SP+, LENK+ and APP+ fibers and APP+ neurons. These results do not provide unequivocal data as to correspondences between cell groups of the medial pallium in amniotes and lungfish. Finally, the rostral dorsolateral wall of the telencephalon comprises the caudal pole of the olfactory bulb, as reflected in the large number of TH+ neurons. In more caudal portions of the dorsolateral wall, most of which corresponds to olfactory cortex, no immunohistochemically distinct region that might be comparable to mammalian isocortex or sauropsid DVR was evident.

In summary, these results indicate that while the evolution of the ventral telencephalon from bony fish to land vertebrates was characterized by a striking degree of conservatism, a similar degree of conservatism is not evident for the dorsal telencephalon.

Supported in part by NIH grants NS11006 and EY02485 (R.G.N.) and NS19620 (A.R.).

383.2 CEREBELLAR AFFERENTS IN THE GREEN SUNFISH, LEPOMIS CYANELLUS. M. F. Wullimann* and R. G. Northcutt (SPON: M. S. Northcutt). Division of Biological Sciences, University of Michigan, Ann Arbor, MI 48109.

The pretectum of perciform teleosts is one of the most complex neural regions to develop in the course of vertebrate brain evolution. Many of the pretectal nuclei receive retinal and/or tectal inputs, but few details are known regarding the efferent projections of these cell groups. Several experimental studies on bony fish species with more primitive pretecta indicate that a number of these nuclei project to the cerebellum. Horseradish peroxidase (Sigma VI) was injected unilaterally into the corpus (8 cases) of green sunfish in order to determine pretectal and additional inputs to the cerebellum. Following survival times of 2-4 days at 22-24°C, the animals were reanesthetized and perfused transcardially with cold phosphate buffer (pH 7.4) followed by 4% glutaraldehyde in phosphate buffer. Brains were removed, embedded in 25% gelatin, and cut at 35µm. Sections were reacted with o-dianisidine, tetramethyl benzidine or Hanker-Yates reagents.

Unilateral cerebellar injections retrogradely labeled cells in the following diencephalic and pretectal nuclei: ipsilaterally in the dorsal (basal optic nucleus of Braford and Northcutt, '83) and ventral (accessory optic nucleus of Braford and Northcutt, '83) accessory optic nuclei, central and periventricular pretectal nuclei, and paracommissural nucleus of Ito et al. ('82). At midbrain levels, retrogradely labeled cells were seen ipsilaterally in nucleus isthmi, lateral nucleus of the valvula, perilemniscal nucleus, and bilaterally in the dorsal tegmental nucleus (lateral tegmental nucleus of Braford and Northcutt, '83). At more caudal levels, retrogradely labeled cells were seen contralaterally in the inferior olivary nucleus and the ventral and intermediate gray columns of the spinal cord. Cells of the lateral reticular nucleus, inferior raphe, locus coeruleus, and nucleus of the commissure of Wallenberg were labeled bilaterally.

Our results suggest that the cerebellar corpus of sunfish receives substantial telencephalic and visual inputs. The paracommissural and dorsal tegmental nuclei are known to receive telencephalic inputs, and both nuclei project to the corpus in sunfish, as in other ray-finned fishes. The central and periventricular pretectal nuclei, as well as the dorsal and ventral accessory optic nuclei, receive direct retinal input (Butler and Northcutt, '81) and also project to the corpus of the cerebellum. There are extensive tectal projections to many of these nuclei (Northcutt, '82), as well as cerebellar projections to the optic tectum, which suggests that the pretectum, tectum, and cerebellum are complexly involved in visually mediated behaviors.

Supported in part by the Janggen-Pohn-Stiftung, Switzerland (MFW) and NIH grants NS11006 and EY02485 (RGN).

383.3 BRAINSTEM NEURONS PROJECTING TO THE SPINAL CORD IN GOLDFISH: AN HRP STUDY. H.E. Sloan and L.S. Demski. School of Biological Sciences, University of Kentucky, Lexington, KY 40506.

Gelfoam pledgets containing HRP (Sigma VI) were placed at either rostral (3-8), middle (14-16) or caudal (24-26) vertebral levels of transected or hemisected SC in adult goldfish (10-14 cm standard length). Following survival times of 3, 4, 7 or 9 days at 26±2°C animals were perfused and brains were sectioned in either transverse, horizontal or sagittal planes. Tissue was processed using Hanker-Yates or TMB protocols and examined with light microscopy. Diencephalic cells which project to SC occur in the preoptic area (see Sloan and Demski, Soc. Neurosci. Abstr. p. 854, 1984), zona limitans-dorsal hypothalamic area as well as the periventricular thalamic and the posterior tuberal nuclei at the level of the posterior commissure. Cells of the posterior tuberalis project bilaterally while the other filled cells have ipsilateral connections. Labeled mesencephalic cells are in the nucleus of the medial longitudinal fasciculus, (nMLF), a nucleus ventrolateral to nMLF in the rostral tegmentum, and an isthmal tegmental nucleus ventral to the nucleus lateralis valvulae. The majority of labeled cells in the rostral tegmental nucleus are contralateral to the implant while other labeled nuclei have bilateral projections. Rhombencephalic cells distributing fibers to SC occur in reticular nuclei (superior, medial and inferior), inferior raphe, nucleus of the descending trigeminal tract, octaval nuclei (magnocellular, descending, and tangential) and the facial lobe. Labeled cells of the facial lobe project ipsilaterally while cells of other nuclei have bilateral connections with a larger ipsilateral component. Labeled cells were absent from the vagal lobes, cerebellum, optic tectum and telencephalon. Supported by NIH grant NS 19431-02.

383.4 THE PRIMARY PROJECTIONS OF THE TRIGEMINAL NERVE IN THE GOLDFISH, CARASSIUS AURATUS. R. L. Puzdrowski, Div. Biol. Sci's., Univ. of Mich., Ann Arbor, MI 48109.

The central projections of individual rami of the sensory component of the trigeminal nerve were traced with HRP. Adult goldfish (8-14cm total length) were anesthetized with MS222, and individual rami were exposed and transected. A gelfoam pledget soaked with 40% HRP (Sigma VI) was placed on the proximal stump of the transected branch. After a survival time of 7-11 days at 22-26°C, the animals were reanesthetized and transcardially perfused with phosphate buffer (pH 7.4) followed by a 2% glutaraldehyde solution. The brains were sectioned transversally at 40µm and processed according to the Mesulam ('78) TMB protocol or by the Hanker-Yates ('77) protocol.

The sensory rami of the trigeminal nerve of goldfish are distributed over the head through three nerve trunks, the supraorbital, infraorbital and hyomandibular.

The fibers of the trigeminal sensory nerve enter the medulla as a single root accompanied by the trigeminal motor nerve. The sensory component caps the ascending secondary gustatory tract and courses caudally as the descending trigeminal tract (DTV). As described in carp (Luiten, '75), the DTV was found to project ipsilaterally to five termination sites. Four of the sites lie dorsomedially to the branchiomeric motor nuclei. The fifth site, the medial funicular nucleus (NMF), receives the bulk of the fibers of the DTV. Each trigeminal ramus was found to project to all five terminal sites. In general the rami of the infraorbital and hyomandibular trunks terminate ventrally to the ramus of the supraorbital trunk in the terminal sites dorsomedial to the branchiomeric motor column. This projection pattern is reversed in the NMF where the supraorbital trunk projects to the ventral portion of the nucleus, the infraorbital trunk to the dorsal portion of the nucleus, and the hyomandibular trunk to the dorsolateral portion of the nucleus. In addition to the above projections, filling of the infraorbital or hyomandibular trunks results in a minor projection from the ventral bundles of the descending facial sensory root to the terminal site at the level of the seventh motor nuclei.

Labeling of trigeminal mesencephalic cells occurred only with filling of the supraorbital or infraorbital trunks. The cells of the mesencephalic nucleus are distributed mediolaterally along the floor of the optic ventricle in the region of the posterior commissure. Following filling of the infraorbital trunk, labeled cells were observed throughout the nucleus. In contrast, filling of the supraorbital trunk results in labeling of only medially situated cells.

(Supported in part by NIH grants NS11006 and EY02485.)

383.5 PRIMARY TRIGEMINAL PROJECTIONS IN THE PACIFIC HAGFISH M.C. Ronan Dept. of Biology, Wesleyan University, Middletown, CT 06457

The central projections of primary afferents comprising major nerves of the trigeminal complex in the Pacific hagfish, Eptatretus stouti, were examined by transganglionic transport of horseradish peroxidase (HRP). In adult hagfish, 28-57 cm long, one or more branches of the opthalmic (17 cases), externus (12 cases), or dentalis (4 cases) nerves were uni- or bilaterally transected distal to their ganglia. Gelfoam pledgets, saturated with concentrated HRP (Sigma VI), were placed on the proximal nerve stumps. In three other animals, the facial or vagus nerves were similarly labeled. Animals survived 14-22 days at 10-14°C. After transcardial perfusion with 4% glutaraldehyde, the fixed brains were sectioned transversely at 40 µ and processed according to a modification of the Hanker-Yates procedure.

The nerves of the trigeminal complex join the brain stem in the prominent rostrolateral horns of the Y-shaped medulla. HRP-filled trigeminal afferents continue caudally in the large descending trigeminal tract of the dorsolateral medulla. Within the trigeminal tract, afferents associated with the major trigeminal nerves segregate into separate fascicles, each surrounded by a thick band of densely packed cells. Opthalmic afferents are situated in the dorsal and dorsomedial tract; externus afferents are found immediately lateral to the opthalmic field. Dentalis afferents are located ventrolaterally. In a single clearly labeled case for each, facial nerve fibers were seen to terminate in the dentalis field while primary vagal afferents coursed along the ventral and lateral borders of the same field. Heavily-labeled fibers in all trigeminal fascicles were traced as far as the rostral spinal cord.

The opthalmic, externus, and, to a lesser extent, the dentalis fields include both a medial, coarse-fiber fascicle and a separate lateral, fine-fiber fascicle, perhaps indicating the presence of two modalities in each nerve. Afferents in the most caudal branch of the opthalmic nerve are confined to the dorsal portions of both the medial and lateral opthalmic fields. Tract fascicles preserve their integrity throughout the extent of the trigeminal tract, but are further partitioned at more caudal tract levels by thin bands of cells. HRP injections of the midbrain reveal the neurons in the tract cellular bands as one source of ascending 2° trigeminal projections. These cells lying among the afferent fibers are likely the nucleus of the descending trigeminal tract.

Anatomical evidence suggests that the somatosensory system of the head, unlike the visual and octavolateralis systems, is well developed in hagfishes. The trigeminal tract occupies 20-25% of the total medullary volume, appears to be somatotopically organized, and may contain multiple modalities. (Supported by a Grass Fellowship at Friday Harbor Laboratories.)

383.6 LAMINATED AREA POSTREMA OF GOLDFISH: ULTRASTRUCTURE, IMMUNOREACTIVITY AND AFFERENTATION. Y. Morita and T.E. Finger. Dept. of Anatomy, Univ. Colorado Med. Sch., Denver, CO 80262.

The area postrema is the most caudal of the circumventricular organs. This specialized nucleus in the dorsocaudal medulla is well vascularized and is characterized ultrastructurally by fenestrated sinus capillaries and abundant connective tissue elements in a broad perivascular space. The proposed functions of the area postrema involve homeostatic reflex responses which are triggered by blood-borne chemicals, including functions such as emesis, osmoregulation, and cardiovascular control.

In goldfish, the area postrema is a fused midline structure extending along the dorsal surface of the caudal medulla. The area postrema is adjacent to the underlying commissural nucleus of Cajal which serves as the primary general visceral sensory nucleus. Although many of the ultrastructural features of the area postrema in goldfish are similar to those of other vertebrate species, the area postrema in goldfish is of interest in terms of being organized as a laminar system: meninx, vasculature, pallisade region, neuronal somata, and ventral neuropil. The pallisade region contains neuronal processes extending upward among more numerous astrocytic processes. These glial processes exhibit invaginations and coated vesicles typical of pinocytosis. In addition, vescicular and tubular membranous structures frequently occur within the glial processes.

Most neurons of the area postrema exhibit tyrosine-hydroxylase-like immunoreactivity. Each neuron has two types of dendritic specializations. A short foot process extends dorsally to reach the external basal lamina of the capillaries. No synaptic specializations occur on these foot processes, so the probable function of these processes is detection of blood-borne chemicals which leak out from the fenestrated capillaries. The other class of dendrites arising from the neurons of the area postrema are long, thick, basal dendrites which extend ventrally into the commissural nucleus of Cajal. These ventral dendrites receive numerous synaptic contacts, both within the ventral neuropil of the area postrema and within the commissural nucleus. At least two morphological types of terminals can be identified contacting the ventral dendrites. Some primary afferent fibers of the vagus nerve terminate within the area postrema as well as in the commissural nucleus. Thus neurons of the area postrema can act not only as direct chemoreceptive interoceptors, but may also receive input from other elements of the peripheral and central nervous system.

(Supported by NIH grants NS15258 and NS00772)

383.7 ORGANIZATION OF THE PRIMARY GENERAL VISCERAL SENSORY NUCLEUS IN THE GOLDFISH: ORGAN REPRESENTATION AND IMMUNOCYTOCHEMISTRY. T.E. Finger and Y. Morita. Dept. of Anatomy, Univ. of Colo. Med. Sch., Denver, CO 80262.

In many species of fish, such as the goldfish Carassius auratus, the general visceral sensory nucleus, or commissural nucleus of Cajal, is clearly distinct from the more rostrally situated special visceral (gustatory) centers. This allows for ready separation of general visceral from gustatory systems within the brainstem. The commissural nucleus receives direct input from primary sensory fibers of the vagus nerve roots which innervate the viscera (Morita et al., J.Comp.Neurol. '80). In the present study, HRP was used to label various peripheral branches of the vagus nerve or their endorgans. The commissural nucleus also was examined by immunocytochemical means in order to determine cytological boundaries.

The commissural nucleus is broadly divisible into two principal zones, medial and lateral. The medial zone lies caudomedial and ventral to the lateral zone, and is characterized by high levels of immunoreactivity to supstance P, tyrosine hydroxylase, serotonin and FMRF-amide antisera. Some somata immunoreactive for tyrosine hydroxylase also occur within the medial zone. Some of the substance P-like immunoreactivity in the caudal portion of the medial zone is diminished following transection of the vagus nerve. The substance P-immunoreactive terminals in this area form asymmetric synapses onto dendritic elements of the medial zone.

HRP labeling studies demonstrate that the medial subnucleus contains vagus nerve terminals of fibers which innervate the subdiaphragmatic (actually, sub-transverse septum) viscera. Sensory fibers which innervate supradiaphragmatic structures such as the heart, posterior pharynx, and esophagus terminate in the lateral subnucleus of the commissural nucleus. In addition, a small number of primary afferent vagal fibers project bilaterally to the area postrema and dorsal motor nucleus of the vagus. The visceral motor neurons innervating the supradiaphragmatic vagus tend to be segregated from those innervating subdiaphragmatic branches of the nerve. There are approximately 30 cardiac preganglionic parasympathetic neurons in a 15-20 cm goldfish and are located in a diffuse column situated just medial to the main body of the dorsal motor nucleus of the vagus.

(Supported by NIH grants NS15258 and NS00772)

383.8 MORPHOLOGY OF THE MACULA NEGLECTA IN THE BOWFIN, AMIA CALVA. W.M. Saidel and C.A. McCormick. Dept. of Anatomy, Georgetown Univ., Washington D.C., 20007.

The morphology of the macula neglecta (mn) of the bowfin, Amia calva was studied using light and scanning electron microscopy, and its central connections were determined using horseradish peroxidase (HRP) tract tracing methods. The mn consists of two asymmetric patches of sensory epithelia located at the base of the common crus immediately caudal to the utriculo-saccular duct in the posterior semicircular canal. The medial sensory patch forms a ridge across the canal and the lateral patch protrudes from a bulge in the canal's lateral wall. A gelatinous cupula overlies the sensory epithelia.

The ciliary bundles of most hair cells (hc) in the mn are characterized by long kinocilia and shorter stereocilia similar to those seen in semicircular canal cristae, and unlike those seen in otolithic endorgans. A kinocilium is located at the caudal pole of the ciliary bundle of hc's in the medial patch and at the rostral pole of hc's in the lateral patch. The surface area of the lateral patch is 60% of the medial patch (n=4), although the absolute areas varied in different specimens. Hc number was estimated in each patch by counting the number of hc bases in sonicated tissue. Hc density averaged 788±100/(100μm)$^2$ (n=18) in the medial patch and 880±92/(100μm)$^2$ (n=9) in the lateral patch, leading to a total number of about 8100 in an adult mn. 132±10 (n=4) nerve fibers innervate the mn for a convergence ratio of about 61 hc's/nerve fiber.

The distal portion of the mn nerve bifurcates into 2 branches, each branch innervating one sensory patch. The two branches merge proximally and join the posterior ramus of the eighth nerve. The proximal portion of the mn nerve was impaled with an HRP-coated minuten insect pin in 5 additional anesthetized Amia. After 6-10 days survival (28°C), the brains were processed as in a previous study (McCormick,'81). The mn nerve projects to the ventral divisions of the four octavus nuclei present in Amia and to the medial portion of the eminentia granularis. The pattern of distribution is similar to that of the posterior semicircular canal nerve. However, the medullary projection from the mn is very sparse, the majority of mn fibers terminating in the eminentia.

The macula neglecta is found in at least some species of all vertebrate classes, but its function has been little studied. Its function is unknown among bony fish, but its morphological features in Amia suggest a vestibular function.

Supported by NSF BNS 18343 and NIH NS1509-07.

383.9 ASCENDING CONNECTIONS OF THE TORUS SEMICIRCULARIS IN THE TADPOLE, RANA CATESBEIANA. K. Rubinson and C. Brown*. Dept. of Physiology & Biophysics, NYU Medical Center, New York, NY 10016.

Previous studies have indicated the contemporaneous existence of distinct acoustic and lateral line nuclei in the premetamorphic bullfrog (Jacoby, J. and Rubinson, K., J. Comp. Neurol., 216:152-161, 1983). Prior to the involution of the lateral line system, we have demonstrated descending efferent projections from the torus semicircularis (Jacoby J. and Rubinson, K. Brain Res., 292:378-381,1984). These toral projections appear to involve both acoustic and lateral line areas of the brainstem. To date, no demonstration of a toral-thalamic projection has been reported for the tadpole although such is known to exist in the adult bullfrog (Wilczynski, W., J. Comp. Neurol., 198:421-433, 1981).

We have injected horseradish peroxidase (HRP) into the torus semicircularis of bullfrog tadpoles, at Taylor and Kollros stages II-XI. In these various animals, we have traced ascending projections from the subnuclei of the torus to the ipsilateral thalamus with heavy terminal labelling in the central thalamic nucleus and the lower portion of the lateral thalamic nucleus. A small region of terminal labelling was found in the posterior entopeduncular region. In addition, filled cells, indicating neurons which project to the torus, were found in the posterior thalamic nucleus with dendrites extending laterally into and through the lateral nucleus. A few retrogradely filled cells were found on the medial edge of the central nucleus. No filled cells were found in the lateral nucleus.

This pattern is similar but not identical to that described for the auditory torus of adult bullfrogs. The additional regions of termination and filled cells may be attributable to the still functional lateral line system.

Supported by Grant NS15252.

383.10 ORGANIZATION OF THE RETICULO-SPINAL PROJECTION FROM THE ISTHMIC REGION IN THE FROG (Rana esculenta). B.G.Grover* and U.Grüsser-Cornehls* (SPON: European Neuroscience Association). Inst. of Physiol., Freie Universität Berlin, West Berlin, FRG.

It is difficult to compare the cytoarchetecture of the reticular formation in anurans to that in sauropsids and mammals. Most reticular cells in the former are found in or at the periphery of the central grey. Further, the distortion of the mes- and metencephalon resulting from the great development of the optic tectum make topographic comparison difficult. In the present study the distribution and dendritic morphology of reticular cells labelled after spinal applications of HRP or WGA-HRP were investigated, with particular attention to the mes- and metencephalon. Applications of tracer were made either by injection into the spinal grey via micropipettes or by lesioning the white matter with a tracer coated razor blade fragment. Additional cases were available in which injections had been made into the tectum and basal forebrain. Survival times of eight to 14 days were allowed. Alternate serial sections were processed on the slide with DAB and BDHC or TMB.

Axons of cells in the laminar nucleus of the torus semicircularis (TSl) and the anterodorsal (AD) and posteroventral (PV) nuclei of Potter descend ipsilaterally to at least lumbar levels and appear to terminate at all levels, principally ipsilaterally. Labelled cells are found in the rostral 3/4 of TSl but not in its medial or lateral parts. The rostral pole of AD is found at the level of midline fusion of the tori semicirulare. At this level cell labelling in TSl and AD is contiguous. Cell size and primary dedritic structure in TSl and AD are very similar. Further, both areas receive fibers from the tectum and forebrain, although fibers to TSl are sparser. These findings suggest that TSl and AD may represent extrusions of the same population of cells. The TSl-AD complex resembles, in its connections and topological relations, the intercollicular nucleus of sauropsids and the cuneiform area of mammals.

Labelling in AD is found ipsilateral to spinal injections. In the rostral 2/3 of PV labelling is primarily ipsilateral and found in the same locations on both sides. Caudal to the nucleus isthmi, ipsilateral labelling in PV tends to be found medially and contralateral labelling laterally. Labelled cells in the white matter of the isthmus were found contralateral to spinal injections. Although various nuclei of the upper pons may be represented in this area, more information is necessary to determine what parallels to amniote organization might exist.

383.11 STUDIES ON THE TERMINAL NERVE OF ELASMOBRANCH FISHES. L.S.Demski, R.D.Fields and T.H.Bullock. School of Biological Sciences, Univ. of Kentucky, Lexington, KY 40506 and Neurobiology Unit, Scripps Institution of Oceanography, La Jolla, CA 92093

Based on light microscopic analysis in stingrays (Urolophus halleri) and thornbacks (Platyrhinoidis triseriata), the terminal nerve (TN) consists of three ganglia distributed along a nerve that is separate from the olfactory tract (OT). A distal ganglion sits on a vascular sinus on the rostrodorsal surface of the olfactory bulb (OB). Its branches follow the sinus along the margin between the OB and the olfactory epithelium. Proximal ganglia are located between the OT and the surface of the forebrain. The more distal one is spindle-shaped and grades into the other. The most proximal ganglion or "white body" (WB) is round and has a lobular appearance with clusters of large cells separated by fibers of the TN. It sits on a vascular sinus on the forebrain surface and has branches that either extend along nearby vessels or enter the telencephalon directly. At the EM level the TN of the rays and the dogfish (Squalus acanthias) is characterized by many non-myelinated axons with diameters of .25-1.2µm. Many of the fibers contain clusters of dense core vesicles (DCV) with diameters to about .2µm. Neurons in the WB of dogfish have a multilobular nucleus with cytoplasm full of DCV. Synapses with clear vesicles occur in the ganglia and adjacent nerve. A few larger processes (up to 2.7µm) were observed in stingrays. They also contained DCV and were sometimes surrounded by multiple cytoplasmic membranes. In stingrays nerve processes (.8-2.5µm) appear to leave the TN and enter perivascular spaces. These endings also contain abundant DCV and resemble the large processes described above. Transfer of material from the nerve fibers to the vessels is suggested. Unit and multiunit responses were recorded from the TN-complex in stingrays using glass and metal microelectrodes. Fish were anesthetized in MS 222 and then immobilized with d-tubocurarine. Most units fired at a rather slow steady rate varying from 2 to about 8/s. In a few cases however, bursts of up to 15 to 30 or more/s occurred for periods up to 3-4s. Attempts to influence the activity of these units with light flashes, sounds in air, rubbing of skin, infusions of chemical solutions in the nares and water movements over the body were unsuccessful. Supported by NIH and NSF grants.

383.12 SPINAL PROJECTING NUCLEI IN THE BRAINSTEM OF AN ELASMOBRANCH, THE THORNBACK GUITARFISH, PLATYRHINOIDIS TRISERIATA. W.L.R. Cruce and R.G. Northcutt. Neurobiology Program, Northeastern Ohio Universities College of Medicine, Rootstown, OH 44272 and Division of Biological Sciences, University of Michigan, Ann Arbor, MI 48109.

It has recently been hypothesized (Cruce and Newman,'84, Amer.Zool.24: 733-753) that the reticulospinal nuclei of non-mammals are homologous to those of mammals. This hypothesis emerged from work in reptiles (e.g., Newman, et al.,'83, JCN 215: 17-32) and should be tested in representatives of other vertebrate classes. We have begun this by looking at an elasmobranch where we have found enough distinctly different spinal projecting nuclei that we believe we can recognize mammalian homologies. We have indicated these homologies by adopting, particularly for reticular nuclei, the mammalian names (using those of Newman,'85, J.Hirnfsch. 26(2)). These constitute a working hypothesis of homologies to be tested in the future, e.g. by investigating transmitter immunocytochemistry, afferent connections or ascending efferent connections.

Animals received unilateral placements of horseradish peroxidase (dried on a pin) into various levels of the spinal cord. After survival periods of 5-34 days, the animals were perfused, the brains removed and sectioned, and alternate sections were reacted with the tetramethyl benzidene or Hanker-Yates procedures. Sections were analyzed with the aid of a computer-microscope drawing system.

The following nuclei were identified and found to project to the spinal cord bilaterally (b), ipsilaterally (i) or contralaterally (c): reticularis dorsalis (b), reticularis ventralis (b), descendens nervi trigemini (b), ambiguus (c), solitarius (i), reticularis gigantocellularis (b), reticularis magnocellularis (i), raphe magnus, reticularis paragigantocellularis (i), octavus descendens (b), reticularis pontis caudalis pars a (i), reticularis pontis caudalis pars b (b), octavus magnocellularis (i), nucleus "B", reticularis pontis oralis pars medialis (i), reticularis pontis oralis pars lateralis (c), coeruleus-subcoeruleus (b), parabrachialis (Kolliker-Fuse) (c), mesencephalicus lateralis (c), pedunculo-pontine pars compacta (i), pedunculo-pontine pars dissipata (c), ruber (c), interstitialis fasciculi longitudinalis medialis (i), accessory oculomotor (Edinger-Westphal) (b), periventricularis pretectalis pars dorsalis (c), posterior tuberculum (i), ventromedialis thalami (i). Previously the majority of these nuclei have been grouped within the superior, middle, and inferior reticular nuclei. This is the first report in any fish of spinal projecting brainstem nuclei with a level of complexity comparable to that of mammals. Supported in part by grants from the Stark County United Way (WLRC) and NIH grants NS11006 and EY02485 (RGN).

383.13 PECULIAR INTRACRANIAL CIRCULATION IN AN ELASMOBRANCH: THE RETE MIRABILE CRANICA IN THE GENUS MOBULA. J. Schweitzer and G. Notarbartolo-di-Sciara*. Neurobiology Unit, Scripps Institution of Oceanography, Univ. of Calif., San Diego, La Jolla, CA 92093

For two centuries cranial blood supply has been studied in diverse species of batoids and sharks, yet the unusual cephalic circulation in the highly specialized devil rays (Mobulidae; genera Manta and Mobula) has received little attention. We describe the morphology of the mobulid rete mirabile cranica (RMC) using histological, scanning electron microscopic, and plastic corrosion cast techniques. It is a massive arterial network grossly divisible into a "caudal RMC" supplying blood to the brain and an expanded more complex "precerebral RMC" nested within the large cranial cavity rostral to the brain. The precerebral rete in a 45 kg M. thurstoni with a 100 g brain weighs 40g (compare to a 30 g brain in a nurse shark (Ginglymostoma cirratum, no rete) of the same weight).

Although important interspecific differences are apparent among the retia of the 4 Mobula species studied, all share a common plan. The RMC originates from the posterior portion of the profundae cerebri arteries which lie ventral to the brain and form the sides of a vascular triangle, the base of which is anterior and formed by the joining of the paired internal carotids; the vertex is posterior and median, corresponding to the anterior extreme of the spinalis impar artery. Blood enters the spinalis impar from the paired dorsal aortae through small communicating vessels and from there diverges to flow both cranially and caudally. Cranial blood is supplied exclusively from the spinalis impar and paired internal carotids and enters the brain through vessels of the caudal rete which branch posteriorly from both profundae cerebri. Vessels branching more anteriorly course rostrally to form the precerebral RMC, a massive network of convoluted arteries (each ca. 1mm diameter with thick muscular walls) encased in a gelatinous matrix anterior to the telecephalon. Within the gelatinous matrix the precerebral RMC is a paired structure divided along the midline, across which the 2 sides do not communicate except by means of a single rostral transverse artery. The precerebral rete takes the shape of the cranial cavity and completely envelops the olfactory nerves to the level of the olfactory bulbs at its anterolateral extreme. Some of the large vessels taper and branch to ca. 160 um, forming a secondary arterial system. Many of the these smaller arteries course parallel to the primaries and give rise to a mesh of finer (ca. 30 um) tertiary vessels which ensheath the largest arteries. Both secondary and tertiary vessels are embedded in the adventitia of the primaries, with which they communicate by numerous arterioarterial anastomoses.

The RMC clearly is not a counter-current device, but its tremendous complexity and fine structure suggest some specialized function(s). The secondary arterial system may be involved in plasma skimming and the production of cerebrospinal fluid; significantly, in mobulids the lateral ventricles, and probably the choroid plexuses, are greatly reduced.

Supported by NIH and NSF grants to T.H. Bullock

383.14 NEW VIEWS ON THE NEUROPILE OF THE EYESTALK OF THE PROCAMBARUS CLARKI. J.P. Machado-Salas, B. Pérez*and J.Espinosa* Lab. Neuromorfología.Neurociencias.UIICSE.ENEP Iztacala.UNAM.Tlalnepantla 54030.Edo. de México.MEXICO.

While studying some structural aspects of plasticity shown by the neurosecretory system of the eyestalk of the P.clarki,we realized that the structural and ultrastructural features of this organ was far from been fully studied.Actually some of the available data is null or scarce and in some respects is oudated.For this reason, we have used silver stains and some ancillary neurohistological techniques to study the normal eyestalk of this particular crayfish, as an adequate prelude for further ultrastructural studies.

The eyestalks of mature female crayfish were sectioned and immediately fixed in buffer-formaldehyde;afterwards, some eyestalks were immersed in the Golgi solution (osmic-dichromate) and the remaining tissue was processed with PAS, luxol-fast-blue and Nissl's techniques.In all cases, we made transverse and longitudinal sections.

Our results have shown: a) a rather complex vascular pattern, which is highly sophisticated at the level of the medulla externa, b) here, we saw two rows of cell nests surrounded by vascular meshes, c) high cellularity of the external medulla contrasts with the almost acellular panoram shown by the twoother medullas, d) the peripheral cellular systems, that surround the core of the eyestalk and includes the X-organ, showed three types of neurons:small, medium and large, e) the latter are few and some of them are strongly positive for PAS stain. f) the nerve fibers that originate at the inferior portion of the external medulla, develop a bipenate pattern, which repeats in every section as 3 long and 4 to 6 short bipenated columns, g)the sinus gland shows the typical loose vascular pattern and the presence of neurosecretory granules, h) finally, the 140 microns-thick Golgi sections, have provided further data on: the penetration of the retinal fibers, the vasculo-cellular relationships, a rich variety of nerve cells which processes cover a full range of anatomical varieties and a better understanding of the tridimensional features of these neuropiles.

These data shall be discussed in terms of current physiological knowledge of this structure.

384.1 EPILEPTOGENIC EFFECTS OF CARBACHOL MICROINJECTED IN THE BRAINSTEM. Z. Elazar. Dept. of Physiology and Pharmacology, Sackler Medical School, Tel Aviv University, Israel, 69978.

Experiments were performed in chronic rats to determine the sensitivity of the brainstem reticular formation to the convulsant effect of carbachol. Carbachol was microinjected in hippocampus, mesencephalic reticular formation (MRF) and pontine reticular formation (PRF). EEG activity from hippocampus, MRF, PRF, motor cortex and the site of microinjection was monitored. Cervical EMG was also monitored.

In hippocampus, amounts of carbachol at threshold for local electrical seizures (0.5-1 μg in 1 μg saline) induced immobility or behavioral excitation. Higher amounts of carbachol induced clonic convulsions. Hippocampal seizures mostly spread to reticular formation.

In MRF, amounts of carbachol 200-500°/o higher than in hippocampus were necessary to induce local electrical seizures, which were similar graphically to hippocampal seizures. MRF seizures spread to PRF, hippocampus and motor cortex. These seizures could be accompanied by the following motor phenomena: immobility, behavioral excitation, facial clonies, forelimb clonies, whole body clonic jerks and generalized clonic convulsions.

Amounts of carbachol similar with those inducing Grand Mal convulsions when injected in MRF, induced when injected in PRF signs of REM sleep: local EEG desynchronization, cortical desynchronization, sustained theta waves in hippocampus and muscle atonia. The threshold for local electrical seizures and convulsions was in PRF 200-400°/o higher than in MRF.

Intracerebral injections of 6-OHDA lowered the threshold for PRF local seizures and convulsions.

We conclude as follows: 1. local organized electrical seizures can be induced in the brainstem reticular formation by chemical stimulation. This is in contrary to results published so far according to which electrical stimulation of the reticular formation induces convulsions but not local EEG seizures. 2. PRF has a higher threshold for epilepsy than MRF. 3. Locus coeruleus noradrenergic mechanisms control the sensitivity to epilepsy of the PRF. 4. REM sleep or epilepsy can be induced from the pons depending on the intensity of chemical stimulation.

384.2 SYNCHRONOUS PAROXYSMAL DISCHARGES IN NEOCORTICAL SLICES FROM CHEMICALLY KINDLED RATS. E. Barkaie*, A. Friedman*, R. Lobel-Yaakov* and M.J. Gutnick*, (Spon: R. Foster) Unit of Physiology, Faculty of Health Sciences, Ben Gurion University of the Negev, Beersheva, Israel.

Kindling refers to an experimental model of epilepsy in which repetitive daily delivery of low-intensity electrical or chemical stimuli gradually induces a permanent change in the epileptogenic sensitivity of forebrain structures, such that initially subconvulsive stimuli become capable of evoking paroxysmal activity. The purpose of the present study was to determine whether the kindled state in neocortex is correlated with consistent changes in the activities of individual neurons. Intracellular recordings were made in neocortical slices from rats that had previously been chemically kindled.

Fifteen adult rats were kindled by systemic administration of an initially subconvulsive dose of pentylenetetrazol (PTZ) (30 mg/kg ip every 48 hrs). After each injection, the animal's convulsant response was classified on a scale of 1-4. The first PTZ injection never caused any obvious convulsive effect; severity of subsequent responses increased progressively and class 4 seizures were observed in all animals by the 7th-20th injection, at which time regular PTZ injections were discontinued. In each animal, a single injection of 30 mg/kg PTZ still evoked a class 4 response after a drug free period of a month or more. An equivalent number of litter mates received saline injections. Intracellular recordings were made in slices of parietal neocortex (400 μm thick) that had been prepared from kindled and control rats and maintained *in vitro* at 36°C in oxygenated Ringer solution (2 mM Ca, 5 mM K). Recordings and data analysis were done blind.

In slices from all kindled rats, but not from control rats, low intensity electrical stimuli to the white matter evoked all-or-none paroxysmal extracellular field potentials which occured in synchrony with intracellularly recorded depolarization shifts and superimposed spike bursts. The characteristics of these kindling-related paroxysmal responses were very similar to those previously reported for epileptogenesis in neocortical slices exposed to convulsant agents.

Intracellular injections of the fluorescent dye lucifer yellow CH were made to test whether the kindled state might be associated with an increased tendency for neocortical neurons to be dye-coupled, and hence, electrotonically coupled. While dye-coupling was present in slices from kindled animals, its incidence was no greater than in control.

384.3 DURATION OF POST-ICTAL REFRACTORINESS IN THE GENETICALLY EPILEPSY-PRONE RAT (GEPR). C. E. Reigel, Jr.*, J. W. Dailey, J. A. Ferrendelli and P. C. Jobe. Department of Basic Sciences, University of Illinois College of Medicine at Peoria, Peoria, IL 61656, Department of Pharmacology, Louisiana State University Medical Center in Shreveport, Shreveport, LA 71130 and Departments of Pharmacology and Neurology, Washington University School of Medicine, St. Louis, MO 63110.

There are currently two strains of genetically epilepsy-prone rats (GEPRs), each demonstrating a characteristic pattern of convulsion in response to sound. The moderate seizure animals (GEPR-3s) exhibit a generalized clonic convulsion, whereas the severe seizure animals (GEPR-9s) exhibit a generalized tonic convulsion, each in response to sound. In both strains, wild running is the initial response to sound, preceding the actual convulsion.

Although it is known that GEPRs retain their sound-induced seizure susceptibility for life and that GEPR-3s and GEPR-9s each demonstrate a predictable pattern of convulsion, little is known about the duration of post-ictal refractoriness to sound-induced convulsions in these animals. GEPRs have been sound stimulated once daily for extended periods of time with no decrease in the severity of convulsion. Nonetheless, protocol for anticonvulsant testing in our laboratory requires that GEPRs recover one week from their last sound-induced convulsion before anticonvulsant testing takes place. This minimizes the possibility of confounding post-ictal refractoriness with an anticonvulsant effect. The present study was performed to determine specifically the duration of post-ictal refractoriness of GEPR-3s and GEPR-9s to sound-induced convulsions.

In the present study, GEPRs were sound stimulated twice, with the inter-stimulus interval varying between 0.5 and 24 minutes. Latency to onset of wild running, latency to onset of convulsion and seizure severity were determined at both time points.

Seizure severity returned to normal approximately four times faster in GEPR-3s than in GEPR-9s. Seizure severity was normal within three minutes in GEPR-3s and within twelve minutes in GEPR-9s. In both GEPR-3s and GEPR-9s, latency to onset of wild running took longer to return to normal than seizure severity. Increased latency to onset of convulsion returned to normal in both GEPR-3s and GEPR-9s at a slower rate than any of the other indices of post-ictal refractoriness. 384.4 MANNITOL PREVENTS NECROTIC EDEMA ASSOCIATED WITH KAINIC ACID INDUCED SEIZURES. J.P. Olson*, F.E. Samson, T.L. Pazdernik* and S.R. Nelson. Departments of Anatomy, Pharmacology and the Ralph L. Smith Res. Ctr., University of Kansas Medical Center, Kansas City, Kansas 66103.

Repetitive kainic acid (KA) induced seizures in rats produces selective brain damage. Early cellular edema accompanies the seizures and may contribute to the necrosis observed 24 hrs later by interfering with the vascular perfusion of the affected areas as suggested by Sperk et al. *Neurosci.* 10:1301, 1983; Lassman et al. *Neurosci.* 13:691, 1984. Mannitol was infused to determine if the necrotic edema could be prevented by dehydrating the brain during the cellular edema phase. Male Wistar rats (250-325g) were used. Twelve to 24 hrs after cannulation of the femoral vein, the rats were injected with KA (12mg/kg, s.c.) and the ensuing behavior was scored on a 4.0 scale with a 2.0 and above indicating repetitive clonic seizures. At the onset of the clonic seizures (2.0), mannitol (1.6M) or isotonic saline was infused at 0.1ml/min for approximately 30 min. The seizures were stopped with diazepam (5-10mg/kg, i.v.) 60 min after the seizure onset and the rats were sacrificed 24 hrs later for measurement of brain edema (specific gravity change). KA-induced seizures produce significant ($p<0.05$) decreases in specific gravity (necrotic edema) from vehicle treated control in piriform/entorhinal cortex (27% vol increase) and hippocampus (10% vol increase) when infused with saline. No edema was present in thalamus and paricetal cortex. In rats treated with mannitol during the seizure there was no significant edema in any area measured (piriform/entorhinal cortex, hippocampus, thalamus and parietal cortex). Thus, the early cellular edema associated with KA induced seizures appears to play an important role in the later development of regional tissue necrosis.Supported by: U S Army DAMD 17-83-C-3242.

384.5 INCREASE IN THE NUMBER OF HIPPOCAMPAL $^3$H-GLUTAMATE BINDING SITES IN RATS INBRED FOR A GENETIC PREDISPOSITION TO ACOUSTIC STIMULUS INDUCED SEIZURES. S.A. Mills*. C.E. Reigel, P.C. Jobe, and D.D. Savage, Dept. Pharmacol., New Mexico Sch. Med., Albuquerque, NM 87131 and Dept. Basic Sciences, Illinois Col. Med., Peoria, IL 61656 (Spon: R.D. Brown).

Several colonies of genetically epilepsy prone rats (GEPR) have been developed from inbreeding Sprague-Dawley rats exhibiting audiogenic seizures. In response to an acoustic stimulus, rats from the GEPR 9 colony exhibit full tonic extensor seizures, and GEPR 3 rats exhibit running fits followed by clonus. A control colony of rats display no seizure activity. Previous studies have suggested a deficit in monoamine neurotransmission as one factor contributing to the audiogenic seizure responsiveness of GEPR 3 and GEPR 9 rats. Central excitatory neurotransmitter systems have received little study.

The binding of $^3$H-glutamate to a putative glutamate receptor was studied in synaptic membranes prepared from the hippocampal formation (HPF) of controls, GEPR 3, and GEPR 9 rats according to the methods of Werling et. al. (J. Neurochem. 41: 586). At 10 nM $^3$H-glutamate, specific binding was elevated significantly in GEPR 9 rats (0.749 +/- 0.078 pmol/mg prot., n=10) as compared to seizure resistant controls (0.526 +/- 0.065 pmol/mg prot., n=10; $p<0.05$). Specific glutamate binding in GEPR 3 rats was intermediate between that of controls and GEPR 9 rats (0.612 +/- 0.084 pmol/mg prot.). Scatchard analysis of specific binding indicated an increase in total number of binding sites in GEPR 9 rats (19.5 +/- 1.5 pmol/mg prot., n=6) as compared to controls (12.3 +/- 1.1 pmol/mg prot., n=6; $p<0.005$). Total number of binding sites in GEPR 3 rats was 14.8 +/- 3.0 pmol/mg prot. There was no significant difference in the apparent affinity binding constant ($K_d$) in the three groups. These results indicate there is a graded elevation in total number of specific $^3$H-glutamate binding sites in the HPF of GEPR 3 and GEPR 9 rats compared to seizure resistant controls.

GEPR rats have been shown to exhibit kindling stimulus-induced seizures after fewer stimulations than audiogenic seizure resistant controls. Glutamate is thought to be one excitatory neurotransmitter in the HPF. An increase in the number of glutamate receptors in the HPF would suggest a net increase in the excitability of the HPF. An elevation in glutamate binding may explain, in part, why the early stages of kindling are accelerated in GEPR rats. Further, these results indicate that the HPF may be one area contributing to seizure responses of GEPR rats.

384.6 ALTERATIONS IN HIPPOCAMPAL AFTERDISCHARGE ACTIVITY FOLLOWING ADMINISTRATION OF PICROTOXIN, PENTYLENETETRAZOL OR CAFFEINE. L. J. Burdette* & R. S. Dyer. (Spon: L. Grant). Northrop Services, Inc. and U. S. Environmental Protection Agency, Research Triangle Park, NC 27711

Electrical stimulation of the hippocampus results in a train of high amplitude synchronous spike activity, known as the primary afterdischarge (PAD). A period of postictal depression follows and is terminated by the appearance of a second train of spike activity, the rebound afterdischarge (RAD). Although the effects of depressants on hippocampal afterdischarge parameters are well documented, little attention has been directed to the action of stimulants on these measures. The objective of the present investigation was to identify alterations in hippocampal afterdischarge parameters following administration of subconvulsant dosages (half of the minimal convulsant dosage) of picrotoxin, pentylenetetrazol or caffeine.

Long Evans rats (N=104) were implanted with chronic bipolar electrodes in the dorsal hippocampus, with ground and reference screw electrodes placed over ipsilateral and contralateral frontal cortex, respectively. One week later, subjects were assigned randomly to one of four treatment groups: saline (0 mg/kg ip); picrotoxin (2 mg/kg ip); pentylenetetrazol (20 mg/kg ip); or caffeine (75 mg/kg ip). Afterdischarge threshold testing was initiated fifteen minutes after injection. Beginning at 10 μamps, current (2 second train of 50 Hz biphasic pulses) was increased in 10 μamp steps every minute until a PAD was elicited. Afterdischarge threshold, the duration of the PAD, postictal depression and RAD, and frequency of wet dog shakes (WDS) were analyzed.

Hippocampal afterdischarge parameters were affected differentially by the three convulsants. Caffeine dramatically prolonged RAD (threefold increase) without altering PAD duration or other variables. This dissociation between PAD and RAD suggests that different mechanisms may be involved in terminating the two spike trains. Because caffeine has been shown to occupy adenosine receptors at physiological concentrations, adenosine may be implicated in terminating rebound activity in the hippocampus, an adenosine-rich structure. Picrotoxin and pentylenetetrazol decreased WDS frequency; all other parameters remained unchanged. As picrotoxin is a known GABA antagonist, this observation is compatible with evidence that dentate granule cell discharge, inhibited by GABA, is necessary to observe wet dog shakes. Surprisingly, no treatments altered thresholds, or the duration of the PAD or postictal depression relative to control values. Discriminating pharmacological probes may further elucidate mechanisms responsible for hippocampal afterdischarge parameters.

384.7 EFFECT OF NONSTEROIDAL ANTI-INFLAMMATORY DRUGS ON PENICILLIN FOCAL MODEL OF EPILEPSY IN RAT. M.C. Wallenstein.
New York University, New York NY 10010

Nonsteroidal anti-inflammatory drugs (NSAIDs) inhibit the action of cyclo-oxygenase on arachidonic acid which can lead to production of endoperoxides, prostaglandins or thromboxanes. These metabolites play a role in many functions of the body. A previous study in the rat suggested that this inhibition of CNS arachidonic acid metabolism by NSAIDs decreases and/or blocks the motor component of seizures induced by systemic pentylenetetrazol without having a similar consistent effect on the electrocortical component of the seizures (Wallenstein, 1985). This suggested an "anticonvulsant" action without a concurrent overall anti-CNS excitatory action.

In the present study, this hypothesis was tested on a focal model of epilepsy. Penicillin-G (500 units in 5 μl) was administered to the frontal cortex of conscious, free-moving rats chronically implanted with stainless steel cannula and supracortical screw electrodes. In a series of randomized tests each rat was used as its own control. Penicillin induced CNS excitation was quantified by measuring such parameters as onset latency to, and number of, electrocortical spikes and seizures, myoclonus, and convulsions.

Pretreatment with paracetamol significantly decreased the number of penicillin-induced seizures. Ibuprofen significantly decreased the number, and delayed onset, of electrocortical seizures. Mefenamic acid significantly delayed onset, but increased the number, of electrocortical seizures. However, all of these NSAIDs significantly decreased the number of motor seizures (i.e. convulsions). These results are consistent with the hypothesis that the NSAID induced effect on motor seizures results from inhibition of arachidonic acid metabolism while the drug-specific actions result from either tissue-specificity of NSAIDs (Flower and Vane, 1974) or from actions not related to cyclo-oxygenase inhibition (Collier and Sweatman, 1968; Levy and Lindner, 1971; Phillis and Wu, 1981).

384.8 EFFECT OF PRECOLLICULAR TRANSECTION ON ELECTROSHOCK AND PENTYLENETETRAZOL-INDUCED SEIZURES IN RATS. R.A. Browning and D.K. Nelson*. Southern Illinois University, School of Medicine, Carbondale, IL 62901.

The motor components of experimentally-induced seizures (convulsions) have long been used to assess seizure severity and to evaluate potential antiepileptic drugs. Convulsions in experimental animals generally consist of clonic and/or tonic components. We have recently suggested that clonic convulsions in rats can be divided into at least two subtypes: (1) face and forelimb (F&F) clonus which is seen in the early stages of pentylenetetrazol (PTZ) seizures as well as in minimal electroshock seizures and (2) running-bouncing (R/B) clonus which is observed in the latter stages of PTZ seizures and in rats undergoing minimal audiogenic seizures.

Previous studies have shown that tonic convulsions and R/B clonus are suppressed by lesions in the pontine reticular formation, while clonus is not. Therefore, we have proposed that both tonic convulsions and R/B clonus require a neural substrate in the brainstem for expression, while F&F clonus depends on a discharge emanating from the forebrain. In order to test this hypothesis further, we have examined the effect of a precollicular transection on convulsions induced by minimal electroshock (a.c.EST), maximal electroshock (MES) and PTZ.

Brain transections (between the diencephalon & midbrain) were made in male Sprague-Dawley rats (260-360g) under ether anesthesia and seizure testing was carried out 3 hours after transection or sham-surgery. Sham-operated rats treated with PTZ (50 mg/Kg i.p.) displayed the following sequential convulsive pattern: F&F clonus → twisting clonus → R/B clonus → tonus, while transected rats displayed only R/B clonus → tonus. Similarly, the transection was found to abolish F&F clonus in rats receiving a.c. EST., although R/B clonus or tonus could still be elicited when higher stimulating currents were employed. Transected rats subjected to the usual MES stimulus (150 mA, 0.2 sec.) exhibited tonic flexion, but failed to display hindlimb extension. However, transected rats subjected to higher stimulus MES (200 mA, 0.4 sec.) displayed a typical maximal convulsion consisting of tonic flexion, tonic hindlimb extension and clonus.

These findings support the hypothesis that tonic and some types of clonic convulsions can occur independently of seizure discharge in forebrain structures, while clonus restricted to the face and forelimbs seems to depend on structures within the forebrain for expression.

384.9 ABNORMALITIES IN BRAIN NOREPINEPHRINE LEVELS IN GENETICALLY EPILEPSY-PRONE RATS. J.W. Dailey, C.E. Reigel, Jr.*, K.H. Ko*, M.T. Acurio*, J.E. Penny and P.C. Jobe. Depts. of Pharmacol., Psy. and Anat., LSUMC, Shreveport, LA 71130, Dept. of Pharmacol., Sch. of Pharm., Seoul Natl. Univ., Seoul, Korea and Dept. of Basic Sci., Univ. of IL, Coll. of Med., Peoria, IL 61656.

The seizure prone-state of the genetically epilepsy-prone rat (GEPR) is characterized by susceptibility to sound-induced seizures and hyperthermic seizures. Some GEPRs also appear to experience spontaneous seizures and dolorogenic seizures. In addition, the GEPR exhibits abnormal responses to electroshock, pentylenetetrazole, bicuculline and barbiturate withdrawal seizures. We have previously shown (Biochem. Pharmacol. 30:3157, 1981) that manipulations that decrease synaptic norepinephrine increase seizure severity whereas manipulations that increase synaptic norepinephrine decrease seizure severity in the GEPR. We have also reported (Fed. Proc. 43:2505, 1984) that there are widespread deficits in brain norepinephrine concentration and turnover rate in the GEPR. These studies showed that at least two types of brain norepinephrine deficits exist. One type of deficit is graded in that moderate seizure GEPRs (GEPR3) have moderate decrements in norepinephrine concentration and severe seizure GEPRs (GEPR9) have severe decrements in norepinephrine concentration. In the other type of deficit, the decrements in norepinephrine are of equal magnitude in both moderate (GEPR3) and severe (GEPR9) seizure animals. Because of these and other data we have hypothesized that deficits in brain norepinephrine partially regulate both seizure severity and seizure susceptibility in the GEPR.

We are now carrying out studies designed to trace the noradrenergic deficits to smaller and smaller brain areas and to determine in which areas deficits are graded and in which areas they are not. For this study we examined norepinephrine concentration in six brain areas of animals whose seizure characteristics had been confirmed by testing. That is, each animal had been exposed to an acoustic stimulus three times at weekly intervals. In each of the three tests each animal experienced its characteristic convulsion. The brain areas examined were inferior colliculus, superior colliculus, medulla, midbrain tegmentum, basal pons and pons tegmentum. In each of these areas GEPRs exhibited abnormally low brain norepinephrine concentrations when compared with control. None of the areas had graded deficits. That is, severe seizure animals (GEPR9) did not have greater deficits than moderate seizure animals (GEPR3). We conclude that norepinephrine in these brain areas may regulate seizure susceptibility but not seizure severity in the GEPR. (Supported in part by NS16829.)

384.10 ABNORMAL BRAIN 5-HYDROXYTRYPTAMINE LEVELS IN GENETICALLY EPILEPSY-PRONE RATS. P.C. Jobe, C.E. Reigel, Jr.*, K.H. Ko*, M.T. Acurio*, J.E. Penny and J.W. Dailey (SPON: John J. Stewart). Depts. of Pharmacol., Psy. and Anat., LSUMC, Shreveport, LA 71130, Dept. of Pharmacol., Sch. of Pharm., Seoul Natl. Univ., Seoul, Korea and Dept. of Basic Sci., Univ. of IL, Coll. of Med., Peoria, IL 61656.

The genetically epilepsy-prone rat (GEPR) is susceptible to sound-induced seizures and to hyperthermic seizures. These animals also exhibit abnormal sensitivities to electroshock and several of the chemical convulsants. Presently there are two colonies of seizure susceptible GEPRs maintained at the University of Illinois College of Medicine in Peoria. One colony is composed of moderate seizure animals (GEPR3) that experience a wild running phase that terminates in generalized clonus when sound-stimulated. The second colony is composed of severe seizure animals (GEPR9) that experience a wild running phase that terminates in a tonic extensor convulsion when sound stimulated. A colony of seizure resistant controls is also maintained. The breeders used in the control colony are tested and are known to be resistant to sound-induced seizures.

Pharmacologic studies have suggested that brain 5-hydroxytryptamine may play an important role in regulating seizure susceptibility and severity in the GEPR. Also, previous pathophysiologic studies in large brain areas have demonstrated widespread abnormalities in brain concentrations of 5-hydroxytryptamine.

For the present report we dissected the brain into smaller areas in order to begin to trace the deficits in 5-hydroxytryptamine to specific tracts. In this study we determined 5-hydroxytryptamine levels in 6 brain areas of animals that had been sound-stimulated and had experienced convulsions. In the medulla, midbrain tegmentum, superior colliculus and pons tegmentum 5-hydroxytryptamine levels were significantly lower than control in moderate seizure (GEPR3) and severe seizure (GEPR9) animals. These deficits were not greater in the severe seizure animals than in the moderate seizure animals. That is, they were not graded. In the basal pons and the inferior colliculus the 5-hydroxytryptamine levels in moderate seizure (GEPR3) animals were significantly lower than control and significantly lower than the levels in severe seizure (GEPR9) animals. The levels in severe seizure animals did not differ from control. These results suggest that abnormalities in 5-hydroxytryptamine concentration in the medulla, midbrain tegmentum, superior colliculus and pons tegmentum may play a role in the regulation of seizure susceptibility in the GEPR. Because the severe seizure (GEPR9) animals did not have lower 5-hydroxytryptamine levels than control, the data do not suggest a similar role for this biogenic amine in the inferior colliculus and basal pons (supported in part by NS 16829).

384.11 DIFFERENCES BETWEEN STRYCHNINE AND PENICILLIN EPILEPTOGENESIS SUGGEST A LAMINAR ORGANIZATION OF NEOCORTICAL INHIBITION. A.B. Chatt and J.S. Eberaole. Department of Neurology, Yale University School of Medicine, New Haven, CT 06510 and Epilepay Center, VA Medical Center, West Haven, CT 06516.

We have demonstrated recently that stellate layer 4 of cat striate cortex is the lamina most susceptible to the epileptogenic effects of PENICILLIN, a partial blocker of GABA mediated inhibition; while superficial pyramidal layers 2 and 3 are uniquely sensitive to the epileptogenic effects of STRYCHNINE, a putative blocker of GLYCINE mediated inhibition. Based on this very distinctive tissue segregation of convulsant sensitivities, we have concluded that laminar differences in inhibitory mechanisms may exist in cat visual cortex. In this report, we present evidence that these two convulsants appear to differentially influence extrinsically (thalamocortical) and intrinsically (local circuit, LCN) evoked cortical activity.

Epileptogenesis, in our model, proceeds through two distinct stages before large negative epileptiform potentials are recorded simultaneously from each cortical layer. The first stage is the enhanced amplitude of the normal (physiologic) evoked response (EPR) which has been shown to be a result of extrinsic, thalamocortical afferent barrages. The second is the late response (LR) occurring later in time than the EPR and believed to be the result of intrinsic/ LCN activity.

Regardless of the lamina injected, we have never seen PENICILLIN epileptogenesis without an initial EPR in layer 4, site of the major thalamic input to the cortex; making penicillin's action in this regard critical to the onset of epileptiform abnormalities in all cortical layers. Autoradiographic evidence indicates that $^{14}C$-labeled penicillin in contact with layer 4 may be critical to the generation of these EPRs. STRYCHNINE's epileptogenic action, however, appears to be independent of both layer 4 and the extrinsically evoked EPR. Only injections into the superficial pyramidal layers, where extrinsic influences are considerably reduced, ellicited epileptiform activity reliably; with LRs occurring there without prior EPRs in layer 4. Injection directly into layer 4 seldom induced multilaminar epileptiform alterations, but when it did, this activity occurred very late (4-6 min, post-injection) there and simultaneously in the superficial layers as an intrinsically-mediated LR; perhaps indicating that strychnine diffusion into the most sensitve superficial layers is necessary to initiate epileptogenic alterations.

STRYCHNINE, therefore, exerts it's epileptogenic action principally where direct thalamic driving is minimal and it's influence can most easily be seen on LCN-mediated cortical potentials. PENICILLIN's principal action is on thalamically evoked cortical activity.

384.12 **CORRELATIONS BETWEEN ANTICONVULSANT ACTIVITIES WITH PLASMA AND BRAIN CONCENTRATIONS OF AHR-11748, A NEW ANTIEPILEPTIC.** M. A. Osman*, L. K. Cheng*, D. N. Johnson, and G. J. Wright*. (SPON: J. A. Rosecrans). A. H. Robins Research Lab, Richmond, VA 23261-6609.

In order to correlate the anticonvulsant effects of AHR-11748, (3-[3-(trifluoromethyl)phenoxy]-1-azetidinecarboxamide), with its concentrations in the plasma and brain, groups of 16 mice received intraperitoneal doses ranging from 10 to 225 mg/kg. Thirty min after dosing, half of the mice in each group were subjected either to maximal electroshock (ES) or Metrazol (M) challenge. The other animals were sacrificed by decapitation, and plasma and brain samples were collected and pooled (n = 4). Concentrations of AHR-11748 were determined by a specific HPLC method. The results showed that the plasma and brain concentrations of AHR-11748 were directly proportional to the doses administered. The concentrations in the brain were consistently higher than those in plasma; the tissue-to-plasma ratio was 3.4 ± .38 over the entire dose range. When the concentration of AHR-11748 was 48.0 µg/g in the brain (14.5 µg/mL in plasma), then 50% protection against ES was observed; 77.0 µg/g in the brain (21.4 µg/mL in plasma) was correlated with 100% protection. The brain and plasma concentrations were about 3.5 times higher to provide corresponding levels of protection after M challenge. The duration of action (protection against ES) of AHR-11748 was determined in mice dosed with 60 mg/kg of AHR-11748 intraperitoneally. Total protection was observed up to 2 hr after dosing and the effect was reduced to 10% after 4 hr. The decline in pharmacologic effects correlated with to the elimination profiles of AHR-11748 in the plasma and brain.

384.13 **AHR-11748, A POTENTIAL ANTIEPILEPTIC AGENT.** David N. Johnson, Brian F. Kilpatrick,* and Ewart A. Swinyard,* A. H. Robins Research Labs, Richmond, VA 23261 and U. Utah, Salt Lake City, UT 84112.

AHR-11748 (3-[3-(trifluoromethyl)phenoxy]-1-azetidinecarboxamide) was effective in mice and rats in preventing seizures induced by electrical (maximal electroshock) and chemical (sc Metrazol, bicuculline, picrotoxin) challenge. The pharmacologic profile of activity of AHR-11748 most closely resembled that of phenobarbital and valproic acid, and differed from that of phenytoin and ethosuximide. The potency of AHR-11748, administered IP, was approximately 1/2 to 1/5 that of phenobarbital; compared with valproic acid, AHR-11748 was approximately 2 to 6 times more potent. The drug was well absorbed orally; the oral $ED_{50}$s were approximately 1 1/2 times greater than the intraperitoneal $ED_{50}$s. Tolerance to the anticonvulsant effects did not develop in rats when the drug was administered daily for 5 days. In concentrations up to $10^{-4}$M, AHR-11748 did not displace or enhance $^{3}$H-GABA from mouse whole brain synaptosomes, nor did it displace or enhance $^{3}$H-flunitrazepam from rat cortex synaptosomes. Further, AHR-11748, at $10^{-4}$M, did not displace $^{35}$S-TBPS binding from rat whole brain synaptosomes. Behavioral effects in mice after large doses of AHR-11748 included ataxia, muscle weakness, and decreased spontaneous motor activity. The $ED_{50}$s for the rotorod and the loss of righting reflex tests were 203 and 413 mg/kg, IP, respectively. AHR-11748 was relatively weak in blocking morphine-induced Straub tail in mice; its $ED_{50}$, 35 mg/kg, IP, was approximately 50 times greater than that of diazepam. AHR-11748, at 5 mg/kg, IV, produced a 35% suppression of the polysynaptic linguomandibular reflex with essentially no effect on the monosynaptic patellar reflex in cats. These data suggest that AHR-11748 is a potential antiepileptic agent without marked central muscle relaxant properties. (Supported, in part, by contract number NO. 1-NS-4-2361 from the Epilepsy Branch, National Institute of Neurological and Communicative Disorders and Stroke [NINCDS], NIH, to Dr. Swinyard.)

384.14 SEIZURE INDUCTION BY FOCAL INFUSION OF EXCITANT AMINO ACIDS INTO THE INFERIOR COLLICULUS AND SUPERIOR COLLICULUS. B.S. Meldrum*, M.H. Millan* and C.L. Faingold. Dept. of Neurology, Institute of Psychiatry, London SE5 8AF UK and Dept. Pharmacology, Southern Illinois Univ. Sch. of Med., Springfield, IL 62708 USA.

The inferior colliculus (IC) is reported to play an important role in audiogenic seizures (AGS) in the Genetically Epilepsy Prone (GEP) rat. Electrical and chemical stimulation of the IC produce wild running seizures (WRS) [6] which are a major component of AGS in the GEP rat. AGS can be blocked by infusion of an excitant amino acid antagonist into the IC of GEP rats [4]. Recent studies [5] also suggest that an excitant amino acid may be a normal neurotransmitter in the IC, and elevation of aspartate levels is observed in the IC of GEP rats during AGS [2].

This study examined if seizure could be induced by infusion of N-methyl-D-aspartate (NMDA). Guide cannulae were implanted in normal rats over IC or superior colliculus (SC). At least one week later 10-20 nM of NMDA in 0.25-0.5 µl of phosphate buffer was infused (over 4 min) bilaterally. The animals were tested for AGS (electrical bell at 109 db) and observed for spontaneous WRS. All of the 18 rats injected in IC exhibited seizures, 39% showed AGS only, while 61% showed spontaneous WRS and AGS. Of the 15 rats injected in SC, 60% did not exhibit seizures, 32% showed only spontaneous WRS, and only one exhibited AGS. Vehicle infusion alone was ineffective. Preliminary data indicated that infusion of excitant amino acid into reticular formation (RF) did not cause AGS, although spontaneous seizures were sometimes observed.

These data, along with the proposed action of excitant amino acids in normal neurotransmission in IC [4] and the elevation of aspartate levels in IC during AGS [2] as well as the blockade of AGS by an excitant amino antagonist injected into IC [4] suggest that amplified release of an excitant amino acid in IC may be an important mechanism in the etiology of genetic susceptibility to AGS. The efficacy of excitant amino acid infusion in IC contrasts with the ineffectiveness in SC and RF and suggests the relatively specific involvement of IC in induction of AGS susceptibility. The induction of spontaneous WRS by infusion into the SC may activate the proposed seizure pathway which involves the substantia nigra [3]. This may be one of the output pathways along with those of the RF [1] which mediate the components of AGS. However, activation of these pathways by acoustic stimuli may require input from auditory nuclei primarily via the IC.

384.15 ACCUMULATION OF FREE ARACHIDONIC ACID AND LIPOXYGENASE REACTION PRODUCTS FOLLOWING BICUCULLINE-INDUCED STATUS EPILEPTICUS IS LOCALIZED IN RAT CEREBRAL SYNAPTOSOMES. Nicolas G. Bazan and Dale L. Birkle*. Louisiana State University Medical Center, LSU Eye Center, New Orleans, LA 70112.

Free fatty acid (FFA) accumulation is one of the earliest detectable biochemical events after stimulation of the central nervous system, e.g. electroconvulsive shock and ischemia. Accumulation of FFA may be the result of an overstimulation of mechanisms for membrane tailoring, that operate normally during neurotransmission. To test this we have studied the metabolism of the major accumulated FFA, arachidonic acid (20:4, n-6) in rat cerebral synaptosomes and microsomes following bicuculline-induced status epilepticus. Rat brain was prelabeled in vivo by the bilateral, intraventricular injection of 1 µCi [1-$^{14}$C]20:4. Thirty min later, rats were intubated, paralyzed with tubocurarine and placed on mechanical ventilation. Scalp electrodes were attached for monitoring of the EEG. One hr after injection of 20:4, rats were treated with bicuculline (10 mg/kg, ip.) and killed by decapitation during the status epilepticus phase, as assessed by EEG. Lipids were extracted from the subcellular fractions immediately upon isolation, or the fractions were incubated at 37° C for 60 min in the presence or absence of 45 mM $K^+$. Analysis of labeling of prostaglandins (PGs) and lipoxygenase reaction products (HETEs and leukotrienes) were done by high performance liquid chromatography. The identity of HETEs was confirmed by gas chromatography-mass spectrometry. In addition the endogenous FFA levels were measured. In control groups the level of FFA was high, due to release during subcellular fractionation; however a 25% increase in 20:4 was detectable in synaptosomes from bicuculline-treated animals. There were no detectable changes in FFA levels in the microsomal fraction. We detected four lipoxygenase reaction products in the synaptosomal and microsomal fractions. The major products in synaptosomes were 12-HETE and $LTB_4$ and in microsomes, $LTB_4$ and a mono-HETE (as yet identified but not 15-HETE, 5-HETE or 12-HETE). All of the major PGs were detected in both fractions, with higher activity in microsomes. Bicuculline treatment elevated lipoxygenase reaction products in synaptosomes and microsomes, although the profile of products was differentially stimulated. PGs were increased in microsomes, and decreased in synaptosomes. In incubated synaptosomes there was a marked stimulation of $PGD_2$, which was more pronounced in bicuculline treated animals. Depolarization by $K^+$ caused effects similar to bicuculline in synaptosomes, and had no effect in microsomes. The results indicate that bicuculline-induced seizures cause the release of 20:4 from synaptic membranes and increase the production of eicosanoids in synaptosomes.

384.16 AUDIODESENSITIZATION INDUCES AN ENDOGENOUS ANTICONVULSANT SYSTEM THAT PREVENTS SPONTANEOUS SEIZURES IN GERBILS AND HAMSTERS. Paul L. Prather* and W. B. Iturrian. Pharmacology Dept., Univ. Georgia, Athens, Ga. 30602

In epileptics, a postictal phase prevents a second seizure for varying intervals - occasionally lasting days. The neurological mechanisms are obscure but activation of endogenous anticonvulsant system(s) is an attractive possibility with profound implications. We are attempting to study the chemical basis for such long term anticonvulsant effects and demonstrate protection from the hereditary spontaneous seizures (SS) of gerbils and hamsters using a nonconvulsive technique - Audio-desensitization (ADS).

Gerbils that are genetically epileptic have brief tonic-clonic seizures which are elicited by vague stimuli such as handling but become refractory for a postical period lasting 2 or 3 days. In contrast the spontaneous seizure of the sz hamster (Bio 86.93) persists for 2 or 3 hours without an apparent postictal protective phase. Sound does not precipitate the seizure in either species.

LVK hamsters can be audiosensitized for sound induced seizure susceptibility at 28-31 days of age (Iturrian and Johnson, Experientia 27: 1193, 1971). Audiogenic seizures only occur 14 to 21 days later and 60 sec. sound exposures (audiodesensitization) at 3 day intervals prevents SS completely. ADS apparently acts through the induction of an endogenous anticonvulsant protein (Fed. Proc., 41: 1073, 1982).

We now demonstrate that this same audiodesensitization regimen protects sz hamsters from spontaneous or pentylenetetrazol induced seizure. Although ADS resulted in a less dramatic reduction in the incidence of spontaneous seizure in the gerbil it reproducibly causes a 50% reduction in seizure incidence. The regimen of ADS is very important. Surprisingly a single 316 sec (95 dbA) sound blocked postictal depression allowing gerbils to convulse twice within a 3 hr. period; although only 22% seizured 7 days later, in contrast to the 64% observed in controls. ADS is blocked by ether or cycloheximide when administered during each of the desensitization regimen exposures suggesting a protein dependent memory-like process.

384.17 A Chronic Feline Model of Limbic Epilepsy. R. G. Fariello, G.T. Golden, P.F. Reyes*, G.G. Smith*.Neurology and Research, VAMC Coatesville PA 19320 and Thomas Jeff. Med. College, Phila. PA 19107

Epilepsy research is handicapped by the lack of suitable inexpensive, durable animal models. Injection of cobalt powder in the hippocampus or amygdala of cats provides 45 - 60 days of epilepsy. Intralimbic injection of alumina gel gives rise to a longer lasting model but the method of induction does not allow exact quantification of the technique and destruction of small anatomical structures occur prior to the generation of epileptic activity.

Since several medical intractable human limbic epilepsies are multifocal in nature, we have investigated the effect of micro injections of 3.8 µl aqueous solution of cobalt chloride in the hippocampus and amygdala of the same experimental animal. Three cats received this treatment under general anesthesia,thereafter EEG and behavior were monitored on a daily basis. One cat received injections of equal volume and molarity of ferric chloride. Of the cobalt animals two were sacrificed at one month and one after eight months; the $FeCl_3$ cat is still alive after six months. All the cobalt animals were having active electro-behavioral seizures and interictal activity at the time of sacrifice. The following types of seizures were observed: 1) infraclinical, 2) partial complex with or without secondary generalization, 3) convulsive tonic clonic status epilepticus. The $FeCl_3$ cat did show transient interictal spiking but to this day has not developed any ictal discharges. No anticonvulsive treatment was attempted except for administration of diazepam and phenytoin acutely in 4 episodes of generalized tonic clonic status epilepticus which occurred in two animals, three times in one cat at one,four and six months, one time in another cat ,four weeks post cobalt. The interaction between foci, the onset and spread of interictal and ictal activity, the involvement of contralateral structures and of the Substantia Nigra will be illustrated. In two animals ipsilateral Nigral stimulation consistently triggered ictal discharges mostly but not exclusively arising from the hippocampus with sudden spread to other limbic structures, electro-clinical seizures and often secondary generalization. The histopathological features of the model will also be described. These preliminary results are encouraging and ongoing experimentation is aimed at refining this potential model of perhaps permanent epilepsy in cat.

## DISEASES OF THE NERVOUS SYSTEM: EPILEPSY, KINDLING

385.1 IBOTENIC ACID-INDUCED LESIONS OF THE HIPPOCAMPUS FACILITATE AMYGDALA KINDLING IN RATS. D.D. Walczak*, L.E. Jarrard, and J.L. Meyerhoff (SPON: F.J. Manning) Dept of Medical Neurosciences, Walter Reed Army Institute of Research, Washington, D.C. 20307.

In order to study the importance of the hippocampus in the kindling process in the rat, the hippocampus (CA1 - CA3, dentate gyrus) was lesioned with multiple injections of ibotenic acid (IBO), a procedure that destroys cells while sparing fibers-of passage. Control animals received lowering of the needle at the same sites as the hippocampals (sham-operated controls). A mixture of pentobarbital and chloral hydrate was used for surgical anaesthesia. Immediately after injections of IBO, stainless steel bipolar electrodes were implanted in the left amygdala, and stainless steel screw electrodes were placed over the frontal cortex. Animals were allowed to recover for two weeks prior to the initiation of kindling. Kindling stimuli (left amygdala, 1 sec train of 1 msec biphasic pulses, 60 Hz, 200 uA base-peak) were given daily. Cortical and amygdala EEG, and behavioral convulsions were recorded after each stimulus. Histological analysis of the resulting lesions (cell stain and Fink-Heimer silver stain) indicated extensive damage to both dorsal and ventral hippocampus with the only sparing being limited to small areas in the posterodorsal dentate gyrus and CA1 cell field.

The cumulative afterdischarge measured in drug-naive and drug treated rats is a sensitive indicator of changes in CNS excitability. Facilitation of the development of motor seizures is defined in this study as a drop in the amount of cumulative afterdischarge required to elicit stage 5 seizures. Inhibition is defined as an increase in cumulative AD to reach stage 5. Lesions produced no significant changes in latency to kindle to stage 3 or to stage 5, and no significant differences in daily seizure score. However, daily afterdischarge duration was significantly lower ($p = 0.0503$), and the cumulative afterdischarge duration was lower in lesioned rats (481.1 sec + 80.6 lesion vs. 711.2 sec + 97.4 sham). Thus, lesioned animals kindled at the same rate as the sham-lesioned controls, but did so with less elicited epileptiform activity. This facilitation of the kindling process in lesioned rats raises new questions about the role of the hippocampus in the development of amygdala kindled seizures.

385.2 FUNCTIONAL 2-DEOXYGLUCOSE MAPPING OF PROGRESSIVE STATES OF STATUS EPILEPTICUS INDUCED BY AMYGDALA STIMULATION IN RAT. A. Handforth* and R. Ackermann (SPON: J. Engel, Jr.) Dept. of Neurology, Div. of Nuclear Medicine and Biophysics, UCLA School of Medicine, Los Angeles CA 90024.

Delivery at 2 Hz of short trains of bipolar pulses to the amygdala for 20-50 minutes via implanted electrodes has been found by us reliably to elicit status epilepticus (SE) which is self-sustaining for hours and does not require prior kindling. In this model several distinct states of SE may be elicited, which differ in severity. The least severe state consists of continuous non-habituating exploration (ambulatory SE). Next in severity is a state of continuous mastication (class 1 SE). More severe is a state of vigorous nodding, rearing, and frequent clonus (class 2+ SE).

Quantitative assessment of glucose metabolism in each of these states was conducted using $^{14}$C-2-deoxyglucose (2DG) autoradiography. The 2DG was injected at least 20 minutes after SE induction. The most common pattern associated with ambulatory SE was unilaterally increased 2DG uptake indicative of activation in limbic and related structures. These included amygdala, hippocampus, subiculum, entorhinal cortex, olfactory areas, septal nuclei, bed nucleus of stria terminalis, dorsomedial thalamus, nucleus accumbens, medial prefrontal cortex, and part of substantia nigra. Variable bilateral involvement of amygdala, hippocampus, substantia nigra and dorsomedial thalamus was also noted. A less common pattern seen in ambulatory SE was considerably more restricted, involving the amygdala, dorsomedial thalamus, bed nucleus of stria terminalis, and medial prefrontal cortex. The pattern corresponding to class 1 SE was a bilateral representation of the more common ambulatory SE pattern. In class 2+ SE there was, in addition, recruitment of the neocortex (especially prefrontal), caudate-putamen, motor thalamic nuclei and substantia nigra.

These results suggest that a small number of nuclei participate in the earliest states of sustained seizure discharge induced by amygdala stimulation. With seizure progression more limbic-related structures are involved, at first ipsilaterally, then bilaterally. As clonus is attained, more neocortical areas and subcortical motor nuclei are recruited.

Supported by PHS grant # 15654 and DOE contract # DE-AC03-76-SF00012.

385.3 DEVELOPMENT OF A COMPUTER AUTOMATED KINDLING AND EEG MONITORING DEVICE FOR THE STUDY OF KINDLING STIMULUS-INDUCED SPONTANEOUS SEIZURES. C. Gage*, P. Madden* and D.D. Savage. Dept. Pharmacol., Univ. New Mexico Sch. Med., Albuquerque, N.M. 87131.

Kindling is a phenomenon in which repeated administration of a subconvulsive dose of electrical current leads to the gradual development of limbic and motor seizures. Kindling has been proposed as a model of limbic epilepsy. While kindled animals have a permanent susceptibility to stimulus-induced seizures, they rarely display spontaneous EEG or motor seizure behavior. Further, kindling stimulus-induced seizures are relatively unaffected by agents approved for treatment of limbic epilepsy.

Continued application of kindling stimulations well beyond the number required to "kindle" an animal can lead to the occurrence of spontaneous limbic and motor seizure activity. Phenytoin, which has little effect against kindling stimulus-induced seizures, reduces the number of spontaneous seizures in animals kindled to the spontaneous seizure state. The production of animals kindled to spontaneous seizures by manual methods is difficult and time consuming. A computer assisted system has been built to stimulate rats on a programmed schedule and monitor EEG activity during kindling stimulations and interstimulus intervals.

Bipolar electrodes are implanted into the right angular bundle of the entorhinal cortex and the left basolateral nucleus of the amygdala of Sprague-Dawley rats. One week later, rats are placed in chronic EEG recording cages and kindling stimulations given eight times a day at three hour intervals. Between stimulations, the number of EEG spikes are counted by computer and spike frequency analyzed every two seconds. When spike frequency criteria are satisfied for two adjacent sampling intervals, EEG activity is recorded on paper. EEG tracings are analyzed daily for evidence of spontaneous electrographic seizure activity. Animals are observed at least one hour a day during weekdays for evidence of spontaneous motor seizure behavior.

Several preliminary observations have been made using this system: 1.) Class 4 angular bundle kindled motor seizures occur with fewer stimulations in animals stimulated around the clock as compared to three times a day during daylight hours. 2.) Spontaneous electrographic seizure activity in amygdala is observed after 60 to 80 stimulations. 3.) Spontaneous motor seizures have been observed in all stimulated animals. These spontaneous motor seizures resemble motor seizures observed with kindling stimulations, ranging from Class 0 to mild Class 4 types. 4.) After 150 stimulations, the stimulations were discontinued and the animals monitored for four weeks. Both electrographic and motor seizure responses were still present at the end of four weeks. 5.) This computer assisted kindling and EEG monitoring system appears useful for the production and subsequent study of animals exhibiting spontaneous seizures.

385.4 THE DEVELOPMENT OF ANGULAR BUNDLE KINDLED SEIZURES IS ACCELERATED IN RATS WITH A GENETIC PREDISPOSITION TO AUDIOGENIC SEIZURES. D.D. Savage, C.E. Reigel and P.C. Jobe. Dept. Pharmacol., U. New Mexico Sch. Med., Albuquerque, NM 87131 and Dept. Basic Sci., U. Illinois Sch. Med., Peoria, Ill., 61656 (Spon: H.E. Laird).

Experiments were undertaken to examine the kindling phenomenon in three colonies of Sprague-Dawley rats inbred for characteristic seizure responses induced by an acoustic stimulus. In response to an acoustic stimulus, rats from a GEPR-9 colony exhibit running fits followed by full tonic extensor seizures. GEPR-3 colony rats exhibit running fits followed by clonus and rats from the GEPR-0 colony display no seizure behavior in response to an acoustic stimulus. Previous studies have suggested that deficits in monoamine neurotransmission are one factor contributing to the audiogenic seizure responses of GEPR-3 and GEPR-9 rats. Recently, graded elevations in the number of glutamate receptors in hippocampal formation of GEPR-3 and GEPR-9 have been observed.

A bipolar electrode was implanted in the right angular bundle of the entorhinal cortex of male rats from each of the three colonies. One week later, kindling stimulations (700 microampere biphasic square wave pulses, one millisecond in duration at 60 Hz. for two seconds) were administered three times a day at minimum intervals of four hours. Motor seizure behavior in response to the kindling stimulation was scored using the seizure classifications of Racine (1972). After exhibiting three Class 5 motor seizures, the rats were killed and electrode placement verified histologically.

The mean total number of kindling stimulations required for each colony to exhibit three motor seizures of each seizure class was determined. The results indicated that the early stage of kindling development (Class 0 to 1) was significantly accelerated in both the GEPR-9 and GEPR-3 rats, compared to the GEPR-0 rats. The middle stages of kindling development (Class 1 to 3) and the later stages (Class 3 to Class 5) were accelerated to GEPR-9 but not GEPR-3 rats, as compared to the audiogenic seizure resistant controls. Thus a differential and graded acceleration of kindling development was exhibited by GEPR-3 and GEPR-9 rats.

These results suggest the possibility that some brain area(s) involved in the early stages of kindling development may have an altered excitability in both GEPR-3 and GEPR-9 animals. In addition, some other brain area(s) involved in the later stages of kindling development may be altered in GEPR-9 rats also. Alternatively, some brain area(s) responsible for an acceleration of the early stages of kindling may be altered to a greater degree in GEPR 9 than GEPR-3 rats such that later stages of kindling development are facilitated. These putative alterations may, in part, underlie the differential seizure responses of GEPR-3 and GEPR-9 rats to an acoustic stimulus.

385.5 **FREQUENCY DEPENDENT INITIATION OF KINDLED SEIZURES.** **J.H. Goodman*, R.W. Homan, and I.L. Crawford. Dept. of Neurology, University Texas Health Science Center at Dallas and Epilepsy Research Center, VAMC, Dallas.**

**The role of current intensity in the generation of kindled seizures has been studied extensively. However, the dependence of the initiation of kindled seizures on stimulus frequency has not been well characterized. We examined the effect of different stimulus frequencies on eliciting seizures in amygdaloid kindled rats. Adult male Sprague-Dawley rats were bilaterally implanted with electrodes in the basolateral amygdalae. Each animal was stimulated once a day for one second with 400 uA, 60 Hz bipolar, square wave pulses (0.5 msec duration) until three consecutive Stage V seizures occurred. At this time the animal was considered fully kindled. The following stimulus paradigm was used to test: (1) whether Stage V kindled seizures could be elicited by stimulating at frequencies less than 60 Hz, (2) to determine the minimal frequency required to elicit a kindled seizure. Each animal was stimulated once daily at a given test frequency for 60 seconds or until a Stage II seizure was observed. The number of stimuli delivered, the time to reach Stage II and whether a Stage V seizure was attained were recorded. The frequencies tested ranged from 1 to 10 Hz with all other stimulus parameters kept constant. We observed that Stage V seizures could be elicited with stimulus frequencies less than 60 Hz. The minimum frequency which caused a Stage V seizure (5 of 8 animals) was 3 Hz; the apparent threshold frequency under these conditions. At frequencies greater than 3 Hz all animals had a Stage V seizure. For animals stimulated at 5 Hz the mean (±SEM) number of stimuli delivered to each animal ranged from 80.3±11.8 to 224.3±41.3. The average time for each animal to Stage II ranged from 9.8±0.8 to 44.9±8.3 seconds. Increasing frequency of stimuli was inversly related to the number of stimuli necessary to evoke a seizure; however, the time to a Stage II decreased dramatically. For example, at 7 Hz the time to Stage II ranged from 8.7±1.2 to 31.9±2.3.**

**These results demonstrate that frequency can be a factor in the ability to elicit kindled seizures. The utility of using frequencies less than 60 Hz is that one can expand the time to elicit a seizure and it may possibly provide a more sensitive index of seizure threshold.**

385.6 ACTIVATION OF MULTIPLE UNIT ACTIVITY IN THE LOCUS COERULEUS PRODUCED BY AMYGDALA KINDLING. Carlos A. Jimenez-Rivera*, Gerald K. Weiss* and Anna Maria Voltura*. (SPON G. Wild). Department of Physiology, University of New Mexico, School of Medicine, Albuquerque, New Mexico 87131.

Activation of the noradrenergic (NA) system of the rat brain by stimulating the locus coeruleus (LC) lengthens only the early stages in the development of amygdala kindled seizures while lesions of the ascending LC projections accelerates the process. We have hypothesized that activation of the LC during the early stages (1&2) of amygdala kindling contributes to the normal delay of these stages. This activation is produced by the afterdischarges (AD) that occur following an amygdala kindling stimulation.

We designed experiments to record multiple unit activity from the LC during the development of amygdala kindled seizures. Sprague-Dawley rats were implanted with small, monopolar electrodes in the LC and one bipolar amygdala electrode. The protocol consisted of amygdaloid stimulation three times per day at 90 min. intervals (400 u Amp, 1 msec, 60HZ) until 3 consecutive stage 5 were achieved.

We recorded multiple unit activity bilaterally from the locus coeruleus during kindling of the amygdala in the unrestrained rats. We recorded the amplified signal from the LC and the amygdala and the output of a window discriminator (mentor-N750) adjusted to trigger only on unit activity that is at least two times the level of the baseline noise. The discriminator allowed us to screen out large artifactual signals, those that are often due to movement.

Multiple unit activity increases following the afterdischarge for a short time and decreases before the next AD in the amygdala. We often observed a very short period of inhibition during the amygdala AD.

These results are consistent with the idea that LC activation produced by AD's during amygdala kindling may provide a negative feedback that contributes to an inhibition of the seizure spread. This could be the basis for the longer time normally spent in the early stages of the kindling process. (Supported by Grant DHHS SO6 RR 08139-11 NIH)

385.7 SEIZURE THRESHOLD DETERMINATION AND STABILITY IN AMYGDALOID-KINDLED RATS. G. Cloutier*, W.W. Pugh. North Carolina Foundation for Mental Health Research, Raleigh, NC 27611 and Medical Division, Burroughs Wellcome Co., Research Triangle Park, NC 27709

Adult male Long Evans rats were implanted with bipolar stimulating/recording electrodes in the unilateral amygdala. Standard kindling procedures were employed to develop the amygdaloid-kindled model of complex partial epilepsy. An animal was considered fully kindled after three consecutive generalized seizures were elicited. Behavioral (clinical stages 0-5, post-ictal depression) and electrophysiological (after-discharge duration, post-ictal spiking) parameters were examined. An additional measure, seizure threshold, was also investigated. Kindled animals were tested for seizure threshold at intervals ranging from five minutes to five days. Electrical stimulation (60 Hz, 1 sec) was delivered beginning with low currents and increasing the stimulation current every five minutes until a generalized seizure (after duration >30 sec, behavioral state >2) was evoked. While seizure threshold determination is not usually defined in conventional terms of ictal (after-discharge, behvioral state) or post-ictal (post-ictal spiking, post-ictal depression) events, it also remained stable in the fully kindled animal. However, seizure threshold is modified or changed depending upon several variables. The first and most consistent is the interval period between generalized seizures. With very short intervals (5 minutes) the animal is refractory to a generalized seizure at currents up to two times normal threshold. Extending the seizure intervals decreased seizure threshold relative to increasing intervals. The greatest change in seizure threshold vs. seizure interval occurred in the first twenty-four hours. While additional decreases in threshold with increasing seizure intervals in excess of 24 hours were occasionally observed, the average animal exhibited stable seizure threshold over time with seizure intervals of at least 24 hours. A second determinant of seizure threshold was the overall state of health of the animal. Chronic pathology such as peritonitis or osteomyelitis decreased seizure threshold in direct correlation to the progression of the disease. Drugs were a third modifier of seizure threshold. Influences on seizure threshold, ictus and post-ictus by opiate agonists and antagonists are currently under investigation in this epilepsy model.

385.8 GENETICALLY EPILEPSY PRONE RATS SHOW A DEFICIT AND DEVELOPMENTAL DECLINE IN MEDIAL GENICULATE BENZODIAZEPINE RECEPTORS. J.E. Franck, D.L. Hjeresen, D.G. Baskin, P.C. Jobe and P.A. Schwartzkroin. Depts. of Neurological Surgery and Psychology, Univ. Washington, Seattle, WA 98195 and Division of Metabolism and Endocrinology, VA Medical Center, Seattle, WA 98108.

The genetically epilepsy prone rat (GEPR), type 3, shows an abnormally high seizure susceptibility to a variety of stimuli including high intensity sound. Recent evidence indicates that neural abnormalities are, in part, at the level of auditory nuclei. There appear to be alterations in the GABAergic neuron population in inferior colliculus, and abnormal increases in glucose utilization in response to high intensity sound in GEPR colliculus, medial geniculate and auditory cortex. Our results lend further support to the notion that auditory pathway abnormalities in these animals underlie their seizure susceptibility, and indicate that these deficiencies operate at the level of receptors mediating inhibitory function.

We have examined the GABA receptor-chloride ionophore-benzodiazepine receptor complex in the medial geniculate of 24 and 31 day old unstimulated GEPRs and normal age-matched Sprague Dawley rats using quantitative autoradiogaphy of $^{3}$H-Flunitrazepam (FLU). Other work by us indicates that audiogenic seizure susceptibility does not develop in the GEPRs until 27-30 days of age. We wished to determine if differences in inhibitory receptors paralleled this behavioral phenomenon. Mounted tissue sections were incubated in increasing concentrations of $^{3}$H-FLU with or without unlabelled diazepam according to accepted neurochemical procedures. The slides were apposed to tritium sensitive film with brain mash standards containing various known concentrations of tritium. The film was exposed for two weeks, and computer-assisted densitometric analysis was performed on medial geniculate.

We found that 31 day old GEPRs have lower $^{3}$H-FLU binding in the medial geniculate than do age matched controls. This difference was not only seen quantitatively, but appeared quite dramatic on visual inspection. Scatchard conversion of the densitometric data demonstrated that both affinity and receptor number are lower in the epileptic mutants at this age. When 24 day GEPRs were examined, they also showed a lower receptor affinity, but the receptor number was comparable to that seen in normal rats. These data suggest that the GABA receptor complex in GEPR mutants is abnormal in at least the thalamic component of the auditory system. Furthermore, the pathology appears to be progressive and may parallel the development of audiogenic seizure susceptibility in these animals.

(Supported by NIH Grant, NS 07144; NS 20482).

385.9 ALTERATIONS OF TRH RECEPTORS IN BRAINS OF AMYGDALOID KINDLED RATS. S. Kajita*, M. Okamoto, K. Akiyama*, N. Ogawa† and M. Sato. Depts. of Neuropsychiatry, and †Neurochemistry (Institute for Neurobiology), Okayama University Medical School, Okayama 700, JAPAN.

Thyrotropin releasing hormone (TRH), a tripeptide, has been recently implicated in seizure disorders. We previously demonstrated that ICV administration of γ-butyrolactone-γ-carbonyl-L-histidyl-L-prolineamide citrate (DN 1417), a potent analogue of TRH, suppressed progression of amygdaloid (AM) kindling and AM kindled seizures in a dose dependent manner (Sato et al, Neurosci. Abst., 10:407, 1984). To investigate the proposed anticonvulsant action of TRH, both TRH-like immunoreactivity (TRH-LI) and specific TRH receptor binding were examined in rat brains kindled from left AM. Male Sprague Dawley rats received an electrical stimulation of sine wave (400 μA, 60 Hz, one second) once daily until stage 5 convulsion was achieved successively for five days. Subsequently, the animals were decapitated either 48 hours (48h.K) or 7 days (7d.K) after the last seizure, and the brains were dissected into 7 regions for the biochemical determinations which were performed as previously described (Ogawa et al, Peptides, 3:669-677, 1982). Animals with sham operation (SO) were used as control. In 48h.K group, TRH-LI was significantly elevated in the amygdala plus piriform cortex (SO, 91 ± 10; 48h.K, 303 ± 27***) and hippocampus (SO, 32 ± 7; 48h.K, 135 ± 19***), where values are expressed as mean ± S.E.M. (pg/mg protein) and *** means P<0.001 vs SO. In 7d.K group, however, TRH-LI in those brain areas did not increase significantly, indicating that the change in TRH-LI may result from a preceding seizure. By contrast, specific [3H]TRH binding at a single concentration of 12 nM increased significantly in the striatum of the two kindled groups (SO, 18.6 ± 2.4; 48h.K, 28.9 ± 2.0*; 7d.K, 36.1 ± 2.6**, mean ± S.E.M. of fmol/mg protein, *:P<0.05 and **:P<0.01 vs SO), but did not change significantly in other brain areas. Scatchard analyses of saturation isotherm of specific [3H]TRH binding indicate that both Kd and Bmax increased significantly (P<0.01) in the striatum of 7d.K as compared to SO. An inhibitory role of the striatum for generalization of epilepsy has been well documented. In light of this notion and together with our pharmacological evidence for TRH, the present study suggests that changes in the number of striatal TRH receptors may be associated with long-lasting seizure susceptibility of AM kindled rats.

385.10 SPONTANEOUS RHYTHMIC SYNCHRONOUS EVENTS IN HUMAN EPILEPTIC BRAIN AND NORMAL MONKEY HIPPOCAMPUS. M.M. Haglund and P.A. Schwartzkroin, Dept. of Neurological Surgery, Univ. of Washington, Seattle, WA 98195

The in vitro slice preparation has been used to study human epileptic tissue from both lateral temporal neocortex and medial temporal regions (including hippocampus). Spontaneous rhythmic synchronous events (SRSEs) arising primarily from medial regions of human temporal lobe (Science 223:709-712, 1984) have been further characterized. Hippocampus of normal monkey has also been studied in order to determine whether these events are indicative of tissue epileptogenicity, or whether they are manifestations of the circuitry of normal medial temporal lobe regions.

Our studies in human brain suggested the following characteristics of the SRSEs: 1) These events appear to be postsynaptic potentials. SRSEs often displayed multiple components, with the reversal potential of the primary component similar to that of a chloride-mediated IPSP. SRSEs were blocked by $10^{-5}$ M bicuculline methiodide in the bathing media. 2) Slices displaying SRSEs also had functional IPSPs. 3) Cell polarization did not block or alter the occurrence or frequency of SRSE activity. Orthodromic stimulation interposed between spontaneous events could reset the SRSE rhythm. 4) Two distinct cell populations participated in SRSE activity. The predominant cell type resembled the pyramidal cell of hippocampus; in these cells, SRSEs could be quite complex, but triggered only one or two action potentials. The other cell type was more similar to the hippocampal interneuron; spiking activity associated with the SRSEs occurred as burst discharge. This burst normally "led" the event in the pyramidal cell type.

Because normal control tissue is difficult to obtain from human brain, we examined the hippocampus of normal monkey in experiments similar to those carried out on human epileptic tissue. Spontaneous rhythmic synaptic events were recorded from the pyramidal cell region of hippocampus, but not from dentate granule cells or from pyramidal-like cells of lateral temporal neocortex. These SRSEs were identical in all respects to those recorded from the human epileptic brain. These findings suggest that SRSE activity does not reflect tissue epileptogenicity per se. However, given that synchronous activity is an essential feature of epilepsy, the existence of synchronous synaptic events in brain tissue which tends to be epileptogenic is particularly interesting. The circuitry and cell characteristics underlying generation of such rhythmic activity may be important determinants of the tendency of this tissue to produce epileptic discharge.

These studies were supported by NIH grants NS15137, NS18895, NS20482, and NSF grant BNS82009906.

385.11 CHRONIC ELECTRIC STIMULATION OF CENTROMEDIAN THALAMIC NUCLEI IN THE TREATMENT OF MEDICALLY UNCONTROLABLE SEIZURES. F.Velasco, M.Velasco*, C.Ogarrio*, J.Almanza* H.Ranqel*. Funcional Neurosurgical Service, Mexico City General Hospital, S.S., México (PO BOX 73032).

Ten patients suffering of clinical and EEG primary generalized incapacitating seizures, in spite of high dose and blood levels of anticonvulsant drugs, without evidence of severe or progressive brain damage proven by computarized axial tomography, underwent stereotactic implantation of electrodes, aiming both centromedian nuclei of the thalamus. Four contact, platinum-iridium, semiflexible electrodes, isolated but at the tips were used. Through these electrodes bipolar, biphasic, electrical stimulation (ES), was carried out, using pulses of 60-100 Hz., 0.1 msec duration, 200 to 500 microAmps, in trains of 1 min. every 5 min., alternating right and left sides, in daily sessions of 2 hrs. EEG recordings from scalp and depth electrodes were taken for periods of 4 hrs./day, starting 4 days prior the beginning of ES to 5 days after the onset of ES and weekly thereafter. Psychometric evaluation using Weis, MMPI, discrimination and memory tests, was performed before, 15 and 90 days after the onset of ES. Type and frequency of clinical seizures were monitored 24 hours a day for a minimun of 6 weeks and thereafter an ordinary record has been kept by the patient's family.
In 8 patients seizures were dramatically reduced or abolished since the begining of ES. In 3 of these patient anticonvulsive drugs were discontinued and in the other 5, reduced to half the initial dose. The other 2 patients showed significant improvement, although continued to have ocassional seizures and anticonvulsive medication was mantained. EEG seizures and interictal spikes were significantly reduced ($p<0.01$), particularly in the scalp leads. From the centromedian nuclei, interictal spikes and tonic discharges were recorded in the absence of clinical seizures. Psychometric tests performance was also significantly improved.

385.12 PROTECTIVE EFFECTS OF MOSSY FIBER LESIONS AGAINST KAINIC ACID-INDUCED SEIZURES AND NEURONAL DEGENERATION. Maxine M. Okazaki and J. Victor Nadler. Dept. Pharmacology, Duke Univ. Med. Ctr., Durham, NC 27710.

Intracerebroventricular (i.c.v.) administration of kainic acid (KA) produces a specific pattern of neuronal degeneration that probably results from the convulsant action of KA on the limbic system. Previous studies demonstrated that lesions of the hippocampal mossy fiber pathway prevent the destruction of CA3 pyramidal cells by i.c.v. administration of KA to anesthetized rats, whereas lesions of other pathways are ineffective. Mossy fiber lesions were suggested to prevent CA3 cell death by attenuating hippocampal seizures. The present study was undertaken to evaluate this hypothesis.

Male rats were subjected to either of two procedures: unilateral transection of the mossy fibers over a 4-mm length of the dorsal hippocampus or unilateral destruction of dentate granule cells with colchicine. Immediately afterward, rats were chronically implanted with a cannula in the lateral ventricle ipsilateral to the treated hippocampus and with bipolar EEG electrodes bilaterally in the hippocampal CA3 area and the basolateral amygdala. Unanesthetized animals were infused through the i.c.v. cannula with 1.41 nmol of KA. EEG was monitored for 4 hr after the infusion and the incidence and extent of neuronal degeneration were determined by silver impregnation coupled with cresyl violet.

Control animals developed repeated seizures which, after about 1 hr, became continuous, amounting to a status epilepticus. Ictal events appeared first either in the hippocampus ipsilateral to the cannula or simultaneously in both hippocampi. Mossy fiber transection protected 6 of 15 subjects from the development of status epilepticus, but destruction of mossy fibers with colchicine conferred no such protection. In many experimental rats, however, ictal events appeared in the contralateral (untreated) hippocampus prior to the ipsilateral (treated) hippocampus. Histological examination of control brains revealed massive neuronal degeneration in the ipsilateral CA3-CA4 area and much less damage to the contralateral CA3. Mossy fiber lesions always substantially reduced or abolished neuronal cell death in the ipsilateral hippocampus, even when the ipsilateral hippocampus experienced several hours of continuous seizure. Neurons in other brain regions were protected from degeneration only when the mossy fiber lesion prevented the development of status epilepticus.

These results suggest that the hippocampal mossy fibers constitute an important, though not an obligatory, link in the circuit responsible for the spread of KA seizures. Degeneration of CA3 pyramidal cells appears to be related not simply to the duration of seizure activity per se, but specifically to seizure activity conveyed by the mossy fibers. (Supported by NIH grant NS 17771.)

385.13 MORPHOLOGICAL EVIDENCE FOR INCREASED INHIBITION OF BASKET CELLS IN THE DENTATE GYRUS OF MONGOLIAN GERBILS. G.M. Peterson and C.E. Ribak. Department of Anatomy, University of California, Irvine, CA 92126.

More GABAergic neurons are found in the hippocampal formation of seizure-sensitive (SS) gerbils than in seizure-resistant (SR) gerbils. This difference has been found in all subregions of the hippocampal formation, but is most predominant in stratum granulosum of the dentate gyrus (Peterson et al., Brain Res., 1985). Furthermore, many mossy tufts (the en passent terminals of the dentate gyrus granule cell axons) are virtually depleted of vesicles in SS gerbils whereas almost all mossy tufts have a normal appearance in SR gerbils. To explain the mechanism by which increased numbers of inhibitory local circuit neurons can lead to increased excitation, we have proposed a model of disinhibition in which the basket cells inhibit one another, thereby effectively removing the granule cells from recurrent inhibition. To test this hypothesis with anatomical methods we have made immunocytochemical preparations to localize GAD and to identify GAD-immunoreactive basket neurons within or subjacent to stratum granulosum. These neurons were examined for GAD-immunoreactive axosomatic terminals. Plastic-embedded 1 um thick sections were used for the purpose of counting these GAD-immunoreactive terminals which form a pericellular nest around GAD-immunoreactive somata in SS but not in SR. GAD-immunoreactive neurons in the SS dentate gyrus generally had 2-3 times more GAD-immunoreactive terminals surrounding their somata then did the GAD-immunoreactive cells in the SR dentate gyrus. To correlate these light microscopic structures with their presumed ultrastructural counterparts, ultrathin sections were examined to identify the synaptic contacts made by the GAD-immunoreactive terminals adjacent to GAD-immunoreactive basket cells. These contacts were identified as the typical GABAergic axosomatic symmetric synapses in both SS and SR brains. These data show that GABAergic cells in the SS dentate gyrus have more GABAergic inhibitory axosomatic contacts and suggest that these basket cells are inhibited more than in the SR. This inhibition of basket cells may be sufficient to remove the tonic inhibition of granule cells and to cause a disinhibition which results in bursting discharge of granule cells. The loss of recurrent inhibition in this way may lead to seizure activity in the SS gerbil.

386.1 SLOW FIELD POTENTIALS AND "BURSTLETS" DETERMINE BURST RATE IN PENICILLIN-PERFUSED HIPPOCAMPAL SLICES. J.H. Schneiderman. Dept. of Medicine, University of Toronto, Toronto, Can.

Field potential recordings in the distal apical dendrites of penicillin-perfused guinea pig hippocampal slices reveal two distinct phases. In 3.4 mM penicillin a slow field potential averaging 2.8 (range 1.2 to 4.3) seconds in duration may account for the entire interval between bursts in rapidly bursting preparations but in slower slices may be responsible for as little as 20% of the interval. The remainder of the interval consists of low amplitude, rhythmic potentials which we have called "burstlets" because they have the same configuration as the full bursts but are much smaller (75 to 250 uV compared to 1 to 5 mV). They are rarely seen with somatic recording electrodes at high concentrations but when the penicillin concentration is reduced to 0.85 or 0.425 mM their amplitude increases and they are present at the soma. In low-dose penicillin the frequency of full bursts is reduced in a dose-dependent fashion and their threshold is increased. The duration of the slow field potential is unchanged. The increase in interburst interval is due to a prolonged "burstlet" phase.

The peak of the slow field potential is negative in the apical dendrites and positive at the soma. It occurs prior to the peak of pyramidal cell afterhyperpolarization but is coincident with the peak of glial depolarizations. The entire slow potential is sensitive to changes in extracellular potassium concentration but the early portion is also sensitive to changes in extracellular chloride. The slow field potential tends to outlast the intracellularly recorded AHP as well as the glial depolarization. The later portion of the field potential often cannot be recorded at the soma but is negative in the apical dendrites. The depth profile of the slow potential is complex and suggests more than one site of generation.

In the dendrites the "burstlets" consist of a positive potential followed by a longer lasting negative phase. At the soma they are positive with superimposed negative spikes. The cellular correlate of these events is usually a depolarizing-hyperpolarizing sequence but occasionally at the same membrane potential either component may occur in isolation. They have the characteristics of postsynaptic potentials in that their frequency is not affected by membrane potential but their amplitudes are altered appropriately. The depolarizations were rarely of sufficient magnitude to reach threshold for firing action potentials. The "burstlets" appear to reflect synchronous synaptic activity which results in bursting of small numbers of neurons. The hyperpolarizing phase is accompanied by small glial depolarizations, suggesting that under these circumstances the IPSPs may be mediated by potassium.

386.2 STIB: AN IN VITRO MODEL OF KINDLING? A.C. Bragdon, D.M. Taylor*, L.C. Rigsbee*, J.O. McNamara and W.A. Wilson. Veterans Administration and Duke Univ. Medical Centers, Durham, NC 27705.

**Kindling** is an animal model of epilepsy in which repeated delivery of electrical stimulus trains to limbic structures produces a permanent, abnormal increase in neuronal excitability. The mechanisms underlying kindling are unknown. It would be advantageous to have an in vitro model of kindling with which to study these mechanisms.

**Stimulus train-induced bursting (STIB)** is an in vitro model of epileptogenesis in which repeated delivery of electrical stimulus trains to hippocampal area CA3 produces a long lasting, abnormal increase in neuronal excitability in hippocampal slices from naive rats. The similarities between kindling and STIB suggest STIB may be an appropriate model for studying the mechanisms of kindling.

To strengthen the relevance of this in vitro model to in vivo phenomenon, we sought to determine whether hippocampal slices from kindled animals behave as though they have already undergone STIB.

Male Sprague-Dawley rats received daily stimuli in the right lateral entorhinal cortex until 3-5 Class 5 seizures occurred. Implanted, unstimulated rats served as paired controls. Each kindled-control pair was studied one day following the last seizure of the kindled rat. Investigators preparing and studying the slices remained blinded to the rats' kindling status until after the data were analyzed. Two to three slices from the same hippocampus of each rat received our STIB protocol: Slices were studied in medium containing 3.3 mM K+, 1.3 mM Ca++, and 1.2 mM Mg++. Extracellular field potentials were recorded in s. pyramidale of CA3b. Electrical stimuli were delivered to s. radiatum of CA3. After stable responses were established, stimulus trains (60 Hz, 2 sec) at twice baseline intensity were delivered every 5 minutes until triggered and spontaneous bursts, and afterdischarges were produced or until 10 trains were delivered.

Slices from the four kindled animals achieved STIB distinctly faster than slices from the control animal. The number (mean ± SEM) of stimulus trains needed to induce each type of epileptiform activity was:

| | Triggered bursts | Spontaneous bursts | Afterdischarges |
|---|---|---|---|
| **Kindled** | 0.7 ± 0.3 | 4.6 ± 0.8 | 5.3 ± 1.4 |
| **Control** | 5.6 ± 1.2 | 8.4 ± 0.8 | 8.9 ± 0.9 |
| | p<0.0005 | p<0.005 | p<0.05 |

These findings raise the interesting possibility that the same mechanisms may underlie the development of both kindling and STIB.

386.3 TRANSFER BETWEEN PICROTOXIN AND ELECTRICAL KINDLING IN THE RAT. D.P. Cain. Dept. of Psychology, U. of Western Ontario, London, Ontario, CANADA N6A 5C2.

The hypothesized participation of GABA systems in seizure development has been the subject of research in a number of laboratories but the exact nature of the participation of GABA systems in the kindling of convulsions is not clear. Therefore, kindling was examined using the intraperitoneal (i.p.) or intracerebral (i.c.) administration of repeated doses of picrotoxin, which blocks GABA-mediated chloride conductance. Transfer to electrical kindling was then tested in the same rats.

Four groups of male hooded rats received repeated, spaced (48hr) i.p. injections of picrotoxin in doses of 1.5, 2.0, 2.5 or 3.0 mg/kg and were videotaped for 1 hr, after which the tape was scored for convulsive behavior. Another group received repeated, spaced (48hr) injections of picrotoxin directly into the basolateral amygdala using a chemitrode, and the EEG was monitored for 1-6 hrs. Different rats in this group received a constant dose ranging from 1.0-10.0 ug. Another group that had been electrically kindled in the basolateral amygdala received repeated, spaced (48hr) i.p. injections of picrotoxin at 1.5 mg/kg and were videotaped and scored.

The i.p. picrotoxin groups showed a steep dose-response effect: the lowest dose (1.5 mg/kg) did not kindle at all, the middle doses (2.0 and 2.5 mg/kg) kindled generalized convulsions after a mean of 12 and 4 injections, respectively, and the highest dose (3.0 mg/kg) evoked a generalized convulsion after the first injection. The rats in the 2.0 and 2.5 mg/kg groups were then electrically kindled in the amygdala and kindled after a mean of 6.3 ADs, which was significantly faster than a saline control group (13.2 ADs; $p < .002$). The rats that had been electrically kindled prior to transfer to i.p. picrotoxin displayed a generalized convulsion after 12.75 injections; the control rats did not progress beyond stage 2 after 15 injections. In the i.c. group there was no clear evidence of a dose response effect, apparently because the moderate to high dose rats (2.5-10 ug) had considerable brain damage both near the cannula tip and in neuroanatomically related pathways, and AD could not be evoked.The low dose rats (1.0-2.0 ug) showed significantly faster electrical transfer kindling (6.3 ADs; $p < .02$) and considerably less brain damage.

The results show that repeated i.p. or i.c. picrotoxin can kindle convulsions and that kindling transfers strongly to electrical kindling. Thus, despite evidence of a lack of loss of GABA-mediated inhibition as causative in electrical kindling (Kalichman, 1982; Tuff et al., 1983), picrotoxin kindling transfers strongly to electrical kindling, as do many other types of chemical kindling. A common mechanism possibly located in reticular or brainstem areas may be partly responsible for the transfer effect.

386.4 PHYSIOLOGICAL LEVELS OF ESTRADIOL AND KINDLED EPILEPTOGENESIS. Gary G. Buterbaugh. Department of Pharmacology and Toxicology, University of Maryland School of Pharmacy, Baltimore, MD 21201.

Forty adult, female Sprague-Dawley rats were ovariectomized and implanted with an amygdala bipolar electrode and a s.c. silastic capsule containing cholesterol or 10% estradiol ($E_2$) in cholesterol to deliver serum levels of 40-50 pg $E_2$/ml. Ten days later, daily amygdala stimulation (1 sec of 60 Hz, biphasic square-wave pulses of 1 msec duration) at twice afterdischarge (AD) threshold was continued until two stage V seizures. Rats with $E_2$ required significantly fewer AD's (11.5±0.6 vrs 14.9±0.7) and less AD sec (593±39 vrs 825±65) to kindle. The difference in AD's to kindle was uniform throughout acquisition; the difference in AD sec was limited to the stages of generalized seizures. These differences were limited to electrode tip placements in the basal-lateral or cortical amygdala nuclei. AD in the contralateral cortex appeared earlier during kindling of rats with $E_2$ and with cortical amygdala nucleus placements. Preliminary results indicate that the effect of $E_2$ on kindling rates is even more marked when rats are kindled by stimulation of the frontal cerebral cortex.

Following kindling, the treatments were reversed in some rats. After 10 stimulation-free days, an increased retention of postictal myoclonic jerks was found in $E_2$-replaced rats (4.8±1.3 vrs 1.3±0.5). The presence of $E_2$ during kindling and/or post-kindling was also associated with 2-5 sec EEG bursts accompanied by brief motor seizures which sometimes developed into a secondary stage V seizure. These post-kindling events were unrelated to electrode tip placement during kindling.

Fourteen days after kindling, rats were administered pentylenetetrazole (PTZ), 20 mg/kg i.p., 20 minutes before suprathreshold stimulation. PTZ increased the severity of the stage V convulsion but did not effect AD duration. Rats with $E_2$ showed a significant increase in myoclonic jerks compared to rats without $E_2$ regardless of the presence of $E_2$ during kindling.

Sixteen days after kindling, rats received 5 suprathreshold stimulations at 48 hr intervals. These stimulations resulted in an increasing number of myoclonic jerks, EEG bursts and secondary stage V seizures. Rats without $E_2$ showed no evidence of EEG bursts or secondary seizures.

The results suggest that the effect of $E_2$ on kindled seizure acquisition is related to mechanisms of seizure generalization and may depend upon the specific neuronal circuitry accessed by AD. The effects of $E_2$ on fully kindled seizures suggest that excitatory effects of $E_2$ interfere with, or suppress the acumulation of, postictal seizure inhibition. (Supported by PHS NS 20670)

386.5 STATUS EPILEPTICUS FACILITATED BY PILOCARPINE IN AMYGDALA KINDLED RATS. Hillary B. Michelson, David O. Keyser* and Gary G. Buterbaugh. Department of Pharmacology and Toxicology, University of Maryland School of Pharmacy, Baltimore, Maryland 21201.

Ten male, Sprague-Dawley rats, 90-100 days-old, were kindled by daily amygdala stimulation (1 sec of 60 Hz biphasic square-wave pulses, 1 msec duration) until two stage V convulsions. Three weeks later, rats (N=9) were administered pilocarpine, 20 mg/kg ip, 20 minutes before suprathreshold stimulation. The resulting stage V primary seizure was little effected by pilocarpine. However, the usual postictal depression was replaced by hyperactive exploratory behavior (N=6); within 30-90 sec, myoclonic jerks and EEG spikes appeared, followed by bursts of high-frequency EEG spiking and motor arousal which increased in frequency and severity until self-sustained continuous convulsions (status epilepticus; STEP) developed. In two rats, the primary seizure diminished and then merged into STEP. One rat developed STEP after a 7 minute delay. One rat was administered pilocarpine, 8 mg/kg iv, immediately after termination of the primary seizure; STEP a-peared within 45 sec. Stage II seizures during kindling were not effected by pilocarpine.

The STEP initially consisted of 10-12/sec, 600-1000 uV EEG discharge accompanied by stage III/IV convulsions. Brief (0.5-2 sec) periods of EEG suppression and motor arrest gradually dissappeared as stage I/II convulsions became continuous. In 3 rats, the STEP was allowed to continue for 4-5 hours when it gradually terminated to severe postictal depression.

Scopolamine, 25 mg/kg ip, prevented the pilocarpine-facilitated STEP, but had little effect on fully developed STEP. Several anticonvulsant drugs were tested after 1-2 hrs of STEP. Combinations of two or more drugs were necessary in most cases to terminate the seizures; diazepam (20 mg/kg) + phenytoin (40-80 mg/kg) was the most effective combination.

Juvenile, male, Sprague-Dawley rats were kindled by hourly amygdala stimulation when 28 days-old. Pilocarpine failed to facilitate STEP when these rats were 42-48 days-old and when 60-65 days-old. However, two of these rats developed STEP when tested at the adult age of 70-80 days-old.

The results indicate that amygdala-kindled epileptogenesis is associated with a marked sensitivity to muscarinic receptor activation during the immediate postictal period. This receptor activation may overcome postictal inhibition to result in prolonged and self-sustained EEG and motor seizures, which may require the fully mature brain for development and which are paradoxically resistant to muscarinic receptor antagonism. Pilocarpine-facilitated status epilepticus should be a useful model for the study of the mechanisms of STEP, the importance of postnatal maturation to STEP and the effectiveness of anticonvulsant drugs to terminate STEP.

386.6 TAURINE IN FOCAL EPILEPTOGENESIS. P. Ente*, G. T. Golden, R. G. Fariello,(SPON: C. Bianchi). Neurology and Research, VAMC Coatesville PA 19320 and Thomas Jeff. Med. College, Phil. PA 19107

Taurine (TAU), a sulfur-containing amino acid, is differentially distributed in the mammalian CNS with the highest concentrations found in the cerebellum, striatum, hypothalamus and pineal gland. Lack of a specific antagonist for TAU has hampered studies seeking evidence for a pathogenic role for TAU in focal epilepsy, by demonstrating that specific blockage of TAU causes epilepsy.

Recently, a novel antagonist TAG (6-aminoethyl-3-methyl-4H, 1,2,4-bennzothiadiazine-1, 1-dioxide) has been discovered. TAG antagonizes the actions of TAU in vitro and in vivo. In preliminary studies aimed at characterizing the specificity of TAG, we have observed that an aqueous solution of 50 mM/ml TAG applied to the cortex of urethane anesthetized Sprague-Dawley rats consistently induces transient epileptogenic interictal discharges. The TAG-induced epileptiform activity was suppressed by an equimolar solution of GABA but potentiated by topical equimolar TAU and unaffected by glycine and B-alanine. The present evidence suggests that the epileptogenic action of TAG is unrelated to its antagonism for TAU. Specific bloackage of TAU responses is seen with TAG concentrations of 200 uM, whereas at 400 uM, glycine and B-alanine responses are also antagonized. In our experiments, concentrations of 200-400 uM did not elicit epileptiform activity, thus the TAU block cannot be considered essential for the appearance of epileptic spikes. Only at TAG concentrations known to have non-specific effects, did epilepsy appear and become potentiated by TAU and blocked by GABA. Thus it appears that other factors besides the TAU antagonism are responsible for generating the paroxysmal discharges. Possibly TAG (at high concentrations) has GABA antagonistic properties, and this may be responsible for the observed epileptogenic effects.

In other experiments, we have studied the effects of TAG application on multi-unit activity of cortical neurons. No change in firing rate was observed with concentrations having specific TAU antagonistic effects. Changes in the firing pattern occurred only when much higher concentrations were used. In addition, TAG cortical superfusion at concentrations between 200 uM to 75 mM failed to break electrical caudate stimulation-induced cortical inhibition.

The present studies do not support current speculation of a role for TAU in cortical physiology, nor of an involvement of TAU in cortical epileptogenesis. We are presently looking at single unit responses of cells in a TAG-induced (50mM and below) epileptic interictal focus and studying the responses of single cells in the TAG focus to microiontophoretic application of GABA, Glycine, and B-alanine.

386.7 **STIMULUS TRAIN-INDUCED BURSTING (STIB) IN HIPPOCAMPAL AREA CA3 IS INHIBITED BY BACLOFEN.** **H.S. Swartzwelder, C.P. Sutch*, A.C. Bragdon and W.A. Wilson. VA and Duke University Medical Centers, Durham, NC 27705.**

**Baclofen (Lioresal) is used clinically to treat spasticity, but has received little attention as a potential antiepileptic agent. Within hippocampi rendered epileptic by various means, area CA3 is the focus from which spontaneous epileptiform activity originates. Ault and Nadler (1982) have shown that baclofen inhibits the synaptic output of CA3 pyramidal cells, apparently as an agonist at $GABA_B$ (bicuclline insensitive) receptors. To explore its antiepileptic potential, we tested baclofen's effect on Stimulus Train-Induced Bursting (STIB), a new model of epileptogenesis (Stasheff et al, Soc Neurosci Abstr 10: 549, 1984 and Brain Res, in press).**

**Transverse, 625 um hippocampal slices were prepared in standard fashion from 150-200 gm, male, Sprague-Dawley rats, and studied in physiological medium containing 3.3 mM K+, 1.8 mM Ca++ and 1.2 mM Mg++. Extracellular field potentials were recorded in s. pyramidale of CA3. Electrical stimuli (100-600 uA, 50 us) were delivered to s. radiatum of CA3. After stable responses to single stimuli were established, stimulus trains (2 sec, 60 Hz) were delivered every 5 minutes until triggered and spontaneous population bursting was elicited. Baclofen, dissolved in ACSF, was bath-applied to the slices at varying concentrations to determine its effect on evoked and spontaneous activity.**

**Baclofen was remarkably effective in suppressing epileptiform activity in a dose-dependent fashion at concentrations which did not alter normal evoked responses. At 0.1 uM, baclofen abolished spontaneous bursting (SB), while triggered bursts (TB) were unaffected. At 1 uM, baclofen restored TBs to the waveform of normal evoked potentials. Normal orthodromic population spikes (OPS) were minimally affected at 1 uM, but were generally suppressed at concentrations above 10 uM. $ED_{50}$s for suppression of SB, TB and OPS were 0.03, 0.3, and 3.0 uM, respectively.**

**Baclofen is remarkably effective in restoring normal activity to this epileptogenic neural network. Further experiments to explore the antiepileptic efficacy of this drug are warranted.**

**This research was supported by the Veterans Administration and NIH grant NS-17771.**

386.8 A QUANTITATIVE IN VITRO AUTORADIOGRAPHIC STUDY OF MU AND DELTA OPIOID BINDING IN THE HIPPOCAMPAL FORMATION OF KINDLED RATS. B.J. Crain, K.-J. Chang and J.O. McNamara. Depts. of Anatomy, Anesthesiology, Medicine (Neurology), Pathology and Pharmacology, Duke University Medical Center and the Epilepsy Research Center, VA Medical Center, Durham, NC 27710 and Dept. of Molecular Biology, Wellcome Research Laboratories, Research Triangle Park, NC 27713.

Recent studies have shown that opioid peptide levels are altered in hippocampal formation of kindled animals. We therefore studied the distributions of mu and delta opioid binding sites in hippocampal formation of kindled and control rats using quantitative in vitro autoradiography. Animals received daily stimulations of the amygdala until they experienced three Class 5 seizures. Paired control animals underwent implantation of electrodes but were not stimulated.

Mu binding sites, labeled with $^{125}$I-FK-33824, showed a highly organized laminar distribution. Twenty-four hours after the last kindled seizure, mu binding was significantly decreased by 26% in stratum pyramidale of CA1 and by 16% in stratum radiatum and stratum oriens of CA1 and stratum moleculare of the suprapyramidal blade of the dentate gyrus. No differences were seen between kindled and control animals at 7 or 28 days after the last kindled seizure.

Delta binding sites, labeled with $^{125}$I-D-ala$^2$-D-leu$^5$-enkephalin in the presence of the morphiceptin analog PL-032, also showed an organized laminar distribution. Twenty-four hours after the last kindled seizure, delta binding was decreased throughout hippocampal formation but was significantly decreased by 21% only in stratum moleculare of the suprapyramidal blade of the dentate gyrus. Seven days after the last kindled seizure, delta binding was significantly decreased by 10-20% throughout CA1, CA3, and the dentate gyrus. At 28 days after the last seizure, however, no differences were found between kindled and control animals.

Since the decreases in mu and delta opioid binding are transient, they are unlikely to be the molecular basis of the permanent kindling phenomenon. Rather, since iontophoretically applied opioids increase granule and pyramidal cell firing rates, these changes in opioid binding may represent protective adaptive responses to repeated seizures.

386.9 **POTASSIUM-INDUCED EPILEPTIFORM ACTIVITY IN HIPPOCAMPAL AREA CA3 VARIES MARKEDLY ALONG THE SEPTO-TEMPORAL AXIS.** W.A. Wilson, A.C. Bragdon and D.M. Taylor* (SPON:W. Anderson). Depts. of Pharmacology and Medicine (Neurology), Duke University and VA Medical Centers, Durham, NC 27705.

The hippocampal slice preparation is widely used to study the physiology and pharmacology of epilepsy. Most such studies implicitly treat the excitability of different slices as uniform, regardless of their sites of origin along the hippocampal septo-temporal axis. This is despite well documented septo-temporal variations in a number of anatomical and biochemical parameters. Having observed that temporal-end slices appeared more excitable in area $CA_3$ than did septal slices, we set out to address this question directly.

Male, 220-385 gram, Sprague-Dawley rats were decapitated and both hippocampi removed. Slices 625 um thick were prepared from each hippocampus, and placed in holding chambers containing medium (ACSF) continually bubbled with a 95% $O_2$ - 5% $CO_2$ gas mixture. ACSF composition in mM: KCl 3.3, $CaCl_2$ 1.8, $MgSO_4$ 1.2, NaCl 120, $NaHCO_3$ 25, $NaH_2PO_4$ 1.23, dextrose 10. As they were taken from the tissue chopper, slices were placed sequentially in individual comparments of the holding chamber in order to keep track of their original location along the septo-temporal axis. Slices were studied in "high $K^+$" ACSF identical to that above except that [KCl] was 7 mM. Extracellular recording electrodes were placed in s. pyramidale of $CA_3$b. After slices equilibrated in high $K^+$ ACSF for at least 15 minutes, spontaneous population bursts were counted over at least 5 minutes. Angle of slicing (perpendicular at the temporal end vs. perpendicular at the septal end), order of slicing (temporal to septal and vice versa), and order in which slices were studied were systematically varied to ensure that none of these factors was-responsible for the observed differences.

Burst frequency showed a marked departure from uniformity along the septo-temporal axis. Burstsper minute increased from 33.1±3.1 (mean ± SEM) in the most temporal slice to a maximum of 54.9±2.8 in the third slice from that end, then declined gradually to a minumum of 8.2±4.1 in slice 13, near the septal end.

These data are important for two reasons. First, they suggest that particular attention should be directed to the temporal (ventral) hippocampus in in vivo and in vitro studies of neuronal activity in epilepsy. (For technical reasons, often only dorsal hippocampus is studied in vivo.) Second, they demonstrate that slice location along the septo-temporal axis is an important confounding variable for which one must control when comparing results between slices.

Supported by the Veterans Administration and NIH grants NS 17771 and GM 47105.

386.10 DEPOLARIZATION SHIFT AND AFTERDISCHARGE GENERATION IN PENICILLIN-TREATED IMMATURE HIPPOCAMPAL SLICES: THE ROLE OF NMDA RECEPTORS. R.J. Brady & J.W. Swann, Section for Developmental Neurophysiology, Wadsworth Ctr. for Labs & Research, NYS Department of Health, Albany, NY 12201

Our laboratory has previously examined penicillin's ability to produce epileptiform discharges in the CA3 region of hippocampal slices obtained from immature rats 9-19 days of age (Swann & Brady, Dev. Brain Res. 12 (1984), 243-254). It was demonstrated that this treatment resulted in spontaneously-generated and stimulus-evoked intracellular depolarization shifts (DS) with coincident extracellular epileptiform bursts. These events were of a longer duration and lower frequency than the epileptiform activity seen under identical conditions in hippocampal slices taken from mature rats. The immature tissue was also shown to possess a pronounced capacity to produce prolonged afterdischarges of up to 30 sec in duration. The present studies investigate the ability of N-methyl-D-aspartate (NMDA) receptor antagonists to suppress ictal-like activity in the CA3 region of penicillin-treated immature hippocampal slices. Bath application of the potent NMDA-receptor antagonists 2-amino-7-phosphonoheptanoate (APH) and ketamine (KET) block spontaneous burst and afterdischarge generation. To produce this effect, a concentration of 5 mM APH is necessary while only 10 µM KET is needed.

Ketamine, a dissociative anesthetic, is thought to be a non-competitive inhibitor of the NMDA response. At concentrations that have strong anticonvulsant-like actions, bath application of KET suppresses NMDA responses. Intracellular and extracellular recordings of the response of TTX ($10^{-6}$g/ml) treated immature hippocampal slices show that bath application of 10 µM KET reversibly blocks responses to iontophoretically applied NMDA but not quisqualate or kainate. Intracellular records show that KET application does not significantly alter the resting membrane potential or conductance of CA3 pyramidal cells. 10 µM KET blocks spontaneous penicillin-induced epileptiform activity; slightly lower KET concentrations do not completely abolish this activity, but instead eliminates afterdischarges, decreases the duration of the DS and epileptiform burst and increases the burst frequency. These latter effects transform the pattern of discharges to one closer to that seen in slices taken from mature rats. In the presence of 10 µM KET, orthodromic stimuli will not evoke afterdischarges but will instead elicit a DS and epileptiform burst much like that seen in a mature slice. Taken together these results suggest that the NMDA receptor is an integral part of the mechanism of afterdischarge generation and that differences in the NMDA receptor population could explain the differences seen between mature and immature hippocampus.

386.11 LOCAL EXCITATORY INTERACTIONS AND EPILEPTOGENESIS IN THE CA3 REGION OF IMMATURE HIPPOCAMPUS. J.W. Swann, R.J. Brady, & K.L. Smith.* Sec. for Develop. Neurophysiol., Wadsworth Ctr. for Labs & Research, NYS Dept. of Health, Albany, NY 12201

Previous studies from this laboratory have shown CA3 pyramidal cells of 1 to 2 week old rat hippocampus to have a marked capacity to generate prolonged (20-30 sec) afterdischarges when exposed to GABA A antagonists. Extracellularly these afterdischarges ride on the envelope of a prolonged negative field. Current Source-Density analysis suggests the negative field is produced by an inward current, generated at the edge of the cell body layer in stratum oriens -- a region referred to as the infrapyramidal zone (IPZ). Coincident intracellular recordings show pyramidal cells undergo a prolonged depolarization during slow potential generation. Experiments reported here were undertaken in normal media in an attempt to determine the physiological origins of these events.

High gain extracellular DC recordings from the IPZ have revealed localized spontaneous negative fields which are 0.5-1 mV in amplitude. These events rise rapidly from baseline and are 100-500 msec in duration. The frequency of unit firing increases during their course. Intracellular recordings from immediately adjacent pyramidal cell bodies reveal large (4-10 mV) unitary epsps coincident with these spontaneous negative fields. The time course of the epsps follows closely that of the fields. Orthodromic stimulation of distant pyramidal cells recruit these epsps. At threshold stimulation strength they are variable in latency, and often fail to be elicited, which suggests they are at least disynaptically mediated. Higher stimulation strength results in an orthodromic epsp followed by a large biphasic ipsp. These latter events mask the underlying di or polysynaptic epsp although at these times the coincident slow field is summated and several mV in amplitude. With repetitive (2Hz X 10sec) stimulation, the negative field becomes greatly potentiated. Simultaneous intracellular recordings reveal first a hyperpolarization of individual pyramidal cells followed by a gradual transition to a depolarized state. Often upon cessation of stimulation, a self-sustained afterdischarge ensues.

Since the unitary epsps recorded are most likely a product of pyramidal cell to pyramidal cell interactions, we have begun to examine the effects of excitatory amino acid antagonists on these events and afterdischarge generation. NMDA receptor antagonists (e.g. kynurenic acid) appear to selectively decrease the size of the spontaneous slow fields and prevent afterdischarge generation. These data suggest that an unusual degree of excitatory interaction may exist between immature CA3 pyramidal cells and could be a major factor contribution to the pronounced capacity of this region to undergo ictal-like discharges.

387.1 ALPHA ADRENOCEPTORS AND AUDIOGENIC SEIZURE ACTIVITY IN DBA MICE. C.E. Lints, C. Nyquist-Battie, and D. Stearn*. Depts. of Psychology and Biological Sciences, Northern Ill. U., DeKalb, IL 60115.

We have previously reported that, compared with the seizure resistant C57BL strain, the DBA midbrain contains a higher density of beta adrenoceptors at an age (19-23 days) when these mice are most susceptible to audiogenic seizures (AGS). At this same age pindolol, a potent beta antagonist, produced dose-dependent anticonvulsant effects suggesting a proconvulsant action for beta receptors in these animals.

The present experiments compared alpha adrenoceptor densities and affinities in like-aged (19-23 days) C57BL and DBA mice. In these equilibrium studies the alpha-1 and alpha-2 binding sites on washed membrane preparations were labelled with (3H)-WB4101 and (3H)-yohimbine, respectively. Non-specific binding was that determined in the presence of (-)-norepinephrine (NE). Total amount of ligand bound and $K_D$ were determined by Scatchard analysis, and strain comparisons were made using two-tailed t-tests. Protein was determined using the Biorad Protein Assay Kit. There were no significant strain differences in affinity, as measured by $K_D$, for any of the brain regions studied. However, at this age of peak AGS susceptibility, the DBA midbrain contained a higher density of alpha-1 and a lower density of alpha-2 adrenoceptors than that of the seizure resistant C57BL mouse.

The effects of tolazoline, a nonselective alpha antagonist, on AGS activity were evaluated in 30-day-old DBA mice to screen for the possibility that these alpha receptor abnormalities are related to AGS. At this age the mice are less susceptible to seizures and both pro- and anticonvulsant effects can be easily assessed. Tolazoline had a triphasic action, with both the lowest and highest doses producing anticonvulsant effects and the intermediate doses producing proconvulsant effects. At this same age prazocin, a selective alpha-1 antagonist, produced dose-dependent anticonvulsant effects suggesting that the alpha-1 receptors also have a proconvulsant action. Yohimbine, a selective alpha-2 antagonist, had proconvulsant activity at a low dose that could be associated with autoreceptor blockade; higher doses produced anticonvulsant effects possibly due to yohimbine's local anesthetic-like action.

Taken together with our previous report of a higher midbrain beta receptor density, these results are consistent with the hypothesis that the DBA midbrain contains a locus of noradrenergic hyperexcitability that may be involved in the initiation and/or modulation of AGS in these genetically seizure-prone animals. They also suggest that the adrenoceptor subtypes can be independently regulated and that more than one mechanism may be involved (i.e. synaptic transmitter level and/or genetic predetermination).

387.2 ANTAGONISM OF STRYCHNINE SEIZURES BY INTRATHECAL AMINISTRATION OF AMINO ACIDS AND ANTICONVULSANTS. D.K. Boyd*, P.A. Boxer and R.J. Anderson. Warner-Lambert/Parke-Davis Pharmaceutical Research, Ann Arbor, MI 48105.

Spinal seizures induced by strychnine are among the most refractory to treatment with anticonvulsant drugs. Systemic administration of amino acids, even glycine, fail to antagonize these seizures, presumably due to their inability to cross the blood brain barrier. The purpose of the present study was to determine whether direct application of drugs to the spinal cord would prolong or prevent strychnine seizures. In order to administer compounds intrathecally, mice were anesthetized with diethyl ether, the articulation between the 4th and 5th lumbar vertebrae was exposed and the L5 spinous process removed. All drugs were administered intrathecally in 5 microliters, 2 to 4 hrs after recovery from the anesthesia. Since subcutaneous administration of strychnine is often fatal and the latency to seizure is highly variable, we chose to induce a strychnine seizure via an intrathecal injection. Without pretreatment, an intratechal injection of strychnine (10 mM) produced seizures characterized by tonic hindlimb extension with a latency of 40 $\pm$ 15 sec. The optimum delay in the onset of these seizures was seen when the animals received an intrathecal injection of glycine two minutes before the strychnine injection. There was a concentration-dependent increase in the time to seizure with glycine concentrations of 30 to 1000 mM. Pretreatment with the inhibitory amino acid agonists, taurine (100, 300 mM), B-alanine (300 mM) and threonine (300 mM), significantly prolonged the seizure latency. On the other hand GABA (100 mM), glutamate (100 mM), sarcosine (300 mM) and serine (300 mM) produced no significant effects. The anticonvulsant diazepam (1 mM) significantly prolonged the seizure latency, while valproic acid (10 mM) had no effect. These results demonstrate that high local concentrations of several amino acids and anticonvulsants in the spinal cord prolong the onset of strychnine-induced seizures. However, none of these drugs was able to prevent the eventual development of a seizure, indicating that they have a short duration of action relative to strychnine.

387.3 EFFECTS OF DAILY MAXIMAL ELECTROSHOCK INDUCED SEIZURES (MES) AND CHRONIC PENTYLENETETRAZOL (PTZ) TREATMENT ON ANION AND CATION TRANSPORT AND MUSCARINIC AND BENZODIAZEPINE (BZ) BINDING. H.S. White*, S.Y. Chow*, T. Honda*, D.R. Gehlert*, R.T. McCabe, J.K. Wamsley and D.M. Woodbury. Depts. of Physiol., Pharmacol. and Psych., Univ. of Utah, S.L.C., UT 84108.

The present investigation describes the effects of daily MES and daily sub-convulsive injections of PTZ on seizure susceptibility, cerebral cortical (CC) anion and cation transport processes, and regional binding of $^3$H-N-methyl scopolamine (NMS) and $^3$H-flunitrazepam (FLU). One group of 40 rats was given a daily MES stimulus (150 ma for 0.2 sec at 60 Hz) through corneal electrodes for 3 weeks while another group received a daily subconvulsive dose (35 mg/kg, i.p.) of PTZ for 3 weeks. Once weekly, both minimal and maximal electroshock seizure threshold (EST) was determined and the values compared to a control group whose EST was also determined weekly. At the end of 3 weeks, 95% of the MES group exhibited a maximal tonic-clonic seizure following a MES stimulus as compared with 60% at day zero. In addition, the duration of the extensor (E) phase of the tonic-clonic convulsion increased and the flexor (F) phase decreased. This resulted in a 67% increase in the E/F ratio. All of these findings indicate increased brain excitability. Daily MES produced a significant increase in the minimal EST and a significant decrease in the maximal EST. At the end of 3 weeks, those animals receiving a daily subconvulsive dose of PTZ exhibited extensive CNS stimulation that was manifested by prolonged (>30 min) and sustained myoclonic jerks. Daily MES and PTZ produced a marked gliosis in the CC as suggested by an increase in DNA. Preliminary results suggest that although the number of glial cells are increased, their ability to regulate the extracellular environment of the brain is impaired since intracellular sodium was increased and intracellular potassium was decreased.

Autoradiographic localization of muscarinic and BZ receptors on tissue slices of brain was determined using standard autoradiographic techniques. Muscarinic receptors labeled with $^3$H-NMS were significantly increased in the striatum (16%) and superior colliculus (20%) and significantly reduced in the substantia nigra (25%) by daily MES stimulation. These findings are in agreement with a decrease in maximal EST. BZ receptors labeled with $^3$H-FLU were increased in the caudate putamen (51%) and superficial and deep layers of the CC. These findings are consistent with an increase in minimal EST, since an increase in inhibitory receptors within these areas would tend to inhibit the initiation of a minimal seizure. In contrast to daily MES, daily injections of PTZ produced marked and significant reductions in BZ binding in the nucleus accumbens (47%) and in the molecular (53%) and granular (44%) layers of the cerebellum. These findings suggest that there is a decreased inhibitory output from the cerebellum, and are consistent with the marked and prolonged myoclonic jerks observed following chronic administration of PTZ. Scatchard analysis of saturation data are presently under investigation. These studies illustrate the utility of chronic PTZ and MES as two distinct neurophysiological and neurochemical models for the study of epilepsy.

387.4 THE ROLE OF GABA AGONISTS AND ANTAGONISTS IN SEIZURE MODULATION IN A GENETIC MODEL OF GENERALIZED EPILEPSY. R.J. Lee*, A. Depaulis, R.W. Olsen and P. Lomax. Department of Pharmacology, School of Medicine and the Brain Research Institute, University of California, Los Angeles, CA 90024.

Recent studies have demonstrated a decrease in [$^3$H]-flunitrazepam binding in the brain of the seizure sensitive (SS) strain of Mongolian gerbil as compared to the seizure resistant (SR) strain. This abnormality in benzodiazepine binding may reflect changes in GABAergic neurons which might be involved in the seizure diathesis in the SS strain. Additionally, an increase in GAD immunoreactivity was found in the hippocampus of SS gerbils. To investigate the involvement of GABAergic transmission in modulating seizures a GABA agonist, muscimol, and a GABA antagonist, picrotoxin, were injected into the substantia nigra (SN) or the hippocampus (H) of SS gerbils.

Adult gerbils of either sex with consistent seizure scores ranging from 2-5 (on a scale of 0-6) were used in all experiments. The animals were anesthetized with pentobarbital (65 mg/kg) and bilateral cannula guides were implanted stereotaxically into either the SN or H. A post-operative period of at least 7 days was allowed before any testing was carried out. Gerbils were arranged in a Latin square design and either control (sterile water) or different doses of either muscimol or picrotoxin were administered via a microinjection syringe connected by polyethylene tubing to an injection cannula. Following injections, gerbils were tested by the triple handling technique. Seizure incidence and severity were noted.

In the SN, muscimol (50 ng) was found to inhibit seizures completely, while muscimol (25 ng) decreased the incidence of seizures to 20% (controls demonstrated 100% incidence of seizure activity). Picrotoxin (0-80 ng) injected into the SN did not induce any significant changes in seizure activity. Hippocampal injections of muscimol (25 ng and 50 ng) did not produce any significant changes in the seizure parameters.

These pharmacological findings confirm previous biochemical observations that GABA transmission in the SN is involved in suppressing seizure activity in the SS gerbil. The results are also consistent with other models of epilepsy: ECS (Iadarola and Gale, Science 218:1237, 1982) and kindling (McNamara et al., Eur. J. Pharmacol. 86:485, 1983).

387.5 EFFECT OF CHRONIC SENSORIMOTOR SEIZURES ON GABA AND BENZODIAZEPINE RECEPTORS. E.M. Santori*, T. Der, and R.C. Collins. Neurology and Neurological Surgery, and the McDonnell Center for the Study of Higher Brain Function, Washington University School of Medicine, St. Louis, MO 63110.

Clinical observation and animal experiments have documented that recurrent focal neocortical seizures progressively increase in severity. To gain insight into the basic mechanisms mediating the expansion of focal seizures, we have chosen to investigate GABA and benzodiazepine receptor changes.

Male Sprague-Dawley rats were stereotaxically implanted with bipolar electrodes in the cortical forelimb sensorimotor overlap zone. Once daily, the rats were stimulated with a two second train of monophasic pulses (1 msec duration; 50 HZ). Control animals were implanted with electrodes and received similar handling, but were not stimulated.

At the time of sacrifice the rats had been subjected to a mean of 41 stimulations. AD duration increased from an initial mean of 12 seconds to 109 seconds. Initially, the seizure response primarily consisted of clonic and tonic forelimb movements. By the end of the study, animals commonly showed bilateral convulsions with rearing and balance loss.

Rats were sacrificed 24 hours after their last stimulation. Brains were processed for quantitative autoradiography of GABA and benzodiazepine receptors using 3H-muscimol (MUS) and 3H-flunitrazepam (FLU), respectively. To survey the entire brain for changes in receptor density the binding was assayed at near saturating concentrations of each ligand.

MUS and FLU specific binding were unchanged in the focus and seizure pathways.

| | FLU (fmole/mg) | | MUS (fmole/mg) | |
|---|---|---|---|---|
| | control | seizure | control | seizure |
| Focus | 287 | 279 | 520 | 550 |
| Caudate | 116 | 123 | 310 | 340 |
| Globus pallidus | 161 | 159 | 300 | 300 |
| Ventrobasal thalamus | 143 | 146 | 750 | 880 |
| Substantial nigra | 307 | 291 | 350 | 380 |

Visual survey of the chronic seizure forebrains failed to reveal any unilateral binding changes. In addition, no bilateral perturbations of amygdaloid or hippocampal ligand binding were detected. These data suggest that sensorimotor kinding does not alter the density of GABA or benzodiazepine receptors within seizure pathways.

## HISTORY OF THE BRAIN

388 HISTORY OF THE BRAIN. F.A. Brewer*, E.M.R. Lomax*, L.H. Marshall, Y.V. O'Neil*, and H.W. Magoun. Brain Research Institute, UCLA, Los Angeles, CA 90024.

The objectives of this exhibit of 42 posters are to educate neuroscientists in an awareness of their rich heritage and roots in the past, to remind them of the importance of original source materials, and to demonstrate the usefulness of oral history in preserving antecedent events. Section I describes how three leading American publications in the history of neuroanatomy and neurology came into existence. They are The Founders of Neurology, The Human Brain and Spinal Cord: A Historical Study Illustrated by Writings from Antiquity to the Twentieth Century, and Garrison's History of Neurology. Section II of the exhibit traces the history of the human brain of particular clinical interest with emphasis on handedness and brain function. The evolution of the human brain is shown with evidence of lateralization in lower life forms and in early cultures. The search for the neural substrates of speech and consciousness is depicted from the Renaissance through the nineteenth century. Sections III and IV utilize the fascination of regional reminiscences in exploring the development of an early school of neurology in Los Angeles in the setting of its initial medical schools and hospitals. That story leads to an account of human commissurotomy and the shared Nobel prize in physiology or medicine in 1981. A free brochure describing the exhibit is available.

At the request of the authors the Society for Neuroscience wishes to retract abstracts 115.10 and 115.11 appearing in the 1984 Abstract Volume.
