# CONTENTS – PART 2

***5086 volunteer abstracts, 18 symposium and workshop abstracts, 4 special lecture abstracts.**

# 1985 PROGRAM COMMITTEE

Perry B. Molinoff, M.D., *Chairperson*
University of Pennsylvania School of Medicine

Neal H. Barmack, Ph.D.
Neurological Sciences Institute, Portland

Ellen F. Barrett, Ph.D.
University of Miami Medical School

Monroe W. Cohen, Ph.D.
McGill University

David P. Corey, Ph.D.
Massachusetts General Hospital

Harold Gainer, Ph.D.
National Institutes of Health

Irving Kupfermann, Ph.D.
New York State Psychiatric Institute

Raymond J. Lasek, Ph.D.
Case Western Reserve University

Paul R. Lennard, Ph.D.
Emory University

Jennifer S. Lund, Ph.D.
University of Pittsburgh School of Medicine

Jeffrey F. McKelvy, Ph.D.
State University of New York, Stony Brook

Jose L. Ochoa, M.D., Ph.D.
University of Wisconsin Medical School

Maryann Ruda, Ph.D.
National Institutes of Health - National Institute of Dental Research

Lawrence P. Schramm, Ph.D.
Johns Hopkins University School of Medicine

Nicholas C. Spitzer, Ph.D.
University of California, San Diego

Ann E. Stuart, Ph.D.
University of North Carolina

Richard F. Thompson, Ph.D.
Stanford University

James W. Truman, Ph.D.
University of Washington

Joseph T. Coyle, M.D., *Consultant*
Johns Hopkins University School of Medicine

William D. Willis, Jr., M.D., Ph.D., *ex officio*
Marine Biomedical Institute

Bernice Grafstein, Ph.D., *ex officio*
Cornell University Medical College

Bruce S. McEwen, Ph.D., *ex officio*
Rockefeller University

# CHRONOLOGICAL LIST OF SESSIONS

**CONTINUED FROM *SOCIETY FOR NEUROSCIENCE ABSTRACTS*, VOLUME 11, PART 1**

*(see page viii for Thematic List of Sessions.)*

## WEDNESDAY – CONT.

**Sessions end at 12:45 PM, Friday, October 25.**

# THEMATIC LIST OF SESSIONS

**(Includes slide and poster sessions, symposia, and workshops only.)**

## Theme A: Development and Plasticity

| Session Number | Session Title | Type | Day and Time |
|---|---|---|---|
| **2.** | **Actions of nerve growth factor in the central nervous system** | **Symp.** | **Mon AM** |
| 337. | Autonomic nervous system | Poster | Thu PM |
| 177. | Biochemical and pharmacological correlates of development I | Poster | Tue PM |
| 328. | Biochemical and pharmacological correlates of development II | Slide | Thu PM |
| 354. | Biochemical and pharmacological correlates of development III | Poster | Thu PM |
| 193. | Cell lineage: differentiation and development I | Slide | Wed AM |
| 236. | Cell lineage: differentiation and development II | Slide | Wed PM |
| 309. | Cell lineage: differentiation and development III | Poster | Thu AM |
| 214. | Development and plasticity I: aging | Poster | Wed AM |
| 261. | Development and plasticity II: aging | Poster | Wed PM |
| 376. | Development and plasticity: motor systems | Poster | Fri AM |
| 67. | Development and plasticity: normal and transplanted visual system | Poster | Mon PM |
| 133. | Development and plasticity: olfactory system | Poster | Tue AM |
| 8. | Development and plasticity: retina and optic nerve | Slide | Mon AM |
| 134. | Development and plasticity: sensory system I | Poster | Tue AM |
| 135. | Development and plasticity: sensory system II | Poster | Tue AM |
| 141. | Development and plasticity: visual pathways I | Slide | Tue PM |
| 235. | Development and plasticity: visual pathways II | Slide | Wed PM |
| 298. | Development and plasticity: visual system plasticity | Poster | Thu AM |
| 267. | Development of invertebrates I | Poster | Wed PM |
| 282. | Development of invertebrates II | Slide | Thu AM |
| 120. | Developmental disorders I | Poster | Tue AM |
| 366. | Developmental disorders II | Slide | Fri AM |
| 161. | Endocrine control of development I | Poster | Tue PM |
| 262. | Endocrine control of development II | Poster | Wed PM |
| 52. | Endocrine effects on development and behavior | Slide | Mon PM |
| 388. | History of the brain | Poster | Mon AM |
| 117. | Limbic system: development and plasticity I | Poster | Tue AM |
| 151. | Limbic system: development and plasticity II | Slide | Tue PM |
| **91.** | **Molecular synaptogenesis: transition from growth cone to synapse** | **Symp.** | **Tue AM** |
| 178. | Morphogenesis and pattern formation I | Poster | Tue PM |
| 292. | Morphogenesis and pattern formation II | Poster | Thu AM |
| 180. | Neural plasticity in adult animals I | Poster | Tue PM |

| 384. | Diseases of the nervous system: epilepsy | Poster | Fri AM |
| 385. | Diseases of the nervous system: epilepsy, kindling | Poster | Fri AM |
| 132. | Diseases of the nervous system: genetic diseases, models | Poster | Tue AM |
| 270. | Diseases of the nervous system: immunology, virology | Poster | Wed PM |
| 129. | Diseases of the nervous system: ischemia, trauma | Poster | Tue AM |
| 128. | Electroencephalography and evoked potentials | Poster | Tue AM |
| 357. | Limbic system and hypothalamus I | Poster | Thu PM |
| 358. | Limbic system and hypothalamus II | Poster | Thu PM |
| 359. | Limbic system and hypothalamus III | Poster | Thu PM |
| **138.** | **Molecular bases of the immune response to neural antigens** | **Symp.** | **Tue PM** |
| 98. | Structure and function: cortical and subcortical organization I | Slide | Tue AM |
| 154. | Structure and function: cortical and subcortical organization II | Poster | Tue PM |
| 203. | Structure and function: cortical and subcortical organization III | Poster | Wed AM |

## Theme I: Neural Basis of Behavior

| Session Number | Session Title | Type | Day and Time |
|---|---|---|---|
| 280. | Aging: behavior and plasticity | Slide | Thu AM |
| 213. | Aging: neural basis of behavior | Poster | Wed AM |
| 115. | Biological rhythms I | Poster | Tue AM |

## FUTURE ANNUAL MEETINGS

| | | |
|---|---|---|
| 1986 | November 9—14 | Washington, DC |
| 1987 | November 16—21 | New Orleans |
| 1988 | November 13—18 | Toronto |
| 1989 | October 29—November 3 | Phoenix |
| 1990 | October 28—November 2 | St. Louis |

219.11 CHANGES IN NEURONAL FUNCTION PRODUCED IN CAT PRIMARY SOMATOSENSORY CORTEX BY THE IONTOPHORETIC APPLICATION OF ACETYLCHOLINE. R. Metherate*, N. Tremblay* and R.W. Dykes. Depts. Physiology, Neurology and Neurosurgery, and Surgery, McGill University, Montreal, Quebec, Canada.

It is known that acetylcholine (Ach) increases the firing rate of some neurons in cat primary somatosensory cortex. However, little is known regarding the influence of Ach on neuronal responsiveness to afferent inputs. Because Ach has also been correlated with long term changes in membrane resistance (Woody et al, 1978), experiments were designed to search for changes in responsiveness over extended time periods. Cats were anesthetized with sodium pentobarbital, a craniotomy performed over somatosensory cortex and stimulating electrodes placed in the ventroposterior thalamus. Individual barrels of 5-barrel micropipettes were filled with a carbon fiber, Ach (1.0M), glutamate (0.5M), atropine (25mM) and sodium chloride (3M). Single neurons were recorded though the barrel containing the carbon fiber and subjected to various combinations of the drugs delivered iontophoretically. During data collection, somatic stimuli and/or pulses of glutamate were applied at regular intervals before, during, and after Ach delivery. Lesions were placed at two levels in penetrations of interest and, after the experiment, the electrode trajectory was reconstructed from the histological section containing the electrode track.

301 neurons were studied in 45 cats. As expected Ach increased firing rates in some cells, (17.2%) and decreased it in others (2.3%). Atropine blocked the increased firing due to Ach. Ach either enhanced or diminished the responsiveness of a cell to tactile stimuli or to iontophoretically-applied glutamate (46%; 27/59). Generally, these alterations disappeared and the cell responses returned to control values within 5 min.

In contrast, when Ach was delivered simultaneously with glutamate or when Ach was delivered during strong stimulation of the receptive field, altered responsiveness occurred in 80% (43/54). It often lasted for more than 7 min and sometimes more than 1 hr.

These observations suggest that 1) long-term or plastic changes can occur in individual somatosensory cortical neurons, 2) Ach may be a mediator of these changes, and 3) that the changes also depend upon factors related to neural activity of the modified neuron. Such a mechanism may underlie the reorganization of cortex following digit amputation (Merzenich et al, 1983) while is accompanied by local increases in Ach receptors (Sampson et al, 1984). (Supported by NIH, FRSQ and MRC).

219.12 GABAERGIC INHIBITION IN THE SECOND SOMATIC SENSORY AREA OF CATS. K.D. Alloway and H. Burton. Dept. of Anatomy & Neurobiology, Washington University School of Medicine, St. Louis, MO 63110.

Many interneurons in somatosensory cortex are believed to be GABAergic. Previous reports have indicated that blocking GABAergic receptors in somatosensory area I increases the receptive field size of rapidly-adapting neurons but does not alter their adaptive properties (Hicks and Dykes, 1983). We have commenced a series of experiments aimed at determining the role of GABA in shaping the dynamic properties of neurons in the second somatic sensory cortical area (SII).

Cats, previously implanted with a chamber over SII, were anesthetized with ketamine and acepromazine, placed in a sling apparatus, and non-traumatically immobilized. Following isolation of single neuron activity, ketamine was discontinued and the animal was artificially respired and paralyzed with flaxedil. Acepromazine continued to be administered to provide tranquilization. Single units were recorded with a platinum wire in the central barrel of a 9-barrel glass pipette. Side barrels contained 5-6 mM bicuculline methiodide (BMI), 0.25 M GABA, 0.3 M glutamate, and 1.0 M sodium chloride. All electrode penetrations were made in the part of SII representing the glabrous skin of the central pad. Vibrotactile stimulation of the central pad was used to activate isolated SII neurons.

At this time, results have been obtained from a sample of 12 SII neurons. All cells responded to iontophoretic applications of glutamate with an increase in spontaneous activity that was dose-dependent; thresholds for activation ranged from 10 to 40 nA. By contrast, GABA produced a dose-dependent inhibition of both spontaneous (when present) and stimulus-evoked activity; current levels needed to produce at least a 50% decrease in stimulus-induced activity were variable and ranged from 5 nA (2 neurons) to 100 nA, with a mean of about 35 nA for all 12 neurons.

Two neurons have been studied throughout exposure and recovery from BMI. For both cells 10 nA ejected sufficient quantities of BMI to block the inhibitory effects of GABA on stimulus-induced activity. This dose of BMI caused only a moderate increase in spontaneous activity, but notably increased response entrainment to sinusoidal cutaneous vibration. Thus, both cells responded with greater periodicity to a 20 Hz stimulus following BMI and often exhibited a burst of 2 or 3 spikes in the same portion of the stimulus cycle. Several additional cells responded to BMI with an increase in stimulus-evoked activity but were not tested with sinusoidal stimulation. These preliminary results suggest that a GABAergic inhibitory circuit may limit the temporal fidelity of cortical responses to vibrotactile stimuli.

Supported by NINCDS grants NS09809 and 5T32 NS07071.

219.13 CORTICAL CONNECTIONS OF AREAS 2, 1, AND 5 OF SOMATOSENSORY CORTEX IN MACAQUE MONKEYS. T. P. Pons and J. H. Kaas. Department of Psychology, Vanderbilt University, Nashville, TN 37240.

The cortical connections of electrophysiologically defined parts of the body representations in somatosensory cortex of 13 macaque monkeys, (12 Macaca mulatta, 1 M. fascicularis) were determined after separate or combined injections of wheat germ agglutinin (WGA) conjugated with horseradish peroxidase, tritiated WGA or tritiated proline. After extensive microelectrode mapping of a portion of the body representations in areas 3b, 1, 2, and 5 and careful determination of electrophysiological borders between areas, small restricted injections of tracers were made usually into the hand or foot representations in areas 1 and 2. All cortical connections were reciprocal; however, there were differences in the laminar patterns of connections between areas.

Following injections of tracers into the hand or foot representations in area 2 label was consistently observed in areas 3a, 3b, 1, 4, 5, 7, and in the S-II region. The densest label following area 2 injections was in the S-II region and the sparsest label was in area 4. Separate foci of label were usually found rostrally and caudally in area 4. In one case with an injection into the foot representation, additional label was observed in the region of the supplementary motor area. Following injections of tracers into the area 1 hand and foot representations, cortical label was observed in areas 4, 3a, 3b, 2, 5, 7, and the S-II region. Again the densest connections were with the S-II region. In one case with an injection into the foot representation, additional label was observed in the region of the supplementary sensory area. After an injection in the representation of the forearm in area 1, dense label was observed in the part of area 5 that has been shown to contain a cutaneous representation of the forearm and wrist in anesthetized animals (Pons et al., '85, Brain Res.). In a single case in which the forearm representation in the highly cutaneous zone of area 5 was injected with tracer, dense label was observed in the portion of area 1 representing the arm and forearm. Additional label was seen in areas 4, 7, and the S-II region. A lateral portion of area 5 was also labeled. Feedforward laminar patterns with terminal label concentrated in layer IV, and feedback patterns with label concentrated in nongranular layers suggest that the processing of cortical information proceeds from area 3b to both areas 1 and 2. Areas 1 and 2 then relay information to areas 5 and 7 and to the S-II region. Each of these areas in turn feed back onto areas earlier in the processing sequence. Thus, the cortical processing of somatosensory information has both serial and parallel components. Funded by NIH Grant NS16446.

219.14 THE REPRESENTATION OF THE FACE, ORAL CAVITY, AND TEETH IN AREA 3b OF SQUIRREL MONKEYS, SAIMIRI SCIUREUS. C. G. Cusick and J. T. Wall. Dept. of Psychology, Vanderbilt University, Nashville, TN 37240.

In order to study the topographic organization of mechanoreceptor inputs from the face and oral cavity in somatosensory cortex of monkeys, fine grained microelectrode mapping experiments were performed in squirrel monkeys with up to 389 recording sites within the face region of the dorsolateral surface of the brain. Separate representations of the face were were identified in areas 3b and 1, and the representation in area 3b was determined in detail.

Within area 3b, cortex related to the chin was just lateral to that devoted to the hand. More caudally, area 3b was activated from the lateral face. Caudomedially, the area 3b-1 border represented skin on the midline of the upper head with the scalp, supraorbital skin, nose, and midline of the upper lip, forming a mediolateral cortical sequence. More rostrally, the area 3b-1 border represented the lateral lower lip, followed by the teeth and oral structures. Along the rostromedial border of area 3a with 3b, the somatotopic organization varied. The pattern in 3 monkeys closely resemblesd the organization in S-I of non-primates and prosimians in that the midline of the lower lip projected to the 3a-3b border, which represented the chin, lower lip and lower teeth in caudorostral sequence. In two cases, the upper lip was represented at the 3a-3b border, between the chin and teeth, and lower lip was displaced from the border. The upper lip was either continuously represented from the area 3a-3b to the area 3b-1 border, or the representation was split by the lateral lower lip.

The representation of the teeth was explored up to 83 recording sites in a single experiment. The representation in area 3b was roughly topographic and surprisingly large, ( 4 $mm^2$). Receptive fields varied in size, with fields on incisors including fewer teeth than fields on the molars. Receptive fields for molars usually included both upper and lower teeth. In general, the lower incisors were represented caudally, adjacent to the representation of the lower lip, and the molars were located more rostrally. The upper incisors were usually along the 3a-3b border. In different cases, the upper incisors were either adjacent to the upper lip, the chin, or the lower lip caudally, or to the palate rostrally. The variability of the representation of the lips and teeth in area 3b in squirrel monkeys differs markedly from the relatively consistent representations of the hand in these monkeys. Supported by NIH Grant DE06554.

219.15 THE SOMATOTOPIC ORGANIZATION AND CONNECTIONS OF A THIRD AREA OF SOMATOSENSORY CORTEX IN RODENTS. L. A. Krubitzer, M. A. Sesma, and J. H. Kaas, Dept. of Psychology, Vanderbilt University, Nashville, TN 37240.

In contrast to carnivores and primates where a number of cortical representations of the body surface have been found, only two somatosensory representations, the primary (S-I) and secondary (S-II) somatosensory areas, have been reported in rodents. In the present study, anatomical and electrophysiological methods were combined to determine the organization and connections of somatosensory cortex in grey squirrels, Sciurus carolinensis. Grey squirrels offer the advantages of larger brain size and generally more distinct architectonic subdivisions than do common laboratory rodents. Microelectrode mapping methods were used to define subdivisions of somatosensory cortex, and microlesions were placed to mark physiological borders. Then, wheat germ agglutinin conjugated to horseradish peroxidase (WGA-HRP) was injected into physiologically identified sites within S-I, S-II, or into a newly identified representation, the parietal ventral area (PV). The cerebral hemispheres were flattened, and alternate sections were reacted for WGA-HRP, or stained for myelin.

The results revealed reciprocal connections between S-I and the following fields: (a) S-II; (b) motor cortex; (c) the parietal ventral area (PV) caudal to S-I and ventral to S-II; (d) the parietal medial (PM) area caudal to S-I and medial to S-II; and (e) the parietal rhinal area (PR) ventral to PV and just dorsal to the rhinal sulcus. Like S-I, S-II had reciprocal connections with motor cortex, PV, PM, and PR.

Injections in PV confirmed connections with S-I and S-II, and revealed additional connections with motor cortex, PM, and PR. Callosal connections were with PV, PR, S-I, and S-II. Recordings in PV revealed neurons responsive to light tactile stimulation of skin and hairs. Receptive field sizes for neurons in PV were larger than those for S-I but similar to those for S-II. PV was somatotopically organized as an inverted "homunculus" with the limbs directly medially, the trunk ventrally, and the face congruent with the representation of the upper lip and nose in S-I. At least part of PV was also activated by auditory clicks.

The results indicate that grey squirrels have at least three somatotopically organized cortical representations of the body surface, and potentially as many as five somatosensory fields. One of these fields, PV, appears to be bimodal.

Supported by NIH Grant NS16446.

219.16 LOCALIZATION OF HUMAN SENSORIMOTOR CORTEX IN SURGERY BY RECORDING OF SOMATOSENSORY EVOKED POTENTIALS. T. Allison, C.C. Wood, D.D. Spencer*, P.D. Williamson*, W.R. Goff* and G. McCarthy. VA Medical Center, West Haven, CT 06516 and Yale Univ. Sch. of Med., New Haven, CT 06520.

The traditional means of localizing sensorimotor cortex involves mapping sensory and motor responses elicited by electrical stimulation of the cortical surface. This procedure accurately localizes sensorimotor cortex but is time consuming and is best carried out in an awake, cooperative patient. We have developed cortical surface somatosensory evoked potential (SEP) recordings as a technique for localizing sensorimotor cortex in patients operated under general as well as local anesthesia. Using a 64-electrode grid placed in the vicinity of the hand representation area of sensorimotor cortex, SEPs to contralateral median nerve stimulation were recorded. In 24 patients the validity of SEP localization was verified by independent localization by cortical stimulation; in all cases the two methods were in agreement. In 17 patients the hand area was successfully localized under general anesthesia by SEP recording without cortical stimulation. Three criteria are useful for localization; (1) Polarity inversion of N20-P30 potentials to P20-N30 potentials as electrode locations cross the central sulcus from the postcentral to the precentral gyrus; these potentials are thought to be generated in area 3b of somatosensory cortex. (2) P25-N35 potentials are largest in a small region of postcentral gyrus about 1 cm medial to the largest N20-P30; these potentials are thought to be generated primarily in area 1 of somatosensory cortex. (3) Regardless of specific component identification, large SEPs are recorded only from sensorimotor cortex.

219.17 ANATOMICAL DETERMINATION OF THE EXTENT OF OVERLAP IN THE SENSORIMOTOR REGION OF THE TAMMAR WALLABY, *MACROPUS EUGENII*.

L. Mayner. Department of Behavioural Biology, R.S.B.S. Australian National University, Canberra, A.C.T. 2601, Australia.

Physiological and anatomical studies have shown conclusively that in the American opossum, *Didelphis virginiana*, the motor and somatosensory neocortical regions are totally overlapped. Anatomical studies on Australian marsupials, the possum, *Trichosurus vulpecula*, and native cat, *Dasyurus viverrinus*, have shown that there is only partial overlap between the motor and somatosensory neocortical regions. However, the physiologically defined neocortical motor area of the possum was found to be far more extensive than that determined anatomically. A physiological study on the Australian wallaby (Lende, R. *Science*, 141: 730, 1963) showed that there was total overlap between the motor and somatosensory neocortical areas in this Australian marsupial. The aim of this study was to determine the extent of overlap between motor and somatosensory regions in the neocortex of the wallaby. The sensorimotor area occupies the whole of the parietal neocortical region in the brain of the wallaby. The sensorimotor region was found to contain two prominent layers, layers IV and V, throughout the entire extent of the region. Following HRP injections into the physiologically defined body subdivision of the sensorimotor area label was located in the ventrolateral nucleus, VL, as well as the ventral posterolateral nucleus, VPL. HRP injections into the rostral head subdivision of the sensorimotor region gave rise to label in VL as well as the ventral posteromedial nucleus, VPM. However, HRP injections into the caudal head subdivision of the sensorimotor region gave rise to label only in VPM. The caudal head subdivision was found physiologically to represent the upper lip and vibrissal face regions. Thus, there is extensive, but not total, overlap between the motor and somatosensory neocortical areas in the wallaby. Since layer V is prominent in the caudal head subdivision of the sensorimotor region this could suggest that the physiologically defined motor region is more extensive than the VL projection field. Thus, the VL projection field is not delineating the entire extent of the motor region, this could be a feature inherent to Australian marsupials which appear to exhibit only partial overlap between the motor and somatosensory regions.

219.18 **INTERRELATIONSHIPS BETWEEN CYTOCHROME OXIDASE, GABA AND METABOLIC (2DG) LABELING IN PRIMATE SI CORTEX.**

**Sharon L. Juliano, Oleg Favorov* and Mark Tommerdahl*. Dep Physiology, University of N. Carolina, Chapel Hill, NC 27514.**

**In the visual system of primates, specific cerebral cortical locations (known as "blobs") preferentially take up stain for the mitochondrial enzyme cytochrome oxidase (CO). These blobs of cells possess discrete functional characteristics and exhibit precise positional relationships to cells which stain for GABA. Also, depending on the stimulus conditions, these blobs of cells either overlie or interdigitate with patches of cortex which are active during 2-deoxyglucose (2DG) experiments. We have initiated studies in the primate somatosensory cortex (SI) which explore the relationships between CO, 2DG and/or GABA. In these studies, macaca fascicularis monkeys underwent a 2DG experiment in which a tactile stimulus was delivered. Following the 2DG experiment, sequential sections were processed for 2DG, stained histochemically for CO and stained immunohistochemically for an antibody directed against GABA. As in earlier studies, the labeling produced by 2DG was clearly patch-like. Although less distinctly patchy, the labeling obtained with CO was not homogeneous but showed clear and consistent fluctuations in the density of uptake. A computer image analysis system allowed us to digitize both the 2DG and CO sections and to generate two- or three-dimensional maps of each form of labeling. When the 2DG and the CO labeling obtained from adjacent sections were compared either as individual sections or as unfolded cortical maps, a distinct relationship between the two forms of label was seen. The two patterns of activity were reciprocally complimentary for the stimulus conditions used in these 2DG experiments (brush strokes to the hand or arm). In other words, regions of cortex exhibiting elevated 2DG activity displayed low mitochondrial enzyme (CO) activity while cortical regions of low 2DG uptake displayed high concentrations of CO. The neural elements which stained heavily for GABA demonstrated no absolute relationship to either the 2DG or CO labeling. However there was a tendancy for the cortical regions which stained heavily for GABA to be coincident with regions of increased 2DG uptake, while regions of SI cortex which stained poorly for GABA tended to be coincident with regions of increased CO activity. Although the functional significance of these relationships needs further investigation, the regions of SI cortex which contain high CO activity may represent functional zones which are excited by stimulus conditions different from those used during the 2DG experiments.**

219.19 MORPHOLOGY AND LAMINAR DISTRIBUTION OF NEURONS WITH GLUTAMATE-LIKE IMMUNOREACTIVITY IN THE RAT SOMATOSENSORY CORTEX. F. Conti*, A. Rustioni, P. Petrusz*. Department of Anatomy, University of North Carolina, Chapel Hill, N.C. 27514.

Electrophysiological, biochemical and autoradiographic studies strongly suggest a neurotransmitter function for Glutamate (Glu) and/or Aspartate (Asp) in the mammalian cerebral neocortex. The present study was aimed at determining the morphology and the laminar distribution of the neurons that contain Glu in the rat somatosensory cortex using an immunocytochemical technique. For this purpose, an approach similar to that described by Ottersen and Storm-Mathisen (J. Comp. Neurol., 1984) was used.

An antiserum was raised in rabbits against glutamate conjugated to hemocyanin by glutaraldehyde. The characterization of this antiserum has been described elsewhere (Hepler et al. J. Histochem. Cytochem, 1985). Adult, male Sprague-Dawley rats were perfused with normal saline followed by a fixative containing either 4% paraformaldehyde and 0.3% glutaraldehyde or 5% glutaraldehyde in phosphate buffer. Free-floating, 25 μm thick vibratome sections and 7 μm thick paraffin sections were stained using the double PAP technique.

In all cases so far studied about 30% of neurons in the somatosensory cortex were immunoreactive. These were present in all layers, although in different proportions. Immunoreactive neurons were least numerous in layers I and IV (6.6% and 18%, respectively) and most numerous in layers V and III (38% and 35%, respectively). The proportion of positive neurons was 32% in layer II and 30% in layer VI. In all layers, except layer I, most of the immunoreactive neurons were pyramidal in shape, although non-pyramidal positive neurons were also observed.

The present results are in good agreement with those of previous studies in showing that a significant number of somatosensory cortical neurons probably use Glu and/or Asp as neurotransmitter. Furthermore, the laminar distribution as well as the morphology of stained neurons support the view that Glu and/or Asp are neurotransmitters in the descending corticofugal and in the associative and callosal cortico-cortical pathways. This hypothesis can now be tested by combining the immunocytochemical technique used in the present study with retrograde labeling of the neurones projecting to the different targets of the somatosensory cortex.

219.20 PHYSIOLOGICAL AND PHARMACOLOGICAL STUDIES ON NEURONAL FUNCTION IN THE RAT CEREBRAL CORTEX IN VITRO. N. Hori,* I. Hirotsu*, T. Ishihara,* N. Katsuda* and D.O. Carpenter (SPON: J. Ramaley). Dept. of Pharmacology, Faculty of Dentistry, Kyushu Univ., Fukuoka 812, Japan, Lab. of Experimental Pharmacology, Suntory Inst. for Biomedical Research, Mishima-gun Osaka, 618 Japan and Wadsworth Center for Labs & Res., NY State Dept. of Health, Albany, NY 12201.

The physiologic and pharmacologic properties of the neuronal network within the neocortical columns was examined in an in vitro rat somatosensory cortex preparation. Rectangular brain slabs (0.6 X 0.6 X 2.3 mm) were cut from the somatosensory cortex perpendicular to the pial surface. Procedures used for incubation and recording of electrical activities were similar to those used for thin brain slices (Hori et al., 1982). Electrical stimuli (negative 1-10 V, 0.05 msec) were applied to the white matter by a single electrode and evoked antidromic spikes and orthodromic responses in all the layers of the cortex (I-IV). The width of functional neuronal columns was 250 to 300 μm as indicated by the pattern of excitation observed upon shifting the recording or stimulating electrodes laterally.

In normal Ringer solution stimulation of the white matter evoked a single antidromic spike and/or orthodromic spike in layers II and IV. Intracellular recordings show various responses including an antidromic spike followed by an EPSP or IPSP, no antidromic spike but an EPSP with superimposed spikes, etc. When the slice was perfused with a solution containing d-tubocurarine ($10^{-4}$ M) or bicuculline ($10^{-5}$ M), a well synchronized repetitive train of spikes (interval, about 5 msec) was observed and these trains, except for a short latency antidromic spike, were completely blocked in low $Ca^{2+}$ and high $Mg^{2+}$ solutions. Similar repetitive spikes were obtained in atropine ($10^{-4}$ M), but the train showed less synchronization and was of shorter duration. Intracellular recordings showed that atropine ($10^{-4}$ M) depolarized the membrane by about 10 mV. These results suggest that at least two kinds of interneurons may be involved in the control of the pyramidal neuron. One of those is an excitatory interneuron which may have inhibitory nicotinic receptors and the other is an inhibitory interneuron which may release GABA and have excitatory muscarinic receptors. If these two interneurons receive the same recurrent projections from the pyramidal cells (Lorente de No, 1938), curare and bicuculline may induce a synchronized repetitive train of spikes. Atropine also may inhibit the activity of the inhibitory GABA neuron, and then the pyramidal cell becomes more excitable.

219.PO VIBROTACTILE STIMULATION AS A TOOL FOR CORTICAL MAPPING IN MAN WITH POSITRON EMISSION TOMOGRAPHY. H. Burton, P.T. Fox*, M.E. Raichle. Depts. Anatomy & Neurobiology, Neurology & Neurological Surgery, and Radiology, Washington U. Sch. Med., St. Louis, MO 63110.

Regional cortical responses to vibratory stimuli were recorded in 24 normal, human volunteers using positron emission tomographic (PET) measurements of regional cerebral blood flow (rCBF). An intravenous bolus of $^{15}O$-labeled water was administered as a blood flow tracer (J. Nucl. Med. 24:782). Each subject underwent a series of 8 sequential, 40-sec, CBF emission scans with an inter-scan delay of 8-10 min (for isotope decay). No stimulus was given during the initial or final scans in a series. Stimuli were applied during the intervening 6 scans, with stimulus onset preceding scan initiation by 40-60 sec. All subjects underwent large amplitude stimulation (LA) of the fingers (D1-5) of one or both hands (2 mm amplitude; 130 Hz; 5 cm tip). One protocol (n=9) included: LA stimulation of the halux; lip, left & right D1-5 and bilateral, alternating (2 Hz), flexion-extension finger movements (FM). Highly-discrete, small amplitude stimulation (SA) of individual digit pads was also tested across a range of frequencies (20-300 Hz sinusoids; <500 μm amplitude; 2 mm tip; n=5). All responses were computed as % change in rCBF from resting-state value (J. Neurophysiol. 51:1109). Anatomical localization within PET images was determined stereotactically relative to the AC-PC line (J. Comput. Assist. Tomogr. 9:141).

Intense, focal increases in rCBF occurred in every individual in the cerebral hemisphere contralateral to LA finger stimulation (mean 31%). No significant cerebral responses were detected ipsilateral to any unilateral stimulus. Handedness did not affect response magnitude or location. The post-central gyrus (SI) was the response locus for LA and SA, as determined from the mean stereotactic coordinates of the areas of maximal rCBF change. Response locale systematically varied with the body part stimulated, distributing across cortex in a medial-to-lateral/superior-to-inferior sequence from lower limb (halux), to upper limb (D1-5), to face. Moreover, D1 (thumb) responses lay lateral to and separated from those of D5 (SA). Antero-posterior separation was obtained between the loci of peak response to FM (anterior) and LA, although considerable response overlap occurred partly due to the magnitude of LA and FM responses and to limited spatial resolution (13 mm in plane). Application of different stimulus frequencies (20-300 Hz; SA) to the same digit did not affect response localization.

The consistency and magnitude of LA responses make this tool well-suited for clinical PET research, e.g., to test perfusion reserve in cerebrovascular disease. SA stimulation, however, is preferable for PET studies of somatosensory cortical localization, as this stimulus is discrete and well-characterized.

219.PO PROJECTION PATTERNS FROM THE VENTRO-BASAL COMPLEX OF THE THALAMUS TO THE RAT BARREL CORTEX. S. M. Lu* AND C.-S. Lin; DEPARTMENT OF ANATOMY, DUKE UNIVERSITY, DURHAM, N. C. 27710

Previous electrophysiological studies of layer IV neurons in the posteromedial barrel subfield (PMBSF) of primary somatosensory cortex (SI) have suggested that a large portion of barrel neurons, especially those residing in the sides of barrels, respond to more than one contralateral mystacial whisker (Simons & Woolsey, '79). It is possible that such barrel neurons receive converging input from thalamic axons of the ventro-basal complex (VB) representing different whiskers. The goal of the present study was to determine whether single VB axons innervate more than one barrel.

A mixture of 10% HRP (Boehringer Grade I) and 2% WGA-HRP (Sigma) was iontophoretically injected into the VB for 20 minutes using 4 uA of positive current. The anterogradely HRP filled axons and their terminals were then visualized with the DAB-GOD method (Itoh et al., '79).

The branching of VB axons may occur at different levels, ranging from the white matter to upper layer V. Some VB axons have a branch that innervates the center of one barrel, and another branch that innervates the side of an adjacent barrel. Others innervate only one barrel.

In addition, both large and small diameter axons arborize in layer I. Some of the large axons also send collaterals to layers VI, V, IV and II/III.

The terminal fields of VB axons form patches which are located mainly in the centers of the barrels in layer IV. Heaviest VB terminals are found in layer IV and decrease gradually to layers II/III. Less dense terminal fields are found in layers I and VI.

In conclusion, we have found evidence that individual VB axons may innervate more than one barrel. This may be an anatomical basis for the finding that barrel neurons respond to more than one whisker. (Supported by NS 06233 to C. S. Lin).

220.1 PHARMACOLOGICAL PROPERTIES OF OPIATE-INHIBITED ADENYLATE CYCLASE IN RAT STRIATAL MEMBRANES. S.R. CHILDERS, P. NADEAU AND P. NIJSSEN. Department of Pharmacology, University of Florida College of Medicine, Gainesville, FL 32610.

A well established second messenger system coupled to opiate receptors is inhibition of adenylate cyclase. Previous studies (Childers and LaRiviere, J. Neurosci. 4, 2764-2771, 1984) have shown that the small (10-20%) inhibition of adenylate cyclase by opiates in brain membranes can be increased to 30-40% maximal inhibition by preincubation of membranes at pH 4.5, which alters function of GTP-coupling (N) proteins, decreasing function of the stimulatory unit $N_s$ while increasing function of the inhibitory unit $N_i$ in brain membranes. We have used this technique to quantitate the pharmacological properties of opiate-inhibited adenylate cyclase in rat striatal membranes. All experiments were conducted in buffer containing 100 mM NaCl and 50 μM GTP. Under these conditions, opioid peptides were good agonists, inhibiting adenylate cyclase by 30-40% with $IC_{50}$ values between 0.2 and 0.8 μM for enkephalin, delta receptor enkaphalin analogs (DSLET, DADLE), beta-endorphin, and several dynorphin analogs. Morphine and mu-receptor enkephalin analogs (morphiceptin, FK-33824) were weaker, with $IC_{50}$ values betwen 5 and 20 μM, and were often not full agonists, with maximal inhibitions of 20-25%. Naloxone, levallorphan, and naltrexone were equipotent in blocking inhibition by all agonists studied; however, the delta antagonist ICI-174864 was ineffective in antagonizing opiate inhibition. Irreversible blockade of [$^3$H]-opiate binding sites by 80% with naloxone azine, p-nitro-phenyl-naloxone or p-nitro-phenyl-oxymorphone did not affect either basal or opiate-inhibited adenylate cyclase. These results suggest that receptors coupled to opiate-inhibited adenylate cyclase in striatal membranes may not correspond to any of the classical opiate receptor types determined in receptor binding studies.

220.2 [$^3$H](+)SKF10,047 BINDING IN RAT AND MOUSE BRAIN. R. Sircar and S.R. Zukin. Depts. of Psychiatry and Neuroscience, Albert Einstein College of Medicine, Bronx, NY 10461.

Martin in 1976 postulated the existence of the sigma class of opioid receptors based on the pharmacology of the drug N-allyl-normetazocine (SKF10,047). While the ability of this agent to precipitate withdrawal in morphine-dependent animals stems from its potent mu-antagonist actions, its stimulant and psychotomimetic properties cannot be explained on the basis of interactions with the classical opioid receptor types. Increasing behavioral and biochemical evidence supports the concept that the unique effects of SKF10,047 and those of phencyclidine (PCP) and its derivatives are mediated via a common sigma opioid/PCP receptor. The (+) sigma opioids, devoid of activity at classical opioid receptors, thus seemed promising as "pure" molecular probes of sigma opioid/PCP receptors. In this study the binding characteristics of [$^3$H](+)SKF10,047 (25.5Ci/mmol) in rat and mouse brain homogenates were determined in the presence and absence of excess nonradiolabeled (+)SKF10,047 by a rapid filtration assay (4°C, 5mM Tris-HCl, pH 7.4). Scatchard analysis revealed a curvilinear plot in both species. Computer-assisted, non-linear regression analysis indicated a statistically valid fit of the data to a two-site but not to a one- site model. In order to determine the identities of the sites, displacement studies with opioids, PCP derivatives, dioxalans and neuroleptics were carried out. Haloperidol and pentazocine were potent displacers of [$^3$H](+)SKF10,047 from the high-affinity site; potencies of drugs at this site did not correlate with their potencies for eliciting PCP-, SKF-like or other known behaviors. The potencies of drugs at the low-affinity sites agreed with the rank orders previously determined for binding to PCP/sigma opioid receptors. In at least these two species [$^3$H](+)SKF10,047 thus interacts with two classes of binding sites: the sigma opioid/PCP receptor and a higher-affinity site whose behavioral significance is at present unknown.

220.3 NALTREXONE-INDUCED SUPERSENSITIVITY: FUNCTIONAL CORRELATES IN THE MOUSE AND RAT. B.C. Yoburn, G.S.F. Ling, G.W. Pasternak and C.E. Inturrisi*, Depts. of Pharmacology and Neurology, Cornell Univ. Med. Coll. and Lab of Neuro-Oncology, Memorial Sloan-Kettering Cancer Center, New York, NY 10021.

Long-term exposure (8 day) to the opiate antagonist naltrexone (NTX) produces an approximately 50% increase in opioid binding sites in rat brain and increases morphine's analgesic potency by 1.5 times compared to placebo-treated rats (Yoburn et al., Life Sci., 1985, in press). Rats exposed to NTX for 24 hrs show no significant changes in binding or analgesia. In an effort to see if NTX-induced alterations extended to another opiate effect and another species, we examined the effects of NTX exposure on respiratory depression in rats and morphine analgesia in mice.

Mice were implanted with a single NTX (8 mg) (N=13) or placebo pellet (N=15) for 8 days. The pellets were removed and 24 hrs later baseline nociception was determined using the tailflick procedure. Groups did not differ ($p>.05$) in baseline flick latencies. Mice were injected with 1.5, 3.0 or 6.0 mg/kg morphine, s.c., and tested for analgesia at 30 and 60 min. Mice that did not flick by 10 sec in either test were defined as analgesic. Significantly more mice pretreated with NTX were analgesic (62%) than placebo-treated (20%) mice ($p<.05$).

In the second experiment, rats were implanted with two, 35 mg NTX (N=6) or placebo (N=6) pellets for 8 days. The pellets were removed, arterial and venous catheters inserted and 24 hrs later baseline blood samples were taken and rats injected with 3 mg/kg morphine, i.v. Blood samples were drawn periodically for 90 min and measured for pH, $pO_2$ and $pCO_2$. There were no significant differences ($p>.05$) prior to morphine (pH = 7.54, 7.52, $pCO_2$ = 40.20, 41.37, $pO_2$ = 90.14, 87.89; for NTX- and placebo-treated, respectively). Following morphine, equivalent respiratory depression was observed for both groups ($p>.05$). Peak mean responses at 7.5 min post-drug were: pH = 7.47, 7.44, $pCO_2$ = 47.03, 46.83, $pO_2$ = 69.42, 76.83; for NTX and placebo-treated, respectively.

These studies extend the phenomenon of NTX-induced supersensitivity to morphine analgesia to another species; the mouse. In the rat, NTX treatment does not produce supersensitivity to morphine-induced respiratory depression. This finding may be related to a selective functional upregulation of receptors regulating analgesia ($\mu_1$) but not receptors mediating opiate-induced respiratory depression ($\mu_2$) in the rat. (Supported in part by NIDA Grants DA-01457 and DA-02615.)

220.4 METAPHIT, AN IRREVERSIBLE INHIBITOR OF PHENCYCLIDINE (PCP) RECEPTORS, ACYLATES A PORTION OF [$^3$H]3-PPP BINDING SITES IN RAT BRAIN. L. L. Coughenour*, W. G. Berghoff*, M. F. Rafferty* and T. A. Pugsley*. (SPON: J. Woods). Warner-Lambert/Parke-Davis, Pharmaceutical Research, Ann Arbor, MI 48105.

Metaphit (1-[1-(3-isothiocyanatophenyl)cyclohexyl]piperidine), a derivative of PCP, specifically acylates about 50% of the binding sites in rat brain striatal and hippocampal membranes labeled by [$^3$H]-PCP (Rafferty et al., FEBS 181:318, 1985). The benzomorphan or sigma opiates and PCP and its derivatives bind to both [$^3$H]PCP labeled sites and [$^3$H]benzomorphan labeled sites in a strikingly similar manner (Quirion et al., PNAS, 9 79:5881, 1981; Zukin and Zukin, Mol. Pharmacol. 20:246, 1981) suggesting that the psychomimetic effects of both the benzomorphan opiates and PCP may be mediated through a common receptor. Recently, a non-opiate, (+)[$^3$H]3-(3-hydroxyphenyl)-N-n-(1-propyl)-piperidine ((+)[$^3$H]3-PPP), has been reported to bind with high affinity to the sigma opiate receptor in rat brain (Largent et al., PNAS, 81:4983, 1984). There are some discrepancies between [$^3$H]-PCP labeled binding sites and radiolabeled sigma opiate binding sites, notably that the potent dopaminergic antagonist haloperidol inhibits (+)[$^3$H]3-PPP binding and the binding of the benzomorphan opiate [$^3$H]-SKF-10047 with nanomolar affinity and does not have high affinity for [$^3$H]-PCP binding (Largent, ibid; Tam, PNAS, 81:5618, 1984). If PCP, (+)3-PPP and the sigma opiates are binding to the same site, metaphit would be expected to acylate the sigma opiate receptor as well as the PCP labeled receptor. We have investigated the effects of metaphit on the binding of (+)[$^3$H]3-PPP to the sigma opiate receptor in rat brain membranes. Acylation of whole rat brain membranes (Rafferty et al.) and (+)[$^3$H]3-PPP binding assays (Largent et al.) were carried out as described. Metaphit acylated 40% of the binding sites labeled by (+)3[$^3$H]3-PPP (Control Bmax: 25 pmoles/mg tissues, Kd: 60 nM; Metaphit treated Bmax: 15.3 pmoles/mg tissue*, Kd: 58 nM) without a change in affinity. Thus, Metaphit appeared to acylate (+)[$^3$H]3-PPP binding sites in a manner similar to [$^3$H]PCP binding sites. In control membranes PCP inhibited the binding of (+)[$^3$H]3-PPP ($IC_{50}$ = 2.4 μM) in a distinctly biphasic manner (slope 0.64), but in metaphit treated membranes the affinity of PCP was decreased 5 fold, and the slope of the inhibition curve approached unity. In rat brain (+)[$^3$H]3-PPP appears to label two sites; one of which binds (+)3-PPP and PCP with high affinity and is sensitive to acylation by Metaphit. *$p<$ 0.005, Student's t test; N = 3 separate experiments done in triplicate.

220.5 NALTREXONE INDUCES DIFFERENTIAL UP-REGULATION OF RAT FOREBRAIN MICROSOMAL AND SYNAPTIC MEMBRANE μ OPIOID RECEPTORS. A.M. Moudy, J.W. Spain* and C.J. Coscia (SPON: K. Smith). Departments of Biochemistry and Physiology, St. Louis University Sch. Med., St. Louis, MO 63104.

Chronic administration of the opiate antagonist, naltrexone, to rats has been shown to result in up-regulation of their brain opioid receptors. Using subcellular fractionation techniques we have resolved brain opioid receptors into two membrane populations, one associated with synaptic plasma membranes (spm) and the other enriched in smooth endoplasmic reticulum and Golgi (microsomes) (Roth et al., J. Biol. Chem. 256, 10117, 1981). In this study we addressed the question of whether naltrexone induces up-regulation uniformly in these two populations. Rats were administered naltrexone by subcutaneously implanted osmotic minipumps which delivered 5 mg/kg/day of this long-lasting antagonist for 7 days. Thereupon, forebrain μ opioid receptor levels were determined by homologous displacement of [$^3$H]D-ala$^2$-mePhe$^4$-gly-ol$^5$ enkephalin followed by estimation of binding parameters using the LIGAND program.

Receptor levels in crude membranes rose 77% after treatment. Microsomes displayed a 92% increase in μ receptor concentration, representing an almost two-fold greater change than that associated with spm fractions (51%). This difference was statistically significant ($p<0.01$). Neither changes in binding affinities ($K_d$ = 1.4 nM) nor membrane protein content were detected. These results establish that naltrexone induces up-regulation of both microsomes and spms. Furthermore, they are consistent with the hypothesis that microsomal and spm opioid receptors represent discrete populations of intracellular and cell surface sites, respectively. Supported by NSF grant BNS 81-14947 and NIH grant HL 07050.

220.6 REGIONAL STUDIES OF SUFENTANYL INHIBITION OF $^3$H-NALOXONE BINDING IN THE RAT BRAIN BY QUANTITATIVE AUTORADIOGRAPHY. W.A. Geary, II and G.F. Wooten. Dept. of Neurology, Univ. of Virginia, Charlottesville, VA 22908.

We have examined regional competition curves of the mu-selective agonist sufentanyl (Janssen, Belguim) against 3.0 nM $^3$H-naloxone binding( 51 Ci/mmol, Amersham) to determine regional densities of mu binding in intact rat brain tissue. $^3$H-naloxone was used as a nonselective probe for multiple opioid binding subtypes (James and Goldstein, Mol. Pharmacol. 25:337-342, 1984); sufentanyl (0.25-12.5 nM) was used to selectively demonstrate regional mu binding activity by competitive inhibition (James and Goldstein, ibid, 1984). Quantitative autoradiographic procedures were employed to measure binding to in vitro incubated 20 μm cryostat sections of rat brain; quadruplicate serial sections were prepared every 200 μm in the coronal plane from the level of the olfactory bulb through the locus ceruleus (roughly 250 sections per rat); $n \geq 2$ rats for each sufentanyl concentration studied. All experiments were performed in phosphate buffered saline; quantitative analysis was carried out as previously described (Geary and Wooten, J. Pharm. Exp. Therap. 225:234-240, 1983). All data were corrected for differential autoabsorption of tritium (Geary and Wooten, Brain Res. 1985, in press).

Twenty-four brain regions were analyzed for sufentanyl competition for $^3$H-naloxone binding; regions were chosen based on previous reports of variable densities of opioid binding subtypes. Sufentanyl displaced $^3$H-naloxone binding monophasically in all regions examined. In addition, the percent inhibition across all brain regions was highly uniform. Noteworthy was the apparent ability of a low concentration of sufentanyl (12.5 nM) to displace a large percentage (70%) of naloxone binding in areas rich in either kappa (amygdala) or delta (striatum) binding subtypes. Our data suggest three possible conclusions: 1) while sufentanyl exhibits selective binding to mu sites in rat brain homogenates in $Na^+$-free buffers, the selectivity is largely reduced in $Na^+$-containing buffers with intact tissue, 2) under our binding conditions, naloxone itself binds exclusively to the mu binding site, or 3) only one high affinity opioid binding activity exists in intact rat brain when exposed to physiological $Na^+$ concentrations.

220.7 ONTOGENESIS OF μ-OPIOID RECEPTOR IN CHICK BRAIN. T. Geladopoulos and A. Vernadakis (SPON: N. Sakellaridis). Depts. of Pharmacology and Psychiatry Univ. Colo. Sch. Med., Denver, CO 80262.

Previous studies from this laboratory have shown stereospecific $^3$H-etorphine binding during early embryogenesis in the chick (Dev. Brain Res. 4:23-29, 1982). In this study we report the binding patterns of $^3$H-dihydromorphine ($^3$H-DHM, a selective μ agonist). $^3$H-DHM binding was studied at days 5,6 and 20 of embryonic age. At days 5 and 6 whole brain was used, and at day 20 cerebral hemispheres. Binding assays were performed by filtration. Non-specific binding was determined in the presence of $5 \times 10^{-7}$M levorphanol. Data were analysed using a Morrow Microdecision computer. Scatchard analysis of saturation curves (0.05-10 nM) revealed a single binding site for $^3$H-DHM at day 20. The $K_d$ and the $B_{max}$ were 1 nM and 50 fmol/mg protein, respectively. However, at day 5 and 6 a biphasic binding pattern of $^3$H-DHM was found. The $K_d$ for the high affinity site was 0.25 nM for both day 5 and day 6. The $B_{max}$ was 6 fmol/mg protein at day 5 and 14 fmol at day 6, reflecting an increase in binding sites that appear at day 6 with the affinity remaining constant. The low affinity binding undergoes changes in both affinity and number of binding sites. At day 5 the $K_d$ was 1.3 nM, the $B_{max}$ 5 fmol, and at day 6, 2.5 nM and 30 fmol, respectively. These data indicate the $^3$H-DHM binds to more than one receptor site during different developmental stages. Displacement binding studies were performed using various cold ligands. Levorphanol had a more pronounced inhibitory effect at day 20 than at days 5 and 6, whereas D-Ala$^2$-D-Leu$^5$-enkephalin (DADL, a δ specific agonist) showed more pronounced inhibition at days 5 and 6. These data indicate that by 20 days, the μ receptor is mature, and that during early embryogenesis the $^3$H-DHM binding site responds to both μ and δ ligands in an atypical manner. Furthermore, we propose that the low affinity binding may represent δ receptor. Additional saturation binding studies were performed in the presence of $5 \times 10^{-7}$M levorphanol and 1 μM DADL in order to possibly eliminate the low affinity binding. At day 20, the $^3$H-DHM binding was nearly unaffected by the presence of DADL, supporting the idea for an already mature μ opioid receptor. The high affinity binding at day 5 and day 6 was also not affected by the presence of DADL. However, the $K_d$ of the low affinity binding was dramatically increased. These results indicate that during early development the opioid receptor might not be differentiated to distinguish ligands assigned to μ and δ receptors in the adult. The functional role of the various types of opioid receptors during early embryogenesis remains to be elucidated. However, it is suggested that low affinity opioid binding sites may be involved in cell differentiation. (Supported by Research grant HD 18894 from NICHD)

220.8 SPECIFIC BINDING OF [$^3$H]-PHENCYCLIDINE TO RAT BRAIN MEMBRANES. Peter J. Egofske* and Ronald L. Kochman. Dept. of Biological Research, G.D. Searle & Co., Skokie, Ill. 60077.

The binding of [$^3$H]-phencyclidine (PCP) to rat brain synaptic membrane preparations (P2) has been studied. Kinetic binding data for [$^3$H]PCP, obtained by both rapid filtration and centrifugation methods, indicate multiple binding sites for [$^3$H]PCP. The binding of [$^3$H]PCP to rat brain membranes was found to be dependent upon homogenate protein concentration, pH, temperature, buffer, and ionic strength. Using a rapid filtration method, the specific binding of 10nM [$^3$H]PCP was found to be a linear function of homogenate protein concentration between 0.1 and 0.7mg/ml and maximal binding was obtained between pH 7.8 and 8.8 for 5mM TRIS-HCl buffer (37° C). Saturation was complete within 20 minutes when the incubation was carried out at 25° or 37° C; however, at 0° C, saturation was not complete until after 45 minutes. At equilibrium, specific binding at 0° C decreased by 50% when compared to the 25° or 37° C incubations. Specific binding of [$^3$H]-PCP decreased by a factor of two when the concentration of 5mM TRIS-HCl was increased to 50mM. After [$^3$H]PCP was incubated for 130 minutes at 37° C, greater than 95% of the bound radioactivity was determined to be intact drug. Heat-denaturation of the membranes destroyed the specific binding of [$^3$H]PCP. Competition studies between mu and sigma opiate ligands, PCP analogs and unlabeled PCP, against [$^3$H]PCP were carried out, using the rapid filtration method.

220.9 THE EFFECT OF MET-ENK VERSUS MORPHINE ON VARIOUS ASPECTS OF PHYSICAL DEPENDENCE. K.A. Steece, R.F. Ritzmann, J.M. Lee, J.Z. Fields, and F.A. DeLeon-Jones. West Side and Hines VA Med Ctrs, Chgo, IL, 60612.

Morphine and enkephalins act via different receptors, mu (u) and delta (S), respectively. Chronic administration of either morphine or methionine enkephalin (met-enk) results in development of physical dependence (p.d.). Data suggests there are some differences in p.d. produced by morphine and met-enk with regards to withdrawl symptoms as well as certain neurochemical systems. In particular, chronic met-enk treatment appears to up-regulate D2-DA receptors in the hypothalamus which positively correlates with an increased sensitivity to apomorphine(APO)-induced hypothermia. This is similar to that observed in chronic morphine treated animals. In the striatum, in contrast to morphine treatment where there is an up regulation and increased sensitivity to DA agonists, neither striatal D2-DA receptors nor APO-induced stereotypy appears different in chronic met-enk treated animals. Acute administration of 3H-met-enk (icv), with and without enzyme inhibitors, suggests that there are no significant differences in met-enk distribution in these two areas which may account for these differences. It has been demonstrated that opioid peptides induce S receptor down-regulation in vitro. On the other hand, it is generally agreed that morphine does not have a similar affect on the u or S receptors. Thus it is of interest to determine whether S receptor down-regulaion in vivo occurs with chronic administration of met-enk and if so, if the time course of change follows the development of the symptoms of p.d.. The differences in morphine and met-enk regulation of u and S receptors, respectively, may account for some of the differences observed in the symptomologies of p.d. on these compounds. In addition, since both of these areas are abundunt in S receptors, there may be a difference in regulation of S receptors in the striatum and hypothalamus. Preliminary studies suggest that there is no change in striatal S receptors following chronic treatment with met-enk. However, this does not rule out the possibility that there may be a change in ligand recogition site regulation beyond the receptor per se, ie: N-protein or cation effect.

220.10 NALBUPHINE: AN AUTORADIOGRAPHIC OPIOID RECEPTOR BINDING PROFILE OF AN AGONIST/ANTAGONIST ANALGESIC. W.K. Schmidt*, E.B. De Souza and M.J. Kuhar (SPON: B.E. Lerer). Lab of Neuroscience, Addiction Research Center, NIDA, Baltimore, MD 21224, Dept. of Neuroscience, Johns Hopkins Univ. Sch. of Med., Baltimore, MD 21205, and Pharmaceuticals Research and Development Div., Du Pont Pharmaceuticals, E.I. du Pont de Nemours, Willmington, DE 19898.

Nalbuphine is a potent analgesic with a low side effect and dependence profile in animals and man. Results from previous studies suggest that nalbuphine is primarily a kappa-agonist/mu-antagonist analgesic (Schmidt et al., Drug and Alcohol Dependence 14:339, 1985). The present study was designed to examine the characteristics of nalbuphine binding to mu, delta and kappa opioid receptors and to localize the sites of action of nalbuphine in the CNS using in vitro labeling light microscopic autoradiography.

Mu, delta, and kappa receptors were selectively labeled with 1.8 nM $^3$H-dihydromorphine, 4 nM $^3$H-D-ala$^2$-D-leu$^5$-enkephalin in the presence of 30 nM morphine, and 1.6 nM $^3$H-(-)ethylketocyclazocine in the presence of 30 nM morphine and 100 nM D-ala$^2$-D-leu$^5$-enkephalin, respectively. In displacement studies in rat brain homogenates, nalbuphine had the highest affinity ($K_i$; mean $\pm$ SEM) for mu receptors (0.46 $\pm$ 0.06 nM) with progressively lower affinities for kappa (29.0 $\pm$ 6.0 nM) and delta (59.5 $\pm$ 5.2 nM) receptors. In autoradiographic studies in slide-mounted sections of guinea pig brain and monkey spinal cord, nalbuphine (300 nM) completely displaced the binding at mu and kappa receptors without significantly altering the binding at delta receptors.

Next, we studied the autoradiographic distribution of $^3$H-nalbuphine binding sites in guinea pig and monkey CNS. Preliminary experiments were carried out in slide-mounted sections of guinea pig forebrain in order to determine the optimal binding parameters and to characterize the binding of $^3$H-nalbuphine in brain. The binding of $^3$H-nalbuphine was saturable and showed a curvilinear profile indicating the presence of two binding sites with apparent $K_d$ values of 0.52 and 11.4 nM. Morphine and U-50,488H which have high affinities for mu and kappa receptors, respectively, inhibited $^3$H-nalbuphine binding with $IC_{50}$ values of 0.9 and 10 nM, respectively. In saturation studies, morphine (50 nM) and U-50,488H (100nM) selectively eliminated the high and low affinity components of $^3$H-nalbuphine binding, respectively. The autoradiographic distribution of $^3$H-nalbuphine binding sites in the CNS corresponds well to the distribution of mu and kappa receptors. In addition, CNS areas (Laminae I and II of the spinal cord, substantia gelatinosa of the trigeminal nerve, periaqueductal grey, and thalamic nuclei) that mediate analgesia contain high concentrations of $^3$H-nalbuphine binding sites. In summary, these data demonstrate that nalbuphine acts on mu and kappa opioid receptors and provide anatomical loci in the CNS where nalbuphine may produce its actions. Supported by DA00266, NS15080 and MH00053.

220.11 REPEATED ELECTROCONVULSIVE SHOCK DOWN-REGULATES THE OPIOID RECEPTORS IN RAT BRAIN. Y. Nakata[1], K.J. Chang[2], C.L. Mitchell, and J.S. Hong[1]. [1]Lab. Behav. Neuro. Toxicol., NIEHS/NIH, Research Triangle Park, NC 27709, [2]The Wellcome Research Laboratories, Research Triangle Park, NC 27709.

It has been suggested that endogenous opioid peptides may mediate electroconvulsive shock (ECS)-elicited behavioral alterations, such as analgesia, retrograde amnesia, changes in seizure threshold or postictal depression. This notion is supported by our previous report that repeated ECS increases the [Met$^5$]-enkephalin-like immunoreactivity (ME-LI) in certain limbic areas of the rat brain, such as septum, amygdala, nucleus accumbens and hypothalamus whereas the level of hypothalamic β-endorphin remains unaltered. Our recent study using in vitro cell free translation or blot hybridization using a rat preproenkephalin A cDNA clone to estimate the level of mRNA coding for preproenkephalin A suggests that the increase in hypothalamic ME-LI after repeated ECS is due to an increase in biosynthesis. Recently, we observed that levels of dynorphin A (1-8)-like immunoreactivity (DN-LI) in several brain regions are also greatly affected after 10 daily ECSs: Namely, an increase in hypothalamus, caudate nucleus, septum and a decrease in hippocampus. These observations suggest that the metabolism of these two opioid peptide-containing neurons can change in response to repeated seizures. The purpose of this study was to determine the possible changes of opioid receptors which may occur as a consequence of the activation of enkephalin and dynorphin systems after repeated ECS. An in vitro receptor binding technique was used to monitor the changes in receptors.

Ten consecutive daily ECS delivered to the rats through ear-clip electrode with the following parameters: 85 mA, 50 Hz, 1 msec pulse interval for a total duration of 1 sec, which produce maximal tonic and clonic convulsions, caused reductions of mu and delta opioid receptor binding in hypothalamus, hippocampus, and caudate nucleus, but not in frontal cortex and brain stem. These changes of opioid receptor binding were not observed in rats receiving a single ECS. Scatchard analysis revealed that ECS-induced reduction of mu and delta receptor binding was due to a decrease in the binding sites but not to a change in the binding affinity. Time course studies showed that 7 days after the end of 10 consecutive daily ECSs, both mu and delta receptor binding remained lower than those of sham-controls. However, the effects of ECS on the opioid receptor binding disappeared in 2-3 weeks. These observations are consistent with the hypothesis that ECS treatments increase the release of opioid peptides in certain brain regions which in turn down-regulate the opioid receptors.

220.12 DISTRIBUTION OF OPIATE RECEPTOR SUBTYPES AND ENKEPHALIN AND DYNORPHIN IN THE HIPPOCAMPUS OF SQUIRREL, GUINEA PIG, RAT, AND HAMSTER. (Sponsor: J. Heym) S. McLean*[1], R. Rothman[3], K. Rice*[2], A. Jacobson*[2] and M. Herkenham[1]. [1]Lab. Neurophysiol, NIMH, [2]Lab. Chemistry, NIADDK, Bethesda, MD, 20205 and [3]Lab. Preclinical Pharmacol., St. Elizabeths Hospital, NIMH, Washington, DC 20032.

The distribution of mu, delta, and kappa opiate receptor subtypes was compared to the immunocytochemical distribution of dynorphin B and enkephalin in the hippocampus of four rodent species: squirrel, guinea pig, rat and hamster. For immunocytochemical determinations, 30 μm-thick sections from paraformaldehyde-fixed brains were incubated with dynorphin B or enkephalin antisera and processed by the avidin-biotin complex method. The three major opiate receptor subtypes were localized by in vitro binding in unfixed slide-mounted tissue sections utilizing binding conditions for selective and maximal occupation of mu, delta and kappa sites by [$^3$H]D-ala-$^2$MePhe$^4$-Gly-ol$^5$-enkephalin, [$^3$H]D-ala$^2$-D-leu$^5$-enkephalin and [$^3$H]bremazocine, respectively. Selectivity for the mu site is derived from the specificity of the ligand itself. For delta sites 30 nM oxymorphone was included in the incubation medium to block high affinity binding to the mu site. Sections enriched in kappa sites were preincubated with etonitazene and fentanyl derivatives, BIT and FIT, agents that irreversibly alkylate the mu and delta sites, respectively, then incubated with [$^3$H]bremazocine at 4°C in the presence of 0.4 M NaCl. Following binding the tissue was washed, blown dry and apposed to LKB Ultrofilm for two months.

Dense labeling of fibers immmunoreactive for enkephalin and dynorphin-like material is present in the mossy fiber system of all species. Occasional fibers reactive for enkephalin or dynorphin are seen in most layers of the hippocampus.

In all species, mu and kappa receptors are similarly but not identically distributed in the hippocampus, predominantly in the molecular layer of the dentate gyrus and pyramidal cell layer of CA3 and CA4. Kappa binding in the mossy fiber sytem is dense in the squirrel and guinea pig but sparse in the rat and hamster. In contrast to the mu and kappa patterns, delta receptors are lowest in the pyramidal and granule cell layers and in the mossy fiber system of all four species. Delta receptors overlap with the mu and kappa receptors in the dentate molecular layer, but are more extensively distributed in stratum radiatum and stratum oriens.

Whereas the patterns of opiate receptor subtypes show interspecies variability, the opioid peptides do not. Furthermore, the opiate receptor subtypes are more extensively distributed throughout the hippocampus than are the peptides, and the laminar patterns of receptor binding bear no consistent relationship with the distribution of endogenous opiate-like material.

220.13 [$^3$H]Naloxone Autoradiography: Distribution of Lambda Opiate Binding Sites in Rat Brain. David C. Perry[1] and Wolfgang Sadee[2], Department of Pharmacology[1], George Washington University Medical Center, Washington, D.C., 20037, and Department of Pharmaceutical Chemistry[2], University of California, San Francisco, CA, 94043.

Recent in vivo and in vitro studies describe an opiate binding site in rat brain (the lambda site) which is distinct from the previously described mu, delta, kappa, or sigma sites (Grevel and Sadee, Science 221: 1198, 1983). We have employed in vitro receptor autoradiography techniques with [$^3$H]naloxone to determine the distribution of this site in rat brain. Frozen 10 µm sections were incubated for 20 minutes at 4 C with 4 nM [$^3$H]naloxone, then rinsed for 3 minutes with ice-cold buffer, dried and exposed to tritium-sensitive film to visualize bound radioactivity. Non-specific binding was defined as that remaining in the presence of 1 µM naloxone; lambda sites as those remaining in the presence of 300 nM diprenorphine (Grevel and Sadee, 221: 1198, 1983). Lambda sites were widely distributed throughout the brain, showing a unique pattern of distribution. Total binding (no drugs added to incubation) resembled previously published reports for the distribution of mu opiate receptors. Lambda site distribution was significantly different; many areas enriched in mu sites showed little or no lambda binding. The major regions showing significant lambda binding were the cortex (esp. laminae I and II); the amygdala; the cerebellar gray matter; several thalamic nuclei; and the hippocampus. Lambda sites in the first four regions are relatively evenly distributed: [$^3$H]naloxone labeled both mu and lambda sites, in varying proportions, but with generally similar distribution within the region. The finding in the hippocampus was more striking, however. An intensely labeled band was seen which appeared to consist almost entirely of lambda sites; this band was congruent with the mossy fiber tract (i.e., pyramidal cell layer of the dentate gyrus and fields CA3 and CA4). This localization of lambda sites may shed some light on their possible function; opiates exhibit unique excitatory effects on the pyramidal cells of the hippocampus, and the mossy fiber tract demonstrates intense dynorphin immunoreactivity (Chavkin, et al., J. Neurosci 5: 808, 1985).

## PROCESS OUTGROWTH: MOLECULAR MECHANISMS

221.1 CHANGES IN THE PHOSPHORYLATION AND DISTRIBUTION OF VINCULIN DURING NERVE GROWTH FACTOR INDUCED NEURITE OUTGROWTH. Simon Halegoua*, (SPON:D.Deutch) Dept. of Neurobiology and Behavior, SUNY at Stony Brook, Stony Brook, N.Y. 11794.

Nerve growth factor (NGF) treatment of PC12 cells was used to study the mechanism of neurite initiation and elongation. The distribution of focal adhesion sites and of the cytoskeletal protein, vinculin, was determined in large fused, multinucleated PC12 cells. In the absence of NGF, focal adhesion sites were restricted to the cell periphery in an even distribution as seen by interference reflection microscopy. By indirect immunofluorescence microscopy using affinity purified anti-vinculin antibodies, vinculin assembly (foci) was also found to be restricted to the cell periphery apparently at focal adhesion sites. Within four hours after NGF treatment of the cells, the distribution of both vinculin and focal adhesion sites began to change. Focal adhesion sites became further restricted to discrete protruding portions of the cell periphery. Immunofluorescence localization of vinculin displayed larger, brighter vinculin foci at the tips of the cell margin extensions, concommitant with the loss of foci at locations between the protrusions. As the formation of neuritic growth cones proceeded from discrete locations at the cell margin, both focal adhesion sites and vinculin foci remained with the tips of growth cone extensions. Both focal adhesion sites and vinculin foci were rarely seen in the perikarya of cells with elongating neurites, and these were always confined to extending portions of the cell body margin. Occassionally, vinculin foci could be seen at the proximal protruding portion of the neurite and at discrete locations along the neurite, usually at protruding tips along the legnth. By immunoprecipitation of vinculin from $^{32}$P labeled cells, vinculin was also found to become more heavily phosphorylated within one hour of NGF treatment. Based upon these and previously reported data on neurite extension, a model is presented for the mechanism by which NGF directs the formation and elongation of neuritic processes.

221.2 NGF-SENSITIVE PHOSPHOPROTEINS FROM PC12 CELLS ARE DIFFERENTIALLY LOCALIZED BETWEEN CELL BODIES AND NEURITES. J.M. Aletta and L.A. Greene*. Dept. Pharmacology, NYU Med. Cen., New York, NY 10016.

We are interested in identifying and characterizing the molecules involved in the growth, motility, and structural maintenance of neurites. In order to achieve this goal, we have developed an isolated neurite preparation from NGF-treated PC12 cells. Cells are initially plated within small cloning cylinders placed on collagen-coated culture dishes to produce small discrete clusters which form an extensive radiating neuritic network during exposure to NGF for 3-5 weeks, at which time the cell bodies can be surgically excised (see Estridge and Bunge JCB 79: 138, 1978).

By metabolically labeling such cultures with [$^{32}$P]-ortho-phosphate, we have found that the relative levels of several phosphoproteins are remarkably enriched in the neurites compared to unfractionated cells cultured with NGF as above or in dispersed monolayers, or compared to the excised cell bodies. Specifically, five such phosphoproteins ($M_r$ 55, 64, 72, 80, and ~ 300 kd) are consistently detected by SDS PAGE and 2-D IEF SDS PAGE. This result is obtained whether the 1 hr labeling period is carried out before or after removal of the cell bodies. In separate experiments with unfractionated PC12 cell cultures we have observed that long term NGF treatment is a prerequisite for the detection of each of these phosphorylated forms in substantial quantity. Various criteria indicate that the 55 kd phosphoprotein is a tubulin, while the 64, 72, 80, and 300 kd species are microtubule-associated proteins. The 55 kd protein comigrates with the tubulin complex on 2-D gels and phosphorylation of at least the 55 and 64 kd proteins is markedly reduced in cultures treated with the microtubule depolymerizing agents nocodazole or podophyllotoxin, 50 µM, for 2-15 hrs. Drug treatments, however, do not produce visible deterioration of neurites or their attachment to the substrate. This indicates that these two phosphorylated forms are not likely to be required to stabilize the overall structure of the neurite.

Further analysis of the 2-D gels has revealed several other phosphoproteins preferentially localized to neurites. Of particular interest are two protein spots present only in samples from NGF-treated PC12 cells. Withdrawal of NGF from neurite bearing cultures for 6 hrs prior to harvesting results in their dephosphorylation. Readdition of NGF to sister cultures for the last 1/2 hr of the 6 hr period, however, is sufficient to allow re-phosphorylation of these two substrates. These are candidates for growth related functions since the withdrawal and readdition of NGF are known to produce rapid effects on the motility and structure of PC12 neurites and growth cones. Supported by grants from March of Dimes, NIH (NS16036) and a postdoctoral fellowship to JMA from the Muscular Dystrophy Association.

221.3 HETEROGENEOUS DISTRIBUTION OF LECTIN BINDING SITES ON THE CELL SURFACES OF DEVELOPING CENTRAL NERVOUS SYSTEM NEURONS. K.L. Lankford* and W.L. Klein. (Spon: B. Menco) Dept. Neurobiology and Physiology, Northwestern University, Evanston, IL 60201.

In order to investigate the overall organization of the plasma membrane of developing neurons, wholemounts of cultured embryonic chick retina neurons were labeled with lectin-conjugated 10 nm gold colloidal particles and examined with transmission electron microscopy. This technique provided a complete overview of the distribution of lectin binding sites with high resolution localization of specific labeling.

A heterogeneous distribution of wheat germ agglutinin-gold colloidal particle (WGA-GCP) labeling was observed in both pre-fixation and postfixation labeled specimens. The heterogeneous pattern of labeling was apparent in both serum supplemented and defined medium cultures. The density of labeling was highest on filopodia (285 WGA-GCPs/$um^2$) and lamellipodia (264 WGA-GCPs/$um^2$), but significantly lower on the growth cones themselves and the cell bodies (125 WGA-GCPs/$um^2$). In addition, patches of high density labeling could be detected within each region. In a representative growth cone region, 40% of the label was contained within 14% of the total cell surface area. Labeling tended to be particularly dense on the tips of filopodia, supporting the theory that glycoproteins mediate filopodial adhesion. Preliminary results suggest a similar pattern of distribution of Concanavalin A binding sites. The pattern of lectin labeling suggests that morphologically and functionally discrete regions of the cell surface are biochemically different.

The procedures utilized here for localization of lectin binding sites can also be applied to antibody labeling techniques. Labeling of wholemounts using gold-conjugated secondary antibodies should provide useful insight into the distribution of known neuronal antigens.

(Supported by NIH grant NS21088 to W.L. Klein.)

221.4 **CHARACTERIZATION OF A NEURONAL PROTEIN THAT BINDS PLASMINOGEN ACTIVATOR.** Randall N. Pittman. Department of Pharmacology G3, University of Pennsylvania School of Medicine, Philadelphia, PA 19104.

A urokinase-like plasminogen activator is spontaneously released by distal processes and growth cones of cultured rat sympathetic neurons (Pittman, Dev. Biol., in press). After being released, the neuronal plasminogen activator binds to a protein on the surface of sympathetic neurons. The complex between plasminogen activator and the surface protein is irreversible and has a MW of 68 kDa.

PC 12 pheochromocytoma cells treated with nerve growth factor (NGF) also have a protein on their surface that forms a 68 kDa complex with plasminogen activator. A MW of 50 kDa was determined for the PC 12 protein by solubilizing NGF-treated PC 12 cells followed by SDS gel electrophoresis, blotting onto nitrocellulose and probing the nitrocellulose with $^{125}$I-urokinase. This same protein not only binds plasminogen activator but can also bind (via a different site) to a component in the extracellular matrix (ECM). This was determined by solubilizing membranes from NGF-treated PC 12 cells with Tween-20 followed by exposing the solubilized proteins to extracellular matrix from bovine corneal endothelial cells. The matrix was washed extensively with isotonic Tris followed by washes of increasing salt concentrations. Whereas all proteins detected in Coomassie- or silver-stained gels were eluted in 0.1-0.2 M NaCl, the 50 kDa protein (detected by its binding to $^{125}$I-urokinase) eluted from the matrix between 0.4 and 0.6 M NaCl, indicating a strong binding to a component in the ECM.

Experiments are currently in progress to determine if the 50 kDa surface protein which binds components of the ECM as well as plasminogen activator is involved in process outgrowth, to determine if the binding of plasminogen activator to this protein alters its affinity for the ECM, to identify the component(s) of the ECM to which it binds, and to produce immunological probes to the 50 kDa protein.

Supported by a fellowship from the MDA to RP and grants from the McKnight Foundation and NIH (NS 20917) to Paul Patterson.

221.5 DEVELOPMENTAL REGULATION OF A GROWTH CONE MEMBRANE PROTEIN, GAP-43, IN RAT CNS. R. D. Jacobson and J. H. P. Skene, Dept. of Neurobiology, Stanford University, Stanford, CA 94305.

Axonal growth in several types of neurons has been shown to be associated with increased synthesis of a few neuronal proteins which are transported rapidly into axons (Skene and Willard, J. Cell Biol. 89: 86, '81; Benowitz et al., J. Neurosci. 3: 300, '81; Skene and Kalil, Neurosci. Abstr. 10: 1030, '84). To determine whether synthesis of similar growth-associated proteins is a general characteristic of developing CNS neurons, we have studied one growth-associated protein, GAP-43, in developing and adult rat brain. Rat CNS proteins were radiolabelled in vivo by intracerebral injection of $^{35}$S-methionine, cerebral cortex and cerebellum were removed and homogenized, and 100,000g particulate fractions were subjected to 2D gel electrophoresis. Proteins were visualized by Coomassie Blue staining, to measure steady-state abundance, and fluorography, to measure rate of synthesis.

A heavily labeled protein from both cortex and cerebellum of neonatal rats co-migrates on two-dimensional gels with GAP-43 from regenerating toad optic nerves. This rat "GAP-43" has a pI of approximately 4.6 and an apparent molecular weight of about 47K on 12% polyacrylamide gels. The apparent molecular weight of both the toad and rat proteins decreases with increasing acrylamide concentrations, suggesting atypical SDS binding, or unusual shape, or both. Both synthesis and abundance of GAP-43 remain high during the first two postnatal weeks, then decline over the next six weeks to trace, but still detectable, levels in adults. In vitro translations of cortex poly-$A^+$ RNA from neonatal animals yields a protein with a similar pI, and apparent molecular weights changing with gel concentrations, as GAP-43. Labeling of this protein is much higher after translation of neonatal cortex RNA than after translation of a similar amount of RNA from adult cortex, indicating that much of the developmental regulation of GAP-43 synthesis occurs through specific changes in GAP-43 mRNA.

To confirm that GAP-43 in the rat CNS is neuronal and axonally transported, we prepared purified growth cones from neonatal and fetal rats (Pfenninger, et al., Cell 35: 375, '83). GAP-43 was highly enriched in a growth cone membrane fraction, compared with whole brain homogenates. Similarly, the small amount of GAP-43 in adult brains was enriched in synaptosomal membrane preparations. Growth cone membranes contain an order of magnitude more GAP-43 than adult synaptosomal membranes, supporting the hypothesis that the protein plays a role in axon elongation. However, the presence of significant amounts of GAP-43 in adult synaptic terminals suggests an additional function.

Supported by NIH grant NS20178, an NRSA fellowship to RDJ, and a Sloan Foundation fellowship and Searle Scholars award to JHPS.

221.6 EXPRESSION OF pp60-src PROTO-ONCOGENE IN DEVELOPING RAT AND REGENERATING FISH CENTRAL NERVOUS SYSTEM. J. G. Steedman* and G. E. Landreth (SPON: D. Cotanche). Departments of Anatomy and Neurology, Medical University of South Carolina, Charleston, SC 29425.

The proto-oncogene, pp60-c-src, whose retroviral homolog is the transforming factor of Rous sarcoma virus, is expressed at high levels in the vertebrate nervous system. Using a monoclonal antibody to the viral oncogene, we have investigated the expression of pp60-src in the embryonic rat brain and in the regenerating optic nerve of goldfish by assaying for tyrosine kinase activity of immunoprecipitated protein, by Western blot analysis of $I^{125}$-labelled immune complex, and by immunohistochemical localization under the light microscope.

The activity of pp60-src in the developing rat brain rose from embryonic day 12 (E12) to a maximum at E16-17, thereafter dropped steadily through early postnatal life and was lowest in adult brain. Activity was found to be highest in forebrain relative to other areas. Immunohistochemical localization of pp60-src was in accord with these findings. At E16, pp60-src was preferentially localized in a band in presumptive cerebral cortex in the region of the newly forming cortical plate. Reaction product was located in processes of these actively migrating cells, and was not observed either in nuclei or subventricular or marginal zones. Earlier and later stages of development failed to show reaction product above background, suggesting that at present our methods may not be sensitive enough to localize pp60-src when expressed at lower levels.

In retinae of goldfish whose optic nerves were regenerating following optic nerve crush, identical methods showed elevated levels of pp60-src expression, rising to a peak of activity at 7-8 days.

In other cell types, pp60-src causes the appearance of cell-surface ruffles suggesting the induction of cytoskeletal reorganization by pp60-src. The extension of filopodia and neurites by newly differentiated or regenerating neurons is a feature of normal cell activity that involves such cytoskeletal reorganization. Our hypothesis is that the comparatively high levels of this proto-oncogene activity seen in the developing and regenerating nervous system reflect cell-surface mediated events associated with the elaboration of neuritic processes.

221.7 EFFECTS OF 12-O-TETRADECANOYLPHORBOL-13-ACETATE(TPA) ON AXONAL ELONGATION IN SENSORY GANGLIA - AN ELECTRON MICROSCOPIC STUDY. L. Hsu and E. Zycband*, Dept. of Anatomy, UMDNJ-School of Osteopathic Medicine, Piscataway, NJ 08854.

Previously we reported on the neurite-promoting effects of the phorbol ester tumor promoter 12-O-tetradecanoylphorbol-13-acetate (TPA) in chick sensory ganglia explants (Hsu et al, Cancer Res., 44:4607-4614, 1984). The addition of TPA to serum-less growth medium which did not contain Nerve Growth Factor enhanced the differentiation of ganglionic neurons promoting the development of the rough endoplasmic reticulum and Nissl substance. The Golgi complex within these neurons was greatly enlarged and a significant increase in cytoplasmic microtubules and neurofilaments was evident. At low (10 ng/ml) concentrations of TPA, the tumor promoter elicited the rapid outgrowth of long, radial neurites. Along the lengths of these axons numerous varicosities were encountered which were filled with vesicular and cytoskeletal components. These presumably were depots of membranous reserves occurring at sites of extension. Distally, growth cones and their motile filopodial regions were also prevalent. In contrast, explants maintained in control medium without TPA developed much fewer of these structures. With high (100 ng/ml) concentrations of TPA neurite outgrowth was very dense with the formation of thick but short fascicles. From the explant core, axons extended and merged to form short, compact bundles. The axons within such fascicles were distinctively wider than those found in control explants or explants treated with low concentrations of TPA. Microtubular bundles were the dominant components within these axons which were congested with a variety of vesicular profiles including many autophagic vacuoles. Growth cones or filopodial regions were conspicuously absent. In explants treated with high concentrations of TPA degenerative changes involving the formation of deep clefts in some of the neuronal soma and the appearance of dense matrix in certain axons were observed.

Our results suggest that alterations in axonal morphology by TPA was dose-dependent. At low concentrations, TPA promoted the development of membranous and motile structures associated with the elongation process. In contrast, as a result of the dense outgrowth of neurites produced by high concentrations of TPA, formation of thick fascicles led to the retraction of axons and the cessation of elongation.

This work was supported by the New Jersey State Commission on Cancer Research.

221.8 **A NOVEL ROLE FOR SEROTONIN AND OTHER NEUROTRANSMITTERS: THE CONTROL OF NEURITE OUTGROWTH.** S.B.Kater, P.G.Haydon, A.D.Murphy* and D.P.McCobb. Department of Biology, University of Iowa, Iowa City, IA 52242. *Department of Medical Physiology, University of Calgary, Calgary, Alberta, Canada T2N 4N1.

The characteristic morphology of individual neurons is a result of the combined actions of a variety of extrinsic signals upon the intrinsic properties of the individuals. Such extrinsic signals act to promote, guide and finally to halt neurite extension. Recently we have demonstrated in cell culture experiments that serotonin has the potential to act as an extrinsic regulatory agent of outgrowth cessation (Haydon et al, Science 226: 561, 1984; J. Neurosci. Res. 13: 135, 1985). This neurotransmitter selectively inhibits active neurite extension and growth cone motility of specific identified neurons of Helisoma. By acting locally at the growth cone, serotonin inhibits the outgrowth of neuron 19 while having no effect on neuron 5. However, since the environment that growth cones encounter in cell culture is clearly different from that in nerve trunks, for example, it is important to determine whether serotonin is capable of such an action within the nervous system in the presence of processes such as transmitter uptake and degradation. Accordingly, we placed the nervous system of Helisoma into organ culture where, following axotomy, neurons extend neurites at a reliably constant rate. Under such conditions the addition of serotonin to the bathing medium for the duration of culture (2 days) significantly and selectively reduced the extent of outgrowth attained by specific neurons as determined by the intracellular injection of Lucifer Yellow. In situ the extent of neuron 19's outgrowth was significantly reduced by the presence of serotonin, whereas the outgrowth of neuron 5 was unaffected. In addition, the outgrowth of the identified neuron C1 was assayed. Just as with neuron 19, the outgrowth of C1 was significantly inhibited by the presence of serotonin. Thus in situ serotonin selectively inhibits the outgrowth of specific identified neurons.

In preliminary experiments performed to assess the potential involvement of cyclic AMP in mediating serotonin's inhibitory effects on outgrowth, the action of the potent activator of adenylate cyclase, forskolin, was tested in cell and organ culture experiments. Forskolin mimicked the effect of serotonin on neuron 19, causing an inhibition of neurite outgrowth. Furthermore, forskolin3 caused an inhibition of neurite extension from neuron 5 despite the fact that this neuron was unresponsive to serotonin. This indicates that the extension of neurites from neuron 5 is capable of being inhibited, and suggests that neurotransmitters other than serotonin may have this action on neuron 5. Taken together our data point towards a role for neurotransmitters in regulating the formation of neural architecture in addition to acting in their classical role of synaptic transmission.

Supported by NIH grants NS18819, HD18577 and NS15350.

221.9 **DOPAMINE: AN ADDITIONAL REGULATOR OF NEURITE OUTGROWTH IN *HELISOMA*.** D.P. McCobb, P.G. Haydon, and S.B. Kater. Dept. of Biology, University of Iowa, Iowa City, IA 52242

Serotonin has striking inhibitory effects on regenerative neurite outgrowth from specific identified neurons of *Helisoma* buccal ganglia (Haydon et al, Science 226: 561, 1984, Haydon et al, J Neurosci Res 13: 135, 1985). Dopamine is endogenous to the buccal ganglia and, like serotonin, has been shown previously to elicit motor program activity. This study tests whether dopamine can also regulate neurite outgrowth of buccal ganglion neurons.

Identified buccal ganglion neurons were placed in isolated cell culture. The advance of individual growth cones over the substratum was monitored photographically for two hours before and after addition of neurotransmitters to the culture medium in bolus dose.

**Percentage of Growth Cones Inhibited by Serotonin and Dopamine**

| | 5-HT | DA |
|---|---|---|
| neuron 5 | 0 | 0 |
| neuron 19 | 93.3 | 76.5 |
| neuron P5 | 100 | 0 |

Growth cones of neuron 19 initially respond to dopamine and serotonin similarly. The above data for DA are at 50 µM; at 1 µM DA inhibited 60% of neuron 19's growth cones. The inhibition is accompanied by morphological changes at the growth cone, often including a sharp reduction in filopodial number. Individual growth cones on a single neuron 19 may exhibit different responses to DA; most may stop while some are apparently unaffected. Thus sensitivity to the agent differs locally on a neuron. Unlike neuron 19 growth cones in the presence of serotonin, which are permanently inhibited, neuron 19's growth cones in dopamine may recover from the inhibitory effects. Even in the continual presence of 50 µM DA some neurons will resume outgrowth within 2 hours. This transient effect, as opposed to a long lasting inhibition, is very similar to the response of growth cones of neuron P5 to serotonin. As is true with synaptic transmission, the nature of a transmitter's action is governed by the target cell rather than the transmitter itself. The developmental roles of serotonin and dopamine may involve permanently shaping dendritic arbors, or, in the case of some specific neurons, they may serve as more dynamic and transient regulators of growth cone traffic during growth cone migrations.

The sets of neurons afffected by DA and 5-HT are distinct. Serotonin inhibits outgrowth of neuron 19, has no effect on neuron 5, and transiently inhibits the outgrowth of pedal ganglion neuron P5. Dopamine effects neuron 19 as described, has no effect on neuron 5, and clearly has no effect on neuron P5. The two transmitters may therefore play distinct regulatory roles.

221.10 ROLE OF SCHWANN CELLS AND THEIR EXTRACELLULAR MATRIX IN PROMOTING NEURITE GROWTH IN VITRO. M.D. Ard, R.P. Bunge and M.B. Bunge. Dept. Anat. & Neurobiol., Washington Univ. St. Louis, MO 63110.

The ability of Schwann cells to enhance the rate of growth of neurites has been tested in a tissue culture model of nerve regeneration. Implants were aggregates of fetal rat dorsal root ganglia (DRG) neurons (supporting cell free) which had been maintained in culture for 5-8 weeks. Recipients were model "injured nerves" created in vitro by growing a DRG explant on collagen for 4-6 weeks so that neurites of the extensive outgrowth were ensheathed and myelinated by Schwann cells. Then the explant was cut out, leaving the Schwann cells and their extracellular matrix (ECM) along with degenerating neurites in the culture dish. Three days later, the freshly axotomized implants were placed at the peripheral edge of the prepared outgrowth of Schwann cells and matrix. Regenerating neurites grew from the implant in all directions, some onto the prepared outgrowth and others onto bare collagen. Models of injured nerves were of four types: 1) organotypic nerves, in which DRG neurites were accompanied not only by ensheathing Schwann cells but also by fibroblasts (SC+ECM+FB); 2) Schwann cells ensheathing DRG neurites in the absence of fibroblasts but in the presence of culture medium adequate for formation of myelin, basal lamina and collagen fibrils (SC+ECM); 3) ECM remaining in cultures of type 2 after cells had been extracted with detergents (ECM only); and 4) Schwann cells ensheathing DRG neurites in incomplete culture medium which does not allow the formation of ECM or myelin by Schwann cells (SC only). At the end of 4 days of neurite regeneration, neurite lengths on the prepared outgrowth and on plain collagen were compared.

The results showed that Schwann cells with ECM, ECM alone, or Schwann cells without ECM promote neurite outgrowth. Using Wilcoxon's signed rank test at a significance level of 0.05, neurites growing among Schwann cells or Schwann cell ECM were shown to be longer than neurites growing on plain collagen. The median ratio of neurite length on prepared outgrowth to neurite length on bare collagen in each category was: 1) SC+ECM+FB, 1.8; 2) SC+ECM, 1.7; 3) ECM only, 1.6; and 4) SC only, 1.3. (In an additional experiment of type 2 (SC+ECM) in which transplantation was onto 1 day rather than 3 day prepared outgrowth, the median ratio of neurite length was 1.0.) Explants of embryonic rat cerebral cortex also showed significantly enhanced neurite growth on the prepared outgrowths. The neurite-promoting activity appears to be attached to cell surfaces and ECM rather than to diffuse throughout the culture medium. We conclude from this study that Schwann cell ECM alone is as effective in promoting outgrowth from peripheral and central neurons as is ECM accompanied by Schwann cells. (Supported by NIH grants NS 15070, NS 09923 and training grant 52252.)

221.11 RAT SCHWANNOMA NEURITE PROMOTING FACTOR IS A LAMININ-HEPARAN SULFATE PROTEOGLYCAN COMPLEX. G.E. Davis*, M. Manthorpe and S. Varon (Spon: J. Hatton). Dept. Biology, Sch. of Med., Univ. of Calif. San Diego, La Jolla, CA 92093.

Recent studies indicate that a substratum-binding neurite promoting factor produced by rat Schwannoma cells contains the extracellular matrix glycoprotein, laminin (Davis et al., J. Neurosci., in press) which itself has potent neurite promoting activity (Manthorpe et al., J. Cell Biol. 97: 1882-1890, 1983). However, it is evident that laminin is not the only extracellular matrix component present in the purified Schwannoma factor preparation. Several lines of evidence indicate that heparan sulfate proteoglycan is complexed with laminin in this factor. First, during its purification, a highly sulfated component, labelled with $^{35}SO_4$, copurifies with laminin antigens detected by ELISA. Second, nearly all of the sulfated material is degradable with nitrous acid suggesting that it is heparan sulfate. Third, the purified factor cross-reacts with antibodies directed against a basement membrane-derived heparan sulfate proteoglycan. The purified factor can also be distinguished from purified laminin due to its greater affinity for DE52 ion-exchange columns and greater buoyant density in cesium chloride gradients, both of which probably reflect the presence of proteoglycan.

Previous studies have indicated that purified laminin and heparan sulfate proteoglycan interact with one another primarily through ionically sensitive mechanisms (Fujiwara et al., Eur. J. Biochem. 143: 145-157, 1984). However, the Schwannoma factor complex may be held together by different (possibly hydrophobic or lectin-like) mechanisms since it is stable to very high salt (~2M CsCl) during cesium chloride gradients in 0.4M guanidine-HCl buffer. It is not clear whether this high affinity interaction is the result of a direct laminin-heparan sulfate proteoglycan interaction or through a "bridging" molecule which has high affinity for both components. By SDS-PAGE, two additional protein bands at approximately 150 and 35 kD are observed in the Schwannoma factor preparation. These currently unidentified protein bands may serve in such a "bridging" role. The 150 kD band might be related to the sulfated extracellular matrix protein, entactin (Carlin et al., J. Biol. Chem. 256: 5209-5214, 1981), which has a similar molecular weight and has also been found in association with laminin in different cell conditioned media. Since laminin appears to be the active neurite promoting protein in the Schwannoma factor complex, the additional components may be important for the proper binding and organization of biologically active laminin in vivo on cell surfaces and basement membranes.

221.12 OUTGROWTH OF EMBRYONIC RETINAL CELL AXONS IN XENOPUS IS PROMOTED BY A FACTOR, PROBABLY NOT LAMININ, ON THE SURFACE OF A GLIAL CELL LINE. W.A. Harris. Department of Biology, University of California, San Diego, La Jolla, CA 92093.

By maintaining for many generations cells that grow out of explanted or dissociated embryonic Xenopus retinas, we have been able to grow several morphologically distinct cell lines. One such line (XR1) is composed of a cell type which closely resembles one that in primary cultures provides a very attractive membrane surface for neurite outgrowth. The similarity is both morphological and immunohistochemical for both are large flattened cells which stain heavily for Glial Fibrillary Acidic Protein but not Vimentin. In primary cultures, retinal axons much prefer to adhere to and grow on the surface of these large flattened cells than on the collagen substrate. Naturally we wondered whether the XR1 cells maintained the ability to support neurite outgrowth. We found that retinal axons grow freely over a confluent layer of XR1 cells whereas they do not do so over a line of kidney epithelial cells(A6). Moreover,we found that XR1 cells lay a factor onto the collagen substrate which remains after the cells are removed from the surface by hypoosmotic shock. This factor strongly enhances neurite outgrowth. A6 cells do not contribute such a factor. It is perhaps a little surprising that we have not been able to recover this activity from medium conditioned by XR1 cells, which leads us to suspect that it is membrane bound or secreted only at attachment sites. We have some reason to conclude that the factor in question may not be laminin. While it is true that using antisera to human and mouse laminin XR1 cells stain heavily and leave laminin impressions on culture dishes, so do A6 cells. Laminin purified from both human and mouse sources when attached to our culture dishes failed to promote neurite outgrowth, while the same treated dishes were proven effective in promoting neurite outgrowth, while the same treated dishes were proven effective in promoting neurite outgrowth from other neuronal types from rat CNS. Antiserum to human laminin which effectively blocked the outgrowth of chick ciliary ganglion neurons grown on human laminin treated dishes had minimal inhibitory effects on the outgrowth of Xenopus retinal axons grown on XR1 cell conditioned surfaces. Finally, while it is clear that the pial surface of the embryonic central nervous system contains a basement membrane which stains heavily for laminin and that the pioneering retinal ganglion cell axons grow in proximity to this layer of extracellular matrix in the developing optic tract, it seems equally clear at the light microscopic level that the growth cones of many of these neurons are not in intimate association with this basement membrane and are probably not in contact with it. For these reasons we speculate that XR1cells are providing a neurite promoting factor which is either highly species specific laminin or not laminin, and furthermore that in the Xenopus embryo laminin is not essential to the oriented outgrowth of retinal ganglion cell axons. Support by NIH.

221.13 ISOLATED SPINAL CORD NEURONS DIFFERENTIATE AND GROW IN EARLY HYDRATED COLLAGEN LATTICE CULTURE. J.R. Cochran* and P.W. Coates. Department of Anatomy, Texas Tech University HSC School of Medicine, Lubbock, Texas 79430.

Dissociated neurons from day 10-11 chick embryo spinal cord were obtained by a combination of gentle mechanical disruption and trypsinization. Low density hydrated collagen lattices (HCL) were cast in 35 mm tissue culture dishes and conditioned with Medium 199 with 1% antibiotic-antimycotic and 10% fetal calf serum. Cells were plated at $10^5$ per ml per dish, and incubated in a humidified incubator at 37° C (95% air + 5% $CO_2$). At the end of each of 3 days, cultures were fixed for morphological and quantitative evaluation. Within 24 hr, at least some neurons exhibited one long process, interpreted as being an axon, and one or more shorter, tapered and sometimes branched processes interpreted as being dendrites. Phase contrast and light microscopy of Nissl and silver stained HCL revealed multipolar and other neurons with morphologically differentiated features. Only single neurons, i.e., not in contact with other cells or cell processes, and with at least one process longer than the cell diameter, were analyzed statistically. A minimum of ten neurons were measured on each day of the test period for eight different experiments using a Bioquant II Image Analyzer in combination with a phase contrast microscope. Results were compared using ANOVA with Newman-Keuhl's Multiple Range Test. The mean length of axons and dendrites alone and combined as total new growth per neuron, and the mean number of branch points, segments and terminals all increased from 50 to over 250 percent ($P \leq 0.05$) from day 1 to day 3. There was also a trend for the number of primary processes to increase over the test period. These observations extend previous work showing enhanced neurite outgrowth from spinal cord explants in HCL culture (Coates, Anat.Rec.208:33A,1984). The present data show that isolated spinal cord neurons differentiate and grow in early HCL culture. (Partial support from the APA and Tarbox Institute.)

221.14 A SYNTHETIC TETRAPEPTIDE INHIBITS DORSAL ROOT GANGLION CELL ADHESION TO ONE, BUT NOT ANOTHER, CELL BINDING REGION OF FIBRONECTIN. S.L. Rogers, P.C. Letourneau*, L.T. Furcht and J.B. McCarthy*. Dept. of Anatomy, Univ. of Minnesota, Minneapolis, MN 55455.

The adhesive extracellular matrix (ECM) glycoprotein fibronectin (FN) appears to be involved in neural crest cell migration and differentiation, and supports neurite extension by peripheral neurons in vitro. Mechanisms of cell interaction with ECM components like FN can be studied using proteolytic fragments of the molecule, with the aim of identifying the domains of fibronectin that mediate cell attachment and defining relevant cell surface receptors. A 75Kd "cell binding" region (Hayashi and Yamada, J. Biol. Chem.,258:3332,1983) and heparin binding region (Rogers et al., J. Neurosci.,5:369,1985) mediate cell type-specific activities, including neurite extension. We have used a synthetic tetrapeptide (Arginyl-Glycyl-Aspartyl-Serine; purchased from Peninsula Laboratories) representing the "cell binding determinant" of FN (Pierschbacher and Ruoslahti, Nature,309:30, 1984) in competitive inhibition assays to distinguish dorsal root ganglion (DRG) cell adhesion to this determinant from adhesion to the 33Kd heparin binding cell attachment fragment. Tissue culture wells were treated with FN (20 and 5 ug/ml), the 75Kd fragment (molar equivalents of 100 and 20 ug/ml FN), the 33Kd fragment (molar equivalents of 100 and 20 ug/ml FN), laminin (20 ug/ml) or polyornithine (100 ug/ml). Dissociated embryonic chick DRG cells were cultured on these substrata in serum-free medium for 1-3 hours in the presence and absence of tetrapeptide ($10^{-3}$ M). Nonadherent cells were then removed by rinsing, and attached cells fixed with glutaraldehyde and quantified with an Optomax image analyzer. In the presence of tetrapeptide, cell attachment to FN was reduced by up to 60% relative to controls, with the greatest effect at low concentrations of FN. Inhibition of attachment to the 75Kd fragment reached 80% at low levels of the substratum-bound fragment. In contrast, attachment to the 33Kd fragment was never reduced more than 20% by the tetrapeptide, and it had relatively little (laminin) or no (polyornithine) effect on attachment to the other substrata. These observations support our hypothesis that DRG cells can interact with the two cell binding regions of FN via distinct surface properties. We are now investigating the role of the cell binding tetrapeptide in neurite extension on FN.

221.15 PROMOTION OF ADHESION AND NEURITE OUTGROWTH FROM RETINAL AND TECTAL EXPLANTS BY SCHWANN CELL CONDITIONED MEDIUM. L.K. McLoon. Dept. of Opthal., Univ. of Minn., Minneapolis, MN 55455.

The role of non-neuronal cells in the guidance or promotion of axonal outgrowth is poorly understood. Recent work has indicated that central nervous system tissue (CNS) grown on various non-neuronal monolayers in vitro results in preferential outgrowth of the neurites on glial as compared to non-glial cells (Fallon, 1985; J. Cell Biol.). We have examined the ability of Schwann cell conditioned medium to promote adherence and neurite outgrowth from embryonic retinae and tecta in explant culture. Schwann cell conditioned medium (SCCM) was obtained from cultures of newborn dorsal root ganglia by standard procedures (Salzer et al., 1980; J. Cell Biol.). Retinae and tecta were dissected from rat pups on embryonic day 14 and placed in explant culture on a variety of substrates. Explants were cultured on tissue culture plastic, collagen and polylysine substrates in supplemented MEM. A second set of explant cultures were set up on the same three substrates and SCCM was added. The retinal and tectal explants were examined for adherence and neurite outgrowth at 1, 2 and 5 days in vitro. Neither the retinal nor the tectal explants adhered well to the plastic or collagen coated substrates. Both retina and tectum adhered well to polylysine coated dishes. Minimal or no neurite outgrowth was seen from the retinal explants grown on a polylysine substrate. As early as 1 day in culture tectal explants grown on polylysine substrates showed rapid extension of neurites, which tended to be heavily fasciculated. The addition of SCCM to retinal explants resulted in an increase in the adhesion of the explants, even on to plastic and collagen substrates. There was also a rapid extension of neurites from these retinae. Although the outgrowth was mainly radial, many crooked fascicles were also seen. Tectal explants, however, did not respond to the SCCM with increased neurite outgrowth, nor did they show increased adherence to previously unfavorable substrates.

Thus it appears that there is a factor in Schwann cell conditioned medium that has the ability to promote neurite outgrowth from embryonic retina in vitro. (Supported by NIH grant EY05432 and the Minnesota Medical Foundation.)

221.16 PROTEINS ASSOCIATED WITH GROWTH OF RAT HINDBRAIN NEURONS IN VITRO S. Finklestein, N.I. Perrone-Bizzozero and L.I. Benowitz. Departments of Neurology and Psychiatry, Massachusetts General Hospital; and Mailman Research Center, McLean Hospital, Belmont, MA 02178

Using conditions that were either permissive or inhibitory to neurite outgrowth, we examined the relationship between outgrowth and the expression of specific proteins in vitro. Freshly-dissected hindbrain from E17 rat embryos was mechanically dissociated and plated in Minimum Essential Medium (Eagle's; with added glucose, glutamine, vitamins, and gentamycin) onto poly-L-lysine coated culture dishes at a density of 3 X $10^6$ cells/ml. Cultures were incubated at 37°C in a 5% $CO_2$/humidified air atmosphere for 48h. They also received either: (a) 5% fetal calf serum/5% heat-inactivated horse serum, which allowed neurite outgrowth; (b) no serum, which allowed cell survival but no outgrowth; or (c) serum plus tunicamycin, which prevented protein N-glycosylation as well as neurite outgrowth. Tunicamycin was either present for the full 48h, or only for the last hour before labeling. Cultures were labeled with 40 uCi of $^{35}S$-methionine (1000 Ci/mmole) in methionine-free medium for 1 hour, and then incubated for an hour in an excess of non-radioactive methionine. Cells were homogenized, and the particulate fraction subjected to 2-dimensional gel electrophoresis and fluourography.

Cultures grown under the various conditions showed striking differences in neurite outgrowth, as well as in overall protein synthesis and the synthesis of specific molecular species. Of particular interest was a highly acidic 48,000 dalton (48 kD) protein that was synthesized heavily only under conditions of active neurite outgrowth (Table). The properties of this protein resemble those of a rapidly-transported glycoprotein that appears in the regenerating goldfish optic nerve (Perrone-Bizzozero and Benowitz, these abstracts), and may also be similar to the 43 kD protein described in association with axonal growth in other developing and regenerating neural systems (J.H.P. Skene, Cell 37 :697, 1985). Positive identification is now being undertaken using enzyme cleavage methods.

| Culture Conditions | Total Radioactivity in Particulate Protein Fraction (cpm) | 48 kD Acidic Protein |
|---|---|---|
| Serum alone | 2 X $10^6$ | +++ |
| No serum | 2 X $10^5$ | +/- |
| Serum + tunicamycin (48h) | 2 X $10^5$ | - |
| Serum + tunicamycin (1h) | 1 X $10^6$ | - |

Supported by the American Heart Association, the American Paralysis Association (RC 84-04), and NIH EY 05690.

221.17 NEURITE GROWTH FROM EARLY NEURAL TUBE EXPLANTS IN DEFINED AND SERUM-SUPPLEMENTED MEDIA. D.B.Wayne* and M.B.Heaton. Dep't. of Neuroscience, Univ. of Fla. Coll. of Med., Gainesville, FL 32610.

The trigeminal region of chick metencephalic neural tube was explanted into culture at stage 10-12 (40-45 hours). This early date preceeds most neuronal differentiation in that region. Culture at this time must support the continued differentiation of the neurons within the explant. This differentiation includes the initiation of neurites rather than the early regenerative events observed with tissue excised at later developmental times. The growth observed in defined supplements as opposed to serum-supplemented medium differed both quantitatively and qualitatively. The explants were plated on a combined collagen and polyornithine (coll/PORN) substratum. A basic medium of Ham's F-12 with glutamine, penicillin/streptomycin, and fungizone was supplemented with either 11 ml.of fetal calf serum or the following constituents: progesterone (20nM), putrescine (100$\mu$M), insulin (o.5 mg/100ml), transferrin (o.5 mg/100ml), sodium selenite (o.5$\mu$g/100ml), bovine serum albumin (50 mg/100ml) and a potassium concentration adjusted to 20 mM. Camera lucida drawings of the explants were made after 4, 8 and 12 days in culture. Neurite outgrowth was quantitated by counting the numbers of neurites which intersect concentric circles of an overlying template. Outgrowth is expressed as a percent of the total outgrowth possible, that is, relative to the maximum outgrowth demonstrated within that group. The defined medium groups consisitently demonstrated a greater percentage of outgrowth at each age. The averaged growth was at day 4 (n=16), serum=11.2%, defined=64.8%; at day 8 (n=16), serum=6.7%, defined=43.8%; and at day 12 (n=8), serum=6.9%, defined=44.3%. In both conditions, most neurite growth was confined to the mat of primarily non-neuronal cells which surround the explant core. The non-neuronal cells formed a denser and more closely packed cell mat in the serum-supplemented condition. Neurite growth cones extended off the cellular mat onto the coll/PORN substratum more frequently in the defined than in the serum-supplemented condition. In defined medium, those neurites which grew onto the exposed substratum extended further from the explant periphery than did those in serum-supplemented medium. In the defined medium employed, metencephalic explants show a healthy outgrowth of neurites, thus indicating that the differentiation of some brainstem neurons is not dependent on the presence of serum in culture and, in fact, may be hindered in some way by the presence of serum.

(Supported by NIH grant NS20387 to M.B.Heaton.)

221.18 AN ANTIBODY WHICH BLOCKS OUTGROWTH OF SUBPOPULATION OF NEURITES. M. Yamamoto, A.M. Boyer*, H. Tanaka and J.N. Wood*. Dept. of Biochem. & Neuropath., E.K. Shriver Ctr., Waltham, MA 02254.

Guidance of axonal outgrowth is an important problem to understand the highly organized neuronal connections between specific neuronal cell groups. A monoclonal antibody, 4D7, raised against embryonic rat forebrain, recognized polypeptide antigens which might play a role for proper axonal growth of subpopulation of neurons.

Immunocytochemical study with 4D7 was carried out on developing (E10-P14) and adult mouse brain. From E10-E17, the selective population of axons was labeled, which contrasted sharply with the staining of an anti-neurofilament antibody (C2). At E10, motoneurons and their axons were the only 4D7 immunoreactive population in entire nervous system. At this stage, however, C2 already showed many more groups of fibers, for example, neurites from the dorsal root ganglion (DRG). At E12-13, axons from DRG, trigeminal ganglion, motoneurons, VIIIth, VIIth, IInd cranial nerves, commisural fibers in the ventral part of the hindbrain, fasciculus retroflexus (FR), fibers running along the dorsal surface of the cerebellum were positive. At E14-15, staining was only seen in the cortex, FR and optic tract. In the cortex, 4D7 immunoreactivity is associated only with the intermediate zone (IZ). The staining in the IZ became thinner at E17 and at P0, only weak staining remained in cortical white matter. From P0-P14, the juxtaposition of the external granule cell layer and the molecular layer in the cerebellum was the only region which was immunoreactive with 4D7. In adult, no staining was observed.

The tissue culture prepared from E13-15 rat brainstem and grown in serum free medium, revealed the immunoreactivity on the plasma membrane of a subpopulation of neuronal processes. 4D7 positive cells were distinct from GFAP positive cells. Addition of 4D7 antibody (purified IgM, 20ug/2ml of media) in the same culture blocked neurite outgrowth of 4D7 immunoreactive cells. They showed only short stubby neurites. The other neurites which did not show 4D7 immunoreactivity showed no effect. Control cultures treated with another IgM anti-mouse antibody did not show any significant change on 4D7 positive neurites. This effect of 4D7 antibody was observed on cultures plated on various substrates (poly-L-lysine, fibronectin, collagen and laminin).

The 4D7 antibody recognized two immunoreactive protein bands (110kD & 140kD) by Western blot on homogenate of E15 mouse brain.

Thus, the 4D7 antigens, which are expressed on a subpopulation of developing axons in a short period of time might play a crucial role for axonal growth. Supported by NIH grant HDO-5515-15.

222.1 EFFECT OF DIFFERENT CARBOHYDRATES ON SYMPATHETIC ACTIVITY IN HEART AND INTERSCAPULAR BROWN ADIPOSE TISSUE (IBAT) OF THE RAT. M.C. Walgren , J.B. Young*and L. Landsberg*. Dept of Medicine, Beth Israel Hospital and Harvard Medical School, Boston, MA 02215.

Sucrose ingestion increases sympathetic nervous system (SNS) activity, an effect which may contribute to the thermogenic response to carbohydrate (CHO). Because different CHOs stimulate insulin secretion to a variable extent and insulin is a potential link between dietary CHO and SNS activation, the possibility that CHOs might differ in their potency as sympathetic stimulants was examined in the following studies. Norepinephrine turnover (NETR), a measure of SNS activity in tissues of experimental animals, was measured in rats (CD males, 150-175g, Charles River) fed a lab chow ration supplemented (to increase caloric intake by 50%) with corn starch (CS), sucrose (S) or fructose (F) for a 10 day period. These studies also contained a control group (Ch) which was fed a chow ration (8g/100g BW) equal to that given rats consuming the supplemented diets. Compared to Ch-fed rats, NETR in both heart and IBAT was increased in animals receiving supplemental CS or F. Small differences between isocaloric supplements of CS and S and between F and S in stimulating NETR in either heart or IBAT, though suggested in several experiments, were not consistently present. In one study, NETR in heart increased from 24.0ng/h in Ch to 33.1 in S ($p<.05$ vs Ch) and to 50.1 in CS ($p<.05$ vs Ch), and in IBAT NETR increased from 11.6ng/h in Ch to 17.4 in S ($p<.05$ vs Ch) and to 30.3 in CS ($p<.05$ vs Ch). F and S augmented cardiac NETR from 21.4ng/h to 46.9 ($p<.05$ vs Ch) and 55.6 ($p<.05$ vs Ch), respectively. In addition, the possibility that saccharin, which may slightly increase insulin secretion, might also stimulate NETR was examined. Five days of feeding a saccharin-supplemented chow diet (0.2% by wt, estimated to be comparable in sweetness to a 50% sucrose supplement) did not alter NETR in either heart or IBAT compared to that observed in Ch-fed rats (13.9ng/h in Ch, 13.5 with saccharin, $p>.05$). In summary, a) CHO-induced stimulation of SNS activity in heart and IBAT occurs in response to ingestion of CHOs other than sucrose and is not appreciably affected by the type of CHO consumed; and b) the sweet taste of CHO-containing food does not appear to influence the SNS response to CHO. These data indicate that if insulin is an important link between dietary CHO and SNS activity, then the SNS response to CHO is not sensitive to differences in insulin secretion observed following ingestion of various CHOs.

222.2 SYMPATHETIC AFFERENT AND PREGANGLIONIC NEURONS LABELLED BY HORSERADISH PEROXIDASE APPLIED TO THE HYPOGASTRIC NERVE AND THE SACRAL SYMPATHETIC CHAIN OF THE RAT. I. Nadelhaft and K.E. McKenna. VAMC and University of Pittsburgh Med. Sch., Depts. of Neurological Surgery and Pharmacology, Pittsburgh, PA 15240.

The major afferent and efferent innervation of the urinary bladder and other pelvic viscera comes, via the pelvic nerve, from neurons in the L6-S1 cord and dorsal root ganglia (DRG) [ Nadelhaft and Booth JCN 226, 238 (1984)]. The sympathetic innervation of these areas arises in the upper lumbar cord and the axons are located in the hypogastric nerve and the sympathetic chain. Horseradish peroxidase (HRP) was applied to either the cut hypogastric nerve (unilateral) or the sympathetic chain (bilateral, between the L6 and S1 sympathetic chain ganglia). Animals were sacrificed 2 days later and sections processed with tetramethylbenzidine as the chromagen for HRP. Hypogastric afferents were found bilaterally in smaller DRG neurons from T13 to L3 (90% in L1-L2). Doubling the numbers from the hypogastric experiment to compare with the results from the sympathetic chain experiment, resulted in an average of 200 sensory neurons. Sympathetic chain afferents were located in DRG from T11 to L2 (90% in T13-L2). A total of 200 neurons were found. By comparison, HRP applied to the pelvic nerves labelled an average of 3000 neurons in L5-S2 DRG (95% in L6-S1) and none were found elsewhere.

Hypogastric preganglionic neurons were located bilaterally in spinal cord segments L1-L3, with the majority (75%) in L2. Within the segments, the majority (70%) were found in the dorsal gray commissure and the remainder at the intermediolateral edges of the gray matter. Sympathetic chain preganglionic neurons were located in spinal cord segments T11 to L2 with the majority (78%) in L1-L2. Within the segments, the majority (90%) were found at the intermediolateral edges of the gray matter with the balance distributed in the intermediate gray and the dorsal gray commissure. There were no neurons found in the sympathetic cord when HRP was applied to either the pelvic or pudendal nerves.

In summary: 1) Sympathetic afferents innervate the pelvic viscera via two pathways: the hypogastric nerve and the sympathetic chain. There are approximately one sixth as many sympathetic afferents as there are parasympathetic afferents. 2) The spinal cord distribution of sympathetic preganglionic neurons sending axons into the hypogastric nerve is strikingly different from those sending axons into the sympathetic chain. The former are mainly located medially whereas the latter are located laterally. Perhaps this organizational difference is reflected in a functional difference (as yet undetermined).

222.3 EVIDENCE FOR LOCAL NEURAL MODULATION OF SYMPATHETIC INFLUENCES ON THE FELINE BLADDER. D.C. Rudy* and J.W. Downie. Depts. of Pharmacology and Urology, Dalhousie University, Halifax, Nova Scotia B3H 4H7

The bladder is sympathetically innervated by the hypogastric nerves and by the sympathetic chain via the pelvic nerves. Both of these sympathetic supplies produce a brief contraction (volume decrease) followed by a more prolonged dilation (volume increase) in the bladder. Our initial studies showed that the dilatory component of the response to sympathetic stimulation is enhanced as intravesical pressure (IVP) is increased and this relationship persists in decentralized bladder preparations. Herein we describe our studies of this phenomenon. In chloralose-anesthetized cats the bladder was decentralized by section of sacral spinal roots, both hypogastric nerves (HGN) and one sympathetic chain (SC). The IVP was controlled by a reservoir with large surface area via a bladder cannula. HGN and SC stimulation evoked similar contraction-dilation responses in the bladder although both phases were usually larger for HGN stimulation. Raising IVP from 5 to ≥10 cmH20 increased the proportion of cats showing the dilation component from 40% to 82% for HGN stimulation, and from 46% to 65% for SC stimulation. As well, the magnitude of the relaxation response was similarly increased in 62% with HGN stimulation and in 42% with SC stimulation. Effects of increasing IVP were more reliable in later experiments where IVP was increased to ≥20 cmH20. In a separate group of cats the dilation from sympathetic nerve stimulation was compared to that produced by a maximal dose (5 µg ia) of isoprenaline (IP). At 5 cmH20 (low IVP), IP produced a significantly greater bladder dilation than either HGN or SC stimulation. At 20-30 cmH20(high IVP), the IP-induced response was larger but the HGN now produced an equivalent response. The ratios of dilation responses at high vs. low IVP were IP=2, SC=7 and HGN=28. Assuming that IP acts on smooth muscle only, the ratio of >1 indicates that end organ factors can contribute to enhancement of responses at high IVP. However, the much larger ratios seen for the /mpathetic nerve-mediated dilations indicates that end organ factors are not sufficient to account for these changes. Furthermore, in several cats there was no dilatory response to sympathetic stimulation at low IVP despite a clear IP response. The equivalence of responses at high IVP for both HGN stimulation and IP rules out the argument that a difference in agonist concentration plays a role. We therefore conclude that the increased bladder distension produced by raising IVP in this preparation activates a local mechanism that modulates the sympathetic neural input to the bladder. This modulation is exerted mainly at a level other than the end organ and therefore is likely to be on the nerves themselves. The nature of the modulatory influence is unclear but may be a humoral substance (e.g. prostaglandin) or a "local reflex" arc. (M.R.C. and A.U.A. supported.)

222.4 EFFECTS OF OVARIAN HORMONES ON AUTONOMIC RESPONSE OF RAT'S URINARY BLADDER TO CARBACHOL. H. R. Amouzadeh* and S. Sangiah. Dept. of Physiol. Sci., Oklahoma State Univ., Coll. of Vet. Med., Stillwater, OK 74078

Estrogen and progestrone have been extensively investigated for their role in modulating the mechanical activities of various smooth muscles. It has been shown that estrogen potentiates the in vitro autonomic response of rabbit's urinary bladder and guinea pig's gallbladder. Progestrone, however, has been shown to have an inhibitory effect on guinea pig's gallbladder. Adult male albino Sprague-Dawley rats weighing between 350 to 500g were divided into three groups. Group one (n=15) received subcutaneous (SC) injection of peanut oil for 6 to 9 days. Group two (n=10) and group three (n=6) were treated with SC injection of 17-β-estradiol (400 µg/kg) and progestrone (2mg/kg) in peanut oil for 9 and 6 days respectively. Detrusor muscle strips of uniform size (6mm x 2mm) from the bladder of each rat were cut under light anesthesia and suspended in isolated organ bath (20 ml). The contractile response of these strips to various doses of carbachol (0.5-100 µM) were recorded using a physiograph. 17-β-estradiol treatment shifted the dose response curve to the left while progestrone treatment shifted it to the right. These results are consistent with the previous reports and demonstrate the modulatory effect of ovarian hormones on contractile response of rat's urinary bladder. Mechanism(s) of these effects are currently being investigated.

222.5 **TRACER DIFFUSION FROM INJECTION SITES DISTORTS ORGAN INNERVATION MAPS: LIMITING DIFFUSION PREVENTS LABELING OF VAGAL PREGANGLIONIC NEURONS AFTER TRUE BLUE INJECTIONS IN THE PANCREAS** E.A. Fox* and T.L. Powley. Lab. of Regulatory Psychobiology, Purdue Univ., West Lafayette, IN 47907.

Although visceral mapping studies have typically provided minimal or no controls for tracer leakage, diffusion from injection sites is probable on the basis of several published observations: 1) the serosal and mesenteric membranes which surround the viscera are permeable to HRP and other small molecules, 2) IP injections of HRP and True Blue (TB) result in significant labeling of dorsal motor nucleus of the vagus (DMN) neurons, 3) physical isolation of an HRP-injected organ can decrease the DMN cell label as well as prevent spinal cord label, and 4) nerve soaks with tracers generally result in greater localization and fewer labeled cells than organ injections. Such observations suggest that viscerotopic maps based on tracer injections may be distorted or exaggerated because of spread of tracer and subsequent uptake by terminals in other tissues. In the present experiment, the effects of a diffusion barrier on the pattern of cell labeling after tracer injections in the pancreas were examined.

Male Sprague Dawley rats received two 7.5µl injections of 10% TB in the splenic lobe of the pancreas (n=4). These TB injections labeled cells in the DMN, nucleus ambiguus (NA), and celiac ganglia (CG), replicating the results of earlier experiments. In other groups of animals receiving the same TB injection, a barrier formed from a plastic wound spray (pyroxylin solution, New Skin) was applied to the surfaces of either the stomach and adjacent intestines (n=4) or the splenic pancreas (n=8). Just prior to sacrifice (72-73h after TB injections), 6 of the latter rats and an additional 5 control animals (TB alone) were tested for insulin secretion in response to right (RCV) and then bilateral (BCV) cervical vagus stimulation. Placing the barrier either on the viscera adjacent to the pancreas or on the pancreas itself prevented virtually all labeling of DMN and NA cells and reduced the labeled CG cells by 50-70%. RCV and BCV stimulation produced comparable increases in insulin secretion in animals with and without the barrier.

The combined observations of normal insulin secretion and intact labeling of many CG cells after barrier application indicates that the innervation of the pancreas was still functional and suggests that the barrier did not reduce cell labeling by neurotoxic effects. Thus, the failure to label vagal preganglionics when tracer diffusion from the pancreas injection site was limited suggests that the number of DMN parasympathetic preganglionics innervating the pancreas may have been significantly overestimated in previous tracer experiments. Further, diffusion may complicate the interpretations of cell labeling after injections in other viscera. (USPHS grant AM27627 and David Ross Fellowship)

222.6 DISTRIBUTION AND ORIGIN OF CALCITONIN-GENE RELATED PEPTIDE IMMUNOREACTIVE FIBERS INNERVATING THE PANCREAS IN THE RAT. C.Sternini, K.Anderson* and N.Brecha. Center for Ulcer Research and Education and UCLA School of Medicine, VA Medical Center Wadsworth, LA, CA 90073.

Calcitonin-gene related peptide immunoreactivity (CGRP-I) has been reported in the nervous and endocrine systems. Using new CGRP antisera raised in rabbits against [Tyr]-rat CGRP(23-37) coupled to keyhole limpet hemocyanin via glutaraldehyde we studied the distribution of CGRP-I in the rat pancreas and the possible origin of the CGRP immunoreactive fibers innervating this organ. Normal, capsaicin- and 6-hydroxydopamine (6-OHDA)- treated and vagally denervated rats were perfused with a paraformaldehyde solution. In some rats the fluorescent retrograde tracer Fast Blue (FB) was injected into the pancreas, placed on the pancreatic surface or dropped into the abdominal cavity. Pancreata and the structures which are presumed to give rise to the fibers innervating the pancreas were removed and sectioned. Tissue sections were processed by the indirect immunofluorescence technique. Specificity was determined by incubating sections with preimmune serum or primary antiserum preabsorbed with 10uM rat CGRP. In the exocrine pancreas CGRP-I is localized to varicose processes distributed among the acini, in the intralobular and interlobular connective tissue and to the duct system as well as to scattered cells disseminated among the acini. In the endocrine pancreas thin immunoreactive processes are present around and throughout the islets and single or clustered labeled cells are distributed mainly at the periphery of the islets. Particularly numerous fibers are associated with blood vessels. In rats treated neonatally with the small diameter sensory neurotoxin capsaicin there was a marked reduction or a complete elimination of CGRP immmunoreactive fibers innervating the pancreas and blood vessels. Treatment with the sympathetic neurotoxin 6-OHDA and subdiaphragmatic vagotomy did not affect the immunoreactive staining. CGRP containing cell bodies are colocalized with most of the FB labeled cells in the dorsal root ganglia, but only with few FB positive cells in the nodose ganglia. No CGRP positive cells were observed in the coeliac ganglion. In the brainstem some somata of the rostral part the nucleus ambiguus contain both FB and CGRP-I. These results demonstrate that 1)CGRP-I in the pancreas is localized to endocrine-/paracrine-like cells and to nerve fibers, 2)CGRP immunoreactive fibers originate from extrinsic sensory sources and 3)CGRP containing neurons which give rise to fibers innervating subdiaphragmatic viscera are mainly located in spinal dorsal root ganglia. These observations suggest that CGRP may have both an endocrine and neurotransmitter role in the control of pancreatic functions.

222.7 HISTOCHEMICAL EVALUATION OF THE ACTIVITY OF SINGLE ENTERIC NEURONS: VERIFICATION OF THE CYTOCHROME OXIDASE TECHNIQUE. G.M. Mawe and M.D. Gershon. Anatomy and Cell Biology, Columbia University, Coll. of P&S, New York, NY 10032.

Wong-Riley and others have established that the histochemical activity of the mitochondrial enzyme, cytochrome oxidase (C.O.), reflects the metabolic activity of CNS neurons. Experiments were done to determine whether the C.O. activity of enteric neurons could be acutely influenced by pharmacologically opening and closing voltage-dependent $Na^+$ channels in vitro, a finding that would indicate that the technique reflects neuronal metabolism in gut as well as brain. Dissected preparations of guinea pig myenteric plexus were incubated in oxygenated krebs solution ($37^{o}$) for 8 hours. Experimental groups contained veratridine (0.1uM - 0.1mM), tetrodotoxin (TTX; 0.5uM) and veratridine + TTX. C.O. activity was demonstrated by incubating formaldehyde (4%)-fixed tissue with cytochrome C (0.3g/l) and diaminobenzidine (0.5g/l) for 1 hour. Intensity of C.O. activity was evaluated by counting numbers of active cells/ganglion area and by densitometrically measuring light transmission through the C.O. reaction product. In control preparations, there were 100±3 neurons/ganglion, of which 48±3 neurons/ganglion showed significant C.O. reaction product. This indicates that C.O. activity is not uniform among enteric neurons. The numbers of C.O.-active cells per unit of ganglionic area, and the density of reaction product within labelled neurons, was increased significantly by veratridine at all concentrations examined ($p<0.001$), however, values for tissue treated with TTX or veratridine + TTX were not significantly different from the controls. Intracellular electrophysiological experiments indicated that at 1uM veratridine caused myenteric neurons to fire intermitent bursts of spontaneous action potentials but to maintain their resting potential. Higher concentrations of veratridine (>5uM) caused membrane depolarization and prevent neuronal discharge. The degree of depolarization was concentration-dependent. Maximal stimulation of histochemically determined C.O. activity by veratridine occurred at 1.0um. Less stimulation was seen at 5uM but C.O. activity thereupon increased again as the concentration of veratridine was raised (to 0.1mM). These data indicate that C.O. activity probably does provide a histochemical reflection of the metabolic activity of myenteric neurons. It is likely that the initial intense stimulation of C.O. activity at a low concentration of veratridine is due to repetitive discharge of action potentials. The later activation of the enzyme may be related to attempts by depolarized neurons to pump out $Na^+$ that veratridine caused to accumulate in the cells. The C.O. histochemical technique should thus be very useful in identifying which enteric neurons are active in the control of intestinal activity. Supported by grants NS12969 and NS07062.

222.8 **AN EM ANALYSIS OF THE FIBER COMPOSITION OF THE HEPATIC BRANCH OF THE VAGUS.** J.C. Prechtl* and T.L. Powley, (SPON: W. Pak) Lab. of Regulatory Psychobiology, Purdue University, West Lafayette IN 47907.

The hepatic branch of the abdominal vagus has been the subject of an extensive series of physiological analyses. Although this research is complemented by LM descriptions of the nerve (e.g. Prechtl & Powley, JCN, in press: rat; Kemp, Aust. N. Z. J. Surg., 1973: dog), an EM analysis of its fiber content is lacking and its projection through the lesser omentum has not been fully described. We have done an analysis of the fine structure of the hepatic branch in several animals taken from a larger series prepared for an ultrastructural characterization of the abdominal vagus.

The abdominal vagi of six adult male Sprague Dawley rats (Hormone Assay, Chicago) were prepared for electron microscopy. From each specimen a complete montage (X10,000) of the hepatic was assembled and all the fibers were counted. To photograph the hepatic branch as a coherent bundle we sampled it immediately (<130 µ) after it separated from the anterior vagus (n=5); one sample was taken slightly more distally. For LM analysis, we also took broad cross-sections of the hepatic branch within the lesser omentum approximately halfway between the esophagus and hepatic artery, at a site where the nerve is often surgically and/or electrophysiologically manipulated. Supplementary data on the branching patterns were also obtained from osmicated whole mounts.

The hepatic branch contained 2887±287 unmyelinated fibers and relatively few (21±4) myelinated fibers. However, half (54±5%) of these myelinated fibers were clustered together. Converging evidence from whole mounts and the montages indicate that these myelinated fibers formed a subpopulation that was already segregated on the medial side of the anterior vagus, initially remained aggregated in the medial side of the hepatic branch, and then formed a coherent small fascicle which separated from the hepatic early in its course. Soon after the hepatic branch began its rostromedial trajectory in the lesser omentum parallel with the hepato-esophageal artery, it contained an endoneurial paraganglion (cf. also Prechtl and Powley, in press). The EM specimen in this series was not unlike paraganglia which have been reported in other autonomic nerves; it was well vascularized and contained numerous cells with dense-cored vesicles. Further distally, the hepatic branch formed a plexus of 3-6 bundles which subsequently recombined to form 3 or 4 major bundles (40-80 µ in diameter). Also conspicuous at this segment were 2-3 small fascicles (<20 µ in diameter). In addition to the hepato-esophageal artery and vein accompanying the hepatic bundles, a lymphatic vessel was also a regular feature. The volume of the lymphatic was greater than that of the vein and artery combined.

222.9 **DIFFERENT FREQUENCY- AND TEMPORAL-RESPONSE PROFILES FOR ENDOCRINE PANCREATIC HORMONES, GASTRIC ACID, AND CARDIOVASCULAR PARAMETERS USING CERVICAL VAGAL STIMULATION IN THE ANESTHETIZED RAT.** H.R. Berthoud and T.L. Powley, Lab. of Regulatory Psychobiology, Purdue University, West Lafayette IN 47907.

The viscerotopic and functional organization of the vagal preganglionic motor neurons is not well defined. Since previous research has demonstrated that efferents innervating the abdomen include subpopulations with different soma sizes and different axon diameters and, further,since it is well established that cardiovascular preganglionics consist predominantly of large neurons with B-fiber processes, we examined the possibility that different functional pools of vagal efferents to the abdomen might have different physiological properties. The experiment determined the frequency-response and the temporal-response profiles of one gastric (acid secretion), two pancreatic (insulin and glucagon secretion) and two cardiovascular (mean arterial blood pressure and heart rate) responses.

Either the right or left peripheral end of the cut cervical vagus was stimulated with constant intensity (1mA) and pulse duration (1msec), and variable frequency (pps) or train duration in 12 h food-deprived, urethane/chloralose anesthetized, adult male Sprague Dawley rats. Potential sympathetic responses resulting from surgical trauma, anesthesia or stimulation were suppressed by continuous infusion with α- and β-blockers. Blood was sampled continuously using a method of simultaneous transfusion of whole donor blood. Gastric acid was measured on-line with a continuous gastric irrigation procedure.

Stimulation with 10 min trains of 1,2,4,8 and 16 pps resulted in 3 distinct response profiles: Gastric acid output was half-maximal at below 1 pps, a frequency at which both of the pancreatic responses and both of the cardiovascular responses were less than 10% of their maximal values, and peaked at 2 - 4 pps. Plasma insulin and glucagon responses were half-maximal at 3 - 4 pps, and the cardiovascular responses reached half-maximal at well above 8 pps. These characteristic response profiles were similar for both right and left cervical vagal stimulation. Prolonged stimulation at 4pps for 60 min produced distinctly different temporal response profiles as well. In addition to confirming the accepted view that vagal motor units supplying the heart are fast-conducting large-caliber fibers, the present data suggest the possibility that gastric and pancreatic efferents in the rat consist of two different classes of neurons, a pool with predominantly fine C-fibers innervating the gastric parietal cells and a pool with somewhat larger C-fibers innervating the endocrine pancreas.

Supported by NIH Grants AM 27627 and AM 20542.

222.10 AFFERENTS TO THE NUCLEUS TRACTUS SOLITARIUS-DORSAL MOTOR NUCLEUS OF THE VAGUS IN THE PIGEON. M.L. BERK. Dept. of Anatomy, Marshall Univ. Sch. of Med., Huntington, WV 25704.

The nucleus tractus solitarius(NTS) and the dorsal motor nucleus of the vagus(DMN) of the pigeon are composed of cytoarchitectonically distinct subnuclei, which have organ specific connections (Katz and Karten, '83). This study represents the initial phase of a project to determine the central neural connections of NTS-DMN which could modulate the functions of specific organs. Afferents to NTS-DMN were determined by stereotaxically placed iontophoretic injections of either 25% horseradish peroxidase or 2% wheat germ agglutinin-horseradish peroxidase(WGA-HRP) into various rostral-caudal levels of the dorsomedial medulla. After a two day survival, the pigeons were perfused, brains sectioned, and tissue reacted with tetramethylbenzidine.

Retrogradely labeled perikarya were found in the forebrain at the following four loci: 1) many labeled soma adjacent to the ventrolateral border of the lateral ventricle of the ipsilateral telencephalon (stereotaxic level A10 to A7.25; labeled cell group bordered by n. accumbens), 2) numerous labeled cells in n. periventricularis magnocellularis (PVM) of the hypothalamus (bilateral representation), 3) a well-defined group of large, multipolar neurons in the stratum cellulare externum (SCE) of the lateral hypothalamus (stereotaxic level A6.00; unilateral representation), and 4) a few labeled parvocellular neurons in the medial preoptic area. The telencephalic cell group may be comparable to the mammalian bed nucleus of the stria terminalis. In the brainstem, contralateral NTS soma are retrogradely labeled. Additional brainstem input to NTS-DMN requires further study.

The specific subnuclei of NTS-DMN that are innervated by PVM of the hypothalamus have been previously demonstrated (Berk and Finkelstein, '83). In the present study, the projection of SCE neurons of the lateral hypothalamus to NTS-DMN subnuclei were investigated by anterograde transport techniques. Projections were observed to particular NTS subnuclei which include medialis superficialis, lateralis dorsalis, and medialis ventralis. Labeled fibers only project to the DMN subnucleus ventralis parvocellularis. The pattern of SCE innervation of NTS-DMN subnuclei is similar to PVM input except SCE fibers are fewer in number. The peripheral visceral connections of these NTS-DMN subnuclei (Katz and Karten, '83) suggest that the hypothalamus could modulate the functions of abdominal viscera as well as information from the aortic nerve.

In conclusion, medial and lateral hypothalamus and a telencephalic cell group have major inputs to NTS-DMN. The specific NTS-DMN subnuclei innervated by the telencephalic cell group awaits investigation. (Supported by the NIH Grant NS20512 and a grant from AHA, W.Va. affiliate)

222.11 **A QUANTITATIVE ASSESSMENT OF THE ROLE OF THE DORSAL MOTOR NUCLEUS OF THE VAGUS IN CONTROLLING GASTRIC ACID SECRETION.** W.B. Laughton* and T.L. Powley (Spon: G. S. Wasserman). Lab. of Regulatory Psychobiology, Purdue University, West Lafayette IN 47907.

Anatomical studies have implicated the dorsal motor nucleus of the vagus (DMV) as an important source of vagal preganglionic fibers to the abdomen (e.g. Kalia & Mesulam JCN,193:467; 1980). Data from physiological experiments have indicated that vagally mediated responses can be activated by stimulation of the dorsal medulla, however, these largely qualitative studies do not provide independent evidence that the DMV per se is the anatomical substrate effectively being stimulated in these studies, nor do they allow any inferences to be drawn concerning possible localization of function within the DMV.

Male Sprague-Dawley rats bearing pre-implanted gastric fistulae were food deprived overnight, anesthetized, and equipped with arterial and venous catheters. α- and β-blockers were administered. Semi-microelectrodes were introduced into the brainstem, and electrical stimulation (50μA, 50Hz, 1msec, 10 min) was carried out, with concomitant on-line monitoring of gastric acid secretion. Two-hundred and five electrode sites in 147 animals were located throughout the medulla. Sites located within the DMV and extending throughout its rostrocaudal extent yielded the strongest responses. Consistent with this conclusion, a "centroid" for activation of gastric acid was calculated by weighting each electrode placement proportionately to the magnitude of the gastric acid response resulting from its stimulation. These values were then entered into center-of-mass equations, allowing calculation of a weighted mean electrode location. This site was within the DMV, at approximately the mid rostro-caudal extent of the nucleus (i.e. AP level 6.52, 0.68mm lateral on Palkovits and Jacobowits (1974) atlas). That sites effective in eliciting gastric acid secretion did in fact tend to cluster around this derived centroid point was indicated by a significant negative correlation (r=-0.38, p<.001) between a)the magnitude of the acid response and b)the distance between the centroid point and the electrode location, and by the regression equation: A=19.1-8.3*D (A=acid response; D=distance), indicating that points farther from the centroid (in three dimensional space) were less effective than more proximal points. The magnitude of the acid response fell off less sharply as electrode location varied in the rostrocaudal dimension than in the coronal plane, consistent with the columnar shape of the nucleus.

No evidence was found for a differential representation of gastric secretomotor fibers along the rostrocaudal extent of the DMV as had been implied by some anatomical data, nor was there evidence for a left-right assymetry of function.

222.12 BRAINSTEM NEURONAL RESPONSE TO AUTONOMIC MECHANISMS GOVERNING GASTRIC WALL TENSION. W.D. Barber and T.E. Burks, Departments of Anatomy and Pharmacology, College of Medicine, University of Arizona, Tucson, Arizona 85724.

This study has characterized a novel population of neurons in the solitary system (nucleus and tractus solitarius) in the brainstem of the cat which responded to moment-to-moment changes in gastric activity. The response of these neurons has provided further insight into central autonomic mechanisms which regulate visceral activity in this region of the medulla oblongata. Electrophysiological studies by others have reported that vagal fibers convey information from "in-series" receptors in the gastric wall which respond to both passive distention and active contraction of the stomach. Our study has shown that neurons in the solitary region, which responded to changes in gastric wall tension, had thresholds ranging from nondistended levels of intragastric pressure up to 10 cm of water. The local gastric intraarterial injection of substances which altered wall tension was accompanied by changes in the activity of these units. The relationship of unit activity and gastric wall tension was evaluated before and after the local intraarterial administration of atropine (10 ug/kg) at levels of intragastric pressure ranging from nondistended levels to 15 cm of water. Following atropine there was a decrease in unit discharge rate ranging from 32.08% ± 5.78 to 34.76% ± 9.17 when compared to pretrial values at the same level of intragastric pressure. This suggests that the discharge of these brainstem units reflects an unloading of the "in-series" receptors in the stomach wall due to the action of atropine upon the neuroeffector junction. The functional significance of this response suggests that it may play a role in receptive relaxation of the stomach during intake of food or drink to accommodate the ingested volume. In addition, unit activity related to the cardiovascular and respiratory systems was commonly observed in the subnuclei of the solitary system where these gastric responses were recorded. The neuronal connections and interactions among cell populations residing in the solitary complex suggests that this region may be an important site in the integration of peripheral and central influences which mold and shape visceral activity. (Supported by USPHS Grant AM31804)

222.13 INFLUENCE OF PERIPHERAL VS. CENTRAL (NUCLEUS TRACTUS SOLITARIUS) BOMBESIN ON GASTRIC PRESSURE IN THE RAT. S.E. Spencer, W.T. Talman. Lab. of Neurobiology, Univ. of Iowa and Vets. Admin. Med. Center, Iowa City, IA 52242.

Microinjections of the tetradecapeptide, bombesin (BOM), into the nucleus tractus solitarius (NTS) increases gastric tone. Tonic gastric pressure also increases when BOM is delivered intravenously (i.v.). We have, therefore, sought to determine if BOM acts both centrally and peripherally to modulate gastric pressures (GP). Thirty adult male rats were anesthetized with alpha-chloralose and instrumented for recording intra-arterial pressure, GP, and for the delivery of i.v. drugs. Each rat was placed in a stereotaxic frame, paralyzed, and ventilated via a tracheostomy tube. The dorsal surface of the brain stem was exposed and microinjections (25 nl) of BOM or saline vehicle were made through glass micropipettes stereotaxically placed into the dorsomedial NTS. Injection sites were marked with pontamine blue and confirmed histologically. In some experiments the spinal cord was transected at C1 and the vagi were transected bilaterally in the neck. BOM was delivered i.v. in 0.1 ml saline followed by a 0.1 ml heparinized saline flush. Alterations in tonic and phasic GP were statistically analyzed and expressed as mean ± standard error of the mean. BOM, but not vehicle, microinjected into the NTS or given i.v. elicited dose dependent increases in tonic GP. The central, but not peripheral, injection of BOM significantly increased the amplitude of phasic gastric waves. With injections into the NTS, the threshold dose for changing phasic GP was 7.8 fmoles, while the threshold dose for changing tonic GP was 7.8 pmoles. In contrast, tonic, but not phasic, GP increased after the i.v. injection of 7.8 pmoles of BOM. Higher doses of i.v. BOM did produce phasic and tonic GP changes. Doses of 7.8 pmoles in the NTS increased tonic GP by 0.5 ± 0.1 cm $H_2O$ and produced a maximal increase in the number of giant phasic waves greater than three times the mean phasic wave amplitude, from 0.7 ± 0.2 to 10.3 ± 2.8 per 5 minute period (n=4). A 7.8 pmoles dose of i.v. BOM did not change the number of phasic giant waves but increased tonic GP by 1.0 ± 0.2 cm $H_2O$ (n=4). Spinal cord transection and bilateral cervical vagotomy blocked tonic and phasic gastric changes following any dose of BOM injected into the NTS; however, GP responses after doses of 7.8 pmoles of i.v. BOM were not blocked. These data suggest that BOM may act both centrally (NTS) and peripherally to modulate tonic GP. BOM may modulate phasic gastric activity primarily through mechanisms in the NTS.

222.14 PREGANGLIONIC PARASYMPATHETIC NEURON PROJECTIONS FROM THE DORSAL MOTOR NUCLEUS OF THE VAGUS TO THE STOMACH AND SMALL INTESTINE IN CAT AND RABBIT. Y. Torigoe*, D.G. Lontok*, F.A. Magarro*, R.D. Cernucan*, J.S. Nishimoto* and R.H.I. Blanks. Depts. of Anatomy and Surgery, Coll. of Med., Univ. of Calif. Irvine, Irvine, CA 92717.

Motion sickness, a multisymptom disorder characterized by abnormal gastrointestinal motility and emesis is, in part, induced by vestibular effects upon the parasympathetic outflow of the gut. The location of preganglionic parasympathetic neurons projecting to the abdominal viscera was examined using the technique of retrograde transport of horseradish peroxidase (HRP). HRP was injected into, or exposed to: 1) the sub-diaphragmatic part of the anterior vagus nerve; 2) the stomach, and 3) portions of the small intestine (duodenum, jejunum, and ileum). The vast majority (97%) of the preganglionic parasympathetic neurons from the vagus nerve are located within the dorsal motor nucleus of the vagus (DMV). The remainder are found in the nucleus of the tractus solitarius, the nucleus ambiguous and the nucleus retroambigualis. The components of the anterior vagus at the level of the diaphragm arise equally from the left and right nuclei as do the projections to the somach and small intestine. Within any one section, the labelled neurons of the DMV tend to cluster within the medial, central or lateral part of the nucleus, but consideration of the total labelling shows no indication of a systematic medial-to-lateral topography. However, there are strong rostral-to-caudal labelling differences which depend upon the location of the injection site. More proximal organs (e.g., stomach, duodenum) receive a greater number of fibers from the rostral portion of the DMV, whereas more distal organs (e.g., jejunum, ileum) receive fewer efferents and these arise predominantly from the caudal portion of the DMV. These data suggest that the DMV is viscerotopically organized, finding which should be considered in future studies of the brainstem control of visceral reflexes and parasympathetic outflow during vestibularly induced motion sickness. (Supported by NASA Grant #NAG2-288 to RHIB. YT is a recipient of NASA Research Associate Award #MAGW-70.)

222.15 IONTOPHORETIC CHARACTERIZATION OF THE HYPOTHALAMIC AND MESENCEPHALIC NEURONS RESPONDING TO GASTRIC DISTENSION, AFTER THE VAGAL TRANSECTION. I. Zarco de Coronado, F. C. Barone and M. J. Wayner. Depto. de Fisiología, Fac. de Medicina, 70250, UNAM, México and Brain. Res. Lab. 601 University Ave. Syracuse, N. Y. 13210.

We have previously reported that mesencephalic and hypothalamic neuronal responses were transiently attenuated after the transection of the bilateral cervical vagus. The observations here reported were planed to obtain evidence from unit recordings for chemosensitive changes as underlaying mechanisms of these vagal effects.

In urethane anesthetized rats gastric distension was produced by introducing 5-10 ml of water at 20-38ºC, during 20-30 sec, in a rubber balloon placed into the stomach. Extracellular action potentials were recorded through the central barrel of a seven barrel microelectrode. They were amplified by a high input impedance preamplifier and audioamplifier and displayed in conventional oscilloscope and ratemeter. Five of the outer six barrels were respectively filled with 2M monosodium glutamate (Glut) 2M acetylcholine chloride (ACh) 0.5M noradrenaline bitartrate (NA) 1M gamma aminobutyric acid (GABA) 0.5M dopamine HCl (DA) or some specific blockers. The resting outing barrel was filled with 2M sodium chloride and was used for current balancing. Dose response relations for each chemical and gastric distension effects were determined before and after the bilateral cervical vagus transection. Ocasionally the chemicals were applied during the gastric distension.

Both, the gastric distension and the topical stimulation reproduced, in the above mentioned areas of the CNS, the already described effects. The transection of the vagus, besides to attenuate the response to the visceral stimulation, produced an increase or decrease, in different proportion, in the responses to the neurotransmitters. ACh was especially affected in that case.

We conclude that these alterations in the effectiveness of the neurotransmitters to induce the mesencephalic and hypothalamic responses as a consequence of the interruption of the afferent vagal information, may determine, in this condition, the modification of the neuronal responses to the gastric distension.

222.16 PARAVENTRICULAR NUCLEUS MICROSTIMULATION, LESION, AND OXYTOCIN EFFECTS ON GASTRIC VAGAL NEURONS R.C.Rogers and G.E.Hermann Department of Physiology, Univ. Nevada Sch. Med., Reno, NV 89557

The hypothalamic paraventricluar nucleus (PVN) is known to make direct, monosynaptic connections with preganglionic parasympathetic neurons in the medulla as well as sympathetic neurons in the lateral horn of the spinal cord. Additionally, the PVN makes substantial direct projections with visceral afferent "relay" nuclei such as the nucleus of the solitary tract (NST). The PVN is, therefore, in position to regulate autonomic function by a) directly controlling autonomic outflow via action on the preganglionic neurons or b) altering the gain or setpoint of autonomic reflexes by changing the response properties of neurons receiving visceral regulatory input. Furthermore, oxytocin appears to be an excellent candidate peptide neurotransmitter for these PVN autonomic pathways.

As part of our continuing studies of PVN regulation of gastric function, we have found that a) gastric acid secretion, in response to vagal sensory stimulation is suppressed following unilateral PVN lesions on the side of the sensory input and b) PVN microstimulation markedly enhances the response of NST neurons to gastric inflation. The responsible pathway is probably monosynaptic. In addition, we have developed a composite glass-metal pico-injection/recording electrode which allows us to inject sub-picomolar amounts of putative peptide neurotransmitter onto small, identified neurons. Using this arrangement, we have collected preliminary evidence that electrophysiologically-identified gastric dorsal vagal neurons are activated by extremely small (850fm) amounts of oxytocin injected in their vicinity.

This evidence, together with previous data collected in other laboratories as well as our own, suggest that the PVN may control gastric or other autonomic functions by controlling both the output of autonomic "motor" neurons as well as the sensitivity of the afferent limb of reflex arcs which "drive" these motor neurons.

222.17 INCREASED HEXOKINASE ACTIVITY IN THE HYPOTHALAMUS OF RATS WITH DIABETES INSIPIDUS. F.R. Calaresu, W.E. Turton* and T.L. Krukoff. Dept. of Physiology, Univ. of Western Ontario, London, Canada N6A 5C1.

Two commonly used methods to study metabolic activity in discrete areas of the central nervous system under different physiological conditions are the 2-deoxyglucose (2-DG) technique, which provides information about the activity of the first step of the glycolytic pathway, and the cytochrome oxidase (COX) technique which provides an index of general metabolism. Another method that may also be used as a marker of metabolic activity is the measurement of hexokinase (HK) activity, which demonstrates glucose utilization in the brain. Experiments were done to compare HK activity in the hypothalamus of rats with diabetes insipidus (DI) (N=6) and of Long-Evans rats which were water deprived (WD) for 2 days (n=4) with that of control rats (n=4). The animals were anesthetized (sodium pentobarbital, 50 mg/kg i.p.) and perfused transcardially with saline; the brains were removed, frozen, sectioned (18 μm) on a cryostat and mounted on glass slides. Transverse forebrain sections were processed for HK histochemistry as described previously (Acta Histochem., 28: 286, 1967). Changes in HK activity were assessed by counting the number of neurons containing HK activity above background and by estimating the area of increased activity using a Zeiss Videoplan Microprocessor connected to a Zeiss microscope. HK activity was significantly increased bilaterally in the caudal aspect of the supraoptic nucleus (SON) in DI (15.8 ± 1.4 cells in a representative transverse section) and in WD rats (18.0 ± 1.1 cells) compared to control animals (6.8 ± 1.7 cells). No significant change in HK activity of the paraventricular nucleus of the hypothalamus (PVH) was observed. These results suggest that the increased HK activity of the caudal SON in DI and WD rats was associated with hyperactivity of the cells in this region which normally produce vasopressin. The lack of change in HK activity in the PVH compared to the caudal SON could be due to a lower number of vasopressin neurons in the PVH (J. Neur. Transmiss., 36: 195-215, 1975). These results in DI rats are in partial agreement with those obtained using COX histochemistry (Brain Res., 280: 160, 1983), but are at variance with the results obtained using 2-DG (Brain Res., 275: 189, 1983). It has been suggested that the 2-DG technique demonstrates metabolic changes primarily in nerve terminals (Science, 205: 723, 1979) while COX and HK histochemistry appear to show the level of metabolic activity in cell bodies more clearly than the 2-DG method. The present experiments demonstrate that HK histochemistry may be used as a marker of metabolic activity in discrete regions of the central nervous system.

(Supported by the Medical Research Council of Canada).

222.18 THE PARAVENTRICULAR NUCLEUS IS NOT REQUIRED FOR INHIBITION OF GASTRIC ACID SECRETION FOLLOWING INTRACISTERNAL BOMBESIN. M.W. Gunion and Y. Taché. Center for Ulcer Research and Education, Wadsworth Vet. Adm. Med. Ctr., Los Angeles, CA. 90073; and Dept. of Medicine, U.C.L.A., Los Angeles, CA 90024.

Injections of bombesin into either the paraventricular nucleus or the cisterna magna suppress gastric acid secretion. To determine if the paraventricular nucleus has any role in the mediation of the effect of intracisternally administered bombesin, bombesin was administered intracisternally to rats which had previously received electrolytic lesions of the paraventricular nucleus.

Under ether anesthesia, bilateral lesions of the paraventricular nucleus were made in adult male albino rats (232-285 g) using a platinum electrode (400 u diameter) insulated except for the conical tip (500 u exposed) and 1.0 mA anodal current of 20 s duration. On the third day after lesioning, food, but not water, was removed. On the fourth day after lesioning, rats were anesthetized with ether and given intracisternal injections of bombesin-14 (500 ng) or vehicle (0.1% BSA in 0.9% NaCl; both 10 ul). A ligature was immediately placed around the pylorus through a small abdominal incision. Exactly 2.0 hr postinjection the rats were decapitated, and gastric contents, blood, and the brain were saved. Lesion placement was confirmed by assessment of 50 u brain sections stained with thionin.

Paraventricular nucleus lesions did not alter ($p>.05$) the decreases in gastric acid concentration, secretion volume, and total acid output, or the increases in gastric acid pH and serum gastrin, which followed bombesin administration (bombesin effects all $p<.05$). Enhanced acid secretion in lesioned rats ($p<.01$) appeared to be more likely due to damage of areas adjacent to the paraventricular nucleus, rather than to destruction of the nucleus itself.

The results suggest (1) that the paraventricular nucleus is not involved in bombesin-induced inhibition of gastric acid secretion, and (2) that there is more than one central nervous system site at which bombesin may inhibit acid secretion.

(Supported by NIADDK AM30110, AM33061, and AM17328 (Y.T.). The authors thank J. Rivier for his generous donations of bombesin.)

222.19 EFFECTS OF VENTROMEDIAL HYPOTHALAMIC LESIONS ON THE CEPHALIC PHASE OF GASTRIC ACID SECRETION. William L. Parkinson* and Harvey P. Weingarten. Department of Psychology and Intestinal Disease Research Unit, McMaster University, Hamilton, Ontario, Canada.

The ventromedial hypothalamus (VMH) is implicated as a brain site exerting an inhibitory influence on gastric acid secretion. For example, VMH lesions produce elevations in basal gastric acid output (Weingarten et al., Am. J. Physiol. 239:G221, 1980). Although the effects of VMH lesions on basal acid secretion are well characterised, little is known about VMH control of the cephalic phase of acid secretion. The available data are inconsistent: VMH lesions have been reported to exaggerate (Weingarten et al., Am. J. Physiol. 239:G221, 1980) or eliminate (Ridley et al., Am. J. Physiol. 209:319, 1965) the cephalic phase of gastric acid secretion. Experiments were conducted to further analyze the effects of VMH lesions on this response.

Rats were implanted with chronically-indwelling gastric cannulae to permit measurement of acid secretion in the unanesthetized state. Some animals sustained bilateral electrolytic lesions of the VMH; others served as sham-operated controls.

In the first experiment, the cephalic phase of gastric acid secretion was elicited by peripheral injection of 2-deoxy-glucose (2DG) or insulin. The absolute acid response of VMH rats to 2DG (100 mg/kg) was larger than controls. This difference was eliminated when the stimulated response was corrected for the increased basal secretion characteristic of VMH animals. Insulin produced a dose-related increase in acid secretion in controls. In contrast, VMH rats produced responses that were similar to controls at the lowest dose of insulin (.25 U/kg) but failed to show increases in acid secretion to higher doses (.50 & .75 U/kg).

In a second experiment, the cephalic phase of acid secretion was activated by the anticipation of eating. Food-deprived rats were trained to expect a meal in a distinctive environment. Prelesion, all animals showed large gastric acid responses when placed in this environment. VMH lesions significantly reduced the magnitude of the anticipatory response even though behavioural data indicated that these animals continued to expect the food.

These data demonstrate that VMH lesions have different effects on the cephalic phase of gastric acid secretion depending on the procedure used to activate that response.

222.20 GASTRIC DISTENSION MODIFIES THE ELECTRICAL ACTIVITY OF THE OLFACTORY BULB. D. E. García-Díaz*, H. U. Aguilar-Baturoni, R. Guevara-Aguilar and M. J. Wayner. (SPON: L. Cintra McClone). Depto. de Fisiología, Facultad de Medicina, UNAM, México 04510, D. F., and Division of Life Sciences, University of Texas at San Antonio, San Antonio, TX. 78285.

In a previous paper we reported that olfactory bulb cells responded to vagal nerve stimulation (García-Díaz, D. E., Brain Res. Bull., 12 (5): 529-537, 1984). The aim of this work was to demonstrate that influences from the stomach modifies the electrical activity of the olfactory bulb.

Unitary discharges in the olfactory bulb were extracellularly recorded in 10 Wistar and 7 Sprague-Dawley rats, anesthetized with chloral hydrate 400 mg/Kg or urethane 1.5 g/Kg body weight, while gastric distension was performed by means of a pediatric urinary latex catheter inserted through the esophagus into the stomach: 37 neurons located in the periglomerular layer of the olfactory bulb, were sensitive to gastric distension; 12/37 units responded with inhibition alone, 8/37 exhibited inhibition-excitation effect and 17/37 responded with tonic or phasic activation. Generally, the latency of responses to gastric distension was inferior to one second. All those cells which responded to gastric distension, responded also to vagus nerve stimulation; this effect was suppressed by the section of the vagus nerve at the cervical level. Three ml was the threshold volume infused in the gastric camera that was necessary to get an inhibition discharge activity of the olfactory bulb neurons, but when more than 8 ml were infused, increase in their firing rate was observed.

The results of the present experiment indicate that the discharge frequency of the olfactory bulb neurons, and particularly the periglomerular cells, are modulated by visceral afferents.

222.21 EFFECTS OF THE INTRATHECAL ADMINISTRATION OF SUBSTANCE P ON BLOOD PRESSURE, HEART RATE AND ADRENAL SECRETION OF EPINEPHRINE. C.L.Riphagen, L.Bauce*, W.L:Veale and Q.J. Pittman. University of Calgary, Calgary, Alberta, Canada T2N 4N1

Stimulation of the ventral medulla causes the release of substance P (SP) at spinal levels, possibly from descending SP fibres which have their cell bodies in the brain stem. This release is accompanied by increases in blood pressure (BP) and heart rate (HR) which can be abolished by intrathecal (IT) administration of a SP antagonist. SP immunoreactive fibres surround the adrenal preganglionic neurons (PGN) in the intermediolateral nucleus (IML) of the spinal cord. Large doses of SP, given IT, have previously been reported to increase the levels of circulating catecholamines. In this study we have attempted to correlate the release of epinephrine (EPI) from the adrenal glands, in response to IT SP, with the accompanying increases in BP and HR.

Male Sprague-Dawley rats (250-350g) were anesthetized with Inactin(0.12g/kg i.p). An IT cannula was passed through an incision in the atlanto-occipital membrane and threaded down the subarachnoid space to the T9-T11 region. The trachea was intubated and a cannula (PE50) was inserted into the left carotid artery to monitor BP and HR. The adrenal vein was exposed via a midline incision. After a 30 min. equilibration period, two 30ul blood samples, taken 10 min. apart, were obtained directly from the adrenal vein using an heparinized microcapillary tube with the tip pulled to a sharp point. These samples were used to obtain baseline EPI values. IT injections of SP(7.4nmoles, n=5; 100pmoles, n=5) or vehicle only (5-ion solution, n=5) were made in 15 animals. Blood samples were obtained 2, 15 and 30 minutes after IT injections. All blood samples were centrifuged immediately and the plasma portion was stored at -20°C prior to assay for EPI, using HPLC/EC detection.

Results were as follows:

| | max Δ BP (systolic) mmHg | max Δ HR b.p.m. | % Δ EPI after 2 min. |
|---|---|---|---|
| CONTROL | + 0.2 ± 0.66 | 0 | + 9.75 ± 18 |
| SP,100pmoles | + 18.4 ± 5 | + 23 ± 6.6 | + 98.4 ± 32 |
| SP,7.4nmoles | + 34.7 ± 7 | + 35 ± 9.4 | + 509 ± 112 |

Values = mean± s.e.m.

These results suggest that the cardiovascular responses to spinal SP may be mediated in part by the increased output of adrenal EPI as a result of activation of adrenal PGNs in the IML.

222.22 RELATIONSHIP BETWEEN NORADRENERGIC AND SEROTONERGIC UNIT ACTIVITY AND THE CARDIAC CYCLE IN AWAKE, FREELY MOVING CATS. D.A. Morilak, C. Fornal, S. Auerbach, and B.L. Jacobs, Prog. in Neurosci., Dept. of Psych., Princeton Univ., Princeton, NJ 08544.

Noradrenergic (NE) neurons of the locus coeruleus (LC) and serotonergic (5HT) neurons of the raphe nuclei dorsalis (NRD) and magnus (NRM) have been hypothesized to play a role in cardiovascular regulation. We have thus examined the discharge of these neurons in relation to the cardiac cycle in awake, freely moving cats. Single-unit recordings of NE and 5HT neurons were obtained by means of chronically implanted flexible microwires. Units were identified on-line by previously described pharmacological and electrophysiological criteria. Unit spikes were digitized with a Schmitt trigger and stored on magnetic tape. The EKG signal was fed through a Schmitt trigger set to deliver a pulse at the peak of the R-wave. Computer-generated peristimulus time histograms of unit activity were then constructed around the R-wave. The activity of 5HT neurons in both NRD and NRM showed no consistent relationship to the cardiac cycle. In contrast, LC-NE neurons showed a consistent pulse-synchronous modulation such that the level of unit activity was least during the 40 ms period preceding the R-wave (during atrial systole), and was maximal from 100-140 ms following the R-wave. The activity of non-NE neurons in LC showed no consistent relationship to the cardiac cycle, excluding mechanical artifact as a possible source of the relationship. These data demonstrate that the excitability of LC-NE neurons is influenced by input from cardiovascular afferents whose activity is phase-locked to the heart beat. Atrial stretch receptors may be involved since they discharge during the observed period of neuronal suppression and are silent when LC-NE activity is highest. Since these receptors regulate blood volume by inhibiting vasopressin release, our results are consistent with previous observations that increases in blood volume suppress LC-NE unit activity in the anesthetized rat, and that the activity of these neurons may facilitate vasopressin release. Our results indicate that the activity of LC-NE neurons in unanesthetized, behaving animals can be influenced by physiological variables operating within their normal ranges. This supports the hypothesis that LC-NE neurons may play a role in the regulation of the cardiovascular system, perhaps as part of a more general CNS modulatory function. Supported by NIMH grant MH 23433 and a NSF pre-doctoral fellowship to D.A.M.

222.23 RESPONSE OF SEROTONERGIC DORSAL RAPHE NEURONS TO ENVIRONMENTAL HEATING AND PYROGEN ADMINISTRATION IN FREELY MOVING CATS. C. Fornal, D. Morilak, S. Auerbach and B.L. Jacobs. Prog. in Neurosci., Dept. of Psychol., Princeton Univ., Princeton, NJ 08544.

Serotonergic neurons of the dorsal raphe nucleus (DRN) have been hypothesized to play a role in thermoregulation. These neurons project to the anterior hypothalamic-preoptic area where microinjection of serotonin evokes thermoregulatory responses. Several studies have examined the relationship between body temperature and dorsal raphe unit activity in anesthetized animals. In general, previous results have been equivocal or contradictory. Since anesthesia affects both unit responses and central thermoregulation, we examined the effects of acute environmental heating and pyrogen-induced fever on serotonergic DRN cells in unanesthetized freely moving cats. Single unit activity was recorded using movable electrode bundles consisting of 32 and 64 μm dia. insulated, nichrome wires implanted in the DRN. Serotonergic neurons were initially identified by their slow and regular discharge pattern and complete cessation of activity both during REM sleep and in response to the specific serotonin agonist 5-methoxy-N,N-dimethyltryptamine (250 μg/kg, i.m.). After obtaining baseline unit activity, the temperature in the recording chamber was raised to 43°C and maintained until cats displayed continuous panting for one min (about 30-40 min after the onset of heating). Serotonergic unit activity was not significantly changed from baseline at any time during the period of environmental heating. We also examined the unit activity of serotonergic DRN neurons in response to the synthetic pyrogen muramyl dipeptide (MDP; 50 μg/Kg, i.v.). MDP produced an increase in body temperature within 30 min. The peak elevation ranged from 2.0 to 2.5°C above baseline and occurred 1-2 h post-injection. Body temperature returned to baseline levels within 6 h. Cats appeared lethargic and slept most of the time during the peak febrile response. Serotonergic DRN units showed no significant change in activity following MDP administration. These results indicate that the thermoregulatory responses associated with both environmental heating and pyrogen-induced fever are not accompanied by changes in serotonergic DRN unit discharge. This, however, does not exclude a role for these neurons in thermoregulation since serotonin release may be modulated directly at the axon terminal. Supported by NIMH grant MH 23433 and postdoctoral fellowship MH 08869.

222.24 RELATION OF BODY TEMPERATURE TO AMBIENT TEMPERATURE OF CATS WITH DORSOLATERAL PONTINE TEGMENTAL LESIONS. L. Amini-Sereshki and A. R. Morrison. Dept. of Animal Biology, Sch. of Veterinary Medicine, University of PA, Philadelphia, PA 19104 U.S.A.

Small bilateral dorsolateral pontine tegmental lesions induce paradoxical sleep (PS) without atonia (Henley, K. and A.R. Morrison, Acta Neurobiol. Exper. 34:215-232, 1974). Cats in PS without atonia do not exhibit heat-gain responses, such as shivering, piloerection, or assumption of a protective curled body when placed in the cold (Hendricks, J.C., Exp. Neurol., 75:700-710, 1982), demonstrating in a vivid way the suppression of thermoregulation that characterizes PS (Parmeggiani, P.L., Physiol. in Sleep. J. Orem ed., Acad. Press, New York, 97-143, 1980). These cats also show an alteration of thermoregulatory responses to thermal load during wakefulness. When placed at cold ambient temperatures ($T_a$), they start to shiver, piloerect, and curl their bodies at 15-17°C. Intact cats start to shiver at a $T_a$ of 8-10°C. At high $T_a$, the lesioned cats begin panting at a lower $T_a$ (33-35°C) than intact cats do, suggesting that the thermoneutral zone narrowed (Amini-Sereshki, L. and A.R. Morrison, Soc. for Neurosci. Abstr., 9:112, 1983).

The present experiments initiate a search for reasons for the increased sensitivity to ambient temperature of these lesioned cats. We recorded the brain temperature ($T_b$), measured in the depths of the cerebral cortex via thermistors, as an index of body temperature, at different $T_a$s during wakefulness. $T_b$s were recorded on several trials at $T_a$s between 5 and 40°C before (N=1) and after (N=2) placement of pontine lesions. Each session consisted of 30 minutes exposure to a fixed $T_a$.

The $T_b$s of cats with lesions, like those of normals, did not drop when the cats were exposed to low $T_a$s for 30 minutes. At room temperature the $T_b$ of a lesioned cat was also similar to that of the intact animal. $T_b$ rose in both intact and lesioned cats exposed to high $T_a$s. The rise of $T_b$, however, started at a lower $T_a$ in the lesioned cats, and it rose to a higher value than that of the intact cat at the same $T_a$.

Results of the experiments at low $T_a$s suggest that the lesions resulted in a greater influence of skin temperature on hypothalamic sensitivity at an as-yet-undetermined level of the neuraxis or the periphery. Since the body temperature did not remain at the same level as that of the intact animal at high $T_a$s, lesions appear to have altered hypothalamic control over lower level thermoregulatory mechanisms, either by damaging pathways or cells locally involved in thermoregulatory mechanisms.

Supported by NIH grants NS 20794 and NS 13110.

222.25 EFFECTS OF COLD EXPOSURE ON BRAIN LEVELS OF VASOPRESSIN AND OXYTOCIN IN THE RAT. N.W. Kasting. Dept. Physiol. Fac. Med., Univ. British Columbia, Vancouver, B.C. V6T 1W5

Experimental evidence has suggested that vasopressin (AVP) may be a neurotransmitter in thermoregulatory pathways subserving fever production. Its specific role may be to inhibit heat gain mechanisms in the septal (SEP) or diagonal band (DB) areas of the brain, areas in which there are AVP-containing nerve terminals and AVP receptors. No specific function for oxytocin (OXY) has been proposed in thermoregulatory pathways but it is also found in these areas of the brain. We sought to determine if levels of AVP or OXY changed in certain brain areas upon cold exposure. AVP-containing cell bodies are located in supraoptic nucleus (SON), paraventricular nucleus (PVN), suprachismatic nucleus (SCN) and bed nucleus of the stria terminalis (BST). Nerve terminals of AVP are found in DB, SEP, and PIT. The preoptic/anterior hypothalamus (POA) is the area most intimately involved in integration and regulation of thermoregulatory responses.

Wistar male rats were assigned randomly to control or cold exposed groups. The cold exposed group were kept for 3 days at 6°C. The animals were then quillotined, brains frozen and discrete areas removed for extraction and assay of AVP and OXY.

AVP levels increased relative to controls in DB, SEP, and SCN. OXY levels increased only in DB. No changes were observed in plasma, PIT, POA, SON, PVN or BST. Control animals showed a significant positive correlation in AVP content between certain areas of the brain: SON vs PIT; SON vs SCN; BST and POA; and DB vs SEP. These correlations disappeared in cold exposed rats but were replaced with positive correlations between: SON vs POA; and PVN vs POA.

The increases in AVP content in SEP and DB areas (suggesting decreased release) where AVP has been demonstrated to inhibit heat gain effectors is of considerable interest since cold exposure causes maximal functioning of heat gain effectors. The meaning of the observed changes in correlation of AVP content between brain areas is not yet clear although involvement of the POA, an important thermoregulatory center in the brain, in these changes is of compelling interest.

Supported by MRC Grant MA 7972.

222.26 THE ROLE OF β-ADRENERGIC RECEPTORS IN ADRENAL CORTICAL CELL PROLIFERATION. M.A. Holzwarth, B. Bartnicke*, N. Kleitman, Department of Anatomical Sciences and Program in Neural and Behavioral Biology, University of Illinois, Urbana, IL 61801

The autonomic nervous system mediates the compensatory adrenal cortical growth which occurs in the remaining adrenal following unilateral adrenalectomy. This growth, a proliferative response of cells of the zona glomerulosa, is measurable by increased adrenal weight and DNA, RNA and protein content. Evidence for the role of the sympathetic nervous system in the mediation of this response has been recently reported. The adrenal cortex is innervated by catecholaminergic nerves which are eliminated by neonatal chemical sympathectomy. Sympathectomy prevents the compensatory adrenal cortical growth response to unilateral adrenalectomy (Am. J. Physiol. 248:E261). The mechanisms and adrenoreceptors by which the sympathetic nervous system affect this response remain unelucidated.

In vitro incorporation of $^{3}$H-thymidine into adrenal DNA was found to be a more sensitive and reliable measure of cell proliferation than the previously utilized measure of total DNA content. A time course of compensatory growth was established: A significant increase in the rate of DNA synthesis could be demonstrated 18, 24, 48 and 72 hrs after unilateral adrenalectomy, but not after 6, 12 or 120 hrs. To investigate the role of adrenoreceptors in this response, β-adrenergic agonist, isoproternol (5 mg/kg BW) was administered for 24 hrs. While isoproterenol has been reported to stimulate cell proliferation in other tissues, in the adrenal it significantly decreased (44%) $^{3}$H-thymidine incorporation into DNA relative to the saline-injected controls ($p<0.01$). Furthermore, isoproterenol administration inhibited the usual increase in the rate of DNA synthesis observed 24 hrs after unilateral adrenalectomy. These results are corroborated by the observation that blockade of β-adrenoreceptors with propanolol (10 and 25 mg/kg) or Sotolol (25 and 50 mg/kg) resulted in increased compensatory adrenal cortical growth relative to saline-injected controls ($p<0.05$). Thus, β-adrenergic receptors appear to inhibit DNA synthesis. We conclude from these results that activation of β-adrenergic receptors is not the mechanism by which catecholaminergic neurons stimulate cell proliferation in the compensatory growth response. But rather, it is possible that the trigger for compensatory adrenal growth involves a release from this β-adrenergic inhibition. (Supported by NSF PCM-8109756 and NIH PHS-5T32GM07).

222.27 PLASMA ACTH AND ADRENAL CATECHOLAMINE SECRETORY RESPONSES TO TRIGEMINAL SUBNUCLEUS CAUDALIS STIMULATION: EFFECT OF STIMULUS PATTERN. D.A. Bereiter, W.C. Engeland* and D.S.Gann. Brown U., R.I. Hospital, Endocrine Lab, Providence, R.I. 02902

Trigeminal subnucleus caudalis(TC) is a primary relay nucleus for nociceptive afferent input from the head and facial regions. Neurons within the magnocellular (deep) portions of TC project rostrally to the diencephalon and caudally to the spinal cord. The goal of this study was to assess the effect of the pattern of electrical stimulation(ES) of TC on the release of ACTH and on adrenal catecholamine secretion, hormonal responses which are presumed to accompany nociceptor neuron activation.

Adult cats were anesthetized with chloralose/urethane after induction with ketamine. Catheters were placed in the descending aorta(arterial blood pressure), femoral vein(ACTH concentration), brachial vein(drug and dextran infusions), and the lumboadrenal vein(adrenal catecholamine secretion). After tracheostomy, animals were paralyzed with gallamine and artificially ventilated. Animals were placed in a stereotoxic frame using blunt ear bars and the dorsal surface of the caudal medulla was exposed for electrode (concentric bipolar) placement using the obex as the reference point. Cathodal stimulation consisted of 300 pulses delivered over 15sec (75μA, 0.2ms duration, 20cps) in a continuous pattern (50ms intervals) or in a burst pattern(10ms intervals). All cats received both stimulus patterns at each electrode site. Blood samples were collected at -5,0,1,3 and 6min and assayed for ACTH by RIA and adrenal catecholamines by HPLC-EC.

The results indicate that stimulation of the magnocellular TC evoked an increase in ACTH(>30pg/ml) by +1min regardless of stimulus pattern. ACTH returned to baseline by +6min after continuous pattern ES, but remained elevated at +6min after the burst pattern ES. The mean prestimulus adrenal epinephrine secretion($\bar{E}$) and norepinephrine secretion($\bar{NE}$) rates were 16.5±4.7 and 29.4±5.5ng/min, respectively.TC-ES by continuous pattern did not affect adrenal $\bar{E}$, whereas stimulation by burst pattern caused a significant increase in adrenal $\bar{E}$(+26.8±12ng/min). Continuous pattern TC-ES caused a variable change in adrenal $\bar{NE}$, whereas the burst pattern evoked a consistent increase in adrenal $\bar{NE}$(+17±4.3ng/min). The mean ratio of $\bar{E}/\bar{NE}$ was 0.64 ± 0.21 prior to TC-ES and was not altered by continuous pattern TC-ES, whereas the burst pattern TC-ES evoked an increase (by +1min) in the $\bar{E}/\bar{NE}$ ratio. Arterial pressure decreased slightly (-4.7±3.3mmHg) after continuous pattern TC-ES, whereas burst pattern caused a slight increase (+4.9± 3.7mmHg).

We conclude that the magnocellular laminae of TC contains neural elements which contribute to the control both of ACTH and of adrenal catecholamine secretion. These data indicate that stimulation of the magnocellular TC evokes a prompt increase in plasma ACTH independent of stimulus pattern. In contrast, adrenal $\bar{E}$ is sensitive to the pattern of stimulation since burst pattern stimuli caused a greater increase in adrenal $\bar{E}$ than was seen after continuous pattern stimuli. This study was supported by NIH Grants AM-26831 and GM-27946.

222.28 DIFFERENTIAL SYMPATHOADRENAL CATECHOLAMINE RESPONSES TO CENTRAL AND PERIPHERAL NICOTINE. G.R. Van Loon, J.A. Kiritsy-Roy* and S.A. Mousa*. VA Medical Center and Departments of Medicine and Pharmacology, University of Kentucky, Lexington, KY 40511.

Nicotine increases catecholamine secretion through its peripheral effects on sympathetic ganglia and nerves and on adrenal chromaffin cells, but brain-mediated effects of nicotine on catecholamine secretion have not been described. In this study, we compared the effects of centrally- and peripherally-administered nicotine on plasma concentrations of catecholamines. Furthermore, since tolerance to the effects of nicotine has been described, we also compared the effects of initial and subsequent central and peripheral injections of nicotine on catecholamine secretion. Adult male Sprague-Dawley rats were prepared at least two days before experimentation with an indwelling carotid cannula housed in a flexible spring which allowed drug administration and blood sampling to be carried out without the stress of handling. In some rats, a stainless steel guide cannula was stereotaxically positioned 1.5 mm above the right lateral brain ventricle at the same time. For studies of peripheral nicotine, either nicotine 0.5 mg/kg or saline was administered intraarterially three times at 70 min intervals. For studies of central nicotine, animals were handled briefly to lower a drug-filled injector through the guide cannula into the lateral ventricle. Thirty min later, 2 μl of test solution was microinjected over 2 min. Nicotine 30 nmol was administered intraventricularly, and a time course was established. Then, nicotine 30, 60, or 120 nmol was injected daily for 7 days, and blood was sampled before and at the time of peak response, 2 min after nicotine. The initial peripheral administration of nicotine increased plasma concentrations of both norepinephrine (NE) and epinephrine (EPI) markedly; NE increased by 30.0 ± 4.6 nM and EPI increased 14.7 ± 3.0 nM. These catecholamine responses were blocked by the simultaneous administration of hexamethonium. The initial central administration of nicotine produced dose-related increases in plasma EPI, but in contrast to peripheral nicotine only the highest central dose tested increased plasma NE concentration. Nicotine 120 nmol intraventricularly increased plasma NE by 1.7 ± 0.6 nM and plasma EPI by 13.0 ± 3.2 nM. That is, this central dose of nicotine produced an equal EPI response but only about 1/20 of the NE response produced by peripheral nicotine. Thus, central administration of nicotine appeared to stimulate predominantly sympathetic outflow to the adrenal medulla with very little or no effect on outflow to sympathetic nerves. In contrast, peripheral administration of nicotine appeared to be associated with stimulation of both adrenal medulla and sympathetic nerves. Furthermore, tolerance was demonstrated for the NE responses to both central and peripheral repeated nicotine administration, but tolerance for the EPI response was demonstrated only to central administration of nicotine.

222.29 COMPENSATORY ADRENAL CORTICAL GROWTH OCCURS AFTER SUPPRESSION OF ANGIOTENSIN II. N. Kleitman and M. A. Holzwarth. Neural and Behavioral Biology Program and Department of Anatomical Sciences, University of Illinois, Urbana IL 61801

Recently, we reported that the zona glomerulosa of the rat adrenal cortex is innervated by catecholaminergic fibers. Elimination of these nerves by chemical sympathectomy inhibited compensatory adrenal growth, a neurally mediated, proliferative response to unilateral adrenalectomy. Because angiotensin II (AII) stimulates adrenal cortical cell proliferation in vitro, and sympathectomy may affect the renin-angiotensin system, we tested whether suppression of AII prevents the compensatory adrenal growth response.

The angiotensin converting enzyme inhibitor, Enalapril (20 mg/kg per day) was administered to rats in their drinking water for 4 or 7 days. Control animals drank tap water. The efficacy of this treatment was demonstrated by the reduced blood pressure response of treated rats to exogenous angiotensin I relative to their response to AII. Rats were unilaterally- or sham-adrenalectomized on the second or fourth day of Enalapril treatment and were sacrificed 72 hrs later. Significant increases in adrenal weight, and DNA and protein content of unilaterally adrenalectomized rats in all groups indicated that compensatory adrenal growth was not inhibited by Enalapril treatment. The elevation in adrenal DNA content after adrenalectomy confirmed that this was a cell proliferative response. Thus, suppression of AII synthesis did not inhibit compensatory adrenal growth.

We next tested the effect of elevated potassium intake on compensatory adrenal growth. Potassium directly stimulates adrenal aldosterone synthesis while inhibiting the renin-angiotensin axis. 2.5% KCl solution was substituted for drinking water for 7 days (controls drank tap water). High potassium intake increased plasma aldosterone but not corticosterone levels in treated animals. Rats underwent unilateral- or sham-adrenalectomy on the fourth treatment day. 72 hrs later, adrenal DNA content was significantly increased in potassium treated, adrenalectomized animals, again confirming that cell proliferation had occurred in response to unilateral adrenalectomy, however, these rats showed no significant increase in adrenal weight. We conclude that compensatory adrenal growth was not inhibited in the potassium-treated group, even though adrenal weight measures did not indicate the response.

Our findings that neither AII-suppressing treatment inhibited the compensatory adrenal growth response suggest that this response is not dependent on the mitogenic effects of angiotensin. (Supported by NSF Grant PCM-8109756 and NIH PHS-5T32GM07.)

## RECEPTOR MODULATION: UP AND DOWN REGULATION I

223.1 ASCORBIC ACID TREATMENT INCREASES ACETYLCHOLINE RECEPTOR mRNA LEVELS IN CULTURED MYOGENIC CELLS. D. Knaack*, S. Admon*, T. Podleski*, R. Oswald and M. M. Salpeter. Section of Neurobiology & Behavior, Cornell University, Ithaca, NY 14853.

The addition of crude brain extracts to cells from myogenic cell lines can cause a 2 to 5 fold increase in surface acetylcholine receptors (AChR) (Podleski et al., Proc. Natl. Acad. Sci., 75:2035, 1978). It has been shown that ascorbic acid is the principal component of the brain extract responsible for this effect (Knaack & Podleski, Proc. Natl. Acad. Sci., 82:575, 1985), and commercially available ascorbic acid induces an increase in surface AChR similar to that induced by the brain extracts (Knaack, Shen, Salpeter & Podleski, in press). This increase in AChR levels is not paralleled by an increase in creatine kinase nor is it caused by increased growth, survival, fusion, or total protein synthesis. The increased surface AChR is also not due to a decrease in the AChR degradation rate (Knaack, Shen, Salpeter & Podleski, in press).

As an initial approach to understanding the mechanism of AChR induction by ascorbic acid, we examined AChR mRNA in ascorbic acid-treated cells. Poly(A)$^+$ RNA was prepared from the myogenic cell line (L5), with and without ascorbic acid pretreatment. AChR mRNA was studied on northern blots using a cDNA probe for the mouse α-subunit of the AChR (pA59) (Merlie et al., Proc. Natl. Acad. Sci., 80:3845, 1983). A cDNA probe for rat myosin light chain 2 (p103) (Katcoff et al., Proc. Natl. Acad. Sci., 77:960, 1980) was used as control.

Ascorbic acid-treated cultures had dramatically elevated levels of mRNA for the α-subunit of AChR, while levels of mRNA for myosin light chain 2 were not increased by ascorbic acid treatment.

The ascorbic acid effect is thus most likely due to increased synthesis of AChR resulting from elevated levels of mRNA for the receptor.

223.2 REGULATION OF THE ALPHA(+) AND ALPHA SUBUNITS OF RETINAL NA,K-ATPASE BY TETRODOTOXIN AND RD MUTATION, S. Corey Specht, J. Doval Graziani*, A. Colon Magé*, S. Castro Hernandez* and M. Morales*. Dept. of Pharmacology and Laboratory of Neurobiology, Univ. of Puerto Rico Sch. of Med., San Juan, PR 00936.

The synthesis, degradation and distribution of the alpha subunit of Na,K-ATPase in muscle and kidney is regulated by signals arising from Na-transport work load. Neuronal enzyme has two forms of the catalytic subunit, alpha and alpha(+). To determine if both forms of the neuronal enzyme are subject to down-regulation by decreased Na-transport work load, we examined mice lacking photoreceptor cells (rd) as well as rats and mice pre-treated with intraocular Tetrodotoxin to block action potentials. In rd retinae the number of $^3$H-ouabain binding sites per g tissue was not decreased, although both total retinal weight and binding per retina were only one-third the value in wild type mice. Labeling of alpha and alpha(+) was determined by scintillation counting of SDS-polyacrylamide gels. The incorporation of $^{35}$S-methionine into alpha (+) and alpha isolated from rd retinae was similarly proportional to tissue weight, i.e., one-third control values. On the other hand, intraocular injection of Tetrodotoxin decreased incorporation and prolongedthe half life of alpha(+) relative to alpha. Hence complete absence of action potentials may be required for down-regulation. The differential effect on alpha and alpha(+) suggests the possibility that only one of these two forms, probably alpha, is subject to down-regulation. (Supported in part by NS 07464 and MBS-RR-08102.)

223.3 SEX DIFFERENCE IN $\alpha_1$-NORADRENERGIC RECEPTOR BINDING FOLLOWING ESTRADIOL TREATMENT IN THE GUINEA PIG ASSESSED BY QUANTITATIVE AUTORADIOGRAPHY. A.E. Johnson, B. Nock, B. S. McEwen, and H.H. Feder. Institute of Animal Behavior, Rutgers University, Newark, N.J. 07102 and The Rockefeller University, New York, N.Y. 10021.

Noradrenergic (NA) transmission plays an important role in the regulation of ovarian steroid-dependent LH release and in the regulation of lordosis in female rodents. One way in which ovarian hormones might affect NA function is by altering the number of NA receptors. In this regard, estradiol has been shown to affect one $\alpha$-noradrenergic receptor subtype, $\alpha_2$-receptors, in several brain regions of female guinea pigs. In the present study, we examined the effect of E on a second subtype of NA receptor, $\alpha_1$-receptors. For these studies, we used male and female guinea pigs to evaluate possible sex differences in $\alpha_1$-receptor response to estradiol.

Adult guinea pigs were gonadectomized and treated one week later with either 10µg estradiol-17β benzoate (E) or oil for two consecutive days. Two days after the second injection, animals were decapitated, brains were rapidly removed, frozen on dry ice, and stored at -60°C. Brain sections (30µm) were cut and thaw-mounted onto subbed slides. $\alpha_1$-Receptors were labeled using 1.0nM ($^3$H)prazosin (SA=80.9 Ci/mmole) + 10µM phenylephrine. Tissues were exposed to tritium-sensitive LKB Ultrofilm for 6 weeks. Autoradiograms were analyzed using a computer assisted densitometer that converted optical density to fmoles/mg protein using a standard curve derived from brain mash standards that were coexposed with the labeled brain slices.

In the ventromedial hypothalamic nucleus (VMN) of oil treated animals, we found higher levels of prazosin binding in female guinea pigs than in males. Treatment with E decreased prazosin binding in VMN of females but not males. Prazosin binding in the medial amgdaloid nucleus was found to be higher in females than males, but no effect of E was detected.

These results indicate that E might influence NA transmission in brain by altering the number of $\alpha_1$-receptors in addition to $\alpha_2$-receptors. The mechanism whereby E alters noradrenergic receptors has not yet been determined. Estradiol might alter the synthesis of NA receptors, the level of NA activity, or the coupling of receptors to regulatory proteins. In addition, the possibility of E induced tissue alterations resulting in local changes in autoradiographic efficiency cannot be ruled out at this time. Supported by NS07080 (NIH, B Mc) and HD04467 (NIH, HHF).

223.4 DEPLETION OF EXTRACELLULAR CALCIUM INHIBITS ACETYLCHOLINE RECEPTOR BIOSYNTHESIS. M.A. Wozniak*[1], D.J. Goldman*[2], R.J. Bloch[1], S. Heinemann[2], J. Patrick[2]. [1]Dept. of Physiology, Univ. of Maryland School of Medicine, Baltimore, MD 21201, and [2]Molecular Neurobiology Lab, Salk Institute, San Diego, CA, 92138.

The nonfusing mouse muscle cell line, BC3H1, provides a well controlled experimental system in which to study the regulation of nicotinic acetylcholine receptor (AChR) biosynthesis. When this cell line differentiates, large numbers of nicotinic AChRs are inserted into the surface membrane. In controls (1.8 mM extracellular calcium [$Ca^{2+}$]), appearance of new AChR on the cell surface, as detected by $^{125}$I-alpha bungarotoxin, is linear with time. Incubation of cells in $Ca^{2+}$-depleted medium, or in cycloheximide, results in a complete block in AChR membrane appearance after a 2 hr time lag. Previous experiments have indicated that $Ca^{2+}$ is specifically required in a dose dependent manner for the membrane insertion of AChR. Reduction of $Ca^{2+}$ does not affect AChR degradation and only moderately and non-selectively decreases total cell protein and glycoprotein synthesis. (Soc. Neurosci. Abst., 10:1134, 1984).

When cells depleted of $Ca^{2+}$ are placed in control medium, AChRs reappear on the cell surface at control rates after a 4 hr lag. This reappearance of AChR is completely blocked by the protein synthesis inhibitor, cycloheximide, but only moderately decreased by inhibition of RNA synthesis by actinomycin D. To determine directly if mRNA levels of the AChR subunits are altered during incubation in $Ca^{2+}$-depleted medium, polyadenylated RNA was purified from control, $Ca^{2+}$-deprived and actinomycin-treated cells. The RNA was separated on agarose gels and probed with $^{32}$P-labeled cDNA for the alpha, gamma and delta subunits of the receptor. When control, $Ca^{2+}$-deprived and actinomycin-exposed samples are compared, no difference in steady state mRNA levels of the alpha, gamma or delta subunit is detected.

Transport of assembled AChR to the cells surface does not appear to be altered during $Ca^{2+}$ depletion. First, AChR are transported to the cell surface at control rates during the first two hours of incubation in low $Ca^{2+}$ medium. Second, a 6 hr incubation in $Ca^{2+}$-depleted medium results in a 80% decrease in intracellular $^{125}$I-bungarotoxin binding sites, consistent with a continued transport of AChR from a dwindling intracellular pool.

Incubation in low $Ca^{2+}$ medium blocks AChR biosynthesis at a point which follows mRNA synthesis yet precedes transport of assembled AChR to the cell surface. Reduction of $Ca^{2+}$ may interrupt AChR biosynthesis at (i) translation, (ii) essential cotranslational modification, or (iii) maturation and assembly of the subunits into the mature bungarotoxin binding AChR. Experiments are in progress to distinguish among these alternatives.

223.5 QUANTITATIVE AUTORADIOGRAPHY OF $GABA_A$ RECEPTORS IN RAT FOREBRAIN: RECEPTOR DISTRIBUTION AND EFFECTS OF ESTRADIOL. L. H. O'Connor, B. Nock and B. S. McEwen. The Rockefeller University, New York, NY 10021.

Estradiol has been implicated in the modulation of gamma-aminobutyric acid (GABA) function in brain. One way estradiol appears to regulate GABA activity is through effects on $GABA_A$ receptors (Br. Res. 279, 1983,141: Eur. J. Pharm. 103, 1984, 165), a subtype of GABA receptors that shows a high affinity for GABA agonists in vitro. The present study more precisely localizes the effects of estradiol on $GABA_A$ receptors in rat brain using in vitro quantitative autoradiography. A modification of the method of Palacios et al. (PNAS 77, 1980, 670) was used to label $GABA_A$ receptors in rat forebrain. Following 3 x 10 min. preincubation washes, brain slices were incubated with 20nM $^3$H-muscimol + .1mM GABA. The sections were washed for one min. in ice cold buffer, dried and apposed to LKB tritium sensitive Ultrofilm for 19 days. Areas with the highest concentration of $GABA_A$ receptors included frontal cortex layers 2&3, stratum radiatum, stratum oriens and dentate gyrus. Intermediate concentrations of receptors were found in olfactory tubercle, accumbens, bed nuc. of stria terminalis, anterior hypothalamic area, ventromedial hypothalamic nuc. and compact substantia nigra. Areas with lower concentrations of receptors were found in median preoptic nuc., periventricular hypothalamic nuc., septohypothalamic nuc., arcuate and reticular substantia nigra. This distribution of $GABA_A$ receptors confirms and extends previous observations (Br. Res. 222, 1981, 285).

For investigation of effects of estradiol on $GABA_A$ receptors, ovariectomized female rats were injected with 10ug estradiol benzoate (n=8) or sesame oil (n=7) at 0 and 24 hrs and at 48 hrs after the last injection the rats were decapitated. Using a computer-assisted densitometry system that converts optical density to fmol/mg protein, estradiol was found to affect $GABA_A$ receptors in a number of brain areas. It is noteworthy that some of the areas where receptors were affected are known to concentrate estradiol but effects of estradiol were not limited to those areas. For example, in frontal cortex layer 6, an area that contains few estrogen receptors, estradiol caused a decrease in the concentration of $GABA_A$ receptors. The mechanism by which estradiol altera $GABA_A$ receptors in frontal cortex has not yet been determined. Effects of estradiol on $GABA_A$ receptors in other brain areas is currently under investigation.

223.6 RAPID STEREOTAXIC INJECTIONS INTO MOUSE STRIATUM USING A PLASTIC MOLD. David B. Goodale*, Athole G. McNeil Jacobi*, James D. Winkler* and Benjamin Weiss, Departments of Anesthesia and Pharmacology, Medical College of Pennsylvania, 3300 Henry Avenue, Philadelphia, PA 19129

Microinjections of putative neurotransmitters, neuromodulators and drugs into discrete brain nuclei afford the opportunity of dissecting neurochemical mechanisms in the central nervous system. Most conventional stereotaxic techniques, while highly selective, are tedious and time consuming. We have devised a plastic mold that allows rapid and selective microinjections of compounds into specific brain nuclei of mice. For example, the plastic mold system allows for the unilateral 6-hydroxydopamine-induced denervation of the striatal dopaminergic nerve terminals of 20 mice per hour by one operator. The accuracy of this system resulted in 90% of the mice demonstrating contralateral asymmetry and 70% of the mice having greater than 30 contralateral rotations per five minute test period following the subcutaneous injection of apomorphine (0.5 mg/kg). Analyses were also performed on the drug concentration, rate of injection and type of anesthesia optimum for lesioning dopaminergic nerve terminals with 6-hydroxydopamine. The optimum volume of injectant was one microliter, with larger volumes resulting in the spread of the injectant over the ipsilateral cortex. Concentrations of 6-hydroxydopamine as low as 4 ug/ul were effective in producing contralateral asymmetry. The optimum dose of 6-hydroxydopamine was sixteen micrograms per striatum. The neurochemical specificity of this technique was confirmed by comparing the concentrations of dopamine and serotonin in mouse striatum 2 weeks following the injection of 6-hydroxydopamine. A comparison of different anesthetics showed no significant differences in contralateral rotations following lesioning under Halothane, Chloropent or gamma-butyrolactone anesthesia. This procedure has already been used to study the effects irreversible dopaminergic ligands (Thermos et al., Soc. Neuroscience, 1985), the reversal of 6-hydroxydopamine-induced supersensitivity (Winkler and Weiss, Fourth World Cong. of Biol. Psychiat., 1985) and to differeniate the subtypes of dopaminergic receptors (Goodale et al., Pharmacologist, 1985). In addition, the general technique to be described has obvious applicability for administrating other neurotoxins, radiolabeled tracer substances or even for tissue transplantation. Funded by the Department of Anesthesia, Medical College of Pennsylvania and by the Department of Public Welfare, Commonwealth of Pennsylvania.

223.7 **BETA-ADRENERGIC RECEPTOR AUTORADIOGRAPHY IN RATS TREATED WITH DESMETHYIMIPRAMINE.** E.A.Crisóstomo and J.N.Davis, VA Medical Center and Departments of Medicine (Neurology) and Pharmacology, Duke University Medical Center, Durham, NC 27705.

Chronic treatment with the tricyclic antidepressant desmethylimipramine (DMI) decreases beta(B)-adrenergic receptor binding in brain tissue homogenates, and attenuates the production of cyclic AMP in brain slices exposed to isoproterenol. DMI has long been recognized for its ability to inhibit norepinephrine uptake. In vitro autoradiography is a powerful tool for delineating specific regional changes in neurotransmitter receptor densities. We utilized the B-adrenergic ligand [$^{125}$I]-cyanopindolol (CYP) to define the regional regulation of receptors after DMI treatment.

Adult male Sprague-Dawley rats were given either DMI (15 mg/kg, i.p.) or saline for 12 consecutive days. Twenty-four hours after the last injections, the animals were sacrificed and their brains rapidly frozen. Adjacent serial sections were labeled with 43 pM CYP, and either 50 nM of ICI-118,551 or 70 nM of ICI-89,406 as selective $B_2$- and $B_1$-adrenergic receptor antagonists, respectively. Non-specific binding was estimated after incubation with ±propranolol.

We detected dramatic reductions in quantitative densitometric measurements of $B_1$-adrenergic receptor densities in several regions from brains of DMI-treated rats, including cerebral cortex and hippocampus (pyramidal layer $CA_1$ and subiculum). $B_2$-adrenergic receptors were reduced in the molecular layer of the cerebellum and in layer IV of the cerebral cortex. No appreciable differences in densities were observed in the caudate-putamen, dorsal lateral geniculate nucleus and substantia nigra in both receptor subtypes. In addition, minimal to no change was observed in $B_1$ receptor densities in the cerebellar molecular layer and in $B_2$ receptor densities in layer I of the cerebral cortex and in the hippocampal formation.

These data indicate that 1) both $B_1$- and $B_2$-adrenergic receptor subtypes are affected by DMI treatment, and 2) the decreases in B-adrenergic receptor densities in treated animals are heterogenous within projection areas of locus coeruleus neurons. The heterogeneity of these changes suggests that chronic DMI treatment affects discrete post-synaptic targets of noradrenergic fibers. (Supported by the VA and NS06233)

223.8 ALTERATION OF HYPOTHALAMIC $A_1$ ADENOSINE RECEPTORS IN STRESSED ANIMALS. S.M. Anderson, J.R. Leu, and G.J. Kant. Department of Medical Neurosciences, Walter Reed Army Institute of Research, Washington, D.C. 20307-5100.

The investigation of stress-induced changes in neuronal functioning is important to our understanding of mental disorders, stress-induced psychological impairment, and the emotional reactions of fear and anxiety. Data from previous animal studies have demonstrated various pituitary-adrenal responses to stress and also changes in brain neurotransmitters. We are investigating whether stress-induced neuroendocrine and brain monoamine changes are accompanied by concomitant changes in brain neurotransmitter and/or neuromodulator receptors.

We have developed a behavioral paradigm incorporating sustained stress, continuous performance, and disruption of sleep. Animals which are habituated to press a lever to receive food are trained in an active shock escape task. All animals are housed in operant boxes and receive 45 mg food pellets on a FR 1 schedule. Water is freely available from a drinking tube. Lights are on in the boxes from 0600 to 1800 hrs. After a three day acclimation period, stress trials are presented on a variable time schedule. The average inter-trial interval is ten min. Each trial involves a graduated series of shocks, presented through a metal grid floor. A series consists of 5 seconds at five levels of increasing footshock intensity. Eighty percent of the trials can be terminated at any point during the trial by pulling a chain. Twenty percent of the stress trials are inescapable. A matched set of animals housed in identical operant chambers but not exposed to footshock are used as comparative controls.

After three days of shock exposure, stressed animals and matched controls are decapitated; trunk blood samples are collected; and brains are quickly removed and dissected into discrete regions. All samples are frozen and stored for assay at a later date. Blood plasma corticosterone, prolactin, and adrenocorticotropic hormone are measured as endocrinological indices of stress.

In preliminary experiments we have found that food intake by stressed rats was twenty percent less than that by matched controls. Plasma prolactin and corticosterone levels were higher in stressed rats. [$^3$H]Cyclohexyladenosine (CHA) binding to $A_1$ adenosine receptors in hypothalamic membrane preparations from stressed rats was twenty percent higher than in matched controls. However, no differences in [$^3$H]CHA binding were found in tissue preparations from frontal cortex, hippocampus, or striatum, when comparing stressed and control rats. Additional data comparing neurotransmitter and neuromodulator receptors between stressed and control animals will be presented. Changes in patterns of feeding, drinking, and escape responding over the course of the sustained stress period as well as circadian patterns of these responses will be also be discussed.

223.9 BRAIN ADENOSINE RECEPTORS IN MAUDSLEY REACTIVE AND NON-REACTIVE RATS. P. MONTGOMERY*, E. TAMBORSKA*, P.J. MARANGOS and T.R. INSEL. Unit on Neurochemistry, BPB,NIMH and LCS,NIMH, Bethesda, Md. 20205.

Increasing evidence indicates that adenosine functions as a major non-peptide neuromodulator in brain. The mechanism of the central nervous sytem depressant effects of adenosine probably involves the general inhibition of neurotransmitter release by this purine. In an effort to further characterize the adenosine receptor and its relationship to behavior we investigated receptor status in maudsley reactive (MR) and maudsley non-reactive (MNR) rats. These rats have been selectively bred for high (MR) and low (MNR) degrees of fearfulness. Behavioral testing revealed a significant increase in the amount of defecation and a decrease in exploration by the MR rats. The goal of the present study was to determine whether adenosine or benzodiazepine receptors were altered in the MR rats. The brain areas examined included the cerebral cortex, cerebellum and hippocampus. Three separate studies revealed the most marked changes in the cerebellum with MR rats showing increases in adenosine receptors (using [$^3$H] cyclohexyl-adenosine, [$^3$H]CHA as ligand) ranging from 20-40%. Scatchard analysis clearly revealed an increase in receptor number with no significant alteration in the binding affinity. Examination of benzodiazepine receptors of both peripheral ([$^3$H] RO-5-4864 as ligand) and central type ([$^3$H] ethyl-β-carboline-3-carboxylate as ligand) revealed no significant differences between the MR and MNR strains in either of these sites. This latter finding is in contrast to a previous preliminary report (Europ. J. Pharmacol. 50, 455, 1978).

It, therefore, appears that cerebellar adenosine receptors which are thought to reside on granule cell parallel fibers appear to be increased in MNR rats. The relatively unchanged status of adenosine receptors in other brain areas suggest that cerebellar adenosine receptor increases may be a marker for the reactive trait. Since cerebellar granule cells are thought to use glutamate as their neurotransmitter, it would be interesting to further explore the glutaminergic system in MR rats. It is possible that the biochemical substrate for at least some of the behavioral manifestations of the reactive trait may involve alterations in the cerebellar adenosine system.

223.10 ANTAGONIST-INDUCED OPIATE RECEPTOR UPREGULATION IN CULTURES OF SPINAL CORD AND GANGLION EXPLANTS. A. Tempel, R.S. Zukin and S.M. Crain, Department of Neuroscience, Albert Einstein College of Medicine, 1300 Morris Park Ave., Bronx, NY 10461.

Cultures of fetal mouse spinal cord with attached dorsal root ganglia (DRGs) develop high levels of stereospecific opiate receptors, especially in the DRG neurites (Hiller et al., Brain Res. 1978). Exposure of cord-DRG explants to low levels of morphine (1 uM) for two or more days results in the development of tolerance to the opiates (Crain et al., Life Sci. 1979). We have used this system to study the mechanisms underlying the regulation of opioid receptors by chronic antagonist (naloxone) treatment.

Cord-DRG explants were grown in standard growth medium for two weeks and then in medium containing naloxone (10 uM) for an additional 7 days. Aliquots of explant homogenate (0.25 ml), 0.06 mg protein) were incubated in triplicate with 5 nM $^3$H-dihydromorphine (DHM) in the presence and absence of 10 uM levorphanol. $^3$H-DHM binding to explant homogenates was stereospecific and saturable; half-maximal binding occurred at 3 x $10^{-9}$ M ligand. The time-course of opiate receptor upregulation in the spinal cord-DRG cultures was also examined. Half-maximal receptor upregulation occurred at 2 days of naloxone treatment; receptor density was maximal at 5 days. Assays of cultures exposed to naloxone (10 uM) for 5-7 days revealed a 51% increase in $^3$H-DHM binding relative to that in control cultures. This concentration of antagonist is similar to that required to produce upregulation in CNS tissues by in vivo administration (10 mg/kg/day) (Tempel et al., 1984, 1985). Exposure of the explants to naloxone (10 uM) in the presence of the protein synthesis inhibitor, cycloheximide (1 uM) (a concentration which blocks greater than 90% protein synthesis) resulted in receptor density changes that were similar to those observed in cultures exposed to naloxone alone. This finding suggests that antagonist-induced opioid receptor upregulation does not require the synthesis of new receptor molecules.

In order to determine whether upregulation of this type can occur in the absence of the formation of synaptic connections isolated explants of DRGs or cord were grown in the presence or absence of naloxone. Isolated DRG explants exhibited a more pronounced antagonist-induced increase in receptor number than did DRG-cord explants. This finding indicates that antagonist-induced upregulation of opiate receptors can occur in peripheral DRG neurons in the absence of synaptic connections to their target tissues. It also suggests that regulation of these receptors on isolated DRG neurons may be more plastic. 223.11 SYNAPTIC INPUT INCREASES ACETYLCHOLINE SENSITIVITY OF EMBRYONIC CHICK SYMPATHETIC NEURONS IN VITRO. L. Role Anat. & Cell Biol. & Ctr. for Neurobiol. & Behav., Columbia Univ. P&S, NY, NY 10032.

The influence of synaptic input on the development of acetylcholine (ACh) sensitivity of sympathetic neurons has been examined using co-cultures of pre- and post-ganglionic neurons from embryonic chick. Preliminary experiments characterize the pharmacology of the transmission and are consistent with an inductive influence of preganglionic input, to increase the peak ACh sensitivity of the neurons following innervation.

Lumbar sympathetic ganglia were dissociated and maintained in vitro for 2-3 days before the addition of dorsal spinal cord explants containing the preganglionic column of Terni. Innervation is established between 24 and 48 hours of co-culture, as evidenced by whole cell recording of spontaneous synaptic currents (PSC's) in neurons voltage clamped near rest potential ($V_H$=-60mV). The PSC's are abolished by addition of 1 um curare to the recording medium and the extrapolated reversal potential is -7mV, the same as for ACh-induced currents (Role, PNAS 81:2924, 1984) consistent with a cholinergic innervation. The amplitude histogram for ~475 synaptic events in one cell was bimodal with peaks at 20 and 40 pA. 1 um tetrodotoxin decreases the frequency of PSC's by 5-25 fold; The remaining PSC's average 23 pA amplitude. Preliminary single channel recording experiments indicate a single amplitude class of ACh channels which, at rest potential, are ~3pA, suggesting that synaptic currents may be comprised of only 6-12 simultaneous channel openings. Therefore, the total number of ACh channels available for synaptic activation might be an important regulatory step in transmission.

To test this possibility neurons grown in the absence of preganglionic input were compared with neurons co-cultured with dorsal spinal cord explants in their development of ACh sensitivity. Neurons were voltage clamped ($V_H$=-60mV) and known concentrations of ACh applied from a nearby pressure ejection pipette. Peak inward current is dependent on ACh concentration, maximal at 100uM and half maximal at 35uM ACh. The slope of the linear portion of the Hill plot (from 2 to 50uM) indicates a Hill coefficient of 1.2 (r= 0.99). Neurons grown in the absence of preganglionic input were relatively insensitive to ACh (100uM; peak current <100 pA, n=9). In contrast peak ACh-currents in innervated neurons of sibling cultures were 4-20 times greater (16 of 18 neurons tested). Neurons in cultures containing explants but without synaptic input were also more sensitive than neurons grown alone (peak current >100-400 pA, n=11). Thus, presynaptic input regulates the transmitter sensitivity of autonomic ganglion cells in vitro. The increase from approximately 10 to >600 ACh channels per cell reflects a dramatic inductive influence of presynaptic input.

223.12 BIOCHEMICAL EFFECTS IN RATS AFTER LONG TERM TREATMENT WITH FLUVOXAMINE AND CLOVOXAMINE: POSTSYNAPTIC CHANGES.

L.D.Bradford, M.Th.M.Tulp* and J.Schipper*. Dept Pharmacoloy, DUPHAR B.V., P.O.Box 2, 1380 AA Weesp, Holland.

Postsynaptic changes after fluvoxamine (FLUV, a specific 5-HT uptake inhibitor), DMI (NA uptake inhibitor) and clovoxamine (CLOV, which has a dual action in blocking reuptake of both NA and 5-HT) were studied after chronic treatment. Administration of FLUV and DMI (20 mg/kg for 21 days) results in a subsensitivity of the β-adrenergic system, as evidenced by a decrease in $^3$(H)-DHA (dihydroalprenolol) binding sites (Bmax) and a reduction of the isoprenaline stimulated adenylate cyclase response (Racagni and Bradford, 1984). Administration of CLOV twice daily (10 mg/kg i.p.) resulted in a decreased cAMP response, but no change in Bmax. In order to determine if the short plasma half life of CLOV in rats could account for the lack of change in Bmax, we compared the sensitivity of the β-adrenergic system after chronic administration of CLOV (t =1hr) and DMI (t =12hr) via twice daily i.p. injections with that via an osmotic minipump in equivalent doses (20 mg/kg/day) for 21 days. Regardless of the dosing scheme, the decrease in the β-receptor coupled response was similar for both compounds. The alteration in β-receptor number did not correlate with the decrease in adenylate cyclase activity. These data support a multistep process of the down regulation of the β-adrenergic system in which the first step is the uncoupling of the receptors resulting in a decrease in the agonist-stimulated adenylate cyclase without necessarily a change in Bmax.

Chronic treatment with all three compounds resulted in a decrease in 5-$HT_2$ ($^3$(H)-Spiroperidol-labeled) receptors in frontal cortex.

Although acutely FLUV has no effect on the β-adrenergic system and DMI no effect on the 5-HT system, adaptational changes on NA and 5-HT systems are observed after chronic treatment with these compounds. These data taken together indicate a functional coupling between the NA and 5-HT systems which may be important in antidepressant mechanisms of action.

Ref: G.Racagni and D.Bradford (1984) Proc. 14th CINP Congress, Florence, Italy: 733.

223.13 PRESYNAPTIC ADAPTATIONAL CHANGES AFTER LONG TERM TREATMENT WITH CLOVOXAMINE. J.Schipper* and L.D.Bradford (Sponsor: P.Bevan). Dept Pharmac., DUPHAR B.V., P.O.Box 2, 1380 AA Weesp, Holland.

There is increasing evidence that longterm treatment with antidepressants induce adaptational changes in pre- and postsynaptically localized transmitter receptors. There up- and down-regulations of transmitter receptors might have important implications for elucidation of the mode of action of antidepressant drugs as well as for the pathophysiology of affective disorders. In this study we evaluated the presynaptic adaptational changes after clovoxamine (CLOV, which blocks NA and 5HT uptake) and desmethylimipramine (DMI, which blocks NA uptake).

CLOV and DMI were administered for 21 days (20 mg/kg/day) either by twice daily i.p. injection or by osmotic minipumps. After a 24 hr washout period, the functional response mediated by alpha$_2$ and 5$HT_1$ receptors was measured using the $^3$(H)-5HT release from cerebral cortex slices in a superfusion system. In slices from control animals the $K^+$ stimulated $^3$(H)-5HT release was inhibited 74±4% by adding 1 μM 5HT to the superfusion medium. In slices from CLOV and DMI treated rats, 71±10% and 73±8% inhibition was found, indicating the absence of 5$HT_1$ autoreceptor subsensitivity. Administration of 1 μM clonidine (alpha$_2$ agonist) resulted in 40±4% inhibition of $K^+$ stimulated 5HT in slices from control animals which was not significantly different in slices from CLOV and DMI treated rats (41±8% and 37±8%, respectively) indicating the absence of subsensitivity of alpha$_2$ receptors. MHPG levels in cerebral cortex were unchanged after longterm DMI and CLOV treatment, indicating an unaffected NA turnover. It was also determined that 5HT, 5HIAA, DA, HVA and DOPAC levels in the striatum were unchanged after treatment, suggesting a normal 5HT and DA turnover. The only observed change after CLOV and DMI was a reduction of 5$HT_2$ receptor binding sites and a down regulation of β receptor coupled adenylate cyclase (Bradford et al, this meeting). Taken together, these data indicate that a functional down regulation of the postsynaptic β adrenergic receptor system is not necessarily paralleled by adaptional changes in presynaptic processes.

224.1 PURIFICATION OF CRAYFISH GAD AND PREPARATION OF MONOCLONAL ANTIBODIES. R. M. Grossfeld and S. A. Hunter*. Zoology Dept., N. C. State Univ., Raleigh, NC 27695-7617.

Glutamic acid decarboxylase (GAD) activity is maintained for 2 weeks in isolated peripheral nerves of crayfish despite the coincident loss of CAT and AChE activities (Sarne et al., Brain Res. 110:91-97, 1976). GAD activity is lost rapidly from these nerves, however, when an inhibitor of protein synthesis is included in the culture medium. Since glial cells are the primary cellular site of protein synthesis in the isolated nerves (Sarne et al., Brain Res. 110:73-89, 1976) Sarne and co-workers have suggested that these cells are a major source of the nerve's GAD.

Our ultimate goal is to determine whether glial cells of crayfish nerve possess GAD immunoreactivity. We have produced monoclonal antibodies using a partially purified crayfish GAD as the antigen. The starting material for preparation of the antigen is the supernatant of an homogenate of crayfish CNS tissue, which possesses about 75% of the total GAD activity and a comparable fraction of the protein; the GAD activity of the homogenate is stable for at least two months despite repeated freezing and thawing. GAD has been partially purified by subjecting the supernatant to conventional gel filtration chromatography on Sephadex G-200 and ion exchange chromatography on DEAE-cellulose. The estimated molecular weight is about 15,000 when GAD is eluted from Sephadex with phosphate buffer containing 2-mercaptoethanol and pyridoxal phosphate.

The partially purified enzyme preparation has been injected into BALB/c mice, which provide spleen cells for generation of colonies of hybridoma cells. Several colonies of cells secrete antibodies which bind strongly to the GAD preparation as revealed by the ELISA technique. We are currently assessing the specificity of the antibodies for GAD using Western blots of the partially purified nerve homogenate after its electrophoresis in non-denaturing gels. (Supported in part by N. C. Agricultural Research Service Project 5582).

224.2 MEMBRANE FLUIDITY CHANGES IN NEUROBLASTOMA CELLS FOLLOWING DIFFERENTIATION BY GANGLIOSIDES OR PROSTAGLANDIN TREATMENT. M.F.D. Notter and J.F. Leary* Departments of Anatomy and Pathology, University of Rochester Medical Center, Rochester, NY 14642.

Neural cell lines have served as model systems to study neuronal development and differentiation in vitro. We have examined changes in membrane fluidity of mouse neuroblastoma cells following differentiation utilizing fluorescent membrane probes and fluorescence polarization. $N_2AB$-1, a subclone of the neuro 2a mouse neural line, was treated with prostaglandin $E_1$/cyclic AMP which induced morphological and biochemical differentiation after two days. Mitotic and differentiated cultures were trypsinized into single cell suspensions and treated with the following membrane conformational probes: 1,6-diphenyl -1,3,5-hexatriene (DPH), a probe of the hydrophobic core of the membrane; 1-(4-(trimethylamino)phenyl) 6-phenyl-1,3,5, hexatriene (TMA-DPH), a probe of the membrane surface; and 8 anilino-1-naphthalene sulfonate (ANS) which occupies the head group interface region of lipid bilayers of membranes and some cytoplasmic structures. These compounds were used at 1 uM, 1 uM and 100 uM respectively. Cells were exposed to each compound for 30 min at 37° and then analyzed for fluorescence intensity and degree of fluorescence polarization at 360 nm at the single cell level by flow cytometry. Upon microscopic examination, it was seen that each probe bound to $N_2AB$-1 cells in a different pattern. DPH appeared in the membrane in a speckled fashion while TMA-DPH outlined the cell completely. ANS stained both cell membrane and cytoplasm. All three probes indicated an increased fluorescence polarization with differentiated cells as compared to mitotic cells. Cells were then treated with 500 ug/ml gangliosides to establish if exogenous glycolipid treatment altered membrane fluidity. Ganglioside treatment induced neuronal differentiation after 24 hrs and stimulated membrane uptake of these compounds as determined by an increase in tetanus toxin binding to live cells by immunofluorescence and cytometric analysis. Upon exposure to the three membrane probes, it was seen that ganglioside treated cells exhibit more fluorescence polarization with ANS and DPH which both partition within the cell membrane. Ganglioside treated cells showed no difference from control cultures when examined with TMA-DPH, a probe of the cell surface. These data indicate that membrane rigidity follows cell differentiation and that this may be due to an increased incorporation of membrane gangliosides.

224.3 MYO-INOSITOL METABOLISM IN 41A3 NEUROBLASTOMA CELLS: EFFECT OF HIGH GLUCOSE AND SORBITOL LEVELS. M.A. Yorek and B.H. Ginsberg.* Diabetes Endocrinology Research Center, Dept. of Internal Medicine, University of Iowa, Iowa City, IA 52240.

Decreased conduction velocity of peripheral nerves is very common in patients with diabetes. Changes in nerve membrane inositol phospholipids may be responsible at least in part for this problem and in vivo studies have indicated that diabetes may alter inositol metabolism in the peripheral nerve, but the physiological conditions causing this abnormality remain unclear. To ascertain the biological mechanism responsible for this disorder, we have developed a tissue culture system which mimics the altered carbohydrate environment that occurs in diabetes. Neuroblastoma cells were grown in normal conditions as well as in medium supplemented with 30 mM glucose, 30 mM fructose or 1 mM sorbitol. The growth rate of the cells was the same in all four environments as was the total amount of lipid phosphorus/mg of cell protein. Cells grown in the presence of glucose or sorbitol had altered inositol metabolism; both the inositol uptake and the incorporation into phospholipids were decreased by almost 25% in these cells. Fructose supplementation had no effect on either inositol transport or incorporation into phospholipids. Placing cells into glucose supplemented media resulted in an initial small decrease in inositol uptake but a full two weeks of growth in the modified media was necessary to obtain a maximum effect on inositol transport. The effect of glucose and sorbitol was rapidly reversible. After 24 h in normal media inositol transport was restored to control levels. The decrease inositol transport and incorporation into lipids seen with glucose or sorbitol supplementation results in a decrease in the total phosphatidylinositol content within the cell without changing the levels of the other phospholipids. In addition, the uptake of choline, serine or ethanolamine was unaffected by the supplemental conditions. Because the presence of 30 mM fructose had no detrimental effect on the cell metabolism, the reduced inositol uptake observed in this system is probably not due to a change in the osmolarity of the medium. Although glucose may be partially reducing inositol uptake by competing for transport, the time course of the effect implies a more complex mechanism is involved. It is possible that sorbitol or an unidentified intermediate common to both glucose and sorbitol may be responsible for this effect or that glucose or sorbitol may be inducing a membrane change resulting in a suppression of inositol transport. These results suggest that the high circulatory levels of glucose and sorbitol which exist in unregulated diabetes may be partially responsible for some diabetic neuropathy. (Supported by NIH Grant AM25295.)

224.4 FODRIN: SKELETAL PROTEIN CROSS-LINKER IN RAT BRAIN SUBCELLULAR FRACTIONS. Robert Siman and Gary Lynch, Department of Psychobiology, Univ. of California, Irvine, Ca. 92717.

Fodrin is a major protein of mammalian neurons and is a variant of spectrin, a primary component of the cytoskeleton of erythrocytes. While fodrin has been hypothesized to link cytoplasmic actin filaments to neuronal membranes, there is no direct evidence for fodrin-cytoskeletal interaction. We have investigated this issue by immunoprecipitating fodrin from rat brain subcellular fractions with specific antibodies. The fodrin-antifodrin complexes were collected using protein A-bearing Staph. aureus, and the polypeptides co-precipitating with fodrin were identified by gel electrophoresis, peptide mapping, and Western blotting.

In crude microsomal (S2) fractions from cerebral cortex fodrin immunoprecipitates contained, in addition to the Mr= 240,000 fodrin subunits, polypeptides of Mr=300,000, 200,000, 180,000 and 46,000. The first was identified as microtubule-associated protein 1 (MAP1), the last as actin. The identity of the 200,000 and 180,000 polypeptides is currently under investigation. In S2 fractions from brainstem, polypeptides of Mr=300,000, 210,000, 160,000 and 70,000 co-precipitated with fodrin. The former was identified as MAP1, the latter three as the neurofilament triplet. These proteins were not directly recognized by fodrin antibodies, but rather were precipitated as a consequence of their association with fodrin.

To identify proteins associated with membrane-bound fodrin, the fodrin was extracted with low or high ionic strength buffer and immunoprecipitated as before. With either extraction method cortical fodrin co-precipitated with MAP1, MAP2 (Mr=270,000), and actin, while brainstem fodrin co-precipitated with MAP1, actin, and the neurofilament triplet. The fodrin-neurofilament interaction occurred via binding of fodrin to the Mr=210,000 polypeptide. These data demonstrate that fodrin binds to protein components of all three cytoskeletal systems of neurons. Fodrin may play a fundamental role in mediating cytoskeletal-membrane interactions in neurons, and in organizing skeletal proteins for their transit in the slow phase of axoplasmic transport.

224.5 STRUCTURE OF THE AXON HILLOCK AND INITIAL SEGMENT OF FROG DORSAL ROOT GANGLION CELLS. E. Matsumoto* and J. Rosenbluth (SPON: B. Pachter). Departments of Physiology and Rehab. Medicine, New York University School of Medicine, New York, NY 10016

The plasmalemma of the axon hillock (AH) and initial segment (IS) of frog dorsal root ganglion cells and the structure of the overlying satellite cells were examined in freeze-fracture replicas and thin sections. The concentration of P-face particles in the neuronal plasmalemma at the AH (~ 2500/μ2) approximates that in the cell body (CB) and IS membranes (~ 2000/μ2). In contrast, the E-face particle concentrations in the respective regions are strikingly different. The plasmalemma of the CB contains ~ 300 particles/μ2, while that of the AH contains ~ 1000/μ2 and that of the IS ~ 800/μ2. The particle concentrations in the latter two regions approach that at the node of Ranvier, and, moreover, particle size analysis reveals that these particles, like those at the node, include a high proportion (~35%) that are large (≥10nm). In contrast to the uneven particle distribution in the neuronal plasmalemma, particle concentrations in the satellite cell membrane are similar in all three regions (P-face, ~ 1500/μ2; E-face, ~ 1000/μ2). The gross structure of the sheath, however, varies considerably. Around the CB the sheath is composed of one to several thin satellite cell lamellae closely applied to the neuronal plasmalemma. The innermost layer is separated from the neuronal plasmalemma by ~ 10-50nm, and the outermost layer is covered by a basal lamina. At the AH, in contrast, the sheath is split into outer and inner components separated by a broad extracellular space, distinct from the endoneurium, into which trabecular processes of the satellite cells project. These processes are surrounded by a flocculent material similar to the matrix surrounding the node of Ranvier. The split sheath continues over the proximal portion of the IS to varying degrees, extending ~ 5 μ to more than 20 μ from the CB. Externally, the basal lamina of the CB sheath continues over the proximal IS sheath and onto the distal portion. In contrast to the CB sheath, that around the IS is very irregular. In some regions it consists of as many as 50 lamellae. In others, it exhibits node-like interruptions. Patches of dense axolemmal undercoating are also present in this region. Distally, the IS terminates at a heminode, where the satellite cell and the adjacent Schwann cell both extend multiple villous projections toward the axon over a length of ~ 1-3 μ. The axolemma in this region is undercoated as well. It is concluded from these results that the AH and IS of frog dorsal root ganglion cells and the satellite cell sheath surrounding the AH and IS have some of the structural characteristics of the axon and Schwann cell sheath at the node of Ranvier, suggesting functional similarities between the respective regions. Supported by grants from the NIH (NS 07495) and Muscular Dystrophy Association.

224.6 EFFECTS OF OLIGODENDROGLIAL DEFICIENCY ON DEVELOPING AXONS AND AXOLEMMA OF RAT OPTIC NERVE. J.A. Black, M.D. Feliciano*, S.G. Waxman, and B.R. Ransom. Dept of Neurology, Stanford Univ. Sch. of Med., V.A. Med. Ctr. Palo Alto, CA 94305.

The normal sequence of gliogenesis in the rat optic nerve was disrupted by neonatal treatment with 5-azacytidine (5-AZ). This protocol markedly reduced the number of glial cells, especially oligodendrocytes, and myelin sheaths observed in 15 day old rats. Thus, the structure of developing axons and axolemma may be studied in the absence of normal axo-glia interactions.

Rat pups were given subcutaneous injections of 5-AZ at a dosage of 3.3 mg/kg. 5-AZ was dissolved in PBS at a concentration of 3 mg/ml. Injections commenced the day following birth, and were given once daily until 15 days of age.

Control and 5-AZ-treated rats were perfused with 2% glutaraldehyde and 2% paraformaldehyde in 0.14 M phosphate buffer containing 0.1 M sucrose, and was processed by conventional methods.

Morphometric analysis of optic nerves from 2 and 15 day control and 15 day 5-AZ rats was performed. The values are mean ±S.D.

| | 2 d cont. | 14 d cont. | 14 d 5-AZ |
|---|---|---|---|
| | | Optic nerve diameter (μm) | |
| | 186.0±15.3 | 346.4±17.3 | 302.7±38.5 |
| | | Volume density (%) | |
| unmyel. | 53.0±8.0 | 29.2±6.6 | 46.9±8.4 |
| myel. | 0. | 27.0±7.0 | 0.1±0.1 |
| glia | 32.0±9.9 | 36.6±8.4 | 50.7±8.5 |
| e.c.s. | 13.0±3.6 | 6.0±3.1 | 1.6±1.1 |
| bl. v. | 1.0±0.5 | 0.9±2.6 | 0.7±2.2 |
| | | Glial cells/1000μm$^2$ | |
| | 4.3±0.7 | 2.8±0.3 | 3.1±0.4 |
| | | Axonal diameter (μm) | |
| unmyel. | 0.22±0.04 | 0.37±0.09 | 0.38±0.09 |
| ensheath. | 0. | 0.53±0.11 | 0.63±0.15 |
| myelin. | 0. | 0.77±0.18 | 0.80±0.08 |

Analysis of freeze-fracture replicas of optic nerve fibers from control and 5-AZ-treated rats reveal the following intramembranous particle (IMP) densities (mean±SEM):

| Condition | P-face (IMP/μm$^2$) |
|---|---|
| 2 d control unmyel. | 512±50.7 |
| 15 d control unmyel. | 431±17.4 |
| 15 d control internode | 1010±74.1 |
| 15 d 5-AZ (<0.5 dia.) | 651±62.2 |
| 15 d 5-AZ (>0.5 dia.) | 917±34.9 |

These data suggest that gliogenesis in the rat optic nerve may be suppressed by treatment with 5-AZ, and that axonal and axolemmal differentiation may occur in the absence of normal glial interactions. (Supported by NIH NS-15320, NMSS RG-1231 and VA Med. Res. Svc.)

224.7 AN UNUSUAL MEMBRANE SPECIALIZATION IN PRIMARY CULTURE OF THE RAT CEREBRAL CORTEX. J.-H. Tao-Cheng and M. W. Brightman*, Laboratory of Neurobiology, NINCDS, NIH, Bethesda, Maryland 20205

Cerebral cortex from 2 day to 4 week old rats were cultured for 8 to 23 days and processed for freeze-fracture electron microscopy to study their membrane structure. We have found fairly frequently an unusual membrane specialization which consists of parallel rows of particles in both P and E fracture faces. The rows form a slight prominence on the P face and a shallow depression on the E face. The size of the particles and the distance between the particles vary. The length of the rows is usually about 100nm but there are a few that are smaller. The interval between rows is fairly constant at about 35nm. The rows may form a column of 3-10 rows, with 5-6 being the most common. Instead of columns, some rows form an arc or a complete circle where the rows radiate from a particle-free center. In these cases, the total number of rows can reach 30-40. Caveolae usually lie near the periphery of the rows, and the E face has an unusually high density of background particles. The only other specialization within the same membrane is the gap junction. Since no assemblies, tight junctions or characteristic elongated particles are found in the same membrane as the particle rows, the cells are probably neither fully expressed astrocytes nor differentiated oligodendrocytes.

The particle rows resemble the "ciliary necklace" of ependymal cells in vivo in the regular periodicity of the rows, in the size and spacing of the particles, but not in the configuration of the rows. Small patches of similar particle rows have been described in the cell membranes of developing ependymal cells in vivo from 17-21 day fetal rats but not in older animals. If the particle rows are ciliary, they appear in the plasma membrane first, then either migrate or are carried into the ciliary membrane as the cilium begins to elongate.

Although the particle rows in vivo are a feature of immature ependymal cells, it is unlikely that the particle rows in vitro belong to donor ependymal cells that had dedifferentiated because (1) ependymal cells only comprise a very small proportion of cells in primary brain cultures, and (2) the occurrence of the particle rows in our cultures is too frequent to be accounted for by the few ependymal cells. Thus, the particle rows in vitro are probably expressed by a type of non-ependymal glial cell which is most likely in immature forms.

224.8 THE DIFFERENTIATION OF MEMBRANE STRUCTURE IN CULTURED ASTROCYTES. D.M.D. Landis, L.A. Weinstein, and E.L. Coe. Neurology Service, Massachusetts General Hospital, Boston, MA 02114

Assemblies of orthogonally-packed, uniform intramembrane particles are highly concentrated in astrocytic membranes investing blood vessels and forming the surface of the brain, and are less common in astrocytic processes adjacent to neuronal membranes. Astrocytes in primary culture also can acquire assemblies in the presence of certain media, but the assemblies tend to be more uniformly distributed across the cell surface. We have examined the influence of various tissue culture media and substrates on the density of assemblies, their distribution over the cell, the proportion of cells expressing them, and the rate of cell proliferation.

Astrocytes were obtained from the forebrains of 1-2 day rat pups with a combination of mincing and enzymatic digestion, plated in 75cm$^2$ flasks, and fed with new L15 medium plus 20% fetal calf serum at 3 day intervals for 7-10 days until confluent. The cells were re-plated in petri dishes, using methods slightly modified from those of McCarthy and deVellis, and the culture conditions then systematically altered. The rate of growth was estimated by counting cells in a selected field, the proportion of astrocytes estimated by determining the number of cells with glial fibrillary acidic protein, and membrane structure was examined after aldehyde fixation.

The density of assemblies and the proportion of cells expressing assemblies were coordinately affected by the lot of fetal calf serum used to supplement the media. With the most effective fetal calf serum, 89% of the cultured cells manifested assemblies, with a mean density of 20.17/sq micron. With the least effective lot, 62% of cells expressed assemblies, with a mean density of 2.08/sq micron. Addition of glucocorticoid or alteration of potassium concentration in the medium had little effect. The proportion of GFAP+ cells did not vary appreciably.

Although astrocytic membranes adjacent basal lamina in vivo have the highest concentrations of assemblies, culture of astrocytes on a collagen substrate was essentially similar to culture on the plastic alone or on a poly-lysine substrate. Astrocytes grew very rapidly on basal lamina laid down by primary cultures of bovine cerebral endothelial cells, but there was no change in assembly density or distribution.

Various fractions of fetal calf serum are being compared to determine the approximate molecular weight of the component(s) affecting assembly density in cultured astrocytes.

224.9 ANOXIA DOES NOT ALTER MEMBRANE STRUCTURE IN CULTURED ASTROCYTES. L.A. Weinstein and D.M.D.Landis. Neurology Service, Massachusetts General Hospital, Boston, MA, 02114. (SPON: J.J. Halperin)

Freeze-fracture studies of the mammalian nervous system have revealed large numbers of "assemblies", orthogonally-packed aggregates of uniform particles, in the membranes of the astrocytic processes investing blood vessels and forming the brain surface. Astrocytic processes surrounding neuronal structures have fewer assemblies. The function of this specialization of intramembrane particle distribution is unknown, but its concentration at the brain's interface with blood and cerebrospinal fluid suggests a capacity for transport across that interface.

In cerebellar cortex rapidly frozen within 35 seconds of circulatory arrest, the structure of assemblies in the glial limitans is altered, and in tissue rapidly frozen at longer intervals after decapitation there is a progressive disappearance of the particle arrays (J Cell Biol. 88:660, 1982). By contrast, membrane structure in neuronal processes is little changed over the same intervals. The selective vulnerability of astrocytic membrane structure parallels the emergence of swelling in the same processes.

In order to determine whether anoxia per se or some other sequela of circulatory arrest caused the change in membrane structure, we have used the more easily controlled system of primary astrocyte cultures. Astrocytes were obtained from 1-2 day rat pups using methods slightly modified from McCarthy and deVellis; 70-90% of the cultured cells are astrocytic as judged by glial fibrillary acidic protein immunoreactivity. A slightly smaller proportion have assemblies distributed fairly uniformly over the cell surface. Cultures were exposed to 95% nitrogen 5% $CO_2$ or 100% nitrogen (depending on the culture medium buffer system) and fixed with aldehydes after various intervals up to 30 minutes; some cultures were allowed to 'recover' in 95% oxygen and were then fixed. The fixed cultures were fractured, and the number of assemblies in their membranes was counted. We did not observe any change in assembly structure or any change in the range of assembly densities in the anoxic cultures.

We suspect that anoxia in isolation is insufficient to cause the changes previously observed in the astrocytic membranes of cerebellar cortex, and that changes in pH or potassium concentration may also have a role. It is also possible that aldehyde fixation is inadequate to detect the membrane alterations revealed by rapid freezing methods.

## NEURAL PLASTICITY IN ADULT ANIMALS II

225.1 AN ANALYSIS OF SYNAPTIC TRANSMISSION IN THE TRISYNAPTIC PATHWAY OF THE HIPPOCAMPAL FORMATION DURING KINDLING OF THE PERFORANT PATH. T. Sutula, O. Steward, Dept. of Neurology, Univ. of Wisconsin, Madison, WI 53792, and Depts. of Neurosurgery and Physiology, Univ. of Virginia, Charlottesville, VA 22908

Although kindling induces transsynaptic alterations (Messenheimer, et al., Exp. Neur., 1979), the nature of the transsynaptic alterations and the identity of pathways altered during kindling are uncertain. Kindling of the entorhinal cortex (EC) induces an increase in synaptic efficacy similar to long-term potentiation (LTP) in the monosynaptic pathway to the dentate gyrus (DG) (Douglas, Goddard, Brain Res., 1975), (Sutula, Steward, Neurol. 33 (2), 188, 1983). However, recent studies have shown that the DG is not necessary either for the development or maintenance of EC kindling. (Harrison, et al., Soc. Neurosci. Abstr. 10 (1), 346, 1984). Furthermore, repetitive induction of LTP at EC-DG synapses is not sufficient to induce kindling, but facilitates subsequent kindling by EC stimulation (Sutula, Steward, Soc. Neurosci. Abstr. 10 (1), 78, 1984). These observations indicate that LTP at EC-DG synapses cannot be the entirety of the mechanism of kindling, and direct attention to possible alterations in multisynaptic pathways as the underlying mechanism of kindling.

To evaluate the hypothesis that behavioral evolution of kindled seizures proceeds with progressive spread of evoked activity in multisynaptic pathways, the EC was stimulated, and evoked responses were recorded from the hilus of DG and the stratum lacunosum-moleculare of CA1. Input-output relationships were recorded in the monosynaptic pathway (EC-DG) and trisynaptic pathway (EC-CA1) prior to and during evolution of kindled seizures. A single kindling stimulus which evoked AD induced synaptic potentiation in the EC-DG pathway, and the smooth contoured negativity recorded at a latency of 10-12 msec from CA1 (Andersen, et al., Exp. Brain Res. 1966) was replaced by a sharp contoured negativity followed by a high amplitude positivity at 12-14 msec. The alterations in evoked responses recorded from the DG and CA1 developed after one afterdischarge, and persisted through class V seizures.

Increases in synaptic efficacy in multisynaptic pathways of the hippocampal formation occur early in the course of kindling, when behavioral seizures are minimal. The results direct attention to a possible role for synaptic potentiation in the emergence of epileptic activity in multisynaptic neuronal networks. Further study is necessary to define the cellular basis of the alterations in multisynaptic transmission and to determine whether synaptic potentiation develops at each link of the trisynaptic pathway during kindling.

225.2 LONG-TERM POTENTIATION IN LIZARD CEREBRAL CORTEX. J.R. Larson* and G. Lynch (SPON: H.D. Schwark). Center for the Neurobiology of Learning and Memory, Univ. Calif., Irvine, CA 92717.

Long-term potentiation (LTP) of excitatory postsynaptic potentials (EPSPs) following brief periods of high frequency synaptic activation is a prominent feature of mammalian hippocampus. Comparisons of this effect with synaptic plasticities found in more "primitive" cortices of non-mammalian vertebrates may yield important clues about the nature of its cellular substrates. Toward this end, we have developed a new in vitro preparation of reptilian cortex, a structure that bears striking anatomical and histochemical similarities to mammalian hippocampus.

Experiments were performed on desert iguanas (Dipsosaurus dorsalis). The entire cerebral cortex of each hemisphere was isolated and maintained in vitro. Stimulation of lateral (LC) or dorsal cortex (DC) or the pial surface of dorsomedial cortex evoked a short-latency monophasic negative field potential recorded at the pial surface of the medial cortex (MC). Laminar profiles suggested that the response reflected monosynaptic EPSPs generated by LC and/or DC afferents to apical dendrites of MC neurons.

Initial slope and peak amplitude of evoked responses were measured at 10-60 sec intervals for 10-60 min before and 20-300 min after high frequency stimulation (HFS) which consisted of 3-5 trains of 50-100 pulses at 100 Hz. HFS typically induced post-tetanic potentiation (PTP) which decayed within 5 min and LTP which decayed very little thereafter. In 18 of 20 experiments, the slope was at least 110% of control 20 min after HFS (mean ± s.e.m. of 143±5%). In five experiments, mean potentiation was 146% (±16%) 2 hr after HFS. The majority of experiments were performed at 35-40°C but LTP could also be induced at room temperature (24°C).

Experiments using two stimulation electrodes evoking responses in the same population of postsynaptic neurons indicated that the LTP effect was restricted to synapses activated at high frequency.

In contrast to the the reliable LTP seen in apical dendritic synapses of MC neurons, HFS of afferents to basal dendrites of the same neurons did not induce LTP (mean slope of 98±4% of control 15 min after HFS in ten experiments).

These experiments indicate that the in vitro reptilian cortex offers a stable and, compared to brain slices, relatively undamaged preparation that is well-suited for neurophysiological experiments. Moreover, it is clear that the reptilian cortex exhibits a form of synaptic plasticity similar, if not identical, to LTP but that the effect is not as widespread as is the case in mammalian hippocampus. Tests for biochemical and anatomical differences between the projections to the apical and basal dendrites of the MC neurons as well as between these and hippocampal synapses may provide suggestions about the substrates of LTP.

225.3 LONG-TERM POTENTIATION IN THE IN VITRO RAT HIPPOCAMPUS. P.G. DiScenna & T.J. Teyler, Program in Neurobiology, Northeastern Ohio Universities College of Medicine, Rootstown, OH. 44272.

We are presently working on three questions regarding the induction of LTP in area CA1 (Alger & Teyler, 1976; Schwartzkroin & Wester,1975). 1) Why is LTP so capricious? Given the standardization of procedures within a lab, why is the reliability of LTP induction often significantly less than 100%? 2)What, if any is the stimulus threshold for LTP in CA1? While there is evidence to suggest that higher intensity stimulation produces LTP more reliably (Lee,1983; Schwartzkroin & Wester, 1975), recent studies suggest that long-term changes can be elicited with intensities well below spike-threshold (Barrionuevo & Brown, 1983). 3) Is associative LTP limited to neighboring terminal patches or can this phenomenon be produced with inputs that are spatially distinct?

To these ends we are accumulating an internal data base as a control with which to compare the results of experiments aimed at answering these questions. 400um. slices of adult rat hippocampi were obtained using standard slice procedures and maintained in media containing 124mM NaCl, 3.3mM KCl, 2.0mM Ca, 2.0mM Mg, 10 mM glucose and 26mM bicarb. All experiments were run at least 90 min. after slicing. Stimulus intensity was set to elicit a field potential (recorded from the alvear side of the pyramidal cell layer) with a 0-2mv. spike driven from the stratum radiatum. The stimulating electrodes are 75um. tungston wire, sputter-coated with gold to produce a thin bipolar electrode which produces a near-negligible stimulus artefact (Chiaia & Teyler, 1982). The tetanus consisted of three bursts (200ms.) at 200Hz. delivered at 10 sec. intervals.

The initial analyses of 116 experiments (62 experiments monitored for 30 min. and an additional 54 monitored for 60 min.), demonstrated that 93 ( approximately 80%) developed increased synaptic efficacy relative to a 10 min. pre-tetanus baseline (eg. 100-1000% increase in population spike amplitude). PTP, which usually peaked at 500-1000% above baseline, was observed in all experiments with the exception of three cases (These three, however did demonstrate LTP). The decaying effect of PTP and the rising effect of LTP intersect during the 2-5 min. interval post-tetanus.

225.4 A CURRENT-SOURCE DENSITY ANALYSIS OF HIPPOCAMPAL CA1 REGION FOLLOWING LTP. J.S. Taube and P.A. Schwartzkroin. Dept. of Neurological Surgery, University of Washington, Seattle, WA 98195.

One puzzling observation concerning long-term potentiation (LTP) is that the population spike is potentiated more than expected given the potentiation of the population EPSP. An explanation for this differential potentiation is that there is some alteration in the distribution of current sinks or sources. Changes in the density and/or location of dendritic channels could lead to altered sites or thresholds for spike initiation. To test this hypothesis, we performed a current-source density analysis in the CA1 area of the hippocampus before and after a LTP-inducing tetanization.

Guinea pig hippocampal slices (400 um thick) were prepared and maintained in vitro at 35° C. Three extracellular microelectrodes spaced 30 um apart were aligned perpendicular to the CA1 pyramidal cell layer. The three electrodes were moved along a track perpendicular to pyramidale, at intervals of 30 um, from str. moleculare to str. oriens (s.o.). Bipolar stimulating electrodes were placed 200-300 um into str. radiatum (s.r.) to activate the Schaffer collaterals. Six responses were recorded at each point before and after a 100 Hz, 1 sec. stimulus train. The extracellular recordings were analyzed according to the methods of Freeman and Nicholson (J. Neurophysiol. 38:369-382, 1975).

For each experiment, 4 time points were chosen for analysis based on the waveform generated in pyramidale: 1) At a time point before the first positivity, a weak sink sometimes developed following LTP in proximal apical dendrites. 2) During the peak of the first positivity (pop. EPSP), a stronger sink developed in s.r. that varied in distance (0-100 um) from pyramidale. No movement of this sink was detected post-tetanization. A source was also consistently evident between pyramidale and 60 um into s.o. Both sink and source increased in intensity following LTP. 3) The time of the peak negativity (pop. spike) showed the most dramatic changes. Starting in s.r. and going toward s.o., a pattern of sink followed by source was initially evident. Following LTP, a second sink developed and the pattern became sink-source-sink. This pattern varied in location along the neuron axis, but usually began between 0-100 um into s.r. The peak of the source was relatively localized; after tetanization, it moved apically. 4) During the peak of the second positivity (pop. IPSP?), a source was present near pyramidale which grew in intensity following LTP.

These results are consistent with the idea that a stable dendritic sink is potentiated following LTP (i.e., EPSP potentiation). In addition, a novel sink develops post-tetanization, suggesting the induction of a new active zone in these cells and providing a possible mechanism for EPSP-spike dissociation. Finally, it appears that IPSPs are also potentiated by the tetanization.

These studies were supported by NIH grants NS18895 and GM07108.

225.5 CHANGES IN SYNAPSE DENSITY CORRELATE WITH LONG-TERM POTENTIATION IN THE DENTATE GYRUS AT SHORT SURVIVAL INTERVALS. N. L Desmond and W. B Levy. Dept. Neurosurg., Univ. of Virginia School of Medicine, Charlottesville, VA 22908.

Long-term potentiation (LTP) of the entorhinal cortex-dentate granule cell dendritic spine synapses correlates with several morphological changes 10 and 60 min following a spaced conditioning stimulation paradigm[1,2]. Here we report that these same structural correlates exist at shorter survival intervals following brief, high-frequency conditioning stimulation that induces LTP. Conditioning stimulation (24 8 pulse 400 Hz trains, 1 train/5 s) was delivered to one angular bundle. Animals were sacrificed 10 min (N=6) or immediately (2 min group, N=6) following the 24th train. Animals were perfused with mixed aldehydes. Blocks of dentate gyrus were prepared[1] for electron microscopy. Asymmetric shaft and spine synapses were identified double-blind on montages of the dorsal leaf molecular layer. Spine synapses were categorized by shape[1], and these counts were converted stereologically to number of synapses per unit volume of tissue ($N_V$). The middle third of the molecular layer is the region of primary synaptic activation during conditioning stimulation[1]. The $N_V$ for the entire molecular layer is unchanged at both survival intervals following conditioning stimulation, with control $N_V$ values of 2.44±0.09 and 2.32±0.18 synapses/$\mu m^3$ for the 10 and 2 min groups, respectively (mean±sem). In the middle molecular layer, $N_V$ decreases overall with potentiation (10 min group: 4.5% decline from control $N_V$ of 2.57±0.15, NS; 2 min group: 12.1% decline from control $N_V$ of 2.56±0.16, t=-3.063, $p<0.01$). At 10 min, the $N_V$ for concave spine synapses increases 35% from the control $N_V$ of 0.537 synapses/$\mu m^3$ in the middle molecular layer (t=2.108, $p<0.05$) while at 2 min the $N_V$ for concave spine synapses increases 15% over the control $N_V$ of 0.604 synapses/$\mu m^3$ (NS) there. The increased density of concave spine profiles in the middle molecular layer is accompanied by significant decreases in the density of non-concave (simple and ellipsoid) spine profiles there. At 10 min, the $N_V$ for non-concave spine profiles decreases 16.6% from a control $N_V$ of 1.820 synapses/$\mu m^3$ (t=-1.708, $p<0.05$). At 2 min, the $N_V$ for non-concave spine profiles declines 23.0% from a control $N_V$ of 1.757 synapses/$\mu m^3$ (t=-2.018, $p<0.05$). These data extend previously reported changes in spine synapses with LTP[1,2] and add further support to our[2] hypothesis of an interconversion of spine synapses with LTP. The absence of a marked time course of alterations in synapse density with LTP suggests that the interconversion of spine synapses from non-concave to concave occurs rapidly following the induction of potentiation and persists for at least 60 min after conditioning stimulation.

225.6 ULTRASTRUCTURAL IDENTIFICATION OF SYNAPSES OF THE CROSSED TEMPORO-DENTATE PATHWAY OF THE RAT. O. Steward and L. Davis*. Dept. of Neurosurgery, and the Neuroscience Program. Univ. of Virginia, School of Med., Charlottesville, VA 22908.

The crossed temporo-dentate pathway (CTD) from the entorhinal cortex (EC) to the dentate gyrus (DG) has proved to be an excellent site to investigate various types of synaptic plasticity, including long-term potentiation (Levy and Steward, Brain Res., 1979, 175: 233-245, and Neuroscience, 1983, 8: 791-797) and lesion-induced synapse growth. The structural features of CTD synapses have remained obscure, however, since electron microscopic studies have failed to reveal degenerating synapses in the contralateral DG after EC lesions. A clue to why this might be the case is that terminal degeneration of the CTD (as revealed by Fink-Heimer staining) disappears rapidly after lesions (i.e., by 5 days) (Goldowitz, et al., Exp. Neurol., 1975, 47: 433-441). In this regard, it is of interest that the ipsilateral temporo-dentate pathway exhibits two forms of degeneration: the dark dense variety, which is long lasting, and a lucent variety which disappears rapidly (Fifkova, Brain Res., 1975, 96: 169-175, Steward and Vinsant, J. Comp. Neur., 1983, 214: 370-386). It was thus of interest to ask whether the degeneration in the CTD might be of the electron lucent type.

The EC was destroyed unilaterally in adult male Sprague-Dawley rats. Forty-eight hours after the lesion the rats were perfused transcardially with 2% glutaraldehyde/2% paraformaldehyde in cacodylate buffer, and sections of the contralateral DG were prepared for routine electron microscopy. The middle molecular layer of the DG was scanned at high magnification for degenerating profiles.

Synapses exhibiting what appeared to be the electron lucent form of degeneration were observed in the middle molecular layer of the DG at 2 days post lesion. The electron lucent profiles could be demonstrated to be synapses because of the presence of a postsynaptic density. A few dark dense profiles were also observed, but none of the dark dense profiles appeared to make synaptic contacts, thus confirming previous reports of an absence of dark dense degenerating synapses in the contralateral DG after EC lesions. In general, the synapses appeared comparable to those of the ipsilateral temporo-dentate system, in that they terminated on spines. The results suggest that the CTD pathway undergoes exclusively the electron lucent form of degeneration, which accounts for the rapid disappearance of Fink-Heimer degeneration products at the light microscopic level. The reason for the lack of the electron dense form of degeneration is not clear. (Supported by NIH 12333 to OS).

225.7 TIME COURSE OF EMERGENCE OF LTP DURING REINNERVATION OF THE DENTATE GYRUS. T. Reeves, & O. Steward , Neurosurg. Dept., Univ. Virginia Med. Sch., Charlottesville, VA 22908

A current hypothesis regarding the mechanism of LTP is that the increase in physiological potency results from changes in spine shape, which alter the resistance of spines to current flow (Crick, 1982, Trends Neurosci., 5, 44-46; Rall & Rinzel, 1973, Biophys. J., 13, 648-688). One approach to testing this model is to measure the capacity for LTP in fiber pathways undergoing lesion-induced sprouting, where presynaptic structures form on spines of highly abnormal shape early in the reinnervation period. The crossed temporo-dentate (CTD) pathway does not normally exhibit LTP. However, following unilateral entorhinal cortex (EC) lesions the remaining CTD system sprouts, and at long post-lesion intervals will support LTP. This situation is of considerable interest because the synapses begin to operate early in the course of sprouting (Reeves, Smith & Jensen, 1983, Neurosci. Abstr., 9, 985), but at this time they contact abnormally stubby spines that lack narrow necks. If LTP is mediated through a regulation of spine shape one would predict that LTP would be severely disrupted early in the course of reinnervation.

Adult Sprague-Dawley rats received unilateral EC lesions, and survived for various post-lesion intervals (6 to 40 days). Rats were then anesthetized with chloralose-urethane and prepared for acute electrophysiological recording. A bipolar stimulating electrode was positioned in the intact EC, and glass microelectrodes were lowered into the dentate hilus of both hemispheres. Baseline evoked potentials were measured at a test frequency of 0.1 Hz, and then 8 high-frequency trains (400 Hz; duration 20 msec/train) were delivered. Field potentials were again evoked at the test frequency. The CTD system evidenced clear potentiation of the population EPSP as early as 8 days post-lesion (5-10% response increases); the capacity for LTP increased after 8 days, and reached an asymptotic level at around 16 days post-lesion (15-20% response increases). The ipsilateral temporo-dentate pathway, recorded simultaneously, showed similar increases (mean of 22.11%).

The capacity for LTP emerged between 8 and 12 days post-lesion, at a time when spines on the postsynaptic cells are structurally immature (Caceres & Steward, 1983, J.Comp.Neurol., 214 , 387-404; Steward, 1983, J. Neurosci., 3, 177-188). It seems doubtful that such spines would significantly attenuate current flow, and thus changes in spine shape would be unlikely to result in altered current injection into the dendrites. These results suggest that LTP can occur through some mechanism(s) other than changes in spine shape. Supported by NSF grant BNS-8021865-02 (O.S.) and NRSA fellowship NS-07199 (T.R.).

225.8 ALTERED SYNAPTIC REORGANIZATION, FOLLOWING PARTIAL DEAFFERENTATION OF THE RAT DENTATE GYRUS, DURING SHORT-TERM ETHANOL EXPOSURE. E. Orona, B. E. Hunter, and D. W. Walker. Veterans Administration Medical Center, Dept. Neuroscience and Alcohol Research Center, University of Florida College of Medicine, Gainesville, FL 32610.

The phenomenon of reactive synaptogenesis in the dentate gyrus following partial deafferentation was used to quantitatively assess the effects of short-term ethanol exposure. Two groups of adult male Long-Evans rats received unilateral electrolytic lesions of the entorhinal cortex. For the next 40 days, the rats were maintained on nutritionally complete ethanol- or sucrose-containing liquid diets. Horizontal 40 micron frozen brain sections were cut and processed for acetylcholinesterase (AChE) staining. The bandwidth and optical densities of afferent terminal fields were measured in the dentate gyrus using a computer based image analysis system (EyeCom II/DEC 11/23). Reorganization of the commissural/associational (C/A) and cholinergic (primarily septal) afferents was evaluated from 10 x 10 arrays of measurements in each blade of the lesioned and unlesioned dentate gyrus in each animal. These 10 x 10 data arrays consisted of measurements, perpendicular to the molecular layer (ML), made automatically at 10 equally-spaced positions along each blade in each of 10 equally-spaced horizontal sections.

Entorhinal lesion alone produced a 14% decrease in total ML width on the ipsilateral side, compared to the contralateral side; whereas ethanol treatment alone produced a 3% decrease in ML width. The lesion-induced expansion in the bandwidth of the C/A zone was reduced by about 50% in the ethanol, as compared to the control group. There was also less "clearing" of the C/A zone following the lesion in the ethanol animals, in terms of density of AChE staining. In both buried and exposed blades, the lesion-induced effects in the ethanol group were greater dorsally than ventrally. This was true although the ethanol group had generally lighter overall AChE staining than the control group, and although the staining was more intense dorsally than ventrally for both groups. In addition to the differences in the C/A zone on the lesioned side, the ethanol group had a greater "condensation" of AChE reaction-product in the outer molecular layer than did the control group.

These results coupled with previous data (West et al., Science, 218: 808-810, 1982) indicate that there is a significant alteration in the capacity for synaptic reorganization in the adult CNS following short-term dietary exposure to ethanol.

(Supported by the Veterans Administration, RCDA AA00065 to B.E.H., and NIAAA Grant AA00200 to D.W.W.)

225.9 REVERSIBILITY OF DENDRITIC SPINE DENSITY CHANGES IN RAT HIPPOCAMPUS AFTER CHRONIC ETHANOL CONSUMPTION. M.A. King, D.W. Walker and B.E. Hunter. Department of Neuroscience and Center for Alcohol Research, University of Florida, and Veterans Administration Medical Center, Gainesville, FL, 32610.

CNS pathology can often be observed in humans and animals after chronic ethanol exposure. Although some is due to neuronal death, and is therefore virtually permanent, it was not known whether surviving damaged neurons could exercise any regenerative ability. Human CT scan and neuropsychological data suggest that some recovery from cerebral atrophy and intellectual deficits can occur, and data exist to indicate that neurons possess a dynamic morphology. We quantified dendritic spine density in two neuronal populations in a between-groups design to investigate whether some reversibility from cellular neurotoxic sequelae of chronic ethanol consumption is possible.

Male Long-Evans rats were pair-fed 20 weeks with either nutritionally complete ethanol (8.1-9.7% v/v) (CET), or isocalorically substituted sucrose, liquid diets. The 2 x 2 design required sacrifice of 1 alcohol and 1 control group immediately following alcohol removal (A0, S0), and another pair of groups after an additional 20 weeks maintained on ad lib lab chow/water diets (A20, S20). Brains were coded and prepared with a modification of the Scheibels' rapid Golgi technique. Within the dorsal hippocampus, linear dendritic spine density was measured in strata oriens, proximal and distal radiatum, and lacunosum-moleculare for CA1 pyramidal neurons. Dentate granule neuron spine density was sampled in proximal-distal thirds of the molecular layer. In CA1, CET resulted in an initial non-significant reduction in spine density, but A20 group values were significantly higher after 20 weeks "abstinence" than A0, except in stratum lacunosum-moleculare. Granule cells initially showed a significant increase in spine density that also returned toward normal. No S0-S20 differences were found, and spine densities were comparable to those reported by others. Thus, even though differential initial effects were induced, the tendency to return toward normal spine density levels is consistent with the concept of neuronal recovery.

225.10 SELECTIVE LONG-TERM POTENTIATION IN THE PYRIFORM CORTEX. J. S. Stripling and D. K. Patneau. Department of Psychology, University of Arkansas, Fayetteville, AR 72701.

Electrical stimulation of the olfactory bulb (OB) produces an evoked potential (EP) in the pyriform cortex (PC) characterized by an initial surface-negative wave (period 1) with two components (A1 and B1) which represent, respectively, activation of PC pyramidal cells via the lateral olfactory tract, and feed-forward excitation within the PC. This is followed by a surface-positive wave (period 2) which is temporally associated with inhibition of PC pyramidal cells. Last year we reported that repeated high-frequency stimulation of the OB resulted in both short- and long-term potentiation in the PC which appeared to be selective to period 2, although our electrode placement did not permit a clear assessment of possible changes in B1 as well (Soc. Neurosci. Abstr. 10: 76, 1984). This led us to speculate that increased pyramidal cell excitability might mediate the potentiation of period 2 through recurrent inhibition. Such a mechanism would also result in the potentiation of B1 due to increased feed-forward excitation within the PC. Thus we examined B1 as an operational expression of pyramidal cell excitability.

Male Long-Evans rats were chronically implanted with electrodes in the OB and ipsilateral and contralateral PC. Experimental animals received high-frequency stimulation of the OB in the form of 30 trains delivered at 10-sec intervals; each train consisted of ten 400-microA, 0.2-msec pulses at a frequency of 100 pulses/sec. Control animals received the same number of pulses delivered at a lower frequency (1 pulse/sec). This procedure was repeated three times at 48 hr intervals. Consistent with our previous finding, the experimental treatments produced increasing amounts of short- and long-term potentiation of period 2 in the ipsilateral PC, while the control treatments had negligible effect. This potentiation persisted well beyond its apparent decay in latent form, permitting it to be re-established by low-frequency or paired-pulse stimulation which had little effect in controls. Potentiation of period 2 in the ipsilateral PC was accompanied by the appearance of a component in the contralateral PC of the same polarity and similar latency which could not be elicited in unpotentiated animals.

Neither A1 nor B1 was altered by the experimental treatment, arguing against the possibility that potentiation of period 2 is a consequence of increased pyramidal cell excitability. The polarity of the potentiated component in each PC and the absence of changes in period 1 suggest that investigation of long-term potentiation in the PC should concentrate on inhibitory mechanisms.

225.11 FUNCTIONAL CORRELATES OF SELECTIVE LONG-TERM POTENTIATION IN THE PYRIFORM CORTEX. D. K. Patneau and J. S. Stripling. Department of Psychology, University of Arkansas, Fayetteville, AR 72701.

Recent research from our laboratory has established a selective form of long-term potentiation restricted to late components of the evoked potential (EP) elicited in the pyriform cortex (PC) by olfactory bulb (OB) stimulation (see Stripling and Patneau, this session). The initial wave of the EP, representing both a mono- and di-synaptic EPSP in PC pyramidal cells, remains unchanged, while the second wave, temporally associated with IPSPs in PC pyramidal cells, is altered dramatically by high-frequency trains. The present experiment tested the hypothesis that this potentiation may reflect a functional increase in inhibition within the PC.

In naive animals paired-pulse stimulation produces facilitation of the mono-synaptic EPSP component of the EP (A1) and inhibition of the di-synaptic EPSP component (B1). Facilitation of A1 has been attributed to increased neurotransmitter release due to $Ca^{++}$ accumulation in presynaptic terminals (Bower & Haberly, 1984), while inhibition of B1 is apparently due to recurrent and feedforward inhibition within the PC (Haberly & Bower, 1984). We assessed functional inhibition within the PC by examining the expression of B1 at various interpulse intervals and current intensities in both potentiated and control animals. Paired-pulse depression of A1, a functional change observed only in potentiated animals, was also assessed.

Male Long-Evans rats with chronically implanted electrodes in the OB, ipsilateral PC, and contralateral PC received either high-frequency (100 pulses/sec) or low-frequency (1 pulse/sec) stimulation of the OB at 48 hr intervals. Potentiated animals displayed paired-pulse inhibition of B1 at longer intervals than did controls. Depression of A1 was also observed in potentiated, but not control, animals at brief paired-pulse intervals. This depression of A1 was correlated with a change in the potential recorded in the OB which may reflect increased inhibition of OB mitral cells, resulting in decreased transmission from the OB to the PC. The change in B1 inhibition, however, was not directly related to changes in either the potentials recorded in the OB or the size of A1.

These findings support the conclusion that LTP in the PC represents a selective enhancement of inhibitory mechanisms and suggests that a similar form of potentiation occurs within the OB. The implications of these findings for models of olfactory processing and the functional significance of long-term potentiation will be discussed.

225.12 ON THE ROLE OF POSTSYNAPTIC EXCITABILITY DURING LONG TERM POTENTIATION IN THE RAT SUPERIOR CERVICAL GANGLION. C.A. Briggs and D.A. McAfee. Beckman Res. Inst./City of Hope, Duarte, CA 91010.

Long-term potentiation (LTP) of nicotinic synaptic transmission in the rat superior cervical ganglion is accompanied by an hours-long potentiation of the evoked release of acetylcholine (ACh). While this presynaptic mechanism could account for LTP, our present experiments use exogenous cholinergic agonists to test the idea that postsynaptic mechanisms such as receptor potentiation may also contribute to LTP.

Ganglia were maintained in vitro (21°-24°C) by superfusion with oxygenated Locke's solution containing atropine (2 uM) to block muscarinic transmission. Nicotinic fast-EPSP's elicited by preganglionic stimulation were recorded by intracellular microelectrodes in single postganglionic neurons. Cholinergic agonists were applied by pressure ejection from an extracellular micropipette. Preganglionic tetanic stimulation (20 Hz, 20 sec) induced LTP of nicotinic synaptic transmission. The amplitude of the nicotinic excitatory postsynaptic potential (EPSP) was potentiated by 45%-220% and the amplitude of the depolarizing response to ACh or carbachol was increased by 12%-30% fifteen minutes after the tetani. Both ACh and carbachol are potent muscarinic agonists. Thus, it is possible that these exogenous agonists (0.3-1 mM in the pipette) surmounted the atropine (2 uM) antagonism, allowing the cell to express muscarinic rather than nicotinic potentiation. When dimethylphenylpiperazinium (DMPP; 30-300 uM in the pipette) was used as a selective nicotinic agonist, responses to its application were not potentiated during LTP even though synaptic responses were. LTP was not correlated with measurable changes in membrane potential or resistance in the postsynaptic neuron.

In three other experiments, the sucrose gap technique was used to record from a population of postganglionic neurons in response to preganglionic stimulation, and to superfused DMPP (100 uM, 30 sec). Both responses could be reversibly blocked by nicotinic antagonists. The postganglionic response to nerve stimulation was increased by 72%-103% 15 minutes after preganglionic tetani (20 Hz, 20 sec), but there was no increase in the response to DMPP.

Thus, nicotinic LTP does not appear to be accompanied by increased nicotinic receptor responses in the postsynaptic neuron. However, preganglionic tetani did appear to increase the response to exogenous ACh and carbachol, perhaps by postsynaptic potentiation of muscarinic responses.

225.13 METHOXYFLURANE DOES NOT BLOCK LONG-TERM POTENTIATION. D.L. Tauck and J.J. Kendig. Department of Anesthesia, Stanford University School of Medicine, Stanford, CA 94305

Long-term potentiation (LTP) is the increase in synaptic efficacy induced by a short burst of presynaptic stimuli. Although the mechanism underlying LTP is unknown, some anesthetics, ketamine and phencyclidine, block LTP while diazepam and sodium thiopental do not (Stringer and Guyenet, 1984, Brain Res. 258:159-164). We were interested in whether or not the volatile, general anesthetic methoxyflurane might interfere with the production of LTP.

Hippocampal slices prepared from male rats (100-150g) were maintained in vitro at 35±0.5°C. The slices were perfused with warmed, oxygenated saline from below and exposed to a flow of humid, warm 95:5 $O_2$:$CO_2$ gas across the top surfaces. A concentric bipolar stimulating electrode was placed in stratum radiatum of field CA1 to activate the Schafer-commissural fibers. An extracellular recording electrode was positioned in stratum pyramidale. Slices equilibrated for 2-1/2 hours after the dissection. By this time the amplitude of the evoked response had stabilized. Only those slices capable of firing at least an 8 mV population spike were studied.

The amplitude of the population spike was measured at several submaximal stimulus intensities to generate an input/output curve (population spike amplitude vs. stimulus intensity). After the input/output curve for a given preparation had been stable for 30 minutes, methoxyflurane was added to the $O_2$:$CO_2$ which aerated the perfusate and flowed over the slices. The concentration of drug in the gas was monitored near the slices. Another input/output curve was generated in the presence of the drug after an evoked response had been stable for 20 minutes. Methoxyflurane has no effect on the input/output curve at 0.1%, a concentration below the anesthetic range in humans (minimum alveolar concentration is 0.16%). Higher concentrations (0.2% and 0.3%) shifted the input/output curve to the right in a dose-dependent manner, depressing both the population spike and the underlying synaptic potential.

A tetanus (100 Hz), one second in duration, was presented at a stimulation intensity which evoked a 1-3 mV population spike. Fifteen and thirty minutes after a tetanus, the input/output curve was always shifted to the left - indicating the occurence of LTP - whether or not methoxyflurane was present. Therefore, unlike ketamine and phenacyclidine, methoxyflurane does not block LTP in the in vitro hippocampus.

225.14 DIFFERENTIAL INDUCTION OF ASSOCIATIVE LTP. S.R. Kelso and T.H. Brown. Division of Neurosciences, Beckman Research Institute of the City of Hope, Duarte, CA 91010.

Long-term synaptic potentiation (LTP) in the hippocampus has previously been shown to exhibit associative properties, whereby high-frequency activation of a weak synaptic input will result in a long-lasting enhancement of synaptic efficacy if, and only if, temporally paired with the activation of a separate, stronger synaptic input.

In the present study, three independent stimulating electrodes were placed in region CA1 of the hippocampal slice to stimulate Schaffer collateral/commissural projection fibers. Stimulation intensities were adjusted to elicit a weak synaptic response (200-300uV) with each of two electrodes (W1 and W2) and a much stronger synaptic response (2.5-3.0mV) with the third electrode (S). High-frequency stimulation delivered to W1 and W2 or to S alone (closed arrows), failed to elicit LTP in either W1 or W2. Stimulation trains were then delivered to all three synaptic inputs using differential paradigms (open arrows), in which trains to one weak input began 200 ms before trains to S (forward-paired) and the other weak input began 600 ms after trains to S (backward-paired). With these paradigms, the synaptic response to the forward-paired weak input exhibited associative LTP, while the response to the backward-paired weak input did not.

The occurrence of differential associative LTP demonstrates the potentiality of hippocampal synapses to express the type of associative plastic modifications that could provide a substrate for some of the functions in which the hippocampus is believed to participate. 225.15 **A MUSCARINIC AGONIST (ETHMOZINE) PREVENTS LONG-TERM POTENTIATION IN THE HIPPOCAMPAL SLICE.** J. Krontiris-Litowitz, J. E. Skinner, and L. Birnbaumer*, Sect. Neurophysiol., Depts. Neurol. and Cell Biol., Neurosci. Prog., Baylor College of Medicine, Houston, TX 77030

Long-term potentiation of synaptic efficacy (LTP) is a use-dependent cellular model for learning and memory. In the hippocampus both in vivo and in vitro studies have shown that beta-receptor stimulation is necessary for LTP to occur. Most learning disorders, however, have been associated with loss of cholinergic function. Beta-receptor stimulation of adenylyl cyclase is known to be regulated by cholinergic stimulation of the inhibitory regulatory protein, $N_i$. We therefore hypothesize that cholinergic agonists will inhibit LTP in the hippocampus.

In the CA1 region of the hippocampal slice (350 microns thick) population-spike field-potentials were evoked by low frequency (0.2 Hz) stimulation of the Schaffer collaterals. High frequency stimulation (HFS, 100 Hz for 2 secs) of these same axons was used to elicit LTP. In control experiments, all slices perfused with artificial CSF (CSF) demonstrated LTP (n=5). When lnM of Ethmozine, a muscarinic ligand, was applied to the bath during HFS, 5 of 7 slices failed to manifest LTP. Slices perfused with Ethmozine in the absence of HFS and then washed with CSF prior to the delivery of HFS demonstrated normal LTP (n=5). Thus Ethmozine plus HFS inhibits LTP.

In experiments where each slice served as its own control, HFS was delivered during perfusion with CSF (LTP1), then a second HFS was delivered during perfusion with 1 nM Ethmozine (LTP2). All slices demonstrated LTP1, but LTP2 was blocked in 8 of 15 slices. In the remaining 7 slices, LTP2 was significantly reduced in magnitude ($p<.05$). In 4 slices that had not demonstrated LTP2, a third episode of LTP was attempted, but could not be achieved (LTP3) until 3-h after washout (3 out 4 slices showed LTP3). This long-term effect was confirmed in three additional slices. First LTP was inhibited by pairing HFS with Ethmozine-treatment (1 nM). The Ethmozine was then washed out, and HFS presented once every 15 min. In all 3 slices LTP did not occur until approximately 3-h after washout.

Further studies indicated that the effect of Ethmozine is due to its muscarinic action. In a third series of experiments atropine (100nM) was co-perfused with Ethmozine (lnM) during the HFS. All slices demonstrated LTP (n=7). In a series of receptor binding studies in hippocampal homogenates, Ethmozine displaced [3H]-QNB (1.0 nM) from muscarinic receptors. The mean $IC_{50}$ of Ethmozine was $10^{-5}$M. We conclude that a muscarinic agonist, only in the presence of HFS, inhibits the development of LTP. This use-dependent long-term anti-LTP effect may have an important role in the process of learning and memory.

225.16 INCREASE IN THE MAGNITUDE OF LONG TERM POTENTIATION AFTER ENRICHMENT OF THE SLICED HIPPOCAMPAL TISSUE WITH GM1 MONOSIALOGANGLIOSIDE. A. Wieraszko* and W. Seifert. Max-Planck-Inst. f. biophys. Chemie, Dept. Neurobiology, 3400 Göttingen, W.-Germany.

Brief high frequency stimulation (HFS) of most hippocampal circuits evokes a long lasting increase in their synaptic efficiency. This phenomenon called long term potentiation (LTP) has attracted attention as a potential model for memory (G. Lynch and M. Baudry, Science, 224:1057, 1984). Although the molecular mechanism of LTP is still far from clear, most of the experimental evidence points to the synapse as locus of LTP. Among a variety of synaptic molecules, gangliosides are potential candidates. They are highly and specifically concentrated in nerve ending membranes and are involved in several events taking place at the synapse including direct participation in the neurotransmission (A. Wieraszko and W. Seifert, Neuroscience Letters, 52:123, 1984). The aim of the present investigation was to check whether a change in the ratio of individual endogenous gangliosides can influence the magnitude of LTP in the rat hippocampal slice.

LTP was induced by stimulation of Schaffer collaterals with 3 x 200 Hz, 10 sec intervals. The magnitude of potentiation was calculated taking into account the size of the population spike (record in pyramidal cell layer) before, 2 min and 15 min after HFS. Two approaches were used to modify endogenous gangliosides. First, slices were incubated for 3 hrs with neuraminidase from Vibrio Cholerae (0.13 U/ml). This enzyme liberates sialic acid from polysialogangliosides converting them into GM1. This treatment causes about 1.5-fold decrease in the level of polysialogangliosides and about 3-fold increase in GM1. The enzyme-treated slices showed a higher magnitude of potentiation 2 min (63 %, $n = 44$, $p < 0.001$) and 15 min (44 %, $n = 44$, $p < 0.05$) after HFS.

A similar increase in the size of LTP has been observed when slices were incubated with 71.4 μM GM1 for 3 hrs. It is well known that exogenous GM1 is incorporated into the nerve cell membranes becoming physiologically active. Both, enzyme and GM1 treatments had no influence on the size of the population spike when low frequency stimulation (0.06 Hz) was applied. It is concluded that enrichment of synaptic membranes in GM1 improves the tissue ability to demonstrate plastic changes.

225.17 SYNAPTIC STRUCTURAL ALTERATIONS FOLLOWING NEURONAL STIMULATION T.L. Petit, J.C. LeBoutillier*, and M. Klaiman*. Division of Life Sciences, University of Toronto, Scarborough, Ontario M1C 1A4.

Research from several different areas has indicated that structural changes may occur as a result of synaptic stimulation, suggesting that the synapse might be a critical element in the plastic response of the neuron. The present study was conducted to examine the effects of stimulation on the synapse, using a neurochemical stimulant, in vivo, to avoid the possible confounding effects of electrode damage or in vitro manipulations. Adult male Sprague Dawley rats were injected i.p. with 12 mg/kg kainic acid and observed for varying lengths of time before being sacrificed for neuroanatomical examinations. Kainic acid is known to be a powerful excitatory stimulant, driving cells of the CA3 area into high rates of firing. The axons of the CA3 neurons form the Schaffer Collaterals which project to the stratum radiatum of CA1 pyramidal cells; therefore, this area was examined in detail following kainic acid administration. Animals were anaesthetized and perfused with universal fixative, the hippocampus removed, and the CA area dissected and prepared for electron microscopy. Tissue blocks were stained with either osmium followed by uranyl acetate and lead citrate, or ethanol phosphotungstic acid (EPTA). Photographs were taken and examined with the Bioquant II Image Analysis System. The data indicate a general increase in synaptic parameters following neuronal activation.

This research was supported by a grant from the Natural Sciences and Engineering Council of Canada to T.L.P.

225.18 STRESS IMPAIRS LONG-TERM POTENTIATION IN RODENT HIPPOCAMPUS. Michael R. Foy, Mark E. Stanton, Seymour Levine & Richard F. Thompson. Departments of Psychology and Psychiatry, Stanford University, Stanford, CA 94305

The study of long-term potentiation (LTP) by means of the in vitro hippocampal slice preparation has proven to be both a popular and rewarding technique for investigating neural plasticity. It has been shown with this technique that a number of peripheral hormones and central neurotransmitters, which are associated with stress in intact animals, can modulate LTP when applied directly to the hippocampal slice. In the present study, we demonstrate an impairment of LTP in hippocampal explants taken from rats exposed to inescapable tail-shock.

One week prior to testing, adult male rats were pair-housed in climate controlled facilities on a 12 hr light/dark cycle with food and water available ad lib. One animal in each pair (Stress) was placed in a restraining tube and received tail shocks (1 mA, 1 sec) every minute for 30 min. The other animal in each pair (Control) was taken directly from the home cage and received no restraint or tail shock. In vitro hippocampal slices (400 um) were then prepared immediately from these animals according to standard methods. Extracellular recordings of the population field potential were taken from the CA1 cell body layer in response to stimulation (0.1 msec pulses) of Schaffer collateral afferents, before and after tetanus (100 Hz for 1 sec). There were no differences between the Stress and Control animals in cell excitability pre-tetanus as determined by the stimulus intensity required to produce a population field potential of constant amplitude (1 mV). Within the first minute post-tetanus, post-tetanic potentiation was found in both Stress and Control slices. In contrast, Control animals exhibited LTP (250% of baseline at 30 min), whereas Stress animals exhibited no LTP following tetanus (95% of baseline at 30 min).

These data indicate that stress can significantly modulate neural plasticity within rodent hippocampus. Some of the variability of results seen in previously reported LTP experiments may be accounted for by the behavioral state of the animal. These findings also demonstrate an interface between behavioral manipulations of the intact animal and neurophysiology in vitro in a mammalian model system. Finally, these data raise the possibility that the humoral status of the intact animal may be an important factor modulating in vitro neural plasticity.

225.19 ROLE OF BRAIN EXTRACELLULAR PROTEINS IN THE MECHANISM OF LONG-TERM POTENTIATION IN RAT BRAIN HIPPOCAMPUS. Victor E. Shashoua and Gary W. Hesse*, Ralph Lowell Laboratories, McLean Hospital, Harvard Medical School, Belmont, MA 02178

In previous studies in this laboratory (Science 212:1148-1151, 1981) long-term potentiation (LTP) of rat brain hippocampal slices was found to enhance the synthesis and release of proteins into the extracellular medium. Pulse-chase experiments (Brain Res. 306:61-66, 1984) showed that the releasable protein pool had an apparent half-life of about 4 h. The major components of this fraction are a class of brain glycoproteins (the ependymins) whose turnover rate increases following the acquisition of new patterns of behavior.

Investigations of the molecular properties of the ependymins indicate that these highly soluble extracellular proteins can rapidly aggregate to form an insoluble fibrous matrix if calcium is removed from the medium by the addition of the calcium chelating agent, EGTA, or by dialysis. This observation led to the proposed hypothesis (Cell. Molec. Neurobiol. 5:183-307, 1985) that the ependymins form an extracellular matrix at local sites where neurophysiological events can cause a transient depletion of $Ca^{2+}$. Such calcium depletion phenomena have been noted following stimulation of rat brain hippocampus in vivo and in vitro (Krnjevic et al., Can. J. Physiol. Pharmacol. 60:1643, 1982). The observed decrease of calcium following LTP is of sufficient magnitude to allow the polymerization of ependymins at the potentiated site and where the matrix formed might then be the framework for structural modification of synapses that have been reported for LTP. We have therefore prepared monoclonal anti-ependymin sera and used them to explore the possibility that ependymin aggregates form at specific sites following LTP. Potentiated, rat brain hippocampal slices were fixed and then stained with the antisera. Immunocytochemical studies at the light microscopic level show the presence of highly fluorescent sites within the stratum radiatum below CA1. Electron microscopic studies of these regions stained by the horseradish peroxidase and the ferretin labeled antibody method show the presence of multiple synaptic endings with extracellular matrices highly staining at local sites. Control unpotentiated slices stained by the same antibody procedure showed no such labeled sites. The results suggest that the ependymins may have an important function in the mechanism of LTP and raise the possibility that these extracellular glycoproteins may have a functional role in modifying neuronal connectivity patterns.

## ACTION POTENTIALS AND ION CHANNELS IV

226.1 DEVELOPMENT OF ION CHANNELS IN DROSOPHILA: LATE EVENTS. L. Salkoff. Dept. Anatomy & Neurobiology, Washington University School of Medicine, St. Louis, MO 63110.

An entire picture of developing membrane electrical properties can be observed in the flight muscles (DLM) of Drosophila. This is possible because the DLM can be voltage clamped throughout most of its development, and because mutant analysis aids in the separation of the various currents. The developmental history of membrane electrogenesis begins in the mid-pupal period and extends into the second day of adult life. Of five prominent extrajunctional ion currents which can be observed, only two are fully mature before the adult ecloses from the pupal case. These are the two voltage-activated potassium currents: the fast rapidly inactivating current, $I_A$, and the slowly activating current, $I_K$. A fast transient calcium current ($I_{Ca}$) is the third current to develop and rapidly matures at the time of adult eclosion. Surprisingly, two more ion currents develop in the adult stage: one is a fast, transient $Ca^{++}$-dependent potassium conductance ($I_{Acd}$) that reduces membrane excitability by restricting the amplitude of the spike-like muscle response; another is a late developing inward conductance (Ip) that increases membrane excitability by carrying a noninactivating persistent inward current.

The two late developing currents radically change the voltage responses of the adult DLM membrane. In very young adult cells subjected to a depolarizing stimulus, the membrane responds with action potentials that overshoot 0 mV and show little or no spike adaptation. In older adults the voltage responses no longer overshoot 0 mV and, when subjected to a stimulus of sufficient duration, the membrane undergoes a progressive depolarization that inactivates all transient currents. This results in a depolarized plateau response that can continue for two seconds or more.

Both fast transient $K^+$ currents, $I_A$ and $I_{Acd}$, function in the role of fast spike repolarization. However, the late developing current $I_{Acd}$ can apparently completely supplant $I_A$ in this role. This is seen in the mutants of the Shaker locus which completely eliminate $I_A$ (but not $I_{Acd}$). In young adult fibers before the development of $I_{Acd}$, spikes in mutant fibers are repolarized much more slowly than in wild-type. After the development of $I_{Acd}$, however, the spike repolarization rate in wild-type and mutant fibers is indistinguishable.

(Supported by NSF Grant BNS 8311024 to L. Salkoff.)

226.2 CLONING OF A GENE AFFECTING SODIUM CHANNELS IN DROSOPHILA. K. Loughney* and B. Ganetzky. (SPON: C.-F. Wu) Lab. of Genetics, Univ. of Wisconsin, Madison, WI. 53706

The $para^{ts}$ (paralytic, temperature-sensitive) mutation in Drosphila has been shown to block conduction of nerve action potentials in a temperature-dependent fashion (Wu and Ganetzky, Nature 286:814, 1980). This result together with genetic (Ganetzky, Genetics 108:897, 1984) and pharmacological (Suzuki and Wu, J. Neurogenetics 1:225, 1984) studies suggest that $para^{ts}$ affects sodium channels. To identify and characterize the product of this locus, we have cloned the para gene via transposon tagging. We isolated a new mutant allele, $para^{hd2}$, that arose by insertion of a transposable P element into $para^+$. In situ hybridization to polytene chromosomes confirmed the presence of a P element at the known cytological location of para. Reversion of $para^{hd2}$ back to wild-type was associated with loss of the element from this site.

Using the P element as a molecular "tag" we isolated a DNA fragment from the $para^{hd2}$ strain that mapped to the para region by in situ hybridization. This fragment was used subsequently to isolate from a wild-type library additional overlapping clones of DNA in the para region. The site of the P element insertion as well as an inversion breakpoint (both of which cause a para phenotype) have been localized within a few kilobases of each other on a molecular map of this region. The extent of the para gene is now being further localized by analysis of other chromosome rearrangements that cause para mutations. Attempts to identify the $para^+$ transcript and to isolate a cDNA clone are underway.

(Supported by research grant NS1539 and a Research Career Development Award NS00719 from the NIH.)

226.3 EXPERIMENTAL AUTOIMMUNE PARALYSIS ASSOCIATED WITH VOLTAGE-GATED SODIUM CHANNELS. Y. Rosenthal*, D. Teitelbaum*, T. Brenner* and H. Meiri (SPON: M. Gavish). Dept. of Physiology and Biophysics, Technion Faculty of Medicine, Haifa 31096; Dept. of Chemical Immunology, Weizmann Inst., Rehovot 76100; Dept. of Neurology, Hadassah Medical School, Jerusalem 91010, Israel.

A sodium channel-specific monoclonal antibody (mAb) denoted SC-72-38 modulates channel conductance (Barhanin et al., PNAS, in press). These mAb's bind to a channel epitope at the external surface of the membrane, depress in a dose-dependent reversible manner the compound action potential of mouse sciatic nerve, and label the channels at the node of Ranvier.

Within 7-10 days after injecting hybridoma SC-72-38 into the peritoneal cavity of isogenic mice (CD2F1), walking difficulties developed, followed by complete hind-leg paralysis. The onset and severity of the paralysis were correlated with the development of a myeloma in the peritoneal cavity and the accumulation of ascitic fluid there. This paralytic disease was specific to SC-72-38 and was not found with hybridomas that release mAb's against other sodium channel epitopes or irrelevant sites. Metastases were not found in the mouse nervous system until terminal stages of the disease. Neither hybridoma cells nor blood cells penetrated the peripheral nerve trunk.

Indirect immunofluorescence labeling revealed that hind-leg paralysis was accompanied by mAb infiltration into the sciatic nerve trunk. These mAb's bound to the channels at nodes of Ranvier, thereby depressing impulse conduction of mouse sciatic nerve. Internalization of mAb-channel complexes was then found.

A series of pathological changes was then developed in the Schwann cells that participated in the disease progression. Schwann cell identification was according to their bipolar structure and by the use of two specific markers: 1) a mouse mAb generated against myelin basic protein and 2) a rabbit polyclonal antibody generated against galactocerebroside.

At early stages of the paralysis, Schwann cells at internodal regions respond to mAb infiltration into the nerve by hypertrophy and by increasing their sodium channel density as revealed by immunofluorescence. These channels can then absorb the free mAb's dispersed among the nerve fibers. A partial recovery from the paralysis can then develop as the Schwann cells internalize channel-mAb complexes. However, the segmental demyelination that consequently develops causes severe paralysis. Proliferation of the Schwann cells is then started, and they migrate to the bare axolemma and remyelinate it. These reactive Schwann cells can then contribute channels to the remyelinated axons to support a temporary recovery of impulse conduction. However, continuous nerve invasion by the mAb's that are constantly produced by the proliferating hybridomas depresses the recovery process.

226.4 AGONIST-ANTAGONIST EFFECTS OF BUPRENORPHINE ON ACTION POTENTIALS OF FROG SCIATIC NERVE FIBERS. J. Lee* and G.B. Frank* (Spon. W.F. Dryden), Department of Pharmacology, University of Alberta, Edmonton, Alberta, Canada, T6G 2H7.

Most opioid antagonist drugs are antagonists at low concentrations and agonists at higher concentrations. Thus at low concs they will antagonize the effects of other opioid agonists but at higher concs they will have additive effects. Therefore these opioid antagonist/agonists do not fit the classical mechanism for 'partial antagonists'. This mechanism proposes that 'partial antagonists' produce a smaller effect when they occupy all the drug receptors in a tissue than the effect produced by 'full agonists.' At a high conc the 'partial antagonist' will displace the full agonist from the receptors and produce its maximum effect which is smaller and thus give the appearance of an antagonistic effect. Two further consequences of this mechanism are that at low concs the 'partial antagonist' will produce a response which is additive with the effects of other opioid agonists and that at high concs a complete antagonism will not be produced. Recently, it has been reported that some opioid drugs act like classical 'partial antagonists' (Martin, W.R. Pharmacol Rev., 35: 283,1983). One of these is buprenorphine whose effects we have investigated on the sterospecific opoiod receptor located on frog sciatic nerve A fibers (Hunter, E.G. and Frank, G.B. Can. J. Physiol. Pharmacol., 57: 1171, 1979). These opioid receptors are located on or near the intracellular openings of the sodium channels. The experiments were conducted at room temperature using small bundles of nerve fibres dissected from desheathed nerves. Action potentials were recorded from a sucrose gap apparatus in which the chambers were separated by rubber membranes. The drugs were added to an isotonic KCl solution in one of the end chambers. Thus to reach their site of action on the other side of the sucrose gap, the drugs had to diffuse through the axoplasm of the axons. Action potentials were recorded from 2 to 15 mins for the first hour and every 30 min thereafter. A typical experiment lasted 4 hr. In preliminary experiments it was found that $10^{-6}$ M buprenorphine produced about a 10% reduction in the action potential amplitude and $10^{-4}$ M produced about a 30% reduction. Naloxone, an often used opioid antagonist/agonist, had no effect at $10^{-8}$ M but at $10^{-4}$ M it reduced the action potential by 40%. At $10^{-8}$ M naloxone antagonized the effect of buprenorphine but at $10^{-4}$ M it had an additive effect. Meperindine, a full agonist, at $3 \times 10^{-4}$ M reduced the action potential by about 43%. Buprenorphine ($10^{-6}$ M) had an additive effect with this concs of meperidine but at $10^{-4}$ M it antagonized the effect meperidine. Thus the results obtained so far support the suggestion that buprenorphine acts like a classical 'partial antagonist' on this preparation.

226.5 BATRACHOTOXININ-A ORTHO-AZIDOBENZOATE: A RADIOACTIVE, PHOTOACTIVATABLE PROBE FOR THE BATRACHOTOXIN BINDING SITE OF VOLTAGE-SENSITIVE SODIUM CHANNELS. G.B. Brown. The Neurosciences Program and Dept. of Psychiatry, University of Alabama at Birmingham, Birmingham, AL 35294.

Several neurotoxins acting at the voltage-sensitive sodium channel of excitable cells have provided invaluable tools for the isolation, purification and assessment of the sub-unit composition of this important integral membrane protein. Thus, the tetrodotoxin-binding component has been purified to homogeneity in several laboratories from a variety of sources including rat brain (Hartshorne, R.P. and Catterall, W.A., J. Biol. Chem. 259:1667, 1984), rat muscle (Barchi, R.L., J. Neurochem. 40:1377, 1983) and electroplax of electric eel (Miller, J.A. et al., Biochem. 22:462, 1983). In each case a subunit of $M_r \sim 270$ kDaltons has been identified. In rat brain synaptosomes, α-scorpion toxin also labels two additional components of $M_r \sim 37$ and 39 kDaltons.

Batrachotoxin (BTX) binds to a sodium channel site distinct from that for either tetrodotoxin or α-scorpion toxin. It would therefore be of interest to determine the identity of the BTX-binding subunit. Since solubilization of the sodium channel results in loss of BTX binding (unpublished observation), the experimental approach to this problem must include covalent bonding of a BTX derivative in situ prior to solubilization and purification. To this end, a radioactive and photoactivatable derivative of BTX, [$^3$H]batrachotoxinin-A o-azidobenzoate (BTX-OAB), has been prepared by partial synthesis and found to retain binding affinity and specificity similar to that for BTX itself. The specific activity of this compound is 30 Ci/mmole. Radioligand binding experiments using a vesicular preparation from rat brain indicate that BTX-OAB in the presence of α-scorpion toxin binds to the BTX sodium channel site with a $K_d$=45 nM. Pre-irradiation of BTX-OAB with UV light (254 nm) reduces the extent of specific binding whereas irradiation of the pre-equilibrated toxin/tissue mixture results in irreversible incorporation of approx. 10% of specifically bound label. Initial experiments to identify the site(s) of covalent incorporation reveal that 90% of specifically-bound radioactivity is associated with a low-molecular weight, non-protein component, presumably of lipid origin, suggesting that the BTX binding site lies at the membrane lipid/channel protein interface. Additional studies to characterize the lipid component as well as the protein component(s) which incorporate BTX-OAB are in progress.

226.6 THE BLOCK OF BATRACHOTOXIN-MODIFIED Na CHANNELS BY TETRODOTOXIN IN NEUROBLASTOMA CELLS. L.-Y.M. Huang, Marine Biomedical Institute, The University of Texas Medical Branch, Galveston, TX 77550.

The block of single batrachotoxin (BTX) modified Na channels by tetrodotoxin (TTX) was studied in neuroblastoma NG108-15 using patch clamp techniques. BTX, a specific activator of Na channels, activated Na channels at hyperpolarized potential (e.g., -90mv) and eliminated both fast and slow inactivation (Huang, L.-Y.M. et al., P.N.A.S., 79:2082, 1982). This specific property of BTX-modified Na channels allowed us to study single Na channels under stationary conditions. Depending on membrane potential, the BTX-modified Na channels were open for tens to hundreds mS which was much longer than those observed in normal Na channels. After the application of TTX at concentrations ranging for 10-100 nM, the channel started to flicker between open and blocked states. The amplitudes of open channels were not affected. Both the histograms of open-state duration and block-state duration could be fitted with single exponentials. The blocking and unblocking rate constants were voltage-dependent. The blocking rate constant increased and the unblocking rate constant decreased when the membrane potential was hyperpolarized. The apparent dissociation constant calculated from rate constants was about 30 nM at 0 mV. This voltage-dependent block of TTX in neuroblastoma cells was qualitatively similar to the voltage-dependent block of saxitoxin observed in BTX-modified Na channels incorporated into planner lipid bilayer (French, R., et al., Biophys. J., 45: 301, 1984).

226.7 **SODIUM CHANNEL BECOMES RESISTANT TO IONIZING RADIATION WHEN ITS CONFORMATION IS MODIFIED BY BATRACHOTOXIN.** **J. E. Freschi and A. Moran*. Physiology Department, Armed Forces Radiobiology Research Institute, Bethesda, MD 20814.**

**We studied the dose-response relationship between gamma radiation and batrachotoxin (BTX)-stimulated sodium influx in neuroblastoma cells in tissue culture. We also tested the hypothesis that changes in sodium channel conformation may alter the radiosensitivity of the channel.**

**Experiments were done on N18 neuroblastoma cells in 24-well cluster trays. Cells were grown in Delbecco's Modified Eagles Medium supplemented with 10% (vol/vol) fetal bovine serum and 1 mM dibutyryl cyclic AMP for 3 to 4 days. Trays were irradiated in a cobalt-60 facility. Sodium fluxes were assayed using methods modified from those developed by Catterall (Mol. Pharmacol., 20: 356, 1982).**

**We found that gamma radiation inhibited toxin-stimulated $^{22}Na$ uptake at doses beyond a threshold of 200 to 300 Gy. Saturation of the response occurred at doses above 2000 Gy. Over the dose range of 200-2000 Gy there was no increase in nonspecific (leak) influx of $^{22}Na$.**

**To study the effect of channel conformation on radiosensitivity, N18 cells were irradiated under conditions that altered the fraction of sodium channels in the closed, inactivated, or toxin-opened states. Reduction of sodium permeability resulted when the cells were in the closed or inactivated, non-conducting states. However, when the cells were in the toxin-opened, conducting state, gamma radiation had no effect at doses up to 2000 Gy.**

**Our results support earlier electrophysiological studies that showed that high doses of ionizing radiation are required to produce a measurable decrease in sodium permeability. In addition, our data suggest that by changing the sodium channel conformation, BTX appears to alter radiosensitive chemical bonds in the gating or ion-conducting portion of the channel.**

226.8 USE-DEPENDENT BLOCK OF SODIUM-DEPENDENT ACTION POTENTIALS OF MAMMALIAN CENTRAL NEURONS IN CELL CULTURE BY SODIUM VALPROATE. M.J. McLean and R.L. Macdonald, Dept. of Neurology, Univ. of Michigan, Ann Arbor, MI 48104

Effects of sodium valproate (NaVP) were studied on action potential (AP) firing patterns of mouse spinal cord and cortical neurons in primary dissociated cell culture. Experiments involving intracellular microelectrode recording techniques were conducted in protein-free balanced salt solutions at 37°C. At concentrations equivalent to therapeutic anticonvulsant levels in cerebrospinal fluid (10-120 μM), NaVP limited sustained high frequency repetitive firing (SRF) of sodium-dependent action potentials elicited by long duration (450 msec) depolarizing current pulses in both spinal cord and cortical neurons without abolishing spontaneous activity. In NaVP-containing solution, the maximal rate of rise ($\dot{V}_{max}$), an index of the inward sodium current, declined with the firing of successive APs until firing failed. Steady-state hyperpolarization reduced or prevented the limitation of SRF. Identical paired pulses applied at variable intervals elicited APs at frequencies of 400-500 Hz in control solution, but only 50-200 Hz in NaVP-containing solution. $\dot{V}_{max}$ of a single AP elicited after a conditioning train required less than 50 msec to recover to the velocity of the first AP of the conditioning train in control solution and 90-350 msec in the presence of NaVP. Thus, the limitation of SRF by NaVP was use-, time- and voltage-dependent. The limitation appeared to result from slow recovery of sodium channels from inactivation. The accumulation of channels in the inactive state could then explain the use-dependent reduction of $\dot{V}_{max}$. The occurrence of this in vitro effect at therapeutic concentrations suggests that limitation of SRF is a plausible mechanism, at least in part, for the anticonvulsant action of NaVP.

226.9 MECHANISM AND SITE OF ACTION OF DELTAMETHRIN IN CRAYFISH AXONS. L.D. Brown* and T. Narahashi. Dept. of Pharmacol., Northwestern Univ. Med. Sch., Chicago, IL 60611

Deltamethrin is one of the most potent synthetic pyrethroid insecticides. It is classified as one of the type II pyrethroids which contain a cyano group at the α position. It has been shown that several type II pyrethroids modify the nerve membrane sodium channels to give rise to a prolonged current in much the same way as type I pyrethroids (without an α cyano group) do (Lund, A.E., and T. Narahashi, Pesticide Biochem. Physiol., 20:203, 1983). However, the degree to which the sodium current was prolonged was much greater with type II pyrethroids than with type I pyrethroids.

This study was aimed at elucidating the mechanism whereby deltamethrin prolonged the sodium current and determining the site of action in the channel. Intracellular microelectrodes were used to record resting and action potentials from crayfish giant axons (19.5°C). Membrane depolarizations of 10 to 40 mV occurred at deltamethrin concentrations between 0.3 μM and 10 μM. With prolonged exposure the action potential was blocked. Prolonged washing did not restore the axon to normal function. Tetrodotoxin (300 nM) antagonized the depolarization caused by deltamethrin indicating that sodium channels are responsible for the action.

In sucrose-gap voltage-clamp experiments with internally perfused crayfish axons (10°C), deltamethrin (10 μM) evoked a slowly decaying tail current following a depolarizing voltage step. The tail current accumulated with repetitive pulsing (1 Hz). The tail current declined to 50% of the initial amplitude within ~ 3 minutes and to baseline within 2 to 30 minutes.

Pretreatment of axons with (-)-cis tetramethrin (100 μM), an inactive type I isomer, has been shown to antagonize the action of the active (+)-isomers of tetramethrin (Lund, A.E., and T. Narahashi, Neurotox., 3:11, 1982). The depolarizing action of 1 μM deltamethrin on intact crayfish axons was not affected by pretreatment with (-)-cis tetramethrin (100 μM). In one sucrose-gap voltage-clamp experiment using an internally perfused axon in which (-)-cis tetramethrin (100 μM) and deltamethrin (10 μM) were perfused simultaneously, there was no antagonism between them. These data are indicative of separate sites of action in the sodium channel for the type I and type II pyrethroids.

226.10 MODULATION OF SODIUM CHANNEL GATING KINETICS BY DELTAMETHRIN. K. Chinn* and T. Narahashi. (SPON: S. Holloway). Dept. of Pharmacol., Northwestern Univ. Med. Sch., Chicago, IL 60611.

Pyrethroids have been shown to alter the kinetics of sodium current in squid and crayfish giant axons. Sodium current is maintained during prolonged depolarization and turns off slowly upon repolarization. The present study examines the effects of the pyrethroid deltamethrin on whole cell and single channel sodium currents of mouse neuroblastoma N1E 115 cells using patch clamp technique. Exposure to deltamethrin (10 μM), slightly reduced (~15%) the whole cell peak inward current evoked by a voltage step from -100 mV to -30 mV and markedly prolonged the current, producing a plateau phase. The decay of the modified current could be expressed by the sum of two exponential functions with time constants of ~5 msec and ~1.3 sec at 11°C, the slow time constant being two orders of magnitude faster than the time constant in modified axons. Tail currents observed on repolarizing the membrane back to -100 mV also decayed much faster (time constants ~2 sec and ~6 sec) than in the axons. The current-voltage curve after drug modification attained a peak at a potential 10 to 20 mV more negative than control, but the reversal potential was not significantly affected. Single sodium channel currents were evoked in excised patches by depolarizing the membrane from -100 mV to -30 mV. After drug application (10 μM), the mean channel open time became very prolonged (~1.7 sec at 11°C) compared to control preparations (~2 msec). Single channel current amplitudes were not affected by the drug. The summed average of single channel current traces obtained during depolarization showed that the drug did not affect the initial rising phase of current but that the current peaked at a later time (5-10 msec in control and ~50 msec after drug exposure). The averaged current declined slowly, attaining almost zero after 4 sec. The channels also remained open on repolarization for periods of up to 30 sec.

In conclusion, the pyrethroid deltamethrin lengthens the open time of individual sodium channels, thereby causing prolonged sodium currents during and after a depolarizing pulse. The modified channels open at potentials more negative than control. Supported by NIH grant NS 14143.

226.11 ACTION OF PUMILIOTOXIN-B (PTX-B) AT THE NEUROMUSCULAR JUNCTION.
K.S. Rao*, J.E. Warnick, J.W. Daly, and E.X. Albuquerque. (SPON: L. Goldman) Dept. Pharm. & Exp. Ther., Univ. Maryland Sch. Med., Baltimore MD 21201.

PTX-B, an indolizidine alkaloid obtained from the skin of the neotropical frog Dendrobates pumilio, facilitates and then depresses muscle twitches. The potentiation, unaccompanied by an effect on spontaneous transmitter release, acetylcholinesterase activity or on delayed rectification, was suggested to be related to events involving $Na^+/Ca^{2+}$ exchange (Albuquerque et al., Mol. Pharmacol. 19:411, 1981). The present investigation was carried out to yield further information about the action of PTX-B at the cellular level.

PTX-B, at concentrations as low as 50 nM, produced repetitive activity in the extrajunctional regions of glycerol-shocked muscle fibers of the frog, Rana pipiens. A single transmembrane stimulus evoked either a single action potential with prolonged negative after-potential or a train of action potentials with an average frequency of 60-100 Hz and lasting for >3 sec. In the train, each action potential was super-imposed on prolonged depolarizing after-potential (15-20 mV) of the preceeding action potential. The amplitude and duration of the depolarizing after-potential increased, the train duration decreased in a concentration-dependent manner. At a high concentration of PTX-B, (1.5 μM) the spike amplitude in the train progressively decreased and ultimately was blocked as the magnitude of the after-potential reached its peak (40-60 mV). It seems that the toxin induces repetitive action potentials by elevating and prolonging the depolarizing after-potential.

At low $[Ca^{2+}]_o$ (<300 μM), PTX-B neither induced repetitive action potentials nor prolonged the depolarizing after-potentials. On the other hand, high $[Ca^{2+}]_o$ (10 mM) and the substitution of $Ca^{2+}$ with $Cd^{2+}$ (500 μM) substantially suppressed the repetitive activity but did not abolish the depolarizing after-potential. Further, the toxin failed to induce repetitive activity when the $[Na^+]_o$ was 33% of normal. In addition to these postsynaptic effects, the toxin increased the electrical excitability of the motor nerve terminals and evoked repetitive endplate potentials that are suggestive of a presynaptic action. The data indicate that the toxin may act at presynaptic as well as at postsynaptic sites to evoke repetitive activity in response to a single stimulation. This repetitive activity may be explained by a change in membrane conductance parameters for $Na^+/Ca^{2+}$, which is critical for the generation of repetitive activity in the nerve and muscle. (Supported by USPHS Grant NS-12063.)

226.12 VOLTAGE-SENSITIVE, SPONTANEOUSLY OCCURRING CHLORIDE CHANNELS IN CULTURED SPINAL NEURONES.
*J.F. MacDonald, D.G. Owen and J.L. Barker. *Playfair Neuroscience Unit, Toronto, Canada and Laboratory of Neurophysiology, NINCDS, NIH, Bethesda, MD 20205, USA.

Depolarization of cultured mouse spinal neurones can result in the activation of a Ca-dependent $Cl^-$ current ($I_{Cl(Ca)}$) which may contribute to the regulation of membrane excitability in these cells (Owen, Segal and Barker, 1984). In order to assess the relative sensitivity of the gating of $I_{Cl(Ca)}$ to intracellular $[Ca^{++}]$ and membrane potential, patch-clamp recordings (inside-out configuration) were made from cultured mouse spinal neurones (2-4 weeks). $Cl^-$ channels were isolated using symmetrical Tris-Cl solutions containing 10mM $Na^+$ and 1uM TTX. The pipette solution also contained (mM): 1 $Mg^{++}$, 4 $Ca^{++}$. The bath solution contained 1mM $Mg^{++}$ and $[Ca^{++}]$ was varied between 0.01uM and 0.5uM. $Cl^-$ channels were observed in 20 of the 30 patches studied and at all $[Ca^{++}]$s, although in some cases they were latent for many minutes following patch formation. The dependence of channel activity on bath $[Ca^{++}]$ proved equivocal although channels were clearly active in many patches with free $Ca^{++}$ as low as 10nM. Some patches contained at least two classes of $Cl^-$ channel (based upon amplitude distributions), while in others there was apparently a single population. The following analyses were obtained for such a patch. All voltages refer to the pipette tip potential. Current amplitudes were normally distributed at all potentials between +/- 60mV. The elementary current-voltage relationship was curvi-linear such that the single channel conductance was 49pS at -60mV and 25pS at +60mV. Sub-conductance states were extremely rare in this patch and were not considered in the analysis. Channel openings were both infrequent and brief at positive tip potentials but increased in frequency and tended to occur in bursts at more negative tip potentials. At all potentials studied (-60mV to +60mV) the distribution of channel opentimes could be described by two exponential functions whose time constants (tau) varied with voltage ($tau_1$=ca. 1ms, $tau_2$=5ms at +30mV; $tau_1$=3ms and $tau_2$=23ms at -60mV). Opening probability increased at negative potentials (H=39mV), such that p=0.55 at -60mV. Although this population of $Cl^-$ channels would be expected to be most active at depolarized potentials in the whole cell, their identity and possible involvement in $I_{Cl(Ca)}$ remains to be established.

226.13 DIVALENT CATION PERMEABILITY OF N-METHYL-D-ASPARTATE CHANNELS.
M.L. Mayer and G.L. Westbrook. Laboratory of Developmental Neurobiology, NICHD, NIH, Bethesda, MD 20205

The reversal potential of currents evoked by selective agonists acting at kainate, quisqualate and NMDA receptors is similar and close to 0 mV (Mayer & Westbrook 1984 J. Physiol. 354: 29-53); single channel recording also suggests a non selective cationic mechanism since Cs ions permeate through ion channels linked to NMDA receptors (Nowak et al 1984 Nature 307: 462-465). The permeability of amino acid activated ion channels to divalent cations is unknown, but several results suggest differences between NMDA and non-NMDA receptor linked responses: replacement of Na by choline produces a more negative shift of the reversal potential of responses triggered by kainate than of those evoked by NMDA (Mayer & Westbrook 1985 J. Physiol 361: 65-90); Mg ions selectively block ion channels activated by agonists acting at NMDA receptors (Nowak et al 1984; Mayer & Westbrook 1985); in addition hippocampal LTP, which is blocked by intracellular injection of the calcium buffer EGTA (Lynch et al 1983 Nature 305: 719-721), is prevented by selective NMDA receptor antagonists (Collingridge et al 1983 J. Physiol 334: 33-46).

To directly examine the role of divalent cation permeability we measured the reversal potential of responses to the selective agonists NMDA and kainate in mouse spinal neurones under voltage clamp and bathed im media containing either 1 mM Ca + 140 mM Na or 20 mM Ca + 112 mM Na. The reversal potential of NMDA responses varied with the extracellular Ca concentration - 1 mM Ca: + 1.5 ± s.d. 1.0 mV, n = 8; 20 mM Ca: + 13.5 + 2.2 mV, n = 10. The reversal potential of responses to kainic acid was unaltered - 1 mM Ca: + 1.3 + 1.2 mV; 20 mM Ca: + 1.7 + 1.4 mV.

We then considered the possibility that ion channels linked to NMDA receptors behave as multi-ion pores (Hille & Schwarz 1978 J. Gen. Physiol 72: 409-442) and possible interactions between permeant monovalent cations, permeant divalent cations (Ca) and impermeant divalent cations (e.g. Mg). In media containing 100 μM Ca with no added Mg NMDA-activated currents have a positive slope conductance between -80 and 0 mV (Mayer & Westbrook, 1985). However on extending the current voltage relationship over the range -220 to + 30 mV we discovered a region of negative slope conductance between -90 to -150 mV; this may be a consequence of contamination by residual Mg estimated at 5 μM. At potentials negative to -150 mV NMDA current voltage plots show an increase in slope suggesting that Mg ions may permeate if the electric field is made large enough; Ca ions may also knock Mg ions past the blocking site since the NMDA current voltage plot at negative potentials became more linear in 5 mM Ca.

226.14 GAP JUNCTIONS: PERMEABILITY TO TEA AND CONDUCTANCE ARE PROPORTIONAL, SUGGESTING ALL-OR-NONE GATING.
V. Verselis*, R.L. White*, D.C. Spray, M.V.L. Bennett. Dept. of Neuroscience, Albert Einstein College of Medicine, Bronx, N.Y. 10461.

The permeability ($P_j$) of gap junctions to tetraethylammonium ions (TEA) was measured in pairs of blastomeres isolated from embryos of Rana pipiens. Junctional conductance ($g_j$) was quickly and reversibly modulated in a double voltage clamp procedure, and the changes in $P_j$ to TEA were evaluated. Intracellular activity of TEA was measured with ion-selective electrodes filled with Corning liquid ion exchange resin (code # 477317) which is highly selective for quaternary ammonium ions. $P_j$ to TEA was proportional to g among cell pairs that were maintained in the maximally coupled state (transjunctional voltage held at zero). $P_j$ for a 1 uS conductance was 6.5 E (-10) $cm^3$sec. When $g_j$ was reduced by application of a transjunctional voltage, the rate of transfer depended upon the polarity of the applied potential. Although equal $g_j$ values were obtained with $V_j$'s of equal magnitude but opposite polarity, moderate hyperpolarization of the TEA-injected cell greatly reduced the rate of transfer relative to similar hyperpolarization of the recipient cell. When corrected for the additional driving force that transjunctional voltage imposed on the TEA ions, $P_j$ was still linearly related to $g_j$. TEA ions are about 8A in diameter. Presumably $g_j$ is largely determined by permeability to K+ ions which are 6A in diameter. Thus the proportionality of TEA permeability to $g_j$ suggests that channel closure induced by voltage is all-or-none.

227.1 POTASSIUM CURRENTS IN FROG CARDIAC MYOCTYES. EFFECTS OF ACETYLCHOLINE, BARIUM AND POTASSIUM. M. A. Simmons and H. C. Hartzell*. Anatomy Dept., Emory University, Atlanta, Ga. 30322

Previous studies have revealed the presence of three K currents in the heart: a time-independent inwardly rectifying current ($I_{K1}$), a delayed outward current ($I_K$) and an ACh-activated current ($I_{ACh}$). Some disagreement exists regarding the exact number of components of these currents and whether or not each current is independent. This confusion may be partly due to the syncytial nature of cardiac tissue complicating the analysis of voltage-clamp studies using multicellular preparations. We have used the whole cell recording configuration of the patch-clamp technique to record potassium currents in enzymatically dissociated single cells from frog atrium. Na currents were blocked by TTX and Ca currents with Mn. In response to 100 msec voltage steps, a quasi-instantaneous current was observed, $I_{K1}$. The instantaneous current-voltage relation for $I_{K1}$ exhibited inward-going rectification with a negative slope between -60 and -20 mV. Ba (5-500 $\mu$M) blocked this current in a concentration-dependent manner (85% inhibition at 50 $\mu$M). Increasing $[K]_o$ greatly increased this current negative to $E_{rev}$. With longer depolarizations positive to -30 mV, a time-dependent outward current was observed, $I_K$. This current has been fully characterized according to its activation, time constants and ion transfer function. $I_K$ was maximally activated at +20 mV. The time constants of activation of $I_K$ were rather long, ranging from 1 sec at +30 mV to 4 sec at -30 mV. The fully activated current-voltage relation was linear. Ba (250 $\mu$M) did not affect $I_K$. The current elicited in response to iontophoretic ACh at different membrane potentials exhibited inward rectification. In contrast to $I_{K1}$, however, increasing $[K]_o$ decreased the ACh conductance negative to $E_{rev}$. Additionally, $I_{ACh}$ was less sensitive to Ba blockade than $I_{K1}$ (45% inhibition at 50 $\mu$M). ACh did not affect $I_K$. These results indicate that ACh does not act on the $I_K$ channel and that the K channel activated by ACh differs in its properties from the $I_{K1}$ channel. Hence, it is concluded that ACh opens a unique K channel in frog atrium.

227.2 ACETYLCHOLINE ALTERS THE CURRENT THROUGH THE INWARD RECTIFIER CHANNEL OF THYMUS CELLS IN CULTURE. F. Moody-Corbett and P. Brehm, Dept. Physiology, Tufts University School of Medicine, Boston, MA

Cells of the thymus can express both nicotinic and muscarinic acetylcholine (ACh) receptors (Rossi and Trenkner, Neurosci. Abs., 725, 1984). In order to understand the functional properties of these receptors we have been using the method of whole cell voltage clamp to examine the effects of ACh on thymus cells grown in culture.

The thymus was removed from 8-10 week old rats and individual cells dispersed by gentle shearing. The cells were plated on tissue culture dishes and fed every 3-4 days with Dulbecco's Modified Eagle Medium buffered with sodium bicarbonate, supplemented with 10% fetal calf serum and penicillin-streptomycin. Whole cell voltage clamp recordings were made using conventional patch clamp techniques. The electrode contained (mM) 140 KCl, 1 BAPTA, 10 HEPES ( pH 7.3) and the external recording solution contained (mM) 140 NaCl, 5 KCl, 1 $CaCl_2$, 1.6 $MgCl_2$, 10 HEPES (pH 7.3) with $10^{-6}$g/ml TTX.

When cells were held at -60 mV and stepped to different membrane potentials, the resultant instantaneous currents were highly non-linear at potentials more negative than -70 mV (see Fig.). The current-voltage relations obtained during application of 10 $\mu$M ACh indicate a reduction in the amount of inward rectification observed at potentials more negative than -90 mV (see Fig.). In contrast to this effect on hyperpolarizing potential jumps, no effect of ACh was observed on currents recorded in response to depolarizations to potentials more positive than -60 mV. The effects of ACh were also observed as a decrease in net inward current provided that the cells were held at potentials sufficient to activate inward rectification. Similar results were obtained with 10 $\mu$M muscarine. Addition of 5 mM CsCl to the recording solution linearized the current-voltage relations suggesting that potassium current mediates the inward rectification. In cells in which the rectification was blocked by Cs, no effects of ACh on holding current or the current-voltage relations was observed. These effects of ACh and muscarine suggest that cholinergic agonists cause a transient decrease in potassium current flowing through the inward rectifier channel. This modulation may play an important role in the immunological response of thymus cells.

227.3 PROPERTIES OF THE INWARDLY RECTIFYING POTASSIUM CHANNEL IN ACUTELY DISSOCIATED HIPPOCAMPAL PYRAMIDAL CELLS. J. R. Huguenard and B. E. Alger, Univ. of MD. Sch. Med., Baltimore, MD 21201.

Modulation of K-dependent conductances is an important mechanism of neuronal excitability control. We have begun to study modulation of K channels in neurons using the acutely dissociated hippocampal cell preparation (1). There is at least one, and perhaps two, large K-dependent channels which can be recorded from hippocampal neurons. The channel conductances range from 100-250 pS, depending on the recording conditions. One channel shows inward rectification (2,3) while the other is similar to the large Ca-dependent K channel which has been characterized in several different cell types (2).

With an on-cell patch configuration and 150 mM K and 0 Ca in the patch electrode we predominantly record large unitary inward currents. The single channel conductance shows inward rectification. In the region of -100 to -120 mV patch potential (assuming -50 mV resting potential) the conductance is about 200 pS, whereas at the resting potential it is approximately 100 pS. The channel is markedly voltage-dependent; hyperpolarization decreases the probability of channel opening. Single channel currents recorded on-cell cannot be reversed with depolarization. If, however, the electrode is withdrawn to obtain an inside-out patch in 150 mM K, a large channel with a linear conductance of about 250 pS is observed. The single channel currents in this case are readily reversible near 0 mV. On the other hand, when the patch electrode contains 2 mM Ca, depolarizations near 100 mV can activate a large outward channel with a conductance of about 100 pS.

We examined some properties of the inward rectifier channel to investigate its relationship to the macroscopic inwardly rectifying K conductance (`Q' current) in hippocampal neurons (3). With the inside-out patch configuration we find that this channel activity can be reversibly abolished by a low calcium (Ca)-containing solution ($\leq 10^{-8}$ M) or by ATP (0.5 mM in $10^{-7}$ M Ca). These properties typify large Ca-dependent K channels in other cell types. Interestingly, carbachol, 10-50 uM, can reversibly inhibit both large inward and outward channels in an on-cell patch.

This evidence confirms previous observations of a large inwardly rectifying K channel in hippocampal neurons. The channel has features which are unexpected based on the properties of the inwardly rectifying `Q' current; namely, inhibition by: a) low Ca, b) large hyperpolarizations, and c) carbachol. The observation that both types of large K channel can be blocked by carbachol suggests that some of the excitatory effects of cholinergic neurotransmission are due to this inhibition.

227.4 THREE OUTWARD IONIC CURRENT COMPONENTS OF NEURONS FROM CAT SENSORIMOTOR CORTEX. W. Spain*, P.C. Schwindt, M.C. Chubb and W.E. Crill, Dept. of Physiology & Biophysics, Univ. of Washington Sch. of Med., Seattle, WA 98195.

Outward ionic currents of large layer V neurons from cat sensorimotor cortex were investigated in an in vitro brain slice using a single microelectrode voltage clamp (SEVC). Sodium currents were abolished by TTX. During voltage steps from a holding potential at resting potential (RP: -60 to -80mV) three distinct outward current components could be distinguished.

A current qualitatively similar to $I_A$ of Connor & Stevens (J.Physiol. 213:21-30, 1971) was first seen at -55mV. Inactivation commenced at -65mV and was complete at about -45mV. Thus, $I_A$ is only partially inactivated in the subthreshold voltage range in these cells. Peak $I_A$ occurred within 2-5 ms in different cells. The time constant of $I_A$ inactivation showed little voltage dependence in a given cell and varied from 2.5 to 7 ms among cells. Because of its rapid onset and inactivation properties, $I_A$ may play a role in spike repolarization in addition to influencing membrane potential during repetitive firing.

A second transient outward current ($I_{KT}$) first appeared at about -50mV. Inactivation of $I_{KT}$ commenced at about -60mV and became complete at about -40mV. $I_{KT}$ also had a rapid initial rise, but inactivated much more slowly than $I_A$ (time constant: 350 ms at -40mV). Qualitatively, this current resembles $I_K$ of molluscan neurons. One likely function of $I_{KT}$ is spike repolarization.

A steady, non-inactivating current ($I_{KS}$) became dominant at potentials positive to -40 mV, but was mixed with $I_{KT}$ at more negative potentials. $I_{KS}$ could be activated when $I_{KT}$ was completely inactivated. Because of the great conductance increase associated with $I_{KS}$ activation, it could be studied only over a limited voltage range with the SEVC. $I_{KS}$ appeared to develop with 2 time constants: a rapid onset was complete in about 60 ms, whereas a subsequent slow phase did not reach a steady value during 1 sec voltage steps. $I_{KS}$ deactivated with a time constant of 180 ms or longer at RP. $I_{KS}$ appears to be composed of at least 2 pharmacologically separable subcomponents, one of which is sensitive to muscarine (Chubb et al, Neurosci. Absts. 10:1181). An $I_{KS}$ -like current was observed after somatic outward currents were blocked by somatic injection of $TEA^+$ or $Cs^+$, and this current was largely eliminated by substitution of $Co^{++}$ for $Ca^{++}$ in the perfusate. These observations suggest that one component of $I_{KS}$ is largely dendritic and, furthermore, is $Ca^{++}$-mediated. $I_{KS}$ activation appears to be responsible for the long-lasting afterhyperpolarization seen in these cells following repetitive firing (Schwindt et al, Neurosci. Absts. 10:871). Supported by NIH grants NS16792 and GM07266.

227.5 VOLTAGE CLAMP ANALYSIS OF RAPIDLY ACTIVATING POTASSIUM CURRENTS IN BULLFROG SYMPATHETIC GANGLION CELLS. B. Lancaster,† P. Pennefather & P. R. Adams. Dept. of Neurobiology, SUNY Stony Brook, NY 11794. †Faculty of Pharmacy, University of Toronto, Ont. M5S 1A1.

We have examined the degree to which the fast Ca-activated K current ($I_C$) and the delayed rectifier ($I_{DR}$) can be evoked by short depolarizing commands in bullfrog ganglion cells. Two microelectrodes were used to voltage clamp the cells as described previously (Adams, Brown & Constanti, J. Physiol. 330: 537).

Depolarizing voltage jumps of 2-3 msec duration from holding potentials of -40 mV evoke an inward Na current followed by a large outward current. The I/V relation at the end of the pulse shows a negative conductance region between +20 and +70 mV. This is attributed to a decrease in $I_C$ as Ca current declines at more positive potentials (>+20 mV) followed by an increase in $I_{DR}$.

The contribution of $I_{DR}$ to total outward pulse current is observed more clearly in the outward tail currents after repolarization. $I_{DR}$ contributes a slow component (decay $\tau$ =10-20 msec at -40 mV, showing an e-fold change per 22 mV) to the total outward tail which appears after voltage jumps to >+40 mV. After commands to <+40 mV, tail currents are well described by a single exponential with faster time constant (decay $\tau$ =2-4 msec at -40 mV, showing an e-fold change per 40 mV). The fast tails correspond to $I_C$ since they are abolished by Cd or 0 Ca. These results are consistent with a major role for $I_C$ in spike repolarization.

During very positive commands, $I_C$ contribution to total outward current should be small as $E_{Ca}$ is approached. However, $I_C$ tails, after a peak at +20 mV, decline to a non-zero limiting value after steps to >+70 mV. These residual outward tail currents may be generated by Ca tail currents.

A complication in examination of tail currents is K accumulation resulting from large K efflux during the pulse. Assuming 140 mM $[K]_i$, $E_K$ is at -101 mV in 2.5 mM $[K]_o$. The reversal potential for $I_C$ tails after a 2 msec command to 0 mV (typically evoking 50 nA of outward current) is -55 mV, indicating that $[K]_o$ is 16 mM. Longer commands cause even greater K accumulation, generating a sag in the outward current. Attempts to alleviate K accumulation with high $[K]_o$ Ringer are further complicated by effects of raised $[K]_o$ to increase $I_{DR}$. Indeed, in the presence of 40 mM $[K]_o$ a negative slope conductance region is no longer observed between +20 and +70 mV even though analysis of tail currents indicate that $I_C$ is decreasing in this range.

227.6 A MONOCLONAL ANTIBODY WHICH SELECTIVELY BLOCKS TWO TYPES OF IONIC CHANNELS IN MAMMALIAN NEURONS : A PATCH-CLAMP STUDY AND IMMUNOFLUORESCENT VISUALIZATION. Irene Zeitoun*, Hamutal Meiri, Carla Distasi* and Michel Simonneau*. Dept. Physiol., Rappaport Family Institute for Research in the Medical Sciences, Technion-Israel Institute of Technology, Haifa 31096, Israël; *Laboratoire de Neurobiologie Cellulaire & Moléculaire, CNRS, 91190 Gif sur Yvette, France.

Monoclonal antibodies (MAb's) were generated against the eel electroplax membrane fragments (EMF). The selection of suitable antibodies, which could modify the channel activity, was made according to (i) a Toxin-Modulated Solid-Phase Radio-Immuno-Assay (TM-SP-RIA), using as antigen the EMF and rat brain synaptosomes (RMV), with the same density of $Na^+$ channels, to test cross reactivity,(ii) an immunofluorescent staining technique (Meiri H. et al., Brain Res., 310, 168-173, 1984). The binding of one clone, SC-79-17 ($IgG_1$), to EMF and RMV was decreased by veratridine, but scorpion toxin was ineffective. TTX inhibited this MAB binding only to RMV. This clone stained nodes of Ranvier of rat and mouse sciatic nerve. It increased and prolonged the compound a.p. of rat optic and sciatic nerve, then partially blocked it. TTX which blocks $^{22}Na$-flux was more effective in the presence of SC-79-17, suggesting a close association between these two sites (TTX and antibody sites). Patch-clamp studies revealed that SC-79-17 blocks partially whole-cell $Na^+$ and $K^+$ currents, in embryonal teratocarcinoma that had differentiated into neurons (Eddé et al, J. Physiol, 346, 82P, 1984) and in mouse neonate dorsal root ganglion cells. The whole-cell $K^+$ current blocked by the MAb was a $Ca^{++}$ activated $K^+$ current. $Ca^{++}$ currents were not affected. Application of the MAb on outside-out patches provided evidence that only the large conductance (200 pS in symmetrical $K^+$) $Ca^{++}$ activated $K^+$ channels were blocked by SC-79-17.

227.7 A $Ca^{++}$-DEPENDENT $K^+$ CURRENT IS INCREASED IN THE PARAMECIUM MUTANT, teaA. T.M. Hennessey, Y. Saimi, and C. Kung (SPON: M.D. Bownds). Laboratory of Molecular Biology and Department of Genetics, University of Wisconsin, Madison, Wisconsin 53706.

One advantage of using Paramecium as a model system for studying ion channel functions in excitable membranes is that their membrane ion channels can be altered by mutation. Paramecium is a eukaryotic, unicellular ciliate which swims by the coordinated beating of the thousands of cilia which cover its body. Depolarizing stimuli trigger the opening of voltage dependent $Ca^{++}$ channels to produce $Ca^{++}$ action potentials and consequent ciliary reversals. Ciliary reversals cause the cell to swim backwards. Since the swimming behavior is dependent upon proper ion channel functions, behavioral mutants can be generated which have electrophysiological defects. The behavioral mutant teaA does not dramatically alter its swimming behavior in depolarizing solutions (such as $TEA^+$ and $Na^+$) whereas wild type show ciliary reversals and backward swimming.

Voltage clamp analysis has shown that the teaA mutant has a larger $Ca^{++}$-dependent $K^+$ current than wild type (in a $Ca^{++}$-$K^+$ solution). There are no other changes in ionic conductances in teaA. The large $Ca^{++}$-dependent $K^+$ current of teaA can be eliminated by: 1) removing the inward $Ca^{++}$ current. This was done by constructing the pawnB-teaA double mutant. The pawnB virtually lacks the inward $Ca^{++}$ current but is not allelic to teaA, 2) blocking the $Ca^{++}$-dependent $K^+$ current with internal $Cs^+$ (this current is not efficiently blocked by external $TEA^+$), and 3) chelating internal $Ca^{++}$ with injected EGTA. Tail current analysis showed that the $Ca^{++}$-dependent $K^+$ current was not only larger in teaA but faster activating as well. The activation of this current is so fast in teaA that it short-circuits the action potential and inhibits depolarization induced ciliary reversals in the free swimming cell.

227.8 GENETIC ALTERATIONS OF SINGLE-CHANNEL CURRENTS IN DISSOCIATED CNS NEURONS OF DROSOPHILA. Y.-A. Sun and C.-F. Wu. Dept. of Biology, Univ. of Iowa. Iowa City, IA 52242.

Ionic channels are integral membrane proteins and may be subject to genetic manipulation. Mutations of Hk and eag genes in Drosophila have been shown to increase nerve excitability. Using dissociated CNS neurons from Drosophila larvae, we analyzed the effects of these mutations at the single-channel level. Different types of $K^+$ currents were recorded from cell-attached membrane patches on the soma of type III neurons and neuroblasts (Wu et al., J. Neurosci. 3:1888, 1983). The cells were bathed in Drosophila physiological saline, with the addition of 3 μM TTX, 5mM $CoCl_2$ and 1 mM $CdCl_2$ to block $Na^+$ and $Ca^{++}$ channels. The patch electrodes were filled with the same solution.

Three distinct classes of single-channel $K^+$ currents can be readily recorded from these cells, namely, delayed rectification, inward rectification and $Ca^{++}$- dependent $K^+$ currents. Previous voltage-clamp measurements demonstrated that the amplitude of the delayed rectification current is reduced in $eag^1$ larval muscles (Wu et al., Science 220:1076, 1983). Single-channel recordings from $eag^1$ cultured nerve cells revealed that a decrease in channel conductance (to about 60% of the normal value, 11 pS) rather than in channel density is responsible for the reduction of the macroscopic current. This also raised the possibility that the eag gene may code for a structural component of the delayed rectification channel.

A population of CNS neurons in $Hk^1$ flies have been reported to display abnormal pace-maker activities not found in normal neurons (Ikeda and Kaplan, PNAS 66:765, 1970). In cultured $Hk^1$ nerve cells inward currents of an unusually high unit conductance (about 40 pS, as compared to 16 pS of normal inward rectification channels) were activated by membrane hyperpolarization. Preliminary analysis indicates that this may reflect a novel conductance state of the inward rectification channel. Since the inward rectification current reverses at a potential more positive (> 20 mV) than the resting potential, activation of these high conductance channels may greatly increase neuronal excitability.

Supported by NIH grants NS 00675 and NS 18500 and a grant from the Searle Scholars Program.

227.9 CLONING OF A GENE AFFECTING POTASSIUM CHANNELS IN DROSOPHILA. R. Drysdale* and B. Ganetzky. Lab. of Genetics, Univ. of Wisconsin, Madison WI 53706

The eag mutation in Drosophila causes spontaneous repetitive firing of action potentials in motor axons and abnormal release of transmitter at the larval neuromuscular junction (Ganetzky and Wu, J. Neurogenet. 1:17, 1983). The results from voltage clamp studies of larval body wall muscles (Wu et al., Science 220:1076, 1983) as well as single channel recordings from dissociated neurons (Sun and Wu, Abstr. Soc. Neurosci. In Press) indicate that eag causes a reduction in a delayed rectification potassium current ($I_K$).

To learn more about the product of this gene and its role in membrane excitability we have isolated clones of the eag locus. The cloning strategy took advantage of a chromosome inversion broken at one end in the eag locus and at the other in a previously cloned region of the chromosome. A junction fragment of DNA, which includes a portion of the eag locus, was isolated by screening a genomic library of the inversion using available probes from the cloned segment. The eag portion of the junction fragment was then used to screen a wild-type library to isolate additional overlapping clones in the eag region. We are now defining the extent of the eag gene within this cloned region by analyzing at the molecular level chromosome rearrangements and transposon insertions that cause mutant eag phenotypes.

227.10 CALCIUM AND CYCLIC AMP-MEDIATED REGULATION OF Ca AND K-CURRENTS IN HERMISSENDA GIANT NEURONS. Juan Acosta-Urquidi. MBL, Woods Hole, MA 02543 and Friday Harbor Laboratory, Friday Harbor, WA 98250.

Previous work employing voltage-clamp techniques has addressed the role of 2nd messenger-mediated modulation of ICa and distinct K-currents in giant identifiable pedal and pleural neurons in the Hermissenda CNS. Intrasomatic injection of two distinct species of Ca-calmodulin (CaM) dependent kinases, phosphorylase kinase and TACK (J. Biol. Chem. 258:12632, 1983), produced complex modulation of K-currents and ICa (Soc. Neurosci. Abstr. 9:501, 1983; 10:1129, 1984). Further studies showed CaM-KII (labelled TACK) predominantly enhanced ICa and IBa (ave. 31.2%, N=18 cells, P<.001), but in some cells, increases and decreases of ICa were obtained. CaM-KII also reduced both delayed rectifier, IK(v) (30.4%, N=7, P<.005), and IA (27.8%, N=6, P<.01). Increased rate of IK(v) inactivation was also observed in some cases. Effects on IK(Ca) tracked the effects on ICa, but further work is needed to detect CaM-KII direct effects on IK(Ca). In cells LP1-3, 5-HT (1-10 uM) predominantly enhanced ICa and IK(Ca) and consistently reduced leakage conductance (Soc. Neurosci. Abstr. 10:145, 1984). 8-BTcAMP (1 mM) also reduced leakage and increased ICa. Leakage is reduced by Cd (1 mM) and 4-AP (5 mM), but not EGTA injections. 5-HT effects were re-examined, including pleural cells. In Ba-ASW, to remove IK(Ca) contamination, 5-HT (10 uM) predominantly reduced IBa (40%, 7/9 cells) and consistently reduced leakage conductance (-50 to -120 mv, from Vh-40 mv). Forskolin (FORSK, 25-50 uM), an activator of adenylate cyclase, reduced leakage (40%) in Ca and Ba TEA ASW plus added Cd. FORSK reduced IBa (45%, 7/8 cells) and reduced IA and increased its decay rate, as reported (J. Neurosci. 4:2772, 1984). FORSK also reduced IK(v) (40%, 7/8 cells), increased IK(v) decay rate, increased IK(v) twin pulse inactivation (P1/P2), and delayed recovery of inactivation following preconditioning hyperpolarization. The wide range of effects of Ca-CaM and cAMP-mediated effects on diverse ionic currents poses new questions regarding the substrate specificity for the phosphorylation-mediated regulation of channel activity.

I thank D. L. Alkon, Lab. of Biophysics, NIH, MBL, for the use of facilities.

227.11 $I_{K-Ca}$ BUT NOT $I_A$ IS REDUCED DURING IN VITRO CONDITIONING OF HERMISSENDA TYPE B CELLS. (Spon: R.Cholewiak). L.Grover* & J.Farley, Prog. in Neurosci. & Behavior, Princeton Univ., Princeton, NJ 08544.

Pairing-specific reductions in two $K^+$ currents ($I_A$, Alkon et al., Science, 1982; and $I_{K-Ca}$, Farley & Alkon, Farley et al., Soc. Neurosci. Abstr. 1983,1984) have previously been described for Type B photoreceptors on retention days following learning. Cumulative depolarization of B cells has been proposed as one acquisition mechanism leading to the long-term reduction of $K^+$ currents. We have asked whether the reductions in $I_A$ and $I_{K-Ca}$ observed during retention are also produced during acquisition of learning.

Under current clamp, axotomized B cells were exposed to an in vitro simulation of the associative conditioning procedure. Cells were exposed to either 5 pairings (ITI=1.0 min) of light (110 μW; 15 sec) followed immediately by 15 sec of depolarizing current stimulation (Vm= ∿-20 mV), or five unpaired presentations of these same stimuli, with cells receiving both treatments in a counterbalanced order. 10 of 13 cells exhibited a pairing-specific cumulative depolarization ($\bar{x}$ ± s.d.; paired: 6.1 ± 2.2 mV; unpaired: 4.4 ± 1.8 mV; p <.05), when measured 1.0 min following training. B cells were also exposed to the in vitro conditioning protocols under voltage-clamp control ($V_h$=-60 mV) and comparisons of $I_A$ and $I_{K-Ca}$ were made before and after conditioning. $I_A$, measured as the peak outward current during 500 msec command steps to either -10 or 0 mV, showed no consistent reduction by either paired or unpaired training conditions (see Table 1, below). In contrast, $I_{K-Ca}$ (measured as the steady-state outward current in a 5 mM 4-AP; 100 mM TEA ASW; at both -10 and 0 mV) was reduced in a pairing-specific manner (Table 1). Thus, $I_{K-Ca}$, rather than $I_A$, undergoes persistent, pairing-specific reductions during acquisition, which are independent of any cumulative voltage-dependent inactivation effects.

Table 1

| | $I_A$ (mean ± s.d.; nA) | | | | $I_{K-Ca}$ (mean ± s.d.; nA) | | | |

227.12 PROTEIN KINASE C REDUCES $K^+$ CURRENTS AND ENHANCES A $CA^{2+}$ CURRENT IN HERMISSENDA TYPE B CELLS. (Spon: J.Gaddy) D.Fisher*, S.Auerbach, J.Farley. Prog. in Neurosci., Princeton Univ., Princeton, NJ 08544.

Persistent associative-training-produced changes of two $K^+$ currents ($I_A$[1]; $I_{K-Ca}$[2,3]) and a calcium current ($I_{Ca}$[3,4]) have previously been demonstrated in Hermissenda Type B photoreceptors. The same conductance changes are also effected by serotonin (5-$HT^5$), an endogenous neuromodulator released during associative training[6]. It has been suggested that these changes arise from the phosphorylation of ionic channels. But the identity of the phosphorylation pathway(s) has not as yet been determined. We[7] have previously reported that the tumour promoting phorbol esters, which are specific activators of protein kinase C, produce the same conductance changes resulting from associative training and 5-HT. We now report that intracellular injections of the enzyme produces the same effects.

Iontophoretic injections of PKC, prepared from mammalian brain[8], enhanced the magnitude of the B cells' steady-state light response (before: 19.6 ± .9 mV; after: 23.5 ± .07 mV; p < .05) and input resistance (39.3 ± 1.9 MΩ vs. 57.6 ± 2.1 MΩ ; p<.05) in 13 of 13 cells tested. Heat-inactivated PKC (n=10), buffer (n=5), or material from a non-PKC peak eluting from the DEAE cellulose column (n=3) were all without effect. Under voltage-clamp control ($V_h$=-60 mV), PKC injections reduced $I_A$ (peak outward current at -10 mV; before: 31.7 ± 1.8 nA, after: 10.2 ± 0.8 nA) in 10 of 10 cells, reduced $I_{K-Ca}$ (measured in 10mM 4-AP and 100 mM TEA ASW at -10 mV: 16.3 ± 1.2 nA vs. 8.7 ± 0.9 nA) in 8 of 8 cells, and enhanced $I_{Ca}$ in 7 of 7 cells [measured in 4-AP, TEA, and 300 mM $K^+$ ($E_K$=0 mV) at 0mV: before: 2.9 ± 1.2 nA, after: 5.8 ± 0.9 nA]. Pre-treatment of cells with 5-HT reduced the effects of PKC injections, as did 1-10 nM bath applied concentrations of imipramine, which has been reported to inhibit PKC activation.

Because these effects of PKC are essentially identical to those produced by either associative training or 5-HT application, it is attractive to suppose that 5-HT induced PKC activation is one mechanism by which long-term excitability changes in B cells occur. It is, moreover, a mechanism molecularly distinct from the previously proposed calcium/calmodulin dependent phosphorylation pathway.

227.13 FORSKOLIN-MODULATED MEMBRANE CURRENTS IN APLYSIA TAIL SENSORY NEURONS. D.A. Baxter and J.H. Byrne, Dept. of Physiol. and Cell Biol., Univ. of Texas Med. Sch., Houston, Tx. 77225.

In the sensory neurons that mediate the tail withdrawal reflex serotonin (5-HT) produces a depolarization that is associated with a decrease in their input conductance. Previous studies have shown that 5-HT increases the levels of cAMP in these cells and injection of cAMP or application of the cyclase activator forskolin produces decreases in membrane conductance similar to those produced by 5-HT. To examine further the membrane currents modulated by cAMP we utilized forskolin and voltage-clamp and computer subtraction techniques.

We used surgically isolated sensory cells and conventional two-electrode voltage-clamp techniques and applied 150 ms clamp pulses to various depolarized levels from a holding potential of -70mV (large depolarizations were separated by > 3 min). The procedure was repeated after addition of a saturating concentration of forskolin ($10^{-4}$M) to the bath. Forskolin-modulated currents were obtained by subtracting the responses obtained before and after forskolin addition. At all potentials examined (-40 to +20 mV) forskolin led to the reduction of net outward currents. The kinetics and voltage-dependence of the responses indicated that the forskolin-modulated currents had at least two components. One component, most prominent at low levels of depolarization (-40 to -10mV), was relatively linear with respect to voltage, had an activation time constant (about 7 ms) that was relatively voltage-insensitive, and showed little sign of inactivation during the pulse. The second component was most pronounced at membrane voltages more positive than -10mV. This component exhibited a marked voltage-dependence, had a slower, voltage-dependent activation time constant and displayed inactivation at large depolarizations (> +10 mV). Similar forskolin effects were obtained in ASW with $Co^{++}$ substituted for most of the $Ca^{++}$ (0.1 mM remained). Thus, neither component appears to be due to $Ca^{++}$ influx or nonspecific effects of transmitter release from remaining terminals in the portions of attached neuropil.

The first component has properties consistent with previous descriptions of the S-current (Klein et al, 1982; Siegelbaum et al, 1982) while the second component has not been described previously. We are currently investigating whether the second component is an additional current modulated by forskolin (and presumably cAMP) or a novel component of the S-current itself. These results and others (Boyle et al, 1984; Walsh and Byrne, this volume) indicate that the effects of cAMP on modulating cellular properties of these neurons are rather complex. While complex all the effects may act synergistically to modify synaptic transmission at the sensory-motor neuron synapse. Supported by AFOSR grant 84-0213.

227.14 CYCLIC AMP AND CALCIUM SENSITIVITY OF THE 5-HT RESPONSE IN TAIL SENSORY NEURONS OF APLYSIA. J.H Walsh and J.H. Byrne, Univ. of Texas Med. Sch., Houston, TX. 77225.

Biochemical and voltage clamp studies indicate that 5-HT produces a cAMP-mediated decrease in a resting $K^+$ conductance in sensory neurons involved in the tail withdrawal reflex. The present study was designed to extend the analysis of the cellular and ionic mechanism(s) underlying the 5-HT response of these cells.

To test if each response is produced by a common saturable mechanism, iontophoretic injections of cAMP (0.1 M, 10 ms pulses, 50 Hz for 1 s, 200 nA) were used in conjuction with extracellular pressure microejection of 5-HT (1mM, 0.5 to 1 s pulse) in neurons voltage-clamped at a holding potential of -25 to -37 mV. Injections of cAMP or 5-HT alone produced inward currents associated with decreases in input conductance. Application of 5-HT just prior to a second injection of cAMP resulted in a 75.4 ± 7% (SEM, N = 5) reduction in the amplitude of the cAMP response.

The current elicited by brief microejections of 5-HT onto sensory neurons voltage clamped at a holding potential of -30 to -40 mV appeared to be $Ca^{2+}$-sensitive. The response to 5-HT was attenuated when a variety of $Ca^{2+}$-channel blockers including $Cd^{2+}$ (2 mM), $Co^{2+}$ (30 mM) and $Ni^{2+}$ (15 mM) were added to ASW. In addition, the 5-HT response was also attenuated in ASW solutions where $Ba^{2+}$ was substituted for most of the $Ca^{2+}$ (0.5 mM $Ca^{2+}$ remained). While other interpretations are possible, these results suggest that a component of the 5-HT response may be a modulation of a calcium-activated $K^+$ current ($I_{K,Ca}$). To test this possibility directly $K^+$-currents were elicited by intracellular $Ca^{2+}$ iontophoresis (0.5M $CaCl_2$, 10 ms pulses at 50 Hz for 0.3-2 s, 100 to 1000 nA). The outward currents elicited were 2 to 20 nA in amplitude and persisted for 5 - 25s. Outward currents produced by $Ca^{2+}$ injection were reduced by 31.8 ± 5.6% (SEM, N = 21) when elicited at the peak of the 5-HT response. Upon recovery from the 5-HT response, the outward currents returned to control levels. While control injections of $Ba^{2+}$, $Co^{2+}$, and $Na^+$ (0.5 M) produced no outward current, $Ba^{2+}$ injections (N = 3) produced an inward current associated with a decrease in input conductance, which mimicked both the response to extracellular $Ba^{2+}$ and 5-HT.

These data further support the hypothesis that cAMP acts as a second messenger in the 5-HT response of the tail sensory neurons. In addition, they indicate that 5-HT can modulate $I_{K,Ca}$ as well as the previously described $Ca^{2+}$-insensitive S-current (Siegelbaum et al, 1982).

227.15 CHARYBDOTOXIN SPECIFICALLY BLOCKS CA-ACTIVATED K CONDUCTANCE OF APLYSIA NEURONS. A. Hermann* (Spon: J. Chad). Dept. of Biology, UCLA, Los Angeles, CA 90024.

Charybdotoxin (CTX), a partially purified component of scorpion (Leiurus quinquestriatus) venom, has been recently reported to block potently the large Ca-activated K channels isolated from skeletal muscle and inserted into lipid bilayer (Miller, C. et al., Nature, 313:316, 1985). The present experiments examine the action of CTX on the Ca-activated K current, $I_{K(Ca)}$, of identified neurons in the abdominal ganglion of Aplysia californica. The results show that external CTX blocks the Ca-activated K current, induced by ionophoretic injection of Ca ions into the cells, in a dose dependent manner with a $K_D$ of about 30 nM at a membrane potential of -30 mV. The block is voltage dependent, decreasing with increased positive potential. The time to maximum inhibition is relatively fast, occurring within 1-3 minutes. The action of the venom is reversible after washout, recovery being slower than onset of the block. CTX also suppressed the Ca-dependent hump seen in the N-shaped current-voltage plot of outward current. The venom had little effect on Na or Ca inward currents, the transient K current or the delayed rectifier current. Only high concentrations of the venom (several hundred nM) effect these currents. However, CTX induced an apparent inward shift of steady state current, which was accompanied by a decrease of the membrane resting conductance. The current reversed at about -70 mV, indicating a resting K conductance that is blocked by CTX.

CTX at a concentration of 50-100 nM caused depolarization of spontaneously bursting neurons, and eventually led to repetitive discharge of action potentials. Upon repolarization by current injection, bursting was re-established; however, the number of action potentials was increased and the postburst-hyperpolarization was diminished. These effects were reversible. It is concluded that the bursting discharge is controlled in part by a Ca-activated K conductance.

The results show that CTX is a high-affinity, specific but voltage dependent blocker of the Ca-activated K current in Aplysia neurons.

I am grateful to C. Miller for the gift of CTX. Supported by a Heisenberg grant to A.H., DFG grant SFB 156 and by NSF BNS 83-16417 to R. Eckert.

227.16 CHARYBDOTOXIN (CTX) SELECTIVELY BLOCKS A CALCIUM-MEDIATED POTASSIUM CONDUCTANCE THAT CONTRIBUTES TO THE ACTION POTENTIAL RECORDED OPTICALLY FROM NERVE TERMINALS OF THE FROG NEUROHYPOPHYSIS. A.L. Obaid*, D. Langer* and B.M. Salzberg. Univ. of Pennsylvania, Phila. PA 19104 and Marine Biological Laboratory, Woods Hole, MA 02543.

Voltage-sensitive molecular probes allow one to monitor the action potential in nerve terminals of the frog neurohypophysis by optical means (Salzberg et al., Nature 306:36, 1983). When voltage-sensitive Na and K channels are blocked with Tetrodotoxin (TTX) and Tetraethylammonium (TEA), direct field stimulation of the nerve terminals evokes regenerative responses (Obaid et al.. J. Gen. Physiol. 85:481, 1985) that result entirely from a voltage-sensitive calcium influx. Even in the absence of TTX and TEA, this calcium component of the normal action potential is probably sufficient to mediate hormone release. Both the normal action potential and the calcium response exhibit prominent afterhyperpolarizations that result from a calcium-mediated increase in potassium conductance.

Charybdotoxin (CTX), a protein toxin derived from scorpion venom, blocks calcium-sensitive potassium channels from rat skeletal muscle in planar lipid bilayers (Miller et al., Nature 313:316, 1985). We report here that CTX (50 nM) specifically blocks the component of the optical signal that reflects the calcium-mediated potassium conductance in the nerve terminals of the frog neurohypophysis. This block is apparent in the normal action potential and in the calcium response. In both instances, the undershoot is eliminated and the width and height of the action potential are increased.

Apamin, a low molecular weight fraction from bee venom, is reported to block calcium-mediated potassium conductances in several preparations. As supplied by Sigma (A 5775; lot 104F0166), it yields two peaks by HPLC and has a purity of approx. 50%. This Apamin also blocks the calcium-mediated potassium conductance in the nerve terminals of the frog, but at concentrations ten times higher than CTX, with longer incubation, and without the specificity of CTX. For example we find a reduction in the height of the action potential and in its maximum rate of rise, as though voltage dependent Na channels are also blocked by this material.

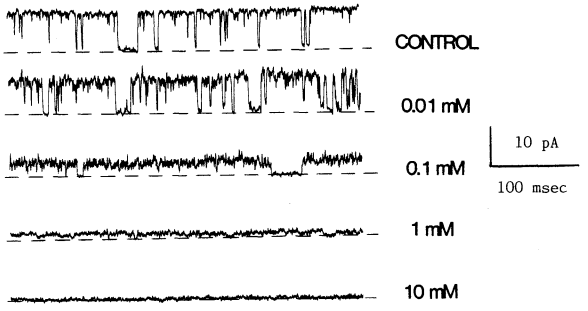
We are grateful to Chris Miller for his generous gift of CTX. Supported by USPHS grant NS 16824.

227.17 ASYMMETRICAL SENSITIVITY OF TETRAETHYLAMMONIUM BLOCKADE OF CALCIUM-ACTIVATED POTASSIUM CHANNELS IN CLONAL ANTERIOR PITUITARY CELLS. B. S. Wong[1] and M. Adler[2]. [1]Dept. of Physiology, Baylor College of Dentistry, Dallas, TX 75246, [2]Neurotoxicology Branch, USAMRICD, APG, MD 21010.

The effects of tetraethylammonium (TEA) ions on blocking single calcium-activated potassium channels were studied in excised outside-out and inside-out membrane patches from the mouse anterior pituitary cell line AtT-20/D16-16 with the patch-clamp technique. Both externally and internally applied TEA resulted in a decrease in the single-channel current. The dissociation constant at zero voltage for the TEA-receptor complex was found to be 52.2 mM and 0.08 mM for external and internal TEA, respectively This is in contrast to single-channel studies in other cell types which demonstrated external TEA as being more effective than internal TEA in blocking ion flows through these channels. The Hill plot analysis of the dose response data yielded a slope of 0.92, indicating a one-to-one stoichiometry for TEA-receptor binding. The blockade by TEA showed little voltage sensitivity over the membrane potential range studied, was independent of the direction of current flow, and could be fully reversed by wash-out in drug-free solution. The results suggest the presence of TEA receptors on both the external and internal membrane surfaces but with different binding affinities. Occupancy of either site by TEA leads to a decrease in the single-channel conductance of calcium-activated potassium channels. The asymmetrical sensitivity to TEA, however, suggests that the end regions of these channels may differ in different cell types.

(Supported in part by BCD Research Fund and the American Heart Association, Texas Affiliate.)

EFFECTS OF INTERNAL TEA



227.18 THE CALCIUM- AND VOLTAGE-DEPENDENT $K^+$ CHANNEL OF CLONAL ANTERIOR PITUITARY CELLS: PHARMACOLOGICAL MANIPULATION AND ROLE IN ACTION POTENTIAL REPOLARIZATION. M.A. Rogawski, B. Dufy and J.L. Barker. Laboratory of Neurophysiology, NINCDS, NIH, Bethesda, MD 20205.

Under voltage clamp, a $Ca^{2+}$-dependent $K^+$ conductance that activates slowly following depolarization and maintains a plateau with persistent depolarization is recorded in $GH_3$ cells (a rat clonal pituitary cell line). To investigate the functional role of this conductance in the firing behavior of these cells, we characterized the properties and pharmacological sensitivity of the underlying single $K^+$ channels in intact and excised outside-out membrane patches. In the cell attached configuration, patch clamp recordings (5.5 mM external $K^+$) revealed large conductance, non-inactivating outward single channel currents whose amplitude varied linearly with membrane potential in the range 0-70 mV depolarized from rest. Often, channel openings occurred simultaneously with action potentials recorded by the patch electrode. The single channel conductance was 55-75 pS and the extrapolated reversal potential was 16 mV hyperpolarized to rest. Burst openings were infrequent and brief at resting potential, but the number of openings increased markedly as the patch was depolarized. The mean burst lifetime also increased with depolarization (in a sigmoidal fashion from 2-11 msec). When the concentration of $K^+$ in the patch pipette was raised, the reversal potential shifted in the depolarized direction as predicted by the Nernst equation for a $K^+$ selective membrane pore. With symmetrical $K^+$ across the membrane, the single channel conductance was approximately double that observed with the normal $K^+$ gradient. External application of $Ba^{2+}$ (10 mM) to the whole cell (but not to the patch) caused a failure of channel opening. In contrast, quinine (5 mM) caused high frequency flickering of the channel. These channel blockers seem to enter the cell and interfere with channel activity from the inside. Tetraethylammonium (TEA; 20 mM) and apamin (5 μM) applied in this manner were without effect. A23187 (10 μM; a $Ca^{2+}$ ionophore) and 4-aminopyridine (10 mM) caused a stimulation of channel activity. The $Ca^{2+}$ sensitivity of the channel was studied in excised outside-out membrane patches. Channel opening was infrequent with 1 μM free internal $Ca^{2+}$ but increased markedly as the concentration was raised 50-fold. TEA (but not apamin) applied to the external membrane face in the outside-out configuration caused a powerful blockade of channel activity. In current clamp recordings, only the specific blockers of the channel ($Ba^{2+}$, TEA, quinine) caused a major broadening of action potentials; other $K^+$ channel blockers that did not interfere with these channels (4-AP, apamin) had little effect on spikes. We conclude that the $Ca^{2+}$- and voltage-dependent $K^+$ channel in pituitary cells plays an important role in the repolarization of the $Ca^{2+}$-dependent action potentials of these cells.

## SPECIAL LECTURE

228 SPECIAL LECTURE. GENE EXPRESSION IN THE MAMMALIAN BRAIN. J.G. Sutcliffe, Research Institute of Scripps Clinic.

About 30,000 polyA$^+$ mRNAs are expressed in the adult rat brain, and more than 50% of these by mass are specific to the brain. Hence, cDNA cloning can easily provide copies of large numbers of brain specific mRNAs for analysis. By DNA sequence analysis of full-length copies of brain specific mRNAs, we generate the amino acid sequences of putative brain specific proteins. Computer comparisons with known protein sequences provides some information about possible function. We synthesize a series of non-overlapping peptides corresponding to short regions within the putative sequence and use antisera to the synthetic peptides to identify the product of the brain specific mRNA. The antisera reveal anatomical and subcellular distributions of each protein, and this information combined with the primary sequence can suggest possible biochemical functions. Thus far these studies have led to the description of a precursor of a family of probable neuropeptides found predominantly in olfactory somatosensory and limbic systems that is the product of a gene which is very closely linked (and may be) the quiverer locus; the two major mRNAs for brain myelin proteolipid protein transcribed from a single gene on the X chromosome; and a large polymorphic family of mRNAs, many of which are specific to the nervous system.

The 5-10,000 genes expressed exclusively in adult rat neurons as polyA$^+$ messenger RNA (mRNA) contain a common element called an ID sequence within their noncoding introns. This element is transcribed specifically in neurons by RNA polymerase III, the enzyme which generates tRNAs and other small RNAs. This transcription begins around the time of birth, and its tissue specificity results from a transcriptional protein exclusive to brain. Subsequently the adult brain specific genes which contain the ID element within their introns are transcribed by RNA polymerase II, the enzyme which generates mRNAs. We believe the Pol III transcription events are equivalent to the process of determination in which the genes which can be expressed in the adult nervous system are selected. Further events during development and experience are necessary for the expression of each particular gene in particular sets of neurons. The ID elements act as enhancers (positive activators) of gene expression when fused to genes whose products can be assayed in transfection experiments. Thus they appear to be neuronal specific regulators of gene expression.

229 VISUAL MOTION PROCESSING IN CEREBRAL CORTEX. R. H. Wurtz, National Eye Institute (Chairperson); S. Ullman, Massachusetts Institute of Technology; J. A. Movshon, New York Univ.; W. T. Newsome, State Univ. of New York at Stony Brook; V. B. Mountcastle, Johns Hopkins Univ. School of Medicine.

This symposium summarizes recent advances made in the analysis of visual motion processing in the neocortex of primates. Emphasis is on the functional contribution of cortical areas rather than their anatomical or physiological organization. The introduction by R. H. Wurtz will outline the systems within the primate brain related to motion processing and emphasize the importance of cerebral cortical processing in primates in comparison to other mammals. S. Ullman will review the main problems involved in the processing of visual motion. The problem of measuring visual motion will serve to illustrate recent fruitful collaboration between physiological and computational research. The subsequent presentations will describe investigations of neural activity at three levels of neocortex: the striate cortex, where motion processing is first observed in the primate neocortex, the middle temporal area (MT) in the prestriate cortex, which is probably devoted largely to motion processing, and the parietal cortex, which probably represents one of the highest levels of processing within the cerebral cortex. J. A. Movshon will compare the type of physiological processing occurring in the striate cortex, with that in area MT. Neurons in the striate cortex respond only to the motion of the oriented elements of a complex two-dimensional pattern while cells in area MT integrate signals concerning the movement of the pattern as a whole. Support for the idea that MT is specialized for the analysis of motion will be provided by W. T. Newsome. Chemical lesions of MT reduce a monkey's ability to make pursuit and saccadic eye movements to moving visual targets but not to stationary visual targets. V. B. Mountcastle will describe more complex visual motion processing and the organization of motion directionalities in the parietal cortex.

230 SYMPOSIUM. BIOLOGY OF ISOLATED BRAIN CAPILLARY ENDOTHELIA: AN EMERGING FIELD IN NEUROSCIENCE. W.M. Pardridge, UCLA School of Medicine (Chairman); G.W. Goldstein, University of Michigan Medical Center; P.A. Cancilla*, UCLA School of Medicine; M.A. Moskowitz, Harvard Medical School; F.P. White and G.R. Dutton, Washington State University College of Veterinary Medicine and University of Iowa School of Medicine.

Brain capillary endothelia in virtually all vertebrates make up the blood-brain barrier (BBB) in vivo. Within the context of a barrier paradigm, the brain capillary endothelial cell has generally been viewed as serving a passive and protective role in brain metabolism and function. However, the techniques of cell biology have generated a new paradigm of brain capillary endothelial function, which visualizes dynamic interactions between capillary endothelia and neurons and glia. For example, glial cells are now believed to release as yet undefined trophic factors that are sequestered by capillary endothelia to initiate the genetic expression of unique biochemical properties in the brain capillary endothelial cell. The trophic factors released by brain and the gene products of the endothelial cell are now amenable to investigation using primary culture model systems of brain capillary endothelia. The development of monoclonal antibodies that are specific for surface antigens present in brain microvascular elements may also be employed to investigate the expression in brain capillaries of proteins unique to that cell. In addition to the long-term regulation by brain of gene expression in brain capillary endothelia, model systems now available also make accessible the study of acute signal transduction phenomena in brain capillary endothelia that may be related to the regulation of cerebral blood flow and metabolism on a minute-to-minute basis. Phospholipid-mediated signal transduction pathways have been identified in brain endothelia and the activity of protein phosphorylation pathways in isolated brain capillaries have been found to be nearly as active as that observed in synaptosomal membranes. Finally, peptide receptor transport systems have been identified using isolated brain capillaries and an understanding of the receptor-mediated transport of circulating peptides through the brain capillary endothelia may lead to new strategies for peptide delivery to brain.

## ACTION POTENTIALS AND ION CHANNELS VI

231.1 A NEW METHOD FOR CHANGING INTRACELLULAR CALCIUM CONCENTRATION. R. S. Zucker and R. Y. Tsien*. Dept. of Physiology-Anatomy, Univ. of Calif., Berkeley, CA 94720.

A photolabile calcium chelator has been developed as a tool for rapidly increasing intracellular calcium concentration in single cells. A new class of substance has been synthesized, comprised of 2-nitrobenzhydrol derivatives of BAPTA (1,2-bis(2-aminophenoxy)ethane N,N,N',N'-tetraacetic acid) chelator. One member of this class, designated nitr-2, has been characterized chemically and used physiologically to control intracellular calcium in single neurons. Nitr-2 chelates a single calcium ion with a dissociation constant of 160 nM, measured at an ionic strength of 0.1 M. Ultraviolet light photoisomerizes the 2-nitrobenzhydrol form to a 2-nitrosobenzophenone, with a quantum efficiency of 0.03 for a wavelength of 365 nm, which is the absorbance peak of the difference spectrum for the two forms. Ultraviolet light also photoisomerizes the $Ca^{2+}$-complex of nitr-2 to a $Ca^{2+}$-nitrosobenzophenone with a quantum efficiency of 0.1-0.2. The nitrosobenzophenone has a markedly reduced affinity for calcium ($K_D$=7 μM). Thus exposure of $Ca^{2+}$-nitr-2 to a flash of ultraviolet light causes the release of "caged calcium" from the chelator, with a reaction time constant of about 250 msec. The amount of calcium released depends in a linear manner on the light intensity and duration, for flash energies that isomerize a small fraction of the nitr-2.

Single neurons, about 250 μm in diameter, from the abdominal ganglion of Aplysia californica, were microinjected by pressure with about 10 mM nitr-2, 75% in the calcium form. Since the $K_D$ of nitr-2 for calcium is similar to the resting free calcium level in cytoplasm, the latter is little affected by the injected buffer. Membrane currents were measured under voltage clamp. Calcium-activated potassium current and calcium-activated nonspecific cation current were isolated pharmacologically (using 50 mM tetraethylammonium to block $I_{K(Ca)}$). Both currents could be elicited by focusing light flashes from a xenon arc lamp (about 225 J in 2 ms) onto the filled cell. Both currents reversed at the potentials expected from their ionic selectivities, and reached a maximum at about 25-40 ms. Repeated flashes elicited identical responses. Response amplitude was graded with light intensity.

In summary, photo-isomerization of nitrobenzyl BAPTA derivatives provides a new way to release controlled amounts of calcium relatively uniformly throughout the cell's interior. This should be a valuable tool in the study of calcium-regulated processes. Supported by NIH Grants NS 15114 to R.S.Z., and GM 31004, EY 04372, and a Searle Scholars Award to R.Y.T.

231.2 SINGLE CALCIUM-ACTIVATED CHANNELS WITH HIGH CA-SENSITIVITY AND SMALL CONDUCTANCE IN CULTURED RAT SKELETAL MUSCLE. A. L. Blatz* and K. L. Magleby. Dept. of Physiology and Biophysics, University of Miami, Miami, FL 33101.

Ca-activated K currents occur in most muscle and nerve cells. The channels underlying these currents often give rise to slow hyperpolarizations following action potentials and can serve to regulate low frequency repetitive firing in neurons and cultured skeletal muscle. Romey & Lazdunski (BBRC 118, 669-674, 1984) have shown that the long-lasting afterhyperpolarization in cultured skeletal muscle is not caused by the large conductance (250-300 pS) Ca-activated K channel (BK channel) but is due to another Ca-activated conductance that can be blocked by micromolar amounts of the bee venom apamin. While searching for the apamin blockable Ca-activated channel in cultured skeletal muscle using the giga-seal patch clamp technique we found three additional Ca-activated channels with conductances of about 4, 12 and 32 pS, all considerably less than the BK channel. All of these channels had a greater Ca sensitivity at negative membrane potentials than the BK channel. In most of the membrane patches examined the small conductance Ca-activated channels were present in such high density that the major effect of increasing internal Ca from 1 nM to 100 nM was an increaed inward steady-state current and a dramatic increase in the current fluctuations, with no clear single channel open shut transitions apparent (-40 mV). In some patches, however, the small conductance Ca-activated channels were present at a low enough density for individual single channel currents to be observed. The channels with 12 pS conductance in symmetric 140 $KCH_3SO_4$ were about ten times more sensitive to internal Ca than the BK channels in the same patch. The 12 pS channels were not observed in four patches with 0.75 uM apamin in the external solution (10 uM $Ca_i$). At a holding potential of -40 mV the 12 pS channels were open 6% of the time at 0.1 uM $Ca_i$ and 60% of the time at 10 uM $Ca_i$. The 32 pS channels were active even when apamin was added to the external solution. The small 4 pS channels were apparently the most Ca sensitive, as they would become active before the others when $[Ca]_i$ was increased during a solution exchange. In these experiments K was the major charge carrier through these channels. (The internal solutions contained (mM): 140 KCl or $KCH_3SO_4$, 5 TES buffer (pH 7.2), 0.5 EGTA and sufficient $CaCl_2$ for the specified free $[Ca^{2+}]_i$. External solutions were identical except that $[Ca^{2+}]_i$ was usually 10 nM). We have not yet determined the selectivity of these channels to other cations such as Na. Supported by grant AM 32805 from the NIH and a grant from the Muscular Dystrophy Association.

231.3 CALCIUM CURRENTS IN DEVELOPING MAMMALIAN SKELETAL MUSCLE CELLS. K.G. Beam* and C.M. Knudson* (SPON: L. Marshall) Dept. of Physiol. Biophys., Univ. of Iowa, Iowa City, IA 52242.

We have been using the whole-cell variant of the patch clamp technique to examine inward ionic currents in developing skeletal muscle. Outward currents were blocked with $Cs^+$ in the patch electrode and tetraethylammonium ion in the bath. Two preparations were used: rat and mouse skeletal myotubes grown in primary tissue culture and enzymatically dissociated fibers of flexor digitorum brevis (FDB) muscles acutely removed from 0-25 day old rats.

Three distinct inward currents are present in skeletal myotubes. The largest and most rapidly activated of these is a sodium current. To study calcium currents in isolation, $I_{Na}$ was eliminated by adding TTX (10 uM) and removing extracellular sodium. Elevated extracellular Ca (50 mM) was used in most experiments, both to accentuate the calcium currents and to improve electrode sealing. Under these conditions, depolarizing from the holding potential (-90 mV) to potentials in the range -30 to 0 mV activated a transient inward current ($I_{fast}$) that peaked in 15-30 ms and completely inactivated within about 100 ms. Stronger depolarizations (+10 mV and above) activated a second, slower inward current ($I_{slow}$) that peaked in about 100 ms and inactivated little during a 200 ms test pulse. $Cd^{+2}$ (0.1-0.2 mM) blocked both currents, with the slow current being more sensitive. Holding at a potential of -30 mV completely inactivated $I_{fast}$ with little effect on $I_{slow}$.

A slow calcium current resembling $I_{slow}$ in myotubes has been described for muscle fibers of adult frogs and rats. Further, we observed that such a current is present in FDB fibers of both 0-1 day and 25 day rats. Thus, a current like $I_{slow}$ appears to be present in muscle fibers throughout much of their development.

A current with kinetics resembling $I_{fast}$ of myotubes has not been described for adult rat or frog. In FDB fibers of 0-1 day rats a current like $I_{fast}$ of myotubes is present for the same range of test potentials. In 25 day FDB fibers, such potentials cause a rapidly activating current that shows little inactivation over 200 ms. A current with properties like those of $I_{fast}$ in 25 day FDB fibers has recently been described for muscle fibers of adult frogs (Cota, G.D. & Stefani, E., Biophys J., 47:65a, 1985).

Supported by MDA, and by NIH grants NS-14901 and RCDA NS-00840 to KGB.

231.5 MACROSCOPIC CALCIUM CURRENTS IN ACUTELY-EXPOSED GRANULE CELLS FROM ADULT HIPPOCAMPUS. R. Gray and D. Johnston, Prog. in Neuroscience and Dept. of Neurology, Baylor Coll. of Med., Houston, Tx. 77030.

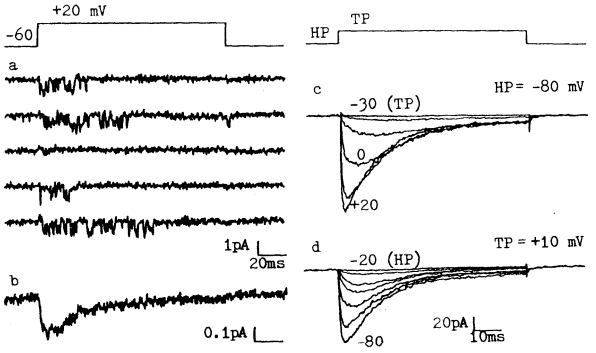
It has been shown recently that β-adrenergic agonists are able to modulate long-term potentiation (LTP) of synaptic transmission at the granule cell mossy fiber to CA3 synapse in the hippocampus (Hopkins & Johnston, Science 226:350). We were interested in the possibility that β-agonists may have direct effects on ionic currents that might underly this modulation of LTP. β-adrenergic agonists have been reported to affect both Ca and K currents in a variety of cell types. We have begun to investigate the properties of isolated Ca currents in acutely-exposed granule cells from the adult guinea pig hippocampal formation.

Hippocampi were dissected from adult guinea pigs and 300 μm transverse slices were made. The slices were then treated with proteolytic enzymes and gently agitated to expose the neural somata (Gray & Johnston, J. Neurophysiol., in press). Granule cells maintained at 15-23°C were voltage-clamped using the giga-seal whole-cell clamp technique. Intracellular solutions included tetraethylammonium (TEA), 3,4-diaminopyridine (3,4-DAP), and Cs to block K currents. The bath solution also included TEA and 3,4-DAP in addition to tetrodotoxin and 2 mM Ca. Using trains of brief voltage steps superimposed on longer depolarizing step commands, we were unable to detect any activation of outward currents in the presence of these K channel blockers.

Isolated Ca currents observed under these conditions showed voltage-dependent activation consistent with $m^2$ kinetics and slow inactivation (accompanied by a conductance decrease) during step voltage commands. At 23°C the time constant for activation of the Ca current varied from 4.5 ms with commands to -20 mV to 1.0 ms with commands to +20 mV. The Ca tail currents could be fit by two exponentials with mean values of 200 μsec and 2 msec. Washout of the Ca current usually occured within 30 min of recording, but could be slowed by cooling to temperatures below 20°C. Application of norepinephrine (1-5 μM) or isoproterenol (0.5-2 μM) from a puffer pipette placed near the clamped cell body was found to cause an increase in the peak amplitude of the Ca current without changes in activation or tail current kinetics. Preliminary computer simulations using compartmental modeling methods (Johnston & Brown, J. Neurophysiol. 50:464; Carnevale et al., Biophys. J. 47:66a) suggest adequate space clamp conditions in the cells chosen for analysis. The possibility that the observed enhancement of a Ca current by β-adrenergic agonists plays a role in synaptic plasticity is currently under investigation. (Supported by NIH NS15772, NS11535, a McKnight Neurosci. Devel. Award, USAMRDC DAMD17-82-C-2254, and AFOSR-85-0178.)

231.6 KINETIC AND PHARMACOLOGICAL PROPERTIES DISTINGUISH N-TYPE CALCIUM CHANNELS FROM OTHER TYPES OF CALCIUM CHANNEL IN CHICK SENSORY NEURONS. A.P. Fox, M.C. Nowycky+ and R.W. Tsien, Dept. of Physiology, Yale Univ. Sch. Med., New Haven CT 06510 and +Dept. of Anatomy, Medical College of Penn., Philadelphia PA 19219.

We find three types of calcium channel on cell bodies of chick dorsal root ganglion cells with quite different conductances with 110 mM Ba in the patch pipette. A ~25 pS channel (L) accounts for long-lasting currents activated at strong depolarizations; an ~8 pS channel (T) underlies transient currents activated at weak depolarizations; a ~13 pS channel (N) with distinctive properties is described here. N-type channel activity (left column) activates with strong test pulses, unlike T-type channels. Unlike L-type channels, it also requires negative holding potentials (HP) for repriming, and shows a fairly rapid time-dependent inactivation, seen in individual sweeps (a) or an averaged current record (b). We often find patches containing >100 N-type Ca channels and few if any T- or L- type channels. These are useful for studying activation or inactivation kinetics (c,d). With test pulses from HP=-80 mV (c), N-type channel activation becomes clear at -20 mV (T-type activity appears at -50 mV and L-type activity appears at 0 mV). When channel availability is tested with pulses to +10 mV (d), inactivation is removed between HP=-20 and -80 mV; in contrast, T-type channels are totally inactivated at HP=-40 while L-type channels are partly available even at HP=0 mV. Unlike L-, N- and T-type channels fail to respond to 5 uM Bay K 8644. Conversely, L- and N-type channels are almost fully blocked by 50 uM Cd, while T-type channels are not. All of these results support the idea of three distinct channel types.



231.7 $^{3}$H-NITRENDIPINE BINDING SITES CORRELATE WITH DIHYDROPYRIDINE-SENSITIVE CALCIUM UPTAKE IN CULTURES OF CEREBELLAR GRANULE CELLS AND NG108-15 HYBRID CELLS. E. Carboni* and W.J. Wojcik (SPON: R. Levy). Lab. Preclin. Pharmacol., NIMH, St. Elizabeths Hosp., Washington, D.C. 20032.

Calcium influx through voltage dependent calcium channels is important in coupling excitation and contraction in cardiac and smooth muscle and in releasing neurotransmitters. In the last few years, the voltage sensitive calcium channel antagonists have been tested in the above systems. Even though they have recognized effects in cardiac and smooth muscle preparations, some controversy exists about their action in neuronal systems. In brain membrane preparation, $^{3}$H-Nitrendipine binding has been well characterized, demonstrating the presence of high affinity sites. Despite the presence of these high affinity binding sites, it has been difficult to show any antagonism of calcium uptake into neuronal tissue by dihydropyridines as nitrendipine or stimulation of uptake by the agonist BAY K 8644.

We have investigated the voltage sensitive calcium channels by measuring $^{45}Ca^{++}$ uptake and $^{3}$H-nitrendipine binding in primary cultures of cerebellar granule cells and in neuroblastoma-glioma NG 108-15 cells. In membranes prepared from 8 day old cultures of granule cells, we found a high affinity $^{3}$H-nitrendipine binding site ($K_D$= 0,71 nM, Bmax= 73.3 fmol/mg prot.), which was displaced by other dihydropyridines with $IC_{50}$'s in the nanomolar range. In those studies involving $^{45}Ca^{++}$ uptake in the intact cells, nitrendipine (100 nM) was able to inhibit the 60 mM $K^+$ induced $^{45}Ca^{++}$ uptake by 60%. This depolarizing concentration of $K^+$ stimulated $^{45}Ca^{++}$ uptake by three times. BAY K 8644 (100 nM) stimulated calcium uptake by five fold in the presence of 60 mM $K^+$ and nitrendipine (100 nM) was able to counteract this stimulation by 75%. BAY K 8644 did not affect calcium uptake with physiological concentrations of $K^+$. Veratridine (50 uM), was able to increase calcium uptake at 5 mM $K^+$ by 2.5 times and BAY K 8644 (100 nM) further increased calcium uptake by 4.2 times. Nitrendipine (100 nM) was able to antagonize the effects of veratridine and veratridine plus BAY K 8644.

In NG108-15 cells, 60 mM $K^+$ stimulated $^{45}Ca^{++}$ uptake by 1.8 times while BAY K 8644 (100 nM) increased uptake by 2.5 times. In this preparation, nitrendipine (100 nM) completely antagonized the calcium uptake induced by 60 mM $K^+$ and by 75% in presence of 60 mM $K^+$ plus BAY K 8644. $^{3}$H-Nitrendipine binding in membrane preparation of these cells gave a $K_D$ = 1.1 nM and a Bmax = 5.76 fmol/mg prot.

In conclusion our data, support the presence of functional 1,4-dihidropyridine sites associated with calcium channels in primary cultures of cerebellar granule cells and in neuronally derived neuroblastoma-glioma hybrid cells.

231.8 VOLTAGE-DEPENDENT CALCIUM CHANNELS IN XENOPUS OOCYTES INJECTED WITH EXOGENOUS mRNA. N. Dascal*, T. P. Snutch*, H. Lubbert*, N. R. Davidson* and H. A. Lester. Divisions of Biology and Chemistry, Caltech, Pasadena CA 91125.

As reported earlier by other groups (e.g., Gundersen et al., Nature, 308:421; Houamed et al., Nature, 310:318), the injection of mRNA from brain resulted in the appearance of ion channels activated by agonist (GABA, kainate, serotonin) and voltage (Na, K, Cl) in oocyte's membrane. 2-3 days after injection of brain, muscle and heart RNA, an additional depolarization-activated current was resolved with 40 mM external Ba, 0 external Cl, and intracellular TEA injections. This current was blocked by 0.1 mM Cd or 2mM Co but not by TTX. The peak amplitude was as high as 150 nA and correlated well with that of the Ca-activated Cl current observed in the same cells in normal physiological solution. We conclude that the Ba current flows through voltage-dependent calcium channels (VDC's).

The Ba currents from heart RNA peak at +10 mV and show little decline during a 1-s depolarization; brain and muscle RNA induces Ba currents with a peak at 0 mV and half-decay times of about 70-80 and 100 msec, respectively. Ba currents in heart- and brain mRNA-injected oocytes were substantially enhanced and prolonged by exposure to the adenylate cyclase activator, forskolin. Similar enhancement was observed for several minutes after direct intracellular pressure injection of cyclic AMP; this effect was repeated several times in a given oocyte.

By comparing results with total, poly(A)$^-$ and poly(A)$^+$ RNAs, we conclude that the calcium channels are synthesized from poly(A)$^+$ mRNA. RNA was injected from rats of various ages; the synthesis of heart VDC is maximal between 6 and 8 days postnatal. Supported by GM-29836, GM-10991, AHA, Bantrell Foundation, Deutsche Forschungsemeinschaft, and Fulbright Award.

231.9 CAN VOLTAGE-SENSITIVE CALCIUM CHANNELS OF THE RAT CHROMAFFIN CELLS BE OPENED AT THE RESTING MEMBRANE POTENTIAL? T.D. Wakade*, R.K. Malhotra*, T.R. Sharma* and Arun R. Wakade.(SPON: R. Margolis). Department of Pharmacology, State University of New York, Downstate Medical Center, Brooklyn, NY 11203.

A number of procedures and agents have been known to induce secretion of catecholamines (CA) from the adrenal medullary cells. The increase in intracellular Ca resulting from opening of potential-sensitive or receptor-linked Ca channels is primarily responsible for triggering exocytotic secretion of CA. We describe here an entirely new approach to evoke enormous secretion of CA in a Ca-dependent manner. The method offers a new tool to study the behavior of potential-sensitive Ca channels of the chromaffin cells and their role in the secretion of CA.

The experiments were carried out on the isolated perfused adrenal gland of the rat (Wakade, J. Physiol. 313: 463, 1981) and the findings were as follows: Perfusion of the adrenal gland with hypertonic solution (HS; 275 mM NaCl-Krebs solution) caused an increase (68 vs. 180 pg/mg) in the uptake of $^{3}$H-tetraphenylphosphonium (TPP), a lipophilic marker used to detect changes in the membrane potential of chromaffin cells. (The uptake of TPP has been shown to be inversely related to the membrane potential.) Reperfusion with normal solution (NS) reduced the uptake of TPP to the control level (180 vs. 80 pg/mg). Although during prolonged perfusion with HS there was no change in the rate of secretion of CA, it increased from about 1 ng to 400 ng/min after switchover from HS to NS, and the secretory response persisted up to 40 min at the level of 80 ng/min. The net uptake of $Ca^{45}$ in the adrenal medulla was markedly enhanced (6-fold) when the perfusate was changed from HS to NS. The increase in the net uptake of $Ca^{45}$ was seen up to 120 min after the changeover of solutions. The increase in the uptake of $Ca^{45}$ was always associated with an increase in the secretion of CA. The secretion evoked by the switchover of HS to NS was reduced in the presence of Ca channel-blockers and by Ca deprivation. If the adrenal gland was perfused with HS made by adding 156 mM choline chloride, arginine hydrochloride, or 312 mM sucrose to Krebs solution, essentially the same phenomenon of massive secretion of CA was observed after switchover to NS. Chronic splanchnectomy, antagonists of nicotine and muscarine receptors or tetrodotoxin did not affect the secretion of CA evoked by switchover from HS to NS. It is concluded that the threshold value for opening of Ca channels of rat chromaffin cells is not fixed at a critical membrane potential level and probably drifts in relation to the resting membrane potential. Furthermore, a relative change in membrane potential rather than the absolute change is sufficient to opening of these Ca channels.

231.10 REGULATION OF NOREPINEPHRINE RELEASE FROM PC12 PHEOCHROMOCYTOMA CELLS BY CALCIUM CHANNEL MODULATORS. S. Kongsamut*, R.M. Nonacs* and R.J. Miller*. Dept. of Pharmacological and Physiological Sciences, University of Chicago, Chicago, IL 60637.

Evoked neurotransmitter release from neurones has usually been found to be insensitive to dihydropyridines (DHP) and other calcium channel blocking drugs. PC12 pheochromocytoma cells can be grown to resemble endocrine cells or neurones depending on whether nerve growth factor (NGF) is added. We therefore investigated the pharmacology of transmitter release from several clones of PC12 cells (PC12T, S or P) grown with or without NGF (50ng/ml).

NGF untreated PC12T cells responded to increasing depolarization with increasing $[K^+]_o$ by releasing preloaded [$^{3}$H]-norepinephrine (NE). Half maximal release of NE occurred at 40mM $[K^+]_o$. The evoked release of NE could be blocked by divalent cations and organic calcium channel blockers. Nitrendipine and BAY K8644 blocked and enhanced depolarization induced release respectively in a dose dependent fashion. In addition, the (+) and (-) isomers of the novel DHP 202-791 enhanced and inhibited [$^{3}$H]-NE release respectively. NGF treatment of PC12T cells resulted in the appearance of short stubby neurites. However, evoked $^{3}$H-NE release from such cells remained sensitive to DHP's. When grown without NGF, [$^{3}$H]-NE release from PC12P cells was also sensitive to DHP's. NGF treatment of PC12P cells resulted in much more extensive morphological differentiation and the appearance of long cell processes. However, evoked [$^{3}$H]-NE release remained DHP sensitive. NGF treatment of PC12S cells resulted in little morphological differentiation and no neurite formation. Either with or without NGF release was DHP sensitive. Interestingly, on long term culture the DHP sensitivity of PC12S cells declined so that eventually evoked release of [$^{3}$H]-NE became completely insensitive to DHP's. This was true for both NGF treated and untreated cells. Treatment of PC12T and S cells with NGF resulted in the appearance of high affinity binding sites for [$^{3}$H]-DAla$^2$,DLeu$^5$-enkephalin [DADLE]. In the case of PC12T cells, binding increased over a two week treatment period from nearly undetectable levels to 20 fmol/mg protein. The $K_D$ was 1.6nM. We are currently examining the opiate sensitivity of transmitter release from these cells.

Treatment of PC12T cells with agents that increased [cAMP] such as forskolin or adenosine augmented evoked [$^{3}$H]-NE release. The extra release produced by these agents was also sensitive to DHP's.

We conclude, (1) that in PC12 cells at any rate the DHP sensitivity of transmitter release does not necessarily correlate with neuronal growth mode and (2) that cAMP enhances [$^{3}$H]-NE release from PC12 cells utilizing a DHP sensitive pathway. We hypothesize that the DHP sensitive calcium channel in neurones may be regulated by cAMP as in the heart and that this may be a mechanism for the modulation of transmitter release from neurones possessing such channels.

231.11 LEPTINOTARSIN-d OPENS RAT BRAIN CALCIUM CHANNELS. M.L. Koenig, J. Connor, T. Hsaio*, and W.O. McClure. Section of Neurobiology, USC, Los Angeles, CA 90089-0371; Dept. Mol. Biophysics, AT&T Bell Laboratories, 600 Mountain Ave., Murray Hill, NJ 07974; Dept. Biol., Utah State Univ., Logan, UT 84322.

Leptinotarsin-d (LPT), a 45,000 dalton protein purified from hemolymph of the Colorado potato beetle, has been shown to effect neurotransmitter release from rat brain synaptosomes by opening presynaptic calcium channels. We have found that LPT has no effect on the calcium channels of Paramecium caudatum, squid optic lobes, cultured PC12 cells, or identified neurons in several gastropod molluscs. The toxin is a potent activator of mammalian calcium channels however (Kd for Ca-dependent release = 3.8 nM), and seems to act with maximal effect on channels derived from the mammalian central nervous system (CNS).

Since a number of calcium channel blockers bind with high affinity to rat brain membranes, presumably to calcium channels, we have investigated the possibility that LPT-stimulated release might be inhibited by preincubation of the synaptosomes with these antagonists. At concentrations of 0.1 to 100 uM, neither nitrendipine nor nifedipine can block LPT-stimulated release of acetylcholine (ACh) from rat brain synaptosomes. Concentrations of verapamil equal to or greater than 10 uM only marginally inhibit (10-15%) the release of ACh in the same system.

We have also studied the effect of LPT on calcium flux across the membranes of CNS neurons by using the calcium indicator dye FURA-2 and digital imaging techniques. Addition of 5 nM LPT to a heterogeneous culture of rat diencephalon cells results in a dramatic increase in the intracellular calcium concentration of some but not all of the cells. The fact that not all cells are affected provides further evidence that LPT is neither permeabilizing cell membranes nor altering the normal calcium exchange mechanisms. Influx of calcium into the affected cells becomes maximal after 8 minutes and cannot be eliminated by extensive washing. If the same cells are washed with a saline solution containing 10 uM nifedipine, the intracellular calcium concentration is rapidly restored to its normal low resting level (<0.1 uM). Thus nifedipine, if added subsequent to LPT exposure, is able to reverse the effect of LPT and block some neuronal calcium channels.

The evidence suggests that both LPT and nifedipine act on a specific class or subtype of brain calcium channel, and may partially explain the discrepancies regarding the effects of dihydropyridines on neuronal calcium channels.

Supported, in part, by the Nelson Research and Development Company and the NIH.

231.12 MODULATION OF VOLTAGE-GATED CALCIUM CHANNEL FUNCTION BY ETHANOL. R.O.Messing*, C.L.Carpenter*, and D.A.Greenberg. Department of Neurology, University of California, San Francisco, CA 94110.

The activity of voltage-gated Ca channels is modified by a variety of drugs and ions, but little is known about long-term modulatory influences on channel function. Chronic exposure to ethanol alters Ca-dependent neurotransmitter release, which may be due to changes in depolarization-induced $Ca^{2+}$ entry into nerve terminals. To determine if the actions of ethanol involve changes in the function of voltage-gated Ca channels, we studied the effects of acute and chronic exposure to ethanol on 50 mM K-stimulated $^{45}Ca$ uptake and [$^{3}$H] nitrendipine ([$^{3}$H] NIT) binding in PC12 pheochromocytoma cells. In acute experiments, $^{45}Ca$ uptake was inhibited half-maximally at 205 mM ethanol and completely at 600 mM. For a series of n-alkanols, the relationship between uptake inhibition and alcohol chain length was linear, implying that inhibition of $^{45}Ca$ uptake is not due to increased osmolality alone. Cells cultured in 200 mM ethanol for 6 days demonstrated a 70-100% increase in K-stimulated $^{45}Ca$ uptake compared to control cells. This increase was not accompanied by a change in the acute response of Ca channels to ethanol, since $^{45}Ca$ uptake was inhibited to a similar extent by ethanol in chronically treated ($IC_{50}$ = 168 mM) and control ($IC_{50}$ = 178 mM) cells. To further investigate the mechanism underlying the increase in $^{45}Ca$ uptake observed in chronically-treated cells, we measured the number of channels present in membranes of cells treated with 200 mM ethanol for 6 days using [$^{3}$H] NIT as a channel-counting probe. Scatchard analysis gave $K_d$ values of 125 and 104 pM and $B_{max}$ values of 28.7 and 12.2 fmol/mg of protein for the treated and control cells respectively. The observed increase in binding site number may reflect a corresponding increase in the number of functional Ca channels, and thus explain the augmented $^{45}Ca$ uptake in cells chronically treated with ethanol. These findings suggest that Ca-dependent neuronal processes may be subject to long-term regulation by alterations in channel number induced by drugs or endogenous factors.

## INVERTEBRATE LEARNING AND BEHAVIOR III

232.1 NEURAL CORRELATES OF HABITUATION AND SENSITIZATION IN THE LEECH. S.R. Lockery and W.B. Kristan, Jr. Dept. of Biol., Univ. of Ca., San Diego, La Jolla, CA 92093.

A sudden increase in light intensity triggers an abrupt longitudinal contraction ("shortening") in Hirudo. Repeated presentation of light reduces probability of shortening and increases latency i.e., produces habituation (Lockery et al., Behav. Neurosci., 99: 333, 1985). Electric shock increases the probability of shortening and decreases latency i.e., produces sensitization. To investigate cellular bases of these phenomena, we used a semi-intact preparation allowing simultaneous recording of behavior and neural activity.

Abdominal segments 2-7 were left intact and ganglia 8-10, with their roots, were exposed for recording. Light and shock were delivered to segment 3. Shortening was monitored by a tension transducer attached at segment 2. A light pulse (18 s) produced a transient increase in longitudinal tension with two components: a small "primary response" with a time to peak tension of < 1 s, and a larger "secondary response" with a time to peak of many seconds. Motor neurons controlling shortening were recorded extracellularly. These cells responded with impulse bursts corresponding to the two components of increased tension.

The semi-intact preparation showed habituation and sensitization analogous to that of the whole animal. Primary response peak tension declined 60% over ten trials (one trial every 100 s). For control animals exposed only to trials 1 and 10, the decline was significantly less (5%). A mild shock immediately after trial 10 increased response on the next trial to 194% of the trial 1 value. Animals not shocked showed significant spontaneous recovery after 45 min. Similar results were obtained for secondary responses.

Changes in the activity of motor neurons correlated well with changes in the primary response. The neural response to light (the increase in firing frequency over baseline during a 1 s light pulse) was measured over 20 trials (one trial every 5 s). The neural response diminished with successive stimulations in parallel with the decline in primary tension. In fact, with data normalized to trial 1, the two curves could be superimposed. Similarly good correlation was obtained for sensitization.

These results demonstrate that motor neuron activity closely predicts the strength of the shortening response. Furthermore, they indicate that the changes responsible for habituation and sensitization in Hirudo are presynaptic to the motorneurons.

232.2 CELLULAR MECHANISMS OF ASSOCIATIVE LEARNING IN HERMISSENDA: CONTRIBUTION OF LIGHT-ACTIVATED CONDUCTANCES. T. Crow. Department of Physiology and Center for Neuroscience, University of Pittsburgh School of Medicine, Pittsburgh, PA 15261.

Positive phototactic behavior of Hermissenda is modified by conditioning when light (CS) is paired with stimulation of the gravity-detecting statocysts (Crow and Alkon, 1978). Associated with the conditioned modification of phototaxis are a number of cellular correlates found in the sensory neurons (type B photoreceptors) of the CS pathway (Crow and Alkon, 1980; Alkon, Lederhendler, and Shoukimas, 1982; Crow, 1982; Alkon, 1984; Crow 1985). Recently, it was reported that conditioning results in a significant decrease in the amplitude of the photoresponse measured after 5 min of continuous illumination (Crow, 1985). The reduction in the photoresponse can not be explained by the previously reported reduction in $I_A$ of conditioned animals since adding 10 mM 4-AP to the bath ASW resulted in an increase in photoresponse amplitude measured after 5 min of continuous light (mean increase = 31.2%, n=7, $t_6$=13.4; $P < .005$). However the reduction in the amplitude of the photoresponses of conditioned Hermissenda could be due to changes in other voltage-dependent currents and/or light-activated membrane currents. In the experiments reported here I investigated the role of light-dependent currents in the reduction of the photoresponse of conditioned Hermissenda with voltage clamp techniques.

The training and testing procedures were identical to those used previously to demonstrate associative learning in Hermissenda (Crow and Alkon, 1978, Crow, 1985). Axotomized type B photoreceptors from conditioned and random control preparations were first dark adapted and then voltage clamped at their dark adapted resting membrane potential. Inward current evoked by a 100 msec light flash was measured in normal ASW and ASW containing 30 uM TTX from a holding potential of -55 mV or from the dark adapted membrane potential. After the light flash the clamp was turned off and the B-photoreceptors were dark adapted and then illuminated for 5 min with white light attenuated-2.0 log units. After 5 min of continuous illumination the B-photoreceptors were again voltage clamped and inward current evoked by a series of 100 msec light flashes was measured and compared to the pre-light adapted light-evoked membrane current. Conditioning resulted in a significant relative decrease in light-evoked inward current measured after 5 min of continuous ilumination as compared to random controls ($t_7$=2.58; $P < .05$). These results suggest that alterations in light-activated conductances contribute to the decrease in the amplitude of the generator potential of conditioned Hermissenda, and are consistent with previous reports of modifications of light and $Ca^{++}$-dependent processes underlying adaptation in type B-photoreceptors.

232.3 LONG-LASTING STIMULATION-INDUCED ENHANCEMENT OF SYNAPTIC TRANSMISSION IN THE CRAYFISH LATERAL GIANT ESCAPE CIRCUIT. M.W. Miller* and F.B. Krasne. Dept. of Psychology, University of California, Los Angeles, CA 90024.

The sensory limb of the crayfish lateral giant (LG) escape circuit is known to exhibit a use-induced depression of synaptic transmission, which underlies habituation of the tailflip response to repeated stimuli (Krasne, 1969; Zucker, 1972). We now report that brief periods of repetitive stimulation at frequencies higher than those which cause depression can cause substantial and sustained enhancement of transmission in the pathway.

Two types of enhancements were noted following trains to the second roots of abdominal ganglia 2-5. These differed in their time course and in the input pattern with which they were elicited.

(1) High frequency (50 Hz) trains delivered for brief durations (2 sec) resulted in a posttetanic potentiation (PTP) which lasted for 5-10 minutes.

(2) Low frequency (4 Hz) trains applied for 10 seconds produced a long-term potentiation ("LTP") which could last for hours.

Application of trains to neighboring ganglia failed to produce enhancements in "test" ganglia, indicating that neither type of potentiation is produced by a widespread interganglionic system such as that underlying sensitization (Krasne and Glanzman, 1984).

The long-term potentiation exhibited "cooperativity" like that noted in hippocampal LTP (Bliss and Gardner-Medwin, 1971; McNaughton et al., 1978). The potentiation produced by trains in which stimuli were stronger (2X) than the test stimuli was greater than that produced by trains in which stimuli were equal to the test intensity. This indicates that the LTP is not simply the result of repetitive firing of the "test" population of fibers but is influenced by coactivity of additional input fibers in the same pathway. Experiments are in progress to determine whether this coactivity sensitive potentiation is, like hippocampal LTP, associative in the sense that trains of strong stimuli to one set of afferents will selectively enhance the effectiveness of other afferents that are stimulated concurrently.

232.4 LONG-TERM FACILITATION OF THE MONOSYNAPTIC CONNECTION BETWEEN SENSORY NEURONS AND MOTOR NEURONS OF THE GILL-WITHDRAWAL REFLEX IN APLYSIA IN DISSOCIATED CELL CULTURE. P. G. Montarolo*, V. F. Castellucci, P. Goelet*, E. R. Kandel, and S. Schacher (SPON: European Neuroscience Association). H. Hughes Medical Institute and Ctr. for Neurobiol. & Behav., Columbia Univ., College of P&S, and NYS Psychiat. Instit., New York, NY 10032.

The gill-withdrawal reflex of Aplysia undergoes short-and long-term sensitization both of which are mediated by facilitation of the direct connection between sensory neurons and motoneurons of the reflex. Recently it has become possible to reconstitute the neuronal circuit mediating this reflex in cell culture (Rayport, S. and Schacher, S., Neurosci. Abst. 10:923, 1984). As in vivo, the synapse between the sensory neurons and gill motor neuron L7 undergoes short-term facilitation when treated with 5-HT, a transmitter which simulates the effects of sensitizing stimuli. In the intact animal, long-term sensitization can be produced by presenting four or more facilitating stimuli at regular intervals. We have used an analogous protocol in the in vitro system, using repeated brief exposures to 5-HT, to explore the cellular and molecular mechanisms of long-term facilitation.

We co-cultured LE mechanosensory cells with the gill motor neuron L7 for six days, at which point the synaptic connections between them had formed and reached a stable amplitude. The EPSPs were determined, and then five bath applications of 5-HT (2 uM, 5 min each) were presented at intervals of 15 min. When retested 24 hrs later, the change in EPSP amplitude in the 5-HT treated cultures (+75 $\pm$ 31%, S.E.; n=6, 10 synapses) was significantly greater ($p<.01$) than the change in EPSP amplitude in control untreated cultures (-12 $\pm$ 8%; n=5, 8 synapses). Similar facilitation also occurred in a separate set of experiments using longer 5-HT exposure periods.

To determine whether this long lasting facilitation is dependent on protein synthesis, we are now studying the effects of protein and RNA nthesis inhibitors. As a first step, we have used anisomycin (10 um) which blocks protein synthesis by more than 90% and has no detrimental effects on evoked LE-L7 EPSPs. Anisomycin was added to cultures 30 min before starting the 5-HT protocol and kept in the cultures until 1 hr following the last 5-HT application. This treatment blocked the 5-HT-induced long-term increase of EPSP amplitudes (-17 $\pm$ 25%; n=4, 6 synapses) without interferring with short-term facilitation, indicating that long- and short-term facilitation can be dissociated. We are examining whether these results are due to a specific inhibition of protein synthesis.

232.5 SITE-SPECIFIC SENSITIZATION IN APLYSIA, LTP, REGENERATIVE BURSTING, AND A POSSIBLE LINK IN THE EVOLUTION OF LEARNING. E.T. Walters, Dept. of Physiol. & Cell Biol., Univ. of Texas Med. Sch., Houston, Texas 77225.

Activity-dependent neuromodulation of sensory neurons in Aplysia has now been implicated as a mechanism for both classical conditioning (Walters & Byrne, 1983; Hawkins et al, 1983) and long-term synaptic potentiation (LTP - Walters & Byrne, 1985). In order to explore the long-term behavioral and cellular effects of procedures known to produce activity-dependent neuromodulation of the tail sensory neurons, I have applied a cutaneous "LTP" training procedure both to restricted sites and to extensive fields in the tail region of intact, freely moving animals and later examined changes in defensive responses and in electrophysiological properties of sensory and motor neurons. The "LTP" training procedure consisted of 10 high frequency trains of shock (either 60 Hz or 25 Hz), each 0.5 sec long, applied to one side of the tail at 5 sec intervals. This brief (45 sec duration) training activated sensory neurons and produced facilitation of their monosynaptic EPSPs to tail motor neurons ($p < .05$) similar to that seen with nerve stimulation LTP (Walters & Byrne, 1985). It also enhanced tail and siphon withdrawals elicited by weak stimulation of the training site (relative to untrained sites) for at least 4 days after training ($p < .025$). While part of this site-specific sensitization may be peripherally mediated, a substantial central contribution was indicated by the greater sensitization seen when the tail was connected to the CNS than when the CNS was disconnected ($p < .05$), and by cellular correlates of the site-specific sensitization observed in sensory neurons in the isolated CNS ($p < .05$). A novel cellular correlate of sensitization was an enhanced likelihood of evoking regenerative bursts (2 to 28 spikes, lasting up to 2 sec) in the sensory neurons of the trained field in response to a 10 msec test depolarization delivered 1 day after training ($p < .01$).

Some have speculated that sensitization was an evolutionary precursor of classical conditioning. Finding that activity-dependent modulation can be a mechanism for both site-specific sensitization and defensive classical conditioning suggests an extension of this hypothesis: activity-dependent modulation in nociceptive systems may have evolved first to encode specific memory (in the form of LTP and regenerative bursting responses) of the sites of tissue damage; in nociceptive cells with a wide dynamic range this mechanism could also encode temporal associations between innocuous signals to one field and damaging events to another - a capacity which would then allow classical conditioning. (Supported by grants MH 38726 from the NIMH and 84-11-104 from the Searle Scholars Program).

232.6 CHOLINERGIC SUPPRESSION: A POSTSYNAPTIC CORRELATE OF LONG-TERM ASSOCIATIVE LEARNING IN PLEUROBRANCHAEA. A. D. Morielli*, E. M. Matera*, M. P. Kovac*, K. J. McCormack* and W. J. Davis. The Thimann Laboratories and Long Marine Laboratories, University of California at Santa Cruz, Santa Cruz, California, 95064

Although the neurotransmitter acetylcholine (ACh) has long been thought to play a role in learning and memory in vertebrates, the evidence for its involvement has been indirect. We here report that after specimens of the marine gastropod mollusk Pleurobranchaea californica have been food avoidance conditioned, the interneurons which command the feeding behavior (the PCN neurons) show a strong suppression of their depolarizing response to ACh.

In order to determine the differential response of PCN cells in brains taken from trained (experimental) and untrained (naive and control) animals, ACh was added to a preparation chamber in which a brain was maintained in sea water at 11°C. A bath concentration of $10^{-4}$ M ACh produced a mean depolarization of 14.1 mv $\pm$ 2.0 (standard error) in the PCN cells of brains taken from naive animals and a mean depolarization of 12.8 mv $\pm$ 4.4 in PCN cells of control animals. In contrast, PCN cells in brains taken from animals trained to avoid a food stimulus showed a mean depolarization of 1.6 mv $\pm$ 0.9 when stimulated with $10^{-4}$ M ACh and were depolarized only when exposed to a ten-fold higher concentration.

Receptors to ACh appear to be located on the soma of the PCN cells. Intracellular recordings were made from 2 adjacent PCN cells, both of which showed similar sensitivity to ACh. ACh ($10^{-2}$ M) was pressure ejected from a micropipette onto the soma of one of the two impaled PCN cells. The cell directly under the ACh pipette became depolarized by 15 mv immediately upon ejection of ACh, while the PCN cell adjacent to it showed no response, suggesting that rather than stimulating cells presynaptic to the PCNs, the ACh has a direct effect on the membrane of the PCN cells themselves.

The PCN cells of untrained animals were depolarized by the muscarinic cholinergic agonist, acetyl-$\beta$-methylcholine, but not by the nicotinic agonist, nicotine. The ACh induced depolarization in untrained animals was blocked by bath application of $10^{-4}$ M atropine, a muscarinic receptor blocker or, in 2 out of 3 cases, $10^{-4}$ M hexamethonium, a nicotinic receptor blocker. The ACh induced depolarization appears to be sensitive to external calcium concentrations and is also blocked by the phospholipase $A_2$ inhibitor quinacrine. These data suggest that the ACh receptors located on the soma of the PCN cells are more similar to the muscarinic receptors than the nicotinic receptors identified in vertebrates and that after avoidance conditioning, the depolarizing response of the PCN cells to ACh stimulation is suppressed.

232.7 LEARNED CHANGES OF FEEDING BEHAVIOR TO EDIBLE AND INEDIBLE FOODS IN APLYSIA. A.J. Susswein, M. Schwarz* and E. Feldman*. Dept. of Life Sciences, Bar-Ilan University, Ramat Gan, Israel 52100.

Aplysia learn to modify their feeding behavior when the behavior is paired with reinforcing consequences. Successful and failed attempts to transfer food from the buccal cavity to the gut respectively act as positive and negative reinforcers. Behavioral change is specific to feeding in response foods of a particular taste and texture. Plasticity is specific to pairing, as shown by lack of behavioral change when reinforcement is explicitly unpaired with feeding responses to a specific food. Memory of the response change persists for at least a week.

We determined whether neural mechanisms underlying regulation of feeding by associative learning may be related to mechanisms responsible for other processes regulating feeding, such as satiation or response decrement to sustained lip stimulation. A number of parametric features of feeding behavior were measured, to determine how they are affected by learning and by other forms of plasticity. If different processes modulating feeding operate via a common mechanism, the various parameters should be affected in a similar manner; by contrast, if unique mechanisms underlie each process the behavioral effects should also be distinct. Parametric features of feeding examined were: 1) efficacy of a feeding response in producing entry of food into the buccal cavity; 2) time that food remains in the buccal cavity after it enters; 3) number of attempted swallows elicited by food within the buccal cavity; 4) time that Aplysia maintain responsiveness to food; 5) specficity of response change to a particular food; 6) memory of response change. On the basis of differences in effects upon these parameters, learned changes in feeding behavior can be distinguished from those due to other processes. The data suggest that different CNS mechanisms are responsible for different forms of behavioral plasticity affecting Aplysia feeding.

Bilateral section of the esophageal nerves innervating the gut specifically impairs learned changes in feeding behavior, but not behavioral change due to sustained lip stimulation. Unilateral nerve section, or section of either of the two major divisions of the esophageal nerve, does not impair learning. These data suggest that stimuli necessary for reinforcement travel in this nerve. Such stimuli inform the CNS as to whether or not an attempt to ingest food was successful. The nature of gut stimuli necessary for learning is currently being explored.

232.8 **OPERANT CONDITIONING OF HEAD-WAVING IN *APLYSIA CALIFORNICA*** D.G. Cook* & T.J. Carew (sponsor: C.F. Stevens) Dept. Psychology Yale University, New Haven, CT 06520

An unresolved question in Psychology is whether classical and operant conditioning are fundamentally different or share a common mechanism. This issue might be clarified by comparing them on a cellular level. *Aplysia* could be useful for this analysis since progress has already been made in understanding the cellular mechanisms of classical conditioning. This led us to ask whether *Aplysia* can exhibit operant conditioning as well.

The operant response we examined was head-waving. Animals were trained to modify this response, increasing its frequency on one side of the body, in order to terminate the presentation of aversive bright lights. All experiments consisted of a 5 min baseline, 10 min of training, and a 5 min (non-reinforced) test. In the first experiment, animals receiving contingent reinforcement (N=10) spent significantly more test time on the non-reinforced ("safe") side compared to baseline ($p<.01$) and compared to yoked controls (N=10, $p<.05$). When the contingencies of reinforcement were reversed (safe side now punished and vice versa) the contingent group showed a marked decrease in responding on the now-punished side, and when the original contingencies were reinstated, they again increased their responding on the safe side. There was a significant trend ($p<.05$) in the contingent group's responding to these reinforcement contingencies, while yoked controls showed no significant trend. Two weeks later both groups of animals were retrained with contingent reinforcement. Both groups now showed significant conditioning ($p<.01$, $p<.05$, respectively) indicating that the previously yoked group was capable of conditioning if exposed to the appropriate reinforcement contingencies. In a second experiment we found that the learning was relatively resistant to extinction. Animals (N=10) were first given contingent training and showed significant learning ($p<.01$). They were the given 10 min of non-reinforced (extinction) training and still exhibited significant retention ($p<.005$). Only following reversed contingency training did they reduce responding on the safe side. In a final experiment we examined the cues used as feedback to learn the operant. To distinguish between visual and internally derived cues (eg. proprioceptive or efference copy) we trained as before but disrupted visual cues by rotating animals 180° before testing. The contingent group (N=10) still showed significant learning ($p<.006$); yoked controls (N=10) once again did not learn. Thus it appears that internal cues are used to code the operant response.

Neurons in both the reinforcement (Jacklet, 1980) and operant pathways (Henning, et al 1979) have previously been identified. Thus it is now possible to begin to analyze the cellular mechanisms of operant conditioning in *Aplysia*.

232.9 CONTEXT CONDITIONING IN APLYSIA CALIFORNICA. R. M. Colwill* (SPON: V. Castellucci). Howard Hughes Medical Institute for Molecular Neurobiology, Center for Neurobiology & Behavior, Columbia University, College of P&S, and N.Y.S. Psychiatric Institute, New York, NY 10032.

Studies of the associative capacities of invertebrates have focussed on learning yielded by pairings of conditioned (CS) and unconditioned stimuli (US). Less attention, however, has been paid to learning about the context in which those pairings occur. That neglect is surprising given the important role that informational theories of Pavlovian conditioning assign to contextual stimuli. Those theories assume that several complex learning phenomena (e.g., sensitivity to CS-US contingency) depend on the development of associations between contextual stimuli and USs. For that reason, it is important to demonstrate contextual learning in preparations used for neurophysiological analyses of learning. This paper examines context-US associations in Aplysia whose nervous system has been studied in detail.

Subjects received shock USs in one context but not in another. The success of that treatment in conditioning the context was evaluated in two ways; first, by the impact of the context on responding, and second, by its ability to interfere with learning. Sixteen Aplysia were exposed to two different contexts: a smooth round bowl containing lemon flavored sea-water and a lined rectangular box containing plain sea-water and an aerator. Several moderate electric shocks were delivered to the mantle shelf in one context but not in the other. To assess context conditioning, we first measured the defensive reaction of each subject in the presence of the contextual cues. Subjects exhibited more fear in the shocked context than in the nonshocked context as indexed by the duration of siphon withdrawal in response to mild siphon stimulation ($p< .05$). The second assessment of contextual conditioning exploited a finding that has been well documented in vertebrates: pairings of a CS and US are less effective when delivered in a context that has previously been associated with that US. Consequently, we examined the ability of the shocked context to interfere with conditioning of a CS that was paired with the mantle shock reinforcer. All subjects received 8 pairings of mild siphon stimulation with mantle shelf shock. For half the animals, that training occurred in the shocked context; for the other half, it occurred in the nonshocked context. All subjects were then given a nonreinforced presentation of the siphon stimulus in a third context (home tank). The duration of siphon withdrawal elicited by the CS was longer if conditioning had taken place in the nonshocked context than in the shocked context ($p<.05$). That outcome suggests that the initial context-shock pairings established a context-US association. These results suggest that Aplysia californica can form an association between a shock US and the context in which that US occurs. That association was revealed both by enhanced defensive reactions in the shock-associated context and by the ability of that context to interfere with conditioning of a discrete CS paired with that shock. To our knowledge, this provides the first demonstration of blocking in Aplysia. That result is of substantial significance because of the central role blocking is accorded by informational theories of Pavlovian conditioning.

232.10 OPERANT CONDITIONING AND DIFFERENTIAL CLASSICAL CONDITIONING OF GILL WITHDRAWAL IN APLYSIA. R. D. Hawkins, G. A. Clark, and E. R. Kandel. Howard Hughes Medical Institute, Center for Neurobiology & Behavior, Columbia University, and N. Y. State Psychiatric Institute, New York, NY 10032.

Associative learning has traditionally been divided into two major categories: classical and operant conditioning. To determine how these two forms are related, it would be desirable to examine them in the same simple behavioral system. Classical conditioning has been demonstrated for gill and siphon withdrawal in Aplysia (Carew et al., 1981), and operant conditioning has been demonstrated for head waving (Cook & Carew, 1985). The cellular mechanism of classical conditioning of the withdrawal response has been analyzed (Hawkins et al., 1983). We now report that the gill component of the withdrawal response, which undergoes differential classical conditioning, also undergoes operant conditioning.

Animals were restrained with hooks attached to the parapodia and a movement transducer was attached to the gill. To study differential classical conditioning, two CS electrodes were clipped to the siphon to deliver the conditioned stimuli (CSs) and a pair of electrodes was implanted in the tail to deliver the unconditioned stimulus (US). During training, stimulation of one CS electrode was paired with and preceded the US by 0.5 seconds, while stimulation of the other CS electrode was specifically unpaired with the US. Fifteen to sixty minutes after 5 training trials, the amplitude of the response to the paired CS was significantly greater than that of the response to the unpaired CS (73% vs. 53% of pretest in 20 experiments, $p<.05$), demonstrating differential classical conditioning.

To study operant conditioning, the same preparation was used except that the mantle shelf was glued to a fixed rod to minimize body movement, and a single electrode was implanted in the siphon. Animals were run in pairs. During the first phase of the experiment, one animal (the contingent animal) received siphon shock each time its gill relaxed beyond a criterion level (approximately 20% of full contraction) and the other animal (the yoked control) received shock at the same time, regardless of its gill position. During the second phase of the experiment, shock was contingent on gill position for both animals. Each phase consisted of two 10 minute training periods alternating with 10 minute extinction periods. Animals which received contingent training in phase I spent a significantly greater percent of the time with their gills contracted beyond the criterion level than did control animals in all segments of the experiment: that is, during training (91% vs. 64% in 20 pairs of animals, $p<.01$) and extinction (38% vs. 22%, $p<.05$) in phase I and also during training (82% vs. 73%, $p<.05$, 1-tail) and extinction (34% vs. 20%, $p<.05$) in phase II, demonstrating operant conditioning.

Since much is already known about the neural control of gill withdrawal, it may now be possible to study the mechanism of operant conditioning as well as the relationship between operant and classical conditioning of this response on the cellular level.

232.11 ACTIVATION OF ADENYLATE CYCLASE IN APLYSIA NEURAL TISSUE BY $Ca^{2+}$/CALMODULIN, A CANDIDATE FOR AN ASSOCIATIVE MECHANISM DURING CONDITIONING. T. W. Abrams, L. Eliot, Y. Dudai and E. R. Kandel. Center for Neurobiology & Behavior, and Howard Hughes Medical Institute, Columbia University, College of P & S, N. Y. State Psychiatric Institute, New York, NY 10032.

In classical conditioning of the siphon withdrawal reflex of Aplysia, the reflex response to the conditioned stimulus, a siphon touch, is enhanced if the CS is presented immediately prior to the unconditioned stimulus (US), a tail shock. On the cellular level, this temporal specificity may be substantially accounted for by the fact that spike activity in the siphon sensory neurons enhances their response to the presynaptic facilitatory input resulting from the US. Thus facilitation of the synaptic connection from the sensory neurons that produce the reflex occurs optimally when action potentials in the sensory neurons have been triggered by the CS just before the presentation of the US (Hawkins et al., 1983). Moreover, our evidence suggests that the $Ca^{2+}$ influx that occurs during this paired spike activity is critical for the enhancement of the facilitation response (Abrams et al., 1983).

We have now begun to analyze the basis of this temporal specificity on the molecular level. Because paired spike activity and the resulting $Ca^{2+}$ influx enhance the elevation of cAMP that mediates presynaptic facilitation in the sensory neurons (Abrams et al., 1984), we have investigated whether the adenylate cyclase in Aplysia nerve cells is modulated by $Ca^{2+}$/calmodulin. Three lines of evidence suggest that the adenylate cyclase in particulate membrane from Aplysia neurons is indeed activated by calmodulin, as is the cyclase in mammalian brain. 1) Stimulation of the cyclase by $Ca^{2+}$ plus 5-HT is substantially reduced by the calmodulin inhibitor R24571 (84 $\pm$ 21% stimulation reduced to 18 $\pm$ 14% stimulation) or by a second inhibitor, W7. 2) After membranes are depleted of endogenous calmodulin by washing first with trifluoperazine and then with EGTA, there is little cyclase stimulation by either $Ca^{2+}$ or 5-HT; in contrast, after addition of mammalian brain calmodulin, $Ca^{2+}$ in combination with 5-HT produces more than two fold activation of the cyclase. 3) Approximately 25% of the adenylate cyclase activity from solubilized Aplysia nervous tissue membrane binds to calmodulin-Sepharose in a $Ca^{2+}$-dependent manner; eluting this activity with EGTA yields cyclase that is stimulated 2-fold by mammalian calmodulin, but is not stimulated by regulatory G protein activators, suggesting that calmodulin binds directly to the catalytic unit. We are presently using the membrane homogenate to investigate whether the dual activation of the calmodulin-dependent cyclase can account for the temporal specificity observed in the conditioning of the reflex.

232.12 ABSENCE OF STIMULATOR-INDUCED AFFINITY SHIFTS IN AN ADENYLATE CYCLASE SYSTEM FROM THE DROSOPHILA MEMORY MUTANT RUTABAGA. Yadin Dudai, The Weizmann Institute of Science, Rehovot 76100, Israel.

The Drosophila mutant rutabaga (rut) fails to remember normally and is defective in a subpopulation (or in a functional state) of adenylate cyclase. We report here that the mutation leaves some tissues in rut with a membrane-associated adenylate cyclase that cannot normally switch between different states of affinity for its ligands. The results described below were obtained with abdominal preparations, in which the rut cyclase defect is especially (but not exclusively) pronounced. The enzyme in normal flies displays a higher affinity for MgATP and a lower affinity for free $Mg^{2+}$ than the residual enzyme in the same rut tissues. The diterpene forskolin markedly increases the Vmax of Drosophila adenylate cyclase and this stimulation is accompanied by a downward shift in the affinity for MgATP (apparent Km is increased ca. 3-fold) and by an upward shift in the affinity for free $Mg^{2+}$ (the apparent Km is decreased ca. 3-fold). In contrast, no shifts in the affinity for MgATP and for free $Mg^{2+}$ are observed in the rut enzyme. The dose-dependence of the forskolin stimulation in rut also differs from normal. When adenylate cyclase is solubilized by Lubrol-PX to a form that is not stimulated by guanyl nucleotides, the rut enzyme displays lower affinity for MnATP than the normal solubilized enzyme. In such a solubilized preparation there are no significant differences between the activation of the normal and the mutant enzyme by free $Mg^{2+}$ and by free $Mn^{2+}$. A striking difference is however observed in the mode of activation of the Lubrol-solubilized adenylate cyclase by forskolin: the normal enzyme is markedly activated by the diterpene whereas the rut enzyme shows only little activation. Taken together with previous results, the data indicate that adenylate cyclase in rut differs from the normal enzyme in several properties (i.e., low Vmax and low affinity for MgATP, defective interaction with $Mg^{2+}$ and lack of stimulation by low $Ca^{2+}$ concentrations). The defects in rut thus seem to be associated both with the catalytic unit and with its mode of interaction with N units. These defects may be due either to a mutation in a gene that codes for a catalytic subunit or in a gene that codes for a yet unidentified regulator which is tightly associated with the catalytic unit. Sustained activation of adenylate cyclase has been suggested to underlie short-term memory in Aplysia (Castellucci et al., Soc. Neurosci. Abst. 9, 169 (1983)). According to such a model, defective stimulation of adenylate cyclase and inability to switch properly between activity states (e.g., due to malfunctioning of "Mg-switches" in the cyclase system, see Iyengar and Birnbaumer, PNAS 79, 5779 (1982)) should result in abortive memory. It is thus possible that lack of the capacity of an adenylate cyclase system to appropriately shift between activity states results in defects in behavioral plasticity. ## MOLECULAR BIOLOGY OF GENE EXPRESSION AND NUCLEIC ACIDS III

233.1

WITHDRAWN

233.2 COMPLETE NUCLEOTIDE AND DEDUCED POLYPEPTIDE SEQUENCES OF BOVINE PHENYLETHANOLAMINE N-METHYLTRANSFERASE. E.E.Baetge, Y.H. Suh and T.H. Joh. Dept. of Neurology, Cornell Univ. Med. Coll., New York, NY 10021,

Phenylethanolamine N-methyltransferase (PNMT) (E.C.2.1.2.28, S-adenosyl-L methionine, phenylethanolamine N-methyltransferase), is the final enzyme in the catecholamine biosynthetic pathway. The enzyme is essential for both the biosynthesis of the hormone epinephrine in the adrenal medulla as well as the neurotransmitter epinephrine in the brain. In an effort to better understand how the expression of the enzyme may be regulated at the molecular level and to further elucidate the molecular structure of the PNMT gene, we have recently isolated a cDNA clone to bovine PNMT (Baetge et al., Neurochem. Intl. 5(no.5):611-617, 1983.

Using this partial length clone, we have screened a lambda gt11 recombinant DNA expression library constructed using bovine adrenal medulla poly(A)+ mRNA as template. A cDNA clone containing the full coding region of PNMT was isolated. The cDNA clone is 1 kb in length and includes 40 bp of 5' and 180 bp of 3' untranslated sequence.

The complete nucleotide sequence of the cDNA was determined by the method of Maxam and Gilbert (1977). We report here the entire primary structure of PNMT as deduced from this nucleotide sequence.

233.3 RATES OF PHENYLETHANOLAMINE N-METHYLTRANSFERASE GENE TRANSCRIPTION DIFFER IN FISCHER AND BUFFALO RATS. M. Evinger, E.E. Baetge and T.H. Joh. Lab. of Neurobiology, Cornell Univ. Med. Coll., New York, NY 10021.

Production of the epinephrine synthesizing enzyme phenylethanolamine N-methyltransferase (PNMT, E.C. 2.1.1.28) differs in two inbred rat strains, Buffalo and Fischer 344. Observations that the Fischer strain exhibits higher levels of epinephrine synthesis and PNMT enzymatic activity have previously been extended by the demonstration that the amounts of immunotitratable PNMT protein and hybridizable PNMT mRNA are greater in the Fischer rats. Quantitative dot blot hybridizations have confirmed that the steady state level of PNMT mRNA in the Buffalo strain is lower both in the adrenal gland, the major site of synthesis, and in PNMT producing regions of the CNS, specifically in the medulla oblongata.

This study analyzes the synthesis of PNMT mRNA in order to determine whether the strain specific differences in PNMT expression are mediated at the level of gene transcription. Transcription of PNMT mRNA has been compared in the cellular nuclei of adrenals isolated from adult male Fischer and Buffalo rats. An in vitro nuclear transcription assay was employed to measure the rate of PNMT mRNA synthesis as a function of the amount of hybridization of $^{32}$P-labelled adrenal mRNAs to a PNMT-specific cDNA (710 bp). The rates of adrenal PNMT gene transcription differ significantly in the Buffalo and Fischer rats. Reflecting the relative levels of PNMT protein and mRNA, transcription of the PNMT gene proceeded at a rat 2-6-fold greater in the Fischer strain. Furthermore, consistent with its intermediate level of enzymatic activity, PNMT mRNA in Sprague-Dawley rats was transcribed at a ratio of 2 : 1 : 0.3 in a comparison of Fischer : Sprague Dawley: and Buffalo rats. Northern blot analysis indicates that PNMT mRNA is the same size in all these strains. Therefore, the rate at which the PNMT gene is transcribed must constitute a major determinant in the strain specificity of PNMT expression in the rat adrenal. Measurement of PNMT mRNA synthesis in its other sites of synthesis will reveal whether an inherent strain specific capacity governs the level of transcription possible for PNMT gene expression. 233.4 RECOMBINANT DNA PROBES FOR GENES EXPRESSED IN THE CEREBELLUM. T.L. Wood* and A.J. Tobin (SPON: J.S. de Vellis). Dept. of Biology and Molecular Biology Institute, Univ. of California, Los Angeles, CA 90024.

We are investigating gene expression in the cerebellum of humans and mice. By differential screening of a human cerebellar cDNA library in pBR322 we have found several RNA species that appear to be preferentially expressed in the cerebellum.

We are using RNA blot hybridization to investigate the regional specificity of the expression of these sequences. Preliminary evidence with this more sensitive technique indicates that some of the sequences previously identified are cerebellum-specific; others appear in the cerebellum and cerebral cortex but not in the neostriatum or liver; still others are found in all three brain regions, but not in liver and kidney. We are currently examining several neuronal and glial cell lines in order to determine whether any of these sequences are neuronal- or glial-cell specific.

We have recently constructed a λgt11 expression cDNA library from adult (3-4 week) mouse cerebella. This library consists of more than 2 x $10^6$ recombinants. We are screening this library for several specific genes of interest using antibodies against cerebellar proteins.

These experiments will allow us to study the regulation of individual genes of both known and unknown functions during the development of the cerebellum.

233.5 CEREBELLUM-SPECIFIC GENES OF THE MOUSE. W.Wille, UAO. Heinlein*, C.Ruppert*, and H.Schaal*. Institute for Genetics, University of Köln, D-5 Köln 41, West-Germany

Three region- and age-specific cDNA libraries from cerebellum and cerebral cortex of the mouse have been constructed (Wille, W. et al., Soc. Neurosci. Abstr. Part 1, 10:374, 1984). Using a three-step procedure our cDNA library from adult cerebellum was screened for sequences expressed in the adult cerebellum exclusively.

First, 3000 randomly picked (out of 250,000) clones were grown as glycerol stocks in microtiter plates and transferred to Whatman 541 filters. The DNA has been prepared on the filters according to Taub, F. and Thompson, E.B. (Anal. Biochem., 126:222, 1982). Identical filters were hybridized with single stranded cDNA from adult mouse cerebellum (CbA-cDNA) and adult total brain minus cerebellum (TBmA-cDNA), respectively. We identified 26 clones which hybridized with CbA-cDNA only.

Second, the plasmids of all 26 clones were digested with BamHI (or BamHI/HindIII) in order to cut out the cDNA inserts. The restriction fragments were separated by agarose gel chromatography, blotted on nitrocellulose filters, and hybridized ('Southern-blot') again with CbA- and TBmA-cDNA, respectively. At least 10 cloned cDNA inserts only hybridized with CbA-cDNA.

Third, the positive clones from the second screening step were hybridized ('Northern-blot') against mouse mRNAs of different origin: poly(A)+mRNAs from adult cerebellum, neonatal (postnatal day 1-2) cerebellum, adult total brain minus cerebellum, neonatal total brain minus cerebellum, adult kidney, adult liver and poly(A)-mRNA from adult cerebellum. For at least 4 of the clones a positive signal on 'Northern-blots' has been observed only with mRNA from adult cerebellum. These clones are named "CebA-#".

The sequence on one of the clones, CebA-117, shows striking homology to portions of the mouse kallikrein gene. For the time being, it is not clear whether CebA-117 is a member of the kallikrein gene family.

Detailed data on the genomic organization, sequence, localization and developmental regulation of cerebellum-specific clones will be presented.

This work was supported by the grants Wi563/3-2 and Wi563/3-3 of the Deutsche Forschungsgemeinschaft (SPP "Biochemie des Nervensystems") to W. Wille.

233.6 MICROINJECTION OF RNA INTO XENOPUS OOCYTES AS A TOOL FOR MOLECULAR CLONING OF A RAT BRAIN SEROTONIN RECEPTOR GENE. H. Lübbert*, N. Dascal*, T.P. Snutch*, H.A. Lester and N. Davidson* (SPON: A.M. Gurney). Divisions of Chemistry and Biology, Caltech, Pasadena, CA 91125.

The low abundance of most voltage and/or neurotransmitter sensitive receptors and ion channels renders it difficult to prepare pure proteins and obtain either amino acid sequence data or antibodies. Since for nearly all channels and receptors these useful tools for molecular cloning are unavailable, we envisioned a cloning strategy based on the observation of Barnard et al. (1982, Proc. R. Soc. Lond. B **215**, 241-246, and later papers) that a number of voltage-sensitive or neurotransmitter-responsive channels appear on the surface membrane of Xenopus oocytes after microinjection of rat brain poly(A)$^+$ RNA.

We propose to use this as a selection system for the cloning of a rat brain serotonin (5-HT) receptor gene. This approach has also aided in the cloning of other genes for which activity tests are applicable. The oocyte membrane contains an endogenous muscarinic acetylcholine (ACh) receptor which is coupled to a chloride channel (Kusano et al., 1977, Nature **270**, 739-741; Dascal et al., 1984, J. Physiol. **352**, 551-574). It has been shown that after injection of rat brain poly(A) RNA into Xenopus oocytes a rat brain 5-HT receptor is also coupled to a chloride channel (Gundersen et al., 1983, Proc. R. Soc. Lond. B **219**, 103-105). The waveform of the response to 5-HT resembles the D1 and D2 components of the muscarinic response of the oocyte membrane. A response to 5-HT inhibits a subsequent response to ACh and vice versa. Similar inhibition is observed if either ACh or 5-HT is applied twice to an oocyte within a few minutes. We suggest that a rat brain 5-HT receptor and the endogenous ACh receptor are coupled to the same chloride channels, perhaps via the same second messenger system.

The first step in our intended cloning procedure was to size fractionate rat brain poly(A)$^+$ RNA by electrophoretic separation through agarose gels. A single ~6 kb RNA fraction, enriched at least 60-fold, was sufficient to induce a serotonin response in the oocytes. The response to serotonin still included the D1 and D2 components. We have constructed cDNA clones of this ~6 kb RNA fraction and are working on a selection procedure for positive clones.

233.7 EXPRESSION OF HIGH AFFINITY, GABA UPTAKE SYSTEM IN XENOPUS OOCYTES MICROINJECTED WITH BRAIN POLY $A^+$-RNA. P. Vijay Sarthy and Brian Hilbush*. Dept of Ophthalmology, University of Washington School of Medicine, Seattle WA 98195.

We are interested in the isolation and characterization of mRNAs encoding neurotransmitter uptake systems. We have used Xenopus Oocytes, microinjected with brain poly $A^+$-RNA, as the expression system to screen for the mRNAs encoding the polypeptide/s involved in GABA uptake. Poly$A^+$-RNA was isolated from developing rat brain and microinjected into mature Oocytes by established techniques. Injected Oocytes were left overnight in modified Barth solution before use. The controls consisted of Oocytes injected with Barth's solution instead of RNA. For measurement of GABA uptake, 8-10 injected Oocytes were pooled and incubated for 10 min with μmolar concentrations of $^3$H-GABA. After brief rinses, radioactivity accumulated was determined by scintillation counting.

In Oocytes injected with RNA, $^3$H-GABA accumulation was about 3-fold higher than in Barth-injected controls. When uptake was measured at 18°, 30° or 37°C, maximal levels of uptake were found in Oocytes incubated at 30°C. At this temperature, $^3$H-GABA uptake continued to increase up to 20 min and declined thereafter. In order to determine the kinetic parameters of uptake, RNA-injected Oocytes were incubated with varying concentrations of $^3$H-GABA (0.1-25 μM) and the $^3$H-radioactivity accumulated was determined. It was found that GABA uptake could be described by a single, high affinity system with a $K_m$ = 7 μm and a $V_{max}$ of 0.12 pmoles/min/mgp. $^3$H-GABA uptake was blocked by DABA (87.4%), β-alanine (92.3%), and Nipecotic acid (72.6%). Furthermore, in $Na^+$-free medium, GABA uptake was reduced to 90.5% of the control. These results establish that Xenopus Oocytes, microinjected with poly $A^+$-RNA from developing brain, express a $Na^+$-dependent, high affinity GABA uptake system.

Supported by NIH Grants EY-03523, -03664, and -01730.

233.8 EXPRESSION OF RAT TUBULIN MULTIGENE FAMILY DURING BRAIN DEVELOPMENT. I. Ginzburg and U.Z. Littauer. Dept. of Neurobiology, Weizmann Institute of Science, Rehovot, Israel.

The diversity of microtubule functions and the temporal employment of microtubules through cell growth and differentiation suggests that the expression of tubulin genes may be tightly regulated. Microtubules are particularly important in the brain where they are involved in cell differentiation and synaptic transmission. In mammalian DNA, hybridization experiments with tubulin cDNA probes have revealed the presence of α-and β-tubulin multigene families. However the number of functional genes is unknown. To study the expression of an individual member of the tubulin gene family, specific cDNA probes were constructed.

Two α-cDNA clones were isolated and sequenced. These two clones share high homology within the coding region, however the 3'-non-coding regions are highly divergent. A strong interspecies homology exists in the 3'-non-coding region when compared with α-tubulin sequences from other mammals i.e. hamster and human cells. The interspecies homology suggests functional requirement for that region. Both α-tubulin genes encode for an identical size mRNA of 1.8-k.b.

The nucleotide sequence of a rat brain β-tubulin has been determined. The coding region shows a high homology when compared to chicken and human β-tubulin sequences. However the C-terminal coding end shows high divergence and no homology is observed at the 3'-non-coding regions. Three β-tubulin mRNA species are present in rat brain. A dominant neuronal 1.8-k.b. species and two minor species of 2.6 and 2.9-k.b. respectively. The 2.9-k.b. and 2.6-k.b. mRNAs represent an early and a late neuronal species respectively. By using oligonucleotide probes we have demonstrated that the three mRNAs are distinct species, which are developmentally regulated.

These data illustrate that the differential expression of the tubulin multigene family during rat brain development, which may suggest for different functions of the various tubulin isotypes. The specific probes and synthetic oligonucleotides are used for in situ hybridization studies of rat cerebellum which show differential tubulin mRNA levels in identified cell types.

233.9 EXPRESSION OF CHICKEN ACTIN GENES DURING MYOGENESIS. L. J. Hayward*[1] and R. J. Schwartz*[1,2]. (SPON: Y. Clement-Cormier). [1]Program in Neuroscience and [2]Dept. of Cell Biology, Baylor College of Medicine, Houston, Texas 77030.

Embryonic muscle development has provided a cell differentiation system to study the regulation of contractile protein genes. Studies in the intact embryo have shown that chemical denervation with d-tubocurarine inhibits the normal appearance of secondary myotubes. However, in the absence of functional innervation, myogenesis in vitro proceeds and follows a succession of morphological stages which include proliferation of myoblasts, fusion of mononucleated cells, and the appearance of myofibrils. We have recently characterized the chicken actin gene family and have shown that actin gene expression is switched during myogenesis. In order to distinguish the regulation of individual actin mRNA species, we have constructed hybridization probes from the transcribed 3'-noncoding region of the single-copy α-skeletal, α-cardiac and β-cytoplasmic actin genes. Fragments (about 200 bp long) 3' to the translational stop codon were isolated from pAC51 (α-Sk), pAC7.5 (α-Ca), and pAC1 (β-Cyt) actin clones, and subcloned into M13 vectors. Each probe hybridizes to a single genomic locus with no significant homology to either of the other two actin mRNA species.

These probes were used to quantitate the steady-state levels of actin mRNAs during embryonic thigh development. α-cardiac and β actin mRNAs composed 48% and 38%, respectively, of the actin transcripts at day 10 in ovo, while α-skeletal actin mRNA made up only 14% of the total actin messages. However, by 17 days in ovo the α-skeletal mRNA had increased over 30-fold and represented over 90% of the total actin mRNA. In contrast, α-cardiac mRNA decreased by 30% from the level found at day 10, and β actin mRNA was reduced by 70%. The expression of actin genes was then examined in primary myoblast cultures. By 36 h in culture, α-cardiac mRNA had increased to levels about 10-fold higher than the α-skeletal message. The α-skeletal expression remained low until 48 h (after fusion had begun), suggesting that these two actin genes are influenced by separate control mechanisms. β actin mRNA levels increased sharply during the proliferative phase prior to fusion but peaked at 36 h and steadily declined thereafter. At the completion of fusion, the α-skeletal mRNA had increased 10- to 30-fold over the initial level in proliferating myoblasts. The α-cardiac expression remained high (40% of total) throughout post-fusion myogenesis. We conclude that primary myoblast cultures partially mimic the in vivo embryonic state. Full induction of α-skeletal actin mRNA and down-regulation of α-cardiac mRNA in the intact embryo may require neural influences not present in culture. The role of innervation upon actin gene expression in myogenesis is currently being investigated.

233.10 CRF INCREASES ACTH SECRETION AND POMC mRNA LEVELS IN ANTERIOR PITUITARY CELLS THROUGH AN ACTIVATION OF cAMP DEPENDENT PROTEIN KINASE. T. Reisine, G. Rougon*, J. Barbet* and H. Affolter*. Lab. of Cell Biology, National Institute of Mental Health and Lab. Math. Biology, National Cancer Institute, Bethesda, MD 20205.

Corticotropin releasing factor (CRF) is the most potent and effective natural stimulant of adrenocorticotropin (ACTH) release. In a tumor cell line of the mouse anterior pituitary, AtT-20/D16-16, CRF also increases the levels of proopiomelanocortin (POMC) mRNA. The levels of a larger sized nuclear RNA species with the expected size of the primary transcript for the POMC gene was also enhanced by CRF suggesting that the peptide activates the POMC gene. 8-Bromo-cAMP stimulates ACTH release and elevates the levels of POMC mRNA in AtT-20 cells and CRF activates cAMP dependent protein kinase in these tumors indicating that the effects of CRF on ACTH secretion and synthesis may be mediated through cAMP dependent protein kinase. To test this possibility, the inhibitor protein of cAMP dependent protein kinase (PKI) was incorporated into AtT-20 cells. This was accomplished by encapsulating the PKI into liposomes which were then coupled to protein A. The liposomes were then applied to AtT-20 cells prelabeled with anti-NCAM antibodies. These antibodies bind to AtT-20 cells and can be internalized. The protein A-bearing liposomes containing the PKI attached to the antibodies bound to the cells and were subsequently endocytosed. This resulted in the delivery of some of the encapsulated PKI into the cell cytoplasm as demonstrated by the blockade of 8-bromo-cAMP-, forskolin- and CRF-stimulated ACTH release but not of hormone secretion induced by $K^+$ or phorbol esters. The PKI also prevents CRF and 8-bromo-cAMP but not phorbol ester from elevating POMC mRNA levels in AtT-20 cells, indicating that CRF acts through cAMP-dependent protein kinase to stimulate ACTH secretion and the POMC gene. The PKI by itself also lowers POMC mRNA levels further suggesting a regulation of the gene by cAMP. The ability of phorbol esters to stimulate both ACTH release and synthesis implies that both responses are controlled by at least two distinct protein kinases.

233.11 CHOLECYSTOKININ mRNA AND PEPTIDE IN RODENT BRAIN: REGIONAL LOCALIZATION AND ONTOGENY. M. J. Iadarola, T. T. Quach*, A. M. Duchemin* and E. Costa. Lab. Preclin. Pharmacol., NIMH, St. Elizabeths Hospital, Washington, D.C. 20032.

The regional location of CCK biosynthesis and storage in rat and mouse brain was studied using specific cDNA hybridization and radioimmunoassay techniques to measure CCK mRNA and CCK immunoreactivity, respectively. The pre- and post-natal development of CCK gene expression and CCK peptide formation was also examined. For the regional distribution, the brain was grossly dissected into seven regions: cerebral cortex, hippocampus, striatum, hypothalamus, midbrain, cerebellum and pons-medulla. Radioimmunoassay was performed with an antibody directed to the C-terminal amide of CCK-8 after extraction of tissue peptides with 90% methanol. In rat brain, rank order (highest to lowest) for tissue content of CCK immunoreactivity (on a per mg protein basis) was cerebral cortex, hippocampus, caudate midbrain, hypothalamus pons-medulla cerebellum.

CCK mRNA was measured by hybridization to a cDNA probe obtained from plasmid pCK2AB5 (Proc. Natl. Acad. Sci. 81: 726, 1984). A 147 base pair AVA I/XMA III restriction fragment was labeled with $^{32}$P-dCTP by nick translation for hybridization. After RNA extraction and enrichment for poly A$^+$ RNA by oligo dT cellulose chromatography, agarose gel electrophoresis was performed followed by transfer to nitrocellulose and hybridization to the cDNA probe. A RNA of approximately 800 nucleotides was observed and there was no obvious CCK mRNA size differences between brain regions. The rank order of regional CCK mRNA content was cortex, hippocampus, midbrain hypothalamus, striatum, brain stem, cerebellum. At the level of resolution afforded by the dissection, cortex, hippocampus and midbrain were the three major regions in which CCK synthesis was observed, all others were near background. Little or no CCK mRNA was observed in striatum despite a high amount of immunoreactive peptide suggesting that the CCK content of striatum was derived mainly from afferent terminals and not from intrinsic perikaryal synthesis. A similar regional profile of CCK mRNA was observed in mouse brain.

The ontogenesis of CCK-RNA and peptide closely paralleled one another. The major appearance of CCK-RNA occurred post-natally as did the peptide immunoreactivity. Peak production occurred between days 7-21.

The results provide a new perspective on the brain CCK system attainable with hybridization techniques. We have defined major sites of CCK synthesis and increased current knowledge on this system acquired mainly by immunocytochemistry and radioimmunoassay. Further studies are aimed at a more precise localization of CCK-RNA production in the midbrain and the use of RNA hybridization to assess the synthesis of utilization of this peptide in CCK-producing neurons.

233.12 TRANSFER HYBRIDIZATION: A NOVEL METHOD FOR mRNA ABUNDANCE DETERMINATION AND cDNA LIBRARY SCREENING. S.A. Stein*, B. Trus* and M. Zasloff* (Sponsor: L. Mercer), Dept. of Neurology, Univ. of Texas Southwestern Medical School, Dallas, Texas 75235 and Section of Human Genetics, Lab. of Molecular Biology, NIH, Bethesda, Md. 20205.

Transfer hybridization, a novel, sensitive (≤ 1 copy of mRNA/cell), and specific method for broad range mRNA abundance determination and cDNA library screening has been developed. A detailed description of the method will be presented using rat brain and rat liver cDNAs. Sensitivity, specificity, and comparative abundance data have been confirmed by solution and dot blot hybridization. Transfer hybridization alone and in combination with sequential colony hybridization on 541 Whatman filter sheets have been used for screening and characterization of rat cerebellum and rat liver cDNA libraries. Quantification and autoradiographic background subtraction on the transfer and colony hybridizations have been accomplished by densitometry with computerized image processing. These methods have also been applied to cDNAs reflective of specific mRNAs that are changed in the euthyroid to hyperthyroid transition.

## TRANSMITTER CYTOCHEMISTRY AND IMMUNOHISTOCHEMISTRY I

234.1 **IMMUNOGOLD LOCALIZATION OF *APLYSIA* NEUROPEPTIDES** T. Kreiner and R.H. Scheller, Dept. of Biological Sciences, Stanford, CA 94305-2493.

Many *Aplysia* neurons use peptides to communicate with their central and peripheral targets. We have raised antibodies to ELH, peptides A + B, ELH, $SCP_B$, R14, and L11 peptides, and have obtained an antisera directed against FMRFamide. Using these reagents, the distribution of immunoreactive cell bodies and processes have been determined. These studies demonstrate that the individual peptides are localized in as few as 12 or as many as 200 central neurons.

We are using EM immunohistochemical techniques to study the subcellular distribution of the peptide products. Ganglia are fixed in increasing paraformaldehyde to 8%, single neurons dissected and prepared either for ultrathin frozen sectioning by embedding in gelatin and 2.3 M sucrose, or dehydrated and embedded in Lowicryl K4M. Thin sections collected on grids with either method are reacted with primary antisera, and visualized using protein A coated gold colloid. The L11 and R14 peptides and $SCP_B$ are localized in dense core vesicles. The R14 peptide is also contained in granular (not as dense) vesicles as revealed by the Lowicryl procedure. Studies to determine the localization of the other peptides are in progress.

Double labeling experiments using antibodies directed against different regions of the R14 peptide precursor have also been performed. In this procedure, tissue sections are reacted with a primary antisera followed by protein A coated 12 nm gold colloid; after blocking all unreacted antisera, a primary antibody directed against a different region of the precursor is reacted with the tissue, followed by protein A coated 6 nm gold particles. Presence of both size particles in the same granules demonstrates that different regions of the R14 peptide precursor are in the same vesicles.

These data imply that many *Aplysia* neurons synthesize large amounts of a specific peptide precursor which is subsequently packaged into dense core and granular vesicles.

234.2 IMMUNOHISTOCHEMICAL LOCALIZATION OF HISTAMINE IN THE BRAIN AND PERIPHERAL NEURONS AND ENDOCRINE CELLS. P. Panula, L. Kivipelto*, M. Kaartinen*, O. Häppölä* and J.-Y. Wu¤. Department of Anatomy, University of Helsinki, Siltavuorenpenger 20, 00170 Helsinki, Finland and ¤Department of Physiology, Penn State University, Hershey, PA 17033, USA.

Antisera against histamine coupled to hemocyanin with carbodiimide were used to locate neurnoal histamine in the brain and peripheral nerves immunohistochemically. In the rat brain, histamine-immunoreactive neurons were found only in colchicine-treated rats. They were located in the tuberal, caudal and postmammillary caudal magnocellular nuclei. Some of these neurons exhibited L-glutamate decarboxylase-immunoreactivity as well. This indicates that some GABAergic neurons may contain histamine. Histamine-immunoreactive nerve terminals were detected in many brain areas. They were numerous in the paraventricular and supraoptic nuclei of the hypothalamus. Moderate densities of nerve terminals were seen in the cerebral cortex, neostriatum and hippocampus.

Only histamine-immunoreactive mast cells were found in the posterior pituitary gland. Lack of immunoreactive nerve fibers may indicate that histamine regulates the pituitary gland at the level of hypothalamic nuclei, where numerous nerve fibers are found.

Small intensily fluorescent cells (SIF cells) in the guinea pig and rat sympathetic ganglia were immunoreactive for histamine. Some histamine-immunoreactive chromaffin cells were detected in the adrenal medulla of the rat, whereas numerous process-bearing cells in the guinea pig adrenal medulla were found.

Nerve fibers in the rat ileum exhibited histamine-immunoreactivity. These fibers were located mainly in the submucosal ganglion cell layer, where immunoreactive nerve cell bodies were also found after local colchicine treatment. Fewer fibers were seen in the myenteric plexus.

Numerous enterochromaffin-like cells in the rat stomach were immunoreactive for histamine. Positive mast cells were also found. Fewer cells were seen in the guinea pig stomach. In both species, the immunoreactive enterochromaffin-like cells were found in the oxyntic gland area.

The histamine-immunoreaction was blocked completely by preabsorption with histamine but not with L-histidine, histidine-containing peptides, catecholamies or serotonin. Affinity-purified antibodies stained the same structures as the crude antiserum.

The results show that histamine is widely distributed in the central and peripheral nervous system and endocrine cells, where in may function as a neurotransmitter or hormone.

Supported by grants from the Sigrid Jusélius Foundation and the Paulo Foundation.

234.3 IMMUNOCHEMICAL AND IMMUNOCYTOCHEMICAL CHARACTERIZATION OF RAT HISTIDINE DECARBOXYLASE. S. Levine, D.H. Park, G. Teitelman and T.H. Joh. Dept. of Neurology, Cornell Univ. Med. Coll., New York, NY 10021.

Histidine decarboxylase (HDC) catalyzes the conversion of L-histidine to histamine in a single biosynthetic step. Several lines of evidence suggest that histamine is a neurotransmitter in the central nervous system. In the present study, we used immunochemical and immunocytochemical techniques to characterize HDC.

HDC was purified from fetal rat liver (17-18 days of gestation). The purification procedure included homogenization in 3 volumes of 100 mM potassium phosphate buffer containing 1 mM DTT, 1 mM EDTA and 10 uM pyridoxal phosphate, centrifugation at 100,000g for 1 h, 25-45% ammonium sulfate fractionation of the supernatant followed by successive column chromatographies on DEAE-cellulose, chromatofocusing on polybuffer exchanger 94 (Pharmacia) and Bio-Gel A-0.5m. These purification steps provided a more than 2,000-fold enrichment in the specific activity of the enzyme and a 20% recovery of the total enzyme activity.

The final purification step involved preparative polyacrylamide gel electrophoresis. The enzymatically active protein extracted from the gels showed a protein band with a subunit molecular weight of 54,000 daltons on SDS-PAGE.

Antibodies were raised against HDC in rabbits by injecting the enzymatically active enzyme eluted from polyacrylamide gel slices. The antibodies were determined to be specific for HDC by several immunochemical criteria. The antisera precipitated HDC activity from a crude enzyme preparation. In Western blot analysis, the antibody immunoreacted with a single 54,000 dalton protein in both crude and partially purified preparations of fetal rat liver.

Using peroxidase-antiperoxidase immunocytochemistry, numerous cells were labelled in the caudal magnocellular and dorsomedial hypothalamic nuclei which extended into lateral, perifornical, posterior and supramammillary substructures. This finding is consistent with the biochemical and immunofluorescent localization of HDC as reported by others. In addition, HDC-like immunoreactive cells were localized in fetal rat liver and stomach of adult rats.

This antibody probe will be used to study the regulation of HDC at the molecular level as well as the anatomy of the histamine system. (Supported by Grant numbers MH24289 and NS 19002. S. Levine is the recipient of a scholarship from the Inst. Invest. Clin., Maracaibo, Venezuela.)

234.4 COLOCALIZATION OF TYROSINE HYDROXYLASE AND PROTEIN-O-CARBOXYLMETHYLTRANSFERASE IN MONOAMINERGIC NEURONS OF THE RAT BRAIN. D.M. Kuhn*, M.L. Billingsley, and C.D. Balaban*, Sec. Biochem. Pharmacol. NHLBI, NIH, Bethesda, MD 20205, and Hershey Medical Center, Pennsylvania State University, Hershey, PA 17033.

In an attempt to determine whether protein carboxylmethylation plays a role in monoaminergic neurons, we have used immunocytochemistry to demonstrate the presence of both protein-O-carboxylmethyltransferase (PCM) and tyrosine hydroxylase (TH) in the same neurons of rat brain. Tyrosine hydroxylase was purified from rat pheochromocytoma cells (PC-12) using ammonium sulfate fractionation, DEAE anion exchange-chromatography, Sepharose-4B molecular sizing and heparin-Sepharose chromatography. TH was homogenous after SDS gel electrophoresis; this fraction was used to produce polyclonal antibodies in rabbits. PCM was purified to homogeneity using DEAE anion exchange and S-adenosylhomocysteine-agarose chromatography and molecular sizing. Polyclonal antibodies were generated in rabbits using gel slices of purified PCM as antigens. Western immunoblot analysis indicated that the antisera against tyrosine hydroxylase recognized only one band of 58,800 daltons which corresponded to the purified subunit of TH. The TH antisera recognized this 58,800 dalton subunit in PC-12 cell extracts, adrenal chromaffin cell extracts, and rat brain striatal homogenates; it did not crossreact with purified phenylalanine hydroxylase nor PCM. PCM antisera recognized a 27,000 dalton subunit corresponding to purified PCM which was also present in brain cytosol, striatal cytosol and additional brain regions; it did not crossreact with either purified or partially purified preparations of TH. Neither antisera appeared to react with any other band in any preparation examined. Both antisera were used to immunolocalize TH and PCM in formalin-fixed sections of rat brain. TH antisera recognized neurons in the substantia nigra, locus coeruleus, brainstem nuclei, and several other discrete regions corresponding to catecholamine neurons. The TH antisera was able to discern fine axonal processes and could be used to trace the nigrostriatal tract. Numerous projection fibers which were TH positive could be seen in the cortex and the cerebellum. Antisera against PCM recognized neurons throughout the rat brain; however, high levels were detected in the substantia nigra and the locus coeruleus. When serial sections were immunostained for TH and PCM, the highly immunoreactive PCM-containing cells were found to be positive for TH. The high levels of both PCM and TH in monoaminergic cells of the rat brain are consistent with studies suggesting that PCM can modulate neurotransmission in monoaminergic neurons. Studies are underway to determine if PCM activity can directly alter TH activity both in vitro and in vivo.

234.5 SUBSTANCE P-LIKE IMMUNOREACTIVITY IN THE SPINAL TRIGEMINAL NUCLEUS OF THE CAT. J.P. Drew*, L.E. Westrum, and R.H. Ho. (SPON: A. B. Harris) Depts. of Biological Structure and Neurological Surgery, Univ. of Wash., Seattle, WA 98195 and Dept. of Anatomy, Ohio State University, Columbus, OH 43210.

Light microscopy (LM) is being used to study the patterns of substance P-like immunoreactivity (SPLI) in the brain stem spinal trigeminal nucleus of the adult cat. The peptide substance P (SP) an identified gut and sialagogic transmitter has also been implicated as an excitatory neurotransmitter. Commercially obtained antibody to SP (Immunonuclear) is being used along with anti-SP prepared according to the protocol of R.H. Ho. The indirect peroxidase anti-peroxidase (PAP) method for immunocytochemistry is being utilized following the protocol of Sternberger. In subnucleus caudalis (SC), heavy immunoreactivity is observed in a continuous lunate distribution extending into lamina I and II, agreeing well with previous studies of this region and the analogous substantia gelatinosa of the spinal cord dorsal horn. In caudal subnucleus interpolaris (SI) the immunoreactivity is observed in dorsal and ventral patches or accumulations dramatically different from the pattern observed in SC. The patterns of immunoreactivity in both SC and SI are surprisingly roughly coincident with those areas identified as receiving dental afferents. The area of transition between the two distinct patterns of immunoreactivity observed in SC and SI appears to be just caudal to the obex. In rostral SI the dorsal and ventral patches of immunoreactivity are observed to gradually diminish and then disappear with the ventral accumulation being slightly more persistant. Irregular accumulations are seen in subnucleus oralis (SO). Besides the more dominant immunoreactive terminals described above, transversely oriented immunoreactive fibers are observed. These fibers tend to predominate dorsally and ventrally in SC, are especially delineated at the SC-SI transition (obex), are scattered in SI and are seen in very small pockets in SO. Our results provide the first detailed description of the pattern of SPLI throughout the entire brain stem spinal trigeminal complex. Since the observed patterns of immunoreactivity have certain similarities to those areas receiving dental afferents, this study will form a necessary control for the analysis of possible changes in this distribution following dental lesions.

234.6 IMMUNOCYTOCHEMICAL STAINING OF VASOPRESSIN BINDING SITES IN THE RAT BRAIN. R. Ravid*, D.F. Swaab*, T. v.d. Woude* and G. Boer* (SPON: European Neuroscience Association), Netherlands Institute for Brain Research, Meibergdreef 33, 1105 AZ Amsterdam ZO, The Netherlands.

Vasopressin (VP) is produced by neurons, released into the bloodstream in order to regulate kidney function as a neurohormone and transported by axons to a great number of brain areas, where it acts as a neurotransmitter or neuromodulator.

An immunocytochemical procedure was developed to localize VP binding sites in the Brattleboro rat (di/di) brain, which is genetically deficient for VP but responds to the neuropeptide. The procedure comprises continuous in vivo administration of VP for a period of two weeks into the lateral ventricle, by means of small Accurel (microporous polypropylene) implants, loaded with 0.15, 1.5 and 15 µg of VP.

VP binding sites were localized immunocytochemically, with a higher resolution than the hitherto described autoradiographic techniques, in two distinct forms: (a) in perineural structures, e.g., in the dorso-rostral part of the lateral septum, striatum, cingulate cortex, the dentate gyrus of the hippocampus and cerebellar Purkinje cells, all mainly in the high dose loaded implants; (b) in neural cell bodies, e.g., in the lateral and medial septum, striatum, cingulate cortex, bed nucleus of the stria terminalis (BST), organum vasculosum of the laminae terminalis (OVLT) and locus coeruleus, all mainly in the low dose loaded implants.

The distribution of VP binding sites only partly overlaps with the sites of VP innervation. The difference in type of staining related to dose might mean that the current immunocytochemical procedure retains both low and high affinity populations of binding sites which may represent two different central effects of VP.

234.7 NADPH DIAPHORASE ACITIVITY IN THE POSTERIOR PITUITARY: RELATION TO FUNCTIONAL ACTIVITY. S. M. Sagar and D.M. Ferriero*, Neurology Service, Veterans Adminstration Medical Center and University of California, San Francisco, CA 94121.

NADPH diaphorase histochemistry stains selective populations of neurons in various regions of the brain (Vincent et al., J. Comp. Neurol. 217: 252-263, 1983). Among the cell populations stained by this method are the magnocellular neurons of the rat hypothalmus, along with their axons in the median eminence and terminals in the posterior pituitary. Since other oxidative enzymes, including cytochrome oxidase and succinic dehydrogenase, have been shown to vary in activity in response to alterations of functional activity, we investigated the possibility that NADPH diaphorase activity also reflects neuronal activity.

Adult, male Long Evans rats were given 2% saline to drink. This regimen has been shown to result in secretion of up to 90% of the stores of oxytocin and vasopressin from the posterior pituitary and to increase the rate of synthesis of the posterior pituitary hormones 4 fold (Gainer et al., J. Cell Biol. 73: 366-381, 1977). Control animals had free access to water. After 7 days, the animals were sacrificed and the posterior pituitary glands were assayed for NADPH diaphorase and protein.

The NADPH diaphorase assay, like the histochemical procedure (Scherer-Singler et al., J. Neurosci, Meth. 9: 229-234, 1983), measures the NADPH-dependent reduction of nitro blue tetrazolium dye (NBT). Aliquots of posterior pituitary homogenates are added to reaction mixture containing 0.05 M Tris-HCl, pH 8.0, 1 mM EDTA, 0.2% Triton X-100, and 0.2 mM NBT. After allowing endogenous substrates to be consumed, the reaction is started by adding NADPH to a final concentration of 0.5 mM. Reduction of NBT is monitored spectrophotometrically at 535 nm.

The mean specific activity of NADPH diaphorase in control rats was found to be 0.54 $\pm$ 0.02 µmol/min/mg protein compared to 0.80 $\pm$ 0.04 µmol/min/mg protein in salt-loaded rats ($p < 0.01$, Mann-Whitney U test, n=10.) There was also a 8% decrease in the mean protein concentration of the posterior pituitaries of the salt-loaded animals, presumably reflecting the diminished hormone stores, but this fails to account for the 47% increase in enzyme specific activity.

Therefore, the activity of NADPH diaphorase, like other histochemical markers of oxidative metabolism, responds to changes in functional activity of neurons. Since NADPH diaphorase, unlike other oxidative enzymes, is also a marker for neuronal populations containing specific neurotransmitter candidates, NADPH diaphorase offers the opportunity to assess the functional activity of certain chemically defined neuronal populations.

234.8 STELLATE NEURONS IN THE TURTLE DORSAL CORTEX CONTAIN $\gamma$-AMINOBUTYRIC ACID AND ITS SYNTHETIC ENZYME. M. Blanton*, J. Shen and A.R. Kriegstein. Dept. of Neurology, Stanford University Med. School, Stanford, CA 94305.

Recent intracellular studies of the dorsal cortex of the turtle, Pseudemys scripta, have demonstrated that the morphologically distinct pyramidal and stellate neurons have characteristic and distinctive membrane properties and synaptic responses (Kriegstein and Connors, Soc. Neurosci. Abst. 10:659). Afferent stimulation excites stellate cells and produces powerful $\gamma$-aminobutyric acid (GABA)-mediated inhibition of pyramidal cells. In order to support the role of stellate neurons as the mediators of this intrinsic cortical inhibition, we used Golgi and immunohistochemical techniques to study dendritic and axonal morphology and to verify that the stellate neurons utilize GABA.

Golgi-impregnated pyramidal and stellate neurons are morphologically distinct. Pyramidal cells have polymorphic or pyramidal somata located in or immediately subjacent to the pyramidal cell layer. Their spine-laden apical dendrites ascend obliquely through the molecular layer to the pial surface while spiny basal dendrites descend through the subcellular zone; axons descend from the soma or a proximal basal dendrite and issue recurrent collaterals. Stellate neurons have multipolar or fusiform somata and aspiny or sparsely spiny dendrites that are often beaded. The dendrosomatic axes of fusiform cells are predominantly horizontal with some oblique or vertical forms present. Horizontal neurons often possess one or more ascending secondary dendrite(s) positioned to allow reception of thalamic afferent excitation in the superficial molecular layer. Axons arise from a proximal dendrite or a soma-dendritic junction and arborize extensively within the layer containing the stellate cell somata. Axonal arborizations of stellate neurons within the pyramidal layer envelope neighboring pyramidal cell somata.

Antibodies directed against the inhibitory transmitter GABA and its synthetic enzyme glutamic acid decarboxylase (GAD) and a histochemical technique which reveals the GABA degradative enzyme GABA-transaminase all label the somata and proximal dendrites of stellate interneurons in all cortical layers. Pyramidal somata, while completely devoid of label, are outlined by darkly staining punctate structures, presumably the terminals of GABAergic interneurons within this layer. Similar presumptive terminals are found in all layers. Therefore, aspiny or sparsely spiny interneurons with locally ramifying axons contain GABA and form a distinct class of neurons which are positioned to mediate the intrinsic inhibition observed in physiological studies of the turtle dorsal cortex.

We thank Donald Schmechel for providing the GAD antiserum. This work was supported by NIH Grants NS00887-01 and NS21223-01.

234.9 SUBSTANCE P (SP) AND VASOACTIVE INTESTINAL PEPTIDE (VIP)-CONTAINING NERVE FIBERS REACH THE OVARY BY TOTALLY INDEPENDENT ROUTES. W.L. Dees*, C.E. Ahmed* and S.R. Ojeda* (SPON:R. Stillman). Dept. of Physiology, Univ. of Texas Health Science Center at Dallas, Dallas, TX 75235.

We have previously shown that the immature ovary is innervated by both SP-and VIP-ergic fibers (Dees et al., Biol. Reprod., in press; Ahmed et al., Endo. Soc., Abs., 1985). To determine the origin of these fibers, juvenile 24-day-old rats were either sham-operated or subjected to transection of either the abdominal vagus nerves (AV), superior ovarian nerves (SON), plexus nerves (PN), or to concomitant AV-SON transection. Six days later their ovaries were fixed in Zambonies fixative and processed for immunohistofluorescent examination of their SP and VIP-ergic innervation. Staining was performed on frozen 10 µm sections using specific antisera (anti-SP Kozlowski #317, and anti-VIP Abe-Reichlin #750) followed by fluorescein isothiocyanate-labelled goat anti-rabbit IgG. Sectioning of the AV affected neither the SP-nor the VIP-ergic innervation of the ovary. In contrast, sectioning of the SON or both the SON and AV nerves completely eliminated VIP-positive fibers from all ovarian compartments innervated by the peptide (i.e. interstitial tissue, follicles and blood vessels) without affecting SP innervation. Sectioning of the PN, however, selectively eliminated SP positive fibers. These results demonstrate that VIP innervation of the ovary is via the superior ovarian nerve, whereas SP innervation is via the plexus nerve. This remarkable anatomical localization is consistent with our view that both peptides regulate ovarian activity by acting on different functional components of the gland.

(Supported by NSF grant BNS-8318017 and NIAAA-06014).

234.10 ENKEPHALIN-IMMUNOREACTIVITY IN THE RAT SUPERIOR CERVICAL GANGLION. S. Soinila, H. Päivärinta, O. Häppölä* and P. Panula. Department of Anatomy, University of Helsinki, Siltavuorenpenger 20 A, SF-00170 Helsinki, Finland

Enkephalin-immunoreactive nerve cells and fibres are known to be present in the superior cervical ganglion (SCG) of the rat (Schultzberg et al., Neurosci 1979:4: 249). The purpose of the present study was to examine the origin and projections of these fibres, as well as presence of enkephalin in cultured sympathetic ganglia.

The indirect immunofluorescence method of Coons was applied on cryostat sections or on explants of SCG after fixation with 4 % paraformaldehyde in 0.1 M sodium phosphate buffer, pH 7.4. Specific antisera to both met-enkephalin$^{5}$-arg$^{6}$-phe$^{7}$ (MEAP) and met-enkephalin$^{5}$-arg$^{6}$-gly$^{7}$-leu$^{8}$ (MEAGL) were used.

Some principal nerve (PN) cells were immunoreactive to MEAP and MEAGL. MEAP-immunoreactive fibres were seen to extend from some PN cells. Small intensely fluorescent (SIF) cells were non-reactive. Immunofluorescent fibres enclosed both PN cells and SIF cells. The number of these fibres decreased after section of the preganglionic trunk. Ligation of the preganglionic trunk resulted in accumulation of immunofluorescent material on both sides of the ligature. Some immunoreactive cells and nerve fibres were observed in the stellate ganglion. No immunoreactive cells were found in the spinal cord at the levels C8-Th3. Ligation of the postganglionic nerves resulted in an increased number of immunoreactive nerve fibres on the ganglionic side of the ligature, irrespective of section of the preganglionic trunk. Some immunoreactive nerve fibres were present in the SCG even after combined pre- and postganglionic nerve division. Cultures of the SCG showed that the PN cells maintain MEAP immunoreactivity in vitro. MEAP- and MEAGL-immunoreactive varicose fibres were observed in the fibre outgrowth.

The present observations indicate that (1) the rat SCG contains both extrinsic and intrinsic enkephalin-immunoreactive fibres; (2) both PN cells and SIF cells may receive innervation by enkephalin-containing nerve fibres; (3) ganglionic neurons projecting to the sympathetic target tissues contain enkephalin.

234.11 IDENTIFICATION OF NEUROHEMAL-ENDOCRINE AND SYNAPTIC-NEUROACTIVE GONADOTROPIN RELEASING HORMONE (GnRH) IMMUNOREACTIVE NEURONS IN MOUSE BRAIN. L. Jennes and W.E. Stumpf. Dept. of Anatomy, University of North Carolina, Chapel Hill, NC 27514.

A combination of immunofluorescence for GnRH with simultaneous visualization of retrogradely transported horseradish peroxidase, injected intravenously, was used to identify populations of GnRH neurons in the mouse which have access to fenestrated capillaries. An average of about 530 immunoreactive GnRH neurons was found, most of which are present in the septum, including the neurons of origin of the nervus terminalis, the nucleus medialis septi, the nucleus triangularis septi, and the nucleus tractus diagonalis throughout its caudal extent. GnRH neuronal perikarya can also be seen in the lateral anterior hypothalamus, the nucleus preopticus medianus and medialis and the rostral nucleus periventricularis hypothalami. In addition, single GnRH neurons occur in the nucleus supraopticus, the bed nucleus of the stria terminalis and the cingulate cortex. The mediobasal hypothalamus does not contain GnRH neurons.

GnRH neurons which take up intravenously injected horseradish peroxidase from the perivascular space of fenestrated capillaries are located in all of the above areas, intermingled with GnRH neurons which do not take up horseradish peroxidase. A preferential topographic accumulation of neurohemal GnRH neurons could not be detected. Under maximal stimulation of GnRH secretion after two weeks of castration, 65% of all GnRH immunoreactive cells had taken up blood borne horseradish peroxidase, while after a 3-day estradiol pretreatment only 35% of all GnRH positive neurons had taken up the enzyme.

While the existence of GnRH neurons with a dual action via collaterals cannot be excluded, the results suggest that two GnRH populations exist, one with access to fenestrated capillaries which is related to neurosecretory endocrine regulation of anterior pituitary gonadotropin secretion, and one without access to fenestrated capillaries which is related to intracerebral neurotransmission only.

Supported by NIH grants NS09914 and NS1761401.

234.12 SOMATOSTATIN-LIKE IMMUNOREACTIVITY IN THE MIDBRAIN OF THE CAT. K.M. Spangler*, B.J. Morley, (SPON: E. Javel) Boys Town National Institute, Omaha NE, 68131

Somatostatin (SS), like many other neuropeptides originally described in the hypothalmus or periphery, has been shown to have a wide distribution in the central nervous system. In a previous study (Morley et al., Dev. Brain Res., in press), we examined SS-like immunoreactivity in the interpeduncular nucleus of young and adult cats. During the course of that study, we noticed some major differences in the distribution of SS-like immunoreactivity in the midbrain, as compared to the rat (Finley et al., Neurosci. 6, 1981, 2173-2192). The material was prepared with a PAP immunohistochemical technique. The primary antibody had been raised against synthetic cyclic SS conjugated to keyhole limpet hemocyanin (Immunonuclear Corp.). In addition to the interpeduncular nucleus, other midbrain nuclei containing cells with SS-like immunoreactivity included the superior colliculus, the lateral reticular formation, the parabigeminal nucleus, the lateral wings of the dorsal nucleus of the raphe, the dorsal subnucleus of the periaqueductal gray, the pretectal complex, the nucleus cuneiformis, the rostral pole of the inferior colliculus, the nucleus of the brachium of the inferior colliculus, and the reticular nucleus of the thalamus. In the superior colliculus, a large number of small neurons in the superficial gray layer contained SS-like immunoreactivity. Additionally, clusters of small cells in the deeper portions of the intermediate gray layer were so labeled. Fibers with dense SS-like immunoreactivity were found in the periaqueductal gray, along the raphe, and in the ventral and lateral tegmentum. Cells surrounded by SS-immunoreactive terminals were present within portions of these areas. These findings suggest a role for somatostatin in the tecto-parabigeminal system and in other midbrain pathways.

Supported by NIH Postdoctoral Fellowship to K.M.S. and NSF Grants BBS 8210029 and BNS 8410198 to B.J.M.

234.13 ORIGIN OF MOTILIN IMMUNOREACTIVE FIBERS IN RAT MEDIAN EMINENCE. G. Nilaver, R. Bodnar, and E. A. Zimmerman. Dept. Neurology, Oregon Health Sci. Univ., Portland, OR 97201, and Dept. Psychology, Queens College, CUNY, Flushing, NY 11367.

Growth hormone releasing factor (GRF) has been implicated in the hypothalamic regulation of pituitary growth hormone (GH) secretion. Lesion studies with monosodium glutamate (MSG) furthermore, have revealed neurons in the arcuate nucleus (ARC) to be the primary source of the GRF somatotrophic fibers that project to the median eminence (ME) (Bloch et al., Nature, 307: 272, 1984). Motilin has also been demonstrated in the hypothalamus by immunohistochemistry and RIA, and shown to facilitate the in vivo and in vitro release of GH in rats (Samson et al., Brain Res Bull, 12: 57, 1984). Motilinergic perikarya in rat hypothalamus have been localized to the preoptic, ventromedial (VMH), and ARC regions, and immunoreactive fibers have been described in the zona externa of the ME (Jacobowitz et al., Peptides, 2: 479, 1981). The precise contribution of the ARC to the motilin immunoreactivity in rat ME however, has not been fully established. Since neonatal administration of MSG produces neurotoxic degeneration of the MBH and ARC (Olney, Science, 164: 719, 1969), and depletes ARC GRF immunoreactivity (Bloch et al., Nature, 307: 272, 1984), we studied the distribution of motilin in the hypothalamus of MSG treated rats and saline controls, employing immunocytochemistry. A few animals from each group were colchicine treated prior to sacrifice. Brains were immersion fixed in Bouins fixative. Hypothalamic sections (100 um; coronal and sagittal) were immunoreacted with a specific rabbit antiserum to synthetic porcine motilin, employing biotinylated protein A with avidin-biotin peroxidase in the preembedding staining technique. Adjacent sections were immunoreacted with an antiserum to rat GRF (generous gift from Dr. C. Hollander). In colchicine treated controls, motilin immunoreactive perikarya were found in the preoptic, VMH and ARC regions. MSG treated rats showed total elimination of GRF immunoreactivity in the ME and ARC, confirming the extent of the MSG lesion. The motilin staining in the ME and preoptic regions of these rats however, was not affected, and was identical to that seen in saline controls. This finding, and the absence of motilin imunoreactivity in the ARC and VMH of MSG rats even upon colchicine pretreatment, suggests perikarya in the preoptic area to be the major source of the motilin immunoreactivity in the ME. Since we find the MSG effect to be selective for GRF furthermore, this model provides an elegant system for studying the relative importance of hypothalamic motilin in the pituitary release of GH. (Supported by NIH grant NS18324).

235.1 DYNAMIC BEHAVIOR IN INITIAL ORDERING OF THE RETINOTECTAL MAP AS REVEALED BY A VITAL-DYE FIBER-TRACING TECHNIQUE.
N. A. O'Rourke and S. E. Fraser. Depts of Developmental & Cell Biology and Physiology & Biophysics, and the Developmental Biology Center, University of California, Irvine, 92717

In the visual system of Xenopus laevis, the axons from the retinal ganglion cells of the eye form a topographic projection onto the optic tectum. The order of the projection is highly regular both during development and after regeneration. Many recent studies have focused on revealing possible mechanisms for this precise order. In contrast to the static view of the system that one might expect from examining the regularity of the projection, some studies indicate that part of the patterning process involves the dynamic behavior of optic fibers. For example, during regeneration, a roughly ordered projection forms initially, which is then refined with time. We have used a newly developed fiber tracing technique to follow the early ingrowth of the optic nerve fibers into the tectum and have found further evidence for dynamic behavior in the initial development of topography in the retinotectal projection.

Previously, anatomical and electrophysiological techniques have been used to obtain static views of development which then must be compiled to provide a glimpse of dynamic behavior. In our study, we have refined a fluorescent dye fiber-tracing technique which allows us to view neuronal projections in living Xenopus embryos. This offers the possibility of following the development of the retinotectal projection in individual animals over a period of days, and thus permits direct observation of the dynamics of neuronal patterning. The technique utilizes fluorescent dextrans, vital dyes, which are microinjected into Xenopus embryos at the one cell stage. At tailbud stages (st 32) labeled eyebud tissue is grafted into unlabeled hosts. The fluorescent dextran fills the axons of the developing retinal ganglion cells, and as the head of the developing larva becomes transparent, growth of the labeled neurons into the tectum can be followed in situ with an epifluorescence microscope.

In order to observe the initial appearance of topography in the projection pattern we grafted labeled half eyebuds into unlabeled hosts. An image intensifying camera was used to repeatedly record the projection pattern in individual animals for the next 2 weeks. Experiments using this technique reveal that dorsal and ventral optic nerve fibers sort out into an ordered projection early in development; in contrast, nasal and temporal fibers initially overlap, then sort out into the adult pattern over a period of days. Thus, patterning of the nasotemporal dimension of the retinotectal projection involves a dynamic process in which fibers gradually sort out to innervate different areas of the developing tectal neuropil.

235.2 **AFFERENT INDUCED ALTERATIONS IN THE DENDRITIC DOMAINS OF TECTAL NEURONS IN THREE-EYED FROGS.**
**L.C. Katz and M. Constantine-Paton Neurobiology Lab. The Rockefeller University, N.Y.N.Y. 10021 and Biology Dept., Yale University, New Haven CT 06511.**

**Recent evidence supports the idea hat topographical map formation involves a phase during which afferent synapses sort according to the proximity relationships among the presynaptic cell bodies. Proposed mechanisms for the phenomenon postulate that the effect is mediated via post-synaptic cells which stabilize groups of synapses on the basis of temporal correlations of their activity. Considerable information on activity-dependent modifications of afferents is available, however little is known about the effects of such modifications on post-synaptic cells. The eye-specific tectal stripes of three-eyed frogs are distinct morphological indicators of zones of correlated synaptic input. We have developed an in vitro tectal preparation which allows us to visualize both afferent stripes and post-synaptic cells. Tetramethylrhodamine isothiocyanate (TRITC), an anterograde tracer, is injected into the vitreous of one eye. Three to five days later the tecta are surgically removed and maintained in cold HEPES buffered glucose supplemented Ringer's solution, in a saturated oxygen atmosphere. Individual tecta are transferred to a recording chamber on the stage of a fluorescence equipped compound microscope for intracellular recording. Under 100X magnification, TRITC stripes are clearly visible, separated by distinct interstripe zones. Lucifer yellow (LY) filled microelectrodes (20% LY in 0.1 M LiCl, 250Ω resistance) are used to impale and fill tectal neurons (1-2 nA, 1-3 min.).**

**Fixed tecta were prepared as wholemounts, and patterns of dendritic arborizations of filled neurons were related to the pattern of labeled stripes. On this basis we distinguished three broad groups of tectal neurons. The first consisted of cells whose highly branched, bushy dendrites (50-100μm diameter dendritic fields) respected the boundaries between stripes and interstripes, often abruptly terminating or bending around such borders. The other two cell groups had widespread, sparsely branched dendrites extending over distances greater than the width of individual stripes (approx. 150μm), and often over several stripes. In one group, the majority of dendritic branches were preferentially located within the stripes of one eye. Soma position was not consistently related to this branching pattern. The final group included neurons with very large (>400 μm) dendritic fields. Such cells show dendritic arborization in both stripe and interstripe zones. In many cases we traced axons for long distances, but in none of these groups did we observe extensive horizontal collaterals. These results suggest that at least some tectal neurons alter their dendrites in order to maximize the the amount of correlated input they receive.**

235.3 EXPERIMENTALLY STABILIZED RETINAL PROJECTIONS TO THE HAMSTER VENTROBASAL COMPLEX ARE FUNCTIONAL.
D.O. Frost and C. Metin (SPON: R.J.J. Benson). Yale Med. Sch., New Haven, CT 06510

Retinofugal axons can form permanent, retinotopic connections in the somatosensory (ventrobasal, VB) nucleus of the Syrian hamster thalamus. This occurs when, in newborn hamsters, the superior colliculus and lateral geniculate body are ablated and alternative terminal space is created in VB by transection of the ascending lemniscal afferents to VB (Frost, D.O., J. Comp. Neurol., 203:227, 1981). The retino-VB projection occurs by the stabilization of an early, normally transient projection (Frost, D.O., Neurosci. Abs., 9:26, 1983) and forms synapses (Campbell, G. & Frost, D.O., this meeting). This study was undertaken to determine whether the anomalous, stabilized retino-VB projection is functional. In 15 hamsters operated as described above and 2 normal hamsters, all at least 10 weeks old, multi-unit recordings were made from the cortical targets of VB, the first and second somatosensory cortices (SI and SII, respectively). Since retinofugal axons terminate only in the diencephalon or mesencephalon, the strategy of recording in the cortex assures that the recording site is post-synaptic to retinofugal axons. Visual stimulation reliably evoked multi-unit responses in SI and SII of operated, but not normal hamsters. Most multi-unit receptive fields (RF's) in SI and SII had a single, clearly defined zone of maximal response, although some had two such zones. The mean area of the zones of maximal response in SI and SII was about 4.1 times the mean size of visual RF's recorded in area 17 of normal hamsters. The visual RF's in the somatosensory cortices were preferentially distributed in the lower visual field. In 7 cases we mapped the visual field representations in SI or SII. In SI and SII the lower temporal to upper nasal field axis was represented along the medial to lateral and posterior to anterior directions, respectively. The differences in orientation between the representations of this visual field axis in SI and SII are those that would be predicted given the differences in orientation between the somatic representations in normal rodent SI and SII. There was no obvious representation of the upper temporal to lower nasal field axis in SI or SII. The orderly cortical representation of only one visual field axis and the existence of RF's with two zones of maximal response are both probably due to the way in which the axes of the visual field representation in VB intersect lines of thalamocortical projection in VB. These results demonstrate that experimentally stabilized retino-VB axons can form functional synapses in VB. They also suggest that neural structures which normally process information specific to one sensory modality have the potential of mediating function for other modalities.

235.4 NUMBER OF NEURONS IN THE MONKEY'S DORSAL LATERAL GENICULATE NUCLEUS DURING DEVELOPMENT
Robert W. Williams and Pasko Rakic, Section of Neuroanatomy, Yale University School of Medicine, New Haven, Connecticut 06510

The refinement of neural connections is often mediated by competitive interactions between axon terminals for targets or trophic molecules. In many cases the end result of this competition is the death of a large fraction of the initial complement of presynaptic neurons. For instance, the segregation of optic axons from right and left eyes in the dorsal lateral geniculate nucleus (DLGn) of fetal rhesus monkeys is associated with the loss of more than half of all retinal ganglion cell axons (Rakic & Riley, '83; Science **219**: 1441), and this loss is evidently due to ganglion cell death rather than the retraction of excess axon collaterals (Lia et al., in press). In the present study we have tested whether a similar process—the segregation of geniculate terminals into ocular dominance columns in striate cortex—is also associated with neuron death, in this case, in the DLGn.

Serial celloidin, polyester wax, and frozen sections of the DLGn of fetal, neonatal, juvenile, and adult monkeys (*Macaca mulatta*) stained with cresyl violet were examined using a 63X oil objective (n.a. 1.4) and Nomarski optics. At younger fetal ages—before embryonic day 90 (E90)—all cells in the DLGn were counted, but after E90, when glial cells became more numerous and could be readily distinguished from neurons, only the latter were counted. Fifty to 100 individual counts were taken at sites located at caudal, middle, and rostral levels extending from the dorsal to ventral surfaces of the nucleus through all laminae and interlaminar zones. A modified Abercrombie correction factor was used to determine average cell density. The volume of the DLGn—calculated from measurements of the cross-sectional area and the thickness of serial sections—was multiplied by the mean cell density to give the final estimate of cell number.

The estimates of cell number showed considerable variation between individuals. Those from fetuses between E70 and E96 ranged from 1,500,000 to 2,200,000 with an average of 1,950,000 (n=7). Estimates from postnatal animals ranged from 1,000,000 to 2,000,000. The average population of neurons in neonates and infants up to 2 months old was 1,410,000 (n=6) and did not differ significantly from the average in juveniles and adults up to 10 years old (1,490,000, n=5). The 20-30% loss of cells in the DLGn between midgestation and maturity may not be entirely due to neuron elimination since counts at the youngest ages (E70 to E87) probably included a small number of early-generated glial cells. These quantitative data are in harmony with observations on the number of necrotic cells in the DLGn: The incidence of pyknotic cells was merely 1 in 5000 from E45—when the last neurons destined for the DLGn are generated (Rakic, 1977, J. Comp. Neurol. **176**: 23)—until E60 (n=4). After E70 pyknotic cells were more common (up to 1 in 1000), and although they persisted during the neonatal period, they were not seen after the 2nd postnatal month. The small size of the pyknotic nuclei indicates that most belong to degenerating glial cells.

Taken together, the results demonstrate that number of neurons in the DLGn is relatively stable during the formation of cellular laminae, the segregation of retinogeniculate fibers, and synaptogenesis in the principal visual centers. Furthermore, since the number of neurons remains unchanged during the formation of ocular dominance columns early in infancy (Hubel et al., 1977, Phil. Trans. R. Soc. **278**: 377), the segregation of the initially diffuse geniculo-cortical projection is not associated with neuron death in the DLGn.

235.5 THE EFFECT OF NEURAL ACTIVITY ON THE FORMATION OF GENICULATE CELL LAYERS. V.A. Casagrande, G.J. Condo and L.A. Durden*. Depts. of Anatomy and Psychology, Vanderbilt University, Nashville, TN 37232.

We investigated the role of retinal afferent activity on the development of cell layers in the lateral geniculate nucleus (LGN) of the tree shrew. In the tree shrew, all six layers develop postnatally. By postnatal day eight (P8), all interlaminar spaces (ILSs) are visible, although they continue to mature after this point. Our previous work has demonstrated that ILS formation is critically dependent upon the input from the retina. If the eyes are removed at birth, spaces between layers never form (Brunso-Bechtold and Casagrande, 1981).

In order to determine if ILS formation is dependent upon the activity of retinal axons, we injected eyes with tetrodotoxin (TTX) to abolish all activity or tried to selectively effect activity, either by injecting 2-amino-4-phosphonobutyric acid (APB) to block activity to the two On-center geniculate layers (1 and 2) or by manipulating illumination to the retina. The first group of tree shrews received either unilateral or bilateral intraocular (0.1 ug) TTX injections every other day from birth to P8-P14. This dose was twice that, by body weight, necessary to abolish activity for 2 days in adults. A second group of animals received either unilateral or bilateral intraocular (500 μM) injections of APB daily for the same period. A third group of tree shrews was reared from birth to P7 in: 1) continuous light, 2) continuous light with one eye patched, or 3) continuous darkness. At the end of each experimental period the animals were perfused, brains were cut, and LGN sections were stained with a Nissl stain or reacted for cytochrome oxidase. Results showed that manipulations of retinal illumination had little effect on LGN cell layer formation. Moreover, APB injections did not prevent the formation of the ILS between the On-center layers. However, APB injections did appear to slow the overall development of the LGN layers, i.e. the ILSs and the cells appeared immature compared with controls. TTX injections appeared to slow cell layer development more dramatically than APB, and in addition appeared to almost completely prevent the development of the ILS between the On-center layers: the remaining ILSs were all obvious though less mature than those of controls.

Taken together, these results suggest that retinal ganglion cell activity per se is not essential for the initial spacing of geniculate cells into layers but may be important for final maturation.

235.6 POSTNATAL DEVELOPMENT OF SPATIAL CONTRAST SENSITIVITY OF NEURONS IN THE KITTEN DORSAL LATERAL GENICULATE NUCLEUS. J.S. Tootle and M.J. Friedlander. Dept. of Physiology and Biophysics, University of Alabama at Birmingham, Birmingham, AL 35294

The spatial processing capacities of neurons in the kitten dorsal lateral geniculate nucleus (dLGN) undergo a period of postnatal development. Two examples are spatial resolution (acuity) and spatial selectivity (reduced response to large stimuli) both which increase postnatally. A metric of choice for characterizing the spatial processing capacities of neurons is the spatial contrast sensitivity function (CSF), which yields several measures of spatial processing as well as a means for quantitative characterization of the receptive field profile. A goal of the present study is to provide the first description of the postnatal development of the spatial contrast sensitivity of dLGN neurons in the A-laminae of the normal kitten. We recorded the responses of dLGN neurons to drifting sinusoidal gratings varying randomly in contrast and spatial frequency. The intersection of contrast-response functions with spontaneous activity was used to estimate thresholds. We report preliminary results from 19 neurons (5 nonlinear, 14 linear) in 4-5 week old kittens and compare them to results from adult control animals (ours and from published reports - Mangel et al. J. Neurophysiol. 50:240-264, 1983, Lehmkuhle et al. J. Neurophysiol. 43:520-541, 1980). The maximum sensitivity, best spatial frequency and spatial resolution of averaged CSFs of kitten cells with linear and nonlinear spatial summation were lower than those of adult X- and Y- cells, respectively. Half the kitten cells with linear spatial summation had significant sensitivity roll-off at low spatial frequencies characteristic of adult X- cells; the remaining half had no such roll-off. Quantitative assessment of the low frequency roll-off was made using the contrast sensitivity ratio (CSR-sensitivity to .125 cycles/degree divided by maximum sensitivity). The mean CSR for kitten linear cells was .77, compared to .56 in the nondeprived lamina of 12 week-old monocularly deprived kittens and .20 in the adult. Kitten cells with nonlinear spatial summation, like Y- cells in the adult, had no low spatial frequency roll-off. These findings confirm our previous result, using the area-response technique, of a heterogeneity of maturity in the strength of surround antagonism in neonatal kitten dLGN. We are currently investigating the degree to which the immaturity of the antagonistic surround mechanism of indivudual dLGN cells reflects poorly developed inhibitory circuitry in the dLGN vs. a similar immaturity in the retina.

235.7 MORPHOLOGY OF PHYSIOLOGICALLY IDENTIFIED RETINOGENICULATE AXONS IN CATS FOLLOWING BLOCKADE OF RETINAL IMPULSE ACTIVITY. M. Sur, P.E. Garraghty and M.P. Stryker. Section of Neuroanatomy, Yale Univ., New Haven, CT and Dept. of Physiology, UCSF, CA.

We are interested in the mechanisms by which retinal axons establish and maintain connections in the lateral geniculate nucleus (LGN). Blocking retinal ganglion cell activity with tetrodotoxin (TTX) in neonatal cats causes abnormal cell responses in the LGN (Archer et al., Science 217:743, 1982). In the present experiments, we investigated the effects of unilateral and bilateral blockade of retinal activity on the terminal morphologies of single retinal axons in the cat LGN.

For one set of experiments, cats were reared with chronic bilateral injections of TTX from 2 weeks of age, a procedure not expected to produce gross receptive field abnormalities in the LGN (Dubin and Stark, IOS 24:138, 1983). At 8-12 weeks, retinal axons were recorded, classified as X- or Y-cell, and injected intracellularly with HRP. X-cell axons in these bilaterally treated cats were found to be broader in terminal arbor than X-cell axons in normal adult cats or normal kittens at comparable ages (Sur et al., Nature 310:246, 1984). Importantly, X-cell axons were always found to be restricted to lamina A or A1 depending on their eye of origin. In contrast, Y-cell axons in bilaterally treated cats were narrower in terminal arbor than Y-cell axons in normal adult cats. Furthermore, some Y-cell axons crossed laminar borders and sprouted into adjacent laminae. Both X- and Y-cell axons appeared to have reduced bouton densities.

For the second set of experiments, cats were reared with unilateral injections of TTX from birth. In these animals, our sample of axons from the treated eye is still too low to permit generalizations. From the untreated eye, X-cell axons appeared normal in terminal morphology and bouton density, as did some Y-cell axons. Some Y-cell axons, however, sprouted into adjacent, treated, laminae.

During normal development, X-cell axons at 3-4 weeks of age have broad terminal fields in lamina A or A1 that get pruned into narrow arbors as Y-cell axons establish connections in these laminae and develop broad terminal arbors. Blockade of impulse activity may arrest the normal development of these arbors within laminae A and A1. The result that X-cell axons remain confined to the appropriate lamina while Y-cell axons sprout is consistent with similar results we obtain in cats enucleated at birth (Garraghty et al., Neurosci. Abst. 10:142, 1984). These studies suggest similar conclusions. X-cell axons establish connections in the LGN early and maintain laminar fidelity. Y-cell axons develop later and can sprout into adjacent denervated or electrically blocked laminae, unless prevented from doing so by normal afferent activity from the other eye.

(Supported by the NEI, March of Dimes and the Sloan Foundation.)

235.8 DEVELOPMENT OF RETINOGENICULATE AXON ARBORS FOLLOWING PRENATAL UNILATERAL ENUCLEATION. D.W. Sretavan, P.E. Garraghty, M. Sur and C.J. Shatz, Dept. of Neurobiology, Stanford Univ. Sch. of Med., Stanford, CA. and Section of Neuroanatomy, Yale Univ. Sch. of Med., New Haven, CT.

The terminal arborizations of retinogeniculate axons undergo stereotyped morphological changes during pre- and postnatal development, giving rise to the adult pattern by 3 months postnatally (Sretavan & Shatz, Nature 308:845, 1984; Sur et al., Nature 310:246, 1984). To further understand the factors controlling the development of ganglion cell arbors within the lateral geniculate nucleus (LGN), we have examined the effect of removing one eye at embryonic day 44 (E44: a time when inputs from the two eyes are extensively intermixed with each other within the LGN) on the subsequent morphology of axons.

In one set of experiments, retinal axons from the remaining eye were filled in vitro with horseradish peroxidase (HRP) at E59 (5 days before birth, a time when the eye-specific layers are normally present). Of the 15 axons reconstructed so far, 7 had expanded terminal arbors that included territory normally occupied by the enucleated eye. However, 6 others (both contra and ipsi to the remaining eye) appeared remarkably normal: The terminal arbors of all were restricted to the LGN region that normally would be appropriate to their eye of origin. Two other axons had terminal arbors intermediate in extent. To learn whether one class of axon is more susceptible to morphological modification by prenatal enucleation, axons were filled intracellularly with HRP at 6 postnatal months, when physiological identification is possible. Of the 5 axons recovered to date, 2 were Y-axons and 3 were X-axons based on a variety of tests. The X-axons were remarkably normal in morphology and had restricted terminal arbors similar in size and shape to normal, with two contralateral X-axons located approximately where layer A normally would have been, and the ipsilateral X-axon located where layer A1 would have been. In contrast, the two Y-axons were highly abnormal. Both were filled contralateral to the remaining eye, yet the terminal arbor of one was restricted to a region of the LGN that normally would have been ipsilaterally-innervated layer A1. The other Y-axon had an unusually extensive arbor located throughout what would have been layers A and A1.

These results demonstrate that the terminal arbors of retinogeniculate axons can expand as a consequence of prenatal enucleation. They further suggest that axons of different functional class may have different capacities, with Y-axons relatively susceptible and X-axons relatively immutable to modification.

235.9 POSTNATAL DEVELOPMENT OF NEURONS WITH GABA IMMUNOREACTIVITY IN THE LATERAL GENICULATE NUCLEUS (LGN) AND VISUAL CORTEX OF THE CAT. R.E. Kalil, R.J. Wenthold and J. Zempel.* Dept. of Ophthalmology and Neurosciences Training Program, Univ. of WI., Madison; Lab. of Neuro-otolaryngology, NIH, Bethesda, MD. 20205; Dept. of Anatomy, Univ. of WI., Madison, WI. 53706.

Gamma amino butyric acid (GABA) is believed to be an inhibitory neurotransmitter in the retino-geniculo-cortical pathway in the cat In the LGN, GABA has been implicated as a transmitter that mediates receptive field surround antagonism, while in visual cortex GABA may play a role in determining the ocularity and selectivity of cortical neurons.

Physiological studies of the LGN and visual cortex in developing kittens have contributed an outline for the expression of these functional properties, but there is relatively little correlative evidence available concerning the development of the GABAergic neurons that are thought to be involved. We have therefore used direct immunocytochemical localization to identify GABA containing neurons in the LGN and visual cortex in cats of different postnatal ages.

The antibodies were made in rabbits against GABA conjugated to bovine serum albumin (BSA) as described by Storm-Mathisen et al. (Nature 301: 517, 1983). The antibodies were purified by affinity chromatography, and their specificity confirmed by immunoblotting.

Sections through the LGN and visual cortex were incubated with GABA antibodies at dilutions that varied from 1/500 to 1/4000, and immunoreactive neurons were then stained using the biotin-avidin method (Vector Laboratories). Cats with normal visual experience ranging in age from newborn to adult were studied. In addition, one cat raised with monocular deprivation for 9 months was examined.

In newborn cats, GABAergic neurons were not seen in the LGN, but were prominent in the adjacent perigeniculate nucleus. At 3 days postnatal, scattered, lightly stained neurons were evident in the LGN primarily in the C layers. By one week after birth, positive cell body staining was clear in the A layers of the LGN. Qualitatively, the density of GABAergic neurons appeared to increase gradually during the next two months, becoming mature between 8 and 12 weeks. Throughout development, cells in the LGN C layers were more densely labeled than those in the A laminae.

Cell somata were stained heavily in the visual cortex of the newborn kitten. Labeled neurons were spindle shaped with leading and trailing processes clearly visible. At 2 weeks postnatal, cell staining was restricted largely to cell somas, and at 3 weeks, stained cells, typically small in size, were distributed uniformly among all cortical layers. This laminar pattern was preserved in older kittens and adults, but in contrast with the LGN, GABAergic neurons in visual cortex developed a range of soma sizes and shapes.

Monocular deprivation from 7 days through nine months produced no obvious change in the pattern of labeled neurons in the LGN or visual cortex.

235.10 BIRTHDATES OF IMMUNOREACTIVE NEURONS IN THE FERRET VISUAL CORTEX. Jean D. Peduzzi, and T. L. Hickey. School of Optometry/The Medical Center, University of Alabama at Birmingham, Birmingham, Alabama 35294.

A combination of immunohistochemical and $^{3}$H-thymidine autoradiographic techniques were used to study the genesis of neuronal sub-populations in the visual cortex of the ferret. In a previous study (Soc. Neurosci. Abstr. 10: 519, 1984), we defined the overall time course of cortical neurogenesis in the ferret (E22-P14). In the present study, each ferret received a single injection of $^{3}$H-thymidine on one of the following days: embryonic day 26 (E26), E30, E34, E38, postnatal day 2 (P2), P6, or P10. Each animal was sacrificed at 2 months of age or older. Frozen sections (15 μm) were incubated in antisera (Immunonuclear) to gamma-aminobutyric acid (GABA) or cholecystokinin (CCK) and processed using the PAP technique. The resulting sections were then processed using standard autoradiographic procedures.

The production of GABA immunoreactive neurons extends throughout much of the period of cortical neurogenesis, a finding that correlates well with their ultimate distribution across all cortical layers. Further, a substantial proportion of those layer I cortical neurons that were generated early in the period of cortical neurogenesis (E26) were immunoreactive for GABA and/or CCK. These layer I neurons are unusual in that they do not follow the general inside-out pattern of cortical neurogenesis.

Supported by EY01338, EY03039 (CORE), and RR05807.

235.11 MIGRATION AND FATE OF TRANSPLANTED VISUAL CORTICAL NEURONS. Susan K. McConnell. Vision Center, Salk Inst., La Jolla, CA 92037, and Neurobiology Dept., Harvard Med. School, Boston, MA 02115.

Neurons in a given layer of the mammalian cerebral cortex tend to have similar morphologies, projection patterns, and physiological properties; these cells are also generated at similar times during development. The relationship between cell birthdate and adult laminar position and connectivity raises the possibility that the ultimate fate of cortical neurons may be determined early in development, prior to migration. To address this question, a preparation has been established in which young cortical neurons from ferrets (which show a substantial period of postnatal neurogenesis) are dissociated and transplanted into host brains, where they migrate and differentiate side-by-side with host neurons.

Cells from the occipital cerebral ventricular zone of newborn ferrets were labeled with $^{3}$H-thymidine and a fluorescent dye (DAPI or Fast Blue), and were mechanically dissociated into a single-cell suspension. These cells were transplanted by pressure injection into the occipital ventricular zone of newborn host ferrets ("isochronic" transplants). Hosts were perfused after survivals of 2 hrs to 2 months, and their brains were processed for both fluorescence microscopy and autoradiography.

For short survivals (up to 12 days), transplanted cells were identified by their fluorescent marker. After 2 hrs survival, cells were clustered at the injection site in or near the ventricular zone. Here cells were round and resembled freshly dissociated cells in vitro. By 2 days, fluorescent cells had streamed radially into the intermediate zone; at these and later times, they were well integrated with cells of host origin. While in the intermediate zone, many cells resembled migrating cortical neurons: they had spindle-shaped nuclei and radially-extending leading processes. Some labeled cells had reached the cortical plate 4-6 days after injection. Here they underwent neuronal differentiation: the cells had oval or round nuclei (often with multiple nucleoli), and by 12 days had pyramidal cell bodies and long apical dendrites. A second class of fluorescent cell was also observed after short survivals. These had assumed positions in all regions of the cerebral mantle; they had round cell bodies and fine processes that radiated irregularly outward, and were presumably glial in nature. After long survivals (up to 2 months), transplanted cells were identified by $^{3}$H-thymidine autoradiography. Labeled cells had pyramidal neuronal morphology and were indistinguishable from surrounding host neurons. 90% of labeled cells were found in layer 2+3, the normal destination of neurons generated postnatally in the ferret.

These results show that transplanted cells respond normally to cues present in the host environment that guide or permit cortical neuronal development, and that transplantation per se does not alter the fate of cortical neurons. Using this preparation, neurons from fetal ferrets can be challenged to alter their fates upon transplantation into the brains of newborn hosts ("heterochronic" transplants). Thus the determinative influences of cell birthday and local environment on the ultimate laminar position and projections of a cortical neuron can be studied.

Supported by PHS EY-05551 to S. LeVay.

235.12 CHARACTERISTICS OF TRANSIENT CORTICAL AFFERENTS TO VISUAL AREAS DURING POSTNATAL DEVELOPMENT IN THE KITTEN. J. Bullier*, C. Dehay* and H. Kennedy. Lab. Neuropsyschologie Experimentale, INSERM-U 94, 16 avenue du Doyen Lépine, 69500 Bron, France.

During its development the central nervous system is characterized by the formation of many connections which do not persist into adulthood. In the kitten one such category of temporary connections are those that link visual cortical areas with regions subserving other sensory modalities as well as motor cortex (Dehay et al. Exp. Brain Res.,57:208-212,1984; Innocenti and Clarke Dev. Brain Res.,14:143-148, 1984). This raises the question of whether these transient connections simply reflect a development stage of poor specificity and whether they may play a functional role. We have sought to answer this question by determining if there are precise boundaries to those regions which project transiently to areas 17, 18, and 19 and if the parent neurons have a specific laminar location.

Injections of the retrograde tracers fast blue or HRP-WGA were made in the grey matter of areas 17, 18, or 19 in kittens aged from 4 to 57 postnatal days. In each animal, the locations of labelled neurons were recorded by an X-Y plotter electronically linked to the microscope stage so as to delimit the entire extent of the cortical territories of origin of these temporary projections. In all animals below 35 days of age, we found retrogradely labelled neurons in limited regions of auditory and somatosensory cortex including primary areas AI and SI, in orbital cortex, limbic cortex and in smaller numbers in motor cortex. These cortical neurons have a particular laminar distribution. In the frontal cortex most of them are located in lamina I, whilst elsewhere at the boundary between laminae I and II and in upper III. This feature distinguishes them from other corticocortical neurons forming permanent callosal or associational connections which are located lower in layers II and III as demonstrated in double label experiments.

These results show that the transient cortical connections to the visual cortex in the kitten are specific in at least two aspects and suggest that they are not merely the result of errors during development. Firstly, they do not orignate from neurons evenly distributed throughout the fronto-parietal and temporal cortex but belong to precise cortical territories. Secondly these transient projections issue from a neuronal population which has a laminar location different from the population of neurons giving rise to stable connections, indicating perhaps differences in birth date and/or in the rate of migration. These specific characteristics would accord with the notion that transient projections may play a dynamic role during maturation of the cortex since it has been demonstrated (Dehay et al. 1984) that their terminals penetrate the grey matter and are in a position to interact with other cortical afferents.

235.13 DEVELOPMENT OF RESPONSE PROPERTIES OF POSTEROMEDIAL LATERAL SUPRASYLVIAN VISUAL CORTEX NEURONS IN THE CAT: IMPLICATIONS FOR FUNCTIONAL COMPENSATION. Maureen A. McCall*, Lillian Tong, and Peter D. Spear. Dept. of Psychology and Neurosciences Training Program, Univ. of Wisconsin, Madison, WI 53706.

Previous experiments have shown that physiological compensation occurs in posteromedial lateral suprasylvian (PMLS) cortex following early visual cortex (areas 17, 18, and 19) damage in cats (Tong, Kalil, & Spear, 1984). The critical period for the compensation ends between 12 and 26 weeks of age. In order to better understand the mechanisms of this compensation, the present study investigated the normal postnatal development of response properties of PMLS cortex neurons. Extracellular recordings were made in kittens at 2, 3, 4, 8, or 12 wks of age, with 3 to 4 kittens at each age. The principle response properties studied were direction selectivity, ocular dominance, orientation selectivity, surround inhibition, rate of adaptation to repeated visual stimulation, and response strength and consistency.

The results indicated that the time-course of development differs for different response properties. For example, direction selectivity was present in only 17% of the cells at 2 wks of age and did not reach adult levels (about 80% direction selective) until 8 wks of age. In contrast, the percentage of binocular cells in 2 wk old kittens (81%) already was similar to that of adults. Receptive-field surround inhibition has a developmental time-course similar to that of direction selectivity. Fewer than 5% of the cells had inhibitory receptive-field surrounds at 2 wks of age and the proportion progressively increased to 32% (adult levels) at 8 wks of age. The presence of fast adaptation to repeated visual stimulation, rarely found in adult PMLS cortex, decreased from 73% of the cells at 2 wks to only 10% at 12 wks. Response strength and consistency, while variable between cells at any age, tended to increase during development. Very few orientation selective cells were seen at any age (0 to 10%).

These findings have implications for mechanisms of physiological compensation observed in PMLS cortex of adult animals that had lesions of the ipsilateral visual cortex at early ages. For example, previous studies indicate that direction selectivity in PMLS cortex is lost following visual cortex damage in adult animals but not following damage in 1 day to 12 wk old kittens. Since few PMLS neurons were direction selective in 2 to 4 wk old kittens, the present results suggest that the appearance of this property following lesions at or before 4 wks of age is due to de novo development and not to the maintenance of an already extant property. In contrast, the appearance of normal binocularity following early visual cortex damage (up to 18 wks of age), but not following chronic adult damage, may be due to the maintenance of a property that already had developed at the time of the lesion.

## CELL LINEAGE: DIFFERENTIATION AND DEVELOPMENT II

236.1 THE ORIGIN OF ASTROCYTES IN THE OPTIC NERVE OF THE NEWBORN RAT. R.P. Skoff and R. Sayre*. Dept. of Anatomy, Wayne State University Sch. of Med., Detroit. MI 48201.

The goal of this study was to determine whether astrocytes in the optic nerve of newborn rats arise from cells which already express astroglial specific markers or from an undifferentiated population of cells. To answer this question, glial fibrillary acidic protein (GFAP) immunocytochemistry was combined with thymidine autoradiography usinging the following procedure. 2 and 4 day old rats were perfused with aldehydes one hour following an injection of [3H]- thymidine. The brain and intracranial segment of the optic nerve were cut sagitally with a Vibratome and the sections immunoreacted with GFAP antisera using the PAP procedure. The tissue was then embedded in Araldite, 2µm thick sections were cut and the sections processed for autoradiography.

At 4 days postnatal (dpn), many thymidine labelled cells are also GFAP+ in the optic nerve, chiasm and tract. Some of the thymidine labelled cells are as intensely GFAP+ as any of the GFAP+. non-thymidine cells, indicating that astrocytes rich in GFAP undergo proliferation in normal development. Other thymidine labelled cells are moderately GFAP+ while still others are marginally stained. Because of the gradation in staining, precise quantitation of the number of GFAP+, thymidine labelled cells is difficult but an estimate of the proliferating cells which are GFAP+ in the optic system at this age is 30- 50%. GFAP+, thymidine labelled cells are present at both the periphery of the nerve and in the parenchyma. At 2 dpn, a few thymidine labelled cells are clearly GFAP+. At this age, immunostaining of cells is less intense than at 4 dpn and definitive identification of GFAP+ cells in the semi-thin sections is often difficult. Accordingly. the number of GFAP+, thymidine labelled cells cannot be determined at this time but our impression is that they account for even a larger percentage of the labelled cells than at 4 dpn.

The combined thymidine autoradiography and immunocytochemistry confirm previous electron microscopic and autoradiographic studies showing that astrocytes in the optic nerve proliferate during the first two weeks of postnatal development (Skoff, R.P. et al. J. Comp. Neurol. 169:291. 312, 1976). These cells are properly named astroblasts. Following division, these astroblasts most likely either reenter the cell cycle as astroblasts or exit to form astrocytes. The results of this study show that cell division and cell differentiation are not mutually exclusive processes in the central nervous system (CNS), a finding which is in keeping with the developmental properties of many other non-CNS cell lines. Most importantly, this study demonstrates that most astrocytes generated in the postnatal optic nerve do not arise from an undifferentiated precursor but from cells already committed to the astrocyte lineage. SUPPORTED BY NS15338, NS18883 and NS18898.

236.2 THE DIFFERENTIATION OF RADIAL GLIAL CELLS. K. Frederiksen*, R. McKay; WHITAKER COLLEGE E25-435, M.I.T., Cambridge, MA 02139; S. Hockfield, C.S.H. Lab, P.O. Box 100, Cold Spring Harbor, NY 11724.

In all vertebrates, the cells of the central nervous system are derived from one specialized region of the embryonic ectoderm. After gastrulation, a signal from the underlying mesoderm causes the neural plate to go through a morphogenetic change to form the neural tube. In previous work, we generated reagents which identify the major cell types of the rat neural tube (radial glial cells, neurons, blood vessels). One of these monoclonal antibodies identifies radial glial cells in embryonic day 15 (E15) rat neural tube. The antibody was shown to recognize a 200 Kd polypeptide on immunoblots. It was also shown that this 200 Kd antigen is expressed in many of the cells in the early neural tube before the neurons start to differentiate. Because of the interest in the origin of neurons and glial cells, we have now extended our studies. We have dissected neural tissue from E10 to adult and dissociated the cells with high yield. Immunohistochemistry on these dissociated cells have enabled us to obtain quantitative data on the proportion of cells which express the radial glial differentiation antigen at different developmental stages. This 200 Kd antigen is expressed in 5-30% of the cells at E10. By E11, greater than 98% of the $10^5$ cells in the neural tube express this antigen. At E15, only 50-60% of the $10^7$ cells in the neural tube express the 200 Kd antigen. At P3, there are no antigen positive cells in the spinal cord, while 50-60% of the cells in the cerebellum and nasal lobe still express the antigen. In the adult CNS, there are no antigen positive cells. These results suggest that both neurons and radial glial cells are derived from a population of E11 neuroepithelial cells which all express the 200 Kd antigen, and confirm the immumohistochemical studies which correlate the disappearance of the antigen with the cessation of cell proliferation and/or neuronal migration in the CNS of the rat.

236.3 GLIAL FIBRILLARY ACIDIC PROTEIN IN RADIAL GLIA OF EARLY HUMAN FETAL CEREBRUM, CEREBELLUM AND SPINAL CORD: A LIGHT AND EM IMMUNOPEROXIDASE STUDY. Ben H. Choi, Division of Neuropathology, University of California Irvine, Irvine, CA 92717.

Glial fibrillary acidic protein (GFAP) is widely recognized to be the major protein constituent of glial filaments, which are distinct from other intermediate filaments. It has been demonstrated by us and by others that radial glia in humans and subhuman primates contain GFAP. Although GFAP is highly resistant to formalin fixation and paraffin embedding, the stainability of GFAP can be greatly influenced by delay in fixation and tissue processing. Thus, GFAP immunoreactivity in paraffin sections of routine autopsy brains derived from spontaneous abortions or stillbirths is highly variable and may lead to mistaken conclusions and interpretations.

In order to assess the nature of GFAP immunoreactivity in radial glia of early human CNS, representative sections of cerebrum, cerebellum and spinal cord of 46 embryos and fetuses ranging from 6 to 20 weeks of ovulation age were processed for GFAP immunocytochemistry using vibratome (10 to 30 μm), paraffin (4 to 6 μm), de-eponized one μm and thin sections. All specimens were obtained by hysterotomy or Porro hysterectomy and were fixed within 10 to 20 minutes after the surgery. For EM and vibratome sections, finely minced samples were fixed in 4% glutaraldehyde for 18 to 24 hours then placed in buffer. Paraffin sections were prepared from tissues fixed in toto in Bouin's fluid for 18 to 24 hours then placed into 80% ethanol until sectioned and embedded. The GFAP antisera from three sources (our own, a gift from Dr. L. Eng, and from Dako) were tested and were found to give identical results.

In all three regions studied, GFAP staining was most prominent and consistent in vibratome and 1 μm sections derived from well fixed specimens. In cerebrum and cerebellum, parallel arrays of radially oriented fibers extending from ventricular to leptomeningeal surfaces were strongly positive for GFAP in fetuses of 10 weeks and older. In spinal cord, GFAP staining was equivocal in 6-week-old embryos but became positive by 8 to 9 weeks. Paraffin sections showed patchy and variable GFAP staining. While radial glia demonstrated delicate and thin staining of GFAP, the ependyma and astrocytes showed strong but patchy staining of GFAP in the same sections. The variability of GFAP staining appeared to depend largely on the status of fixation.

The results of this study conclusively demonstrate that radial glia are demonstrable in early human CNS and that they express GFAP at early stages of development. A great caution must be used when interpreting the results of GFAP immunoreactivity in paraffin sections prepared from autopsy brains with delayed or improper fixation.

236.4 FORSKOLIN INDUCES GROWTH INHIBITION AND DIFFERENTIATION IN CULTURED CELLS FROM RAT BRAIN. O. Kempski*, B. Wroblewska*, H. Kretzschmar*, N. Merkel*, J. Bembry* and M. Spatz (SPON: I. Klatzo). LNNS, NINCDS, NIH, Bethesda, MD 20205

In-vitro studies using cultured brain cells are hampered by the fact that these cells are exposed to high concentrations of growth factors from fetal calf serum (FCS) as well as from artificial media. Therefore they are often in an undifferentiated state and not necessarily representative for a functional cell in-vivo. Previous studies have employed dBcAMP, an analogue of cAMP, to initiate "differentiation" in glial cells (Sensenbrenner M. et al. in: Tissue Culture in Neurobiology, Giacobini et al. eds., Raven Press, New York, 1980). The mode of action of dBcAMP is not clearly defined. Therefore, forskolin which activates the catalytic subunit of adenylate cyclase, was used to study the role of cAMP in the regulation of mitotic activity. Its action on thymidine incorporation and cAMP production was tested in cultured endothelial, smooth muscle, and glial cells from rat brain. GFAP was evaluated as a measure of glial differentiation.

All three cell types showed a forskolin dose-dependent reduction of thymidine incorporation in the presence of FCS. Maximal inhibition was achieved with 100μM forskolin which reduced thymidine incorporation to levels otherwise found in the absence of FCS (75-95% reduction). 5 day exposure of glial cells to forskolin not only caused striking morphological changes similar to those observed after dBcAMP but also led to an increased expression of GFAP which was demonstrated by immunohistochemistry and ELISA. However, the forskolin induced increase of GFAP was lower than that after exposure to dBcAMP. This may be explained by the differences in cAMP levels found after forskolin and dBcAMP. Forskolin (100μM) steeply increased i.c. cAMP (10-20 fold) only during the first hour of exposure in all cell types studied. dBcAMP (.5mM), on the other hand caused cAMP to increase twofold, an increase lasting for more than 24 hours. This phenomenon might be the result of a gradual degradation of dBcAMP to cAMP and butyrate.

These findings emphasize the importance of cAMP in the regulation of mitotic activity. Moreover, the results suggest that forskolin may serve as a tool to initiate differentiation of brain cells in culture.

236.5 INHIBITION OF ADRENERGIC DIFFERENTIATION OF QUAIL NEURAL CREST CELLS BY THE NOREPINEPHRINE UPTAKE INHIBITOR, DESIPRAMINE. M. Sieber-Blum and J. Silverman*. Dept. of Cell Biology and Anatomy, The Johns Hopkins Univ. Sch. of Med., Baltimore, MD 21205.

Autonomic neurons of the vertebrate embryo are derived from the neural crest. We report here that the in vitro differentiation of quail neural crest cells into adrenergic neurons is inhibited by chronic exposure to the norepinephrine (NE) uptake inhibitor, desipramine. By use of a quantitative in vitro colony assay (Sieber-Blum, M. and Cohen, A.M., Develop. Biol., 80, 96, 1980) we determined that proliferation of "pluripotent" progenitor cells and progenitor cells committed to the neuronal and pigmented cell lineages was not affected by the drug. However, expression of the adrenergic phenotype was markedly depressed. The frequency of colonies containing cells that scored positive for glyoxylic acid/formaldehyde-induced catecholamine fluorescence was reduced by 50% in the presence of 1 μg/ml desipramine and by 70-80% in the presence of 5 μg/ml desipramine. Differentiation of neural crest cells into pigmented cells was not affected by these drug concentrations. When mature cultures were exposed to even higher concentrations (10 μg/ml) of the drug, melanocytes were lysed, but catecholamine histofluorescence in adrenergic neurons was not affected. This indicated that desipramine was interfering with the expression of the adrenergic phenotype rather than causing depletion of intracellular neurotransmitter. Our results thus suggested that the high-affinity NE uptake mechanism may play a role in the differentiation of adrenergic neurons of the peripheral nervous system. Results obtained with pharmacologically active analogs were in agreement with this hypothesis. Mazindol, like desipramine a strong NE uptake inhibitor, blocked adrenergic differentiation as effectively as desipramine. Chlorpromazine, a weak inhibitor, was slightly inhibitory. Citalopram, a potent serotonin uptake inhibitor, did not interfere with the expression of the adrenergic phenotype. The local anesthetic, lidocaine, did not interfere with neuronal differentiation, suggesting that the inhibitory effect of desipramine cannot be attributed to a non-specific membrane effect. Neither desipramine nor any of the analogs affected the frequency of unpigmented, pigmented and mixed colonies. Since desipramine is a widely used antidepressant, a closer examination of its teratogenic potential may be indicated. (Supported by NIH grant HD15311.)

236.6 TRANSIENT NEURONS IMMUNOREACTIVE FOR PEPTIDES IN THE FETAL CAT'S TELENCEPHALON. J.J.M. Chun, M.J. Nakamura* and C.J. Shatz, Dept. of Neurobiology, Stanford U. Sch. of Med., Stanford, CA 94305.

During the development of the mammalian cerebral cortex the white matter is a complex zone consisting not only of afferent and efferent axons, but also of migrating cells en route to the cortical plate. Recently, we have found that in the fetal cat this zone is actually a neuropil that temporarily contains both synapses (Chun & Shatz, Neurosci. Abst. 9:692, 1983) and a special transient class of cell, the subplate cells (Luskin & Shatz, J.Neurosci. 5, 1985). 3H-thymidine studies have shown that these cells are generated exclusively during the one week period (E24-E30) preceding neurogenesis of the cortical plate, and disappear shortly after birth in concert with the synapses. (About 1% of the subplate cells survive into adult life where they reside in the white matter.) In order to learn more about the functional significance of this transient zone during development, we have used a variety of anatomical methods to characterize further the subplate cells.

Immunohistochemical studies show that the subplate cells are very likely to be neurons. All are immunoreactive for MAP-2 (which in the adult is neuron specific: Matus et al., P.N.A.S. 78:3010, 1981). Subsets are also immunoreactive for somatostatin, neuropeptide Y and glutamic acid decarboxylase. Immunoreactive cells were conclusively identified as subplate cells in double-label experiments in which fetuses were first injected with 3H-thymidine at E27,28, then between E50 and birth, cortex was reacted for immunohistochemistry and finally the reacted sections were processed for autoradiography. Results indicate that the population of cells generated simultaneously is heterogeneous with respect to transmitter phenotype. Immunostaining also provided information about the morphology of the subplate cells. In general, cells have elaborate processes radiating out from one or two primary dendrites that are often directed towards the ventricular surface; some of the processes are beaded and may project upwards into the cortical plate or run for some distance in the subjacent white matter. The cells can also be retrogradely labeled with horseradish peroxidase (HRP) injections made locally into the telencephalic white matter. EM examination of the HRP-labeled cells confirms at the ultrastructural level their neuronal identity and reveals that they receive simple synapses upon their dendrites.

These results suggest that the subplate cells are a unique neuronal class that subserves a transient function during the development of the telencephalon. They may serve as temporary synaptic targets for ingrowing afferent systems and might also play a neuromodulatory role in the development of the mammalian cerebral cortex.

Thanks to Drs. R. Vallee and D. Schmechel for their gifts of antisera against MAP-2 and GAD. Supported by NIH grants EY02858 and GM07365.

236.7 ENDOCRINE CELLS OF MOUSE EMBRYONIC PANCREAS EXPRESS NEURONAL TRAITS DURING REGENERATION. G. Teitelman, J. Lee*, T.H. Joh and D.J. Reis. Dept. of Neurology, Cornell Univ. Med. Coll., New York, NY 10021.

We have previously reported that cells transiently expressing tyrosine hydroxylase (TH), the first enzyme of the catecholamine (CA) biosynthetic pathway are present in the pancreas of mouse embryos from prenatal day 11 (E11) to E15 of development. At E12, some of the transient catecholaminergic cells (TC cells) also contained glucagon while at E14.5 some TC cells contained insulin. Pancreatic islet cells do not express TH after E15, even though the cells containing pancreatic hormones persisted throughout life. These findings suggest that the TH cells of embryonic pancreas are the precursors of some or all pancreatic polypeptide-containing cells of adult islets.

In this study we sought to determine whether the ability of pancreatic cells to express TH is restricted to only that population present in the gland during early development in vivo. To test this, the pancreatic rudiment was removed at E11, the gut explanted and a new pancreas was allowed to regenerate from the pancreatic duct. To elucidate whether a new population of TH cells will reappear in the regenerated pancreas (RP) explants were fixed after several days in culture, sectioned and processed for localization of antigens according to the peroxidase-antiperoxidase (PAP) method.

It was found that, after nine days in vitro, the RP contained many glucagon or TH cells but only few insulin or somatostatin cells. This finding indicates that a new population of TH cells, unrelated to those in vivo, developed in the RP. To elucidate whether glucagon cells of the RP, as those in vivo, also contain TH, histological sections of the explants were processed following a combined immunohistochemical-autoradiographic procedure that allows simultaneous visualization of two antigens. Thus, the sections were sequentially incubated with diluted solutions of antibodies to TH, $^{125}$I-donkey antirabbit IgG, antisera to glucagon, goat antirabbit IgG, PAP and 3-3' diaminobenzidine (DAB). The sections were then dried, dipped in Ilford L-4 emulsion (diluted 1:1) and developed after one to two weeks of incubation at 4°C in a light-tight box. It was found that, in the RP, some cells contained only glucagon or TH, as indicated by the presence of either DAB precipitate or silver grains over the cytoplasm, respectively. A third group of cells were doubly labeled by DAB and silver grains and, therefore, contained both TH and glucagon. We conclude that 1) a new population of TH cells appear during neoformation of the mouse embryonic pancreas and 2) some of these TH cells of the RP pancreas also contain glucagon. These findings suggest that, as in vivo, TH cells of RP are precursors of glucagon-containing cells. Moreover, they also suggest that the expression of this neuronal trait is a normal maturational event of differentiating peptide cells of pancreas and, perhaps, of peptidergic neurons of peripheral and central nervous system. (Supported by NIH Grant HL18974 and NSF Grant PCM-8303019.)

236.8 DIFFERENTIAL DISTRIBUTION OF NEURONAL CELL ADHESION MOLECULES DURING HISTOGENESIS OF THE CHICK NERVOUS SYSTEM. J.K. Daniloff, C.-M. Chuong, G. Levi*, and G.M. Edelman. Dept. of Developmental and Molecular Biology, Rockefeller Univ., New York, New York 10021.

The neural cell adhesion molecule, N-CAM, appears early during the development of the primary embryonic axis and in regions where inductive events occur. This molecule undergoes cell surface modulation (Edelman, Ann. Rev. Neurosci., 7:339, 1984) and its conversion from embryonic to adult forms may help to stabilize neural connections (Chuong & Edelman, J. Neurosci., 4:2354, 1984). The neuron-glia cell adhesion molecule, Ng-CAM, mediates the adhesion between developing neurons and glia (Grumet & Edelman, J. Cell Bio., 98:1746, 1984) and initially appears in the ventral neural tube at E4 (Thiery et al., J. Cell Biol., 100:442, 1985).

We compared the distribution and dynamics of the expression of N-CAM and Ng-CAM during histogenesis of the nervous system in developing and adult white Leghorn chickens. The antigens were individually localized by fluorescent immunohistochemistry using polyclonal antibodies to each CAM. The neural regions examined included the spinal cord, cerebellum, optic tectum, retina, forebrain, olfactory bulb, sciatic nerve, and dorsal root ganglion. Each CAM appeared in a characteristic spatial and temporal pattern during cell movement, fiber outgrowth, tract formation, and myelination. Anti-Ng-CAM antibodies labeled extending neurites and post-mitotic cell bodies. A major part of this labeling was correlated with established times of cell migration in spinal cord and cerebellum and was found in regions undergoing neurite extension such as the developing white matter of spinal cord and optic nerve. In the developing CNS, Ng-CAM was more abundant on neurites than cell bodies; in the adult, it was markedly decreased in myelinated tracts, but persisted in unmyelinated regions such as the olfactory bulb. In the PNS (e.g. dorsal root ganglia and sciatic nerves), Ng-CAM appeared early on both cell bodies and neurites, and persisted on both in the adult, even in the presence of myelin. Anti-N-CAM antibodies labeled both cell bodies and neurites in the CNS and PNS. Compared with that of Ng-CAM, the distribution of N-CAM was more uniform throughout development, although the staining intensity was diminished in the adult.

The distribution of both CAMs showed dynamic reversals as the nervous system developed and as a result, the pattern of CAM expression was markedly different in embryos and adults. This difference may reflect changes in the roles of selective adhesion of the two neuronal CAMs at different times of development.

236.9 A MONOCLONAL ANTIBODY ANALYSIS OF NEURAL DIFFERENTIATION IN THE OLFACTORY NEUROEPITHELIUM. J. Morgan* and J. Hempstead* (SPON: R. Mangano), Roche Inst. of Molec. Biol., Roche Research Center, Nutley, NJ 07110.

The adult olfactory neuroepithelium contains a population of progenitor neuroblasts that retain the capacity to divide and differentiate into mature, functional, olfactory receptor neurons. Removal of one of the paired olfactory bulbs results in the death of mature receptor neurons in the ipsilateral mucosa. Subsequently, through the proliferation and differentiation of neuroblasts the neuroepithelium becomes reconstituted. However, the dynamics of olfactory neuron differentiation is altered when this is compared to the normal contralateral mucosa. These findings are presumed to indicate that the olfactory bulb can modulate the rate of differentiation of olfactory neurons. We have utilized the paradigm of unilateal olfactory bulbectomy to begin to define some of the molecular and biochemical sequelae of differentiation. As probes to investigate these parameters we employed a previously described panel of monoclonal antibodies (J. Neurosci., 1985, 5: 438-449).

Immediately following bulbectomy there ensues the death of olfactory neurons. However, using a monoclonal antibody to sustentacular cells (SUS-1) it may be seen that these glial-like cells are unaffected by surgery. At late times the neuronal complement of the epithelium is reconstituted. However, there are a number of visible alterations. First, a number of monoclonal antibodies (NEU-4, NEU-9) do not stain or show attenuated staining of ipsilateral mucosa. this is in contrast to other clones (NEU-5) that do not distinguish lesioned from unlesioned epithelium. Further, the NEU-9 antibody reveals a neuronal subset in the ipsilateral mucosa. These are believed to be immature cells since the NEU-9 antigen is expressed early in development when compared to the other neuronal antigens detected by the panel of antibodies. Thus the absence of the olfactory bulb appears to have caused a shift in differentiation towards a more immature state as well as the loss of certain antigenic determinants. A further consequence is the production of neuromas in the ipsilateral mucosa. The presence of these structures have led us to investigate the molecular properties of one particular monoclonal antibody (NEU-5) that stains the neuromas intensely, these are described.

236.10 ONTOGENY OF RAT OLFACTORY EPITHELIUM STUDIED WITH MONOCLONAL ANTIBODIES. A.I. Farbman[1], J.I. Morgan*[2], and J.L. Hempstead*[2]. [1]Dept. of Neurobiology and Physiology, Northwestern University, Evanston, IL 60201 and [2]Roche Institute of Molecular Biology, Nutley, NJ 07110.

Monoclonal antibodies can be used as specific probes to study the phenotypic expression of transient or stable molecular species during neuronal development. It may be possible to monitor the stages of differentiation with these probes and to identify those molecules that play significant roles in neuronal function. We have used some antibodies from a panel of monoclonals made from homogenates of adult rat olfactory mucosa (Hempstead & Morgan, 1985, J. Neurosci., 5:438) to monitor the first appearance of certain proteins of olfactory receptor neurons during development. In immunofluorescent studies on histological sections of adult rat olfactory mucosa, Neu-5 antibody was bound primarily to olfactory nerve bundles and only weakly to perikarya. Neu-4 and Neu-9 bound to both perikarya and axons. Sus-1 bound to sustentacular cells in the main olfactory organ exclusively, i.e., it did not bind to homologous cells in the vomeronasal organ. In rat embryos, Neu-5 and Neu-9 were reactive as early as the 15th embryonic day, but Neu-4 was not demonstrable until the 16th (E16). Sus-1 was faintly reactive at E20. These data will be discussed in the context of a detailed ultrastructural study on developing olfactory receptor cells.

In addition to the existing library, we have made new monoclonals to crude membrane fractions of adult and neonatal rat olfactory mucosa, and to total homogenates of fetal mucosa. Screening was done on frozen histological sections of E20 rat fetal heads by immunofluorescent staining. Various antibodies have been found that are specifically immunoreactive to the luminal surface of olfactory epithelium, olfactory supporting cells and Bowman's glands. Other antibodies were reactive only to the luminal surface of respiratory epithelium, and some to both respiratory and olfactory surfaces.

236.11 REGULATION OF SPECIFIC NEURON TYPE IN FROG RETINA. T.A. Reh, Department of Medical Physiology, The University of Calgary, Calgary, Alberta T2N 4N1, Canada

In most CNS structures, the ratio of differentiated neuronal types is precisely maintained. For example, in the Rana pipiens retina the ratio of ganglion cells to photo receptors to inner nuclear layer cells is 1:3:7.2. Such a precise numerical ratio among the elements could be generated via selective cell production, differentiation or death; however, all of these mechanisms involve some feedback from the tissue to signal that the appropriate number of neurons of a particular class have been generated or maintained. Although the nature of the mechanisms of cell regulation are unknown, I have found that in the frog retina the regulation of density of a particular amacrine cell subclass is critically dependent on the presence of previously differentiated neurons of that type.

There are two monoamine containing cell types in the frog retina: dopamine and serotonin containing amacrine cells. In the present study Rana pipiens tadpoles received unilateral intraocular injections of 6-hydroxydopamine (6-OH-DA). Tadpole retinas were then stained with specific antisera to tyrosine hydroxylase (TH) or serotonin (5-HT) using serial paraffin sections, cryostat sections or whole mounts. The total number of cells in the retinas was counted and their density calculated. 6-OH-DA treatment was effective in eliminating any TH-immunoreactive (TH-IR) cells within 3 days after the injection; however, no change in intensity or cell number was observed when alternate sections were processed for serotonin or substance P immunoreactivity.

In the tadpole, new neurons are generated in a proliferative zone near the ciliary margin. Within one week following the 6-OH-DA treatment, new TH-IR cells begin to appear in this region. By three weeks this area contains numerous TH-IR cells with a density more than three times greater than that in normal retina. This increased staining of TH-IR amacrine cells does not result from a general increase in cell production at the ciliary margin, since the density of 5-HT containing amacrine cells in peripheral retina of 6-OH-DA treated animals does not increase over the control value. Double labelling with $H^3$-thymidine and TH-antiserum shows that all TH-IR cells in these retina were generated after the neurotoxin treatment, indicating that other amacrine cell types do not transdifferentiate into TH-IR amacrines.

In conclusion, 6-OH-DA destroys TH-IR amacrine cells, or irreversibly depletes this enzyme system in these cells. However, the neurotoxin does not destroy the stem cells for these neurons, and proliferation and/or differentiation of TH-IR amacrines is specifically up-regulated following their destruction.

236.12 **A ZONE OF EXCLUSIVE ROD NEUROGENESIS IN THE TELEOST RETINA**
**Russell D. Fernald and John Scholes*, Inst. Neuro., Univ. of Or., Eugene, Or. and MRC Cell Biophysics, London.**

**It has long been known that teleost fish add new retinal cells of all types concentrically from a primary retinal blastema located around the iris margin of the eye (Müller, Zool. Jb. 63:275, 1952). We have found that this primary retinal blastema produces incomplete, embryonic retinal tissue with a fixed, low ratio of rods to cones. Additional rods are produced by specialized neuroblasts located in the outer nuclear layer (ONL) concentrated in a circular front about 100 μm inside the retinal margin. These neuroblasts move outward from older to newer retinal tissue, dividing to augment the sparse rod population produced by the primary retinal blastema.**

**One micron serial sections were made tangential to the edge of the optic globe, near the retinal margin. At this position, the ONL comprises a single sheet of receptor nuclei in which the rod nuclei are arranged in a square lattice. Each square lattice corresponds to an array of four double cones arranged around a single central cone. More centrally, rod nuclei are packed confluently in a layer more than one deep, vitread to and separate from the cone nuclei. Here, there are between 4 and 10 rods associated with each double cone, depending on the size of the retina, with larger retinae having more rods corresponding to each cone.**

**By serially reconstructing the retinal margin from 1 μm sections, we identified cells which are located in the retinal region where rod density abruptly increases. These are elongated in the plane of the ONL with dispersed patchy chromatin, and are often associated with mitotic figures. Based on these observations, we hypothesized that they were the source of rod photoreceptors.**

**To test this hypothesis, we injected $^3$H-thymidine (30 μCi/gbw) and sacrificed the animals at various times after injection. At 24 h, heavy label was clustered over mitotic figures and these putative precursor cells. After 96 hr, the putative precursors were comparatively weakly labelled, while heavy clusters of grains appeared only over differentiated rod nuclei. After long survival times, only rod nuclei were labelled. From this we conclude that these cells comprise a dividing population of rod precursors. Most likely they constitute a separate lineage which achieves the regulatory feat of maintaining uniform rod density as the eye grows.**

## RECEPTOR MODULATION: UP AND DOWN REGULATION II

237.1 **A NOVEL CHEMOSENSORY RECEPTOR FOR γ-AMINOBUTYRIC ACID (GABA) AND GABA-MIMETICS IS SUBJECT TO BOTH UP-REGULATION AND DOWN-REGULATION.**
**H. G. Trapido-Rosenthal* and D. E. Morse* (SPON: S. K. Fisher). Marine Science Institute and Department of Biological Sciences, University of California, Santa Barbara, CA 93106.**

**The free-swimming larvae of the marine gastropod mollusc Haliotis rufescens can be induced to settle from the plankton and metamorphose to the juvenile form by γ-aminobutyric acid (GABA) and stereochemically similar compounds. This induction is mediated by a GABA-receptor that differs in several respects from heretofore characterized types of GABA-receptors. The order of affinities of this receptor for GABA and related compounds is: β-chlorophenyl-GABA (Baclofen) > GABA > muscimol > 3-aminopropane sulfonic acid (3-APS). Induction of settlement by these compounds is positively cooperative, with a Hill coefficient ($n_H$) of approximately 2. The induction of settlement and metamorphosis by these GABA-mimetics can be up-regulated, or facilitated, in a concentration-dependent, stereochemically specific manner, by the L-α,ω-diamino acids, such as L-lysine and L-α,β-diamino propionic acid (L-DAPA). Up-regulation by diamino acids reduces the $n_H$ for inducing GABA-mimetics from 2 to 1, and increases the affinity of the receptor for these inducers (as measured by the apparent dissociation constant) by 30-fold. This up-regulation does not require the simultaneous presence of facilitating and inducing compounds, and the up-regulated state persists for days. Benzodiazepines do not facilitate the interaction of GABA-mimetics with this receptor. The receptor also can be down-regulated, or habituated, by exposing larvae to GABA before they have developed metamorphic competence. The extent of down-regulation is concentration-dependent, and is slowly but completely reversible. Binding of GABA-mimetics to this receptor appears to control an excitatory efflux of chloride ions. These results suggest that up-regulation by DAPA may be caused by a covalent modification of the receptor, converting it to the high-affinity state. They further suggest that down-regulation by GABA may result from internalization or inactivation of the receptor.**

237.2 DECREASED DENSITY OF BENZODIAZEPINE RECEPTORS AFTER CHRONIC ANTIDEPRESSANT TREATMENTS.
B.E. Suranyi-Cadotte, T.V. Dam* and R. Quirion. Douglas Hospital Research Centre, Verdun, Quebec H4H 1R3.

The benzodiazepine (BZ)/GABA system has been extensively implicated in the action of anxiolytic drugs. Anxiolytic effects have also been demonstrated for a number of antidepressant agents. The present study was undertaken to investigate whether an interaction with BZ receptors may be involved in the mechanism of action of antidepressants. Since the therapeutic effects of antidepressants cannot be ascribed to short-term neuroreceptor changes, we have studied the effect of different classes of antidepressants on BZ receptors in rat brain after chronic treatment. In addition, the effect of these agents on β-adrenergic receptors were also assessed to verify antidepressant efficacy.

Male Sprague Dawley rats received twice daily i.p. injections of either saline or 10 mg/kg desipramine, zimelidine, bupropion or adinazolam for 21 days. 24 hours after the last injection, brains were removed and binding assays performed using $^3$H-flunitrazepam and $^3$H-dihydroalprenolol as ligands to identify BZ and β-adrenergic receptors respectively. Chronic treatment with desipramine, zimelidine, bupropion and adinazolam significantly reduced BZ receptor density ($B_{max}$) by 58% to 75% below control values (for all drug treated groups $p < 0.001$ compared to saline group). Chronic treatment with these agents also reduced the number of β-adrenergic receptors, but only by 12% to 22% below control levels.

Although β-adrenergic receptor down-regulation has been previously proposed as a major mechanism involved in antidepressant action, the present results suggest that an interaction with BZ receptor systems may underly, at least in part, the therapeutic effects of antidepressants.

237.3 TRANSCRIPTIONAL REGULATION OF ACETYLCHOLINE RECEPTOR IN CHICKEN SKELETAL MUSCLE AND IN CULTURED CHICK MYOTUBES. B. H. Shieh*, M. Ballivet* and J. Schmidt, Dept. of Biochem., State University of New York at Stony Brook, NY 11794, and Dept. of Biochem., Sciences II, University of Geneva, Geneva, Switzerland.

We have measured levels of mRNA specific for acetylcholine receptor α-subunit in chick skeletal muscle in vivo and in vitro using a genomic DNA probe for an α-subunit segment (amino acyl residues 241 to 314). Total RNA was extracted by the phenol-chloroform procedure and assayed by incubation with an excess of single-stranded $^{32}$P-labeled probe, S1 nuclease digestion, electrophoresis, and autoradiography.

In the calf-musculature of adult chickens, α-subunit message levels were found to be barely detectable. Two days after section of the sciatic nerve a 50fold rise in α-subunit mRNA was observed which reached a peak at three days after denervation and over a period of two weeks gradually declined, to reach near-normal levels after six weeks when signs of functional reinnervation had appeared. The rise in message levels preceded the rise in receptor concentration by over a day.

Cultured chick myotubes produce acetylcholine receptors at a rate comparable to the receptor synthesis in denervated muscle. This synthetic rate increases two- to three-fold in the presence of the sodium channel blocker tetrodotoxin and the calcium channel blocker D600; it is reduced upon addition of veratridine, which activates sodium channels, and ryanodine which activates the sarcoplasmic reticulum. In all cases investigated the level of RNA recognized by the α-subunit probe changed hours before expression of assembled receptor was noticeably affected.

We conclude that electrical activity of plasma membrane controls acetylcholine receptor expression by a transcriptional mechanism.

237.4 THE EFFECTS OF MULTIPLE HIGH DOSES OF METHAMPHETAMINE ON MUSCARINIC CHOLINERGIC RECEPTORS IN THE RAT CNS. R.T. McCabe, G.R. Hanson, J.K. Wamsley, and J.W. Gibb. Departments of Pharmacology, Psychiatry, and Biochemical Pharmacology and Toxicology, University of Utah, Salt Lake City, UT 84132.

Our laboratories and others have demonstrated that multiple high doses of methamphetamine (METH) alter dopamine (DA), serotonin (5-HT), and muscarinic cholinergic nervous systems associated with basal ganglia and mesolimbic structures in the rat. Furthermore, we also have reported a reduction in the number of DA receptors in response to multiple high doses of METH (McCabe et al., Fed. Proc. 44:1829, 1985). Therefore, we investigated the effects of multiple high doses of METH on muscarinic cholinergic receptors paralleled with the METH-induced biochemical alterations in an effort to elucidate the relationship between these receptors and the biochemical events that occur with METH treatment.

Animals were administered METH (15 mg/kg, s.c.) or vehicle every 6 hours for 5 doses. Brains were removed 18 hours following the final dose and coronal tissue slices were obtained. The binding of two muscarinic cholinergic antagonists, $^{3}$H-N-methyl scopolamine (NMS) and $^{3}$H-pirenzipine (PZ), was measured autoradiographically. Both $M_1$ and $M_2$ receptors are labeled with $^{3}$H-NMS (Wamsley et al., Brain Res., 200(1):1, 1980), whereas $^{3}$H-PZ preferentially labels $M_1$ receptors (Wamsley et al., Life Sci., 34:1395, 1984).

The binding properties of muscarinic cholinergic receptors can be characterized on the basis of their affinities for muscarinic cholinergic agonists (Birdsall et al., Mol. Pharmacol., 14:723, 1978). METH treatment elicited a significant reduction in the binding of $^{3}$H-NMS to the high affinity receptors in areas which included the caudate-putamen (33% reduction), nucleus accumbens (24%), olfactory tubercle (40%), superficial layer of the cortex (33%), and CA3 of the hippocampus (24%). The binding of $^{3}$H-NMS to the low affinity receptors also was decreased in the caudate-putamen, nucleus accumbens, and olfactory tubercle of animals treated with METH. Alternatively, the binding of $^{3}$H-PZ to the $M_1$ receptors did not appear to change in response to METH. Thus, a decrease in receptor binding following METH treatment appears to occur exclusively at the $M_2$ receptor sites. The time-course of the METH-induced receptor alterations will be discussed as well as Scatchard analysis of saturation data.

237.5 DRUG RESPONSIVITY FOLLOWING NERVE INJURY IN THE PINEAL GLAND: A MODEL SYSTEM. K. A. Haak*, D. M. Bronstein, and L. D. Lytle (SPON: G. H. Jacobs). Laboratory of Psychopharmacology, Department of Psychology, University of California, Santa Barbara, CA 93106.

Activity of the pineal gland enzyme, N-acetyltransferase (NAT) is controlled by the release of norepinephrine from sympathetic nerves onto postsynaptic pinealocyte β-noradrenoceptors. Receptor stimulation activates adenylate cyclase, leading to increased intracellular concentrations of cyclic AMP and enhanced NAT activity via a protein kinase mechanism. Denervation of the postganglionic sympathetic fibers arising from the superior cervical ganglia results in the phenomenon of denervation receptor supersensitivity, which involves an increased responsiveness of postsynaptic pinealocyte neurochemical mechanisms as a result of the loss of neurotransmitter input. Isoproterenol and other β receptor agonist drugs cause supersensitive-like responses in NAT activity following denervation (see Axelrod, Science, 184:1341, 1974).

In the present experiments we compared time dependent alterations in the actions of drugs thought to depend on noradrenergic presynaptic, pinealocyte β-noradrenoceptor, or pinealocyte intracellular, receptor-linked mechanisms following superior cervical ganglionectomy (SCGX) in rats. Male Sprague-Dawley albino rats weighing 300-400 g were anesthetized with sodium pentobarbital and subjected to bilateral SCGX. Following recovery from surgery rats were given ad libitum access to food and water and exposed to a 12:12 hr light:dark cycle (lights on at 0700 hr). Pineal glands were removed from intact and SCGX animals 1 or 7 days following surgery, then incubated in $10^{-3}$ M HCl vehicle, desmethylimipramine (DMI, $10^{-4}$ M) a presynaptic reuptake inhibitor, isoproterenol ($10^{-5}$ M) or isobutylmethylxanthine (IBMX, $10^{-4}$ M) a drug which inhibits phosphodiesterase catalyzed degradation of intracellular cAMP. The DMI-induced increase in pineal gland NAT activity in intact animals was attenuated in SCGX animals at 1 and 7 days postsurgery. Both isoproterenol and IBMX caused significant increases in NAT activity in intact animals and the enzyme induction caused by these drugs was potentiated in SCGX animals at 1 and 7 days.

These data show that denervation of the pineal gland attenuates the action of drugs whose effects are mediated by presynaptic mechanisms but potentiate the action of drugs acting directly on the receptor or on postreceptor intracellular biochemical mechanisms. (Supported by grant MH-31134).

237.6 $GM_1$ GANGLIOSIDE TREATMENT COUNTERACTS AND NORMALIZES DOPAMINERGIC RECEPTOR SUPERSENSITIVITY INDUCED BY NEUROLEPTICS. A. Leon, L. Cavicchioli*, S. Calzolari*, A. Consolazione* and G. Toffano. Fidia Neurobiological Research Laboratories, Abano Terme, Italy

Striatal dopaminergic (DA) receptor supersensitivity is known to occur not only following chronic treatment with DA antagonists but also following chemical injury of the nigro-striatal pathway. In this context studies from our own and other laboratories have recently documented that chronic $GM_1$ monosialoganglioside treatment counteracts the development of striatal DA receptor supersensitivity in adult rats chronically treated with haloperidol (Agnati, L.F., et al., Neurosci. Letters., 40:293-297, 1983) but not following presynaptic chemical denervation induced by a single unilateral injection of 6-OH-DA directly in the substantia nigra (Toffano G., et al., Acta Physiol. Scand., 122:313-321, 1984).

We now report that chronic $GM_1$ treatment is also capable of facilitating the recovery of receptor normosensitivity in adult rats following haloperidol withdrawal. In particular rats were first treated with haloperidol (2 mg/kg/day i.p.) for 14 days and then, after 5 days of washout, treated with saline or $GM_1$ (30 mg/kg/day i.p.) for 7 or 14 days. Treatment with haloperidol for 14 days produced approximately a 40% increase of the apparent Bmax of striatal $^{3}$H-spiperone binding sites. No modification of the apparent Kd was observed. Post-treatment with $GM_1$ significantly decreased, with respect to saline injection, the apparent Bmax of $^{3}$H-spiperone binding already after 7 days of treatment. After 14 days, the haloperidol-induced receptor supersensitivity completely disappeared in $GM_1$-treated but not in saline-treated animals. Similar $GM_1$ effects were observed following chronic treatment with perphenazine. In addition, $GM_1$ alone did not produce any significant change of $^{3}$H-spiperone binding when administered alone in vivo or after addition in vitro.

The above data indicate that $GM_1$ can effectively not only counteract but also normalize dopamine receptor supersensitivity induced both by butyrophenones and phenothiazines. The mechanism by which $GM_1$ produces this effect is still unknown. Possible effects on striatal dopamine presynaptic activity and/or on neuropeptides which may modulate the dopamine receptor function are currently under investigation.

237.7 ELEVATION OF STRIATAL DOPAMINE RECEPTOR DENSITY AFTER CHRONIC TREATMENT WITH HALOPERIDOL, DOMPERIDONE, OR SULPIRIDE AND ITS PREVENTION FOLLOWING PROLACTIN DEPLETION BY HYPOPHYSECTOMY OR BY CHRONIC TREATMENT WITH CYSTEAMINE. R.E. Hruska, Department of Biochemical Pharmacology, SUNY-Buffalo, Buffalo, NY 14260.

Recently, a role for pituitary hormones in the regulation of striatal dopamine (DA) receptors has been proposed. In most cases, removal of all pituitary hormones by hypophysectomy (Hypox) did not produce a major alteration in the density or the affinity of the striatal DA receptors. However, Hypox altered the increase in density observed after chronic haloperidol (HAL) treatment. When the daily doses of HAL were small (1 mg/kg), Hypox completely prevented the increase in density. When the daily doses of HAL were large (4 or 5 mg/kg), Hypox attenuated the increase in density (Eur. J. Pharm. 76:31 and 85:201). It has been proposed that this change is mediated by the pituitary hormone, prolactin (Life Sci. 30:547). In contrast, chronic treatment with domperidone (DOM) or sulpiride (SUL) elevated serum prolactin levels without altering the density of the striatal DA receptors (Eur. J. Pharm. 93:195).

These studies were designed to readdress the effects of large doses of DOM and SUL, and to use two differentially selective methods for prolactin depletion -- Hypox and chronic cysteamine treatment. Hypox removes all pituitary hormones, while cysteamine treatment depletes prolactin and somatostatin, induces ulceration, and causes depilitation. HAL (1 mg/kg), DOM (1 or 5 mg/kg), and SUL (30 or 100 mg/kg) were administered daily, i.p., for 20 days followed by a 7 day drug-free period. Cysteamine treatment (90 mg/kg, s.c.) preceded each HAL treatment by 2 hours. One hour after the last drug dose, a blood sample was removed from the tail and serum prolactin levels measured by RIA. The densities and affinities of the striatal DA receptors were measured with [$^3$H]spiperone after the 7 day drug-free period.

Chronic treatment with HAL, DOM, or SUL elevated serum prolactin levels and produced an increase in the density of the striatal DA receptors. Hypox prevented the increase in serum prolactin levels and the increase in DA receptor density after these treatments. Cysteamine treatment decreased serum prolactin levels without altering the striatal DA receptor density. Cysteamine treatment also prevented the increase in serum prolactin levels and the increase in density of the striatal DA receptors normally seen after HAL treatment.

These results support the hypothesis that prolactin may exert a modulatory function in the regulation of striatal DA receptor density. This function is likely to be complex since it is only associated with increases in DA receptor density. In addition, the magnitude, duration, and persistence of prolactin elevation required to induce these changes are not known. (Supported in part by MH-38017 and The Research Foundation of SUNY.)

237.8 DOES EXTRACELLULAR COPPER MODULATE PROSTAGLANDIN $E_2$ ($PGE_2$) RECEPTOR ON HYPOTHALAMIC LHRH NEURONS?

A. Barnea, G. Cho, M. Colombani-Vidal, Depts of Ob-Gyn and Physiol, Cecil H. and Ida Green Ctr, Univ of Tex Health Sci Ctr, Dallas, Tx 75235

$PGE_2$ stimulates the release of LHRH (luteinizing hormone releasing hormone) from LHRH neuronal terminals. Disulfide bonds have been implicated in $PGE_2$ binding to its receptor and in $PGE_2$ action, and copper can lead to the formation of such disulfide bonds. Copper has been found in high concentrations in hypothalamic tissue, particularly in axonal terminals. We have hypothesized that copper is present in high concentrations in the extracellular space of LHRH neurons, as a consequence of copper release from copper-rich axonal terminals. Such extracellular copper could facilitate $PGE_2$ action by inducing the formation of disulfide bonds on the receptor itself or on other related molecules that affect $PGE_2$ binding/action. In this study, we addressed the question: Does extracellular copper facilitate $PGE_2$ stimulation of LHRH release from median eminence (ME) explants? ME of male rats were incubated for 5 min with 100 µM copper (in the form of CuHistidine; CuHis) and then for 15 min with 50 µM $PGE_2$ ($Cu/PGE_2$). Release of LHRH during the latter 15-min period was quantified by RIA. Controls were incubated with CuHis or $PGE_2$ alone. Although CuHis and $PGE_2$ each stimulated LHRH release about 2-fold over the basal release (net stimulated release being 3.3 and 2.2 pg/5min per ME, respectively), $Cu/PGE_2$-stimulated release (12.5 pg/5 min per ME) was two times greater ($P < 0.001$) than the sum of CuHis-and $PGE_2$-stimulated release. Thus, copper facilitates $PGE_2$ action. The facilitatory effect of copper was dependent on the dose of copper and of $PGE_2$, and it was demonstrable only if $PGE_2$ was added immediately after CuHis but not 15 min before or 15 min after CuHis. By comparison to $PGE_2$, $PGD_2$ was much less effective in stimulating LHRH release and copper did not facilitate $PGD_2$ action. These results are consistent with a short-lived, $PGE_2$-specific effect of copper on the binding properties of the $PGE_2$ receptor or on the functional state of an early (maybe initial) post-receptor event involved in the process of $PGE_2$ stimulation of LHRH release from LHRH neuronal terminals.

237.9 CENTRAL NEUROTRANSMITTER RECEPTOR CHANGES FOLLOWING CHRONIC EXPOSURE TO LOW LEVELS OF LEAD. J. Offermeier, J.M. van Rooyen and J. Rossouw. Dept. of Pharmacology and MRC Research Unit for the Design of Catecholaminergic Drugs, Potchefstroom University, Potchefstroom 2520, South Africa.

Three groups of Wistar rats were exposed to low concentrations of lead at different stages of their development for periods of 21-23 days. Exposure was initiated at conception (group 1), at parturition (group 2) or after weaning had occurred (group 3). Blood levels of lead achieved during exposure in all 3 groups did not exceed 75µg/dℓ.

When a mass of 160 ± 10g was achieved the rats were sacrificed and radioligand binding studies were performed. The ligands $^3$H-di-OH-alprenolol (for estimation of receptor numbers and receptor affinity of β-adrenoceptors), $^3$H-clonidine (for $\alpha_2$-adrenoceptors), $^3$H-serotonin (for $S_1$ serotonin receptors), $^3$H-ketanserin (for $S_2$ serotonin receptors), $^3$H-naloxone (for opioid receptors) and $^3$H-dopamine for (D2 dopamine receptors) were used.

Lead exposure results in increases in the number of cortical β-adrenoceptors in group 2; the numbers of cortical $\alpha_2$-adrenoceptors in group 1, 2 and 3, the numbers of hippocampal $S_1$ receptors in groups 1 and 2 and the number of striatal D2 receptors in group 2. The number of forebrain opioid receptors in group 3 is decreased by lead exposure. No change in the numbers of cortical $S_2$ receptors results from lead exposure in any of the groups. The affinity of the $^3$H-ligand for hippocampal $S_1$ receptors is significantly decreased while the affinity of the $^3$H-ligand for forebrain opioid receptors is significantly increased in groups 2 and 3 resp.

The results show that exposure to low levels of lead does not only change the receptor numbers but may also result in affinity changes at various central neurotransmitter receptors. The developmental stage at which lead exposure occurs appears to be critical, as manifested by the findings that the changes which occurred in the 3 groups of rats were not identical.

237.10 ELECTROCONVULSIVE SHOCK SELECTIVELY DOWN-REGULATES BETA-1-ADRENERGIC RECEPTORS IN SPECIFIC AREAS OF RAT BRAIN. K.J. Kellar[1], C.A. Stockmeier[1], T.C. Rainbow[2] and B.B. Wolfe[2]. Departments of Pharmacology,[1] Georgetown University School of Medicine, Washington DC 20007, and [2]Medical School, University of Pennsylvania, Philadelphia, PA 19104.

Repeated administration of electroconvulsive shock (ECS) or antidepressant drugs decreases the number of beta-adrenergic receptors in certain areas of rat brain. Ligand binding studies in homogenates have shown that ECS (once daily for 7 to 12 days) decreases these receptors in the cerebral cortex and hippocampus, but not in the striatum, cerebellum or hypothalamus. The pattern of decrease suggested that ECS selectively decreases beta-1-adrenergic receptors, and only in those brain areas in which ECS activates norepinephrine axons (Kellar et al., J. Neurochem. 37, 1981).

Quantitative autoradiography of $^{125}$I-iodopindolol ($^{125}$Ip) binding in the presence of a selective beta-2-adrenergic antagonist (ICI 118,551) or a selective beta-1-adrenergic antagonist (ICI 89,406) has provided a detailed analysis of the anatomical distributions of beta-1- and beta-2-adrenergic receptors, respectively, in rat brain (Rainbow et al., PNAS 81, 1984). We have now measured the effects of repeated ECS (12 days) on beta-1- and beta-2-adrenergic receptors in rat brain using this selective quantitative autoradiographic method. Specific binding was defined as the difference in $^{125}$Ip bound in the absence and presence of 50 uM isoproterenol.

Analyses of the autoradiograms indicated that ECS decreases the binding of $^{125}$Ip in the cerebral cortex, hippocampus, amygdala and thalamus. In each of these areas, only binding to beta-1-adrenergic receptors was decreased. Binding to beta-2-adrenergic receptors was unaffected. Binding of $^{125}$Ip in other areas of brain analyzed to date, including the striatum, cerebellum and hypothalamus, appeared to be unaffected by ECS.

This autoradiographic analysis has revealed selective effects of ECS on beta-1-adrenergic receptors in specific layers of the cerebral cortex, regions of the hippocampus and nuclei of the amygdala and the thalamus. Localization of the effect of ECS on beta-1-adrenergic receptors may aid in determining the anatomical structures involved in antidepressant mechanisms.

237.11 CORTICOSTERONE DECREASES MUSCARINIC, NORADRENERGIC AND GLUTAMATE RECEPTORS IN RAT HIPPOCAMPUS. S. Halpain, B. Nock, G.P. Dohanich, and B.S. McEwen. The Rockefeller University, New York, New York

Steroid hormones regulate a variety of cellular responses, including aspects of synaptic neurotransmission. Studies from several laboratories have shown that steroids can regulate neurotransmitter receptors in neuronal and peripheral tissues. We therefore tested the ability of corticosterone (CORT) to regulate neurotransmitter receptors in the rat brain. Previous work from this laboratory indicated that CORT might regulate certain receptors in hippocampus (Biegon et al, 1985; Brain Res. 332:309).

In the first experiment, male rats were adrenalectomized (ADX) or sham-operated (SHAM). After 2 days one-half the ADX animlas were given 300mg pure CORT in subcutaneous pellets for 5 days; these were supplemented on day 5 with 200mg additional CORT pellet. After 10 days, all three groups were sacrificed and neurotransmitter receptor binding was assessed by standard in vitro autoradiographic methods. Muscarinic receptors were labeled with 1 nM $^{3}$H-N-methylscopolamine (NMS), $\alpha_2$-adrenergic receptors with 2.5nM $^{3}$H-p-aminoclonidine (pAC) and glutamate receptors with 300nM $^{3}$H-glutamate. Binding in various brain areas was measured densitometrically. Corticosterone treatment had a similar effect in decreasing binding for all 3 ligands. CORT-treated animals showed 15-30% lower binding than ADX controls. The SHAM group was either somewhat lower or not significantly different than ADX. This effect was seen in the hippocampal formation ($^{3}$H-NMS and $^{3}$H-glutamate) and in both the hippocampus and lateral septum ($^{3}$H-pAC), two brain areas which highly concentrate adrenal steroids. The effect was not observed in other brain areas measured, including medial septum, striatum, cortex, and areas of the thalamus and hypothalamus. The effect was most pronounced in regions of the dorsal hippocampus; it was either much smaller or not observed at all in regions of ventral hippocampus.

In a second series of experiments we sought to determine the nature of the binding change. Scatchard analysis of $^{3}$H-NMS and $^{3}$H-pAC binding to homogenates of dorsal hippocampus indicated that the effect of CORT was to decrease the maximal number of sites without affecting their affinity for the ligand.

A third study utilized daily injections of CORT instead of implants of CORT pellets in order to more closely mimic physiological exposure to the hormone. Membranes prepared from dorsal hippocampus showed significantly lower $^{3}$H-glutamate binding in CORT-treated ADX rats (10mg daily for 5 days) than in ADX rats given no hormone replacement. Moreover, this change apparently occurs without specificity to a subtype of glutamate receptor, since the ability of chloride to stimulate or quisqualate to compete for $^{3}$H-glutamate binding was not altered. These results suggest that the effect of CORT on neurotransmitter receptor number might be a generalized phenomenon, occuring with many receptor types, but that it is specific to brain areas which selectively bind adrenal steroids.

## CYCLIC NUCLEOTIDES I

238.1 GASTROINTESTINAL MESSENGER SUBSTANCES MODULATE EXCITABILITY IN MYENTERIC PLEXUS NEURONS THROUGH ACTIVATION OF ADENYLATE CYCLASE. J.D. Wood, D.H. Zafirov and J.M. Palmer. Dept. of Physiol., School of Medicine, University of Nevada, Reno, Nevada 89557.

Slow synaptic excitation (slow EPSP) in myenteric ganglion cells can be mimicked by application of several different peptides and biogenic amines. Many of these substances have been linked with activation of adenylate cyclase in other types of neurons and neural tissues. The aim of our investigation was to identify gastrointestinal messenger substances which exert their actions through adenylate cyclase to influence the electrical behavior of guinea-pig AH/type 2 myenteric neurons. Conventional intracellular methods with 3 M KCl-filled microelectrodes were used to record and inject electrical current in neurons from myenteric plexus preparations superfused with carboxygenated Krebs solution in vitro. Putative messenger substances were applied either in the superfusion solution or by pressure ejection from micropipettes. The diterpene, forskolin, a potent activator of adenylate cyclase, mimicked the slow EPSP in myenteric neurons when applied in the superfusion solution (0.05-50 uM) or by pressure microejection (50 uM). Pretreatment with adenosine or 2', 5'-dideoxyadenosine (10-100 uM) applied in the superfusion solution suppressed or abolished the action of forskolin. This suggested that inhibitory purinergic receptors were linked to adenylate cyclase in these neurons, specifically adenosine-$A_1$ receptors, that could prevent intraneuronal accumulation of cyclic AMP induced by stimulatory messengers. Therefore, we reasoned that pretreatment with adenosine or adenosine analogs with high affinity for $A_1$ receptors should offset the electrophysiological effects of excitatory messenger substances that stimulate adenylate cyclase. Vasoactive intestinal peptide (VIP), gastrin-releasing peptide (GRP), bombesin, cholecystokinin-octapeptide (CCK-OP), caerulein, substance P, histamine and serotonin each mimicked the slow EPSP when applied either in the superfusion solution or by pressure microejection. The effects of these substances occurred after blockade of axonal spike generation and synaptic transmission in the presence of tetrodotoxin (1-2 uM), and were potentiated in the presence of 0.1 uM forskolin. Pretreatment with adenosine or adenosine analogs prevented the actions of VIP, GRP, bombesin, CCK-OP, caerulein and histamine. However, the actions of substance P and serotonin could not be blocked with adenosine in the same cells where it had successfully blocked the other substances. Results suggest that VIP, GRP, bombesin, CCK-OP, caerulein and histamine act through adenylate cyclase to effect long-lasting modulation of excitability in AH/type 2 myenteric plexus neurons. Substance P and serotonin exert similar effects on neuronal excitability, but they may do so through mechanisms independent of the cyclic AMP generating system. (Supported by NIH Grant RO1 AM 26742).

238.2 SECOND MESSENGER FUNCTION OF CYCLIC AMP MEDIATES MODULATION OF EXCITABILITY IN MYENTERIC PLEXUS NEURONS. J.M. Palmer, D.H. Zafirov, P.R. Nemeth and J.D. Wood (SPON: C. Ort). Dept. of Physiol., Univ. of Nevada, Reno, NV 89557.

Synaptic input to myenteric neurons of guinea-pig small intestine generates a slow synaptic mechanism of excitation associated with prolonged membrane depolarization and enhanced somal excitability involving ionic conductance changes. This suggests that generation and accumulation of an intraneuronal second messenger might play a significant role in long-term modulation of neuronal excitability. We hypothesized that intrasomal cyclic AMP elevated by putative messenger substances could be the common intermediate step in generation of slow synaptic excitation (slow EPSP) in AH/type 2 myenteric neurons. Conventional intracellular methods were used to record electrical behavior from ganglion cells of myenteric plexus preparations superfused with carboxygenated Krebs solution in vitro. Forskolin, a potent activator of adenylate cyclase, 8-(4-chlorophenylthio) cyclic AMP and 8-bromo cyclic AMP, membrane-permeable analogs of cyclic AMP, and the phosphodiesterase inhibitor, 3-isobutyl-1-methylxanthine (IBMX), were applied in the superfusion solution. Cyclic AMP, 5'AMP and cyclic GMP were iontophoresed into the cell body through the intracellular recording electrode with anodal current pulses. Microelectrodes used for iontophoresis were filled with 0.9 M KCl plus 0.2 M sodium salt of the compounds to be injected and had resistances of 80 to 140 Mohm. Extracellular application of forskolin (0.05-50 uM), 8-(4-chlorophenylthio-) and 8-bromo cAMP (10-100 uM), IBMX (10-100 uM) or intracellular iontophoresis of cyclic AMP simulated alterations of neuronal electrical behavior characteristic of the onset of the slow EPSP. This was manifested as: 1) long-lasting membrane depolarization; 2) enhanced somal excitability with spontaneous and increased stimulus-evoked action potential discharge; 3) anodal-break excitation; 4) decreased membrane ionic conductance; and 5) suppression of post-spike hyperpolarizing potentials. Depolarization during cyclic AMP-induced excitation showed a reversal potential for this effect close to the potassium equilibrium potential. The actions of forskolin and the cyclic AMP analogs were potentiated by IBMX, and occurred after blockade of axonal spike generation and synaptic transmission in the presence of tetrodotoxin (1-2 uM). Intracellular iontophoresis of 5'AMP and cyclic GMP did not affect the electrical behavior of myenteric neurons. Results suggest that the biochemical basis for the slow EPSP myenteric in AH/type 2 neurons is initiated by coupling of membrane receptors for "first messenger" substances with adenylate cyclase in the somal membrane. The ligand-receptor-enzyme interaction then triggers synthesis and accumulation of cyclic AMP which acts as the intraneuronal "second messenger" mediating long-term modulation of somal excitability involved in integrative functioning of the enteric nervous system. (Supported by NIH Grant RO1 AM 26742).

283.3 RECEPTOR-MEDIATED CYCLIC NUCLEOTIDE REGULATION OF IMPULSE FREQUENCY IN PERIPHERAL NERVE. M-Y.Lo* and J.J.Kendig. Dept. of Anesthesia, Stanford Univ. Sch. of Med., Stanford, CA 94305

We have previously demonstrated that refractory period in peripheral nerve is subject to modulation by cyclic AMP (cAMP), the endogenous content of which is increased by β-adrenergic receptor stimulation. Both β-agonists and a lipid soluble cAMP analogue, dibutyryl cyclic AMP (db-cAMP), increase the refractory period and thus decrease the maximum frequency at which the nerve can carry action potentials. We now report an opposing regulation by cyclic GMP (cGMP), possibly mediated by a cholinergic receptor.

Sciatic nerves were dissected from adult frogs (Xenopus laevis), desheathed and mounted in a chamber permitting continuous perfusion of a central 1 cm length of the nerve. The proximal end was laid over stimulating electrodes in a pool of mineral oil. Stimuli were adjusted to be well supramaximal. Recording electrodes were placed in the central perfusion compartment and in a distal pool filled with 140 mM KCl to provide monopolar recording. Drugs were dissolved in frog Ringer's solution buffered with 10 mM HEPES to a pH of 7.4. All experiments were carried out at room temperature. Refractory period was assayed by determining the amplitude of the second of a pair of impulses relative to the first.

A lipid-soluble analogue of cGMP, dibutyryl cGMP (db-cGMP), decreased the refractory period at concentrations of 1 - 2 mM. The effect was discernable 15 - 20 minutes following application, and maximal at 30 minutes. Increase in relative amplitude of the second pulse over controls was confined to interstimulus intervals of 1.0 - 1.2 msec; there was no apparent effect at intervals 1.5 msec or longer. Control experiments showed no decrease in refractory period on switching from one drug-free solution to another over the same time period. The effect of db-cGMP was mimicked by the cholinergic agonist carbamylcholine, $2x10^{-5}$M; onset time of the effect was approximately the same as for db-cGMP, but the maximum effect was achieved later, at 40 minutes. Neither agent appeared to affect the amplitude of singly evoked compound action potentials, but both slightly increased their width at half maximal amplitude.

Both cAMP and cGMP are endogenous in peripheral nerves. The responses to db-cGMP and carbamylcholine suggest that in this tissue some neuronal function which influences refractory period is subject to modulation by cholinergic stimulation of cGMP, in a direction opposite to the modulation produced by β-adrenergic stimulation of cAMP.

238. FORSKOLIN, ACTING AT A SITE DISTAL TO CALCIUM ENTRY, ENHANCES THE SECRETORY RESPONSE OF A PITUITARY TUMOUR CELL. S. Guild*, J.W. Kebabian*, and E.A. Frey. Experimental Therapeutics Branch, NINCDS, NIH, Bethesda, MD 20205.

Mechanisms, other than an acute increase in the concentration of cytosolic calcium ($[Ca_i]$), can regulate the physiological process of exocytosis (Baker, P.F. Nature., 310: 629-630, 1984). Cyclic AMP (cAMP) represents one metabolic stimulant of exocytosis. One effect of cAMP upon secretion, the potentiation of stimulated release, was studied in the prolactin-secreting 7315c rat pituitary tumour cell line. We enhanced cAMP synthesis with forskolin (Seamon, K.B. & Daly, J.W. J. Cyclic. Nucleotide. Res., 7: 201-224, 1981). We raised the $[Ca_i]$ with either a potassium challenge, believed to transiently open voltage-dependent calcium channels (Tomiko, S.A., Taraskevich, P.S. & Douglas, W.W. Neurosci., 6:2259-2265, 1981) or ionomycin, a calcium ionophore (Liu, C.M. & Hermann, T.E. J. Biol. Chem., 253: 5892-5894. 1978).

The basal rate of release of prolactin from this tumour was 3.0 ± 0.2 ng prolactin/$10^6$cells/5 mins (mean ± SEM, n=12). A 5 min challenge with potassium (60 mM) increased the rate of prolactin secretion by 3-fold. Treatment of the cells, for 5 mins with forskolin (10 μM), caused only a 0.5-fold increase in the rate of hormone release. However, following such a treatment with forskolin, the potassium-evoked secretory response was doubled. Using the Quin 2 fluorescent dye technique (Tsien, R.Y., Pozzan, T. & Rink, T.J. J. Cell. Biol., 94: 325-334. 1982), the $[Ca_i]$ within 7315c cells was determined to be 107 ± 2 nM (mean ± SEM, n=46). Potassium depolarisation elicited a transient 3-fold increase in $[Ca_i]$. Forskolin did not alter $[Ca_i]$ or the potassium-evoked rise in this parameter. Ionomycin elicited a 4-fold enhancement of prolactin release. Forskolin doubled the ionomycin-evoked release of prolactin. Ionomycin elicited a 7.5-fold increase in $[Ca_i]$, which was unaffected by the pretreatment with forskolin.

These data demonstrate that the secretory response of the 7315c cells, elicited by a fixed increase in $[Ca_i]$, is variable. Forskolin, and by inference cAMP, can increase the amount of hormone released, in response to either potassium or ionomycin, without affecting the stimulated increase in the $[Ca_i]$. We hypothesise that the effect of forskolin is at a site different from, and distal to, the voltage-dependent calcium channel. cAMP is acting upon the capacity of the cell to respond to a fixed increment in $[Ca_i]$.

238.4 STIMULATION OF cGMP SYNTHESIS BY BAY-K-8644 IN MOUSE AtT-20 PITUITARY TUMOR CELLS. S. Heisler* (SPON: L. Larochelle). Unité Bioregulation Cellulaire, Centre hospitalier de l'Université Laval, Québec, Canada, G1V 4G2.

In mouse AtT-20/D16-16 (AtT-20) pituitary tumor cells, BAY-K-8644, depending on its concentration stimulates and antagonizes ACTH secretion. This effect presumably is due to a similar concentration dependent effect on calcium entry in these cells. Because the cytoplasmic enzyme guanylate cyclase is activated by calcium entry in several cells systems, it was of interest to determine whether BAY-K-8644 also had a biphasic effect on the intracellular accumulation of cGMP in AtT-20 cells. It was observed that at concentrations of $10^{-10}$ to $10^{-6}$M, BAY-K-8644 had no effect on basal cGMP levels; however, it did stimulate formation of the nucleotide at concentrations ($10^{-6}$ to $10^{-4}$ M) which were associated with its ability to antagonize basal and (-) isoproterenol-stimulated ACTH secretion. Neither the cationophore A-23187, nor depolarizing concentrations of $K^+$ mimicked the effect of BAY-K-8644 on cGMP formation; similarly, other calcium channel antagonists such as nifedepine or verapamil (up to $10^{-4}$M) were without effect on cyclic nucleotide synthesis though both did inhibit agonist stimulated ACTH secretion. To further test whether cGMP formation was correlated with decreased secretory responsiveness, the effects of known stimulators of guanylate cyclase activity, sodium nitroprusside and sodium azide were assessed on cGMP formation and ACTH secretion. Both sodium nitroprusside and sodium azide in a concentration-dependent fashion, increased cGMP accumulation and both compounds inhibited basal and (-) isoproterenol-stimulated ACTH secretion though to a lesser extent than BAY-K-8644. Conclusions: BAY-K-8644 stimulates cGMP synthesis by binding to sites inaccessible or not activated by other calcium channel antagonists (e.g. low affinity sites). Stimulation of guanylate cyclase in AtT-20 cells is independent of inward calcium current i.e. BAY-K-8644 may stimulate a particulate enzyme. Intracellular cGMP may have a negative, intracellular effect on the ACTH secretory process.

238.6 PROTEIN KINASES IN THE SUPERIOR CERVICAL GANGLION. A.L. Cahill* and R.L. Perlman, Department of Physiology & Biophysics, University of Illinois College of Medicine, Chicago, IL 60680

To understand the role of protein phosphorylation in the control of neuronal function it is necessary to characterize the protein kinases in neuronal tissue, to identify the endogenous protein substrates for these kinases, and to determine the effects of phosphorylation on the activities of these proteins. In this study we have characterized the protein kinase activities in extracts of the superior cervical ganglion of the rat. The ganglion contained cAMP-dependent, cGMP-dependent, $Ca^{2+}$/calmodulin-dependent, and $Ca^{2+}$/phospholipid-dependent protein kinases. All of these kinase activities were largely in the soluble fraction. A clear dependence of the $Ca^{2+}$/phospholipid-dependent protein kinase on exogenous phospholipids could only be demonstrated in partially purified preparations from which endogenous phospholipids had been removed. The ganglion also contained endogenous substrates that were phosphorylated by the cAMP-dependent, the $Ca^{2+}$/calmodulin-dependent, and the $Ca^{2+}$/phospholipid-dependent protein kinases in vitro. These three kinases appear to phosphorylate distinct but overlapping sets of ganglionic proteins. One endogenous substrate was tyrosine hydroxylase, which was phosphorylated by all three of these kinases. Another endogenous substrate was an acidic 83,000 $M_r$ protein that has been identified as the "87k" acidic synaptosomal protein (Wu et al., PNAS 79,5249,1982) and that appears to be a specific substrate for the $Ca^{2+}$/phospholipid-dependent protein kinase.

Electrical stimulation and treatment with various pharmacological agents increases the phosphorylation of a number of proteins in the intact ganglion. We have begun to investigate which stimuli activate each of the protein kinases by determining which stimuli activate the cAMP-dependent protein kinase. In situ activation of cAMP-dependent protein kinases can be assessed by measuring the "activity ratio" of the kinase in extracts of the ganglion. The "activity ratio" is defined as the kinase activity in the absence of cAMP divided by the kinase activity in the presence of cAMP. Electrical stimulation (20 Hz,5 min), 100 μM forskolin, and 2 μM vasoactive intestinal peptide all increased the "activity ratio" of cAMP-dependent protein kinase in the ganglion. Activation of the cAMP-dependent protein kinase may mediate some of the effects of these agents on protein phosphorylation. Nicotinic and muscarinic antagonists did not block the effect of electrical stimulation suggesting that release of a neurotransmitter other than acetylcholine may be responsible for the activation of the cAMP-dependent protein kinase. (This research was supported in part by grant HL 29025 from NIH and by the Earl M. Bane Charitable Trust.)

238.7 **AN IN VIVO ASSAY OF INTRACELLULAR pH AND CALCIUM/CALMODULIN MODULATION OF cAMP PHOSPHODIESTERASE ACTIVITY.** D.J.Green and R.Gillette. Department of Physiology, Neural and Behavioral Biology Program, University of Illinois, Urbana, IL 61801

In vivo, the ventral white cells (VWCs) of Pleurobranchaea display intense minutes-long bursts of action potentials which are critical to the functional role of the VWCs in the consumatory phase of feeding (see Gillette and Green, this volume). Prolonged, endogenous bursting can be mimicked in vitro by intracellular cAMP injection.

Previous results from our lab have demonstrated that calcium and intracellular pH (pHi) modulate the excitability of the VWCs. We sought to examine the sensitivity of the major enzymes underlying the cAMP response - phosphodiesterase (PdE), protein kinase (PK), and phosphatase (PTase) - to the proton and calcium fluctuations that normally occur during bursting. Equivalent injections of cAMP induce an inward sodium current that describes a waveform with a characteristic and constant amplitude and timecourse. We found that selective chemical inhibition of each enzyme induces a characteristic change in the waveform. Notably, PdE inhibition with methylxanthines (IBMX) greatly increases the duration and peak amplitude of the current. PK inhibition via tolbutamide decreases the peak amplitude, with no affect on the duration. Oxidizes glutathione inhibition of PTase increases the peak amplitude, but, like PK and unlike PdE inhibition, does not affect the duration.

Using this in vitro assay of enzyme activities based on the shape of the current waveform, we found that slight intracellular alkalinization or acidification increased the peak amplitude and duration of the cAMP current response, which is consistent with a decrease in the PdE activity. Calmodulin inhibitors such as trifluoperizine (TFP) and W-7 mimicked the affects of IBMX and pHi changes. Depolarization-induced attenuation of the cAMP current was proportional to the extracellular concentration of calcium, and is consistent with an increase in PdE activity.

These results indicate that 1) certain cAMP-related enzymes can be monitored qualitatively in vivo and 2) PdE is the major site of action of pHi and calcium/calmodulin, and that PdE regulates the duration, termination, and interburst interval of cAMP-stimulated burst episodes in the VWCs. Supported by NSF BNS 8308551 to R.G.

238.8 THE EFFECTS OF AN ALKYLATING DERIVATIVE OF OXOTREMORINE (BM 123) ON MUSCARINIC RECEPTORS AND ADENYLATE CYCLASE ACTIVITY IN THE RABBIT MYOCARDIUM. F.J. Ehlert* (SPON: R.D. Crosland). Dept. Pharmacol. UCLA School of Med., Los Angeles, CA 90024.

The effects of a 2-chloroethylamine derivative of oxotremorine, N-[4-(2-chloroethylmethylamino)-2-butynyl]-2-pyrrolidone (BM 123), on heart rate, muscarinic receptor binding properties, and adenylate cyclase activity were investigated in the rabbit myocardium. Isolated hearts were perfused for 30 min with Ringer-Locke solution containing BM 123 (20 μM) and then perfused an additional 90 min without BM 123. Control hearts were perfused in the same manner except for exposure to BM 123. Following perfusion, the intact hearts were homogenized and assayed for muscarinic receptors and adenylate cyclase activity. Treatment with BM 123 caused an initial asystole followed by bradycardia during the 30 min perfusion. Heart rate recovered to control rate during the 90 min wash period. BM 123 treatment caused 75% alkylation of muscarinic receptors as measured by the reduction in the binding capacity of the specific muscarinic antagonist [$^3$H]N-methylscopolamine ([$^3$H]NMS). In control myocardial homogenates, $MgCl_2$ caused a concentration dependent stimulation of adenylate cyclase activity with the $ED_{50}$ for this effect being 2 mM. The $ED_{50}$ value of $MgCl_2$ increased 5 fold in the presence of the muscarinic agonist oxotremorine-M (100 μM). There was no significant difference in the potency with which $MgCl_2$ stimulated adenylate cyclase activity in control hearts and hearts which had been perfused with BM 123 and washed extensively. In control hearts, oxotremorine-M caused a maximal inhibition of adenylate cyclase activity of 46% with the $K_i$ for this effect being 0.079 μM. In hearts which had been perfused with BM 123, the maximum inhibitory effect of oxotremorine-M on adenylate cyclase activity was only 15% with the $K_i$ value being 0.56 μM. The irreversible effects of BM 123 on muscarinic receptor binding capacity and adenylate cyclase activity described above were not observed in hearts which had been perfused with BM 123 and atropine (1 μM) or with the reversible muscarinic agonist oxotremorine-M (20 μM/30 min). The results described here are consistent with the postulate that alkylation of muscarinic receptors with BM 123 has little effect on adenylate cyclase activity by itself but causes a functional blockade of muscarinic inhibition of adenylate cyclase activity.

238.9 MUSCARINE STIMULATES INOSITOL-PHOSPHOLIPID METABOLISM AND INHIBITS ADENYLATE CYCLASE ACTIVITY IN PC12 CELLS. J. Horwitz*, M. Wang*, and R.L. Perlman. (SPON: R. Greenberg). Department of Physiology and Biophysics, University of Illinois College of Medicine, Chicago, IL 60680.

PC12 cells are clonal line of pheochromocytoma cells that have been widely used as a model to investigate the properties of adrenal chromaffin cells and sympathetic neurons. We and others have shown that muscarine increases the accumulation of $^3$H-inositol phosphates in PC12 cells in which the inositol containing phospholipids had been labeled by preincubation with $^3$H-inositol. Muscarine also increases the accumulation of $^3$H-monoacylglycerol and $^3$H-diacylglycerol in cells that had been preincubated with $^3$H-arachidonic acid. These data suggest that muscarinic stimulation increases the activity of phospholipase C in PC12 cells.

More recently, we have investigated the effect of muscarinic stimulation on adenylate cyclase in these cells. PC12 cells contain an adenosine-sensitive adenylate cyclase. Incubation of the cells with adenosine analogs, such as 2-chloroadenosine and phenylisopropyladenosine, causes a large increase in the accumulation of cyclic AMP. Muscarine inhibits phenylisopropyladenosine-induced accumulation of cyclic AMP by up to 70%. This effect of muscarine is presumably due to the inhibition of adenylate cyclase activity, since muscarine inhibits cyclic AMP accumulation in the presence of Ro-1724, a non-xanthine cyclic nucleotide phosphodiesterase inhibitor. The action of muscarine is blocked by atropine, and so is apparently due to the activation of muscarinic receptors in the cells. The EC50 for the inhibition of adenylate cyclase is between 1 and 10 μM. Thus, muscarinic stimulation increases phospholipase C activity and inhibits adenylate cyclase activity in PC12 cells. The relationship between these two effects of muscarinic agonists remains to be clarified. (Supported by NIH grants HL29025 to R.L.P. and HL06701 to J.H.)

238.10 ADENYLATE CYCLASE AND GTP-BINDING PROTEIN MEDIATE SENSORY TRANSDUCTION IN OLFACTORY NEURONS. Doron Lancet, Judith Heldman* and Umberto Pace*. Dept. of Membrane Research, The Weizmann Institute of Science, Rehovot, Israel.

The mechanism of olfactory transduction has been a subject of much controversy and speculation. Our recent studies provide strong evidence that odorants activate adenylate cyclase in the dendritic membranes of olfactory sensory neurons. The putative olfactory receptor molecules appear to be coupled to the transductory enzyme via a GTP-binding protein (G-protein). Our experiments are conducted on a preparation of isolated olfactory cilia (dendritic extensions of the sensory neurons), which contain the sensory molecular apparatus, similar to isolated retinal rod outer segments. The chemosensory cilia from amphibian and mammalian species are found to contain extremely high specific adenylate cyclase activity, 10-30 times higher than brain membranes. Odorants, either individually or in mixture, enhance cyclic AMP production by 120-250%, and they do so in a ligand and tissue specific way. This, together with previously published in-vivo electrophysiological evidence for cyclic nucleotide mediation, strongly support the role of adenylate cyclase in olfactory transduction. Odorant stimulation of ciliary adenylate cyclase occurs only in the presence of GTP, suggesting the involvement of a signal-coupling GTP-binding protein (G-protein). The olfactory G-protein can be identified by ADP-ribosylation with bacterial toxins, and appears to be similar in molecular weight and toxin specificity to the hormonal stimulatory G-protein ($G_s$). Previously published observations that pseudo-hypoparathyroidism patients, who are $G_s$-deficient (Farfel et al, PNAS 78, 3098 (1981)) have severely impaired olfactory thresholds (Henkin, J.Clin.Endocrynol.28,624 (1968)) further corroborate the role of $G_s$ in olfaction. Our results constitute the first direct identification of a molecular component involved in odorant reception, and suggest a similarity between olfaction, photoreception, hormone and neurotransmitter reception. Odorant sensitive adenylate cyclase and olfactory G-protein provide powerful tools for future identification and isolation of the elusive odorant receptor proteins (Chen et al., this volume). An open question is how cyclic AMP affects the odorant-controlled depolarizing ion channels of olfactory sensory neurons. Two important possibilities are cyclic AMP-dependent phosphorylation, and direct cyclic nucleotide gating. We find that olfactory cilia contain cyclic AMP dependent protein kinase and phosphorylated polypeptides, but at present there is no direct evidence for their role in olfaction. Future biochemical and single ion channel recording experiments should help resolve these questions.

Supported by grants from the U.S.-Israel Binational Science Foundation and from the Minerva Foundation.

238.11 GUANINE NUCLEOTIDE EXCHANGE BETWEEN GTP-BINDING PROTEINS RESPONSIBLE FOR THE ACTIVATION OR INHIBITION OF NEURONAL ADENYLATE CYCLASE. M.M. Rasenick and M.M. Marcus*, Dept. of Physiology and Biophysics, U. of Illinois Coll. of Med. Chicago, IL 60680

Synaptic membrane adenylate cyclase (AC) can be activated or inhibited by various neurotransmitters, receptors for which exert their effects on AC through GTP binding proteins. A 42KDa GTP-binding protein (GNs) has been shown to stimulate and a 40KDa protein (GNβ) to inhibit, AC. A third 35KDa protein (NGβ) is associated with GNs and GNi and may regulate AC activity by interacting with these proteins, yet this process is not yet understood.

Hydrolysis-resistant GTP analogs promote activation of AC which persists after buffer washing of the membranes. These same analogs can promote stable inhibition of AC in membranes prepared from brain but not in those from non-neural tissues. We have employed the hydrolysis-resistant GTP photoaffinity analog 5'azdoanilido GTP to study the stable activation and stable inhibition of synaptic membrane AC as well as the interaction among GNs, GNβ and GNB during these processes. When synaptic membranes are incubated with AAGTP ($10^{-7}$ to $10^{-4}$ M) for 3 min at 23°C 1 mM $Mg^{++}$, inhibition of AC, which is stable to washing, results, as long as the membranes are assayed under conditions (23°C, 5 mM $Mg^{++}$) which favor continued expression of AC inhibition. If the membranes are exposed to increasing concentrations of the stable GTP analog, GppNHp under conditions which favor AC stimulation (30°C, 5 mM $Mg^{++}$), the stable AC inhibition is overridden and stimulation of the enzyme occurs. When $^{32}P$ AAGTP is incubated with membranes under the above (inhibitory) conditions and SDS PAGE and autoradiography are performed in the place of the AC assay, stable binding at the 40KDa GNi protein (which also serves as a substrate for pertussis-toxin catalyzed ADP ribosylation) occurs. Under the above conditions where the stable AC inhibition yields to stimulation of the enzyme the AAGTP bound to GNi (before UV photolysis) is shifted to the 42KDa GNs. Substitution of NaF for GppNHp results in a similar shift from AC inhibition to AC activation as well as a similar shift in AAGTP labelling from GNi to GNs. The shift in bound AAGTP is rapid (it occurs within 2 min) and it is stable for 20-30 min. The magnitude of the GNi-GNs shift corresponds to the predominant expression of enzyme activity (inhibition vs. stimulation) but the total $^{32}P$ DPM of AAGTP bound in GNs+GNi proteins reamins constant. Furthermore as the AA-GTP label bound to GNi increasingly switches to GNs, an increasing amount of AAGTP is associated with the GNβ protein. Although no binding site for GTP has been proposed for this protein, the proximity of GNβ to the GNs and GNi proteins may permit covalent binding of the photoaffinity compound. An increased association of the GNβ protein with the AC complex during the apparent exchange of AAGTP between GNi and GNs may serve as the mechanism for this exchange process, and as a biological switch for the activation and inhibition of neuronal AC.

238.12 FUNCTIONAL HOMOLOGY AND IMMUNOLOGICAL CROSS-REACTIVITY BETWEEN ROD OUTER SEGMENT AND SYNAPTIC MEMBRANE ADENYLATE CYCLASE GTP-BINDING PROTEINS. C.A.Moore*, H.E.Hamm and M.M.Rasenick (SPON: J.Mitrius) Dept. of Physiol. and Biophys. U. of Ill. Coll. of Med., Chicago, IL 60680.

Many recent studies indicate that there is a family of GTP-binding proteins with similar structure and function. Two such GTP binding proteins are found in the photoreceptor, where light-activation of cGMP phosphodiesterase (PDE) is mediated by a 39kDa protein (G), and in synaptic membranes where there is a hormone-activated (or hormone-inhibited) adenylate cyclase (AC) whose activity is mediated by a 42kDa ($GN_s$) or a 40kDa ($GN_i$) protein. There appears to be a structural homology (1), and functional interchangeability (2) between G and $GN_s$ and $GN_i$, and all three proteins interact with an apparently common 35kDa β subunit. Recently, a series of monoclonal antibodies has been generated against $G_\alpha$;one of these (4A) blocks light-activated GTP binding to G and PDE activation by the G-GTP complex (3).

In this study, we demonstrated that a mixture of several monoclonal antibodies to photoreceptor $G_\alpha$ specifically cross-react with $GN_s$ from rat synaptic membranes by binding to that protein on nitrocellulose blots. This cross-reactivity is more easily detectable for the subset of $GN_s$ which is solubilized by treatment of membranes with microtubule disrupting drugs (4), and is thus enriched in this fraction. The antibodies appear to cross-react with the β as well as the α subunit, suggesting some level of homology between the two subunits. (However, in the photoreceptor, the antibodies bind to the α subunit several orders of magnitude better than to the β subunit).

Functional studies also suggest a homology between photoreceptor and brain G-proteins. Incubation of 4A with synaptic membranes showed an antibody dose-dependent inhibition of AC, both basal and AC stimulated by GppNHp, $F^-$, forskolin, and $Mn^{++}$. The magnitude of the inhibition was approximately 1.5-2-fold in all cases. Similar results are obtained with pineal membranes, as previously reported (5), and with membranes prepared from C6 glioma cells. In all cases, the magnitude of the inhibition is about 2-fold, and in all cases, the largest inhibition is of the $Mn^{++}$-stimulated AC. Although $Mn^{++}$ is thought to act on the catalytic moiety of AC, in previous experiments reconstitution of $GN_s$ deficient AC by G augmented $Mn^{++}$ activation of AC. Thus, we are investigating the possibility that 4A may mitigate some interaction of $GN_s$ with the AC catalytic moiety. This apparent cross-reactivity between an antibody against G with $GN_s$ is interesting in light of the homology between the two systems, and may provide a valuable tool in studies of both the light- and neurotransmitter-activated systems.

## BIOLOGICAL RHYTHMS III

239.1 MEAL SELECTIONS BY HUMAN SUBJECTS IN TIME ISOLATION. C.P. Pollak* and M.L. Moline* (SPON: L. Schneider). Inst. Chronobiology, Dept. Psychiatry, The New York Hosp.-Cornell Med. Ctr., Westchester Div., White Plains, N.Y. 10605

While many circadian rhythms have been well characterized in human subjects studied in time isolation, the rhythms of meal selection are not completely understood (Aschoff, J., Wever, R., Wildgruber, C. and Wirz-Justice, A. Naturwissenschaften, 71:534, 1984). It is of interest, for example, to determine whether the timing of meals is related to the circadian pacemaker that is responsible for the core temperature rhythm, to a mechanism that controls the sleep-wake cycle, or to a third circadian clock. Human subjects have been studied in conditions of time isolation to begin to resolve this question.

Over forty subjects of both sexes between the ages of 16 and 81 have been studied. Each protocol begins with at least 4 days of entrainment (EN) to a subject's habitual sleep-wake cycle. During EN, four meals are scheduled per day: breakfast, lunch, dinner and snack. During free-running (FR), a subject chooses the timing of daily events, including all meals and sleep periods, and also the meal name and content. A detailed description of food requested and remaining as well as the time of request and the duration of the meal are recorded on a computer-based system. Each sleep period is recorded polygraphically. Analysis of meal naming and timing has begun in 9 of these subjects.

During FR, several changes in meal pattern occurred. The evening snack was dropped by most subjects and replaced by a later dinner. Lunch also occurred later in the circadian day, near the midpoint between sleep offset and sleep onset. Breakfast, by contrast, was requested shortly after awakening on each circadian day by most subjects with little or no change in the waking-to-breakfast interval between EN and FR. Cycle to cycle differences in the length of the circadian day appeared first in the time of sleep offset, followed by parallel changes in lunch time and sleep onset, and in dinner time and sleep onset as well in most subjects. The temporal organization of the waking day thus appeared to contract or expand homogeneously, depending on circadian day length. In those subjects who desynchronized during FR, inter-meal intervals increased in proportion to the increased day length. However, only three meals were selected, named by subjects "breakfast", "lunch" and "dinner" and taken in that order. The meal pattern therefore appeared to be synchronized with the sleep-wake cycle, even when its period exceeded 30 hours.

The results of these studies suggest that lunch and dinner selection may be influenced by timing mechanisms closely related to those that control the sleep-wake cycle. The decision to have breakfast may be more influenced by the awareness of just having slept than by timing mechanisms.

239.2 FOOD AVAILABILITY AS A POTENTIAL ZEITGEBER IN DASYURID MARSUPIALS. G.J. Coleman*, H.R. O'Reilly* and S.M. Armstrong*. Spon: (Dr. F. Guldner). Department of Psychology, La Trobe University, Bundoora, Vic., 3083., Australia.

Past research has shown that there is a circadian oscillator in laboratory rats which is entrained by restricted feeding (Boulos, Z., Rosenwasser, A.M. and Terman, M., Behav. Brain Res., 1:36-65, 1980). However, restricted feeding does not compete with the LD cycle in entraining wheel-running activity rhythms.

Given that Dasyurid marsupials are predominantly carnivorous, the episodic intake of food in the wild and the high nutritive content of that food suggests that food may be an important zeitgeber in these species. A variety of feeding schedules were used to determine whether such schedules would entrain circadian activity rhythms in competition with an LD cycle and also in constant dark (DD) conditions.

Six Kowari (Dasyuroides byrnei), desert dwelling nocturnal marsupials were fed at 1600 hr under a 12:12 LD cycle with lights on at 0600 hr (Stage 1). The meal was shifted to 0930 hr for 57 days (Stage 2), then DD was introduced for 117 days (Stage 3) with no change to the meal-time. Ad lib feeding in DD was then introduced for 58 days (Stage 4). While three Kowari showed activity anticipatory to the meal in Stage 2, the meal did not entrain any animals in stage 3 although there was some evidence of relative co-ordination.

In a second experiment, six Sminthopsis crassicaudata were maintained on an ad lib diet of pet food, presented with a much-preferred meal of mince meat mixture and exposed to a sequence of conditions similar to that in the previous experiment. In none of the conditions did any S. crassicaudata show anticipatory activity to the more palatable meal. There was some evidence of relative co-ordination in Stage 3 and in one animal, there was limited evidence for entrainment to the meal.

In the third experiment, 12 Sminthopsis macroura froggatti were presented with a daily meal at 0900 hr under a 12:12 LD cycle with lights on at 0600 hr for 37 days. Following this, all animals were exposed to periods of 12-18 days ad lib food interleaved with 3-day periods of deprivation, a technique used previously to demonstrate persistent meal-associated rhythms (Coleman, G.J., Harper, S., Clarke, J.D. and Armstrong, S.M., Physiol. Behav., 29:107-155, 1982). The meal-associated activity rhythms previously observed in rats were not seen, but the 3-day deprivation period produced large phase-shifts in the activity rhythms of several S. m. froggati.

It was concluded that meal-feeding does not compete with the LD cycle in entraining dasyurid marsupials, but that the frequent observation of relative co-ordination and phase shifts suggest a different and, perhaps, stronger role for food intake in biological rhythmicity than has been previously observed in rats.

239.3 EFFECTS OF PARTIAL SCN LESIONS ON BODY TEMPERATURE, DRINKING, AND ACTIVITY RHYTHMS IN RATS. Rebecca A. Prosser* and Evelyn Satinoff (SPON: J. Malpeli). Dept. of Psych., Univ. of Illinois, Champaign, IL 61820.

Complete suprachiasmatic nuclear (SCN) lesions which eliminate drinking and activity rhythms do not abolish the circadian temperature rhythm (CTR), but do decrease its amplitude and advance its acrophase in LD, and shorten the free-running period in DD (Prosser et al., THERMAL PHYSIOLOGY, 1984). Here we describe the effects of partial (25-90%) SCN lesions on these rhythms in 5 hooded rats for 8-10 months postoperatively. Body temperature (Tb) was measured every 10 minutes via implanted telemetry devices. The changes in the CTR after partial lesions were similar to but smaller than those seen after complete lesions: the amplitude decreased 0.6 ± .07°C (X ± SEM), the acrophase advanced 33.8 ± 10.9°, and the free-running period decreased from 24.27 ± .38 to 23.75 ± .52 hours. In one rat, the free-running period increased from 23.95 to 24.28 hours. There were significant decreases in nocturnal drinking (from 73 ± 3.1% to 56 ± 3.7%) and activity (from 67 ± 1.4% to 56 ± 2.6%). Drinking became arrhythmic in all 5 rats for varying amounts of time. In one rat it remained arrhythmic for the duration of the experiment (over 8 months). Four rats regained weak drinking rhythms by 2-10 weeks. Two of these rats regained stronger drinking rhythms by 10-20 weeks.

Activity became arrhythmic in 3 of the 5 rats for varying amounts of time. The two rats that remained rhythmic were those which regained the strongest drinking rhythms postsurgery. Two rats lost rhythmicity in activity for only 10 days. In one of these drinking remained aperiodic and in the other there was a weak drinking rhythm after 10 weeks. The 5th rat showed intermittent periods of rhythmic and arrhythmic activity. This rat (which had the increase in free-running period postlesion) regained a weak drinking rhythm after 10 weeks. Thus, in most rats, the drinking rhythm was more easily disrupted and remained arrhythmic longer than the activity rhythm. (Three other rats had drinking and Tb monitored after partial lesions. The drinking rhythm was permanently eliminated in one rat and temporarily eliminated for 10-25 days in the other 2 rats. Tb was rhythmic in all three rats.)

These results indicate that the drinking, activity, and Tb rhythms can be affected differentially by partial SCN lesions. Thus, the circadian pacemaker system of rats can be divided into several components, within as well as outside the SCN.

239.4 DAMPED OSCILLATION OF THE LATERAL HYPOTHALAMIC MULTIPLE UNIT ACTIVITY INDUCED BY RESTRICTED FEEDING SCHEDULES IN RATS WITH SUPRACHIASMATIC NUCLEI LESIONS. S. Kurumiya* and H. Kawamura. Lab. of Physiol. Psychol., Dept. of Neuroscience, Mitsubishi-Kasei Inst. of Life Sci., Machida-shi, Tokyo 194, Japan.

In rats with suprachiasmatic nuclei (SCN) lesions, appearance of anticipatory wheel-running activity under restricted feeding schedules (RFS) and its persistence for several days during the subsequent food deprivation period has been reported (Stephan, F. K. et al., Behav. Neural Biol., 25: 545, 1979).

To investigate the neural mechanism for such a phenomenon, we studied multiple unit activity (MUA) of the hypothalamic feeding area.

In Wistar strain male albino rats with bilateral SCN lesions, two bipolar electrodes for MUA recording were implanted stereotaxically under pentobarbital anesthesia into the lateral hypothalamic area (LH) and ventromedial nucleus (VMH). Motor activity of the animal was measured using a capacitance change between a piece of open-ended wire attached on top of the head and a ground electrode. MUA and movements of the animal were counted electronically every 5 min and every 10 min respectively, and printed out continuously. After recovery from surgery, the rat was placed in a sound-attenuated, temperature controlled room under constant darkness. Water was available at all time.

During 5 days control recording period, when food was always available, no daily rhythm was found in rats with complete SCN lesions in both brain MUA and motor activity. However, during RFS when food was available only for 2h (from 14:00 to 16:00), MUA of the LH indicated gradual increase prior to the beginning of the feeding time and reached to a peak during feeding and decreased thereafter. Such changes indicated a potentiation toward the end of the RFS. It persisted for several days even during food deprivation period after termination of RFS and quickly disappeared. Changes of MUA in VMH was not as significant as in LH.

These findings may suggest existence of, not self-sustained but quickly damping oscillator in the lateral hypothalamic feeding center. Such oscillation was induced only when the RFS was applied with definitely regular periods close to 24h, and was quite different from the self-sustained oscillation induced by SCN.

239.5 DISRUPTION OF CIRCADIAN ACTIVITY RHYTHMS IN THE RAT BY MIDBRAIN RAPHE LESIONS. J. Levine†, A.M. Rosenwasser, J.A. Yanovski†, and N.T. Adler. Dep't of Psychology, University of Pennsylvania, Philadelphia PA 19104.

The midbrain raphe nuclei provide a robust serotonergic input to the suprachiasmatic nuclei (SCN) of the hypothalamus, a putative circadian "master oscillator." This projection may comprise part of a neural network linking the retina, SCN, ventral lateral geniculate, and raphe nuclei. These observations suggest that the raphe may play a role in the coordination of the circadian timing system. An earlier study (Block and Zucker, 1976) showed that raphe lesions could reduce the clarity of circadian activity rhythms in the rat. However, all animals displayed detectable free-running rhythms. Therefore, in the present study we re-examined the effects of raphe lesions on circadian activity rhythms in the rat.

Electrolytic lesions were stereotaxically aimed at the median raphe nucleus. Although post-operative mortality was high, we were eventually able to produce a group of ten such animals. These animals were subsequently maintained in running wheel cages under light-dark 12:12, constant light, and constant dark conditions. Each lighting condition was in effect for at least one month. Under the light-dark cycle all animals showed primarily nocturnal activity. However, under constant conditions five animals showed severely disrupted activity rhythms, while the other five showed more normal free-running rhythmicity.

Histological analysis revealed clear differences between the lesions which disrupted free-running rhythms and those which did not. The effective lesions were generally larger and more dorsocaudally placed, relative to the ineffective lesions. As a group, the ineffective lesions caused extensive damage to the interpeduncular nuclei and relatively less damage to the median raphe. In addition, the dorsal-most extent of the median raphe was spared in all these lesions. In contrast, the effective lesions caused quite extensive damage to the median raphe, and also involved the ventral aspect of the dorsal raphe. These lesions also usually damaged the ventral tegmental nuclei. Overall, it appeared that the area between the median and dorsal raphe nuclei might be critical for the display of free-running circadian activity rhythms.

These results support the hypothesis that the raphe nuclei, and presumably their projections to the SCN, play a major role in the control of circadian activity rhythms. While the exact nature of this role cannot yet be specified, it seems plausible that the raphe nuclei contribute to the maintainance of oscillator coupling in a multi-oscillator neural circadian timing system.

239.6 INTERGENICULATE LEAFLET LESIONS ALTER PHOTIC RESPONSES OF HAMSTER CIRCADIAN RHYTHMS. M.E. Harrington and B. Rusak. Dept. of Psychology, Dalhousie University, Halifax, Nova Scotia, Canada B3H 4J1.

The suprachiasmatic nuclei (SCN) function as a dominant oscillator in the mammalian circadian system (Rusak, B. & Zucker, I., Physiol.Rev. 59:449-526, 1977). In hamsters, the SCN receive putative photic input both directly from the retina and indirectly from the intergeniculate leaflet (IGL) in the thalamus (Pickard, G.E., J. Comp.Neurol. 211:65-83, 1982). We have investigated the effects of destruction of the IGL on photic responsiveness of the circadian system of golden hamsters.

Eleven intact hamsters were housed in constant darkness; phase shifts in running wheel activity rhythms were assessed following 15 min light pulses (40 $\mu W/cm^2$). Pulses were administered at four phases: circadian time (CT) 12 (defined as the beginning of activity), CT14, CT18 and CT20. Eight animals subsequently underwent ablation of the IGL while 3 served as intact controls. Responses to light pulses at the same CT's were assessed and compared to pre-lesion shifts. Six hamsters with complete IGL lesions showed decreases in phase advances caused by light pulses at CT18 and CT20. Advances to pulses at CT20 were reduced by 89 ±35 min in ablated animals and .5 ±22 min in controls. Phase delays elicited by light at CT12 and CT14 were not altered.

In a second study, 20 hamsters were housed in constant light (LL). Ten underwent ablation of the IGL while 10 were intact controls. Six hr dark pulses were given at various CT's and phase shifts of running-wheel activity rhythms were assessed. Eight animals with complete IGL lesions showed smaller advances than controls to dark pulses centered on CT9 and CT17. During 110 days in LL, 7 out of 10 intact animals showed typical "splitting" of activity into two components, while only 1 of the 8 ablated animals displayed dissociated activity components. Possibly related to this difference in propensity to show splitting was the finding that ablated animals had significantly shorter free-running periods in the first 35 days of LL, before any dark pulses were given, than did the intact animals (24.07± .08 vs. 24.26±.18; t-test, $p<.02$).

These results demonstrate that destruction of the IGL in the hamster alters phase-shifting in response to periods of light or dark, and they indicate a role for the IGL in mediating several photic effects on the circadian system.

239.7 **RESETTING THE CIRCADIAN CLOCK IN THE SUPRACHIASMATIC BRAIN SLICE.** M.U.Gillette. Department of Physiology and Biophysics and the Neural and Behavioral Biology Program, University of Illinois, Urbana, IL 61801.

Neurons of the suprachiasmatic nuclei (SCN) of the hypothalamus comprise a primary oscillator which organizes circadian rhythms in mammals. The ability to keep 24 hour time, expressed most directly as an oscillation in neuronal firing rate, is an endogenous property of these neurons and survives isolation using the hypothalamic brain slice technique. However, I have found that the oscillator is sensitive to the phase of circadian time at which the brain slice is prepared: it is reset during preparation at sensitive times and the phase change is maintained up to 32 hours in vitro.

I systematically examined the relationship of circadian time of suprachiasmatic isolation and the phase of the next oscillation in firing rate of SCN neurons in vitro. Suprachiasmatic brain slices were prepared from a total of seventeen Long-Evans rats at a range of times in their 12L:12D circadian cycles. In each experiment, single unit activity of 50-96 neurons in paired SCN, isolated in a single 400 μm brain slice, was sampled over 12-28 hours.

For SCN in hypothalamic slices prepared during the donor's day, single unit activity continued unperturbed in phase, with a maximum and period similar to those observed both in animals implanted with chronic multiunit electrodes and in previous studies on isolated SCN. Isolation of the SCN during the dark portion of the circadian cycle, however, produced marked changes in the phase of the next oscillation. SCN isolation during the first 4 hours of the donor's night produced a delay of up to 4 hours in the peak of the next oscillation in electrical activity. At later times in the dark period, brain slice preparation advanced the phase up to 4.5 hours. The sign and shape of the phase-response relationship for resetting neural activity rhythms in the isolated oscillator is very similar to that for light- or electrode-stimulated resetting of circadian behavioral rhythms in intact animals.

The faithfulness of the phase-shift data from the isolated SCN to that for intact animals indicates that the resetting mechanism is endogenous to the SCN, and that when stimulated, it proceeds normally in vitro. This establishes the usefulness of the suprachiasmatic brain slice for probing the mechanism of the circadian oscillator. Supported by NSF BNS 83-08551 and PHS-BRSG-RR7030.

239.8 THE SUPRACHIASMATIC NUCLEI CONTAIN A TETRODOTOXIN-RESISTANT CIRCADIAN PACEMAKER. W.J. Schwartz, R.A. Gross*, M.T. Morton*. Neurology Svc., Mass. Gen. Hosp. & Harvard Med. Sch., Boston, MA 02114.

Two complementary measures of functional activity, in vivo glucose utilization & multiple unit activity, have helped to establish that the suprachiasmatic nuclei (SCN) contain a working circadian pacemaker. However, energy metabolism in the SCN is already oscillating with a circadian rhythm prenatally, whereas SCN firing rates first appear rhythmic weeks later postnatally. Therefore, SCN action potentials do not appear to be part of the internal timekeeping mechanism of the pacemaker; rather, electrical impulses might function to couple the pacemaker to its input pathways for entrainment and its output pathways for overt rhythm expression. To test this hypothesis, we chronically infused tetrodotoxin (TTX) for 14 d into the SCN of unrestrained rats. TTX blocks voltage-dependent $Na^+$ channels and SCN action potentials recorded from slices in vitro (Neurosci. Abstr. 10:294, 1984).

In the first experiment, adult male rats were entrained to a light-dark (LD) cycle for 2 wks before they were blinded. Free-running drinking rhythmicity was recorded for 10 d, after which cannula assemblies were stereotaxically inserted into the SCN and connected to subcutaneously-implanted mini-osmotic pumps filled with TTX in normal saline or artificial CSF. Control rats received infusions of vehicle alone. Free-running rhythms were recorded during the infusions and for 1 month after pumps were exhausted.

When 1 μM TTX was infused into the SCN, drinking arrhythmicity occurred. Control rats or those with cannulae outside the SCN continued to drink rhythmically. When TTX infusions ended, drinking rhythms resumed with free-running circadian periods ($\tau$) unaltered from those expressed pre-infusion. Phase of the restored rhythms was that predicted by extrapolation of the original (pre-infusion) $\tau$. That is, TTX infusions caused no phase shifts.

In the second experiment, rats were entrained and cannulae inserted as above. During the infusions the animals were exposed to an LD cycle progressively delayed until a completely reversed cycle was attained. When infusions ended, rats were placed in constant darkness and drinking rhythms recorded for 1 month.

In control rats, overt drinking rhythms were phase-shifted by the new LD cycle. On the other hand, TTX prevented this phase-resetting action of light, and no phase shifts occurred. That is, the phase of the restored (post-infusion) rhythms was that expected had the rhythms continued to free-run despite application of the reversed LD cycle.

Therefore, TTX blocked function of both the input & output pathways without disturbing the pacemaker's oscillatory mechanism. $Na^+$-dependent action potentials in the SCN appear to be necessary for the entrainment & expression of overt circadian rhythms, but they are not required for the pacemaker to keep accurate time.

239.9 CIRCADIAN CLOCK IN CELL CULTURE: OSCILLATION OF MELATONIN RELEASE FROM PERIFUSED CHICK PINEAL CELLS. L. M. Robertson* and J. S. Takahashi. Department of Neurobiology and Physiology, Northwestern University, Evanston, IL 60201.

The avian pineal gland contains circadian oscillators that regulate rhythmic release of melatonin. We have developed a dispersed pineal cell culture system in order to begin a cellular analysis of this vertebrate circadian oscillator. Ten chick pineal glands were dispersed with collagenase yielding approximately 2 x $10^5$ cells per gland. The dispersed cells were combined with cytodex-3 beads and cultured in Medium-199 for one week in LD 12:12. During this time the cells attached to the beads and sent out processes. Aliquots were then loaded into 3-5 replicate cell chambers and perifused 0.5 ml/hr with Medium-199. Two-hour fractions were assayed for melatonin content using radioimmunoassay. Initially, the cells were exposed to LD 12:12 for one day followed by constant darkness for four days. Pineal cells exhibited an increase in melatonin release during the first 12 hours of darkness followed by a decrease during 12 hours of light. The melatonin oscillation persisted for four cycles in constant darkness with a period close to 24 hours. The endogenous oscillation exhibited a gradual decrease in amplitude and increase in peak width. In contrast, cells maintained on LD 12:12 for five days expressed a high amplitude oscillation with no dampening of the rhythm. Because the melatonin oscillation from parallel cell chambers did not dampen in LD 12:12, the dampening observed in constant darkness is not due to unfavorable culture conditions but appears to result from a gradual desynchronization of multiple oscillators within the culture. Exposure of pineal cells to three days of constant light caused a strong dampening of the melatonin rhythm. Surprisingly, the overall level of melatonin released was not lower than that found in constant darkness. The apparent lack of light inhibition in constant light could be reversed by return of the cultures to LD 12:12. The melatonin oscillation was present in cells maintained for over one month in culture. This suggests that the components of the oscillating system remain intact in vitro for long periods of time.

In summary, dispersed pineal cells exhibit an endogenous oscillation of melatonin release. The oscillation among replicate cultures was very reproducible and consistent. The rhythmicity persists for at least four cycles with a period of close to 24 hours and is entrainable to a light-dark cycle. The dispersed cell perifusion system should provide an excellent model for a cellular analysis of mechanism. (Supported by Alfred P. Sloan fellowship BR-2366 and NIH grant MH 39592)

240.1 PURIFICATION AND CHARACTERIZATION OF ACETYLCHOLINESTERASE FROM DROSOPHILA MELANOGASTER. A. Gnagey*[1], T. Rosenberry*[2], and M. Forte[1]. [1]Dept. of Biology and [2]Dept. of Pharmacology, School of Medicine, Case Western Reserve University, Cleveland, OH 44106.

The Ace locus in Drosophila is important for neuronal function and development. Mutations and chromosomal rearrangements in this locus affect the production of acetylcholinesterase (AChE). We have purified AChE from wild-type Drosophila and determined its molecular forms in order to compare the enzyme produced by various Ace mutants at the developmental and molecular level. Purification of AChE was accomplished by one-step affinity chromatography according to the method of Rosenberry and Scoggin (J. Biol. Chem. 259:5643, 1984). Using this procedure, we have purified the enzyme over 10,000 fold with a 75 to 80% recovery of the initial enzymatic activity. From 50 gm of fly heads, we can prepare approximately 1 mg. of purified enzyme. In the reduced form, this material shows a single major band at 52Kd; the non-reduced form is 110Kd. Since these values are significantly lower than those observed for AChE from vertebrate tissues, the extent of proteolytic cleavage has been assessed by covalently modifying AChE in freshly prepared homogenates with the specific label, $^3$H-diisopropylphosphofluoridate. Following SDS-PAGE and fluorography, molecular weights for the reduced form are similar to those observed for the purified material (52K Daltons).

In many animal species, AChE exists in several forms which have distinct sedimentation coefficients on sucrose gradients. In Drosophila, two forms are present; a major form which sediments at approximately 6.6S in the presence of TX-100 and a minor form at 4.0S, presumably indicating the dimer and monomer respectively.

Monoclonal antibodies to Drosophila AChE have been produced following in vivo immunization of mice with the purified enzyme. To date at least 17 different cell lines producing antibody against AChE have been identified. These monoclonals are currently being characterized and should be useful in examining the developmental expression of AChE in both wild-type and Ace mutants.

240.2 MOLECULAR FORMS OF ACETYLCHOLINESTERASE AND BUTYRYLCHOLINESTERASE IN THE HUMAN CENTRAL NERVOUS SYSTEM. J.R. Atack and E.K. Perry. (Spon. P.B. Guthrie). Lab. of Neurosciences, NIA, Bldg 10, NIH, Bethesda, MD 20205 and Dept. of Neuropathology, Newcastle General Hospital, Newcastle upon Tyne, England

In the central nervous system (CNS), whilst acetylcholinesterase (AChE; EC 3.1.1.7) is presumed to hydrolyse acetylcholine (ACh) at cholinergic synapses, the physiological function of butyrylcholinesterase (BChE; EC 3.1.1.8) remains unknown. Both enzymes exist as homologous series of six molecular forms that are polymers of a single, catalytically-active subunit. These molecular forms are designated G1, G2, G4 (globular forms) and A4, A8 and A12 (asymmetric forms) according to the absence or presence of a collagen-like "tail" and the number of subunits present. The distribution of these different molecular forms varies from tissue to tissue in a manner that is thought to somehow reflect the physiological function of that particular tissue (Massoulie and Bon, Ann. Rev. Neurosci., 5:57, 1982). Thus, for example, different distributions of AChE have been reported to occur in fast and slow rat muscle (Groswald and Dettbarn, Neurochem. Res., 8:983, 1983). In light of these observations, the present study was undertaken to determine whether or not specific distributions of both AChE and BChE molecular forms occur in relation to distinct anatomical and neurochemical features of the human CNS. The regions selected for these studies were the cerebrospinal fluid (CSF) and, in descending order of specific AChE activity, the postmortem; caudate nucleus, nucleus basalis of Meynert, substantia nigra, cerebellum, spinal cord, hippocampus, temporal cortex, fornix and parietal cortex - range 28 to 0.5umol/min/g wet weight. In contrast, the levels of BChE activity varied much less from region to region - range; 0.72 to 0.25umol/min/g wet weight in the cerebellum and parietal cortex respectively.

In all regions studied, including the CSF, the majority of the AChE activity was present as the G4 form with the G1 form constituting most, if not all (depending on the region), of the remaining activity. The ratio of G4:G1 AChE varied from 21 in the caudate nucleus to 1.7 in the temporal cortex. Similar to AChE, BChE was present as both the G4 and G1 forms. However, the ratio of G4:G1 BChE varied much less from region to region - range, 3.3 to 0.9 in the substantia nigra and temporal cortex respectively.

The observations that the G4 form of AChE was the major form associated with both cholinergic and non-cholinergic structures suggests that this particular form is functionally important not only in the hydrolysis of ACh at the cholinergic synapse but in the other physiological functions of AChE in the CNS (Greenfield, TINS, 7:364, 1984). Since there was a relatively even distribution of BChE and its molecular forms throughout the widely differing regions of the CNS examined, we were unable to deduce any physiological function for this enzyme.

240.3 EFFECT OF VARIOUS SYNTHESIS INHIBITORS ON THE DYNAMICS OF DOPAMINE AND ITS METABOLITES IN THE RAT AND MOUSE CORPUS STRIATUM. P.S. McQuade, J.W. Richard* and M. Thakur*. Douglas Hospital Research Centre and Dept. of Psychiatry, McGill University, Verdun, Quebec H4H 1R3 Canada.

The relationship between the synthesis of a neurotransmitter and its release has been investigated using a great many paradigms. In our model, the simultaneous measurement of dihydroxyphenylacetic acid (DOPAC), homovanillic acid (HVA) and dopamine (DA) concentrations reflect the total synthesis of the neurotransmitter while the concentrations of 3-methoxytyramine (3-MT) are an index of any changes in the functional release of DA. Since the dynamics of dopamine metabolism and 3-MT changes, in particular, are very different in the rat and the mouse, a number of synthesis inhibitors were compared in these two species. The animals were microwaved after treatment, the striata were removed and DA, HVA, DOPAC and 3-MT were measured simultaneously by negative chemical ion gas chromatography-mass spectrometry. α-methyl para-tyrosine (250 mg/kg; i.p.), an inhibitor of tyrosine hydroxylase, produced a rapid decline in DA concentrations twenty minutes after injection in both species while decrease in 3-MT concentrations only commenced between 1 and 2 hrs. DOPAC concentrations declined simultaneously with DA concentrations. Interestingly 3-MT concentrations were maximally reduced in the rat by 2 hrs while in the mouse the decline continued at 4 hrs. NSD-1015, (100 mg/kg; i.p.), an inhibitor of L-DOPA decarboxylase, reduced DA concentrations only in the rat striatum at 1 and 2 hrs. This inhibitor, however, reduced DOPAC and HVA concentrations in both species while increasing 3-MT concentrations. NSD-1015 may thus interfere with either the oxidation of DA or its reuptake from the synaptic cleft. Since the dynamics of 3-MT are so vital to our model, tropolone, (50 mg/kg; i.p.), a COMT inhibitor, was employed over a very short time course. 3-MT is more rapidly removed in the rat than in the mouse. HVA concentrations decline more rapidly in the mouse than in the rat while DOPAC accumulates more quickly in the rat. This suggests that in the rat a greater proportion of DA is metabolized via the DOPAC pathway. These studies demonstrate that the concentrations of 3-MT are not immediately sensitive to the inhibition of DA synthesis thus suggesting that these neurons possess considerable reserves of releasable DA following DA synthesis inhibition. In contrast DOPAC concentrations are very sensitive to DA synthesis inhibition even in the mouse where the proportion of DA processed via the DOPAC pathway appears to be smaller than in the rat. (Supported by the Medical Research Council of Canada and the Douglas Hospital Research Centre).

240.4 WHOLE BODY TURNOVER OF CATECHOLAMINE IN CHRONIC SCHIZOPHRENIA AND DEPRESSION: EVIDENCE OF LOW DOPAMINE TURNOVER IN CHRONIC SCHIZOPHRENIA. F. Karoum, C. Karson*, W. Lawson*, A. Roy* and R.J. Wyatt. Neuropsychiatry Branch, NIMH, Intramural Research Program, Saint Elizabeths Hospital, Washington, D.C. 20032

Whole body turnover of norepinephrine (NE) (sum NE) and dopamine (DA) (sum DA) were measured in a group of 43 chronic schizophrenic patients, 10 depressives with melancholia and 10 without melancholia. Age and sex matched controls were also studied. Whole body turnover of the amines were measured by adding up the molar excretion of the amines and their metabolites. The results obtained showed that in chronic schizophrenia sum DA but not sum NE is significantly lower than normal controls. As a result, the ratios of sum DA/sum NE were also significantly lower in the chronic schizophrenic patients as compared to their age matched controls. Treatment with haloperidol normalizes these ratios. In depressed patients with melancholia, sum NE but not sum DA was significantly high leading also to low ratios of sum DA/sum NE but this time the low ratios were due to elevated sum NE. No differences in sum DA, sum NE and their ratios were detected between the depressed patients without melancholia and their appropriate sex and age matched controls. The results of the present study suggest schizophrenia is associated with a hypoactive peripheral dopaminergic activities; a phenomenon that may also applied to brain dopaminergic systems. In contrast, while depression appears to be associated with normal peripheral dopaminergic systems, peripheral noradrenergic systems appear to be hyperactive. The possibility that a similar situation occurs centrally is suggestive from several reports on noradrenergic receptors down regulation by antidepressants. It is concluded that the assessment of whole body turnover of catecholamines offers a better index to changes in the amines disposition than would measurements of individual amines or their metabolites.

240.5 AN ALPHA TWO ADRENERGIC TONIC INHIBITION OF CATECHOLAMINE METABOLISM IN THE LOCUS COERULEUS OF BEHAVING RATS : EVIDENCES FROM IN VIVO VOLTAMMETRY. L. Quintin,F. Gonon*,M. Buda*, G. Hilaire*, C. Bardelay*, M.Ghignone* and J.F. Pujol*. INSERM U171, 69230 St Genis Laval and Department of Anesthesiology, Hôpital Cardiologique, 69394 Lyon, France.

One of the various regulations controlling the noradrenergic (NA)-locus coeruleus (LC) cell activity has been demonstrated to be alpha-2 adrenergic specific on the basis of electrophysiological data only in anesthetized rats (Svensson et al., Brain Res. 1975, 92 : 291-306, Marwaha et al., J. Pharm. Exp. Ther., 1982, 222 : 287-293). To assess the existence of this inhibition, under rigorously chronic conditions, recordings of LC catechol metabolic activity were performed with in vivo differential pulse voltammetry (Buda et al.,Brain Res.,1983, 273, 197-206 ; Gonon et al., 1983, 273, 207-216). A guiding cannula was implanted in the LC under chloral hydrate anesthesia. After 48h of recovery, in the laboratory, a newly treated and tested carbon fibre electrode was threaded through this cannula to monitor LC catechol oxidation current. Baseline values (100%) were taken as the mean of the absolute height of the 6 catechol peaks recorded during the last 10 min of a 60 min stabilization period. Results are expressed as variation of catechol peak height (% of baseline). Piperoxane 60 $mg.kg^{-1}$ i.p. and yohimbine 10 $mg.kg^{-1}$ i.p. induced a large increase (200% above baseline values) in catechol oxidation current. This increase was dose-dependent : experiment with graded doses of piperoxane i.p. (1 to 100 $mg.kg^{-1}$) allowed determination of a dose-response curve (log-probit method) with an ED50 = 29.7 $mg.kg^{-1}$ piperoxane i.p. These changes in catechol oxidation current noticed in behaving rats were confirmed by combined LC electrophysiological and electrochemical recordings in anesthetized rats (Hilaire et al., Soc. Neurosci. Abstr, 1981, 10 : I-679) and HPLC determinations on LC microdissections. In contrast guanfacine (1 $mg.kg^{-1}$) and clonidine (10 to 200 $ug.kg^{-1}$ i.p.) induced a dose-dependent decrease in LC catechol metabolic activity. Clonidine 50 $ug.kg^{-1}$ i.p. reversed the increase in catechol oxidation peak induced by piperoxane 30 $mg.kg^{-1}$. At variance to the effects induced by alpha-2 agonists and antagonists, prazosin, a highly selective alpha-1 antagonist, only evoked a small increase in catechol oxidation peak (10% above saline effect, p below 0.05). This weak effect is in agreement with the low density of alpha-1 binding sites in the LC (Young et al., PNAS, 1980, 77 : 1696-1700) and may be explained by the hypotension secondary to prazosin. The pharmacological modifications of LC catechol metabolic activity induced by alpha-2 selective drugs, in behaving rats, confirm the existence of an alpha-2 adrenergic specific inhibition on NA-LC cellular activity.

240.6 3-HYDROXYANTHRANILIC ACID OXYGENASE: ACTIVITY IN LESIONED RAT STRIATUM AND IN HUMAN BRAIN TISSUE. R. Schwarcz, R.J. White and W.O. Whetsell, Jr.[1] Maryland Psychiatric Research Center, P.O. Box 3235, Baltimore, MD 21228 and [1]Dept. of Pathology, Vanderbilt University Medical Center, Nashville, TN 37232.

3-Hydroxyanthranilic acid oxygenase (3HAO), the enzyme responsible for the biosynthesis of the endogenous excitotoxin quinolinic acid, has been identified in the rat brain (Abst. Soc. Neurosci. 10, 11.4, 1984). Following its initial characterization, we have now examined the effects of excitotoxic striatal lesions on 3HAO activity in an attempt to elucidate the cellular localization of the enzyme.

Ibotenic acid (IBO, 40 µg/2 µl) was injected unilaterally into the rat striatum to cause degeneration of local nerve cell bodies. Groups of animals were killed at various intervals following the IBO injection and their striata processed for the determination of 3HAO and, as a marker for the success of the lesion, glutamic acid decarboxylase (GAD) activity. The data (N=6 for each group) are expressed as a percentage ± S.E.M. of the contralateral, non-injected striatum (**p<0.01, paired t-test).

| Days after IBO | 3HAO | GAD |
|---|---|---|
| 2 | 136 ± 27 | 53 ± 13** |
| 7 | 439 ± 44** | 55 ± 18** |
| 21 | 316 ± 37** | 50 ± 10** |

Kinetic analyses revealed that the increased 3HAO activity was due to $v_{max}$ changes. This, as well as the time curve of the increase, suggests that the phenomenon constitutes a tissue reaction to excitotoxin-induced nerve cell loss. It is likely that the newly synthesized enzyme is contained in reactive glial cells.

3HAO activity could also be identified in human brain tissue obtained post mortem from subjects who had died without any recognized neurological or psychiatric disease. 3HAO was clearly detectable in those brains (N=9) and showed a 7-fold variation between the areas of highest and lowest activity. In the order of decreasing activity, the enzyme was measured in the medulla (absolute enzyme activity, determined at $v_{max}$:81±16 pmol quinolinic acid formed/hour/mg tissue), substantia nigra, hypothalamus, caudate, globus pallidus, thalamus, putamen, cerebellum, frontal cortex, hippocampus and parietal cortex. These data provide baseline values for future studies of 3HAO in the brains of victims of a spectrum of neurodegenerative disorders.

240.7 RADIOENZYMATIC DETERMINATION OF QUINOLINIC ACID. E. Okuno, A.C. Foster and R. Schwarcz. Maryland Psychiatric Research Center, P.O. Box 3235, Baltimore, MD 21228.

Recent experimental evidence has given rise to the idea that a pathological overabundance of the tryptophan metabolite quinolinic acid (QUIN) may be related to the etiology of neurodegenerative disorders in humans. (Life Sci. 35, 19, 1984). To date, the elucidation of such a possible role of QUIN has been severely limited by the lack of a convenient and sufficiently sensitive assay method.

We now report on a new radioenzymatic assay procedure, which is based on a two-step conversion of QUIN to $^3$H-deamido-NAD (d-NAD). In a non-reversible reaction, QUIN is first converted to nicotinic acid mononucleotide (NAMN) by a homogeneous preparation of quinolinic acid phosphoribosyltransferase (QPRT; cf. Köhler et al., this meeting). NAMN is further converted to d-NAD by a second enzyme, nicotinic acid mononucleotide adenyltransferase. In this step, $^3$H-ATP is used as a donor of the adenyl moiety, thus yielding $^3$H-d-NAD. In both enzymatic reactions, pyrophosphate appears as a side product. Addition of inorganic pyrophosphatase to the incubation mixture thus favors both the production of NAMN and the overall yield of d-NAD.

A batch procedure was found to produce optimal results. Enzymes, cofactors and co-substrates [$Mg^{2+}$ (1.5 mM), phosphoribosylpyrophosphate (0.3mM), $^3$H-ATP (0.1 µM)] and standards or tissue samples were incubated for 2 hours at 37°C in a total volume of 250 µl. Following termination of the reaction, $^3$H-d-NAD was separated from $^3$H-ATP using a Dowex-1x8 anion exchange resin (formate form) and quantitated by liquid scintillation spectrometry.

A linear standard curve was obtained between 2.5 and 250 pmol QUIN, with 2.5 pmol yielding values approximately 50% above blank. QUIN could be measured directly in 1 µl of human urine. The concentration in urine collected from six healthy normal males was 37.2 ± 7.3 µM. After deproteinization, QUIN was also determined in 50 µl aliquots of serum prepared from blood samples provided by the same six volunteers and its concentration found to be 0.41 ± 0.06 µM.

Adjustments are currently being made for application of this assay procedure for QUIN determination in tissue extracts. The development of a rapid, specific and inexpensive method for the accurate determination of QUIN can be expected to prove instrumental for the further assessment of both physiological and possible pathological roles of QUIN.

240.8 QUINOLINIC ACID PHOSPHORIBOSYLTRANSFERASE: PURIFICATION FROM RAT LIVER AND FIRST IMMUNOHISTOCHEMICAL STUDIES IN BRAIN TISSUE. C. Köhler, E. Okuno[1] and R. Schwarcz[1]. Dept. Pharmacology, ASTRA-Läkemedel, Södertälje, Sweden and [1]Maryland Psychiatric Research Center, P.O. Box 3235, Baltimore, MD 21228.

Quinolinic acid phosphoribosyltransferase (QPRT), the enzyme catalyzing the conversion of the endogenous excitotoxin quinolinic acid (QUIN) to nicotinic acid mononucleotide, has been identified in rat brain (J. Neurochem 44, 446, 1985). QPRT is a rate-limiting enzyme in the metabolism of tryptophan to NAD and may therefore regulate the intracellular levels of QUIN. This function, as well as the uneven regional and subcellular distribution of QPRT in the brain, suggested that further investigations of the characteristics of this enzyme may be of value for an understanding of QUIN-induced neurodegenerative phenomena.

Following a seven-step procedure, QPRT was purified 3600-fold, with a yield of 26%, from rat liver. The purified enzyme, subjected to polyacrylamide disc gel electrophoresis, migrated as a single protein band which coincided with QPRT activity. SDS electrophoresis yielded a single band corresponding to a molecular weight of 32,000 for QPRT subunits. Using gel filtration (Sephadex G-150) and sucrose density gradient centrifugation, the molecular weight of the enzyme was estimated to be 160,000.

Rat brain QPRT was partially purified (278-fold) using the initial purification scheme for the liver enzyme and its properties compared to those of the homogeneous liver preparation. Kinetic analyses, inhibition by phthalic acid ($K_i$=1.4 µM), physico-chemical properties and molecular weight determinations indicated the structural identity of QPRT from the two rat tissues. This was further confirmed immunologically, using antibodies raised against purified rat liver QPRT. The same antibodies were also employed to conduct immunohistochemical studies in rat brain. Specific QPRT immunoreactivity was found to be contained in small glial cell throughout the brain. Often, these cells were in close association with nerve cell bodies. Semiquantitative assessment showed pronounced regional differences in QPRT-positive cells, the densest areas being the olfactory bulb and circumventricular cells in the hypothalamus. Generally, the immunocytochemical picture thus parallelled biochemical analyses of QPRT activity. Antibodies raised against rat liver QPRT can therefore be expected to provide a useful tool for the detailed investigation of the brain's QUIN system (cf. also Okuno et al., this meeting).

240.9 EFFECTS OF MPTP AND ITS METABOLITES ON NEUROTRANSMITTER DEGRADING AND SYNTHESIZING ENZYMES. C.W. Abell*, R.R. Fritz, N.T. Patel, R.-S. Shen, W. Gessner and A. Brossi. Div. of Biochemistry, Dept. of Human Biological Chemistry and Genetics, The University of Texas Medical Branch, Galveston, TX 77550 and The Medicinal Chemistry Section, Laboratory of Chemistry, NIADDK, NIH, Bethesda, MD 20205.

The neurotoxin 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP) and a series of its derivatives were tested as substrates and/or inhibitors of monoamine oxidase B (EC 1.4.3.4) (MAO B), dihydropteridine reductase (EC 1.6.99.10) (DHPR) and tyrosine hydroxylase (EC 1.14.16.2) (TH). Initial rates of reaction for the oxidation of MPTP by pure human liver MAO B: antibody complex to its dihydropyridinium ($MPDP^+$) and pyridinium ($MPP^+$) metabolites were determined by measuring increases in absorbance at 340 nm and 290 nm, respectively. The $K_{m,app}$ and $V_{max,app}$ values for MPTP were 316 μM and 229 nmole/min/mg, respectively, while 4-phenyl-1,2,3,6-tetrahydropyridine (PTP) gave values of 221 μM and 196 nmoles/min/mg, respectively. $MPDP^+$ (0.2 mM), MPTP (1 mM) and $MPP^+$ (10 mM), but not PTP (1 mM), irreversibly inhibited MAO B.

Twenty-seven MPTP derivatives were tested as potential inhibitors of human liver and rat synaptosomal DHPR with q-6,7-dimethyl-4-hydroxy-dihydropteridine and NADH as substrates. MPTP, PTP, and the corresponding piperidine derivatives were found not to inhibit DHPR at lower than mM concentrations. All hydroxy derivatives inhibited DHPR noncompetitively and were 100-10,000 times more active than MPTP, and their inhibitory potencies increased with the number of hydroxyl substitutions present on the ring (catechol > phenol), and with the oxidation state of the nitrogen-containing ring (pyridine > tetrahydropyridine > piperidine).

Ten MPTP analogs were tested against rat striatal synaptosomes containing TH and partially purified rat pheochromocytoma TH using a $^{14}CO_2$-trapping microassay. MPTP, $MPDP^+$, $MPP^+$, and 1-methyl-4-(4'-hydroxyphenyl)-1,2,3,6-tetrahydropyridine did not inhibit TH at less than mM concentrations, but dihydroxylated derivatives of 4-phenylpyridine and $MPP^+$ were found to be the most potent mixed type inhibitors of TH ($K_i$ = 9.1 and 4.0 μM, respectively). Furthermore, the inhibitory potency of dihydroxylated compounds increased with the oxidation state of the N-containing ring (pyridine >> tetrahydropyridine > piperidine).

These results definitively demonstrate that pure human MAO B can oxidize MPTP to the reactive intermediate, $MPDP^+$. This compound and its oxidation product, $MPP^+$, are relatively weak inhibitors of DHPR and TH, but their hydroxylated derivatives are potent inhibitors at μM concentrations.

240.10 EFFECT OF DEBRISOQUIN ON BRAIN, CEREBROSPINAL FLUID AND PLASMA CONCENTRATION OF HOMOVANILLIC ACID AND 3-METHOXY-4-HYDROXY-PHENYLGLYCOL IN PRIMATES J. D. Elsworth,* D. E. Redmond, Jr. and R. H. Roth, Departments of Pharmacology and Psychiatry, Yale University School of Medicine, New Haven, Connecticut 06510

Debrisoquin is an antihypertensive drug which inhibits monoamine oxidase, but does not readily pass the blood-brain barrier. Its administration in man decreases plasma homovanillic acid (HVA) and 3-methoxy-4-hydroxyphenylglycol (MHPG) concentrations. In the monkey debrisoquin changes the arteriovenous concentration difference across the brain for MHPG, but not for HVA, indicating that somehow it may alter brain MHPG production without entering the brain. This study determines whether, in primates, debrisoquin administration alters actual brain tissue or CSF concentrations of HVA and MHPG. Such data are necessary to assess the validity of using the drug either to estimate the proportion of centrally derived HVA or MHPG present in plasma or to amplify a change in centrally produced HVA or MHPG measured in plasma. Even though there is evidence that peripherally produced MHPG may be under a degree of central control, there is interest in determining the origin of MHPG found in brain, CSF or plasma. MHPG measured in brain or CSF may be dependent to some extent on the concentration of blood-borne MHPG. By comparing the magnitude of decreases at these sites, the present study allows, in addition, an estimation of the influence that peripherally produced MHPG has on centrally measured MHPG.

Monkeys (Cercopithecus aethiops sabaeus) were treated by i.m. injection twice daily for one week with debrisoquin (0.3 mg/kg for 2 days, then 0.6 mg/kg for 2 days, then 1.5 mg/kg for 3 days). Samples of brain, CSF and plasma were taken 3 hrs after the last dose and their concentration of HVA and MHPG determined by gas chromatography-mass spectrometry and compared with values from untreated controls.

Statistically significant reductions were found in mean (± SE) plasma MHPG (70±3%) and plasma HVA (58±5%) concentrations. No change in HVA concentration was observed in CSF or brain. A statistically significant drop in CSF MHPG (39±9%) concentration occurred. Although mean MHPG concentration was lower in all 7 measured brain regions of the debrisoquin treated animals compared with controls, the reduction reached statistical significance only in cerebellum. The mean decrease in the 7 regions was 14±4%. Thus, the effect of debrisoquin on HVA production appears confined to the periphery; whereas, concomitant with a large decrease in plasma MHPG concentration, CSF MHPG was moderately reduced and that in brain slightly affected. This may be due to a limited contribution of peripheral MHPG to the central compartment and/or by an indirect action of debrisoquin on central MHPG production.

## EXCITATORY AMINO ACIDS: GLUTAMATE AND GLUTAMATE ANALOGS

241.1 CHANGES OF THE BRAIN CONTENT OF QUINOLINIC ACID: POSSIBLE CORRELATION WITH BRAIN PATHOLOGY. F. Moroni, G. Lombardi* and V. Carlà.* Department of Preclinical and Clinical Pharmacology "M. Aiazzi Mancini"; University of Florence, 50134 Firenze, Italy.

Quinolinic acid (QUIN) is an excitotoxic tryptophan metabolite present in the brain of various animal species, including man. Possible changes of its brain concentration could be associated with neuropathology. In order to study how the brain content of QUIN is related to the tryptophan availability to the brain, its content was mass-fragmentographically measured in various brain areas of rats fed with tryptophan-free diet or in situations characterized by an abnormally high concentration of this amino acid in the blood. In the same brain areas the concentration of other tryptophan metabolites (5-hydroxytriptamine: 5HT; and 5-hydroxyindolacetic acid: 5HIAA) were also measured. In young adult rats fed with standard laboratory food the brain concentration of QUIN was: 1.5±0.04 (pmol/mg tissue) in the cortex; 0.4±0.05 in the cerebellum; 1.1±0.02 in the diencephalon; that of 5HT and 5HIAA were, respectively, 0.9±0.1 and 0.91±0.06 in the cortex; 1.98±0.12 and 2.45±0.25 in the caudate; 2.06±0.18 and 0.88±0.10 in the diencephalon. When rats were fed for 21 days with tryptophan-free diet (supplied by Piccioni, Brescia, Italy) the basic symptoms of pellagra appeared and the brain content of 5HT and 5HIAA markedly decreased (-70%). On the contrary, the cortical content of QUIN doubled. Thus, the rat brain seems able to synthetize QUIN utilizing metabolic pathways not always related to tryptophan and the possibility exists that this excitotoxin plays a role in the neuropathology of pellagra. On the other hand, tryptophan administration to rats resulted in a dose-dependent increase of the cortical content of 5HIAA and QUIN. Other experiments were performed in rats bearing a portocaval anastomosis, a situation characterized by a high blood content of aromatic amino acids. Under those conditions, the levels of 5HIAA and QUIN in various brain areas, increased by a factor of two, four weeks after surgery. This increase of 5HIAA and QUIN was also present in autoptically obtained human cortex derived from patients who died after hepatic coma. Thus, when the liver tryptophan metabolism is impaired, the brain content of QUIN increases. Therefore, this excitotoxin may be involved in the neurological pathology associated with liver diseases.

241.2 ASTROGLIAL REACTION TO INTRACRANIAL QUINOLINIC ACID INJECTION. H. Björklund*, L. Olson* and R. Schwarcz[1] (SPON: E.D. French) Dept. of Histology, Karolinska Institute, Stockholm, Sweden and [1]Maryland Psychiatric Research Center, Baltimore, MD 21228.

Astroglial reaction to intrastriatal and intrahypothalamic injections of the endogenous excitotoxin quinolinic acid (50 μg in 1 μl) was studied in adult rats, using immunohistochemistry with antiserum to glial fibrillary acidic protein. Animals were sacrificed 6 hours, 24 hours, 3, 7 and 30 days or 1 year after the injection. Six and 24 hours after quinolinic acid, the amount of glial fibrillary acidic protein-like immunoreactivity in the injected striatum was lower than in controls but returned to a normal level at 3 days. Not until 7 days was a clear striatal gliosis apparent, as evidenced by an increased density of glial fibrillary acidic protein-positive structures and brightly fluorescent, clearly hypertrophic cells. This gliosis was even more developed in animals sacrificed 30 days postoperatively. A weak astrocytic reaction was also observed in the ipsilateral corpus callosum at 6 hours after quinolinic acid. By 3 days, a marked gliosis, restricted to the injected hemisphere, was present throughout the corpus callosum, septum and cortex cerebri. In animals sacrificed 30 days after the quinolinic acid injection, the extrastriatal astrocytic reaction was clearly diminished, although the striatal gliosis was still prominent. One year post injection, no obvious gliosis could be observed in the cortex cerebri or the corpus callosum while striatal tissue, now markedly reduced in volume, was clearly gliotic. Using neurofilament antiserum, increased fluorescence intensity was noted in striatal nerve bundles during the first day after an intrastriatal quinolinic acid injection and persisted 1 year postoperatively.

In animals treated intrahypothalamically, a spherical central area almost devoid of glial fibrillary acidic protein-immunoreactivity was noted around the injection site 7 days after quinolinic acid administration. Around this area, gliosis was observed. Apart from a very restricted gliotic reaction around the needle track, no astrocytic reaction was observed in nicotinic acid injected control animals under any experimental condition.

We conclude that quinolinic acid causes both reversible and long-lasting gliosis when injected into the rat striatum. As a natural brain metabolite, quinolinic acid may constitute a particularly valuable tool for the elucidation of a possible role of glia in neurodegenerative disorders.

241.3 SIGNAL TRANSDUCING SYSTEMS FOR EXCITATORY AMINO ACID RECEPTORS: A MODEL STUDY ON CEREBELLAR GRANULE CELLS IN CULTURE. J. T. Wroblewski*, F. Nicoletti*, A. Novelli, A. Alho*, A. Guidotti and F. Costa (SPON: W. D. Blaker). Lab. Preclin. Pharmacol., NIMH, St. Elizabeths Hosp., Washington, D.C. 20032.

It may be expected that different subclasses of the excitatory amino acid receptors express their function by the activation of distinct coupling mechanisms associated with their recognition site. It has been demonstrated in various systems that excitatory amino acid agonists activate guanylate cyclase, increasing levels of cGMP. Our recent studies also indicate their functional role in promoting the hydrolysis of inositol phospholipids in slices of hippocampus, immature cerebellum and in cultured granule cells. Several lines of evidence indicate the possible coupling of excitatory amino acid receptors with increased conductance of $Ca^{2+}$ channels. The present study uses a primary culture of cerebellar granule cells obtained by 8-days old rats, consisting of an essentially homogeneous population of glutamatergic cells, showing a strong response to excitatory amino acids and devoid of the interference by the glial compartment. Our data indicate that the action of excitatory amino acid agonists results in the activation of two distinct types of $Ca^{2+}$ channels. Kainic acid strongly increases $Ca^{2+}$ uptake into granule cells through voltage-insensitive channels, since its action is not potentiated by veratrine or inhibited by tetrodotoxin. In contrast $Ca^{2+}$ uptake stimulated by classic NMDA receptor agonists strongly depends on the depolarization of the membrane indicating the involvement of voltage-sensitive $Ca^{2+}$ channels. The action of glutamate seems to indicate the occupancy of multiple receptor sites coupled both to voltage-sensitive and insensitive $Ca^{2+}$ channels. Similar differences among the above excitatory amino acid agonists are seen with respect to their ability to increase the intracellular levels of cGMP. However, different relations are observed when the hydrolysis of inositol phospholipids is monitored. This is especially pronounced in the action of quisqualic acid, which strongly stimulates inositol phospholipid hydrolysis, does not seem to increase intracellular levels of cGMP and behaves as a partial agonist of the kainic acid receptor with respect to $Ca^{2+}$ uptake. The results of the present and our previous work are summarized in a functional model describing the relations between the distinct recognition sites for excitatory amino acid receptor subtypes and intracellular responses involving increased calcium conductance, activation of guanylate cyclase and enhanced hydrolysis of inositol phospholipids.

241.4 EXCITATORY AMINO ACID RECEPTORS ARE COUPLED WITH INOSITOL PHOSPHOLIPID METABOLISM IN THE RAT CENTRAL NERVOUS SYSTEM. F. Nicoletti*, M. I. Iadarola, J. T. Wroblewski* and F. Costa (SPON: P. L. Canonico). Lab. Preclin. Pharmacol., NIMH, St. Elizabeths Hospital, Washington, D.C. 20032.

We have recently demonstrated that a variety of dicarboxylic amino acids, including ibotenic, quisqualic and homocysteic acids but not kainic acid or NMDA stimulate inositol phospholipid hydrolysis in the rat hippocampus. This was inferred from an enhanced accumulation of $^3$H-inositol-1-phosphate ($^3$H-I-1-P) in $Li^+$-treated slices prelabeled with $^3$H-inositol. This stimulation is selectively antagonized by the dicarboxylic amino acid receptor antagonist aminophosphonobutyric acid (APB). L-Glutamic and L-aspartic acids stimulate $^3$H-I-1-P formation by only 30% in hippocampal slices from adult rats but they markedly enhance (more than 15 fold) inositol phospholipid hydrolysis in hippocampal slices from newborn rats. In hippocampal slices from 6-7 day old animals, L-glutamic and L-aspartic acids are as potent as ibotenic acid and 4-7 fold more potent than norepinephrine and carbamylcholine in stimulating $^3$H-I-1-P formation. The action of L-glutamic and L-aspartic acids is markedly reduced in slices from 15 day old rats and is almost absent in slices from adult animals.

L-Glutamic and L-aspartic acids significantly enhance inositol phospholipid hydrolysis also in cerebellar slices from newborn animals and in primary cultures of cerebellar granule cells obtained from 8 day old rats but they fail to induce changes in $^3$H-I-1-P formation in cerebellar slices from adult rats. In primary cultures of cerebellar granule cells, the stimulatory action of L-glutamic acid on inositol phospholipid hydrolysis is antagonized by aminophosphonovaleric acid (APV) and $\gamma$-glutamylglycine but not by APB. This evidence suggests that the hippocampus and the cerebellum express two different molecular organizations of dicarboxylic amino acid receptors coupled with inositol phospholipid metabolism. The stimulation of inositol phospholipid hydrolysis by L-glutamic and L-aspartic acids or by other possible endogenous dicarboxylic amino acid receptor agonists may have an important role in the modulation of excitatory transmission as well as in the cellular mechanism(s) regulating neuronal growth and development.

241.5 CONTRIBUTION OF $Ca^{2+}$ TO NEURONAL EXCITATION ELICITED BY AMINO ACIDS: AN IN VITRO STUDY IN RAT PIRIFORM CORTEX. T.M. Galeno, N. Hori,* J.R. ffrench-Mullen,* and D.O. Carpenter. NY State Dept. of Health, Albany, NY 12201.

N-methyl-D-aspartate (NMA), quisqualic acid (Quis) and kainic acid (KA) have been shown to each activate a pharmacologically distinct receptor. However, the ionic mechanisms underlying activation of these receptors are unclear. On piriform pyramidal neurons, NMA elicits an apparent conductance decrease response whose magnitude increases with depolarization while Quis and KA elicit conductance increase responses whose magnitudes decrease with depolarization. The purposes of this study were to (1) determine, by the use of a $Ca^{2+}$ blocker, the contribution of divalent cations to excitation elicited by ionophoretically applied NMA, Quis and KA, and (2) determine the effects of varying $Ca^{2+}$ or $Mg^{2+}$ concentrations on neuronal sensitivity to these amino acids.

To determine if $Ca^{2+}$ contributes to the extracellularly recorded excitatory response elicited by NMA, Quis or KA, slices were perfused with a control Krebs-Ringer solution (phosphate and sulfate absent) followed by a 1.5 mM $Co^{2+}$ Krebs-Ringer solution. Responses to NMA, Quis and KA were reversibly blocked by $Co^{2+}$ perfusion. In separate experiments, cells perfused with zero $Ca^{2+}$ solutions showed enhanced responsiveness to NMA, Quis and KA compared to each respective control, with the KA response enhanced to the greatest degree. The potentiation of the KA response in zero $Ca^{2+}$ was often so great that attempts to elicit as many spikes in normal medium resulted in cell death. In 2X $Ca^{2+}$ solutions all responses were depressed. All responses were also sensitive to $Mg^{2+}$ but NMA was more sensitive than KA or Quis.

In spite of the difference in the apparent conductance produced by NMA as compared to KA and Quis, these results implicate $Ca^{2+}$ channels in all three responses. All are sensitive to the inorganic $Ca^{2+}$ channel blocker and the responses vary with external $Ca^{2+}$, although the KA response appears to be the most sensitive. In the absence of $Ca^{2+}$, the conductance of another ion, i.e., $Na^+$ may underly this excitation. The data is consistent with recent evidence that inward currents through the $Ca^{2+}$ channel are carried by monovalent cations when the external $Ca^{2+}$ concentration is reduced to a submicromolar level (Hess and Tsien, Nature 309: 453, 1984). The data are also consistent with the hypothesis that KA neurotoxicity is mediated at least in part by $Ca^{2+}$ entrance into the cell during KA receptor activation. There remains the dilemma of how to explain the differences in sensitivity to $Mg^{2+}$ and $Ca^{2+}$ and the differences in apparent conductance elicited by the different agonists.

241.6 CURRENT AND VOLTAGE CLAMP STUDIES ON THE MIXED AGONIST ACTION OF L-GLUTAMATE AND ITS ANTAGONISM BY D-AMINOPHOSPHONOVALERATE ON SPINAL MOTONEURONES IN VITRO.
A. King* and A. Nistri. Dept. Pharmacology, St. Bartholomew's Hospital Medical College, London EC1M 6BQ, U.K.

Glutamate (Glu), quisqualate (Quis) and N-methyl-D-aspartate (NMDA) are potent excitants of spinal motoneurones in vitro. Using intracellular recording from a frog spinal slice preparation we have attempted a direct demonstration of the selectivity of the antagonist D-aminophosphonovalerate (D-APV) against NMDA excitations compared to Glu and Quis.

In control Ringer ($Mg^{2+}$-free, 7°C) superfusion of 2 mM Glu, 30 µM Quis or 30 µM NMDA produced depolarizations of between 10 - 13 mV accompanied by modest conductance increases (20-30 %). Following prolonged superfusion (> 15 minutes) of varying concentrations (0.5 - 10 µM) of D-APV typically the NMDA responses were strongly antagonized while those to Glu were reduced with Quis relatively unaffected. For example 10 µM D-APV produced reductions of 100%, 39% and 10% for these amino acids respectively. A similar profile of antagonism was obtained in solutions containing 0.6 - 1.2 µM tetrodotoxin to abolish indirect effects via interneuronal activation.

Using the single microelectrode voltage clamp technique we have measured small slow inward currents produced in response to superfusion of low concentrations of Glu (1 mM) and Quis (15 µM). In 7 motoneurones maintained at resting potential level (mean -70 mV) in voltage clamp a net inward current of 103 pA was induced by Glu and 127 pA by Quis (6 cells). Characteristically the decay time for the Quis current (mean 106s) was prolonged compared with Glu (42s). D-APV (10 µM) reversibly reduced the Glu induced inward current by 33%, a value which corresponds well with the current-clamp data. In contrast the Quis induced currents were not antagonized (values were 108% of control) by D-APV.

This data confirms directly that D-APV is a selective and potent antagonist of NMDA excitation of motoneurones. The finding that D-APV antagonizes, albeit to a lesser extent, Glu responses of in vitro motoneurones confirms that Glu is a mixed agonist acting on quisqualate and NMDA receptors as described for cultured spinal neurones (Mayer and Westbrook, J. Physiol. Lond., 354: 29: 1984).

The financial support of the Medical Research Council, U.K. is gratefully acknowledged.

241.7 RESPONSE PROPERTIES OF IDENTIFIED CORTICAL NEURONS IN TISSUE CULTURE TO EXCITATORY AMINO ACID AGONISTS AND ANTAGONISTS. J. E. Huettner and R. W. Baughman. Dept. of Neurobiology, Harvard Medical School, Boston, MA 02115

Many neurons in the CNS are believed to use glutamate (Glu) or aspartate (Asp) as a transmitter and at least three types of Glu receptors have been distinguished pharmacologically. We have examined the responses of neurons from the visual cortex in dissociated tissue culture to a variety of Glu agonists and antagonists. In order to study the properties of a particular identified class of cortical neurons, we prelabeled cells in vivo by retrograde transport of a fluorescent tracer.

Dissociated cultures of neurons from the visual cortex of 7-10 day postnatal hooded rats were prepared as previously described (Huettner and Baughman. Soc. Neurosci. Abstr. 10:165 (1984)). Neurons in layer V that project to the superior colliculus were prelabeled in vivo by injecting fluorescent latex microspheres into the colliculus on postnatal day five. After 2-8 weeks in culture, neurons were impaled with intracellular microelectrodes, and amino acid agonists were applied by pressure ejection from a blunt micropipet. Antagonists were added to the perfusion medium and to the agonist pipet.

We have studied the responses of labeled layer V cells as well as the responses of other unlabeled cortical neurons to each of the following agonists: Glu (10-100uM), Asp(100uM), N-methyl-D-aspartate (NMDA, 10-100uM), kainate (1-10uM), and quisqualate (Quis, 0.1-1.0uM). All of these compounds produced rapid depolarizations in every neuron tested. The antagonist 2-amino-5-phosphonovalerate (APV, 20-50uM) completely blocked depolarizations due to NMDA but did not effect responses to kainate or Quis. Depolarizations due to 10-20uM Glu were diminished by APV but responses to higher concentrations of Glu (50-100uM) were not significantly reduced. Kynurenic acid (Kyn) and ϒ-D-glutamylglycine (ϒDGG, both at 250-1000uM) reduced responses to all of the agonists tested while glutamate diethylester at 500uM had no effect.

Our results indicate that the cortical neurons in our cultures posses NMDA receptors as well as receptors for kainate and Quis. In some neurons spontaneous and evoked excitatory post-synaptic potentials were observed, and these could be blocked by Kyn and ϒDGG. This finding suggests that the amino acid receptors described above are involved in excitatory synaptic inputs to these cortical neurons. (NIH EY03502)

241.8 DIFFERING EFFECTS OF GLUTAMATE ANALOGS AND ANTAGONISTS IN THE RABBIT RETINA. S.C.Massey*and R.F.Miller (SPON: A.I.Cohen). Ophthalmol. Dept.,Washington Univ.Sch.of Med.,St.Louis,MO 63110.

Glutamate, the putative neurotransmitter of photoreceptors and bipolar cells in the vertebrate retina, appears to activate a variety of post-synaptic receptors. These may be distinguished by their sensitivity to different glutamate analogs and, on this basis, have been classified as; 1)NMDA receptors,2)QQ receptors, 3)KA receptors and 4)APB receptors. The APB receptor in the retina appears to be uniquely associated with the ON bipolar cell and is not considered here.

In the outer retina, horizontal cells (HC) were directly depolarized by KA. QQ was less potent and NMDLA was ineffective. AP-7, a specific NMDA antagonist, had no effect but PDA and kynurenic acid (KynA), two general glutamate antagonists, hyperpolarized HC and blocked both the light response and the action of KA. These results are consistent with the dark release of an excitatory transmitter from photoreceptors which activates a KA (or QQ?) receptor on HC.

In the inner retina, KA and NMDLA both activate ganglion cells (GC) directly in the presence of $Co^{++}$. NMDLA typically causes burst-firing which is asspciated with small rhythmic oscillations in the membrane potential. Surprisingly, QQ had variable effects and sometimes excited, but more usually, inhibited GC. AP-7 specifically blocked the excitatory action of NMDLA but did not eliminate the light response or features such as directional selectivity. PDA blocked the light input to GC and the actions of KA and NMDLA, but not carbachol, thus demonstrating general specificity against glutamate analogs. KynA also blocked the light input, KA and NMDLA, but not the excitatory action of QQ. These observations suggest that the light driven input to GC is mediated mostly by KA receptors with a smaller component by NMDA receptors. The role of QQ receptors is unclear at this time, but these preliminary data are consistent with the possibility that independent QQ receptors are present on third order neurons of the retina.

241.9 THE EFFECT OF $Mg^{+2}$ ON THE DESENSITIZATION OF THE GLUTAMATE ACTIVATED CURRENT IN ISOLATED FISH HORIZONTAL CELLS. T. O'Dell* and B.N. Christensen. Department of Physiology and Biophysics, University of Texas Medical Branch, Galveston, TX 77550.

Horizontal cells receive an excitatory synaptic input from photoreceptors that is thought to be mediated by glutamate (glu). In order to characterize the glutaminergic responses of horizontal cells, we utilized the whole cell voltage clamp variation of the patch clamp technique (Hamill et al., 1981) to measure current induced by bath application of glu in isolated horizontal cells enzymatically dissociated from catfish retina. Cells were voltage clamped at their resting membrane potential, and concentrations of glu ranging from 1-300 μM were superfused until a steady-state current was recorded.

At concentrations of <100 μM glu, the glu activated membrane current increased monotonically where it remained at a steady-state value for several minutes of superfusion time. There was no indication of desensitization. Application of glu by pressure ejection from a locally placed pipette produced a rapid increase in inward current similar to the response seen during bath application of glu. This shows that desensitization does not occur during the slower superfusion time period of bath application. When the glu concentration was increased to > 100 μM, the inward current reached a peak following which the current declined to a new steady-state level. This time dependent desensitization that occurs at elevated glu concentrations suggests either a low affinity binding site that reduces the channel conductance, or a block of the glu channel by the agonist.

The role of Mg in this desensitization process was investigated by comparing the response in normal extracellular Mg with that obtained from the same cell when Mg was removed. While the early portion of the current showed a peaking equal to that seen in normal Mg, the time-dependent desensitization was removed and the glu induced current remained at a level equal to the initial peak current. These results argue against a block of the glutamate channel and suggest instead that Mg may link the binding of glu to a low affinity binding site that reduces channel conductance.

241.10 **INHIBITION OF $Ca^{++}$-DEPENDENT $^3$H-GLUTAMATE BINDING IN VIVO AND IN VITRO: A POSSIBLE MECHANISM FOR THE CYSTEAMINE-INDUCED SUPPRESSION OF KINDLING.** H.A. ROBERTSON, M.R. PETERSON* AND G.A. COTTRELL. Department of Pharmacology, Faculty of Medicine, Dalhousie University, Halifax, Nova Scotia, Canada B3H 4H7.

It has been suggested that cysteamine suppresses kindled seizures by depleting brain stores of somatostatin (Higuchi, T. et al., Brain Res., 288:359, 1983). However, cysteamine in the high concentrations used (200 mg/kg, i.p.) acts as a copper chelator and a free-radical scavenger and thus affects a wide variety of processes related to neurotransmission. Furthermore, somatostatin depletion and kindled seizure suppression do not follow the same time course (Cottrell and Robertson, this meeting). Another possible explanation for suppression of kindled seizures by cysteamine might be interference with excitatory neurotransmission. Glutamate appears to be the principle excitatory neurotransmitter in the brain. Accordingly, the effect of cysteamine on $Ca^{++}$-dependent glutamate binding sites was studied in vitro and in vivo.

Rats injected with saline or 200 mg/kg cysteamine were killed 24 hours after injection. A "buffy coat" membrane preparation was prepared from cerebral cortex and washed 5 times by centrifugation prior to final suspension in 50 mM Tris-HCl (pH 7.4). Specific binding of $^3$H-glutamate (20 nM) was determined in the presence and absence of 2 mM $Ca^{++}$. Non-specific binding was defined using 200 μM L-glutamate. Incubation at 37°C was terminated by rapid filtration on GF/B glass fiber filters.

Cysteamine inhibited $Ca^{++}$-dependent $^3$H-glutamate binding to cerebral cortical membranes both in vitro and in vivo. First, cysteamine (100 μM) incubated with membranes isolated from saline treated rats suppressed $^3$H-glutamate binding by 35%. Although this is a high concentration of cysteamine, it is within the range attained after systemic administration of 200 mg/kg of the compound. More significantly, however, when rats were given cysteamine (200 mg/kg i.p.) and were killed 24 hours later and $^3$H-glutamate binding to well-washed (5 times) cortical membranes assessed, cortical membranes from cysteamine-treated rats had significantly lower $Ca^{++}$-dependent $^3$H-glutamate binding (40%), even after the extensive washing necessary for glutamate binding studies.

These results suggest that interaction with glutamate binding sites is one possible mechanism by which cysteamine suppresses kindled seizures. It will also be necessary to determine whether cysteamine acts on other receptors and other aspects of neurotransmission. (Supported by the Canadian M.R.C.).

241.11 CHLORIDE ION DEPENDENT ASSOCIATION OF [3] L-GLUTAMATE WITH INTACT PC-12 CELLS. Charles E. Chandler* and E. Edward Mena (spon. C. J. Pazoles), Central Research Division, Pfizer Inc., Groton, CT 06340

Membrane binding assays for L-Glu are typically done using CNS membranes which are lysed and then washed several times in hypotonic medium. The membranes are then added to a defined ionic medium for assay. The binding sites measured in this manner exhibit a complex regulation by various ions. However, $Cl^-$ ions are responsible for the expression of the majority of L-Glu binding to CNS membranes (Mena et al., Brain Research, 243, 387, 1982). The effects of the lysing and extensive washing procedures on the expression of L-Glu binding sites is unknown. However, ionic gradients, which may occur if membranes reseal in the assay medium, could contribute to the ionic regulation of L-Glu binding.

We examined the association of [3] L-Glu (50 nM) with intact PC-12 cells. The cells were harvested with 150 mM Tris acetate (pH 7.4) and washed 3x (1000 xg for 5 min). The association of L-Glu with PC-12 cells was dependent upon the presence of $Cl^-$ ion in the external medium (ie. specific binding of 4933 ± 580 molecules/cell in 50 mM Tris HCl + 100 mM Tris acetate). The $Cl^-$ ion dependent association was saturable (Kd[Glu] = 2.78 µM) and was complete after 20 min at 30°C. Cells which were harvested and washed 3x in either 150 mM Tris HCl or 100 mM Tris HCl + 50 mM Tris acetate did not show any decrease in $Cl^-$ ion dependent association when assayed in 100 mM Tris acetate + 50 mM Tris HCl compared to cells harvested in 150 mM Tris acetate. Both quisqualic acid and ibotenic acid blocked this process (Ki values of 7.4 and 10.6 µM, respectively). However, 2-amino-4-phosphonobutyric acid (AP4) (100 µM) had no effect. Other compounds with no effect were (at 100 µM): N-methyl-D-aspartic acid, kainic acid, glutamic acid diethylester, alpha aminoadipic acid, quinolinic acid, kynurenic acid, AP3, AP5, AP6 and AP7.

Cells were not lysing during the assay since the release of cytoplasmic L-Glu would have raised the external concentration of 2-5 mM, a level over 1000-fold the Kd of the association. In addition, the cells were identical in appearance before and after the assay and only those cells which pelleted through 10% sucrose were recovered in the pellet.

The association of L-Glu with unlysed PC-12 cells has a requirement for $Cl^-$ ions in the external medium, is not affected by attempts to alter the internal/external $Cl^-$ ratios and exhibits rapid association kinetics. Thus, this $Cl^-$ dependent process occurs in intact cells as well as lysed CNS membranes.

241.12 SELECTIVE INHIBITION BY PHENCYCLIDINE ANALOGS OF N-METHYL-D-ASPARATE-EVOKED, BUT NOT KCl-EVOKED, [$^3$H]ACETYLCHOLINE RELEASE IN STRIATAL SLICES. S. McPherson*, P.L. Wood and J. Lehmann, Dept. of Neuroscience, CIBA-GEIGY Corp., Summit, NJ 07901 USA.

Lodge and co-workers have shown that phencyclidine and its analogs, as well as sigma opiate receptor agonists, preferentially counteract the excitation produced via stimulation of N-methyl-D-aspartate (NMDA)-type excitatory amino acid receptors (Berry et al., Br. J. Pharmac. 83:179, 1984). We report here that compounds active at [$^3$H]phencyclidine binding sites also inhibit the NMDA-evoked release of [$^3$H]acetylcholine (ACh), at concentrations well below those which inhibit KCl-evoked [$^3$H]ACh release.

At concentrations from 1 to 10 µM, greater than 50% inhibition of NMDA-evoked [$^3$H]ACh release was caused by phencyclidine, etoxadrol, ketamine, N-allyl-normetazocine, and cyclazocine. The 46% inhibition caused by N-allyl-normetazocine (1 µM) was not antagonized by haloperidol (100 nM), an antagonist of sigma opiate receptors, or by naloxone (100 µM), which antagonizes mu opiate receptors, among others (Su, JPET 223:284, 1982). The inhibition by N-allyl-normetazocine was not stereospecific, in agreement that this compound is not inhibiting NMDA-evoked [$^3$H]ACh release via sigma opiate receptors. The data are most consistent with an action at phencyclidine receptors mediating pigeon catalepsy and the binding of [$^3$H]phencyclidine (Mendelsohn et al., Biochem. Pharm. 33:3529, 1984), although the rank correlation is not perfect.

It can be excluded, however, that N-allyl-normetazocine is acting as a direct antagonist of NMDA-type receptors, since it fails to block lesions induced by intrastriatal injection of quinolinic acid, unlike the competitive NMDA-type receptor antagonists, 2-amino-5-phosphonopentanoate (AP5) and 2-amino-7-phosphonoheptanoate (AP7). Moreover, the slope for inhibition by phencyclidine of NMDA-evoked [$^3$H]ACh release is shallower than that of AP5 or AP7, suggesting a different mechanism of action.

Conclusions:

1. A receptor for phencyclidine and its analogs may be coupled to NMDA-type receptors, analogous to the benzodiazepine/GABA receptor/chloride ionophore complex.

2. This receptor, activated by sigma opiate agonists and phencyclidine and its analogs, is not the sigma opiate receptor, but may be the receptor labeled by [$^3$H]phencyclidine.

241.13 CHARACTERIZATION OF THE RESPIRATORY MOTOR RESPONSES TO PICOMOLE INJECTIONS OF EXCITATORY AMINO ACIDS INTO THE VENTRAL RESPIRATORY GROUP (VRG) OF CAT. D.R. McCrimmon*, J.L. Feldman, H.H. Ellenberger*, J.C. Smith* and D.E. Weese-Mayer* (SPON: C.H. Price). Department of Physiology, Northwestern University, Chicago, IL 60611

We have previously reported that small (0.2-10nl) injections of 1-10mM glutamic acid (Glu) or homocysteic acid (DLH) alters respiratory motoneuronal discharge pattern (Federation Proc. 44:428, 1985). In the current study, the responses to L-Glu and DLH were compared with those elicited by N-methyl-D-aspartic acid (NMDA). In addition, we tested the ability of relatively selective antagonists to block these responses and their effect on spontaneous phrenic nerve discharge. Experiments were performed on chloralose-urethane anesthetized, vagotomized, paralyzed and artifically ventilated cats. Phrenic nerve (5th cervical branch) discharges were recorded bilaterally. Pipettes of up to 7 barrels were used for extracellular unit recording and pressure ejection of precisely measured volumes of drugs; barrels contained the excitatory amino acids (1-10mM) Glu, DLH, and NMDA, the antagonists (1-100mM) 2-amino-4-phosphonobutyric acid (APB), glutamate diethyl ester (GDEE), and kynurenic acid (Kyn), and lidocaine (1-4%), GABA (10-100mM) and saline. Drugs were prepared in 150mM NaCl and adjusted to pH 7. At a given site within the VRG (where inspiratory modulated activity was recorded) the response to each of the excitatory amino acids was qualitatively similar but differed markedly in its magnitude and duration. Increases in VRG unit discharge and phrenic nerve discharge were elicited by injections into the lateral VRG 1 to 2mm rostral to the obex. Injections of as little as 250 femtomoles of L-Glu(0.25nl, 1mM) elicited marked transient increases in phrenic nerve discharge. Larger injections (2-4nl) lead to an alteration in the rhythm of phrenic nerve discharge. The order of potency was NMDA>DLH≥Glu. Decreases in phrenic discharge (consisting of transient apnea in many cases) were elicited by injections into the medial VRG from the level of the obex to about 2.5mm rostral. All 3 antagonists blocked both the excitatory and inhibitory responses with a potency Kyn>GDEE>APB. Injections of the antagonists themselves or lidocaine in amounts which were sufficient to block the responses to excitatory amino acids, had little or no effect on spontaneous phrenic nerve discharge. Similarly, injections of GABA (1-4nl, 100mM) inhibited unit discharge near the electrode tip but had no effect on spontaneous phrenic nerve discharge. These findings suggest that the excitatory amino acids elicit their effects by activating cells located in the VRG but which are not spontaneously active in this anesthetized preparation.

242.1 CHARACTERIZATION OF NEURONAL DISCHARGE IN MEDIAL FRONTAL CORTEX WITH SPONTANEOUS CHANGES IN CARDIORESPIRATORY PARAMETERS ACROSS SLEEP-WAKING STATES. R.C. Frysinger, R.D. Frostig, V.L. Schechtman, J.D. Marks, and R.M. Harper. Brain Research Institute and Department of Anatomy, UCLA, Los Angeles, CA 90024.

Neurons in the medial frontal cortex discharge phasically with the cardiac and/or respiratory cycle, and this discharge is state dependent. The present study examines the relationship of cell discharge in this brain area with spontaneous changes in blood pressure and respiratory parameters across sleep-waking states.

Four adult cats were anesthetized with halothane and electrodes inserted for recording lateral geniculate nucleus and frontal cortex EEG, costal diaphragmatic and nuchal EMG, and eye movement. Microdrives were implanted to permit bundles of nine microwires to be lowered through the infralimbic cortex bilaterally. Arterial pressure was monitored continuously through a chronic femoral arterial cannula advanced into the descending aorta. Recording began 1 week following surgery, and up to five cells were simultaneously recorded along with the relevant cardiorespiratory and state assessment parameters.

Normalized discharge rates of 23 cortical cells have been correlated on a breath-by-breath basis with peak, minimal, and mean arterial pressure, and with $T_{TOT}$, $T_I$, and $T_E$ of the respiratory cycle. Separate analyses were done for each state for each cell, with each state period ranging from 100 to 600 seconds. Results from these analyses were then compared with standard cross-correlation histograms computed between these cells and onset of inspiration and the cardiac R wave.

Negative correlations between rate of discharge of cortical units and $T_{TOT}$ were observed in 17 cells, with ten of these showing a correlation in REM sleep. Two of these ten cells showed such a correlation in both waking and REM sleep states, but cells showing a correlation with $T_{TOT}$ in quiet sleep did not also correlate in REM. Phasic alterations in the discharge rate of four cortical units were associated with transient increases in systolic pressure during phasic events of REM sleep. There was no clear association between discharge timing relationships as revealed by the cross-correlation histogram and the correlation calculated between rate and cardiorespiratory parameters.

These results suggest a) cell discharge in medial frontal cortex is generally correlated with phasic events of REM sleep, and b) cortical cells showing discharge timing relationships to cardiac or respiratory cycles may not show tonic changes in discharge rate associated with fluctuation in cardiac or respiratory parameters.

242.2 ROLE OF THE THALAMUS IN THE CONTROL OF SYMPATHETIC NERVE DISCHARGE. K.J. Varner*, S.M. Barman and G.L. Gebber. Dept. of Pharmacol./Toxicol., Mich. State Univ., East Lansing, MI 48824.

It is well known that patterns of neocortical activity such as the alpha (8-12 Hz) and delta (2-6 Hz) rhythms arise in the thalamus. The present study demonstrates that thalamic rhythm generating networks also exert influences on descending systems controlling sympathetic nerve discharge (SND). Experiments were performed on baroreceptor-denervated cats anesthetized with chloralose. Multicellular activity was recorded from the postganglionic inferior cardiac sympathetic nerve, medial thalamus (0-3 mm lateral to midline) and lateral thalamus. Crosscorrelation analysis revealed that a component of basal inferior cardiac SND was temporally related to the 2-6 Hz rhythm in thalamic activity. In some experiments, simultaneously recorded medial and lateral thalamic activity were sufficiently different so that SND was related only to medial thalamic activity. In other experiments, SND was related both to lateral and medial thalamic activity. That the temporal relationship between thalamic activity and SND was indicative of a functional connection is suggested by the results obtained with electrical stimulation. Single shocks applied to the medial thalamus elicited increases in inferior cardiac SND with onset latencies of 55-75 ms. Threshold responses could be elicited with a stimulus current as low as 70 μA. Sympathetic nerve responses evoked from the lateral thalamus had somewhat longer onset latencies. High frequency (50 Hz) stimulation of medial but not lateral thalamic sites produced marked increases in blood pressure. The increase in blood pressure elicited by medial thalamic stimulation was attenuated for approximately 10 min following the microinjection of 50 nl of 1 M L-glutamate at the site of stimulation. L-glutamate is believed to depolarize neuronal cell bodies but not axons. Thus, it appears that electrically-induced changes in blood pressure involved the activation of the somata of medial thalamic neurons.

Under the influence of subconvulsive doses of the GABA antagonist, picrotoxin, SND was temporally related to thalamic rhythmic activity in decorticate cats. Also, thalamic stimulation elicited increases in SND in decorticate cats in the absence or presence of picrotoxin. These results indicate the existence of a pathway from the thalamus to sympathetic nerves that does not include a cortical relay.

Although a 2-6 Hz rhythm persists in SND of the baroreceptor-denervated cat after decerebration, the period of the rhythm in some experiments is longer than that observed before decerebration. This result implies that brain stem sympathetic rhythm generating networks can be entrained by thalamic oscillators running at somewhat higher rates. If so, the leading focus for generation of the 2-6 Hz rhythm in SND may actually reside in the thalamus under certain conditions. (Supported by NIH grant HL13187.)

242.3 EXCITATORY NEUROTOXIN STIMULATED CARDIOVASCULAR RESPONSES FOLLOWING DIENCEPHALIC MICROINJECTIONS. R.W. Rockhold, C.-B. Jin*, C. Huang*. and J. Farley*. Dept. Pharmacology and Toxicology, Univ. Miss. Med. Cntr. Jackson, MS 39216

Kainic acid (KA), an excitatory neurotoxin which acts, in part, through stimulation of excitatory amino acid receptors, will produce increases in mean arterial blood pressure (MABP) and heart rate (HR) upon microinjection into brain regions in the vicinity of the paraventricular nucleus of the hypothalamus (PVN). The responses are dose-dependent (0.005-4.69 nmol) and accompanied by mydriasis, exopthalmos, increased respiratory rate and twitching of the vibrissae. Unilateral PVN injections (4.69 nmol in 100 nl) of KA, in urethane-anesthetized rats, increased MABP and HR by 61 ± 3 mm Hg and 114 ± 17 bpm, respectively; n = 10). Responses were observed within 30 sec following injections and persisted, at higher doses, for over 2 hr before returning to pre-injection levels. Pressor and tachycardic responses were selectively reversed by phentolamine (1 mg/kg, i.v.) and propranolol (1 mg/kg, i.v.) injections, respectively. Opthalamic, respiratory and motor responses were not altered by adrenoceptor antagonists. These data suggest predominantly sympathetic mediation of the cardiovascular responses. In support of this hypothesis, injection of a vasopressin vasoconstrictor antagonist (5 μg/kg, i.v.) lowered MABP by less than 10 mm Hg. Moreover, magnocellular neurons in the PVN were found to be largely intact upon light microscopic examination 3-7 days following unilateral PVN injections of KA (4.69 nmol) while parvocellular neuronal populations were reduced.

Responses observed following injections of N-methyl-D-aspartic acid (NMDA; 0.005-4.69 nmol) were similar but of much shorter duration (15-30 min). In contrast, L-glutamic acid produced only minimal increases in MABP and HR following unilateral PVN injections of 4.69 nmol.

Injections of KA or NMDA (0.469 nmol in 100 nl) into regions adjacent to the PVN, including the nucleus reuniens of the thalamus, the ventromedial nucleus of the hypothalamus and the anterior hypothalamus also increased MABP and HR.

The results indicate that neuronal soma in anteromedial hypothalamic and ventromedial thalamic regions possess excitatory efferent projections to cardiovascular regulatory areas.

242.4 CARDIOVASCULAR EFFECTS OF PERFUSION OF THE ROSTRAL RAT HYPOTHALAMUS WITH CLONIDINE: DIFFERENTIAL INTERACTIONS WITH YOHIMBINE AND CORYNANTHINE. R.L. Commissaris*, F.C. Beuthin and D.K. Pitts*, Wayne State University, Detroit, MI 48202.

The present studies examined the interaction of two chemically-related alpha adrenoceptor antagonists on the cardiovascular effects of clonidine administered into the anterior hypothalamic/pre-optic (AH/PO) region of the forebrain by the push-pull perfusion technique. Push-pull cannulae were placed bilaterally into AH/PO region of anesthetized, paralyzed and ventilated rats. Perfusion of this area with artificial CSF (0.015 ml/min), yohimbine (5,50 uM) or its diastereoisomer corynanthine (50 uM) for 30 minutes did not affect mean arterial pressure or heart rate. Perfusion of the AH/PO region with clonidine (0.55 - 5.5 mM) resulted in a concentration-dependent reduction of mean arterial pressure and heart rate. The hypotensive effects of clonidine were found to be greater than the bradycardic effects. Co-perfusion with the alpha-2-adrenoceptor antagonist yohimbine (5,50 uM) significantly attenuated the hypotensive, but not the bradycardic, effects of a single concentration (1.75 mM) of clonidine; this selective antagonism of the hypotensive effect of clonidine by yohimbine was concentration-dependent. In contrast to yohimbine, the alpha-1-adrenoceptor antagonist corynanthine significantly attenuated the bradycardic, but not the hypotensive, effects of 1.75 mM clonidine. These results suggest that AH/PO clonidine perfusion depresses both mean arterial pressure and heart rate, and that the clonidine-induced hypotension is due to alpha-2-adrenoceptor activation, while the clonidine-induced bradycardia is due to alpha-1-adrenoceptor activation.

242.5 DISTRIBUTION OF PEPTIDE AND SEROTONIN IMMUNOREACTIVE FIBERS AND TERMINALS IN PARAVENTRICULAR NUCLEUS OF THE CAT. M.M. Caverson, J. Ciriello, F.R. Calaresu and T.L. Krukoff. Department of Physiology, University of Western Ontario, London, Ontario, Canada N6A 5C1.

Recent evidence has shown that the paraventricular nucleus of the hypothalamus (PVH) consists of anatomically separate subdivisions which are involved in the regulation of neuroendocrine and autonomic responses. However, the distribution of biochemically distinct afferent projections to the different subdivisions of the PVH which may influence these responses has not been fully elucidated. In the present study the region of the PVH was investigated in cats for fibers and terminals immunoreactive to neurotensin, leucine-enkephalin, methionine-enkephalin, substance P, somatostatin and serotonin. Cats were perfused with Zamboni's fixative and 50 µm frozen transverse sections of the hypothalamus were cut and placed in antisera (Immuno Nuclear Corp.) for each of the neuroactive substances for 16-18 h at 4°C. The biotin-avidin immunohistochemical procedure (Vecta Stain Kit) was used. Fibers and terminal varicosities containing immunoreactivity for the six substances were found throughout the rostro-caudal extent of the region of the PVH as follows: 1) Neurotensin immunoreactivity had the greatest distribution throughout the PVH region. A dense terminal network was observed in the anterior periventricular area (Pet) which extended dorsolaterally into the ventral aspect of the dorsal component of the PVH (Pad) to form a cap over the fornix. Dense neurotensin immunoreactivity was also found in the ventral aspect of the anterior component of the PVH (Paa). 2) Leucine-enkephalin fibers and terminal varicosities were observed primarily in Pet and in Paa. A moderate density of labeling was found in the ventrolateral aspect of Pad and in the anterior aspect of the parvocellular nucleus (Pv). 3) The distribution of methionine-enkephalin immunoreactivity in the PVH region was similar to that of leucine-enkephalin, except that it was less dense. 4) Substance P, somatostatin and serotonin immunoreactivity had a similar distribution throughout the region of the PVH. Although fibers and terminal varicosities containing these substances were sparse, they were primarily concentrated in Pet, Pv and in the ventral aspect of Paa. These data indicate that specific neuroactive substances innervate different regions of the PVH and suggest that they may function in the regulation and co-ordination of neuroendocrine and autonomic responses.

242.6 ACTIVATION OF SUPRAOPTIC VASOPRESSIN NEURONS BY STIMULATION OF RENAL AFFERENT FIBERS. T.A. Day and J. Ciriello, Department of Physiology, University of Western Ontario, London, Canada N6A 5C1.

Renal nerves are known to contain sensory afferent fibers which are thought to carry information from mechanoreceptors and chemoreceptors located in the kidney. Although activation of afferent renal nerves (ARN) have been shown to alter the firing frequency of hypothalamic cells (J. Autonom. Nerv.Syst. 3:311, 1981), it is not known whether ARN influence the discharge of identified magnocellular neurosecretory cells. The present study was done to determine whether information from the kidney was capable of altering the firing frequency of vasopressin (AVP)-synthesizing neurosecretory cells of the supraoptic nucleus (SON). Following transpharyngeal exposure of the hypothalamus and hypophysis, extracellular recordings were obtained from SON neurosecretory cells identified by antidromic invasion from the neurohypophysis. The effect of electrical stimulation (3-5 pulses, 75-300 Hz, 0.1-1 ms pulse duration) of the central end of severed nerves isolated from the left renal plexus on these cells was determined. Fifty-three spontaneously active neurosecretory cells were tested. As previously described (J. Physiol. 355:237, 1984), these units were classified as AVP or oxytocin (OXY) secreting on the basis of basal activity patterns and response to baroreceptor activation. All contralateral (n=14) and 69% of ipsilateral (total n=26) putative AVP cells tested were excited by stimulation of ARN. Mean latency to onset of excitation was 189 ± 5 ms, suggesting a total afferent pathway conduction velocity of less than 1 m/s. Mean duration of the excitation was 237 ± 17 ms. Stimulus pulse durations of less than 0.3 ms were ineffective in eliciting responses from putative AVP cells. In combination with the low afferent pathway conduction velocity, this was interpreted to suggest that the afferent fibers involved were unmyelinated. Thirteen of the 53 units examined were identified as putative OXY neurons; none of these cells showed any response to stimulation (5 ipsilateral, 8 contralateral) of ARN.

AVP, released into the bloodstream from the neurohypophysis, is known to regulate renal water excretion and exert a significant influence upon general cardiovascular function as a consequence of its vasoconstrictor properties. The present data suggest that afferent signals originating in the kidney exert a stimulatory effect on the activity of AVP neurosecretory cells which is likely to contribute to the regulation of circulating plasma levels of this hormone and the level of arterial pressure.

242.7 NORADRENERGIC MODULATION OF SUBFORNICAL ORGAN INPUT TO THE NUCLEUS MEDIANUS. C.A. Graham*, D.O. Nelson, and A.K. Johnson. Department of Physiology, Northwestern Univ. Med. Sch., Chicago, IL 60611.

The subfornical organ (SFO) is an important neuronal structure mediating cardiovascular and behavioral responses to systemic angiotensin II (AII). SFO projections include the nucleus medianus (NM). Our recent in vitro investigations indicate that this projection is excitatory and may contain AII. Recent neuroanatomical studies have demonstrated heavy ascending noradrenergic projections to the NM which, based on chemical lesion studies, are necessary for mediation of AII-evoked drinking behavior. This study investigated electrophysiologically the role of noradrenergic input on NM neurons receiving SFO input utilizing the in vitro brain slice technique. Sagittal brain slices (400um thick) of the anterior ventral third ventricle (AV3V) were prepared from rats. This preparation allowed direct visualization of the SFO and NM. Spontaneous NM neuronal activity was recorded through one barrel of a multibarrel micropipette. Additional barrels contained norepinephrine, AII, or Saralasin and were connected to a custom micropressure injection system providing 100pl resolution. Low frequency electrical stimulation of the SFO produced short latency exciation of 60% (n=31) of the spontaneously active cells located in the NM. Addition of norepinephrine directly to the perfusing medium (1uM-100uM) or by simultaneous micropressure application (0.2-5nl) markedly enhanced the excitatory response of 80% of NM neurons responding to SFO stimulation. Exposure to norepinephrine reduced spontaneous ongoing activity of most NM neurons. Addition of Saralasin (0.1uM) to the perfusing medium or by direct micropressure application reversibly blocked or attenuated neuronal responses to SFO stimulation. Most of the NM cells were also excited by direct application of AII. Direct activation by AII was also antagonized by simultaneous pressure application of Saralasin. Saralasin alone reduced spontaneous activity in many cases. In a small number of cases (n=8), the enhancing effects of norepinephrine were blocked by application of Saralasin.

Our results indicate that noradrenergic input to NM neurons may enhance neuronal sensitivity to SFO input. Convergence of noradrenergic input and angiotensinergic pathways from the SFO on NM neurons may exist. Current studies are focusing on receptor populations mediating these effects.

242.8 A [$H^3$] 2-DEOXYGLUCOSE MAPPING OF CENTRAL PATHWAYS MEDIATING THE PRESSOR RESPONSE TO ELECTRICAL STIMULATION OF THE SUBFORNICAL ORGAN IN THE RAT. M.B. Gutman*, J. Ciriello and G.J. Mogenson (SPON: M.A. Cook). Dept. of Physiology, Univ. of Western Ontario, London, Canada N6A 5C1.

The subfornical organ (SFO) has recently been shown to be a primary site at which bloodborne angiotensin II activates a neural circuitry associated with drinking behavior and increases in arterial pressure, heart rate and vasopressin secretion. However, the central structures that are part of this neural circuit have not been completely elucidated. The present study was done to identify structures in the central nervous system which are activated by electrical stimulation of pressor sites in the SFO. Experiments were done in sinoaortic denervated rats anesthetized with urethane. Tritiated 2-deoxyglucose (2DG) was administered intravenously while the SFO was electrically stimulated (15 Hz, 150 µA, 1.5 ms pulse duration, 45 min pulse train). Control animals underwent the same surgical procedure, including the placement of an electrode 1.5 mm dorsal to the SFO and then received the same dosage of 2DG one minute after initiation of a 45 minute infusion of phenylephrine (PE) (5-10 µg/kg/min i.v.) and no electrical stimulation. Mean arterial pressure was increased by 37 ± 2 mm Hg during stimulation of the SFO, which was similar to the rise in arterial pressure observed during PE infusion in control animals (37 ± 13 mm Hg). After the 45 minute stimulation or infusion period the brain and thoracic spinal cord was quickly removed and frozen. Transverse sections were cut at 20 µm, quickly dried on cover glass and placed in contact with tritium sensitive film for 8 weeks. Autoradiographs were developed and analyzed for areas having changes in metabolic activity as indicated by the density of photographic emulsion. Increases in density in experimental animals compared to controls were observed in the regions of the nucleus accumbens, the dorsal and ventral components of the nucleus medianus, the septofimbrial nucleus, the nucleus triangularis, the lateral septum, the rostral suprachiasmatic nucleus, the dorsal thalamus, the supraoptic nucleus, the paraventricular nucleus of the hypothalamus, the medial habenula and the intermediolateral nucleus of the thoracic cord. These data have demonstrated that stimulation of pressor sites in the SFO increases the 2DG uptake of several forebrain and spinal cord structures which are likely involved in the control of body fluid balance and arterial pressure.

242.9 **EFFERENT CONNECTIONS OF THE MEDIAL PREOPTIC REGION IN THE RAT.** E.R. Brown*, D.G. Standaert* and C.B. Saper. Depts. of Neurology and Anatomy and Neurobiology, Wash. Univ. Sch. of Med., St. Louis, MO 63110

The medial preoptic region, surrounding the anteroventral third ventricle (AV3V), is involved in the regulation of blood volume, pressure, and composition. In order to better understand the mechanism for this control, we studied the efferent pathways from this area in rats using anterograde transport of tritiated amino acids, as well as a new lectin tracer, PHA-L. Two cell groups were found to project to structures which have been implicated in cardiovascular control: the median preoptic nucleus (MnPO), and the anteroventral periventicular nucleus (AVPV). The projections of these cell groups are similar. One group of descending fibers takes a periventricular route, and innervates both the endocrine and autonomic regulatory portions of the paraventricular nucleus of the hypothalamus. Other fibers innervate the arcuate and periventricular nuclei. Some turn ventrolaterally to run into the supraoptic nucleus, and others extend dorsally to innervate the subfornical organ. The remaining periventricular fibers continue caudally into the periaqueductal grey matter, and some can be traced as far as the dorsal lateral parabrachial nucleus, and, after AVPV injections to the nucleus of the solitary tract and the ventrolateral medulla.

A second group of descending fibers runs dorsolaterally from MnPO and AVPV into the bed nucleus of the stria terminalis, innervating the ventral and lateral parts of the nucleus. Some fibers turn caudally, following the column of the fornix into the lateral hypothalamic area. At the premamillary level, these fibers sweep dorsomedially to join those running from the periventricular system into the periaqueductal gray matter. We have recently found that many of the neurons in AVPV stain immunohistochemically for atrial natriuretic peptide (atriopeptin). Atriopeptin immunoreactive fibers are also found in most of the fiber pathways we have described from AVPV to cell groups involved in central cardiovascular control.

These projections, and those from MnPO, may underlie many of the cardiovascular phenomena observed following stimulation or lesions of the AV3V region.

242.10 **ORIGIN OF ATRIOPEPTIN-IMMUNOREACTIVE INNERVATION OF THE PARAVENTRICULAR NUCLEUS OF THE HYPOTHALAMUS (PVH).** D.G. Standaert*, E.R. Brown*, P. Needleman*, and C.B.Saper. Depts. of Pharmacology, Neurology, and Anatomy and Neurobiology, Wash. Univ. School Med., St. Louis, MO 63110. (SPON: J. Trotter)

Atrial natriuretic factor, or atriopeptin, is a recently described peptide hormone, found within secretory granules in the myocytes of the cardiac atria, that has natriuretic and diuretic properties. We have used antisera raised against synthetic atriopeptin III and a cyanogen bromide fragment of atriopeptigen, the high molecular weight precursor of atriopeptins, to identify atriopeptin-immunoreactive (AP-ir) neurons in the brain of the rat.

The most prominent collection of AP-ir neurons is found in the anteroventral periventricular nucleus (AVPV), adjacent to the tip of the third ventricle. Inspection of the pattern of fiber staining suggests that this nucleus is the primary source of a dense collection of AP-ir fibers that innervate PVH.

We have used several different neuronal tracing techniques to study in detail the AP-ir innervation of PVH. Injections of WGA-HRP into PVH demonstrate extensive retrograde labelling of neurons in AVPV. Very small ionotophoretic injection of PHA-L, an anterograde tracer, into AVPV reveal a dense network of fibers ramifying within the magnocellular and parvocellular parts of PVH. Fluorescent retrograde tracers in combination with immunohistochemistry were used to identify the origin of AP-ir innervation to PVH. Injections of Fast Blue or diamidino yellow into PVH demonstrated that many of the AP-ir cells in AVPV send projections to PVH. In addition, a small number of the AP-ir neurons located in the lateral dorsal tegmental and pedunculopontine nuclei contribute to the AP-ir terminal field in PVH.

Both AVPV and PVH play an important role in the regulation of cardiovascular function. The AP-ir projection from AVPV to PVH may represent the anatomical substrate for interaction between these two nuclei. Thus, atriopeptin may function as a central neurotransmitter as well as a peripheral hormone in the regulation of the cardiovascular system.

242.11 **RELATIONSHIPS OF VISCERAL AFFERENT AND LIMBIC CONNECTIONS IN THE INSULAR CORTEX IN THE RAT.** D.F.Cechetto and C.B.Saper. Depts. of Neurology and Anatomy and Neurobiology, Washington University School of Medicine, St. Louis, MO, 63110.

The presence of a vagal representation in the insular cortex (IC) of the rat and cat has been established both by neuroanatomical and neurophysiological methods. In addition, limbic projections from the amygdala and the medial dorsal nucleus of the thalamus (MD) may converge with visceral afferents in this area. In the present experiments we have investigated the anatomical relationship in the IC of visceral afferent and limbic representations. The IC was explored in 19 rats for units with responses to visceral inputs. HRP was iontophoretically injected at the recording site of one visceral responsive unit in each animal. A viscerotopic organization was observed, in which units in the rostral part of granular IC received taste and gastromechanoreceptor inputs while cardiopulmonary inputs projected to the caudal part of granular IC. Retrograde HRP label indicated that the taste area in IC received afferents from the ventroposteromedial and ventromedial basal nuclei of the thalamus and the rostral part of the medial parabrachial nucleus (PB). The cardiopulmonary area of IC received input from the ventroposterolateral nucleus of the thalamus. However, most of the latter the sites were dorsally located in granular IC. Injections of WGA-HRP in PB showed that the projections to posterior IC were more ventrally located than those to anterior IC. None of the visceral receptive sites showed connections with the amygdala or MD, but WGA-HRP injections into these areas resulted in labeling that was primarily restricted to the agranular IC, which was ventral to all of our recording sites.

In summary, IC appears to be composed of a series of longitudinally oriented overlapping strips including: a) a dorsal granular IC area receiving spinal and trigeminal visceral-related input in a viscerotopic manner, b) a ventral granular and dorsal agranular IC region receiving vagal inputs, and c) a ventral strip including the ventral agranular and ventral part of the dorsal agranular IC, which receives amygdaloid and MD inputs.

242.12 AORTIC BARORECEPTOR DENERVATION ALTERS REGIONAL HEXOKINASE ACTIVITY IN THE FOREBRAIN OF THE RAT. W.E. Turton*, F.R. Calaresu and J. Ciriello. Dept. of Physiology, Univ. of Western Ontario, London, Canada N6A 5C1.

It has been demonstrated that selective denervation of aortic baroreceptors in the rat results in a persistent elevation in arterial pressure (AP). Recently, it has been shown that the paraventricular nucleus of the hypothalamus (PVH) is involved in both the development and maintenance of the elevated AP in this model of experimental hypertension. However, little is known about other central structures that may be associated with the hypertensive process. In the present study, those regions of the brain whose metabolic activity is altered after aortic baroreceptor denervation were functionally mapped using hexokinase (HK) histochemistry, which reflects the rate of glucose utilization in the brain. After recording AP (tail cuff method) and heart rate (HR) for a control period of 4 days, rats were subjected to either bilateral transection of the aortic depressor (ADN) and cervical sympathetic nerves or to sham-ADN transection. Three days after ADN surgery, rats were anesthetized with sodium pentobarbital and perfused transcardially with warm saline. The brains were removed and quickly frozen, sectioned (20 μm) on a cryostat and mounted on glass slides. Transverse forebrain sections were processed for HK histochemistry as described previously (Acta Histochem., 28:286, 1967). Changes in HK activity were assessed by densitometric measurements of areas containing HK reaction product. AP and HR were elevated by 26 ± 4 mmHg and 50 ± 17 bpm, respectively, in the ADN-transected animals compared to sham-ADN transected animals. Significant increases in HK activity were observed in the subfornical organ, in the magnocellular and parvocellular components of the PVH, and in the supraoptic nucleus of the ADN-transected animals. These data have demonstrated that removal of aortic baroreceptor afferent inputs alters the activity of forebrain structures previously implicated in the regulation of body fluid balance and arterial pressure and suggest that these structures are involved in the hypertensive process after ADN transection.

243.1 BRAIN Na,K-ATPase: EVIDENCE FOR MEMBRANE ADAPTATIONS TO CHRONIC ETHANOL AND NORADRENERGIC STIMULATION. A.C. Swann, Department of Psychiatry, University of Texas Medical School, Houston, TX. 77225

We have previously shown that the effects of chronic ethanol on Na,K-ATPase were opposite to those of ethanol in vitro, consistent with a membrane adaptation to the membrane-disordering effect of ethanol (JPET 232:475-479, 1985). There is evidence in vitro that ethanol prevents metabolic effects of norepinephrine (NE) related to Na,K-ATPase stimulation and that norepinephrine increases the sensitivity of Na,K-ATPase to inhibition by ethanol. Exposure to norepinephrine in vivo appears to regulate the number of Na,K-ATPase sites (Brain Res. 260:338-341, 1983). We therefore examined the interactions between ethanol and noradrenergic stimulation in vivo. Repeated noradrenergic stimulation (yohimbine 2 mg/kg bid for one week) reduced the K+ affinity, increased the affinity for ATP, and increased both $\Delta H$ and $\Delta S$ for K+ binding and for the rate-limiting conformational change of Na,K-ATPase. Sensitivity to inhibition by ethanol in vitro and the enhancement of ethanol inhibition by norepinephrine were increased by repeated yohimbine. Repeated yohimbine also reduced the Hill coefficient for inhibition by fluoride ion. These effects were all consistent with increased membrand fluidity, similar to effects of ethanol in vitro and opposite to chronic ethanol. Combined chronic ethanol and yohimbine had effects that were generally intermediate between those of either alone. Depletion of norepinephrine with DSP4 had essentially the opposite effects. Chronic ethanol reduced both the increase in Na,K-ATPase after repeated yohimbine and the decrease after DSP-4. These results suggest that repeated noradrenergic stimulation may affect membrane fluidity in the region of Na,K-ATPase in a manner that alters 1) the coupling of cation transport to energy supply and 2) the response to ethanol. Ethanol appeared to reduce the sensitivity to norepinephrine in vivo.

243.2 PLASMA EPINEPHRINE AND NOREPINEPHRINE DURING CPR IN DOGS. P.J. Foley*, W.A. Tacker*, W.D.Voorhees*, M.A. Elchisak. Biomedical Engineering Center and Dept. of Physiology and Pharmacology, Purdue University, W. Lafayette, IN 47907.

Epinephrine is frequently given during advanced life support for patients with sudden cardiac death syndrome. However, the role of endogenous catecholamines in survival is not known. To determine the sympathomedullary response to cardiac arrest, plasma epinephrine (E) and norepinephrine (NE) levels were measured before, during and after cardiac arrest. Twelve mongrel dogs weighing 20 to 25 kg were anesthethized with pentobarbital sodium (30 mg/kg, i.v.), intubated and catheterized for the following pressures: left ventricular (LVP), aortic (AP) and central venous (CVP). Ventricular fibrillation was induced electrically. Standard American Heart Association CPR was performed using a pneumatically driven device (Thumper®). CPR was standardized in all dogs by adjusting the force of compression to establish and maintain an end-diastolic arterial-venous pressure gradient of 20 to 25 mmHg. No exogenous catecholamines were given. Endogenous plasma E and NE were determined, using HPLC, from blood samples drawn from the CVP catheter before cardiac arrest and at 2.5, 4.5, 9.5 and 11.5 min. during CPR. After 12 min. of CPR, the cardiac ventricles were electrically defibrillated and the dog was allowed to recover. Blood samples were drawn at 5, 10, 15, and 20 min. post-resuscitation. Plasma E and NE increased from prearrest levels of 28.27±4.38 (±SEM) and 152.52±16.39 pmoles/ml to 358.55±75.75 and 280.79±47.90 pmoles/ml, respectively, at 2.5 min. of arrest. E levels peaked at 380.40±54.84 pmoles/ml at 4.5 min. of CPR and fell to 52.79±13.34 pmoles/ml at 20 min. post-resuscitation. NE levels peaked at 1140.73±123.70 pmoles/ml at 11.5 min. of CPR and fell to 472.87±68.07 pmoles/ml at 20 min. post-resuscitation. It is concluded that cardiac arrest causes significant increases in plasma E and NE levels which remain elevated for the duration of the the arrest. After resuscitaion the plasma E and NE levels decrease gradually toward control values. These results are similar to those reported in human patients during CPR.

This work was carried out under a Fellowship Grant from the American Heart Association, Indiana Affiliate, Inc.

243.3 CHARACTERIZATION OF THE ISOZYMES OF PHENYLETHANOLAMINE N-METHYLTRANSFERASE. D.L. Wong, L. Yamasaki* and R.D. Ciaranello. Dept. of Psychiatry and Behavioral Sciences, Stanford Univ. Sch. of Med., Stanford, CA 94305

Phenylethanolamine N-methyltransferase (PNMT) has been purified to homogeneity by the criteria of high sensitivity silver staining of protein analyzed on 12.5 percent sodium dodecylsulfate polyacrylamide gels. The enzyme was purified from bovine adrenal medulla by ammonium sulfate precipitation, acid precipitation, Sephadex G-75 chromatography and affinity chromatography on S-adenosylhomocysteine (SAH)-Sepharose 4B. Isoelectric focusing of the purified enzyme shows that there are at least five isozymes with isoelectric points ranging from 4.5 to 5.5. Enzymatic activity is associated with each isozyme as shown by activity assay of gel slices. Each isozymic species is immunoreactive as determined by immunoblotting and immunofixation using a polyclonal antibody generated against the purified enzyme. This PNMT antibody does not cross-react with dopamine ß-hydroxylase (DBH). Similarly, the PNMT isozymes do not cross-react with polyclonal DBH antibody. Treatment of PNMT with various endo- and exoglycosidases suggests that the differences between isozymes may be partially due to carbohydrate constituents. The carbohydrate components consist of high mannose and complex sugars covalently linked through diacetylchitobiose to an asparagine residue in the polypeptide chain. $K_m$'s for the substrate, norepinephrine, and the cofactor, S-adenosylmethionine, are being determined for each isozyme. Polypeptide mapping of limited proteolytic digests of the deglycosylated isozymes is being used to determine whether any variations in primary structure exist.

243.4 ELECTROPHYSIOLOGICAL EFFECTS OF COCAINE IN THE MESOACCUMBENS AND MESOCORTICAL DOPAMINE SYSTEMS. F.J. White. Dept. Psychology, Univ. of Illinois, Champaign, IL 61820.

Despite the increasing frequency of cocaine abuse, surprisingly little is known about the effects of this psychomotor stimulant on the activity of individual CNS neurons. Although biochemical techniques have shown that cocaine blocks the high affinity uptake of monoamines, the relationship of this effect to the activity of individual neurons remains to be established. Because cocaine's rewarding effects are known to involve the mesolimbic and mesocortical dopamine (DA) systems originating in the ventral tegmental area (VTA) and projecting to various forebrain sites including the nucleus accumbens (NAc) and prefrontal cortex, the present experiments used single unit recording and microiontophoretic techniques to determine the effects of cocaine on the electrical activity of these DA systems.

Intravenous (i.v.) cocaine administration to chloral hydrate anesthetized rats caused a dose-dependent, haloperidol-reversible reduction in the firing of antidromically identified mesoaccumbens DA neurons but failed to alter the activity of mesocortical DA neurons. The ID50 for suppression of the inhibited neurons was 2.96 ± 0.86 mg/kg and was negatively correlated with the basal activity of the neurons. The extent of suppression was seldom greater than 60%, even at high doses. Microiontophoretic administration of cocaine (0.1 M, 60 nA) caused a weak suppresssion of the majority of A10 DA neurons; this effect was also correlated with the basal rate of the cell. At higher currents, decreases in splike amplitude were usually present suggesting a local anesthetic action. The inhibitory effects of cocaine were blocked by coiontophoresis of l-sulpiride (0.05 M). At lower currents (10-20 nA), cocaine significantly increased and prolonged the inhibitory effect of iontophoretic DA (0.01 M) as well as the inhibition caused by antidromic stimulation of the NAc. Recordings from single units within the NAc revealed that cocaine also significantly potentiated the inhibitory effects of both iontophretic DA and electrical (pulse-train) stimulation of the VTA.

These experiments have shown that cocaine can inhibit the activity of mesoaccumbens A10 DA neurons as well NAc cells which receive a DA innervation from the VTA. The mechanism responsible for such inhibition appears to be that of uptake inhibition since cocaine potentiates the effects of both iontophoretic DA and electrical stimulation of the DAergic fibers. These results also provide further confirming evidence that the mesocortical DA neurons lack impulse-regulating DA autoreceptors since these neurons failed to respond to i.v. cocaine administration.

243.5 LATENT NORADRENERGIC NEUROTRANSMISSION IS STIMULATED BY β-PHENYLETHYLAMINE IN RAT HIPPOCAMPAL SLICES. S. Arbilla*, S. Benkirane and S.Z. Langer, Department of Biology, Laboratoires d'Etudes et de Recherches Synthélabo (L.E.R.S.), 58, rue de la Glacière, 75013 Paris, France

The stimulation-evoked release of $^3$H-5HT from rat cerebral slices is modulated by inhibitory $\alpha_2$-adrenoceptors (Langer S.Z. and Moret C., J. Pharmac. Exp. Ther. 222 : 220, 1982). We have used the $\alpha_2$-adrenoceptor mediated modulation of the electrically-evoked release of $^3$H-5HT from rat hippocampal slices as a model to evaluate the in vitro influence of β-phenylethylamine (β-PEA) on noradrenergic neurotransmission.

The slices were labelled with $^3$H-5HT and perfused in a Krebs medium. The calcium-dependent release of $^3$H-5HT was elicited by two periods of electrical stimulation ($S_1$ and $S_2$) at 3 Hz, 24 mA for 2 min. Provided that monoamine oxidase B was inhibited by deprenyl 1 μM, exposure to β-PEA (1 - 10 μM) added 20 min before $S_2$ inhibited the electrically-evoked release of $^3$H-5HT in a concentration-dependent manner. In the presence of β-PEA 3 μM, the ratio $S_2/S_1$ was : 0.53 ± 0.03, $p < 0.001$, n = 11 ; (control : $S_2/S_1$ = 0.83 ± 0.03, n = 8). Under the same experimental conditions, 6-F-NA 0.1 μM significantly inhibited $^3$H-5HT release ($S_2/S_1$ = 0.34 ± 0.02, n = 5, $p < 0.01$). Idazoxan 1 μM added before $S_1$ antagonized the inhibitory effect of β-PEA 3 μM ($S_2/S_1$ = 0.90 ± 0.05, n = 9) (control in the presence of idazoxan : $S_2/S_1$ = 0.99 ± 0.04, n = 9). Inhibition of tyrosine hydroxylase (TH) activity by α-methyl-p-tyrosine (300 mg/kg i.p., 2 h + 100 μM in the Krebs medium) did not affect the inhibition by 6-F-NA 0.1 μM of $^3$H-5HT release ($S_2/S_1$ = 0.34 ± 0.07, n = 4, $p < 0.001$), but it antagonized the inhibitory effects of β-PEA 3 μM ($S_2/S_1$ = 0.89 ± 0.13, n = 4). The antagonism of the effects of β-PEA by the selective $\alpha_2$-adrenoceptor blocker idazoxan indicates the involvement of these receptors in the inhibition by β-PEA of $^3$H-5HT release. The lack of effects of β-PEA on the release of $^3$H-5HT after inhibition of TH activity indicates that β-PEA acts indirectly on $\alpha_2$-adrenoceptors through the release of newly synthesized noradrenaline, namely by promoting a latent noradrenergic neurotransmission in a similar manner as it was shown for amphetamine on dopaminergic neurotransmission (Langer, S.Z. and Arbilla, S., Trends in Pharmacol. Sci. 9 : 387, 1984).

In conclusion, in rat hippocampal slices, β-PEA inhibits the calcium-dependent evoked release of $^3$H-5HT through the activation of $\alpha_2$-adrenoceptors subsequent to the release of newly synthesized noradrenaline from a special pool of the transmitter.

243.6 A TONIC SEROTONERGIC INHIBITION ON NORADRENERGIC LOCUS COERULEUS CELL ACTIVITY AS DEMONSTRATED BY A SELECTIVE $5HT_1$ AGONIST : RU 24969. J.L. Brassard*, L. Quintin, G. Hilaire°*, C. Bardelay*, C. Oberlander* and J.F. Pujol* (SPON : R. Naquet ), Neuropharmacology, Roussel, 93230 Romainville and °CNRS LA 205, 13397 Marseille, France.

A serotonergic (5HT) input projecting to the noradrenergic (NA) locus coeruleus (LC) (Léger et al. C.R. Acad. Sci. Paris, 1980, 290 : 807-810) has been demonstrated to exert an inhibition on the activity of LC tyrosine hydroxylase (TH) (Renaud et al., Biochem. Pharmacol., 1975, 24 : 1739-1742). To assess whether this inhibition demonstrated on long term basis on the LC-TH would also be evidenced during short term studies, this 5HT/NA interaction was studied in the LC by electrophysiological, electrochemical and HPLC techniques. LC unitary activity (Hilaire et al., Soc. Neurosci. Abstr., 1984, 10, part I : p. 679), LC catechol oxidation peak recordings (Gonon et al., Brain Res., 1983, 273:207-216) and LC microdissections (Buda et al., Brain Res., 1983, 273 : 197-206) were performed as previously described. Combined electrophysiological and electrochemical recordings in the LC (Hilaire et al., 1984) evidenced an increase in unitary activity and catechol oxidation current after an injection of a selective $5HT_1$ agonist, RU 24969 (Hunt and Oberlander, "Serotonin", Plenum, 1981, 547-562) 1 $mg.kg^{-1}$ i.v. This increase in catechol oxidation peak was dose-dependent (ED50 = 1.4 $mg.kg^{-1}$ i.p. of RU 24969, log-probit method). HPLC determinations of DA and DOPAC on LC microdissections showed similar amplitude of variations as changes observed in catechol oxidation current. Furthermore, the 5HIAA/5HT ratio on the same LC microdissections was significantly depressed after RU24969 5 $mg.kg^{-1}$ i.p. Lastly, i.c.v. 5,7 DHT lesions (nomifensine pretreatment 10 $mg.kg^{-1}$ i.p.) almost totally suppressed the increase in catechol oxidation peak noticed after RU 24969 5 $mg.kg^{-1}$ i.p. The increased NA-LC activity after RU 24969 contrasts with the decreased 5HT turnover in the LC. It is consistent with the relief, by a selective 5HT1 agonist, of a tonic inhibition steming from 5HT neurons onto NA-LC perikarya. Such an interpretation is in keeping with the fact that iontophoretically applied 5HT on NA-LC cell suppress LC unitary activity (Segal, J. Physiol., 1979, 286 : 401-415). That 5,7DHT lesions suppress the increased LC cell activity suggests that 5HT1 receptors, stimulated by RU 24969, are located on 5HT neurons either at the level of the raphe perikarya or the 5HT terminals in the LC. This suggestion is reinforced by the fact that another 5HT1 agonist, PAT, iontophoretically applied on raphe dorsalis neurons suppresses their unitary activity (De Montigny et al., Neuropharmacology, 1984, 23 : 1511-1520).

243.7 LOCUS COERULEUS: AUTONOMIC INFLUENCE ON NEURONAL ACTIVITY AND BEHAVIOR. T.H. Svensson, M. Elam*, P. Thorén* and B. Persson*. Department of Pharmacology, Karolinska Institutet, Box 60400, 104 01 Stockholm, Sweden and Departments of Pharmacology & Physiology, University of Göteborg, Box 33031, 400 33 Göteborg, Sweden

In 1929 Cannon outlined various endogenous stimuli for sympathetic activation including haemorrhage, hypotension, hypercapnia, hypoxia and noxious stimuli. In a series of investigations we have showed that brain norepinephrine (NE) neurons in the LC respond with activation to the same stimuli. Here we report experiments demonstrating the cardiovascular and visceral influence on LC activity and evidence for behavioral consequences of such autonomic influence on brain function. Parallel recordings of single units in the LC and sympathetic splanchnic nerve activity (SNA) were performed in chloralhydrate anesthetized rats. Some behavioral results are also reported.

Both LC activity and SNA were highly responsive to peripherally induced alterations in blood pressure or blood volume. All responses of LC neurons were consistently abolished by bilateral, cervical vagotomy. In contrast, SNA changes in response to blood pressure variations were abolished by denervation of arterial baroreceptors but not by bilateral vagotomy. Generally, our results allow the conclusion that not only splanchnic nerves, but also LC neurons are regulated by cardiovascular afferents. However, whereas SNA is controlled by both arterial baroreceptors and cardiac volume receptors, the LC is controlled exclusively by cardiac volume receptors.

We have also found, that visceral events such as filling and emptying of the bladder and distal colon within a physiologically relevant range cause consistent and corresponding alterations in LC activity but not in SNA. Thus, the LC respond to a broad set of internal vegetative stimuli.

Peripheral, cardiovascular events such as changes in blood volume were associated with corresponding changes in synthesis and utilization of NE in brain regions innervated by the LC, i.e. cerebral cortex cerebellum, whereas other brain neurotransmitters such as serotonin (5-hydroxytryptamine, 5-HT) or dopamine (DA) did not show similar biochemically detected alterations. Interestingly, peripherally induced changes in blood volume were also associated with global changes in behavior. For example, volume load caused reduced exploratory activity in rats placed in a novel environment.

Consequently, endogenous autonomic stimuli may via the LC influence the response of the individual to external, environmental demands.

243.8 THE NUCLEUS LOCUS COERULEUS: EXTENSIVE EFFERENTS BUT RESTRICTED AFFERENTS AS REVEALED BY TRANSPORT OF DISCRETELY INJECTED PEROXIDASE-LABELED WHEAT GERM AGGLUTININ. G. Aston-Jones, M. Ennis, W. T. Nickell[1] and M. T. Shipley[1]. Dept. Biology, Wash. Sq. Cntr. Neural Sci., New York Univ., New York, NY 10003, and [1]Dept. Anat. Cell Biol., Univ. Cincinnati Col. Med., Cincinnati, OH 45267.

Knowledge of afferent cells that control discharge of locus coeruleus (LC) neurons is a critically necessary but lacking element in understanding the functions of this pervasive noradrenergic system. The sensitivity and specificity of transport techniques have increased substantially since previous investigations of LC afferents. Therefore, in this and a companion study (Ennis et al., this volume), we have initiated a comprehensive anatomic and physiologic examination of CNS systems that innervate LC.

In the present study, neurons afferent to LC, and efferent LC fiber trajectories, were investigated with discrete injections of wheat germ agglutinin conjugated to horseradish peroxidase (WGA-HRP). Injections were made unilaterally into LC of chloral hydrate anesthetized rats using glass micropipettes (2-4 um tip diameter) filled with a 1% WGA-HRP solution. Survival times of 24-72 h were examined, and frozen 40 um-thick sections were reacted with tetramethylbenzidine. Data are reported here from a total of 4 animals with effective injection sites covering approximately 90% or more of the LC nucleus.

These injections consistently yielded a diverse and ubiquitous system of anterogradely labeled fibers. Pronounced fiber labeling was evident rostrally in, e.g., ipsilateral olfactory bulb and cerebrocortex and bilaterally in hippocampus, while intensely labeled fibers were found caudally in specific regions of the medulla and spinal cord. In particular, distinct patterns of lamination were apparent throughout ipsilateral cerebrocortex, and fiber pathways could be traced into the ipsilateral stria terminalis and external capsule. Labeled fibers were of moderate density in the central cervical nucleus of the spinal cord, bilaterally dense in the vestibular nuclei and inferior olive, and ipsilaterally very dense in the central nucleus of the amygdala.

In contrast to the extensive efferent fiber plexus, retrogradely labeled perikarya were quite restricted and generally few in number. Unlike previous reports, retrogradely labeled somata were not noted in the central amygdaloid nucleus, nucleus tractus solitarius or the spinal dorsal horn cell columns. The contralateral LC was notably devoid of labeled fibers or somata. Areas containing the most numerous retrogradely labeled neurons included the ipsilateral parabrachial and vestibular nuclei and the ventrolateral medullary reticular formation. Afferent innervation of LC also appeared to originate in the medullary parafasicular reticular formation and the cervical spinal gray matter.

Physiologic investigations of LC afferents in our companion study concur with these anatomic data. Supported by PHS grants NS 22320, AA 06607, and the Alzheimer's Disease & Related Disorders Assoc. to G. A.-J.

243.9 ELECTROPHYSIOLOGIC STUDIES OF NEURONS PROJECTING TO NUCLEUS LOCUS COERULEUS. M. Ennis, G. Aston-Jones and M. Segal[1]. Dept. Biology, Wash. Sq. Cntr. Neural Sci., New York Univ., NY, NY 10003, and [1]Weizmann Inst., Rehovot, Israel.

Previous anatomic reports indicate that locus coeruleus (LC) neurons receive afferents from diverse brain areas. Physiologic confirmation of these anatomic studies would substantiate their conclusions. Here, focal LC stimulation was used in an attempt to physiologically identify afferent neurons by antidromic activation. Putative afferent nuclei tested to date include ipsilateral rostral nucleus tractus solitarius (NTS; area of C2 adrenergic neurons), lateral reticular nucleus (LRN), and contralateral LC.

Adjacent paired microwires (50 um-diameter) were used for bipolar stimulation of LC in chloral hydrate anesthetized rats. Extracellular impulses were recorded from conventional glass micropipettes. Stimuli were 0.5 ms in duration, and 0.1-0.8 mA in amplitude. Driven cells were subjected to the following tests for antidromicity: (1) constant latency activation at threshold, (2) activation by pulse pairs of 5 ms intervals or shorter, and (3) collision between spontaneously occurring and driven impulses. All stimulation sites were histologically localized to LC, and recording sites were identified with dye deposited from pipette tips. Continuous low frequency stimulation (about 1/sec) was used to maximize detection of possible non-spontaneous cells during recording penetrations.

Of 9 neurons encountered in 11 histologically verified electrode penetrations through NTS, none were activated by stimulation of the LC. This result is consistent with our previous report (Ennis and Aston-Jones, Soc. Neurosci. Abstr., 1984) that lesions to this area do not alter discharge of LC neurons. This result is also supported by results of our companion study (Aston-Jones et al., this volume) that perikarya in NTS are not labeled following injections of retrograde tracer into LC.

Nine of 26 LRN cells recorded in 5 rats yielded constant latency and high frequency (up to 400 Hz) activation, but failed to exhibit collision between spontaneous and driven impulses. These neurons fired spontaneously at rates up to 20 Hz, and latencies for activation ranged from 1.5 to 3.0 ms. These results may reflect very secure synaptic driving from LC neurons, nearby structures, or fibers of passage. Two other neurons in this area were not spontaneously active, and were driven at latencies of 8 and 14 ms. These cells were shown to follow LC stimulation at frequencies over 300 Hz, but collision testing was not possible.

In 3 rats, 2 of 26 LC neurons recorded during contralateral LC stimulation were antidromically activated; however, the stimulation site for these driven cells was slightly ventral to LC. Eight other LC neurons were synaptically activated, but only at high stimulus intensities. Post-stimulus inhibition was found in all cells examined, with or without preceeding activation. The sparse antidromic activation observed here is consistent with results of our companion study (Aston-Jones et al., this volume) that retrograde labeling was not found between the loci coeruleus.

243.10 PROJECTIONS OF PONTINE NORADRENERGIC CELLS TO CRANIAL NERVE NUCLEI: A RETROGRADE TRANSPORT AND IMMUNOCYTOCHEMICAL STUDY IN THE RAT. R. Grzanna and W.K. Chee*. The Johns Hopkins University School of Medicine, Baltimore, MD 21205.

The origin of noradrenergic (NA) afferents to cranial nerve nuclei was studied by combining retrograde transport of True Blue (TB) with dopamine-ß-hydroxylase (DBH) immunocytochemistry. Discrete injections of TB were made into the motor nuclei of the trigeminal and facial nerve and into the sensory nucleus of the trigeminal nerve at rostral medullary levels (spinal trigeminal nucleus pars oralis) of rats. After 2-4 week survival, brainstem sections were processed for DBH immunocytochemistry using the indirect FITC method to visualize NA cells. Retrogradely labeled NA cells were counted in the locus coeruleus (LC), subcoeruleus (SC), and the A5-A7 cell group and their percentage with respect to the total number of NA cells within each groups was determined. Injections of TB into the trigeminal motor nucleus labeled primarily ipsilateral A7 cells (35%) and rostral A5 cells (18%). No labeled cells were seen in the LC and SC. Tracer injections into the facial motor nucleus labeled ipsilateral A5 cells (32%), contralateral A5 cells (13%) and A7 cells bilaterally (17%). Very few labeled cells ( 1%) were observed in the LC and SC. Injections of TB into the spinal trigeminal nucleus labeled cells in the LC and SC ipsilaterally (10 and 17%) and contralaterally (10 and 11%) in addition to a moderate number of cells in the A5 and A7 group. None of the injections labeled NA cells in the medulla.

A comparison of the labeling pattern of pontine NA cells after injections of TB into each of the 3 brainstem nuclei revealed striking differences: The NA innervation of the motor nucleus of the trigeminal nerve arises almost entirely from cells of the A7 group, while the NA innervation of the motor nucleus of the facial nerve arise primarily from the A5 group. The LC and SC do not project to these brainstem motor nuclei. In contrast, the NA innervation of the spinal trigeminal nucleus arises primarily from cells of the LC. The data indicate that NA afferents to motor and sensory nuclei of the brainstem arise from different subpopulations of NA neurons in the pons each of which has a restricted terminal distribution among brainstem motor and sensory nuclei. The NA innervation of the brainstem is not diffuse but is derived from separate NA cells projecting to restricted regions. This anatomic organization argues against a global influence of NA neurons on functionally diverse brainstem structures and suggests that subsets of NA cells may engage selectively restricted regions within the brainstem. (Supported by NS 16654, NS 21011 and NS 15199.)

243.11 PERSISTENCE OF NORADRENERGIC FIBERS IN THE CEREBELLAR CORTEX OF PURKINJE CELL DEGENERATION (pcd/pcd) MUTANT MICE FOLLOWING DEGENERATION OF PURKINJE CELLS AND GRANULE CELLS. B. Ghetti, S.Y. Felten, J.I. Nurnberger, M. Costanzo*, K. Perry*, R.W. Fuller, C.J. Alyea*, and D.L. Felten. Depts of Pathology and Psychiatry, Indiana University School of Medicine, Indianapolis, IN 46223, Dept. of Anatomy, University of Rochester School of Medicine, Rochester, NY 14642, and The Lilly Research Laboratories, Indianapolis, IN 46285.

Purkinje cell degeneration (pcd/pcd) mutant mice were examined during the course of Purkinje (P) cell death (26 and 35 day old) and at 3, 5, 9, and 12 months of age, by which time 90% of the granule cells also have degenerated (Ghetti et al, in preparation). The glyoxylic acid fluorescence histochemistry for catecholamines was used to investigate possible alterations or reorganization of the noradrenergic (NE) fibers from the coeruleo-cerebellar system in response to the degeneration of two major cell types in the cerebellar cortex, of which one, the P cell, is reported to be the major target neuron. In control mice, noradrenergic fibers traveled in linear and tortuous profiles through the granule cell layer, formed pericellular arrays alongside P cell somata, and branched profusely into both radially oriented (perpendicular to the surface) and longitudinally oriented chains. The density of NE varicosities diminished in the molecular layer with age. In pcd mutants, concomitant with the progressive shrinkage of the molecular layer, there was a progressive increase in the density of NE varicosities. This was most conspicuous at 9 and 12 months of age, at which time the molecular layer has been depleted not only of P cell dendrites, but also of parallel fibers. NE fibers in these zones formed dense parallel bundles of varicose profiles whose density reached 841.9% $\pm$ 178.6% (mean $\pm$ S.D., n=3) at 12 months of age, compared with age-matched controls. Neurochemical measurement of NE content in whole cerebellum of the pcd mutants revealed no change compared with age-matched controls. We conclude that noradrenergic innervation persists in the cerebellar cortex despite the death of P cells and most of the granule cells. Although we found an increased density of varicosities in the molecular layer of mutant mice, progressing with age, we believe that this can be explained on the basis of the resultant geometry of the altered cerebellar cortex. It appears that the health of the environment surrounding the NE fibers in cerebellar cortex has little influence on their anatomical integrity. Supported in part by NIH grant NS 14226 to B.G. and by a MacArthur Foundation Prize Fellowship (DLF).

243.12 MORPHOLOGICAL AND HISTOCHEMICAL CHARACTERISTICS OF DOPAMINE-CONTAINING NEURONS OF THE MAMMALIAN SPINAL CORD, IN VITRO AND IN VIVO. A.P. Mariani*, M.T. Caserta and J.L. Barker. Laboratory of Neurophysiology, NINCDS, NIH, Bethesda, MD 20205

Although catecholamine-containing neurons of the brain are thought to project to the spinal cord, no cell bodies of intrinsic spinal cord neurons are known to be catecholaminergic. Now, by using an aldehyde method for the fluorescent visualization of catecholamines, and immunohistochemistry, the morphology of three distinct classes of dopamine-containing neurons from the spinal cord have been revealed in vitro and in vivo. Dissociated cultures of spinal cords from embryonic (E) day 13 mice or E 14 rats, devoid of dorsal root ganglia, were maintained according to well-established protocols. Five percent of the cultured neurons fixed by the formaldehyde-glutaraldehyde (Faglu) method displayed the bluish-green fluorescence characteristic of catecholamines, and were of three distinct morphologies. The most common type of catecholamine-containing spinal cord neuron was a small bipolar cell (63 percent), with a 16-20 µm diameter cell body and two thick processes projecting from opposite poles of the cell. The second type of catecholamine-containing neuron (27 percent) was relatively large with a 50 µm diameter flattened perikaryon which gave rise to a variable number of varicose and/or spiny processes. Medium-sized multipolar cells with 25-30 µm diameter cell bodies constituted the third type of catecholamine-containing neuron (10 percent) and had four to six processes with secondary and tertiary branches radiating outward from the perikaryon. To better ascertain the identity of the catecholamine, cultures were also stained with antibodies to the catecholamine synthesizing enzymes, tyrosine hydroxylase (TH), dopamine-ß-hydroxylase (DßH) and phenylethanolamine-N-methyltransferase (PNMT). Cells identical in morphology to the types detected by Faglu fluorescence were immunoreactive for TH, but not DßH or PNMT. To find if there were in vivo correlates to the in vitro results, we treated adult rats with a monoamine oxidase inhibitor and perfused them with Faglu. Sections of the thoracic spinal cord displayed catecholamine-containing neurons similar in size and morphology to the small bipolar cells in culture. These neurons had a rostral-caudal, V-shaped organization, beginning in the gray matter near the central canal and extending into the white matter adjacent to the intermediolateral cell column.

244.1 A GRADED RETROGRADE MEMORY IMPAIRMENT AFTER LESIONS OF THE BASAL FOREBRAIN IN THE RHESUS MONKEY.
M.B. Moss and D.L. Rosene. Department of Anatomy, Boston Univ. Sch. of Med., Boston, MA, 02118.

Over the past few years, evidence from neuropathological studies has implicated structures in the basal forebrain (nucleus basalis of Meynert and substantia innominata) in the severe memory impairment of Alzheimer's disease (as well as of other dementia and amnesic disorders). More recently in animals, direct evidence of basal forebrain involvement in memory function has begun to emerge. We now report our observation of a graded retrograde memory impairment following basal forebrain lesions in the rhesus monkey. Seven normal adult rhesus monkeys were trained preoperatively for one and one-half years on a battery of discrimination learning and visual memory tasks. Over the course of this preoperative phase, a total of five different two-choice pattern discrimination problems were administered, at approximately three month intervals, within a series of recognition and associative memory tasks. For the animals designated as the basal forebrain group, the last discrimination problem was administered two days before surgery. Upon completion of this phase of testing, four of the animals received two-stage bilateral ablations of the basal forebrain under direct visual guidance by intracerebral injection of the neurotoxin, ibotenic acid. The remaining three animals served as an unoperated control group. Following three weeks recovery from surgery and one week of other behavioral testing, all animals were retested on the five preoperatively acquired pattern discrimination problems. Monkeys were retrained on one discrimination problem per day and the pairs of patterns were presented in the same order that they were administered preoperatively. For the normal control animals, savings scores for the first pattern discrimination were 82, 100 and 100 (mean score of 94). The four monkeys with BF lesions performed equally well, obtaining saving scores of 83, 88, 96 and 100 (mean score of 92). On the subsequent four pattern discrimination problems, normal monkeys achieved group mean savings scores of 96, 92, 91 and 93 respectively. In contrast, the BF group showed significantly diminished savings over the four pattern discriminations with means of 61, 68, 52 and 23, respectively. The results not only reveal a retrograde memory impairment for associative learning as a consequence of basal forebrain lesions, but also point to a temporal gradient, characterized by a greater savings of remote, as opposed to recent, preoperative learning. Further, these findings suggest the possibility that patients in the early stages of Alzheimer's disease who demonstrate a temporally graded retrograde impairment, may reflect those cases in which neuropathological changes begin in, or primarily affect, the basal forebrain.

244.2 PATTERNS OF ACHE LOSS IN THE HIPPOCAMPAL FORMATION OF MONKEYS FOLLOWING LESIONS OF THE BASAL FOREBRAIN: A QUANTITATIVE HISTOCHEMICAL STUDY. D.L. Rosene and M.B. Moss. (SPON: B. Payne) Dept of Anatomy, Boston University School of Medicine, Boston, MA, 02118.

The basal forebrain of the monkey contains a large population of cholinergic neurons which are known to project to the cerebral cortex and limbic system. However, the specific pattern and extent of cholinergic loss within target sites after basal forebrain damage is not known. Using the enzyme acetylcholinesterase (AChE) as a marker for cholinergic activity, we have employed a quantitative histochemical approach to assess the extent and pattern of cholinergic depletion in the hippocampal formation in monkeys following restricted lesions within the basal forebrain. Under direct surgical exposure, three rhesus monkeys received bilateral lesions of the basal forebrain by intracerebral injection of the neurotoxin, ibotenic acid. Following extensive behavioral testing, the monkeys were sacrificed and then perfused transcardially with quarter-strength Karnovsky's fixative. The tissue was then processed with both the Karnovsky-Roots and Koelle procedures for identification of AChE. The reaction product of the Karnovsky-Roots procedure, copper ferrocyanide, was quantified using a scanning and integrating microdensitometer set at an absorbtion spectra of 485 nm. On the basis of other studies in this laboratory which demonstrate basal forebrain efferent termination in the hippocampal formation, measurements of AChE were made within all laminae of hippocampal sectors CA3, CA1 and the dentate gyrus, as well as in selected sites in the subicular complex. The measurements were taken at four equally spaced rostro-caudal levels throughout the length of the hippocampal formation. In order to control for interslide variability, all measures were expressed as a percentage of the AChE density in the tail of the caudate measured in the same section. Extensive loss of AChE was, on the whole, limited to the most rostral (uncal) part of the hippocampal formation. Within the uncal hippocampus, loss of AChE occured in CA1, the adjacent prosubiculum, specific laminae of CA3, and the presubiculum. In the three more caudal levels of the hippocampal formation, loss of AChE density was found only within specific areas of the subicular complex. The relationship between damage in specific areas of the basal forebrain and the resulting loss of cholinergic activity in the hippocampal formation may help in our eventual understanding of how these two regions may interact in the neuropathological basis of the characteristic memory disorder of Alzheimer's Disease.

244.3 MEMORY DEFICITS IN MONKEYS WITH MEDIODORSAL THALAMIC LESIONS.
E.C. Gower, D.L. Kasdon*, S. Jacobson and N.M. Butters. V A Medical Center, Boston, MA 02130.

The mediodorsal nucleus of the thalamus (MD) is frequently involved in the diencephalic pathology accompanying human memory disturbances. The present ongoing experiments explore the contribution of MD to mnemonic processes by examining (1). the retention of preoperative discrimination learning and (2). the acquisition and retention of new material in monkeys (M. fascicularis) with medial thalamic lesions.

Electrolytic lesions were made bilaterally in the mediodorsal nucleus following retraction of the walls of the interhemispheric fissure, section of the splenium of the corpus callosum, and visualization of the thalamus. The position of MD was calculated and the lesion electrode placed stereotaxically using the observed location of the habenular commissure as coordinate zero. Controls include monkeys subject to splenium section, and normal animals. The lesions have not yet been histologically confirmed.

After a postsurgical recess, monkeys were tested for the retention of three 2-choice visual pattern discriminations which had been learned individually six, three and one week prior to surgery. The three pattern pairs were relearned postoperatively as a concurrent discrimination problem. The experimental group displayed a modest overall deficit in relearning compared with the high level of savings shown by normal and operated control groups. No systematic difference appeared in the retention of individual pattern pairs for normal and control monkeys. In contrast, monkeys with thalamic lesions exhibited a significantly lower degree of retention for the immediate presurgical problem only ($t(4)=2.41$, $p<.05$ (one-sided test)).

All monkeys were further tested with a trial-unique, non-matching-to-sample test of object recognition memory, with sample objects drawn from a pool of 700. Compared with normals and controls, experimental monkeys were moderately impaired in learning the non-matching problem with a delay of 10 seconds, and were further impaired in performance on longer delays. These data indicate that medial thalamic lesions may retard the acquisition of a new rule governing discrimination behavior as well as impair retention of trial-specific events. Moreover the relearning deficit which is specific to pattern pairs presented shortly prior to surgery is reminiscent of the temporally graded retrograde memory defect of amnestic patients. (Supported by VA Medical Research funds).

244.4 SPARING OF VISUAL RECOGNITION AFTER NEONATAL LESIONS OF INFERIOR TEMPORAL CORTEX IN INFANT RHESUS MONKEYS.
C. Hagger*, M. Brickson* and J. Bachevalier. Lab. of Neuropsychology, NIMH, Bethesda, MD 20205.

Visual recognition measured by preferential viewing develops early in infancy and, like visual recognition measured with problem-solving tasks in adults, is dependent on the integrity of limbic structures (Brickson and Bachevalier, Soc. Neurosc. Abstr., 10:137, 1984). Since visual recognition measured with problem-solving tasks in adults is also dependent on inferior temporal cortex (area TE) (Mishkin, Phil. Trans. R. Soc. Lond., B 298:85, 1982), we tested whether removal of this cortical area in infancy would, like neonatal limbic lesions, impair visual recognition measured by preferential viewing.

Twelve infant and 8 adult rhesus monkeys served as unoperated controls, and 3 infants and 3 adults received bilateral area TE lesions. The infants received their bilateral ablations in two stages, at 7 and 21 days of age, while the adults received theirs in one stage. Separate sets of trial-unique objects were shown to the infants at 5, 15, and 30 days of age, while only the first set was presented to the adults. For each of ten trials, animals were exposed to a pair of identical objects for a 30-sec familiarization period, and then, after 10 seconds, the previously exposed object was paired with a new one for two 5-sec recognition periods, with the position of the 2 objects being reversed from one period to the next. Percent of fixation time (PFT) spent on the novel object was measured for each trial.

Like normal adults, the normal infant monkeys between 15 and 30 days of age gazed at the novel stimuli more than at the stimuli already gazed at several seconds earlier (mean PFT: 54%, 66%, and 73% for 15 days, 30 days, and adults, respectively). Surprisingly, however, even though the visual preference for novelty was completely absent in adults with bilateral area TE lesions (mean PFT: 49%), it was preserved in both the 15-day-old infants with unilateral area TE lesions and the 30-day-old infants with bilateral area TE lesions (mean PFT: 64% and 66%, respectively).

These findings support earlier data showing that visual recognition approaches adult levels even in early infancy and suggest further that, although area TE is involved in recognition memory in adults, neonatal removal of this cortical area leads to significant sparing of this function.

244.5 EVIDENCE FOR INVOLVEMENT OF PREFRONTAL CORTEX IN COGNITIVE CHANGES DURING THE FIRST YEAR OF LIFE: COMPARISON OF PERFORMANCE OF HUMAN INFANTS AND RHESUS MONKEYS ON A DETOUR TASK WITH TRANSPARENT BARRIER. A. Diamond and P. Goldman-Rakic, Section of Neuroanatomy, Yale School of Medicine, New Haven, CT 06510.

Infants of 7½-12 months show a developmental progression in performance of Piaget's classic AB task, which taps the child's ability to remember the location of a hidden object. We have shown earlier that lesions of prefrontal cortex in adult monkeys selectively impair AB performance, reducing it to the level of 7½-9 month old human infants (Diamond & Goldman-Rakic, Neurosci. Absts., 1983). We now report that prefrontal monkeys perform like 7½-9 month old human infants on Object Retrieval (OR), a detour problem requiring the subject to suppress the tendency to reach directly to an object. These findings are relevant to the neural basis of cognitive development.

Ss were 25 human infants, tested biweekly from 6-12 months, and 9 adult rhesus monkeys (Macaca Mulatta): 3 with bilateral lesions of dorsolatal prefrontal cortex, 3 with bilateral lesions of parietal cortex, and 3 unoperated.

On each OR trial, a bait (toy for infants, food for monkeys) was placed inside a transparent box open on one side. Experimental variables included: (a) side of box opening (left, right, front), (b) position of box (far left, far right, middle), and (c) position of bait in box (partially out, inside near opening, deep in box). A fully crossed experimental design was used with order of conditions counterbalanced across testing sessions. The bait was always visible, but the experimental variables jointly controlled whether bait was seen through the open or closed sides of the box.

Infants of 7½-9 months and prefrontal monkeys needed to have seen bait through the opening in order to reach in and retrieve it. Otherwise, they reached only at the closed sides of the box through which they saw bait. They also displayed an "awkward reach" when the left or right sides were open, i.e., they reached with the hand farthest from the opening. In contrast, 12 months old infants and intact, and parietal, adult monkeys reached into the box without having looked in, and used the hand nearest the opening.

These results demonstrate a link between the prefrontal cortex and a task quite different from AB. Object Retrieval is not a hiding task, nor is AB a detour task. However, both tasks require association of events separated in time (AB) or space (OR) and both require inhibition of prepotent responses (in AB: tendency to repeat previously rewarded response; in OR: reaching directly to goal). These cardinal functions, impaired by frontal lobe lesions in both monkeys and man, develop during the first year and establish the basic structure for future cognitive achievements.

244.6 A COMPARISON OF CORTICAL AND SUBCORTICAL MEMORY IMPAIRMENTS M. El-Awar* , J.T. Becker, K.M. Hammond* , & F. Boller* , Depts. of Neurology & Psychiatry, Univ. Pittsburgh, Pittsburgh, PA 15213

Alzheimer's Disease (AD) in its early stages affects primarily areas of neocortex, and is often considered a cortical dementia. Parkinson's Disease (PD), on the other hand, primarily affects subcortical areas, and the dementia associated with PD differs from that of AD. In order to compare the nature and extent of the memory loss in these two dementia syndromes, patients with AD (n=12), PD (n=12), and normal control subjects (n=12) were given a battery of neuropsychological tests which included a detailed study of their verbal learning abilities.

All of the subjects were given a short battery of tests to assess the extent of their cognitive decline, including tests of verbal fluency and confrontation naming. The verbal paired-associate learning test consisted of teaching the subjects ten arbitrary associations between word pairs. Training continued until they had either learned all 10 pairs, or they had been tested for 10 trials. One hour after the completion of the acquisition training, the patients were given two tests of recall and two tests of recognition memory to examine their ability to remember the response words, and the specific associations between stimulus and response words.

The patients with AD and PD learned the paired-associates at a slower rate than the controls. The AD patients, however, learned significantly less than the PD patients, in part due to the greater severity of the dementia in AD. Performance of the delayed memory tests clearly distinguished the groups of patients. The PD patients recalled less than the control subjects, while the AD patients, who learned few associations, recalled essentially none. On the recognition tasks both the controls and the PD patients were equally proficient at recognizing the response words and the correct associations. However, the AD patients, although relatively good at recognizing the response words, were unable to recognize the correct associations. Thus, although they had stored information about the response words, they had not stored information about the specific associations.

There were also differences in the types of errors made by the patients during learning. When the AD patients were incorrect, they tended to make semantic associations to the stimulus words (e.g., honey-bee for honey-thread). In contrast, the patients with PD made errors by responding with semantic associations to the response words (e.g., honey-string).

These data, therefore, suggest that the patterns and types of memory impairment in the dementias of AD and PD are different. These differences do not appear to be related to the relative severity of the overall cognitive impairment and may reflect the differential contribution of the CNS structures damaged in AD and PD to memory processing.

244.7 IMPAIRED SPATIAL MAPPING AFTER DISRUPTION OF SOME ROSTRAL CONNECTIONS OF THE HIPPOCAMPAL SYSTEM IN RATS. R. J. Sutherland, G. Prusky*, R. H. Dyck and A. Rodriguez*, Dept. of Psychol., The Univ. of Lethbridge, Lethbridge, Alberta, Canada T1K 3M4.

The integrity of the hippocampal formation (HPC) and retroHPC area is essential for normal use of mapping strategies in solving spatial problems. This has been most clearly demonstrated in rats using the place navigation task (Morris, R. et al., Learn. & Motiv., 12:239, 1980; Nature, 297:681, 1982; Sutherland et al., Soc. Neurosci. Abstr., 6:565, 1980; Behav. Brain Res., 7:133, 1983). Damage to intrinsic HPC components impairs performance in situations requiring either acquisition or retention of spatial mapping (Sutherland et al., Soc. Neurosci. Abstr., 9:638, 1983). In the following four experiments we examine the contribution of HPC connections in the fornix/fimbria to acquisition and usage of mapping and non-mapping spatial localization strategies.

In the first experiment normal rats and rats with fornix/fimbria transection were trained to navigate to an invisible, fixed platform and to a visible, fixed platform in a large circular pool. Unlike normal rats, the fornix/fimbria transected rats could not learn to swim directly to the invisible platform, instead they learned to solve the problem using a stereotyped circumnavigation strategy. Both groups swam directly to the visible platform. Rats with additional bilateral damage to the overlying cingulate cortex were impaired at locating the visible platform and did not acquire an efficient non-mapping strategy to locate the invisible platform. In the second experiment rats were implanted with a stimulation electrode in the fornix and bilateral EEG electrodes in the dorsal HPC and posterior neocortex. All rats acquired a mapping strategy to locate the invisible, fixed platform. Place navigation was disrupted for 60 - 300 sec following fornix stimulation (40 μA, 100 pps, .2 ms for 15 sec) even though HPC and neocortical EEG was unaffected at these intervals. Stimulation immediately after learning a new location disrupted navigation at much longer post-stimulation intervals.

Microinjections of the retrograde fluorescent dye True Blue into the basal forebrain confirmed the existence of major projections to the nucleus accumbens from several limbic structures, most importantly from ipsilateral subiculum, CA1, amygdala, entorhinal cortex, perirhinal cortex, and olfactory bulbs. These structures project differentially to medial and lateral nucleus accumbens. Electrolytic lesions were placed in medial lateral or both medial and lateral nucleus accumbens and the rats were subsequently trained to navigate to the fixed, invisible and fixed, visible platforms. Navigation to the invisible platform was impaired.

These results emphasize the importance of some rostral HPC system connections, particularly with both the acquisition and usage of spatial mapping strategies.

244.8 THE ONTOGENY OF MAPPING AND NON-MAPPING SPATIAL STRATEGIES FOLLOWING NEONATAL HIPPOCAMPAL DAMAGE IN RATS. R. H. Dyck, R. J. Sutherland and M. R. Buday*. Dept. of Psychol., The University of Lethbridge, Lethbridge, Alberta, Canada T1K 3M4.

The ability to use spatial mapping strategies is a late-developing cognitive skill in rats and humans. In the place navigation task, rats do not use an adult-like mapping strategy until some time after the 4th week of life, by which time the hippocampal formation (HPC) has attained a nearly adult degree of anatomical and physiological maturity (Schenk, F., Behav. Neural. Biol., 43:69, 1984). In the present experiments the ontogeny of mapping and non-mapping spatial strategies was examined in normal rats and rats with HPC and/or posterior neocortical damage sustained in infancy.

Within 48 hr after birth rat pups were anesthetized by hypothermia and vinblastine, vincristine or colchicine (.06 - .3 μg/.5 μl) was microinjected bilaterally into HPC or posterior neocortex. Beginning on the day of eye-opening (approx. day 15) the rats received 4 trials daily in the place navigation task with a fixed, invisible platform or a fixed, visible platform. By day 19 all rats were able to swim almost directly from any starting location to the visible platform. Prior to day 24 of life the behaviour of the normal, HPC- and posterior neocortex-damaged rats was indistinguishable in the invisible platform condition. After day 24 of life the control rats began to swim almost directly to the invisible platform from any starting location; the rats with extensive HPC or posterior neocortex damage were never able to navigate directly to the invisible platform. When re-tested as adults the HPC-damaged rats demonstrated acquisition of an efficient non-mapping strategy, involving stereotyped circumnavigation of the pool. Rats with incomplete or unilateral damage eventually learned to navigate directly to the invisible platform.

The results are consistent with the idea that the post-natal maturation of the HPC selectively underlies the ontogeny of cognitive mapping ability and that neonatal HPC damage is associated with little or no sparing of mapping functions.

244.9 DIFFERENTIAL CONTRIBUTION OF PARIETAL CORTEX AND HIPPOCAMPAL FORMATION IN THE RETENTION OF A COGNITIVE MAPPING TASK. B. V. DiMattia* and R. P. Kesner, Dept. of Psychology, Univ. of Utah, Salt Lake City, Utah 84112.

The hippocampal formation (HF) has been labeled the locus of the 'cognitive map' in the brain (O'Keefe & Nadel, 1978). Many studies have demonstrated HF involvement in the acquisition of cognitive mapping tasks, although there is conflicting evidence regarding the role of HF in the retention of such tasks.

However, based on symptomatology from brain damaged humans, one might be tempted to argue that the parietal cortex (PC) is more important for spatial information processing than HF. Parietal lobe patients are impaired in both the acquisition and retention of spatial or geographic information.

In a previous study both PC and HF damaged rats were impaired in the acquisition of the Morris water maze task (DiMattia & Kesner, 1984), which is considered to require cognitive mapping (Morris et al., 1981). The present experiment tested the effects of PC and HF lesions on the retention of this task. Rats were given varying degrees of preoperative training (40 to 80 trials) prior to receiving complete PC (aspiration) or HF (electrolytic) lesions.

Following a 7-10 day recovery period the animals were given 40 retention trials in the maze. The results indicated that, in terms of latency to find the hidden platform, the PC animals were impaired across all postoperative trials, regardless of the number of preoperative trials. However, in general, the HF animals were less impaired than the PC animals and improved across postoperative trials such that their latencies were within normal limits for the last 20 trials in both the 40 and 80 preoperative trial conditions. However, both HF and PC damaged rats were impaired relative to controls in their directional heading toward the hidden platform, regardless of whether the animals had 40 or 80 preoperative trials. This dissociation in performance measures might be accounted for by the fact that a large percentage of the HF lesioned animals tended to use a 'praxic' strategy to find the hidden platform (i.e., to swim in a concentric pattern until they encountered the platform), although some PC rats also employed such a strategy.

These data strongly implicated a role for PC in the retention of spatial information in the rat in tasks that require cognitive mapping. It cannot, however, be argued conclusively that the HF does not play a role in the retention of the task, since there was no recovery for directional heading toward the platform.

244.10 DORSOMEDIAL THALAMIC LESIONS: POST-OPERATIVE IMPAIRMENT OF RADIAL MAZE PERFORMANCE, BRIGHTNESS DISCRIMINATION LEARNING AND CHANGES IN OPEN FIELD ACTIVITY. K. A. Stokes* and P. J. Best. Dept. of Psychology, University of Virginia, Charlottesville, VA, 22901. (SPON.: J. Hahn)

The role of the dorsomedial thalamus (DMT) in memory is not yet clearly understood. Through its connections to frontal cortical and hippocampal systems, a role in spatial information processing might be postulated. Yet results here are equivocal. DMT lesions have variously been found to have no effect on post-operative acquisition of a radial maze habit (Kolb, Sutherland and Whishaw, Behav. Br. Res., 6, 1982, 365) and to produce marked impairments on spatial task performance (Kessler, Markowitsch and Otto, J. Comp. Physiol. Psychol. 96, 1982, 712; B. McNaughton, personal communication). The present experiment investigated behavioural consequences of DMT lesions on three tasks: a pre-operatively well-learned delayed memory for 4 choices task on the 8-arm radial maze; brightness discrimination on a T-maze, and open field activity.

Thirteen male Long-Evans rats were pre-operatively overtrained on the 8-arm maze habit, followed by the delayed memory for 4 choices task. This involved forcing the animals to respond to 4 arms of the maze (the daily sequence of which varied in a random manner), then, after a one hour delay in which the animals were removed from the maze, requiring them to respond to the 4 previously-blocked arms for reinforcement. Radial maze testing, as well as all other behavioural testing,was conducted in a dimly-lit, visually-deprived environment. DMT lesions were performed on half of the subjects after the task had been well-learned (approx. 80 trials). Four days later, testing was resumed. Post-operative tesing revealled that DMT lesioned animals were severely and lastingly impaired on the post-delay 4 choices. Number of entries into incorrect arms, as well as number of perseverative errors increased significantly in the lesioned compared to sham operated animals. Pre-delay responding was impaired as well. Subsequent testing on the simple 8-arm maze task also yielded significantly poorer performance by DMT rats, due mainly to the development of rigid, maladaptive response strategies. Neither could the DMT rats acquire a brightness discrimination task in a T-maze: they instead developed position habits and perseverated on these, regardless of reinforcement contingency. On the third task, open field testing, DMT animals exhibited greater activity levels and enhanced thigmotaxis compared to sham controls.

Thus, DMT animals are impaired on spatial tasks, especially in an environment where minimal cues are available to guide responding. Also, DMT animals exhibit hyperactivity and perseveration which compete with adequate solution of the task at hand.

244.11 LESIONS OF THE NUCLEUS BASALIS MAGNOCELLULARIS IMPAIR MAZE LEARNING IN RATS. D.J. Hughey, G.W. Wenk, and D.S. Olton, Dept. of Psychology, The Johns Hopkins University, Baltimore, MD 21218

Damage to the basal forebrain cholinergic system has been associated with learning and memory impairments in both humans and animals (Bartus et al., 1982; Hepler et al., 1985). The following experiment examined the maze learning ability of rats with lesions of one component of this system, the nucleus basalis magnocellularis (NBM). Bilateral lesions were made in male, Sprague Dawley rats by the microinfusion of ibotenic acid into the NBM, which decreased the level of cholinergic markers in frontal cortex by approximately 45%. Control operations consisted of infusions of phosphate-buffered saline.

Rats were food-deprived to 85% of their ad lib. weights and began maze training within 7-10 days of surgery. The maze was a 14 unit T maze whose walls were constructed of 18" high Plexiglas. A curtain surrounded the perimeter of the maze in order to lessen the availability of extramaze cues. Each rat was given one trial daily for thirty days. An error was recorded each time a rat entered a blind alley.

At the beginning of training, both groups averaged approximately 15 errors per trial. The performance of both lesioned and control rats improved with training, but the latter did so at a faster rate. By the end of training, control rats had an average error score of approximately 2 errors per trial. In contrast, the lesioned rats finished training with an average of approximately 7 errors per trial.

These results demonstrate that the functional integrity of the NBM and its projection areas is important for learning the correct path through a maze. Thus, these data add to our understanding of the association between central cholinergic activity and behavior, and they may have implications for the study of animal models of the cholinergic component of Alzheimer's Disease.

244.12 Cholinergic Neurons, Learning and Recovery of Function. L.E. Harrell, T.S. Barlow* and D. Parsons*. Department of Neurology, V.A. Medical Center and University of Alabama, Birmingham, AL 35294.

Central cholinergic activity has been implicated in learning/memory processes as well as spatially cued behavior. The following two experiments were designed to evaluate the role of the cholinergic septohippocampal projection (SHP) in these types of behaviors. Both experiments employed as a behavior task the radial 8-arm maze (RAM) since performance of this task appears to be dependent on both cholinergic activity and hippocampal integrity.

Exp. I examined the interaction of individual learning strategies and recovery of function following destruction of the SHP. Ten adult rats were trained to approach 8 baited arms of a RAM. Five rats appeared to acquire the task by choosing arms non-sequentially, relying on distal environmental cues (spatial strategy; SS), while 5 employed sequential arm entry (non-spatial strategy; NSS). Rate of initial task learning was not different between groups. Lesions of the SHP result in disruption of task performance in both groups preoperatively. Postoperatively, animals employing a SS preoperatively switched to a NNS, and relearned the task significantly faster than those employing a NSS preoperatively, who continued to use this strategy.

Results of Exp. I suggested that the cholinergic SHP was important for the maintenance of spatially mediated behavior. Exp. II addressed this issue by examining acquisition of a modified version of the RAM (where only 4 arms are baited, thereby blocking the use of NSS), after SHP destruction. Control animals easily mastered the task in 39.7 $\pm$ 5.0 trials. Learning was observed over time with reduction of total selections, errors, and responses to baited and unbaited arms. Lesioned animals showed no evidence of learning after extended trials. They did develop over time some response sequencing strategies so that arm choices were no longer random.

The data from these two experiments suggest that (1) the cholinergic SHP is important for the acquisition and maintenance of spatially mediated behaviors, (2) different learning strategies can be employed to acquire the same behavior, (3) rate of recovery after brain injury can be influenced by preoperative learning strategies, and (4) loss of cholinergic function can modify learning strategies. These results suggest that losses of cholinergic neurons in Alzheimer's Disease may lead to different deficits depending on pre-morbid learning strategies.

245.1 EFFECTS OF INTRASEPTAL INFUSION OF GABA AND L-GLUTAMATE ON THE RAT'S ACOUSTIC STARTLE RESPONSE. O. A. Elabanjo* and J. H. Evans*. (Spon: R.Neuman) Department of Psychology, Memorial University of Newfoundland, St. John's, Newfoundland, Canada A1B 3X9

It has been shown that lesioning the medial septum (MS) results in increased amplitude of the rat's acoustic startle response (ASR) [Miller and Treft. Physiol. and Behav., 23, 645, 1979], but because lesioning destroys cell bodies, and terminals as well as fibers coursing through the MS, this type of treatment does not permit further analysis as to which aspect of the MS is involved in startle modulation.

To this end, the present study set out to use cell-specific inactivation by infusing 1M GABA, and cell-specific excitation by infusing 0.5M L-Glutamate into the MS. 0.9% w/v saline was used as the control vehicle. Thirty male Sprague-Dawley rats, divided into three equal groups were infused with 1.5ul of one of these solutions immediately before being presented with 80 trials of 110db white noise at a 10 sec. inter-trial interval. The premise was that GABA should act to increase the ASR's amplitude on early trials, saline should have no effect, while L-Glutamate should decrease it. Since GABA and L-Glutamate have been shown to act on cell bodies, any effect of the treatment may then be attributed to the actions on the cell bodies in the MS and not the fibers.

The results show that L-Glutamate significantly depressed startle on the first 5-trial block relative to the saline control. GABA-infused rats did not differ from saline control on this measure. Cannula placements were verified by histological methods in all subjects.

245.2 LONG-TERM POTENTIATION AND THE SUSTAINED INCREASE IN GLUTAMATE RELEASE WHICH FOLLOW TETANIC STIMULATION OF THE PERFORANT PATH ARE BOTH BLOCKED BY D(-)AMINOPHOSPHONOVALERIC ACID. M.A. Lynch, M.L. Errington and T.V.P. Bliss (SPON: W.C. Abraham). National Institute for Medical Research, Mill Hill, London NW7 1AA, U.K.

D(-)aminophosphonovaleric acid (APV), a specific antagonist of the NMDA subtype of glutamate receptor, blocks the induction of long-term potentiation (LTP) in the CA1 region of the hippocampus without interfering with synaptic transmission, as first described by Collingridge et al., (J. Physiol, 334, 33, 1983). We have found that D(-)APV has a similar blocking effect on LTP in the dentate gyrus. Using a push-pull cannula with attached electrodes we have examined the relation between the effect of the drug on LTP and its effect on glutamate release. Rats anaesthetized with urethane were perfused with artificial csf for 30 min, and then with csf containing 100 uM D(-)APV for 35 min. Perfusion with control csf was then continued for a further two hours. A control group was perfused with artificial csf alone for three hours. (D)-APV did not significantly affect release, and only slightly reduced the slope of the epsp; the population spike however was reduced by an average of 54% after 35 min. A tetanus (250 Hz for 200 msec) during perfusion with APV failed to produce either LTP or the sustained increase in release of endogenous glutamate which we have previously shown to accompany LTP (Bliss et al., J.Physiol, 361, 50P, 1985). A second tetanus, given after APV had been washed out, induced both LTP and an increase in release of endogenous glutamate (see Table 1). In a separate series of experiments, D(-)APV was found to depress the $K^+$-induced, $Ca^{2+}$-dependent release of preloaded $^{14}C$ glutamate from dentate slices, implying the existence of presynaptic receptors for APV. The possibility exists therefore that the blocking of LTP by APV may be mediated by a presynaptic mechanism.

| | 1st hr | 2nd hr | 3rd hr | 1st hr | 2nd hr | 3rd hr |
|---|---|---|---|---|---|---|
| | glutamate release | | | epsp slope | | |
| APV (n=8) | 100 (14) | 64 (12) | 175 (27) | 94 | 99 | 120 |
| control(n=8) | 100 (12) | 47 (5) | 67 (9) | 99 | 93 | 92 |

Table 1. Values for glutamate release are group averages of one hour means (±SEM), expressed as percentages of mean values in the first hour. Values for the slope of the epsp are 10 min means obtained at the end of each hour, expressed as percentages of mean values obtained during the first 30 min. Test shocks were given every 30 seconds, and tetani were delivered at 60 and 120 min.

245.3 LONG-TERM ASSOCIATIVE POTENTIATION/DEPRESSION AS AN ANALOGUE OF CLASSICAL CONDITIONING. B.Burger and W.B Levy. Dept. of Neurosurgery, Univ. of Virginia Sch. of Med., Charlottesville, VA 22908.

Associative long-term potentiation as studied at the entorhinal cortex-dentate gyrus (EC-DG) synapses may be considered an analogue and candidate process for the actual synaptic changes subserving classical conditioning (CC). In this analogy the response (UCR) is the synaptic response evoked by the ipsilateral EC input (analogue of the UCS). Stimulation of the converging contralateral EC afferents provides the analogue to the CS. If the baseline contralateral response is arbitrarily called subthreshold, then associative activation of both ipsi- and contralateral inputs produces a potentiated response above threshold which resembles the ipsilateral response. Conditioning the contralateral afferents alone does not produce this increase. Furthering this analogy are the effects of preacquisition UCS exposure and preaquisition backward conditioning. Both preexposures depress acquisition of the classically conditioned nictitating membrane response, with backward conditioning more effectively retarding acquistion than simple UCS preexposure[1]. Similarly, using standard procedures for studying contralateral EC-DG synaptic modification[2,3], backward conditioning (ipsilateral then contralateral conditioning) of the contralateral EC-DG response more severely retards CR aquisition (i.e., contralateral potentiation) then simple UCS preexposure. Contralateral then ipsilateral stimulation pairing, with no preexposure, increases the contralateral response 71%, with the potentiation reaching an apparent asymptote relatively quickly. If ipsilateral conditioning stimulation precedes paired conditioning (UCS preexposure), there is only a 60% increase in the contralateral response, with a slightly slower growth in response size. Prior backward pairing (UCS then CS) of ipsilateral and contralateral conditioning stimulation, followed by normal contralateral-ipsilateral pairing, produces a 43% increase, attaining this final level much more slowly than the other two paradigms. (N=10, all groups). Thus, just as found in CC of behavioral responses, the EC-DG analogues of UCS preexposure and backward conditioning preexposure sharply attenuates associative synaptic modification. Although the synapses studied here do not mediate CC of the intact behaving animal, we hypothesize that the qualitative properties of the EC-DG synapses exist at synapses subserving the associative encoding of CC. In particular, the preacquisition effects examined here come from synaptic rather than circuit properties. [1]Siegel & Domjam. Learn.& Motiv. 2(1971)1. [2]Levy & Steward. Br.Res. 175(1979)233. 245.4 THE EXPRESSION OF LEARNING-INDUCED PLASTICITY OF SINGLE NEURONS IN THE AUDITORY CORTEX IS CONTEXT-DEPENDENT. D.M. Diamond and N.M. Weinberger. Center for the Neurobiology of Learning and Memory and Dept. of Psychobiology, U.C. Irvine, Irvine, CA 92717

Previously, we have shown that classical conditioning induces evoked plasticity in the auditory cortex of the cat. Specifically, the single neuron discharges evoked by an acoustic conditioned stimulus (CS) are altered during acquisition of the pupillary dilation conditioned response in 95% of neurons recorded in the secondary field (Beh. Neurosci., 98:189-210). In order to characterize the degree of specificity of such plasticity, we studied aspects of the receptive field properties of auditory cortical neurons by obtaining frequency response functions to isointensity tones before and after behavioral conditioning for each neuron. Evoked plasticity was often specific to the frequency of the CS, rather than reflecting associatively induced general changes in responsivity to other stimuli in the tuning function (Neurosci. Abstr., 10:245). The present report is an analysis of the relation between the manner in which cells develop evoked plasticity on single trials during conditioning and the expression of plasticity in frequency tuning functions.

Details of the procedures are presented in Neurosci. Abst. 10:245. Given that learning produces CS frequency-specific plasticity, it might be assumed that the effect is fixed, i.e., the cell is now excited either more or less by the CS frequency under all circumstances. An alternative is that learning alters the processing of the CS frequency in a manner which is not fixed, but rather is sensitive to the context in which this stimulus is presented. To resolve this issue, we compared the direction of learning induced change to the CS during single trials of conditioning with the response to the frequency of the CS when it was presented within a sequence of tones used to obtain tuning functions. A total of 19 cells were analyzed, of which 100% developed evoked plasticity on either or both single trials and tuning functions. The expression of plasticity was not the same in most cases (13/19).

These findings indicate that the effects of learning upon discharge plasticity in the auditory cortex cannot be characterized simply as an increase or decrease in response to the frequency of the CS, but also reflect the context within which the stimulus is presented. This strongly suggests that the expression of learning-induced evoked plasticity reflects processes that are related to a neural network in which individual components have a differential influence on cortical neurons depending on the context of stimulation.

245.5 EYEBLINK CONDITIONING USING LRN STIMULATION AS A CS IS ABOLISHED BY LESIONS OF THE CEREBELLAR NUCLEI. B.J. Knowlton, D.G. Lavond, J.E. Steinmetz & R.F. Thompson. Dept of Psychology, Stanford Univ, Stanford, CA 94305.

Discrete lesion of the cerebellar interpositus nucleus abolishes or prevents learning of classically conditioned somatic responses without affecting the unconditioned response. This observation has led to examination of afferents to the interpositus as possible CS pathways. The lateral reticular nucleus (LRN) has extensive projections as mossy fibers to the interpositus and cerebellar cortex. In the present study direct stimulation of the LRN was used as a CS in order to examine a) its efficacy as a CS, b) the dependence of the learned response on the cerebellar deep nuclei, and c) the degree of similarity with tone as a CS.

Adult male New Zealand White rabbits were anesthetized and implanted with bipolar stimulating electrodes in the LRN. Training consisted of 108 trials per day (30 sec mean ITI) in which the CS (LRN stimulation, 200 Hz, 350 ms, 60-300 uA) was paired with a coterminating UCS (corneal airpuff, 2.1 $N/cm^2$, 100 ms). A total of 18 rabbits received paired training and overtraining (1-3 days) followed by CS-alone extinction (4 days) and unpaired CS and UCS trials (2 days). CS-alone and unpaired training were given to evaluate the possibility of sensitization. Seven rabbits were then given ipsilateral lesions of the dentate-interpositus nuclei, allowed recovery, and given paired training (5 days). These rabbits were then trained with the air on the opposite eye (typically 2 days). Another 4 rabbits received the CS-alone and unpaired exposures before paired conditioning and overtraining.

All of the rabbits with placements near or in the LRN learned regardless of the order of training. The mean number of trials to criterion (8 CRs in 9 consecutive trials) was 79.5. (Training normally requires over 100 trials with tone as a CS.) Complete interpositus lesions abolished the CR with no recovery (N=5); relearning occurred with incomplete lesions (N=2).

The present study demonstrates that a major cerebellar afferent can act as an effective CS and that the conditioned response associated with this training must use cerebellum. Current studies also demonstrate that stimulation of the dorsolateral pontine nucleus can act as an effective CS, and that classical conditioning occurs with paired mossy fiber (CS) and climbing fiber (UCS) stimulation. We suggest that learning/plasticity occurs within the cerebellum.

245.6 SHORT-DURATION MOSSY FIBER STIMULATION IS EFFECTIVE AS A CS IN EYELID CLASSICAL CONDITIONING. C.G.Logan*, J.E.Steinmetz, D.S. Woodruff-Pak and R.F.Thompson (SPON: M.E.Stanton). Dept. of Psychology, Stanford University, Stanford, CA 94305.

It has recently been demonstrated that electrical stimulation of mossy fiber input to the cerebellum can serve as an effective conditioned stimulus (CS) in classical conditioning of the rabbit eyelid response (Steinmetz, Lavond & Thompson, Bull. Psychon. Soc., 1985). Electrical stimulation of the dorsolateral pontine nucleus (DLPN), when paired with a corneal airpuff unconditioned stimulus (US) in a standard delay paradigm (350 msec CS overlapping in the last 100 msec with the US), results in rapid and robust learning. In such trained animals, reducing the stimulation duration to 12 msec is sufficient to sustain conditioning. The purpose of the present study was to determine whether a short duration (21 msec) stimulation would also be sufficient for acquisition.

Male New Zealand white rabbits were chronically implanted with bipolar stimulating electrodes in the right DLPN and with a recording electrode in the left hippocampus. Following recovery,animals were trained to a criterion of 8/9 CRs with a 21 msec train of DLPN stimulation CS (90-120 uA, .1 msec, 200 Hz), paired with a 100 msec corneal airpuff US beginning 250 msec after CS onset. Thus, there was a 229 msec period between the offset of the CS and the onset of the US. Animals were trained to criterion, overtrained, retrained with a 350 msec tone CS, and then extinguished with unpaired DLPN stimulation-airpuff presentations.

Rabbits required an average of 261 trials to reach criterion with the short duration CS. This is a somewhat greater number of trials to criterion than was required for animals given training with 350 msec DLPN stimulation. Transfer to tone was relatively rapid, and explicitly unpaired presentation of CS and US produced extinction within 5 days in all cases. Such extinction argues against the possibility that sensitization or some other non-associative process was responsible for the original learning.

These data demonstrate that a brief duration CS is sufficient for acquisition of the conditioned eyelid response and suggest that CS onset and stimulus onset asynchrony may be more significant than CS duration for acquisition of the conditioned response. In addition, this preparation allows recording of brain activity after delivery of a stimulation CS.

245.7 CLASSICAL CONDITIONING OF THE RABBIT EYEBLINK DOES NOT OCCUR WITH STIMULATION OF THE CEREBELLAR NUCLEI AS THE UNCONDITIONED STIMULUS P. F. Chapman*, J. E. Steinmetz, & R. F. Thompson (SPON: L. Holt). Department of Psychology, Stanford University, Stanford, CA 94305.

Recently, the cerebellum has been shown to be essential for the development and expression of the classically conditioned eyeblink response in the rabbit. Lesions of the cerebellar nuclei (medial dentate-lateral interpositus) abolish the conditioned response (CR) but not the unconditioned response (UR) (McCormick and Thompson, J. Neuroscience, 4, 1984). In addition the red nucleus (RN), a primary efferent of the cerebellum, has been shown to be a necessary part of the conditioned response pathway (Haley et al, Neuroscience abstracts, 1983). Furthermore, activation of climbing fibers as the unconditioned stimulus (US) via stimulationt of the dorsal accessory olive (DAO) produces conditioned responses identical to those using the standard air puff US (Mauk & Thompson, Neuroscience Abstracts, 1984) and lesions to the DAO cause extinction of the learned response (Steinmetz et al, Neuroscience Abstracts, 1984) Since the DAO is known to be an element of the US pathway, and the cerebellum and RN are elements of the CR pathway, plasticity must occur at the cerebellum, or at an efferent point. Stimulation along this pathway afferent to the site of plasticity should produce normal learning, as with DAO stimulation, whereas stimulation efferent to this site will produce the UR, but not the CR. In this study, male albino

Rabbits were trained using stimulation of the dentate-interpositus (DI) as the US and a tone as the conditioned stimulus (CS). US stimulation consisted of 100 msectrains 0.1 msec cathodal pulses, ranging in frequency from 200-400 Hz, and in intensity from 50 to 500 uA. Stimulation elicited a variety of responses ranging from lateral head movements and front or hind leg movement to eyeblinks. Those animals exhibiting eyeblinks were tested for five days (108 trials per day) using the standard eyeblink paradigm, with a 250 msec interstimulus interval. Animals displayed robust URs, but developed no CRs during the five days of training. After the stimulation training, animals were switched to standard training, using corneal air puff as the US. Within 108 trials, all animals had reached a criterion 8 CRs in 9 consecutive trials, indicating that their inability to learn using the stimulation US was not due to damage to the DI or any interference with the tone perception.

These results suggest that the learning related plasticity that occurs in the conditioned eyeblink response is not efferent to the cerebellum.

Supported by predoctoral fellowship 5T32MH15157-08 (PFC) and by ONR contract N00014-83-K-0238 and NSF grant BNS-81-17115 and a grant from the Sloan Foundation (RFT).

245.8 Neuronal Responses of the Rabbit Cerebellar Cortex During Performance of the Classically Conditioned Eyelid Response. Nelson H. Donegan, Michael R. Foy, and Richard F. Thompson. Department of Psychology, Stanford University, Stanford, CA 94305

Recent work has shown that the cerebellum is an essential element of the neural circuitry responsible for the development and expression of the conditioned eyeblink response in the rabbit (e.g., McCormick & Thompson, 1984). Multiple-unit recordings in the deep cerebellar nuclei and the overlying cerebellar cortex have revealed areas in which neuronal activity precedes and models the learned behavior. In the present study, single-unit recordings were made in the ansiform cortex of the cerebellum ipsilateral to the side of training in order to characterize the types of neuronal responses exhibited by this region to the various components of the trial events (tone CS and airpuff US) and the behavior exhibited on the trial (CR and UR). During the course of the behavioral training and recording sessions, subjects received pairings of an acoustic CS (350 msec, 1 kHz tone) with a corneal airpuff US (100 msec, which overlapped and terminated with the CS). The response measure was EMG activity recorded from the upper eyelid. Recording sessions were conducted after the subjects showed consistent CRs to the tone CS. Thus the majority of the neurons sampled were analyzed when subjects were well trained.

Subsequent analysis of single-unit activity revealed several classes of neural responses correlated with behavior: Units that (1) showed a burst of activity at the onset of the conditioned response and a high level of responding over the course of both the CR and UR, (2) showed inhibition at the onset of the conditioned response and throughout responding, (3) showed increases in activity that preceded and modelled the CR. In some cases the cells could be identified as Purkinje cells because of complex spikes characteristic of climbing fiber input.

245.9 RESPONSES IN MEDIAL HABENULA DURING RABBIT NM CONDITIONING. R.A. Swain* and S.D. Berry. Dept. of Psychology, Miami Univ., Oxford, Ohio 45056.

Several areas of the limbic forebrain show significant neural responses during classical conditioning of the rabbit nictitating membrane (NM) response. An important question that remains, however, is how such activity is relayed to brainstem motor systems that underlie the reflex and conditioned responses. While conditioned neural responses have been described in the hippocampus and lateral septum, further tracing of subcortical outputs has failed to show significant neural responses in hypothalamic targets of septal or hippocampal output. An additional septo-hippocampal output pathway has been traced through the medial habenular nucleus which receives a major projection from the posterior septal region and projects to the interpeduncular nucleus via the fasciculus retroflexus (Herkenham & Nauta, J. Comp. Neur.,173, 1977; Swanson & Cowan, J. Comp. Neur.,186, 1979). In this paper we report significant increases in medial habenular unit activity during rabbit NM conditioning.

New Zealand White rabbits were anesthetized with Ketamine and implanted with stainless steel extracellular recording electrodes in the medial habenular nucleus and CA1 layer of the hippocampus. Animals were allowed 1 week recovery prior to conditioning. Training consisted of 26 blocks of trials, with each block consisting of 8 paired and 1 CS alone test trial. Each paired trial consisted of a 350msec tone (1KHz,85dB) followed after 250msec by a 100 msec corneal air puff (210g/cm2). Control animals were given explicitly unpaired tone and air puff presentations. A CR was defined as at least 1/2 mm of NM extension prior to air puff onset. Neural responses were averaged over the 8 trials of each block and are displayed as poststimulus histograms. In addition, standard scores were computed to quantify responses across blocks.

Initial results indicate a significant habenular response to the UCS (air puff) that appears, like hippocampal and septal responses, to precede and model the behavioral response. The average increase in habenular firing in response to the UCS was greater than 4 standard scores, indicating a significant increase over baseline levels. Figure 1 shows a representative histogram from a medial habenular recording. Arrows indicate tone (left) and air puff (right) onset.

These results suggest that forebrain limbic responses during NM conditioning may be projected to the brainstem via the habenula and its efferents.

245.10 EFFECTS OF SEPARATE AND COMBINED MEDIAL AND ANTERIOR THALAMIC LESIONS ON DISCRIMINATIVE AVOIDANCE LEARNING IN RABBITS. M. Gabriel, S.P. Sparenborg, P. Colletier*, and J. Tenner*. Dept. Psychol., Univ. Illinois, Champaign, IL 61820

The experiment reported here is one of an ongoing series in which the discriminative avoidance behavior of rabbits is used as a model system for study of the neural mechanisms of learning. Past studies of the neuronal activity of the posterior cingulate cortex (area 29) and the anteroventral nucleus (AVN) of thalamus have suggested that these structures are important substrates of the behavior (Gabriel et al., Science, 208: 1050, 1980). Yet, the effects of damage in area 29 or in the AVN were rather minimal, each lesion yielding a significant but only partial impairment of the performance of the well-learned behavior, and no effect on its original acquisition (Gabriel et al., Behavioral Neuroscience, 97: 675, 1983; Ragsdale et al., Neurosci Abstr., 1984). These results suggested that area 29 and the AVN partially subserve performance of the well-learned behavior but that there exists an additional neural system for the mediation of acquisition.

The system comprised by the anterior cingulate cortex (areas 24 and 32) and the mediodorsal thalamic nucleus (MDN) represents a plausible candidate for acquisition, given the very rapid development of associative correlates of training in these structures (Orona et al., Brain Research, 263: 295, 1982). Here we report that bilateral electrolytic lesions of the MDN which spared the AVN ($N = 4$) were associated with a retardation of acquisition ($P<.05$) and impaired asymptotic avoidance performance ($P<.05$) relative to unlesioned controls ($N=10$). Subjects with partial lesions ($N = 4$) in AVN and MDN were not different from controls, but lesions that encompassed more than 50% of AVN and MDN bilaterally ($N=6$) yielded a severe acquisition deficit. None of the subjects in the combined lesion group (but all of the subjects in the control, partial and individual lesion groups), attained the acquisition criterion. In addition, the combined but not the separate lesions abolished all cue-elicited excitatory and discriminative neuronal activity in the cingulate cortex during training (Gabriel et al., Neurosci Abst, 1985). These data suggest that the MDN and the AVN, and their respective cingulate cortical subfields comprise a pair of neural systems that are to a degree functionally specific, respectively, for mediation of original acquisition and maintenance of the well-learned behavior. Yet these systems also manifest functional redundancy in that each contributes substantially to the specialty of the other. Together they comprise a supersystem the totality of which is essential for the learned behavior.

245.11 SEPARATE AND COMBINED MEDIAL AND ANTERIOR THALAMIC LESIONS AND CINGULATE CORTICAL NEURONAL CORRELATES OF AVOIDANCE LEARNING IN RABBITS. P. Colletier*, J. Tenner*, S.P. Sparenborg, and M. Gabriel. (SPON: P. Johnston). Dept. Psychol., Univ. Illinois, Champaign, IL 61820

Past studies have indicated that experimental damage in the anterior thalamic nuclear group, or in the related posterior cingulate cortical subfield (area 29), is associated in rabbits with a decrement in the postasymptotic performance of a discriminative avoidance habit, but such damage does not affect original acquisition to behavioral asymptote (Gabriel et al., Behavioral Neuroscience, 97: 675, 1983; Ragsdale et al., Neurosci Abstr., 1984). In contrast, damage in the mediodorsal thalamic nucleus (MDN) is associated with impaired behavioral acquisition, and combined anterior and medial thalamic damage devastates acquisition (Gabriel et al., Neurosci Abst., 1985). Taken together, these results suggest that the medial and anterior thalamic nuclei and their respective cingulate cortical subfields contribute to the avoidance behavior in a parallel and somewhat redundant fashion, and that both systems together comprise a supersystem that is essential for the behavior.

If the idea of parallel and redundant processing as applied to these neural systems is valid then it should be possible to demonstrate continuing operation of one of the systems when the other is disabled. This expectation was supported by past results indicating that anterior thalamic lesions abolished all excitatory and discriminative neuronal activity normally elicited in area 29 by the conditional stimulus (CS+) during performance of intact rabbits, but such lesions did not block the development of discriminative neuronal correlates of training in the anterior cingulate cortex (areas 24 and 32, op cit., 1983). Here we provide further support for the idea of parallel and redundant contributions of the two systems. Bilateral electrolytic lesions confined to the mediodorsal thalamic nucleus (MDN) eliminated the excitatory and discriminative neuronal correlates of training in area 24, but the neuronal correlates in area 29 survived such lesions. Also, consistent with their devastating behavioral effects, combined anterior and medial thalamic lesions eliminated the excitatory and discriminative neuronal activity in both of the cingulate cortical subfields.

245.12 SHORT-LATENCY NEURONAL DISCHARGES IN THE RABBIT CINGULATE CORTEX PREDICT THE BEHAVIORAL OUTCOME OF TRIALS DURING DISCRIMINATIVE AVOIDANCE CONDITIONING. S.P. Sparenborg and M. Gabriel. (SPON: W.T. Greenough). Dept. Psychol., Univ. Illinois, Champaign, IL 61820

Past studies have revealed that CS-elicited neuronal activity in the cingulate cortex and in the related nuclei of the thalamus becomes discriminative during the course of avoidance conditioning in rabbits. That is, the frequency of action potentials elicited by a tone (CS+) predicting the occurrence of the footshock UCS was greater than that elicited by the tone (CS-) predicting no occurrence of the UCS. We have interpreted the discriminative effects as representing processes involved with the encoding of the differential associative significance of the CSs, but it is possible as well that the effects, even at brief latencies, may covary directly with the behavioral outcomes of the conditioning trials. In order to explore this possibility separate peristimulus histograms were constructed for each of four trial types; a) CS+ followed by a conditioned response (CR), b) CS+ followed by no CR, c) CS- followed by a CR, and d) CS- followed by no CR. The rabbits were trained to locomote in an activity wheel to avoid a footshock UCS whenever they heard the CS+ and they learned to ignore the CS-. Sixty trials daily with each stimulus were presented in a random order until a criterion of discriminative avoidance performance was attained . The four-fold classification of the trials was carried out for 29 cingulate cortical and 18 anteroventral thalamic neuronal records obtained from the session of the first significant behavioral discrimination and for the criterial session.

The results indicated that two distinct aspects of behavioral performance could be predicted on the basis of the average histograms for the first 200 milliseconds following CS onset. As in all past studies, the average CS-elicited activity in cingulate cortex manifested an inhibitory pause measured relative to the pre-CS baseline at 40 - 60 milliseconds after CS onset, and an excitatory discharge from 100 to 400 milliseconds after CS onset. The activity on CS- trials followed by response manifested no inhibitory pause and thus a significant elevation, relative to the activity from 40 - 60 msec in each of the remaining trial types. In addition, the activty elicited by the CS+ on trials with CRs was significantly greater than the activity on CS+ trials without CRs, in the interval from 100 - 200 milliseconds. These effects were restricted to records obtained from the deep laminae (5&6) of the posterior cingulate cortex.

245.13 CONDITIONING-INDUCED WAVEFORMS RECORDED OVER OLFACTORY AND PARIETAL AREAS OF RAT BRAIN. L.M. Grimes* and R.S. Dyer (SPON: M.I. Gage). Northrop Services, Inc. (LMG) and Neurophysiol. Branch, NTD, HERL, USEPA (RSD), Research Triangle Park, NC 27711

The properties of early components of sensory evoked potentials recorded from the scalp of humans and nonhumans are intimately tied to the physical properties of the evoking stimulus. Later components have been linked to cognitive events in humans, nonhuman primates and cats, and may reflect stimulus significance and/or other cognitively applied attributes. The present series of studies explored the possibility that changing the significance of an auditory stimulus might alter the later components of tone evoked potentials in rats.

Skull screw (00-90) electrodes were implanted at sites ranging from 25 mm anterior to 6 mm posterior to bregma, and from the midline to 4 mm lateral. All recordings were referred to a screw over the cerebellum. Auditory evoked potential averages were obtained following 150 presentations of a 10 kHz tone (30, msec, 85 dB SPL) before and 3 hrs after pairing of the tones with footshock (conditioning). The conditioning paradigm consisted of 30 presentations of the tone, followed 500 msec later by a 2 mA, 750 msec footshock. Control rats received footshocks not paired with tones. In conditioned rats, two apparently separate late responses occurred at different electrode sites. One response, largest overlying the cribriform plate (bregma + 10 mm), was a negative wave with a peak latency of about 250 msec, and an amplitude of about 60 uV. Blocking entry to the nose induced mouthbreathing and diminished the response, while removing the blockage reinstated the response. These results suggest that the response may be due to a conditioned breathing (inspiratory) response, perhaps bringing odor molecules in contact with the sensory epithelium of the nose and thereby eliciting a potential akin to Ottoson's. The other response appeared greatest over a parietal site (bregma-3 mm, lateral 3 mm), and was manifested by a biphasic negative (190 msec)-positive (290 msec) waveform with an amplitude of about 40 uV. Both the olfactory and parietal waveforms were eliminated by halothane and ketamine anesthesia. The role (if any) played by stimulus induced movement in the potentials recorded from conditioned animals remains to be determined, as does the relationship between these waveforms and those previously reported in other species.

245.14 DIFFERENTIAL RESPONSE OF A SELECT POPULATION OF PREFRONTAL CORTEX NEURONS TO REINFORCED AND UNREINFORCED CONDITIONED STIMULI. S.L. Peterson. Dept. Medical Pharmacology, Texas A&M Univ., College Station, TX 77843.

Rats were prepared with chronic intracranial implants for the subsequent (7-10 day) recording of the extracellular action potentials from prefrontal cortex neurons using tungsten microelectrodes (9-11 M ). During the recording experiments the animals were unanesthetized, unparalyzed and suspended in a bodysling with their heads fixed in position by way of the intracranial implant. The animals were conditioned to the stimuli prior to the recording experiment. The conditioned stimuli used were high (3000 Hz) or low (400 Hz) pitch tones of 2 sec. duration . The reinforced stimuli (CS+) were followed immediately by a mild, 10 msec. duration electric shock to the hindpaws. The unreinforced stimuli (CS-) were presented unpaired and were always represented by the same tone in an individual animal. Animals had been conditioned to the stimuli prior to the recording experiment.

Only neurons with characteristic large amplitude, positive first deflection action potentials were evaluated (Pirch et al. Exp. Neurol. 82:118, 1983). These select action potentials probably represent cortical pyramidal neurons as related experiments in chloral-hydrate anesthetized rats demonstrate that some of the neurons can be antidromically activated from the ventral tegmental area.

The neuronal activity during the randomly presented CS+ and CS- was compiled in computer generated peri-stimulus time histograms and compared by paired t-test. Neurons in the deeper prefrontal cortex layers (n=5) emitted significant differential responses to the CS+ and CS- which extinguished over 200-300 stimuli when the footshock was withheld. Other neurons in the deeper layers (n=6) also emitted significantly different responses but could not be tested for a sufficient period of time to demonstrate extinction. Neurons in superficial prefrontal cortex layers (n=5) did not emit differential responses.

Since the deeper layers of the prefrontal cortex are innervated by dopamine while the superficial layers are not, this data suggests that only the prefrontal cortex neurons which are innervated by dopamine emit differential responses to reinforced and unreinforced conditioned stimuli. These observations provide evidence for a functional relationship of the reciprocal innervation between the dopaminergic ventral tegmental area and the prefrontal cortex.

245.15 SELECTIVE CHANGES IN SYNAPTIC RESPONSES ELICITED IN A CORTICAL NETWORK BY BEHAVIORALLY RELEVANT ELECTRICAL STIMULATION. U. Staubli, F. Roman and G. Lynch* (SPON: J. Conway). Center for the Neurobiology of Learning α Memory, Univ. of California, Irvine, CA 92717.

The goal of this project was to develop a paradigm for studying the possibility that experience selectively modifies synapses in cortical networks. The olfactory modality was chosen as model system since its primary target area (olfactory cortex) offers the advantage of being organized along well defined anatomical lines with simple but nonetheless cortical properties.

Rats were implanted with 3 bipolar stimulating electrodes aimed at different locations of one olfactory bulb. A single recording electrode was positioned in the dendritic field of the stellate cell layer of the piriform cortex so that biphasic pulses (10-150μA) to each stimulation pole elicited a negative field potential ranging between 1-3 mV in amplitude. The rats were then trained on successive days in an operant chamber to break a light barrier for water reward in the presence of a designated odor, but not to respond to a second odor (a buzzer signalled a wrong response). Asymptotic performance was reached after 3 successive 2-odor discriminations, using a different odor pair each day. (We have found that rats remember both the positive and negative odors in a series of pairs for weeks after this type of training). At this point the natural odors were replaced by electrical stimulation of the olfactory bulb: We found that 4 pulses separated by 10ms given at the frequency of sniffing (6 Hz) were effective in eliciting sniffing, rearing and searching behavior. Duration of stimulation varied between 3s and 15s per trial, with ITIs of at least 30s. The same type of patterned stimulation, but of a different part of the bulb, was used as 'negative' cue and was applied in random order with the 'positive' cue. The rats acquired this type of discrimination rapidly (within 15 min). Evoked responses to single pulses were measured before, immediately and at several time points after the learning session. Stimulation intensity applied to the various poles was identical to that used during patterned stimulation. The responses (20 per pole and time point) were averaged and the slope and amplitude calculated. Comparisons of these measures revealed a substantial increase (up to 160%) after learning in case of the 'positive' and 'negative' electrodes, whereas the potentials evoked by the neutral electrode (no stimulation during the learning session) remained unchanged. The increment of the evoked responses remained stable for at least several days after training (3 weeks being the longest test interval used) as was the memory of the discrimination. These data provide preliminary evidence of long-lasting synaptic plasticity in the bulbar-piriform projections and suggest that this system may be useful in studying the effects of experience on the physiological properties of a well-defined collection of cortical circuitries. (supported by an ONR Grant Δ N00014-84-K0391)

245.16 **NOVEL AND AVERSIVE CHEMOSENSORY STIMULI: DISCRIMINATION BY THE RAT FETUS IN UTERO.** W.P. Smotherman and S.R. Robinson* Laboratory for Psychobiological Research, Department of Psychology, Oregon State University, Corvallis, OR 97331.

Rat fetuses can form conditioned taste/odor aversions in utero as early as Day 17 of gestation. They exhibit reduced activity in utero when reexposed to the aversive CS on Day 19. This conditioned response comprises a similar number and patterning of fetal movements to the behavior observed on the day of conditioning (Smotherman and Robinson, Behavioral Neuroscience 99: 521-530, 1985).

We have further characterized the responsiveness of rat fetuses to a conditioned taste/odor stimulus in utero. As in the original experiments, fetuses were exposed to a mint solution (100%) via intra-amniotic injection on Day 17 followed by ip injection of lithium chloride (LiCl). Two days later, on Day 19, the pregnant female was surgically prepared by chemomyelotomy and placed in a temperature-controlled saline bath to allow direct observation of fetal behavior. Subject fetuses were externalized into the bath, maintaining intact the placental-uterine attachment. While remaining within it's amniotic sac, each fetus was exposed to one of five chemosensory test stimuli: saline, 100% mint (the original mint solution), 50% mint, 200% mint, or a novel solution of lemon extract. Following stimulus presentation, the behavior of each fetus was observed.

The results of this experiment replicate and extend the findings of our original conditioning study. Fetuses presented with a pairing of 100% mint and LiCl on Day 17, when reexposed to 100% mint on Day 19, responded with markedly suppressed activity. Fetal responses to 200% mint were indistinguishable from responses to 100% mint, with reduced frequency of general activity and complex movements as well as fewer individual movements of the forelegs, hindlegs and head. An intermediate level of suppression in general activity and individual movements was evident for the 50% mint solution. But the aversive response of fetuses was specific to mint; saline and lemon solutions elicited similar levels of general fetal activity and lemon actually activated fetal foreleg movements. Three inferences may be drawn from these results. First, fetuses are capable of forming and exhibiting learned behavior in utero. Second, fetuses are capable of discriminating between pairs of chemosensory stimuli, one which is aversive and the other neutral. Third, fetuses may be capable of discriminating between different concentrations of the same taste/odor stimulus.

This research is supported by Grant HD 16102-04 from the National Institute of Child Health and Human Development to WPS.

245.17 THE IDENTIFICATION AND PARTIAL CHARACTERIZATION OF A CELL SURFACE PROTEIN THAT MODULATES REM IN NEONATAL RATS AND LONG TERM SYNAPSE PLASTICITY IN HIPPOCAMPAL SLICE PREPARATIONS. J.R. Moskal*[1], A.E. Schaffner[2] and K.J. Koller[1], Lab. Cell Biol., NIMH[1] and Lab. Neurophys., NINCDS[2], Bethesda, MD 20205.

A monoclonal antibody (B6E11), derived from a panel generated against 5-day postnatal rat dentate gyri, was found to significantly increase REM when injected intrahippocampally into neonatal rats. It was also found to block the formation and maintainance of long term potentiation in hippocampal slice preparations without any effect on normal synaptic transmission. Another antibody (G6E3) from the same panel, same immunoglobulin class ($IgG_1$) and with similar immunohistochemical properties had no effect on these processes. Immunocytochemical staining revealed that B6E11 recognized only dentate gyrus granule, hippocampal pyramidal and cerebellar Purkinje neurons in unfixed frozen sections of adult rat brain. That B6E11 recognizes a cell surface antigen is based on radioimmunoassays with crude membrane fractions, flow cytometric analysis of unfixed dissociated cells from rat brain and the ringed fluorescence found on neurons in primary hippocampal cultures. Immunoblot analysis of hippocampal homogenates subjected to SDS-PAGE revealed that B6E11 recognized a developmentally regulated protein that increases markedly in concentration (per mg of protein) from birth through adulthood and changes in molecular weight from $M_r$=37,000 at birth through 5 days postnatal followed by a doublet of $M_r$=37,000 and $M_r$=42,000 until 20 days postnatal and thereafter is found as a single band of $M_r$=42,000. This protein is also found in adult rhesus monkey hippocampus and is soluble in 2% Triton X-100. Neither B6E11 nor G6E3 were able to inhibit the specific binding of radiolabeled glutamate or kainic acid to either hippocampal or cerebellar membranes. Further experiments are in progress to determine if this antigen is involved in the regulation of a specific receptor or ion channel.

245.18 EFFECTS OF A MONOCLONAL ANTIBODY AGAINST RAT HIPPOCAMPAL DENTATE CELLS ON REM ACTIVITY IN FIVE-DAY OLD RAT PUPS. R.A. Deyo*, R. Conner*, J. Panksepp, and J.R. Moskal*[1] (SPON: K. Koller). Dept. Psychology, Bowling Green State Univ., Bowling Green, OH, 43403, and [1] Lab. of Cell Biology, NIMH, Bethesda, MD 20205.

A series of monoclonal antibodies was generated to the dentate gyrus of five-day old rat pups. Several of these antibodies have been systematically screened for their possible behavioral effects. Results obtained with one antibody, designated B6E11, are herein reported.

In young rat pups, rapid eye movements (REM) are known to correlate highly with leg twitches. We tested 12 five-day old rat pups and found a correleation between REM and leg twitches to be r=0.9799. In a study with 56 five-day old rat pups, the animals were randomly assigned to one of four treatment groups (n=14): (1) active anti-hippocampal antibody B6E11; (2) a second anti-hippocampal antibody G6E3; (3) 0.9% saline solution; or (4) a no-injection group. Animals in groups 1-3 were injected with 1-2 µl bilaterally into the dorsal hippocampus with the appropriate solution. Monoclonal antibodies in pooled ascites fluid were diluted 1:20 in 0.9% saline, or affinity purified by protein A-Sepharose chromatography, and approximately 0.1-1.0 µg of antibody was injected. Leg twitches were then recorded during four successive blocks of 7 min. each. Analysis of variance revealed a significant treatment effect (F=5.05, with 3.52 d.f., p=0.0038). Post-hoc comparisons (Tukey's q-statistic, alpha=0.05) revealed that animals treated with B6E11 had significantly more leg twitches (mean =9.03) than animals treated with G6E3 (mean=5.50), 0.9% saline (mean=5.25), or non-injected animals (mean=5.39). Both B6E11 and G6E3 are $IgG_1$'s, and both recognize only hippocampal pyramidal, dentate gyrus granule, and cerebellar Purkinje neurons in frozen sections of adult rat brain. These antibodies also stain living neurons in primary hippocampal cultures suggesting that they recognize cell surface antigens.

These results demonstrate that the monoclonal antibody, B6E11, specifically elevates REM when injected intrahippocampally. Overall, these results suggest that monoclonal antibody techniques might be utilized to identify the antigen or antigens involved in REM mechanisms.

245.19 A MONOCLONAL ANTIBODY (MAb) TO A HIPPOCAMPAL CELL-SURFACE ANTIGEN WHICH INHIBITS BOTH PRODUCTION AND MAINTENANCE OF LONG-TERM POTENTIATION (LTP) IN RAT HIPPOCAMPAL SLICES. P.K. Stanton, J.M. Sarvey, and J.R. Moskal*[1]. Dept. Pharmacology, Uniformed Services University of the Health Sciences, and [1]Lab of Cell Biology, NIMH, Bethesda, MD

LTP is a long-lasting enhancement of evoked responses after high-frequency afferent stimulation, which has become a popular model of neuronal plasticity and candidate memory mechanism. We have recently shown that protein synthesis inhibitors impair LTP production, and others have shown correlative changes in cell morphology, protein synthesis and phosphorylation. However, little is known of the loci or nature of specific macromolecules required in LTP. Therefore, MAb's were made to 5-day postnatal rat dentate gyri, screened for their ability to recognize cell-surface antigens in the hippocampal formation, and tested for effects on hippocampal responses and LTP. One MAb, called B6E11, impaired production of LTP and suppressed established LTP in hippocampal slices, without long-term effects prior to high-frequency stimulation.

Hippocampal slices (400µm thick) were cut from adult rats (150-300 g) and two extracellular recording sites 200-400 µm apart in somatic or dendritic layers of the dentate or CA1 were chosen. Stimuli were given via perforant path or Schaffer collateral axons respectively. One of two recording sites was randomly chosen for MAb application, the other as control, and MAb pressure-applied near either somas or dendrites of the MAb site. MAb (~0.2-0.6 µg) was ejected (100-200 µm dia., 2-3 times 1 min apart) 15 min before stimulation, and LTP measured 30-min post-stimulation.

Control LTP(% of pre-stimulated spike amplitude) in dentate was 167 ± 9.0%(N=10). In contrast, B6E11-treated somatic and dendritic sites in dentate exhibited marked impairment of LTP: B6E11 soma = 97 ± 6.6%; B6E11 dendrites = 105 ± 14.2% (both $p<.05$, N=7,3,paired t-test). Furthermore, B6E11 applied to cell somas 30 min after high-frequency stimuli suppressed established LTP: Control LTP = 219 ± 22.1%, B6E11 sites = 136 ± 18.4% ($p<.05$, N=5,paired t-test). In contrast, control experiments with another MAb (G6E3) from the same panel, the same immunoglobulin class ($IgG_1$) and similar immunohistochemical properties as B6E11, showed no inhibition of LTP.

In field CA1, where synapses are on apical dendrites further from the cell soma than in the dentate, B6E11, when applied to cell somas, did not impair LTP: Control LTP = 193 ± 22.8%, B6E11 sites = 190 ± 31.5% (N=4). However, B6E11 application to CA1 pyramidal cell dendrites significantly inhibited LTP production: Control LTP = 221 ± 28.9%; B6E11 sites = 124 ± 9.1% ($p<.05$, N=6, paired t-test), and also suppressed established LTP: Control LTP = 129%, B6E11 sites = 98% (N=2).

These results indicate the presence of a cell-surface antigen which, properly expressed, plays a key role in both production and maintenance of LTP. Furthermore, the data in CA1 supply direct evidence that this antigen functions primarily in cell dendrites.

246.1 ONTOGENETIC CHANGES IN THE Na AND H GRADIENTS ACROSS BASOLATERAL MEMBRANE OF CHOROID PLEXUS: A CLUE TO THE MATURATION OF THE CSF SECRETORY PROCESS. C.E. Johanson, Dept. of Pharmacology, Univ. of Utah Sch. Med., Salt Lake City, UT 84132.

Exchange of intracellular hydrogen ($H_i$) for extracellular sodium ($Na_o$), i.e., Na/H antiport, in the basolateral (plasma-facing) membrane of choroid plexus (CP) is thought to be the primary system for moving Na from interstitial fluid into CP epithelium, i.e., the rate-limiting step in CSF formation (Murphy, Ph.D. thesis, 1984, Univer. of Utah). Aronson demonstrated that 1:1 Na/H exchange depends on $[Na]_i/[Na]_o$ (i.e., rNa) being >rH to allow Na and H transport, respectively, into and out of the cell.

The aim has been to analyze cation gradients across in vivo CP basolateral membrane throughout postnatal development; and to relate them to established information about tracer-Na movement across the blood-CSF barrier and CSF secretory capacity. Sprague-Dawley rats (N = 6 for each age) were sacrificed under ether. Plasma [Na] and pH were measured by flame photometry and electrode, respectively. Compartmentation analysis was used to determine CP cell [Na], and pH (by the DMO method). SEM's were <8% of mean values below. [Na] and [H] are in mM and nM.

| | $[Na]_i$ | $[Na]_o$ | rNa | $[H]_i$ | $[H]_o$ | rH |
|---|---|---|---|---|---|---|
| 1 week | 58 | 137 | 0.42 | 63 | 45 | 1.40 |
| 2-3 wk | 46 | 148 | 0.31 | 65 | 40 | 1.63 |
| Adult | 47 | 154 | 0.31 | 87 | 36 | 2.42 |

The inwardly directed Na gradient (i.e., $[Na]_o - [Na]_i$) is nearly 30 mM less at 1 wk than in adults. At 1 wk, rH is only 3 times rNa whereas in young adults rH is 8 times rNa. Since Na-22 rapidly and completely exchanges with stable Na in rat CP, the concentration ratio of radio-Na (i.e., rNa) is likely similar to the activity ratio of stable Na. The substantially lower value of rH at 1 wk suggests a smaller proton-gradient driving force for uptake of Na into the cell. In a previous study in this laboratory systemic metabolic acidosis in adult rats reduced rH from 2.3 to 1.6, and it also decreased Na-22 turnover from plasma to CSF (across CP) by 35%. Since Na transport across CP is proportional to CSF formation, the present data are consistent with previous observations of lower-capacity Na transport in CP and incompletely-developed formation of CSF in the infant (1-wk) rat. Carbonic anhydrase activity, by catalyzing hydration of $CO_2$, furnishes H ions for the Na/H antiporter. Developmental increases in CP carbonic anhydrase activity, in addition to altered transmembrane gradients, undoubtedly contribute to the maturation of the CSF secretory process. Supported by NIH grant NS 13988.

246.2 PROSTAGLANDIN SYNTHESIS ($PGI_2$) IN CULTURED MICROVASCULAR CELLULAR ELEMENTS AND GLIA FROM RAT BRAIN: EFFECT OF ANGIOTENSINS AND BRADYKININ. B. Wroblewska*, O. Kempski*, N. Merkel*, J. Bembry* and M. Spatz. LNNS, NINCDS, National Institutes of Health, Bethesda, MD 20205.

The cellular prostaglandin interaction with angiotensin and kinins has been considered of great importance in the regulation of systemic blood pressure. The general association of prostaglandin synthesis with both peripheral and central vasculature is suggestive of a potential cerebrovascular prostaglandin-peptide interaction which might be involved in local regulation of the microcirculation. Therefore, we investigated the effect of angiotensin (I or II) or bradykinin on prostaglandin synthesis in separately cultured cerebrovascular endothelium and smooth muscle, and compared their responses to that in the glia.

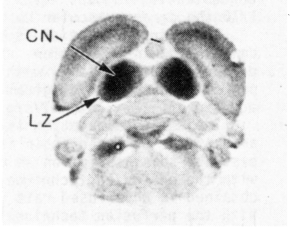
The propagated cultured endothelium and smooth muscle were derived from dissociated isolated cerebral microvessels while the cultured glial cells originated from dissociated cells of cortex. Washed cultures were exposed to medium G-199 with or without the tested substances (5μM) overnight. The synthesis of $PGI_2$ was measured indirectly in the medium of each cell type using radioimmunoassay with [$^{125}$I] 6-keto-$PGF_{1\alpha}$.

The greatest stimulation of prostaglandin release was observed in the medium of the smooth muscle cells exposed to either angiotensin (I or II) or to bradykinin. (The concentrations of 6-keto-$PGF_{1\alpha}$ were up to 100 times over the basal levels). The synthesis of prostaglandin in endothelium and glia was not significantly affected by the addition of angiotensin I. However, a slight enhancement of prostaglandin release from each cell line was observed after incubation with either angiotensin II or bradykinin (20-30% over basal level). Both, the lack and the low response of prostaglandin synthesis to the tested peptides in these cells in contrast to that of smooth muscle might be due to an enzymatic (kinase II) degradation of angiotensin I and bradykinin in the former but not in the latter cells.

These results strongly indicate that the cerebromicrovascular smooth muscle cells represent the most sensitive site for prostaglandin-peptide interaction which may be responsible for the modulation of vascular reactivity. The less responsive synthesis of prostaglandin to angiotensin and bradykinin observed in endothelium and glia suggests that these cells might serve as protectors of smooth muscle by inactivating peptides or by other mechanisms. Thus, each of the cells might have an influence on the cerebral microcirculation through its distinct and interrelated actions.

246.3 DIFFERENCES OF CAPILLARY DENSITY WITHIN THE INFERIOR COLLICULUS: RELATION TO LOCAL CYTOARCHITECTURE AND GLUCOSE METABOLISM. J.D. Fenstermacher, N.M. Sposito*, S.E. Nornes*, A.B. Butler and P.M. Gross, Department of Neurological Surgery, SUNY at Stony Brook, Stony Brook, NY 11794-8122.

The inferior colliculus (IC) of the midbrain tectum is composed principally of a large central nucleus (CN) of densely packed cells surrounded by a lateral zone (LZ) of fiber tracts (van Noort, The Structure and Connections of the Inferior Colliculus, Assen, van Gorcum, 1969). IC receives projections from the lateral lemnisci, cochlear nuclei, and auditory cortices, and is, therefore, a primary relay structure in acoustic processing. IC has the highest rate of glucose metabolism in the brain; moreover, within IC, this rate is greater in CN than in LZ (see Figure). A long-held hypothesis is that complexity of neuronal function, glucose metabolism, and capillary density are related throughout individual structures of the brain (Craigie, J. Comp. Neurol. 31:429, 1920). During auditory stimulation, glucose metabolism in the IC increases in patterns specific to tonotopic cellular organization within CN. We conducted quantitative light microscopic studies to discern a relationship of the capillary bed to the cellular organization and glucose metabolism within IC. Capillary mean diameter, density, and volume were determined from light micrographs of the IC prepared from perfusion-fixed brain sections of adult Sprague-Dawley rats. Glucose utilization was determined by computerized image processing of 14C-deoxyglucose autoradiographs from coronal brain sections of conscious rats.



Mean capillary diameter was similar in CN (4.61 ± 0.23 microns, mean ± SD) and LZ (4.54 ± 0.28 microns). Capillary density and volume, however, were greater in CN than in LZ. Values in CN were 564 ± 77 capillaries/$mm^2$ and 2.15 ± 0.28%, respectively and in LZ were 410 ± 73 capillaries/$mm^2$ and 1.39 ± 0.27%. Areas of high capillary density within CN correlated closely to groups of densely packed cells; LZ contained fewer capillaries, loosely distributed cell groups, and myelinated fibers. Glucose utilization was higher within CN. These studies illustrate the linear correspondence of cellular architecture, glucose metabolism, and capillary density and volume within an individual cerebral structure.

246.4 LOCAL SURFACE AREA AND QUANTITATIVE FINE STRUCTURE OF CAPILLARIES IN WHITE AND GREY MATTER AND A CIRCUMVENTRICULAR ORGAN OF RAT BRAIN. N.M. Sposito*, S.E. Nornes*, A.B. Butler, J.D.Fenstermacher and P.M. Gross (SPON: N.T. Carnevale). Department of Neurological Surgery, SUNY at Stony Brook, Stony Brook, NY 11794-8122.

From 1920 to 1940, E.H. Craigie published a series of reports describing the differences in capillary density among several structures of the rat brain having dissimilar functions. His studies led to the conclusion that "vascular richness must be associated with some special functional requirement" (Res. Publ. Assoc. Nerv. Ment. Dis. 20:310, 1940). We report a quantitative light and electron microscopic analysis of capillaries in individual brain structures having wide differences in neuronal function. The studies were carried out on adult Sprague-Dawley rats perfusion-fixed with 2% paraformaldehyde and 2% glutaraldehyde in 0.1 M phosphate buffer. Analyses were limited to the genu of the corpus callosum (white matter), inferior colliculus (IC, grey matter), and subfornical organ (SFO, a circumventricular organ, CVO). Values presented are the mean ± SD for the number of animals shown in parentheses. *$p<0.05$ compared to IC.

| Light Microscopy of Capillaries | Corpus Callosum | Inferior Colliculus | Subfornical Organ |
|---|---|---|---|
| Density (#/$mm^2$) | 150 ± 8(5)* | 500 ± 38(5) | 580 ± 62(3) |
| Volume (%) | 0.53 ± 0.04* | 1.76 ± 0.07 | 1.53 ± 0.14 |
| Surface area ($mm^2/mm^3$) | 4.1 ± 0.4* | 14.8 ± 1.2 | 15.2 ± 0.7 |
| Electron microscopy of endothelial cells | | | |
| Mitochondria (#/$um^2$) | 1.50 ± 0.11(3) | 1.38±0.34(3) | 0.49±0.11*(3) |
| Junctions (#$um^2$) | 0.46 ± 0.07 | 0.42 ± 0.07 | 0.67 ± 0.09* |
| Vesicles (#/$um^2$) | 2.6 ± 0.9 | 2.4 ± 0.3 | 16.7 ± 2.3* |
| Fenestrations (# / cross section) | none | none | 4.3 ± 0.8* |

The studies demonstrate quantitatively that white matter has fewer capillaries and less capillary volume and surface area than grey matter (IC) and SFO. The findings are consistent with the more energy demanding functions of grey matter and CVO structures. At the ultrastructural level, the SFO has fewer endothelial mitochondria and more intercellular junctions, vesicles, and fenestrations per unit cell area than white or grey matter. These values indicate morphological features which correlate with the lack of blood-brain barrier function in endothelial cells of CVOs.

246.5 A COMPARISON OF VASOPRESSIN BINDING TO PIG CEREBRAL MICROVESSELS, CORTEX, AND HIPPOCAMPUS. A.F. Pearlmutter* and S.I. Harik (SPON: A.V. McGrady), Department of Biochemistry, Medical College of Ohio, Toledo, OH 43699 and Departments of Neurology and Pharmacology, Case Western Reserve University School of Medicine, Cleveland, OH 44106.

Extensive anatomical evidence demonstrates the existence of nerve fibers in the walls of cerebral arteries and veins. Little is known of the influence of peptide neurotransmitters on the regulation of cerebral blood flow. Because injections of arginine vasopressin (AVP) have been shown to influence blood pressure, we tested cerebral microvessels for the presence of specific AVP binding sites. To clarify the nature of AVP binding to cerebral microvessels, we compared the microvessel system with pig cortical and hippocampal membranes, a brain area where we have previously located and characterized high-affinity, specific AVP binding in the rat (Costantini and Pearlmutter, J. Biol. Chem., 259:11739, 1984). Pig brains were collected at a local slaughterhouse and both microvessels and cortex were prepared as described previously (Harik et al., J. Cereb. Blood Flow Metabl, 1:329, 1981). Crude synaptosomal (12K) and membrane (100K) fractions of cortex and hippocampus were prepared by differential centrifugation as described previously (Pearlmutter et al., Peptides, 4:335, 1983). With the cerebral microvessels in 50 mM Tris, pH 7.6, little or no binding could be detected in the absence of metal ion or with 5 mM $Mg^{2+}$ or $Mn^{2+}$; similar results were obtained with pig cortex prepared in the same manner as the microvessels. When 5 mM $Ni^{2+}$ was included in the incubation medium, both microvessels and cortex bound AVP; the binding was of high affinity and saturable. By Scatchard analysis, the pig microvessels had a $K_d$ of 1.6 (±0.4) nM and a $B_{max}$ of 49 (±5) fmoles/mg protein; the cortex had a $K_d$ of 1.6 (±0.6) nM and a $B_{max}$ of 78 (±19) fmoles/mg protein. Although the differences in both $K_d$ and $B_{max}$ were not statistically different, within each set of parallel experiments, the cortex always exhibited about a 30% higher $B_{max}$ than the microvessels. Partially purified pig cortical and hippocampal membranes, both 12K and 100K, were tested for the presence of AVP binding sites. Both brain regions showed specific, high-affinity binding. In the pig cortex, the 12K fraction had a $K_d$ of 1.4 nM and $B_{max}$ of 113 fmoles/mg protein; the 100K membranes gave a $K_d$ of 1.3 nM and $B_{max}$ of 93 fmoles/mg protein. The pig hippocampal membranes also bound AVP; the 12K synaptosomal fraction had a $K_d$ of 1.6 nN and $B_{max}$ of 93 fmoles/mg protein while the 100K fraction had a $K_d$ of 0.9 nM and $B_{max}$ of 85 fmoles/mg protein. These results show that pig cortex and hippocampus bind AVP and that under conditions where specific AVP binding is detected in the cortex, pig microvessels can bind AVP. The binding conditions for AVP in the pig cerebral microvessels more closely resemble that seen previously with rat cortex and with pig cortex rather than a smooth muscle target tissue such as the aorta. This implies that AVP binding to microvessels resembles hormone binding seen in brain tissue. This research was sponsored by NIH grants NS-17848 to A.F.P. and NS-18150 to S.I.H.

246.6 THE BLOOD BRAIN BARRIER IS PERMANENTLY ALTERED BY TRANSPLANTS OF ADRENAL MEDULLA. J.M. Rosenstein. Dept. of Anatomy, George Washington Univ. Sch. of Med., Wash. D.C. 20037.

The adrenal medulla has been used in several neural transplant studies as a potential source of catecholamines. Like autonomic ganglia, the adrenal medulla normally lacks any blood-neuronal barrier. It has been recently shown that autonomic ganglion transplants circumvent the blood-brain barrier (BBB) and permit protein and amine to enter both the transplant and host brain (Rosenstein and Brightman, Science, 221:879). Might the adrenal medulla also subserve such a significant physiological mechanism following transplantation?

Adrenal medullae were dissected from young adult rat donors and transplanted to neonatal or adult recipients into either the IV ventricle or directly into the cerebral cortex. Postoperative times were between 4 weeks, to allow reconstitution of the BBB in the case of intraparenchymal trauma, to six months. A single injection of HRP was made into the femoral vein and allowed to circulate for periods between 3 minutes and one hour. Some animals received an injection of $^3$H dopamine ($^3$HDA) for comparable periods.

In all specimens, the circulating glycoprotein inundated the transplant and adjacent host brain. In IV ventricle transplants, several cerebellar folia were involved and HRP filled the breadth of the vermis to a depth of at least 1 mm. Use of the sensitive chromagen TMB demonstrated that HRP had transgressed the graft and entered and circulated in the CSF. Reaction product was detected rostrally in the cerebral aqueduct and caudally as far as the lumbar spinal cord; the paravascular spaces of the cerebral microvasculature were completely filled. In intraparenchymal allografts, months after the BBB should have been reconstituted, HRP was disseminated into the cortex, corpus callosum and hippocampus in as little as ten minutes. Serial reconstruction indicated that the volume of the permeable brain areas was 2-3 times the volume of the graft. Maximum HRP distribution was reached at 30 minutes indicating that the exudation was time dependent. In allografts that did not survive, no exudation was detected. Systemically administered $^3$HDA was found throughout the transplants and was sequestered in surviving cellular elements.

A fundamental characteristic of the mammalian brain, the BBB, is altered permanently and significantly by autonomic neural transplants by providing entry for circulating protein and amine. (Supported by NS-17468).

246.7 DIETHYLDITHIOCARBAMATE (DDC) CO-ADMINISTRATION ENHANCES LEAD-INDUCED FLAVOR-AVERSION CONDITIONING. D.B. Peele*, R.C. MacPhail*, J.D. Farmer* and L.L. Cook* (SPON:T.O. Brock). Northrop Services, Inc., Research Triangle Park, NC 27709 and U.S. Environmental Protection Agency, Research Triangle Park, NC 27711

Flavor-aversion conditioning represents an adaptive response involving food/fluid avoidance based on the consequences of prior ingestion of that substance. For example, rats treated with lead shortly after consuming saccharin-flavored water, and given a choice between the saccharin solution and tap water several days later, reduce their intake of saccharin in direct proportion to the dosage of lead administered (e.g., Peele, D.B. and MacPhail, R.C., Soc. Neurosci. Abstr., 10: 1207, 1984). The mechanism(s) by which lead administration produces this conditioned flavor aversion is(are) unknown. In an attempt to further characterize this phenomenon, a series of experiments was undertaken to determine whether the extent of flavor-aversion conditioning was related to lead levels in brain.

While only a small portion of orally delivered inorganic lead ordinarily reaches the brain, penetration of lead into brain can be greatly enhanced by co-administration of dithiocarbamates, including diethyldithiocarbamate (DDC), even though body burdens of lead remain roughly constant (Oskarsson, A., Arch. Toxicol., Suppl., 6: 279, 1984). If lead-induced flavor aversions are a function of brain lead levels, then the ability of lead administered in combination with DDC to induce flavor aversions should exceed that of lead administered alone. Experiment 1, therefore, established dosage-effect functions for flavor aversions induced by the sodium salt of DDC (0, 10, 30, 100, 300 mg base/kg, b.wt., i.p.). DDC produced dosage-related conditioned flavor aversions; a dosage of 10 mg/kg was determined to be without effect. In Experiment 2, flavor aversions induced by lead acetate (0, 30, 100 and 300 mg base/kg b.wt.) were assessed in rats jointly treated with either DDC (10 mg/kg) or isotonic saline. Lead produced dosage-related conditioned flavor aversions which were enhanced by the co-administration of DDC. A separate group of rats exposed to identical testing conditions was sacrificed 3 hrs after receiving lead (0 or 30 mg/kg) in combination with either DDC (10 mg/kg) or saline, and whole-brain lead levels were determined by atomic absorption spectrophotometry. The results showed an approximate 4-fold increase in brain lead levels in rats receiving lead plus DDC when compared to rats receiving lead plus saline. These results indicate that lead-induced conditioned flavor aversions may be, in part, determined by concentrations of the metal in brain.

246.8 VALIDITY OF FOUR ASSUMPTIONS OF THE IN SITU BRAIN PERFUSION TECHNIQUE. Seiji Momma and Quentin R. Smith. Lab. of Neurosciences, NIA, NIH, Bethesda, MD 20205.

The in situ brain perfusion technique (Am. J. Physiol. 247: H484-H493, 1984) is a sensitive new method which we have used to measure amino acid transport across the blood-brain barrier. The principle advantage of this technique is that it allows absolute control of perfusate composition for the analysis of saturation and inhibition of cerebrovascular transport. However, there are four assumptions which must be verified before influx measurements for amino acids can be considered accurate. The objective of the following experiments was to evaluate the four assumptions.

The first assumption is that there is negligible mixing of perfusion fluid with circulating blood before the perfusate reaches the brain capillaries. Mixing is important because systemic blood contains amino acids which can competitively inhibit transport across the blood-brain barrier. The contribution of systemic blood to flow during perfusion was calculated from the brain uptake of $^{14}$C-iodoantipyrine during infusion of $^{14}$C-iodoantipyrine into the femoral vein and during brain perfusion with tracer-free fluid. The percent contribution of systemic blood equaled 0.23 ± 0.17% of total flow in the parietal cortex. This low level of mixing is insignificant because the maximal contribution of blood to perfusate amino acid concentration would be only 0.0023 x 0.9 = 0.0021 umol/ml, which is 1/12 the cerebrovascular Km for leucine.

The second assumption is that efflux of amino acids from brain does not contribute significantly to perfusate amino acid concentration in brain capillaries. This assumption is valid because the maximal contribution of efflux to mean capillary concentration is Ccap = Vmax/2F = 0.0027 umol/ml, which is only 1/10 the cerebrovascular Km for leucine.

The third assumption is that cerebral perfusion fluid flow is constant during perfusion. To verify this assumption we measured cerebral perfusate flow with $^{14}$C-diazepam after 3, 25, and 55 s of perfusion with physiological saline. In parietal cortex mean flow equaled 21 ± 2 x $10^{-2}$ ml/s/g and did not vary with perfusion time.

The fourth assumption is that the effective capillary surface area of the perfused brain is comparable to that in vivo. To evaluate this assumption we measured cerebrovascular PA to $^{14}$C-urea with the perfusion technique and compared the value to that obtained in unperfused rats with the i.v. injection technique. With the perfusion technique PA for $^{14}$C-urea equaled 7.0 ± 0.5 x $10^{-5}$ $s^{-1}$ and did not differ significantly from that in unperfused rats (6.6 ± 0.5 x $10^{-5}$ $s^{-1}$), which suggests that the capillary surface area during perfusion does not differ from that in vivo.

Thus, these findings indicate that the brain perfusion technique can be used to obtain accurate values for amino acid transport across the blood-brain barrier.

246.9 PRESENCE OF TRANSTHYRETIN mRNA IN RAT CHOROID PLEXUS: DEMONSTRATION BY IN SITU HYBRIDIZATION

J. Herbert‡ J. Wilcox‡ D.R. Soprano‡ J.L. Roberts, D.S. Goodman‡ and E.A. Schon*(SPON: S. DiMauro). Dept's. of Neurology, Internal Medicine, and the Center for Reproductive Sciences, Columbia University, N.Y. 10032 and Dept. of Microbiology, Temple University, PA 19040.

Transthyretin (TTR), formerly known as prealbumin, is a tetrameric protein composed of 4 identical polypeptide subunits of molecular weight 13,745. Plasma TTR is synthesized in the liver and functions in the transport of retinol and thyroxine. Recent studies have implicated a mutant TTR in the pathogenesis of familial amyloidotic polyneuropathy (type 1).

TTR forms a disproportionately large fraction of human ventricular protein, prompting the suggestion that it is either selectively transported across the blood-brain barrier or is synthesized de novo within the central nervous system (CNS). Immunocytochemical studies have demonstrated immunoreactive TTR within the cytoplasm of choroid plexus endothelial cells in humans and rats (Kato et al., submitted).

Recently we have isolated a cDNA clone from a lambda gt11 human liver expressing library, containing a 550 bp insert encoding an almost-full-length TTR sequence. Northern analysis employing nick-translated probe prepared from this insert identified a single hybridizing band of appropriate size (ca. 700 nt) in RNA extracts from rat brain (Soprano et al., submitted), and have demonstrated that the vast majority of this signal is derived from choroid plexus RNA. To investigate further the possibility of localized CNS TTR synthesis, we performed in-situ hybridization studies on rat brain sections using a $^{32}$P-nick-translated probe. The autoradiographs revealed an intense signal localized over the choroid plexus of the lateral, third, and fourth ventricles. Studies using tritiated probe to determine subcellular localization are in progress. These findings strongly support the suggestion (Soprano et al., submitted) that the choroid plexus is the site of specific de novo intra-axial TTR synthesis. Whether TTR serves a function in the the CNS different from that in the plasma is unknown at present.

246.10 THREE-DIMENSIONAL RECONSTRUCTION OF ENDOTHELIAL VESICLES IN HUMAN AND ANIMAL GLIAL TUMORS. B.L.Coomber, P.A.Stewart, C.L.Farrell* and R.F.Del Maestro*. Dept. of Anatomy, Univ. of Toronto, Toronto, Ont., Canada M5S 1A8, and Brain Research Lab., Victoria Hospital, South Street Campus, London, Ont., Canada N6A 4G5.

Blood-brain barrier disruption in brain tumors results in cerebral edema, a major determinant of morbidity and mortality in the tumor patient. Current treatment for cerebral edema is limited to enhancing resorption of the edema fluid; we cannot yet prevent or even decrease the passage of fluids into the brain parenchyma. Animal models for human brain tumors, that could be used to investigate this problem, have been established; however, recent information indicates that the mechanism(s) of edema formation may be different in different tumor models. In the current study we have examined endothelial vesicles, that are thought to be involved in permeability by forming transcellular channels. Using three-dimensional reconstruction techniques, we compared vesicular arrangement in a rat glioma model with that in highly malignant glioblastoma multiforme tumors and low-grade astrocytomas in humans. Human tissue was obtained at biopsy and fixed within a few seconds of removal, so that optimal preservation of ultrastructure was obtained. Very thin (30-40 nm) serial sections were cut. Suitable areas of microvessel walls were photographed and vesicles were traced through adjacent micrographs. Vesicles were classified according to whether they are connected to other vesicles (fused), to golgi or ER (tubule connected), or unconnected to other cytoplasmic structures (free).

The frequency of each type of vesicle does not differ with tumor type, but is different from normal animal permeable tissue, in which the majority of vesicles are "fused", and often one or more vesicles form channels across the endothelial cell. In the current study, channels across tumor endothelial cells were rare. Unlike permable microvessels we have examined, the presence of fenestrated endothelium is variable in both human tumor vessels and rat glioma vessels. Our tumor endothelial cells were also not like normal animal barrier endothelium, in that the majority of vesicles in barrier endothelium are "tubule connected", and transendothelial channels and fenestrations are never seen. From the above results we conclude that, with regard to vesicular arrangement, tumor microvessels are not like normal brain barrier vessels, nor are they like normal permeable vessels. Therefore, the mechanism(s) of endothelial permeability in brain tumor vessels is unlikely to be same as that in normal permeable vessels.

246.11 LACK OF CORRESPONDENCE BETWEEN INCREASED PROTEIN PERMEABILITY AND NEURONAL ACTIVATION OR DEATH FOLLOWING HARMALINE-INDUCED TREMOR. R. E. Ruth, Inst. Study Dev. Disabil., Univ. Illinois, Chicago, IL 60608.

The β-carboline, harmaline, induces rhythmic tremor caused by increased bursting of inferior olivary (io) neurons. Concomitantly discharges appear in the cerebellum and those brainstem areas receiving cerebellar efferents. Surgical isolation experiments localize the action of harmaline to the io itself. Despite this widespread electrical activation only certain parts of io and the red nucleus manifest increased glucose metabolism (Bardin et al., 1983).

To observe if cerebrovascular protein permeability (CVP-p) increased during such tremors we injected freely moving rats with harmaline (20mg/kg, ip) followed either 2 or 60 minutes later with horseradish peroxidase (HRP, 35mg, iv). One hour after HRP injection rats were anesthetized and perfused. Brain sections were processed for the blue HRP reaction product. Control rats received harmaline alone or HRP alone to assess endogenous peroxidase activity and the normal pattern of CVP-p, respectively. A final group of rats was injected with harmaline and survived two days for neuropathologic examination of io using the Fink-Heimer method.

Under normal conditions HRP was found only in circumventricular organs; no endogenous peroxidase activity was evident. In harmaline/HRP-injected cases profuse reaction product was localized within io. In the cerebellum infrequent, discrete "spots" of reaction product appeared in the vermal molecular layer but nowhere else. No reaction product was observed in other brainstem areas activated electrically by harmaline nor in the red nucleus. Neuropathologic examination indicated no pyknotic or argyrophilic neurons within io, despite tremors lasting at least 4 hours in these cases.

The results indicate only a weak relationship between the anatomical localization of increased CVP-p and increased glucose metabolism. In addition the increased CVP-p within io is not associated with any long-term adverse effects on io neurons.

247.1 CHARACTERIZATION OF DIFFERENCES IN THE PHOSPHORYL RESIDUE OF NON-AGED AND AGED ORGANOPHOSPHORYL CONJUGATES OF SERINE HYDROLASES: $^{31}$P-NMR SPECTROSCOPY OF PHOSPHORYLATED α-CHYMOTRYPSIN. J. Grunwald*[1], Y.Ashani*[1], Y. Segall*[1], D. Waysbort*[1], N. Steinberg*[2] and I.Silman*[2] (SPON: M.Spiegelstein) Israel Institute for Biological Research, P.O.Box 19, Ness Ziona, Israel[1] and The Weizmann Institute of Science, Rehovot, Israel[2].

The powerful acute toxicity and delayed neurotoxicity of organophosphorus (OP) esters is attributed primarily to their irreversible inhibition of serine hydrolases such as AChE and neurotoxic esterases. In several cases, the inhibited enzyme undergoes a process, commonly termed aging, where the inhibited enzyme can no longer be reactivated. In order to provide basic information at the molecular level which may explain the unexpected stability of aged OP-enzyme conjugates, pyrenebutyl-O-P(O)($OC_2H_5$)F(PBEPF) and pyrenebutyl-O-P(O)($OC_2H_5$)Cl(PBEPC) were used to obtain the non-aged form [pyrenebutyl-O-P(O)($OC_2H_5$)Cht] where as pyrenebutyl-O-P(O)$Cl_2$(PBPDC) and pyrenebutyl-OP(O)(O$\Phi NO_2$)Cl[PBP(pNP)C] were used to produce the aged conjugate pyrenebutyl-O-P(O)(OH)Cht of α-chymotrypsin (Cht). The availability of highly purified large quantities of Cht enabled to prepare solutions of OP-Cht conjugates in the millimolar range, allowing not only fluorescence spectroscopy but also $^{31}$P-nmr spectroscopy. For the conjugates obtained from PBEPF, PBEPC, PBPDC and PBP(pNP)C the ratio of absorption at 344 and 280 nm indicated an approximately 1:1 (±15%) stoichiometry of OP and protein in the conjugate.The relative chemical shifts of the phosphorylated non-aged and aged Cht were found to be as predicted from the corresponding $^{31}$P-nmr chemical shifts of model compounds where the $^{31}$P-nmr signals of the non-aged form appeared ~1 ppm and ~1.7 ppm upfield to the aged conjugate for the native and denatured preparations respectively. The non-aged form could be reactivated in the presence of 3-pyridinealdoxime methiodide (3-PAM) whereas no reativation was observed for the similarly treated aged conjugate. The $^{31}$P-nmr results and the reactivation data strongly support the hypothesis that aged form of OP-Cht conjugate contains P-O$^{(-)}$ bond. These results, along with the fluorescence spectroscopy data (see following abstract) may provide partial interpretation for the known resistance of the aged conjugates of serine hydrolases to reactivation.

247.2 CHARACTERIZATION OF DIFFERENCES IN THE ACTIVE-SITE CONFORMATION OF NON-AGED AND AGED ORGANOPHOSPHORYL CONJUGATES OF SERINE HYDROLASES: OPTICAL SPECTROSCOPY OF PHOSPHORYLATED α-CHYMOTRYPSIN. N. Steinberg*[1], A.C.M.Van der Drift*[1], E.Haas*[1], I.Silman*[1],J.Grunwald*[2] and Y.Ashani*[2] (SPON:N.Allon). The Weizmann Institute of Science, Rehovot[1], and Israel Institute for Biological Research, P.O.Box 19,Ness Ziona[2],Israel

Two kinds of stoichiometric conjugates formed between α-chymotrypsin (Cht) and fluorescent organophosphorus (OP) cpds were examined by optical spectroscopy in order to probe their active sites. The non-reactivatable (aged) pyrenebutyl-OP(O)(OH)Cht was prepared by the reaction of either pyrenebutyl-OP(O)$Cl_2$ or pyrenebutyl-O-P(O)(O$\Phi NO_2$)Cl with Cht, whereas the reactivatable (non-aged) conjugate pyrenebutyl-OP(O)-($OC_2H_5$)Cht was prepared by reacting pyrenebutyl-OP(O)-($OC_2H_5$)F with Cht (see preceding abstract). The circular dichroism (CD) spectra of pyrenebutyl-OP(O)-($OC_2H_5$)Cht and of pyrenebutyl-OP(O)(OH)Cht in the tryptophans' absorption region is similar. However, the absorption anisotropy factor ($g_{ab}$) in the pyrene absorption region (ca. 350nm) is markedly more negative for the non-aged than for the aged form of OP-Cht conjugate. Similar results were obtained from circularly polarized luminescence (CPL) measurements. The emission anistropy factor of the aged conjugate obtained by two different inhibitors is the same within experimental error, and is different in both magnitude and sign from that of the non-aged conjugate. Steady-state fluorescence measurements of the conjugates reveal a similar fluorescence profile; the quantum yield of pyrenebutyl-OP(O)(OH)Cht is ca. 20% lower than that of pyrenebutyl-OP(O)($OC_2H_5$)Cht. Supporting evidence was obtained from fluorescence lifetime measurements. The fluorescence decay data of all the conjugates could be described by a two exponent decay function. The short component, ca. 10 nsec, was found to be equal for the aged and the non-aged OP-Cht conjugate, while the long component assumed the values of ca. 88 nsec and 98 nsec respectively. The data obtained by optical-spectroscopic methods clearly indicates different active-site conformations for the aged and non-aged conjugates. It may further be concluded that the position of the pyrene fluorophore relative to the polypeptide chain is different in the two conformations. These differences may be assigned to the different substituents attached to the P-atom.

247.3 VOLTAGE-DEPENDENT SLOW MEMBRANE CURRENTS IN RAT SPINAL DORSAL HORN NEURONS AND THE ACTIONS OF SUBSTANCE P. K. Murase and M. Randić (SPON: J. R. Carithers). Information and Computer Science, Toyohashi Univ. of Technology, Tempaku, Toyohashi, 440 Japan, and Dept. of Vet. Physiol. and Pharmacol., Iowa State Univ., Ames, IA 50011.

Rat (10-26 days old) spinal dorsal horn neurons in vitro were voltage-clamped by means of a single microelectrode sample-and-hold technique. In 22 out of 38 neurons examined, hyperpolarizing voltage commands from relatively positive holding potentials (-36 to -56 mV) elicited a slow inward current relaxation with voltage-dependent properties similar to the M-current, first described in amphibian sympathetic ganglion cells (Brown and Adams, Nature, 283:673-676, 1980). Increasing the bathing medium potassium concentration shifted the reversal potential of the curent relaxation to a less negative potential as predicted for a potassium current. The current is depressed by external $Ba^{2+}$ ions (0.5-4.0 mM), and in a few cells by muscarine (10-100 μM), but not by external $Cs^+$ (1 mM). In contrast, in 24 neurons, slow inward relaxations triggered by steps negative to -70 mV appeared to reflect another current resembling an anomalous rectifier, $I_Q$, of CA1 hippocampal neurons. This current is blocked by external $Cs^+$, but is not sensitive to muscarinic agonists or $Ba^{2+}$ ions. Substance P (SP, $10^{-7}$-$10^{-5}$M, Cambridge Research Biochemicals) reduced the M-like current in dorsal horn neurons irrespective of their muscarinic sensitivity. In addition, SP induced a novel inward relaxations in several cells clamped at a holding potential of -60 mV and subjected to one-second depolarizing voltage jumps. It is concluded that the coexistence of both SP effects in rat dorsal horn neurons might account for the SP-induced depolarization associated with a small conductance change in these cells.

247.4 GANGLIONIC BLOCKADE BY CLONIDINE. D. Christ. South Bend Center for Medical Education, Indiana University School of Medicine, Notre Dame, IN 46556.

Clonidine is an alpha-adrenoceptor agonist with antihypertensive actions. As catecholamines block synaptic transmission in autonomic ganglia by acting at alpha-adrenoceptors, an investigation was initiated to determine whether clonidine had effects on ganglia like the catecholamines. Compound action potentials were recorded from the postganglionic nerves of hamster isolated stellate ganglia that were superfused with an oxygenated, warmed physiological solution. When clonidine was added to the superfusing solution, the amplitude of the compound action potential was reduced. The onset of blockade was rapid, but full recovery usually had not occurred after 30 min in the control solution. Blockade was observed at concentrations of clonidine, as low as $10^{-8}$ M; but $10^{-4}$ M was necessary for complete blockade of the compound action potential. The slope of the concentration-blockade relationship for clonidine was not as steep as the slope of the concentration-blockade relationship for norepinephrine. The blockade at the lower concentrations of clonidine was reduced by yohimbine ($10^{-6}$M), an $alpha_2$-adrenoceptor antagonist; but yohimbine had little effect on the blockade by the higher concentrations of clonidine. In the presence of clonidine, paired preganglionic stimulation resulted in a marked facilitation of the second compound action potential if the stimulus interval was less than 200 ms. The effect of clonidine on ganglionic afterdischarges was also observed. The preganglionic nerve was stimulated at a frequency of 30 Hz for 2 s in the presence of hexamethonium ($10^{-3}$ M) to induce the asynchronous afterdischarges that appear to be mediated by muscarinic cholinergic mechanisms. Clonidine reduced the afterdischarges at concentrations greater than $10^{-9}$ M. $10^{-7}$ M Clonidine produced nearly 100% blockade, thus the afterdischarges were more sensitive to the blocking action of clonidine than the compound action potential. Yohimbine ($10^{-6}$ M) also reduced this action of clonidine. These results indicate that clonidine is very effective in blocking ganglionic transmission that is mediated by nicotinic or muscarinic mechanisms. The effect of clonidine appears to involve an action at $alpha_2$-adrenoceptors in the ganglion.

247.5 ACTIONS OF PHYSOSTIGMINE AND PYRIDOSTIGMINE ON CAT SPINAL CORD RENSHAW CELLS. W.G. VanMeter, K.C. Sikora-VanMeter, and R.C. Wierwille*. USAMRICD, Aberdeen Proving Ground, MD 21010-5425; Dept. of Veterinary Physiology and Pharmacology, Iowa State Univ. Ames, IA 50011, and Dept. of Pharmacology, School of Medicine, University of Maryland, Baltimore, MD 21201.

Responses of a cholinergic transmitting CNS synapse (spinal motoneurone axon collateral-Renshaw cell interneurone) to a tertiary carbamate (physostigmine) and to a quaternary carbamate (pyridostigmine) were compared in adult male cats of mixed breed. After DIAL anesthesia (80 mg/Kg, ip.), laminectomies were performed (S-1 to T-13), the spinal cord transected (T-13) and the spinal roots (dorsal and ventral) from segments L-5 to S-1 were separated, cut and placed on platinum stimulating electrodes. Extracellular unit potentials evoked by antidromic stimulation of the ventral roots were recorded by conventional methods from glass micropipettes (2.7M NaCl;1.0-1.5 micron tips) positioned in the ipsilateral spinal segments (usually L-7). Physostigmine salicylate (MW 413.5) induces a dose-dependent increase in frequencies and a marked increase in duration of the burst response. The latter increases in duration from 50-70 msec during predrug controls to a burst response in excess of 1 second after intravenous administration of the anticholinesterase (0.1-0.5 mg/Kg). Similarly, pyridostigmine bromide (MW 261) alters the burst frequencies and durations but to a much lesser extent (50-70 msec during predrug controls to 100-150 msec). Moreover, the dose range required is of greater magnitude (0.5-5.0 mg/Kg i.v.). Both anticholinesterase-induced responses are insensitive to atropine methyl nitrate (0.3 mg/Kg iv.) and to atropine sulfate (0.5-1.0 mg/Kg iv.) but are antagonized by mecamylamine HCl in a dose dependent manner (0.2-2.0 mg/Kg iv.). This antagonism is dose cummulative, persistent and not reversed by the subsequent administration of either anticholinesterase. An additional series of experiments in which drug treatments were carried out in vivo followed by in vitro histochemical verification of cholinesterase activities, shows pretreatment with either carbamate (physostigmine (0.2 mg/Kg iv.) or pyridostigmine (2.5 mg/Kg iv.)) to be effective in protecting the enzyme from irreversible inhibition by the subsequent administration of soman (0.01 mg/Kg iv.), with the stain being more pronounced with the tertiary carbamate. These data suggest pyridostigmine gains access to the CNS if given in sufficiently high doses and is consistent with a CNS action which heretofore has been inferred from indirect observations (Wolthuis, O.L. and Vanwersch, R.A.P. (1984) Fundam. Appl. Toxicol. 4: S195).

Supported in part by US Army Dept of Defense Contract DAMD17-80-0106.

247.6 EFFECTIVENESS OF PRETREATMENT WITH PHYSOSTIGMINE (PHY) AND MECAMYLAMINE (MEC) AGAINST LETHAL EFFECTS OF IRREVERSIBLE ORGANOPHOSPHORUS (OP) CHOLINESTERASE (ChE) INHIBITORS IN RATS. S.S. Deshpande*, G.B. Viana*, M. Kawabuchi*, A.F. Boyne, D.L. Rickett and E.X. Albuquerque. (SPON: D.R. Burt). Dept. Pharm. & Exp. Ther., Univ. of Maryland School of Medicine, Baltimore, MD 21201.

The reversible ChE inhibitor PHY can protect rats against a lethal dose ($LD_{100}$, 0.13 mg/kg) of sarin (Meshul et al., Neurosci. Abs., 1984). Female Wistar rats (220 g) were injected (i.m.) with PHY (0.1 mg/kg) and atropine (ATR, 0.5 mg/kg) or PHY + ATR and a ganglionic blocking drug MEC (4 mg/kg) or chlorisondamine (2 mg/kg). After 30 min, sarin (0.65 mg/kg, equivalent of 5 x $LD_{100}$ dose) or VX (0.05 mg/kg, equivalent of 4 x $LD_{100}$ dose) was injected subcutaneously. Blood ChE and muscle and brain acetycholinesterase (AChE) were inhibited by 50, 42 and 62% respectively (vs. 88, 82 and 98% in rats receiving sarin alone) in pretreated animals receiving sarin. Pretreatment with PHY + ATR produced 100 and 50% lethality after sarin and VX respectively. PHY + ATR + (MEC or chlorisondamine) reduced VX lethality from 50 to 0%. VX caused a 4-fold potentiation of single twitches (in vivo) of the extensor digitorum longus muscle within 5 min of injection, and the muscle was unable to maintain tension during 2 sec nerve stimulation at 50 Hz. These rats died at 15 min. A 2-fold potentiation of single twitch without loss of ability to sustain tetanus (50 Hz) was seen 30 min after PHY + ATR. An injection of VX (0.05 mg/kg) in these rats produced further twitch potentiation accompanied by failure to maintain tetanic tension and post tetanic depression of single twitches. Partial (at 6 hr) and complete recovery (at 24 hr) of muscle contraction were observed in rats receiving VX after PHY + ATR. In vitro recordings from endplate regions of diaphragm or soleus muscles showed an 8-10 fold increase in miniature endplate potential (MEPP) frequency without any alteration in membrane potential with 0.1 μM VX perfusion. Soleus muscles from rats receiving VX after pretreatment with PHY + ATR showed ~6 mV membrane depolarization at 24 hr. Electronmicroscopic examination of soleus muscles at 24 hr after injection of VX alone (0.005 mg/kg, sublethal dose) disclosed extensive subsynaptic vacuolization of mitochondria, disruption of sarcoplasmic reticulum and subjunctional myofibrillar architecture. In conclusion, PHY + ATR and PHY + ATR + MEC pretreatments were effective in protecting rats from the lethal effects of VX. Inability of PHY + ATR to protect rats from 5 x $LD_{100}$ dose of sarin argues against protection by carbamates of a critical pool of AChE from phosphorylation by OP agents. The mechanism of protection by PHY and MEC against sarin and VX should take into account the direct actions of these agents, PHY & MEC on the nicotinic receptor-ion channel located in the peripheral and central nervous system (Supported by U.S. Army Grant DAMD-17-84-C-4219).

247.7 EFFECT OF MUSCARINIC STIMULATION ON CALCIUM MOBILIZATION, PHOSPHOINOSITIDE METABOLISM AND TRANSMITTER RELEASE FROM PC12 CELLS. Carolyn S. Rabe and Forrest F. Weight Lab of Preclinical Studies, Nat'l Institute on Alcohol Abuse & Alcoholism, Rockville, MD 20852.

The rat pheochromocytoma cell line, PC12, has many characteristics in common with sympathetic neurons. In addition to nicotinic receptors, whose activation stimulates secretion, muscarinic binding sites have been identified on PC12 cells (Nature 297: 152, 1982). However, little is known regarding the functional significance of these muscarinic binding sites. Recently we have studied the effect of muscarinic agonists on intracellular $Ca^{2+}$ mobilization, phosphoinositide metabolism and transmitter release from PC12 cells. Intracellular free $Ca^{2+}$ was measured using the fluorescent $Ca^{2+}$ indicator Quin2. Cells were loaded with 10 uM Quin2 AM for 20 min, washed and resuspended at a concentration of 2 x $10^6$ cells/ml in HEPES buffered saline containing 1.8 mM $Ca^{2+}$. The cells had a resting free intracellular $Ca^{2+}$ level of approximately 110 nM using the calibration method of Tsien et al. (Nature 295: 68, 1982). Addition of muscarinic agonists of the low affinity subtype, $M_2$, methacholine (100 uM) or muscarine (100 uM), caused a 50-60 nM increase in intracellular free $Ca^{2+}$ levels. In contrast, agonists of the $M_1$ subtype, oxotremorine (1 mM) or McN-A-343-11 (1 mM), had no detectable effect on intracellular $Ca^{2+}$ levels. The increase in intracellular $Ca^{2+}$ produced by methacholine was blocked by atropine (100 nM). However, removal of $Ca^{2+}$ from the extracellular medium did not block the ability of the $M_2$ agonists to raise intracellular $Ca^{2+}$ levels. This suggested that the increase in intracellular $Ca^{2+}$ might be the result of mobilization of $Ca^{2+}$ from intracellular stores. Consistent with that hypothesis was the observation that methacholine treatment increased cellular levels of inositol triphosphate ($IP_3$), a metabolite of phosphatidylinositol bisphosphate shown to mobilize $Ca^{2+}$ from intracellular stores in several other cell types (Nature 312: 315, 1984). When cells had been prelabeled with [$^3$H]inositol (5 uCi/ml) for 24 hr, methacholine (200 uM) doubled [$^3$H]$IP_3$ levels within 30 sec (control 993 ± 71; methacholine 1960 ± 15 cpm/mg protein). The rate at which [$^3$H]$IP_3$ levels accumulated slightly preceeded the rate of increase in the Quin2 $Ca^{2+}$ signal. The levels of [$^3$H]inositol bisphosphate and [$^3$H]-inositol phosphate also increased, but with a slightly slower time course. We have also begun to examine the effects of $M_2$ receptor activation on secretion. In the absence of other stimuli, methacholine (100 uM) caused a small stimulation of catecholamine release from PC12 cells which had been preloaded for 30 min with [$^3$H]norepinephrine (500 nM, 23.1 Ci/mmol). Although it is unclear at this time whether the $M_2$ activated secretion was a direct result of $Ca^{2+}$ mobilization, the PC12 cells clearly provide a model system for examining the interrelationship between $M_2$-induced phosphatidylinositol metabolism, intracellular free $Ca^{2+}$ and secretion.

247.8 CHOLINERGIC FUNCTION IN MOUSE SPINAL CORD CELL CULTURES. F.Z.Wang* and P.G. Nelson. Lab. of Developmental Neurobiology, NICHD, NIH, Bethesda MD 20205.

Cholinergic synapses evoke both rapid, transient (nicotinic) and slow, sustained (muscarinic) excitation of mammalian central neurons. Slow, sustained depolarizing responses evoked by cholinergic agonists and reversibly antagonized by atropine were present in cultured spinal cord neurons (Linda M. Nowak & Robert L. Macdonald. J. Neurophysiology 49:792-803, 1983). We investigated cholinergic synaptic responses and responses to cholinergic agonists in mouse spinal cord neurons in cell culture to determine the mechanisms of cholinergic synaptic transmission between mammalian central neurons.

Intracellular recordings were made from dissociated fetal mouse spinal cord neurons and dorsal root ganglion (DRG) cells greater than 4 weeks in culture; in some cases rat superior cervical ganglion (SCG) neurons were added to the spinal cord (SC) cells. Experiments were performed in the presence of 5 mM $Mg^{++}$ and 5 mM $Ca^{++}$ using 3M KAc filled microelectrodes. Cholinergic SC neurons could be identified by the fast EPSP which they elicited in the SCG neurons. Pressure applications of acetylcholine (ACh), muscarine (MUS) or atropine from drug-filled perfusion pipettes were used to assess cholinergic effects on neuronal excitability or synaptic transmission between SC neurons or between DRG and SC neurons. In confirmation of others (Macdonald et al.), ACh or MUS produced an increase in the excitability of more than 3/4 of SC neurons tested; this was associated with an increase in neuronal membrane resistance. In 2 DRG neurons, hyperpolarizing responses were obtained. Excitatory synaptic connections tested with ACh or MUS were augmented while 2 IPSP were substantially diminished. The pre- or post-synaptic locus of these effects have yet to be determined. Stimulation of a SC neuron identified as cholinergic by its innervation of SCG cells could produce a prolonged, recurrent, depolarizing excitation of the cholinergic neuron itself which was blocked with atropine. Relatively rapid, depolarizing synaptic potentials in adjacent SC neurons were elicited by a cholinergic SC neuron, and in 'cholinoreceptive' neurons, ACh produced relatively rapid depolarization.

247.9 TWO RECEPTOR-IONOPHORE COMPLEXES MEDIATE THE ACTION OF GABA IN THE GUINEA-PIG HIPPOCAMPUS. N. Ogata*, M. Inoue*, and T. Matsuo* (SPON: C.H. Wu). Dept. of Pharmacol., Fac. of Med., Kyushu Univ., Fukuoka 812, Japan.

The ionic mechanism underlying the action of γ-aminobutyric acid (GABA) in the hippocampus was studied using brain slices. GABA, either perfused or ionophoresed, produced a triphasic membrane potential change in the pyramidal cells, comprising an initial fast hyperpolarization, a sustained depolarization, and a late hyperpolarization. When GABA was applied at low concentrations, the depolarizing component of the triphasic GABA response was selectively dissipated and the two hyperpolarizing components were fused to a monophasic hyperpolarization. The depolarizing component was augmented by a reduction of external $Na^+$.

The GABA-induced depolarization was markedly augmented by the substitution of external $Cl^-$ with an impermeant anion and was depressed by a low dose of picrotoxin ($10^{-5}$ M). Combined application of picrotoxin and a low concentration of bicuculline ($10^{-5}$ M) eliminated the major part of the depolarizing component in the triphasic GABA response and thus the two hyperpolarizations were fused to a monophasic hyperpolarization. Baclofen, a $GABA_B$ agonist, produces a prominent hyperpolarization due to an activation of $K^+$ conductance in the hippocampus (Inoue et al., Brit. J. Pharmacol., in press). The reversal point of the GABA-induced hyperpolarization approximated that of the baclofen-induced hyperpolarization. In addition, the GABA-induced hyperpolarization was augmented in low $K^+$ medium and reduced in high $K^+$ media but unaffected by a change in external $Cl^-$.

The hyperpolarization induced by baclofen but not by GABA showed prominent voltage dependence. The membrane depolarization markedly attenuated the response to baclofen while the decrease in input resistance was progressively enhanced by hyperpolarizing the membrane. The action of baclofen was strongly antagonized by a low dose ($5x10^{-6}$M) of 4-aminopyridine, whereas that of GABA was insensitive to a very high dose ($10^{-3}$M) of this drug. The slow inhibitory postsynaptic potential (slow i.p.s.p.) evoked by orthodromic stimulation was readily suppressed by a low dose of baclofen but not by GABA.

The results indicate that the GABA response in the hippocampus is mediated by at least two independent receptor-ionophore complexes. One is low-affinity receptors linked to $Cl^-$ channels and responsible for the depolarizing action of GABA, and the other is high-affinity receptors linked to $K^+$ channels and responsible for the hyperpolarization. The initial and late hyperpolarizations induced by GABA may result from activation of a common $K^+$ conductance distinct from the $K^+$ conductance responsible for the hyperpolarizing action of baclofen. The slow i.p.s.p. does not appear to be mediated by GABA, while baclofen may act as a potent agonist for receptors mediating the slow i.p.s.p.

247.10 RESPONSES TO GABA ON THE CELL BODIES AND DENDRITES OF RAT VISUAL CORTICAL NEURONS IN TISSUE SLICES. H. E. Scharfman and J. M. Sarvey. Dept. Pharm., Uniformed Services Univ. of the Health Sciences., Bethesda, MD 20814.

There is substantial evidence that GABA may be the transmitter of many inhibitory neurons in the visual cortex. To investigate the effects of GABA on visual cortical cells, intracellular recordings were obtained from tissue slices (450um thick) of rat visual cortex.

Recordings were obtained from 80 neurons located in layers II-VI (RMP=-65 ± 1.3mV; action potential amplitude=79 ± 1.2mV; $R_{in}$=31 ± 2.8mohms; mean ± sem). Ten cells were stained by intracellular injection of the fluorescent dye lucifer yellow and were identified as both pyramidal and nonpyramidal.

32 of 33 cells responded to pressure application (10-35psi, 5-1000msec pulses) of GABA (10mM) to the soma or dendrites. GABA responses were brief, lasting only seconds, and were associated with a conductance increase. Responses were composed of two components, the first with a reversal potential of -65.5 ± 0.5 mV (n=7), and the second with a reversal potential of -54mV ± 0.9mV (n=4). The first was hyperpolarizing or depolarizing, depending on the RMP, and observed following somatic or proximal dendritic GABA applications. When recording electrodes were filled with 3M KCl, the responses at the soma were only depolarizing, and had a more positive reversal potential (-48mV, n=2). Therefore, it is likely that chloride ions are involved in this response. The second type of GABA response was always depolarizing, and could be recorded after GABA application to any area of the cell.

Subthreshold and suprathreshold responses to synaptic stimulation or intracellular current injection were partially or completely blocked during GABA responses, which supports the hypothesis that GABA has an inhibitory action.

Addition of the GABA receptor antagonist bicuculline methiodide (50uM, n=3) to the perfusing medium blocked GABA responses which reversed near -54mV, but had little or no effect on the responses which reversed at -65mV.

It appears that almost all visual cortical cells respond to GABA applied on their cell bodies and dendrites, and are affected in a similar manner. The effects of GABA are also similar to those of hippocampal pyramidal cells. These studies provide some insight into the inhibitory influences on cortical activity.

247.11 PHENCYCLIDINE (PCP), A NEW POTENT ANTAGONIST FOR GLUTAMATE RECEPTOR. M. Idriss* and E.X. Albuquerque. (SPON: A.T. Eldefrawi). Dept. Pharmacol. & Exp. Therap., Univ. Maryland, School of Medicine, Baltimore, MD 21201.

The general anesthetic and hallucinogenic agent "Angel Dust" [1-(1-phenylcyclohexyl)piperidine; phencyclidine; PCP] is a drug of abuse which, when used chronically or in large doses, has schizophrenomimetic and convulsant properties and triggers unpredictable and dangerous violent behavior. A large number of studies have been devoted to PCP, and it has been demonstrated that this agent is able to affect the release and to interact with the recognition sites of many neurotransmitters. Albuquerque and coworkers initially showed that this agent blocks the voltage-sensitive K channels in the nerve and muscles thus resulting in prolongation of the action potential which can be responsible for increase in transmitter release from nerve terminals in many synapses. Further, the site of action of PCP as a noncompetitive blocker of the nicotinic acetylcholine (ACh) receptor-ionic channel complex involves an increase in affinity of ACh for its recognition site, subsequent desensitization and open channel blockade. Recently we have observed that PCP also interacts with the glutamatergic synapse. Such an action is reported here.

PCP at concentrations between 5 and 40 μM was tested on metathoracic tibialis muscles of Locusta migratoria. The drug produced significant voltage-dependent depression of endplate current (EPC) peak amplitude and accelerated the EPC decay time constant ( $\tau_{EPC}$ ). The depression of EPC peak amplitude induced by PCP was more prominent at hyperpolarized membrane potentials and was coupled with nonlinearity in the current-voltage relationship. PCP caused a significant shortening of $\tau_{EPC}$, and an increase in the drug concentration produced an apparent loss of the voltage-sensitivity recorded under control conditions. At -80 mV holding potential, PCP (5, 20 or 40 μM) depressed the EPC peak amplitude by 10, 50 and 67% and reduced $\tau_{EPC}$ by 28, 50 and 60% respectively. Fluctuation analysis indicated that PCP shortens channel lifetime but does not affect channel conductance. Also the alterations of the EPC characteristics induced by PCP involved a shortening of the EPC rise time.

The present study clearly demonstrates that PCP, at concentrations similar to those for blockade of the neuromuscular transmission, blocks the glutamate receptor ion channel in open conformation according to a mechanism similar to that of the nicotinic synapses. (Supported by U.S. Army Res. & Devel. Command Contract DAMD-17-84-C-4219.)

247.12 INTERACTIONS OF PHENCYCLIDINE (PCP) AND ITS DERIVATIVES WITH THE ACETYLCHOLINE-ACTIVATED ION CHANNEL. L.G. Aguayo* and E.X. Albuquerque. (SPON: G.J. Markelonis, Jr.). Dept. Pharmacol. & Exp. Therap., Univ. Maryland Sch. of Med., Baltimore, MD 21201.

Interactions of the hallucinogenic drug PCP (1-(1-phenylcyclohexyl) piperidine) and some of its analogs with the nicotinic ACh receptor-ionic channel complex were studied using electrophysiological techniques. The peak amplitude and the decay time constant of the nerve-evoked endplate currents (EPCs) recorded from the frog sartorius muscle were reduced by all the analogs in a concentration-dependent manner ($IC_{50}$ between 5 and 90 μM). PCP, TCP (1-[1-(2-thienyl)cyclohexyl] piperidine), and PCE (N-ethyl-1-phenylcyclohexylamine), among other analogs caused a negative slope conductance in the current-voltage relationship and a voltage- and time- dependent blockade of the peak amplitude of the EPC. When the piperidine ring of PCP was substituted by a morpholino ring, as in PCM (1-(1-phenylcyclohexyl) morpholine) and TCM (1-[1-(2-thienyl)cyclohexyl]morpholine), the potency decreased and the negative conductance was eliminated. The removal of the piperidine ring in PCA (1-phenylcyclohexylamine) and the hydroxylation of the cyclohexane ring in PPC (4-phenyl-4-piperidino-cyclohexanol) reduced the potency and produced double exponential decays at potentials between +50 and -50 mV. At -100 mV, the potency for EPC blockade was well correlated with the potency for reducing the decay time constant for all the analogs. The behaviorally active analogs were the most potent EPC blockers, which suggests a synaptic role for the production of behavioral alterations. TCP (5-25 μM) produced a large reduction in the peak amplitude without affecting its decay time constant (dynamic blockade). This blockade was independent of receptor activation and was reversed at positive potentials (i.e. +50 mV). Single channel currents in the presence of PCP (4 μM) or PCM (10 μM) revealed a decrease in channel openings and mean channel lifetime without any change in single channel conductance.

These results suggest that PCP and its analogs block the ionic channel of the nicotinic receptor by two independent mechanisms. The first is a voltage- and time-dependent inactivation which occurs when the channel is in the resting (closed) state and the second a blockade of the open state of the ionic channel. Forward rate constants for open channel blockade ranged between 1 and 4 X $10^7$ $M^{-1}$ $sec^{-1}$. The reverse rate constant (for drug dissociation) was enhanced by analogs expected to have lower hydrophobicity. (Support: USPHS Grants NS-12063 and DA02804.)

247.13 **REMOVAL OF MAGNESIUM INDUCES NMDA RECEPTOR MEDIATED LTP BY TRIGGERING EPILEPTIFORM ACTIVITY.** Eric W. Harris and Carl W. Cotman, Dept. Psychobiology Univ. Calif., Irvine, CA 92717

NMDA (N-methyl-D-aspartate) preferring receptors are highly concentrated in stratum radiatum of hippocampal region CA1. NMDA receptor antagonists do not affect synaptic transmission along the Schaffer collateral input to this area, but do prevent the induction of synaptic long-term potentiation (LTP). $Mg^{++}$ blocks NMDA responses and synaptic responses mediated by NMDA receptors in the spinal cord. Recently, Coan and Collingridge (Neurosci. Lett, 53:21) reported that Schaffer responses were increased by removing $Mg^{++}$, and that a lasting potentiation persisted after reintroduction of $Mg^{++}$. The mechanisms underlying these effects have been investigated. We report that a late component of the Schaffer synaptic response is unblocked by removing $Mg^{++}$, and that the lasting potentiation is caused by epileptiform activity in the absence of $Mg^{++}$.

The selective NMDA receptor antagonists AP5 and AP7 have no effect on the Schaffer synaptic potential or the intracelluarly-recorded EPSP. Removal of $Mg^{++}$ increases the synaptic field potential and CA1 population spike, but the inital portion of the synaptic response is still AP5- and AP7-insensitive. A late component of the synaptic field potential in $Mg^{++}$-free medium is AP5- and AP7-sensitive, however. Addition of AP5 or AP7 also lessened repetitive spiking following Schaffer stimulation and reduced the amplitude of the CA1 population spike.

The lasting potentiation that persists after reintroduction of $Mg^{++}$ is indistinguishable from LTP produced by high frequency stimulation. If slices were first given high-frequency stimulation, there was no additional lasting potentiation after treatment with $Mg^{++}$-free medium. Similarly, after treatment with $Mg^{++}$-free medium, no further LTP was induced by high-frequency stimulation. Furthermore, like LTP, the lasting potentiation following treatment with $Mg^{++}$-free medium could be prevented, but not reversed, by AP5 or AP7. Lasting potentiation after $Mg^{++}$ removal was always preceeded by epileptiform activity in $Mg^{++}$-free medium. However, if CA1 was isolated from CA3 by transsection, even though removal of $Mg^{++}$ induced the AP5- and AP7-sensitive late synaptic response, there was reduced repetitive epileptiform activity and no lasting potentiation. Potentiation could be induced by high frequency stimulation in isolated CA1, or in isolated CA3 by treatment with $Mg^{++}$-free medium.

These results suggest that removing $Mg^{++}$ enhances the early portion of the Schaffer synaptic response by a mechanism unrelated to NMDA receptors (probably by increasing presynaptic release). Removal of $Mg^{++}$ also unblocks NMDA receptors mediating a late part of the synaptic response, which further enhances CA1 and CA3 cell discharge. Repetitive activation of Schaffer fibers results, thereby producing LTP. NMDA receptors are involved in the induction of LTP, but their activation after removal of $Mg^{++}$ does not directly produce LTP.

247.14 EFFECT OF DIAZEPAM, PHENYTOIN, PENTOBARBITAL, AND PENTYLENETETRAZOL ON GABAERGIC INHIBITION MEASURED EXTRACELLULARLY BY PAIRED ORTHODROMIC STIMULATION IN RAT HIPPOCAMPUS IN VIVO. D. M. Rock* and C. P. Taylor. Dept. of Pharmacology, Warner-Lambert/Parke-Davis Pharmaceutical Research, Ann Arbor, MI 48105.

Extracellular field potentials (population spikes) were recorded from the hippocampus of urethane-anesthetized rats. A bipolar stimulating electrode was stereotaxically placed in the hippocampal commissure and an extracellular recording microelectrode was placed in the CA1 cell body region of the dorsal hippocampus. Identical pairs of monophasic pulses (0.5 msec duration, 10-1000 μA) were delivered to the hippocampal commissure. Stimulation of the commissure caused monosynaptic excitation of pyramidal cells and a resulting population spike (2-7 mV). When the delay between two stimuli of a pair was short (< 150 msec), GABAergic inhibition evoked by the first stimulus caused a decrement in the amplitude of the second population spike. Responses at various delays were taken before and after interperitoneal injections of drugs. In each experiment, eight data points were collected at an interstimulus delay resulting in roughly 50% inhibition of the second response. A two-tailed t-test was used to compare data before and after intraperitoneal drug administration. Doses of diazepam, pentobarbital and phenytoin were chosen in relation to previously-measured anticonvulsant activity in rat seizure models (tonic extensor seizures from maximal electroshock or subcutaneous pentylenetetrazol threshold seizures). Subconvulsant doses of pentylenetetrazol were also tested.

Diazepam (1, 4, and 8 mg/kg) and pentobarbital (7.5 and 15 mg/kg) significantly increased GABAergic inhibition in a dose-dependent manner as measured by decrement of the amplitude of paired orthodromic population spikes. Previous studies have shown that both diazepam and pentobarbital enhanced postsynaptic ionotphoretic GABA responses. In our study phenytoin (15 and 65 mg/kg) and pentylenetetrazol (20 mg/kg) both significantly decreased GABAergic inhibition. The current results with pentylenetetrazol confirm those of previous studies in which it attenuated postsynaptic GABA responses. However, some previous studies indicated that phenytoin enhanced GABAergic inhibition. The present results with phenytoin indicate that doses which prevented tonic extensor seizures from maximal electroshock in the rat did not enhance the amplitude or duration of hippocampal paired-pulse inhibition. We conclude that the anticonvulsant mechanism of phenytoin is fundamentally different from that of diazepam or of pentobarbital. However, the cellular mechanism responsible for the apparent decrease of inhibition by phenytoin is not known.

247.15 DITHIOTHREITOL INDUCES EPILEPTIFORM ACTIVITY IN THE GUINEA PIG HIPPOCAMPAL SLICE PREPARATION. J. M. Tolliver* and T. C. Pellmar (SPON: G. N. Catravas). Physiology Department, Armed Forces Radiobiology Research Institute, Bethesda, MD 20814-5145.

The sulphydryl reducing agent dithiothreitol (DTT) can alter the uptake and release of GABA from slices of rat cerebral cortex (Iverson and Johnston, J. Neurochem. 18, 1939, 1971). Considering that this putative neurotransmitter may play a role in the normal function of the hippocampus, it was of interest to examine the effects of DTT on hippocampal function using extracellular recording techniques.

Antidromic and orthodromic population spikes were recorded from the CA1 cell body layer of guinea pig hippocampal slices in response to stimulation of the alveus and stratum radiatum, respectively. The synaptic response (pop PSP) to orthodromic stimulation was recorded from stratum radiatum. Recurrent inhibition was elicited by applying a conditioning stimulus to the alveus at selected times prior to orthodromic stimulation. Slices were superfused with DTT for 30 minutes and then washed with normal solution.

A 30-minute exposure to 0.5 mM DTT resulted in multiple spiking of the orthodromic response (epileptiform activity) (n = 20). This effect appeared within 25 to 40 minutes after starting DTT superfusion and continued without diminution for the length of the observation period (2 hours). The antidromic response was slightly increased in four slices and was not changed in two other slices. Increasing the DTT concentration to 1.0 mM reduced the onset delay of epileptiform activity (n = 3). At 2.0 mM, DTT induced epileptiform activity followed by a rapid loss of orthodromic and antidromic responses (n = 3). Input/output curves were generated to evaluate the site of DTT action. Epileptiform activity elicited by DTT (0.5 mM) was accompanied by an increased orthodromic spike amplitude for a given afferent volley amplitude or pop PSP slope (n = 7). In four of the seven slices, the pop PSP slope evoked by a particular afferent volley size was increased by DTT. The effect of DTT on recurrent inhibition was also examined. DTT (0.5 mM) significantly reduced recurrent inhibition elicited at interpulse intervals of 1 and 3 msec by 25% and 29%, respectively (n = 7). These observations suggest that DDT induces epileptiform activity predominately via postsynaptic mechanisms and possibly also by synaptic mechanisms. Possible effects of DTT currently being considered include reduced recurrent inhibition, membrane depolarization and elevated postsynaptic sensitivity to putative, excitatory neurotransmitters in CA1 pyramidal cells.

247.16 ADENOSINE INHIBITS HIPPOCAMPAL EPILEPTIFORM ACTIVITY. B. Ault* and C.M. Wang* (SPON: A. Tadepalli). Dept. of Pharmacology, Wellcome Research Laboratories, Burroughs Wellcome Co., Research Triangle Park, NC 27709.

Burst firing induced in hippocampal area CA3 by bicuculline, kainic acid or tetanic electrical stimulation provides a convenient model of limbic seizure activity. We have found that the $GABA_B$ receptor agonist baclofen selectively depresses such activity. Since recent data have suggested that adenosine and baclofen-sensitive receptors are linked to a common second messenger system, we have examined the effect of purinergic agonists upon hippocampal epileptiform activity and studied the role of endogenous adenosine.

Extracellular field potentials were recorded from the CA3 pyramidal cell body layer of transverse hippocampal slices (425 μ nominal thickness). Burst activity was induced at rates between 4 and 22/min (means ± S.E.M. of 10.4 ± 0.6 bursts/min, N=49) by addition of bicuculline methiodide (50 μM) to the medium and slightly elevating the $K^+$ concentration (5 mM).

Purinergic agonists could completely suppress burst firing and the following $IC_{50}$ values were determined from dose-response curves: adenosine, 1.5 ± 0.2 μM N=10; 2-chloroadenosine, 0.2 ± 0.07 μM N=3; L-phenylisopropyladenosine, 13.4 ± 2.3 nM N=4; cyclohexyladenosine, 7.9 ± 1.5 nM N=4. These concentrations are approximately tenfold lower than those necessary to inhibit electrically-evoked synaptic potentials in area CA1, which parallels the relative potency difference noted for baclofen.

Theophylline (30 μM) increased the rate of burst firing in the presence of bicuculline and antagonized the effect of exogenous adenosine with a mean dose ratio of 7.5 ± 1.6, N=3. Similar studies using baclofen as an agonist indicated that about half of the antagonism was due to the increase in firing rate. The adenosine uptake inhibitor dipyridamole (0.03 - 1.0 μg/ml) decreased the rate of burst firing. Hippocampal slices in normal medium did not normally show bursting activity. In these preparations, superfusion of theophylline (30 μM) induced burst activity (N=5).

These data show that purinergic agonists are potent inhibitors of epileptiform activity in hippocampal area CA3 and that endogenous adenosine tonically serves to prevent the generation of burst discharges. A deficit in purinergic inhibition could therefore be important in the tiology of limbic seizures.

248.1 EFFECTS OF PHORBOL ESTER ON QUANTAL ACETYLCHOLINE RELEASE AT FROG NEUROMUSCULAR JUNCTION. C. Haimann * (SPON: European Neuroscience Association). CNR Ctr. of Cytopharmacol., Dept. of Pharmacol. and Ctr. Peripheral Neuropathies and Neuromuscular Diseases, 20129 Milano, Italy.

The possible involvement of protein kinase C in quantal transmitter release was studied at frog neuromuscular junction by using a phorbol ester that mimics the physiological activation of this protein by endogenous diacylglycerol (for ref. Nishizuka, Y., Nature, 308: 693, 1984).

Standard electrophysiological techniques were used to record intracellularly miniature endplate potentials (mepps) and endplate potentials (epps) at frog neuromuscular junctions soaked in modified Ringer's solution (0.7 mM $Ca^{2+}$ and 4 mM $Mg^{2+}$) containing 12-O-tetradecanoyl-phorbol-13 acetate (TPA), dissolved with anhydrous dimethyl-sulfoxide (DMSO). The quantal content of the epp was estimated from the ratio of the mean amplitudes of epps and mepps, obtained by averaging several mepps and epps evoked by nerve stimulation at low frequency (0.5 Hz). TPA was applied directly into the experimental chamber at final concentrations ranging from $1 \times 10^{-7}$ M to $3 \times 10^{-6}$ M. TPA induced an increase of the quantal content of about 3 fold. The minimal concentration necessary to elicit an effect was about $6 \times 10^{-7}$ M and the magnitude of the effect was apparently not correlated to the increase in concentration up to $3 \times 10^{-6}$ M. The enhancement of the evoked release developed slowly, reached its maximum in about 60 min and was partially reversible by washing the preparation with the modified Ringer's solution. After this washing period a second addition of TPA did not induce any further increase in quantal content. By contrast, TPA did not significantly affect mepp frequency or amplitude. The lack of effect of mepp amplitude suggests that the observed increase in epp amplitude is not due to gross changes in postsynaptic sensitivity. DMSO was uneffective in modifying quantal content in the range used (0.1-0.3%). Some neuromuscular preparations were also exposed to the TPA analogue 4-alpha-phorbol-12,13 didecanoate, which is unable to activate protein kinase C. This compound did not induce any change in the quantal content of epp or in mepp parameters at concentrations up to $2 \times 10^{-5}$ M.

These findings suggest that the increase in quantal release of acetylcholine evoked by nerve stimulation is due to the activation of protein kinase C. If this suggestion is correct it would imply a modulatory role of protein kinase even at those synapses such as neuromuscular junctions with high safety factor for transmitter release.

Partially supported by an M.D.A. Grant (B. Ceccarelli).

248.2 CHARACTERIZATION OF PHORBOL ESTER-STIMULATED PHOSPHORYLATION OF SPECIFIC PROTEINS IN RAT BRAIN SYNAPTOSOMES. J.K.T. Wang*, S.I. Walaas and P. Greengard. (SPON:R. Lewis). Laboratory of Molecular and Cellular Neuroscience, The Rockefeller University, New York, NY 10021.

The $Ca^{++}$/phospholipid-dependent protein kinase (kinase C) is present in synaptic regions of brain and can be specifically activated by phorbol esters. We now report the characterization of the phosphorylation of proteins in phorbol ester-treated synaptosomes, and a comparison with the phosphorylation induced by $K^+$-depolarization.

Rat cerebral cortical synaptosomes were prelabelled with $^{32}P_i$ and exposed to phorbol esters or to elevated $K^+$. Upon electrophoresis on two-dimensional SDS/polyacrylamide gel, a number of phosphoproteins from phorbol ester-treated synaptosomes showed increased incorporation of radiolabel. The two major substrates were acidic proteins of 87-kilodalton (kDa) and 50kDa. The 87kDa protein, previously reported to be a specific substrate for kinase C and to be enriched in brain (Wu, W.C.-S. et al., PNAS, 79:5249, 1982), was used as a specific marker for kinase C activation. Phorbol esters stimulated the phosphorylation of this protein in a time- and concentration-dependent manner, with the potency series (phorbol 12,13-dibutyrate = phorbol 12-myristate 13-acetate > phorbol 12,13-diacetate >> phorbol 13-acetate > phorbol) being similar to that observed in other systems. Extracellular $Ca^{++}$ was not required for this effect. Most of the substrates stimulated by phorbol esters were also sensitive to $K^+$-depolarization, although the degree of stimulation was less in the latter case. The major difference between the two was that elevated $K^+$, by activating the $Ca^{++}$/calmodulin-dependent (CaM) kinases, phosphorylated nerve terminal vesicle-associated proteins synapsin I and protein III. Phorbol esters, in contrast, had no effect on these proteins. Recent studies have shown that activation of the CaM-kinase system may play a critical regulatory role in neurotransmission at the squid giant synapse (Llinas, R. et al., PNAS, in press). However, kinase C is also activated during depolarization (Wu et al., 1982; present results). The following abstract by Nichols et al. shows that treatment of brain synaptosomes by a phorbol ester results in the modulation of $Ca^{++}$-dependent, $K^+$-induced neurotransmitter release. It is therefore possible that kinase C, by acting on one or more of the substrates described in this report, provides an additional mechanism of regulation of neurotransmission.

248.3 PHORBOL ESTER ENHANCES CALCIUM-DEPENDENT NEUROTRANSMITTER RELEASE FROM RAT BRAIN SYNAPTOSOMES. R.A. Nichols, J.W. Haycock, J.K-.T. Wang* and P. Greengard. Laboratory of Molecular and Cellular Neuroscience, The Rockefeller University, New York, NY 10021.

Depolarization of the synaptic terminal modulates the state of phosphorylation of specific phosphoproteins in a $Ca^{++}$-dependent manner. These changes are largely mediated by $Ca^{++}$-dependent protein kinases, a number of which have been identified. The preceding abstract (Wang, et al) describes the phosphorylation of proteins in synaptosomes treated with phorbol esters, compounds known to activate the $Ca^{++}$/phospholipid-dependent protein kinase (kinase C). Those studies demonstrated that most but not all of the synaptosomal phosphoprotein substrates affected by $K^+$-stimulated depolarization are also modulated by phorbol esters. The results confirmed the finding that kinase C is activated during depolarization of the presynaptic terminal (Wu, et al., PNAS, 79: 5249, 1982). The present study addressed the potential role of kinase C in the regulation of neurotransmitter release from synaptosomes by examining the effects of phorbol esters.

Pretreatment of rat brain synaptosomes in a continuous perfusion system with phorbol-12,13-dibutyrate (PDBu) led to an increase in $K^+$-stimulated, $Ca^{++}$-dependent release of neurotransmitter from prelabeled neurotransmitter pools. An increase was observed at all $Ca^{++}$ concentrations studied (0.05 to 3 mM). At 0.5 mM extracellular $Ca^{++}$, PDBu caused an average increase of 30% (range: 16-66%) in neurotransmitter release. The effect was dependent upon the concentration of PDBu. The PDBu-stimulated increase was observed for all brain regions and neurotransmitters studied (cerebral cortex: norepinephrine, acetylcholine and gamma-aminobutyric acid; corpus striatum: dopamine and acetylcholine; hippocampus: norepinephrine). PDBu had a slight effect (approx. 8%) on $K^+$-stimulated neurotransmitter efflux measured in the absence of extracellular $Ca^{++}$. Net accumulation of neurotransmitter was unaffected by the presence of PDBu. Inactive phorbol esters, such as phorbol, did not affect $K^+$-stimulated, $Ca^{++}$-dependent release. The PDBu-stimulated increase in release was also observed when veratridine or A23187 were used as secretagogues.

As the degree of enhancement of neurotransmitter release by phorbol ester was dependent upon extracellular $Ca^{++}$ and was observed with veratridine and A23187 as well as with $K^+$-stimulated depolarization, we postulate that activation of kinase C in the synaptic terminal results in the modulation of the stimulus-secretion coupling mechanism.

248.4 PHORBOL DIBUTYRATE INCREASES PROTEIN III PHOSPHORYLATION IN BOVINE ADRENAL CHROMAFFIN CELLS. J.W. Haycock, M.D. Browning and P. Greengard. Laboratory of Molecular and Cellular Neuroscience, The Rockefeller University, New York, NY 10021.

Proteins IIIa and IIIb (referred to collectively as Protein III) are members of a family of synaptic vesicle-associated phosphoproteins present in central and peripheral neurons. Protein III is also present in isolated bovine adrenal chromaffin cells. As previously described (Haycock, J.W., et al., Soc. Neurosci. Abstr., 10: 196, 1984), Protein III phosphorylation is increased by acetylcholine (ACh) and other secretagogues. The protein kinase(s) involved in this effect have not, however, been determined. The present studies investigated the possible involvement of two protein kinase systems: cAMP-dependent protein kinase (kinase A) and calcium/phospholipid-dependent protein kinase (kinase C) in the phosphorylation of Protein III in chromaffin cells.

After incubation of the chromaffin cells with $^{32}PO_4$, treatment of the chromaffin cells with phorbol dibutyrate (10-1000 nM) led to an increase in Protein III phosphorylation. Because the phosphorylation of Protein III by treatment with phorbol ester and ACh was not additive, it seemed possible that ACh and the phorbol ester might increase Protein III phosphorylation via common processes.

In that phorbol esters are thought to specifically activate kinase C, a possible role for kinase C in the phosphorylation of Protein III was investigated. Protein III was extracted (Zn acetate precipitation, pH 3 extraction) from treated and untreated chromaffin cells, and the ability of purified, exogenous kinase A (for which Protein III is known to be a substrate) or purified, exogenous kinase C to phosphorylate Protein III was determined. Treatment of the cells with either ACh or phorbol dibutyrate led to a decrease in the phosphorylation of Protein III by kinase A, indicating that both treatments led to an increase in situ in occupation of phosphate acceptor sites accessible to kinase A in vitro. However, kinase C was at least two orders of magnitude less effective than kinase A in phosphorylating Protein III. The fact that Protein III was not an effective substrate for kinase C in vitro suggests that phorbol dibutyrate may enhance Protein III phosphorylation in chromaffin cells indirectly via activation of cAMP-dependent protein kinase.

248.5 EVIDENCE FOR 4 CALCIUM ACTIVATED SITES INVOLVED IN TRANSMITTER RELEASE AND FACILITATION AT THE SQUID GIANT SYANPSE. E.F. Stanley, NINCDS Biophysics Laboratory, MBL, Woods Hole, MA.

Transmitter release has been reported to be proportional to a high power (N) of external Ca, suggesting that several Ca ions cooperate in the release of each transmitter quantum (Dodge and Rahamimoff, 1967). The squid giant synapse has recently been shown to have a high N value of 4 at low stimulus frequencies (Stanley, Biol Bull 167:532, 1984). Repetetive electrical stimulation of the prenerve results in facilitation of the EPSP recorded in the postsynaptic giant axon at stimulus frequencies above 0.3Hz. This facilitation has been attributed to a decline in the number of Ca ions required to activate the transmitter release mechanism: at 1Hz, N=3; 20Hz, N=2; and 80Hz, N=1 (Stanley, Biophys J. 47:55a). The dependence of facilitation on the stimulus frequency was examined in detail in this study in order to examine the transitions from N=4 to N=1.

The stellate ganlion was mounted in a chamber and continually perfused through its aorta, a technique that allows the rapid and controlled exchange of external solutions. The perfusate was artificial sea water containing low Ca (2mM) so that singe EPSPs were reduced to less than 2mV. At this low level of release the transmitter release mechanism is not saturated and the EPSP amplitude follows the fourth power of external Ca. In addition, transmitter depletion during repetetive stimulation is negligable at all but the highest stimulus frequencies. At each frequency tested, a train of stimuli was given to the prenerve until facilitation of the EPSP reached a maximum. The maximum facilitated EPSP was expressed as a percentage of the innitial EPSP in the train. Stimulus frequencies ranged from 0.1 to 90Hz.

The relation between maximum facilitation and stimulus frequency is best described by a curve with three discreet steps the plateaus of which occur at 1-3, 20-40, and >80Hz. It is suggested that each step corresponds to the activation of one of the four Ca-activated sites involved in the quantal release mechanism: thus, at any stimulus frequency the number of Ca sites activated (steps) plus the number of additional Ca ions required to trigger transmitter release (N) equals 4. These results suggest that the activation of transmitter release by Ca involves the triggering of a sequence of identifiable events, requiring the cooperative net action of four Ca ions for completion. Facilitation can be attributed to the activation of the release mechanism to a subthreshold level by the binding of one to three ions.

248.6 PATHOPHYSIOLOGY OF THE LAMBERT-EATON MYASTHENIC SYNDROME: EVIDENCE FOR CALCIUM CHANNEL BLOCKADE. Yong I. Kim, Depts. of Neurology and Biomedical Engineering, Univ. of Virginia School of Medicine, Charlottesville, VA 22908.

Previous studies from our laboratory have indicated that the electrophysiologic features of the Lambert-Eaton myasthenic syndrome (LES) are faithfully reproduced when the human disorder is passively transferred to mice (Kim, Muscle Nerve 8:162-172, 1985, Kim et al., Soc. Neurosci. Abstr. 10:199, 1984). In the present study the subsynaptic mechanism underlying LES was examined using the mouse passive transfer model.

Mice were injected daily (>20 days) with whole plasma or immunoglobulin fractions obtained from the controls and LES patients. In LES animals, quantal content ($m_d$), measured with 1.2 mM $Ca^{2+}$ and 10 mM $Mg^{2+}$, was markedly reduced. The increase in MEPP frequency ($F/F_o$ = test/control) occurring in response to high $K^+$ (17.5 mM) was also partially prevented. Since the elevation of $[K^+]_o$ activates voltage-dependent $Ca^{2+}$ channels and promotes $Ca^{2+}$ influx by depolarizing the motor nerve terminal, this observation alone suggests that $Ca^{2+}$ channels may be blocked at LES terminals, mimicking the action of $Ca^{2+}$ antagonists such as $Mg^{2+}$ and $Co^{2+}$. In this regard, treatment of

| Mean±SEM [No. of fibers] *p<0.001 | Quantal Content ($m_d$) | Relative MEPP Frequency ($F/F_o$) | | |
|---|---|---|---|---|
| | | $K^+$ | LiCl | Sucrose |
| Control | 2.01±0.11[112] | 107±4[115] | 147±8[97] | 131±14[25] |
| LES | 0.42±0.02[107]* | 34±2[99]* | 150±7[95] | 125±10[27] |

normal junctions with 0.25-0.3 mM $CoCl_2$ also reproduced similar presynaptic impairments. This "calcium channel" hypothesis, however, is not compelling because other alternative mechanisms such as abnormal intraterminal $Ca^{2+}$ buffering capacity or reduced ACh release sites can also explain the defects in LES. To clarify these points, the effects on $F/F_o$ of A) 135 mM LiCl (replacing NaCl) and B) 400 mM sucrose (hyperosmosis) were examined under $Ca^{2+}$-free conditions in the presence of 1 mM EGTA. These procedures are thought to stimulate the quantal discharge by increasing intraterminal $[Ca^{2+}]_i$ independently of external $Ca^{2+}$. The resulting MEPP discharges in both cases were similar at the control and LES junctions. Experiments on $CoCl_2$-treated junctions yielded similar data.

These results provide electrophysiologic evidence that the presynaptic impairment in LES is caused by reduced $Ca^{2+}$ entry secondary to the antibody-induced blockade of the voltage-dependent $Ca^{2+}$ channels. (Supported by NIH grant NS18607 and a research grant from the Muscular Dystrophy Association).

248.7 SUPPRESSION OF SYNAPTOSOMAL $^{45}Ca$ UPTAKE BY METHYLMERCURY. William D. Atchison, Urmila Joshi* and John E. Thornburg. Dept. Pharmacol./Toxicol., Michigan State Univ., East Lansing, MI 48824.

Acute administration of methylmercury (MeHg) suppresses synaptic transmission by a presynaptic block of transmitter release. One potential mechanism by which this block may occur is through suppression of voltage-dependent $Ca^{2+}$ entry into the nerve terminal in response to the action potential. Nachshen and Blaustein (J. Gen. Physiol. 83, 941-967, 1984) reported that inorganic, divalent mercury ($HgCl_2$) suppressed the uptake of $^{45}Ca$ during $K^+$-induced depolarization or following predepolarization in rat brain synaptosomes. The objective of the present study was to determine whether MeHg, which is a monovalent cation would also suppress $^{45}Ca$ uptake into synaptosomes. If so, this might explain in part the block of nerve evoked transmitter release reported previously with MeHg (Atchison and Narahashi, Neurotox. 3(3), 37-50, 1982). Synaptosomes were prepared from rat forebrains using conventional methods. The effects of (10-500 µM) MeHg on total $^{45}Ca$ uptake in $K^+$ depolarized ($[K^+]$ = 41 mM) synaptosomes was measured, and compared to that obtained in the presence of $HgCl_2$ (10-500 µM). Inorganic mercury produced a concentration-dependent suppression of depolarization-induced $^{45}Ca$ uptake. Peak inhibition occurred at 200 µM $HgCl_2$, which suppressed $^{45}Ca$ uptake to approximately 5% of premercury control values. These results corroborate those obtained previously by Nachshen and Blaustein. Similarly, MeHg also decreased total $^{45}Ca$ uptake, although the maximal inhibition produced (70% at 200 µM) was less than that produced by $HgCl_2$. The effect of MeHg was more apparent following 10 sec incubation in synaptosomes predepolarized for 10 sec with 41 mM $K^+$ prior to MeHg and $^{45}Ca$ addition than following a 1 sec incubation. A significant decrease in $^{45}Ca$ uptake occurred at 200 and 500 µM MeHg following the 10 sec incubation. $^{45}Ca$ uptake following a 1 sec incubation was also depressed by MeHg, but the decrease was not statistically significant. As Ca uptake during 10 sec is thought to represent flux through slow, non-inactivating Ca channels it appears that the effect of MeHg is most pronounced at this site. The total uptake of $^{45}Ca$ as a function of extracellular Ca in the absence of MeHg saturated at approximately 0.5 mM = $[Ca]_o$. When 200 µM MeHg was present, $^{45}Ca$ uptake also saturated at 0.5 mM $Ca^{2+}$ although the total uptake was only 35-40% of that in the absence of MeHg. Thus, MeHg appears to behave as a noncompetitive, irreversible inhibitor to Ca entry through a slow noninactivating membrane channel. These results are consistent with the block of Ca-dependent, nerve-evoked transmitter release induced by MeHg at the vertebrate neuromuscular junction. (Supported by NIH grant ES03299.)

248.8 FLUOXETINE INHIBITS $[^3H]$-5-HT RELEASE IN RAT SPINAL CORD SYNAPTOSOMES: POSSIBLE $Ca^{2+}$ CHANNEL ANTAGONISM. K.A. Stauderman* and D.J. Jones, Departments of Pharmacology and Anesthesiology, The University of Texas Health Science Center, San Antonio, TX 78284

Fluoxetine has been shown to be a selective and potent inhibitor of neuronal 5-HT uptake systems. However, this compound has a demonstrated ability to inhibit $K^+$-induced $[^3H]$-5-HT release in synaptosomes. Whether this inhibitory effect is mediated through a site-specific interaction is not known. Consequently, experiments were conducted to illuminate the mechanism of fluoxetine-induced inhibition of $K^+$-stimulated $[^3H]$-5-HT release.

$P_2$ fractions obtained from the spinal cords of male Sprague-Dawley rats were incubated at 37°C for 15 min in a buffer solution containing 100 uM iproniazid and 50 nM $[^3H]$-5-HT. Tissue aliquots were then loaded onto filters placed at the bottom of superfusion chambers, washed, and superfused for 30 min with a resting superfusion buffer (containing 3 mM $K^+$). Synaptosomes were then depolarized with either a 15 or 30 mM $K^+$ buffer for 15 min. After depolarization, $[^3H]$-5-HT remaining in the synaptosomes was extracted. Fractions were collected every 2 min. $[^3H]$-5-HT release was expressed as a percentage of total $[^3H]$-5-HT present before collection of each fraction. Test drugs and conditions were present from the beginning of superfusion.

$K^+$-induced $[^3H]$-5-HT release from rat spinal cord synaptosomes, determined as the difference from resting release values, was both $Ca^{2+}$-dependent and dependent on the concentration of $K^+$. At normal $[Ca^{2+}]$ (1.25 mM), 1 uM fluoxetine produced a 35% inhibition of 15 mM $K^+$-induced release and a 17% inhibition of 30 mM $K^+$-induced release. When the $[Ca^{2+}]$ was reduced to 0.125 mM, 1 uM fluoxetine decreased 30 mM $K^+$-induced release 46%. The $Ca^{2+}$-dependence of fluoxetine inhibition suggested the effect may involve presynaptic autoreceptors which regulate 5-HT release and are coupled to voltage-dependent $Ca^{2+}$ channels. Therefore, the effects of agents which alter autoreceptor function were tested in the absence and presence of 1 uM fluoxetine. 5-HT (30 nM) reduced 15 mM $K^+$-induced $[^3H]$-5-HT release by 30-40% and this effect was blocked by methiothepin (100 nM), a 5-HT receptor antagonist. However, methiothepin did not alter the inhibition of release produced by 1 uM fluoxetine. Thus, it appears that fluoxetine is not a 5-HT autoreceptor agonist. Considering fluoxetine's low affinity for neurotransmitter receptors and the structural similarity between fluoxetine and dihydropyridine $Ca^{2+}$ channel antagonists, it is proposed that fluoxetine blocks $Ca^{2+}$ channels, thus inhibiting $[^3H]$-5-HT release in a $Ca^{2+}$-dependent fashion.

248.9 SUBSTANCE B: AN ANTAGONIST OF PURINERGIC, MUSCARINIC AND ADRENERGIC PRESYNAPTIC RECEPTOR-MEDIATED INHIBITION OF [$^3$H]ACETYLCHOLINE RELEASE FROM SYNAPTOSOMES. L.B. Pearce*, C.G. Benishin and J.R. Cooper. Dept. Pharmacology, Yale Univ. Sch. Med., New Haven, CT 06510.

Presynaptic receptor-mediated control of neurotransmitter release although well documented in peripheral systems, has been more difficult to demonstrate in brain, particularly brain synaptosome preparations. While purinergic receptor-mediated inhibition of transmitter release has been demonstrated using electrophysiological recording and iontophoresis or measurement of transmitter release from brain slices, effects on release of [$^3$H]acetylcholine (ACh) from synaptosomes have not been well established. We have observed that guinea pig and rat whole brain extracts contain a factor which we have termed substance B that reverses presynaptic receptor-mediated inhibition of [$^3$H]ACh release. Crude synaptosomes were isolated from guinea pig ileum myenteric plexus and preloaded with [$^3$H]choline. The effect of various presynaptic receptor agonists on dimethylphenylpiperazinium (DMPP)-evoked release of [$^3$H]ACh was quantitated. When extracts of guinea pig brain were added to these assays, inhibition of ACh release produced by (-) phenylisopropyl adenosine, oxotremorine and clonidine was reversed. The factor did not effect evoked release of the transmitter. This factor was found to be associated with purified synaptosomes prepared from both guinea pig and rat brain. Substance B is insensitive to treatment with pronase, phospholipase C or boiling for 30 min., whereas ashing destroyed activity. Gel chromatography of an ultrafiltrate (10,000 MW cutoff) of a brain extract suggests that substance B has a molecular weight of approximately 700. While the nature of substance B remains unclear it is evident that this brain factor reverses presynaptic purinergic, muscarinic, and $\alpha$-adrenergic receptor-mediated inhibition of [$^3$H]ACh release from crude synaptosomes which may explain the difficulty encountered in our laboratory as well as that of others in attempting to demonstrate presynaptic mechanisms in brain. The significance of substance B in control of presynaptic regulatory mechanisms remains to be established. Results, however, of experiments using an intact tissue preparation confirm and extend the above findings (see abstract by Benishin et al.) suggesting a potentially important function.

248.10 SUBSTANCE B INTERFERES WITH MODULATION OF NEURONAL ACTIVITY IN THE INTACT LONGITUDINAL MUSCLE-MYENTERIC PLEXUS OF GUINEA PIG. C.G. Benishin, L.B. Pearce*, and J.R. Cooper. Dept. of Pharmacology, Yale Univ. Sch. Med., New Haven, CT 06510.

The guinea pig ileum myenteric plexus has proven to be a useful model for elucidating cholinergic mechanisms. For example, a variety of agents are capable of modulating the release of acetylcholine (ACh) in the myenteric plexus, whereas these modulatory mechanisms are much more difficult to demonstrate in the brain. Evidence presented in the previous abstract (Pearce et al.) indicates the presence of a substance in brain (Substance B) which prevents the modulation of evoked [$^3$H]ACh release from synaptosomes prepared from guinea pig longitudinal muscle-myenteric plexus. In the present study intact strips of longitudinal muscle-myenteric plexus were suspended in a tissue bath and field stimulated to elicit maximal contractions. Several drugs were used to inhibit the force of contraction including $\alpha_2$ adrenergic and purinergic agonists (clonidine and 2-chloroadenosine, respectively) which are postulated to act via presynaptic mechanisms, as well as agents whose actions are less clearly defined (e.g. morphine and PCP). An extract of brain which was previously shown to reverse the inhibitory effects of $\alpha_2$ adrenergic and purinergic agonists on [$^3$H]ACh release from ileal synaptosomes, was capable of a dose-dependent reversal of the inhibition of contractions by purinergic and $\alpha_2$ adrenergic receptor agonists in the intact longitudinal muscle-myenteric plexus preparation. The brain extract also reversed opiate receptor mediated inhibition of contractions in a dose-dependent manner. Substance B had a minimal effect on electrically induced contractions in the absence of modulation.

Several results suggest that myenteric plexus neurons may contain a small quantity of Substance B which is washed out early in the experiments. Therefore the intact guinea pig longitudinal muscle-myenteric plexus appears to be a suitable bioassay system for quantifying and examining the properties of this agent.

248.11 SELECTIVE ALTERATION OF DOPAMINE AND ACETYLCHOLINE RELEASE DURING ANOXIA OR 3,4-DIAMINOPYRIDINE TREATMENT. G.B. Freeman, V. Mykytyn* and G.E. Gibson. Cornell Univ. Med. Coll., Burke Rehab. Ctr., White Plains, NY 10605.

Hypoxia (i.e. low oxygen) reduces neurotransmitter metabolism through an unknown mechanism. In cortical slices, hypoxia reduces acetylcholine (ACh) release, stimulates glutamate release, but does not alter norepinephrine, serotonin, or $\gamma$-aminobutyrate release. The hypoxic-induced decline in ACh synthesis appears to be linked to altered calcium homeostasis. To further investigate the relative susceptibility of neurotransmitters to impaired oxidative metabolism, the in vitro release of glutamate, dopamine and ACh were determined in mouse brain striatal slices during anoxia. After a 60-min preincubation, the potassium-stimulated (31 mM-KCl) release of dopamine was determined at 0, 0.5, 1.0, 2.5, 5.0 and 10 min. Dopamine release increased 12-fold after 5 minutes and then decreased. Thus, subsequent experiments utilized 5 min time intervals. The potassium-stimulated release of dopamine and ACh in this system were calcium-dependent whereas glutamate release was not. In 31 mM-KCl, 2.3 mM calcium media, anoxia (100% $N_2$) increased dopamine and glutamate release, 56% and 55%, respectively, but decreased acetylcholine release 22%. The omission of calcium during an anoxic incubation with high $K^+$ failed to abolish the increased release of dopamine, while it further decreased ACh release and further increased glutamate release. The selective alteration in the release of these neurotransmitters with anoxia and the previously demonstrated impairment of calcium uptake by anoxia suggest that calcium's role in their release varies. Thus, the effects of 3,4-diaminopyridine, a drug which promotes calcium influx into nerve endings, were investigated. In low potassium media (5 mM-KCl), 100 uM of 3,4-diaminopyridine increased ACh release (+20%) to levels similar to potassium-stimulated samples. In contrast, dopamine release was markedly reduced (-42%). In summary, anoxia impairs ACh release and stimulates dopamine release, whereas 3,4-diaminopyridine has the opposite effect. A variable role of calcium in neurotransmitter metabolism in response to injury or drug treatment may underlie these differences. (Supported by grants NS03346, AG04171, AG05352 and the Burke Relief Foundation.)

248.12 EFFECTS OF DIVALENT CATIONS ON EXCITATORY AND INHIBITORY POTENTIALS IN THE RAT HIPPOCAMPUS IN SITU. J. Casullo* (SPON: K. Krnjević) Dept. Anaesthesia Research, McGill University, Montréal, Québec H3G 1Y6, Canada.

Experiments were performed on rats anaesthetized with urethane or dial and maintained in a stereotaxic head frame. Extracellular field potentials were recorded in the CA1 region of the dorsal hippocampus with the central barrel of 5-barrelled micropipettes. Peripheral barrels were used for iontophoretic applications of 0.1 M $CaCl_2$, $MgCl_2$, $MnCl_2$, or $CoCl_2$. In some experiments somatic and apical dendritic potentials were recorded simultaneously with two multibarrelled pipettes separated by a vertical inter-tip distance of $\approx$ 250 µm.

Fimbrial stimulation (0.8 Hz) at intensities below threshold for evoking a population spike in CA1, induces excitatory and inhibitory postsynaptic currents in pyramidal cells, which generate negative and positive extracellular potentials in stratum radiatum (SR) and stratum pyramidale (SP) respectively. During simultaneous recording from SR and SP, divalent cations applied in either SR or SP produced changes only in the field response recorded at the same level indicating that negative and positive field potentials arise essentially independently. Both types of PSP field responses were consistently potentiated by $Ca^{2+}$ and depressed by $Mg^{2+}$, $Mn^{2+}$, and $Co^{2+}$. Typically, for current applications of 50-100 nA lasting 30 s, $Ca^{2+}$ increased the amplitude of the negative and positive waves by 40% and 20% respectively, while $Mg^{2+}$, $Mn^{2+}$, and $Co^{2+}$ reduced the amplitude of the negative and positive waves by 30-50% and 50-80% respectively. In addition to differences in magnitude there may also be differences in the time course of effects on excitatory and inhibitory potentials when cations are applied at different levels in CA1.

These results suggest that transmitter release from both excitatory and inhibitory terminals can be enhanced by locally applied $Ca^{2+}$ and reduced by locally applied $Mg^{2+}$, $Mn^{2+}$, or $Co^{2+}$. Indeed, when a population spike was evoked by stronger fimbrial stimulation, its amplitude could be depressed by $Ca^{2+}$ and increased by $Mg^{2+}$, $Mn^{2+}$, and $Co^{2+}$ when the cations were applied in SP. Conversely, the spike amplitude was augmented by $Ca^{2+}$ and reduced by the other ions when the cations were released in SR.

248.13 CENTRAL SYNAPTIC EFFECT AND CONVULSIONS PRODUCED BY RUTHENIUM RED INTRAPERITONEALLY INJECTED TO ADULT RATS. A. Feria-Velasco, J. Arauz-Contreras*, A. Palomera* and A. Morales*. Div. of Neurobiology, Unidad de Investigación Biomédica de Occidente, I.M.S.S.. Guadalajara, Jal. MEXICO.

Ruthenium red (RR), a polycationic, hydrosoluble dye combines with several substances at the external surface of cells, including those participating in the configuration of the voltage-dependent $Ca^{++}$ channel. RR when injected intraperitoneally (i.p.) to mice produces flaccid paralysis, whereas when administered intracisternally to mice and cats induces convulsions (Tapia, R. et al.: Brain Res.,116:101, 1976; Kubli-Garfias, C. et al: Neurosci., 7:2777, 1982). In our laboratory when RR has been injected i.p. to adult rats induced hyperexcitability and convulsions after a flaccid paralysis period, suggesting a central effect of the dye (Arauz-Contreras, J. et al., Arch. Inv. Med.,13:271, 1982).

In the present work a systematic study of motor activity, correlated with electrocorticographic recordings (ECG) was carried out following i.p. administration of RR (5-30 $mg.Kg^{-1}$) to adult rats. Synaptosomal ($P_2$) fraction from brains of rats injected with 12.5 and 20 $mg.Kg^{-1}$ RR was obtained at various time intervals after RR administration, to demonstrate ruthenium (Ru)signal by means of X-ray spectrometric analysis (EDAX) on a system adapted to a scanning electron microscope. In corresponding experiments, high affinity $Na^+$-dependent uptake of radiolabeled catecholamines, and $Ca^{++}$-dependent [$^{14}C$] dopamine release induced by depolarizing stimuli, from $P_2$ fraction obtained from rats i.p. injected with 12.5 $mg.Kg^{-1}$ RR were measured.

Rats i.p. injected with RR, showed the previously communicated changes in motor activity in a dose-dependent manner (Arch. Inv. Med.,13:271, 1982). No variations were seen in the ECG during the period of flaccid paralysis, whereas the electromyographic recording (EMG) showed a marked voltage reduction. Typical trains of high voltage spikes were seen in the ECG during the convulsive period, which was correlated with hyperactivity in the EMG. Ru signal in $L\alpha$ and $L\beta$ shells was detected in the EDAX of $P_2$ fraction obtained from rats injected i.p. with RR at 2 and 4 hours after RR administration, and no significant changes were seen in the high affinity $Na^+$-dependent uptake of catecholamines by that $P_2$ fraction. However, the $Ca^{++}$-dependent release of [$^{14}C$] dopamine induced by depolarizing stimuli (high potassium or veratrine) was significantly reduced in the brain $P_2$ fraction obtained from rats injected i.p. with RR.

It can be concluded that besides the peripheral effect of RR in rats, the convulsive episode observed afterwards in a dose-dependent manner is produced by a central action of RR at synaptic level, probably diffusing from areas devoided of blood-brain-barrier. This subject is under investigation in our laboratory.

## POSTSYNAPTIC MECHANISMS II

249.1 GABA-ACTIVATED CHANNELS IN CULTURED CHICK CEREBRAL NEURONS. D. S. Weiss*, E. M. Barnes, Jr.*, and J. J. Hablitz. Depts.of Neurology and Biochemistry and Program in Neuroscience, Baylor Col. of Med., Houston, TX 77030.

To understand the mechanism of the postsynaptic action of the inhibitory neurotransmitter GABA, quantitative physiological measurements of the interaction of the agonist with its receptor are needed. We have approached this problem using cultured neurons from the chick cerebrum. These cultures are essentially glia-free for the first 8-10 days, and the neurons are predominantly GABAergic, as shown by the presence of GAD-like immunoreactivity. Previous studies (Thampy & Barnes, 1984) have shown the existence of a GABA-gated chloride flux in these neurons which is antagonized by picrotoxin and bicuculline. The present electrophysiological studies have identified and begun to characterize functional GABA synapses and channels in these cultures.

The gigaohm patch-clamp technique was used to record whole-cell and single-channel currents from excised membrane patches. Pressure application of 10 and 100 μM GABA produced inward currents in whole-cell recordings. The amplitude of these currents was voltage-dependent and reversed in sign at the chloride equilibrium potential. Currents in response to prolonged application of GABA declined over time. The rate of decline was more rapid with 100 μM GABA. The decline in current was accompanied by a decrease in the conductance change induced by GABA, suggesting a true desensitization. After 6-8 days in culture, spontaneous inhibitory postsynaptic currents were routinely observed. These currents were chloride-dependent, antagonized by low doses (1 μM) of picrotoxin, and prolonged by pentobarbital (100 μM). Under normal conditions, the decay of these currents did not follow a simple exponential time course but could usually be described by the sum of two exponentials. The role of uptake and channel kinetics in determining the decay of spontaneous synaptic currents is being investigated. Under physiological recording conditions, excised membrane patches were observed to contain numerous voltage-dependent ionic channels. Quiescent patches were obtained by recording in isotonic choline chloride solutions. Under these conditions, exposure of patches to GABA resulted in the appearance of discrete unitary agonist-gated channels. GABA channels in these neurons were nonrectifying over a range of membrane potentials from -60 to +60 mV and had a main conductance state of approx. 20 pS.

These results indicate that cultured chick cerebral neurons utilize GABA as their principal inhibitory neurotransmitter. The lack of glial contamination and the apparent predominance of GABAergic neurons make these cultures a useful model system for study of the molecular mechanism of GABA action. (Supported by USPHS grants NS-11535 and AM-17436.)

249.2 **INHIBITION OF ACETYLCHOLINE RECEPTOR INCORPORATION BLOCKS DEVELOPMENTAL CHANGES IN CHANNEL GATING IN XENOPUS MUSCLE.** P. Brehm, L. Bates*, R. Kream and F. Moody-Corbett. (SPON: S. Fink). Depts. of Physiology & Anesthesiology, Tufts University School of Medicine, Boston, MA, 02111.

Acetylcholine receptors on embryonic Xenopus muscle have been shown, by both noise analysis and single channel recording techniques, to undergo developmental alterations in both channel kinetics and conductance. It was further shown that these changes resulted from an increase in the proportion of a high conductance channel with fast channel kinetics. The increase in the proportion of high conductance channels, when followed in cell cultures prepared from dissociated embryonic myotomal muscle, was paralleled by rapid incorporation of newly synthesized receptors. These findings suggest that receptor incorporation may be required for alterations in channel physiology. To test this hypothesis, we inhibited receptor incorporation by blocking protein synthesis during the time in which changes in channel properties normally occur. Simultaneously, we examined whether there was any effect on the acquisition of adult channel gating properties. Cycloheximide, a blocker of protein synthesis, inhibited greater than 90% of receptor incorporation at a concentration of 50 ug per ml, as measured by $^{125}I$ alpha-bungarotoxin binding to developing Xenopus muscle in vivo. Cycloheximide concentrations below 1 ug per ml were ineffective at blocking incorporation while concentrations exceeding 50 ug per ml were slightly more effective (greater than 95% at 100 ug per ml). Inhibition of receptor incorporation at 50 ug per ml cycloheximide was achieved within two hours of treatment thereby permitting its action on changes in channel physiology to be studied. To examine the effects of inhibiting receptor incorporation on channel properties, we applied 50 ug per ml cycloheximide to half of the cultures prepared from stage 17 to 20 embryos, a time prior to developmental changes in channel gating. The cultures were treated with cycloheximide within 12 hours of plating and recorded from after an additional 24 hours. The extent of changes in gating in both drug treated and nontreated co-cultures was quantitated by measuring the percentage high conductance channel openings. In 4 nontreated cultures the percentage high conductance channels increased from 12% (n=16) to 40% (n=10) over the 24 hour period. These values were not significantly different from previously published values from our lab. In contrast, cycloheximide-treated cultures exhibited only 13% (n=17) high conductance channels after 24 hours, indicating a definitive block of the developmental changes in channel gating. These data indicate an ongoing requirement of protein synthesis for developmental changes in channel physiology. Further experiments are in progress to ascertain whether inhibition of receptor incorporation by blockade at levels other than translation yield similar results. Supported by grants from the NIH (NS18205) and Myasthenia Gravis Foundation.

249.3 PHYSOSTIGMINE REDUCES THE SIZE OF THE FOCAL LESIONS INDUCED BY IRREVERSIBLE ChE INHIBITORS AT THE NEUROMUSCULAR JUNCTION OF RATS: AN ULTRASTRUCTURAL ANALYSIS. M. Kawabuchi*, A.F. Boyne, S.S. Deshpande* and E.X. Albuquerque. Dept. Pharm. & Exp. Ther., Univ. of Maryland Sch. of Med, Baltimore, MD 21201.

Anticholinesterase agents such as physostigmine [Phy, a reversible inhibitor of acetylcholinesterase (AChE)] and sarin (an irreversible inhibitor of AChE) are known to interact with the acetylcholine receptor-ion channel complex. Numerous studies have confirmed that blockade of AChE by a variety of anticholinesterase agents causes a subjunctional myopathy (Ariens et al., 1969; Laskowski et al., 1975, 1977). Pretreatment of rats with atropine (500 µg/kg, subcut.) and Phy (100 µg/kg, subcut.) 30 min prior to the injection of a lethal dose of sarin (130 µg/kg) protected 100% of the animals from lethality (Meshul et al., Neurosci. Abstr. 10:920, 1984; Deshpande et al., 1985, in press). In order to evaluate morphologically this protective effect of Phy, light microscopic and ultrastructural observations were performed on the rat soleus neuromuscular junctions. Samples were taken from rats at 1 hr after sarin (80 µg/kg) treatment, at 1 hr and 24 hr after Phy (100 µg/kg) treatment, and from those pretreated with Phy (100 µg/kg) for 30 min, followed by treatment with sarin (80 µg/kg, a sublethal dose) for 1 hr. All treatment drugs were administered subcutaneously. Sarin-treated muscles showed severe disruption of postjunctional folds, extensive subsynaptic vacuolization of mitochondria and sarcoplasmic reticulum; and severe disorganization and disarrangement of the subjunctional myofibrils. Phy had a selective effect in inducing Z line changes without any gross vacuolization and mitochondrial swelling. Such myopathic changes were largely reversed 24 hr after Phy treatment. Pretreatment of Phy prior to sarin offered marked reduction in the severity of the damage induced by sarin. In most motor endplates, myopathic lesions were recognized, but the banding patterns of the subjunctional myofibrils were preserved. Large vacuoles of mitochondrial origin were seen in the area confined to the endplate sarcoplasm. Statistical analysis of the light microscopic sections revealed that Phy induced a 27% reduction in the average length of lesions and 53% reduction in the average width of lesions. Such effective protection could be related to Phy's ability to penetrate the central nervous system, and/or block ionic channels and decrease channel conduction time in the site of the neuromuscular junction (Supported by U.S. Army Grant DAMD-17-84-C-4219).

249.4 MODIFICATION OF PHOSPHOLIPID FATTY-ACID COMPOSITION AND EFFECTS ON NICOTINIC RECEPTORS IN BC3H-1 CELLS. R.E. Sheridan and R. McGee. Department of Pharmacology, Georgetown University, Schools of Medicine and Dentistry, Washington, DC 20007.

BC3H-1 cells are a continuous muscle cell line which express nicotinic acetylcholine receptors. The potential importance of phospholipid fatty acid composition to the functioning of these receptors was examined by growing cells in media supplemented with specific fatty acids and making patch-clamp recordings of single nicotinic, acetylcholine receptors.

BC3H-1 cells were initially grown in Dulbecco's modified Eagles media (DMEM) supplemented with 20 % fetal bovine serum (FBS) for 2 days. The cells then were transferred to media with 10%or 20% FBS and 32 uM BSA either with or without 128 uM arachidonate (20:4). The cells were allowed to grow to confluency, usually an additional two days, and then were transferred to DMEM with either 2% or 0.5% FBS, exposure to 20:4 being continued as appropriate. Control cells were very deficient in polyunsaturated fatty acids as is normally observed in cells grown with FBS; oleate (18:1 was by far the predominant unsaturated fatty acid. Cells grown with 20:4 were greatly enriched with this polyunsaturated fatty acid and 22:4, its elongation product.

The functional activity of nicotinic receptors was assessed by electrical recordings of single-channel currents. The BC3H-1 cells were transferred to a HEPES-buffered saline solution at 20°C and the patch clamp technique was used to record the activity of individual nicotinic receptors in intact, cell attached, patches of membrane. The patch electrode typically contained saline with 1 to 40 uM carbachol. Cells treated with 20:4 did not show acetylcholine receptor mediated currents, even though paired controls (grown without the 20:4 but with BSA) showed high levels of receptor activity. The membrane patches in the 20:4-treated cells were functional, as revealed by the activity of non-cholinergic channels in the membrane. Acute (one hour) exposure of control cells to 20:4 did not alter the conductance, mean open lifetime, or the voltage-dependence of the mean open lifetime of carbachol-stimulated channels. When the treated cells were removed from the unsaturated fatty acid supplement, there was no recovery of activity after 2 days of growth with 0.5% FBS. However, in cells recovered for 5 days in 2% FBS a high level of nicotinic receptor activity was observed. The properties of these receptors were indistinguishable from those of control cells.

These results suggest that supplementing cells with high levels of polyunsaturated fatty acids may alter synthesis and/or turnover of nicotinic receptors but does not seem to alter the properties of remaining receptors.

249.5 INTERACTIONS OF Ca++ CHANNEL ANTAGONISTS WITH NICOTINIC RECEPTORS. L.Adam* and E.G.Henderson. Dept. of Pharmacology, University of Conn. Health Center, Farmington, Conn. 06032.

We have previously shown that certain organic Ca++ channel blockers have direct effects on the nicotinic receptors of both frog and Torpedo electroplax (N.Y.Acad. Sci., in press.) Of the compounds tested (D-600,Nitrendipine,Bepridil,Nicardipine as well as the partial agonist BAY k-8644) Nicardipine (Nicard, 0.03 to 1 uM) and Bepridil (Bep, 1uM) were the most potent in blocking carbamylcholine (carb, 10 and 100uM) and acetylcholine (Ach)-induced contractures of frog sartorius muscle. Block was time and concentration dependent. Nicard (10uM) did not alter the kinetics of neurally evoked endplate currents (EPC's) or block neurally evoked twitches. It also did not block the depolarization caused by iontophoretically applied Ach.

Nicard and Bep accelerated desensitization which is also both time and concentration dependent. The time course for desensitization was studied using the method of Manthey (J.Gen.Phys. 49:963, 1966) to apply carb (100uM) focally on frog cutaneous pectoris muscles voltage clamped to -90mV. An equation similar to that used for acid and base catalyzed reactions was employed to determine a theoretical relationship between Nicard conc. and the rate of nicotinic receptor desensitization. This equation follows from the theoretical basis that the nicotinic receptor bound by Nicard is responsible for the acceleration of desensitization independent of whether the receptor-ionophore complex is in its open, closed, or desensitized conformation. The following equation was employed:

$$k=k^{o}+k_{cat}\,(N/N+K_{d}),$$

where k and $k^{o}$=rate constants in the presence and absence (with all other factors affecting desensitization remaining constant) of Nicard at a conc. of N; $K_d$=diss. constant and $k_{cat}$ is a catalytic coefficient which remains constant as a function of N. Using this equation, an electrophysiological $K_d$=0.61µM for Nicard was determined. When the antagonism by Nicard of $^3$H-PCP binding to Torpedo microsacs was studied, a biochemically measured $K_d$=0.87uM was obtained. These results are significant in describing a $K_d$ using frog muscle in a manner that does not require a second biological system (i.e. Torpedo.) Also, Nicard allows a broad range of concentrations for desensitization studies to be used that do not affect any aspect of the kinetics of EPC's. Nicard has a $K_d$=0.61 uM and does not affect EPC's at 10uM; SKF 525-A, a prototype desensitizing agent alters the kinetics of EPC's at conc. of 2-5uM.

Although Nicard antagonizes PCP binding to microsac membranes, in electrophysiological experiments it enhanced the effects of PCP in altering EPC decay and peak amplitude. Bep, which is 10 fold more potent in antagonizing PCP binding, did not enhance the effect of PCP on EPC's. Studies are in progress to assess the mechanism whereby Nicard and Bep increase the rate of desensitization.

249.6 OPEN-CHANNEL BLOCKADE BY CHLORISONDAMINE (CHL) LEADS TO A STABLE NON-CONDUCTING STATE OF THE ACETYLCHOLINE (ACh) CHANNEL AT THE FROG END-PLATE. A. Neely*, C.J. Lingle (SPON:P.Cancalon). Dept. Biol. Sci., Florida State Univ. Tallahassee, FL 32306.

The effect of the long-lasting ganglionic blocker, CHL, on end-plate currents (EPCs) was studied at the neuromuscular junction (NMJ) of the cutaneous pectoris in the grass frog, Rana pipiens, using conventional two microelectrode voltage-clamp. First, effects were examined on miniature end-plate currents (MEPCs). The major effect of CHL (concentrations 1-10 M) on MEPCs is to shorten the decay time. Changes in amplitude are noticed after prolonged application or high concentrations. The decay is fully described by a single exponential relaxation process in controls and in the presence of CHL. The inverse of the time constant increases linearly with drug concentration, with a slope that increases with hyperpolarization. This observation is consistent with the mechanism of open-channel blockers which are able to plug the pathway for ion flow once the channel is opened following the binding of two ACh molecules (Peper et al, 1982; Physiol. Rev. 62:1271). The presence of a single exponential decay is due to the lack of significant recovery in the time scale of a single MEPCs. Assuming this model, the estimate for the forward blocking rate is $10^{7}$-$10^{8}$ $M^{-1}sec^{-1}$ with a voltage-dependence of 30 mV/e-fold.

Unblocking kinetics were examined with EPCs evoked by iontophoretic application of agonist. Double pulse experiments reveal a slow unblocking process that is agonist-independent suggesting that the channel remains open while blocked. Such slow channel blockade is usually explained by steric interference with the gating mechanism. However, experiments with repetitive iontophoretic pulses reveal an additional fraction of blockade that persists after washout of CHL, despite the subsequent agonist application. Previous studies in the lobster NMJ (Lingle,1983; J.Physiol.339:395) show that full recovery from a similar stable blockade can be obtained only with agonist application suggesting that channel closure occurs with the blocker trapped inside. A similar model may be applied to the frog NMJ with the modification that, following channel closure, the channel is essentially constrained from reopening by the presence of CHL in the ion flow pathway. ( Supported by NIH NS-19139 and MDA grant to CJL ).

249.7 POSTSYNAPTIC POTENTIATION IN FROG NEUROMUSCULAR JUNCTION. E. Kus* and M.I. Glavinovic (SPON: B. Esplin), Departments of Anaesthesia Research and Physiology, McGill University, Montreal, Quebec, Canada H3G 1Y6.

During sustained application of an agonist in a neuromuscular junction there is a progressive loss of response of receptors to it due to desensitization. At the beginning of the steady ACh application prior to desensitization however, the test responses are enhanced due to post-synaptic potentiation (Katz & Thesleff, 1957, J. Physiol. 138, 63-80). Postsynaptic potentiation (PSP) was shown to be particularly pronounced at low temperatures and with cholinesterase inhibited where it was attributed to accumulation of monoliganded presumably non-conducting ACh receptor complexes (Feltz & Trautmann, 1980, J. Physiol. 299, 533-522). The present study is a further attempt to examine how PSP changes with steady ACh application that produces clear desensitization.

The experiments were done on the frog (Rana pipiens) cutaneous pectoris preparation at room temperature (19-20 °C) in physiological Ringer using voltage clamp technique. The end-plates were localized using a (Zeiss) Nomarsi water immersion microscope (x320), and acetylcholine was applied iontophoretically.

Iontophoretic pulses were applied at a frequency of 5 Hz for 5 sec, followed by 15 sec of no application and were chosen to produce initial responses of less than half maximal value (25-45%). This was repeated every 20 seconds, 10-20 times. During an initial short iontophoretic train, amplitudes of the resulting ACh responses first increase and then decrease, and are followed by recovery in between iontophoretic trains. This pattern of response remains throughout ACh application.

PSP (defined as the fractional increase in the ACh response at the beginning of a short iontophoretic train) increases with ACh application between 30 and 145% although ACh responses are reduced to usually less than 20% of their initial value. Essentially the same answer is obtained if desensitization is produced by repeated iontophoretic applications of ACh pulses and PSP tested by inserting ACh pulses at regular intervals.

The increase in PSP is unlikely to be explained by accumulation of monoliganded ACh receptor complexes. The presence of cholinesterase ought to prevent such accumulation. PSP probably increases because desensitized receptors accumulate. Because of their high affinity for ACh, they make the dose response curve progressively more sigmoidal and PSP more evident.

Supported by MDA and MRC (Canada).

249.8 **INHIBITION OF ABNORMAL ELECTRICAL ACTIVITY WITH ELECTRICAL STIMULATION IN-VITRO.** **D. Durand, Applied Neural control Laboratory, Dept. of Biomedical Engineering, Case Western Reserve University, Cleveland, OH 44106**

**Electrical stimulation of the peripheral nerves and muscles has proven very successful in restoring partial motor function in patients suffering from various motor disorders. However, the clinical applications of Functional Electrical Stimulation (FES) in the CNS have fallen short of expectations. A particularly difficult problem is to generate neuronal inhibition using electrical stimulation. Recent studies have demonstrated the role of electrical fields in the synchronization of epileptic discharges, suggesting a possible solution. This study was then designed to investigate the possibility that electrical stimulation could in turn be used to generate inhibition of epileptic-like seizures.**

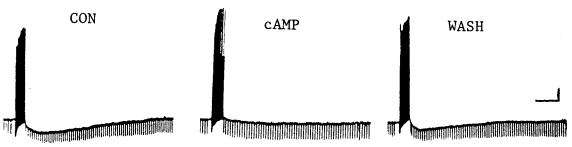
**Transverse hippocampal slices were prepared from Sprague-Dawley rats (150-200g). In order to generate repetitive epileptic activity, 7000 units of penicillin or 200uM of picrotoxin were added to the artificial CSF. Orthodromic responses with 3 to 10 population spikes were triggered with a stimulating electrode in the stratum radiatum and recorded with a glass microelectrode (5 MOhm) located in the CA1 cell layer. A 50um diameter stainless-steel electrode located close to the recording electrode was then activated with a current generator delivering pulses of various amplitude and width. The current pulse was applied following orthodromic stimulation with a variable delay.**

**In all 32 slices that were tested, the application of the current pulse generated a large amount of inhibition (reduction of the amplitude of all the population spikes following the current pulse). The inhibition was directly related to the amount of charge injected. The maximum amount of inhibition (91+4%) was obtained with 94+13nC (N=22) when the stimulation pulse was positive (anodic) and with only 24+4 (N=10) with a negative pulse (cathodic). The time of application of the pulse was the most crucial parameter and was restricted to a time window of 0.5 ms centered on the positive peak preceding a population spike. If applied outside the window, the current pulse could increase instead of decrease the neuronal activity.**

**The mechanisms of the inhibition are not yet clear, but probably involve an intracellular effect inhibiting action potentials and an extracellular "desynchronizing" effect. Both effects are under study with intracellular recording techniques and Current Source Density Analysis methods.**

249.9 REPETITIVE STIMULATION PRODUCES A VERY LONG AFTERHYPERPOLARIZATION IN RAT HIPPOCAMPAL PYRAMIDAL CELLS IN VITRO. A. Williamson* and B.E. Alger (SPON: D.S. Ruchkin). Dept. of Physiol., Univ. of MD. Sch. Med. Baltimore, MD, 21201.

An epileptic seizure is a complex electrophysiological event involving periods of repetitive neuronal firing which can last tens of seconds. We have studied mechanisms which may participate in terminating seizures in the rat hippocampal slice using prolonged (10 Hz, 5 sec.) synaptic stimulation to mimic a seizure. Intracellular recordings from 50% of the cells showed that this stimulation produced a large depolarization during the train followed by a very long hyperpolarization (VLH) which can last 0.5 to 3 minutes at 30°C. The VLH has a peak amplitude of 3-15 mV and an associated conductance increase of 10-50%. We hypothesized that the VLH could be due to an increase in an ionic conductance or to activation of the sodium/potassium pump. The pump may be partially involved since dihydrooubain, a specific sodium/potassium pump inhibitor, reduced the VLH in several cells. The VLH cannot, however, be totally attributed to an electrogenic pump effect. The evidence suggests that a potassium conductance is involved. First, 5 mM cesium chloride blocked the VLH in four out of five cases. Second, the VLH had a null potential of -78 mV in control saline (5.4 mM potassium) which shifted to -69 mV in saline containing 8.1 mM potassium. This value approaches the potential reported for the potassium equilibrium potential in these cells. Third, cyclic AMP, which blocks a calcium-dependent potassium afterhyperpolarization (AHP) evoked by a brief spike train in the hippocampus, significantly reduced the VLH. (See Fig 1. Calibration: 5 mV and 10 sec.) The VLH may differ from the AHP, however, since carbachol, which also blocks the AHP, reduced the VLH duration and increased or had no effect on either the VLH amplitude or conductance. Our data suggest that a very long-lasting calcium-dependent potassium potential is activated by repetitive synaptic stimulation and may, therefore, play a role in seizure termination.



249.10 VOLTAGE-CLAMP ANALYSIS OF A SYNAPTICALLY ACTIVATED LATE HYPERPOLARIZATION IN HIPPOCAMPAL CA3 NEURONS. R. H. Thalmann and J. J. Hablitz. Depts. of Cell Biology and Neurology and Program in Neuroscience, Baylor Col. of Med., Houston, TX 77030.

Activation of the mossy fiber input to hippocampal CA3 neurons, at levels that are subthreshold for action potential (AP) generation, produces two successive hyperpolarizing potentials. The early component is chloride mediated, whereas the late hyperpolarization (LH) is thought to represent an increase in potassium conductance. The amplitude of the LH is linearly related to membrane potential over the range -60 to -120 mV (Thalmann, R. H., Neurosci. Lett. 46:103). Using current- and voltage-clamp techniques, we investigated the nature of the conductance change underlying the LH.

Intracellular recordings were obtained from CA3 neurons of rat hippocampal slices maintained in vitro. Synaptic potentials were elicited via bipolar stimulation of the mossy fiber pathway. Using current-clamp techniques, the conductance underlying the LH was estimated from the change in the voltage deflection produced by a train of hyperpolarizing current pulses. At the peak of the response (approx. 140 msec after the stimulus), the average conductance increase was 15.3 ± 6.2 nS, while the half-decay time of the response was 120 ± 23 msec. These values were relatively constant over the voltage range -55 to -110 mV. The reversal potential for the LH was between -90 and -95 mV. Under voltage-clamp conditions, using a single-electrode time-share circuit, two currents were observed, corresponding to the early and late hyperpolarizing potentials. At a holding potential of -55 mV, an early, large outward current was followed by a less prominent slow outward current. The initial current generally peaked in 10-12 msec, reversed at -75 mV, and had a slope conductance of approx. 80 nS. The second current peaked at approx. 120 nS and reversed near -95 mV. Plots of current amplitude versus membrane potential were linear, and linear regression lines fitted to the data indicated a conductance of 12.3 ± 4 nS. The decay of this current, in contrast to that of the early response, was not demonstrably voltage dependent over the range studied.

These results suggest that the synaptically evoked early and late hyperpolarizing potentials arise from different ionic mechanisms. The consistency of the conductance underlying the LH, regardless of whether or not APs or voltage transients occurred in the impaled cell, indicates that the late hyperpolarization arises, at least in part, as a consequence of activation of transmitter- rather than voltage-gated channels. The potassium conductance that presumably underlies the LH appears to differ from several previously described voltage-gated potassium conductances in its lack of rectification and voltage sensitivity of decay. 249.11 INTRA- AND EXTRACELLULAR ANALYSIS OF SPONTANEOUS ACTIVITY IN HIPPOCAMPAL NEURONS IN CULTURE. A.T. Malouf and D.L. Gruol. Div. of Preclin. Neurosci. and Endocrin., Scripps Clinic and Research Foundation, La Jolla, CA 92037

Extracellular unit recordings from rat hippocampal neurons (HPNs) derived from fetal tissue and maintained in culture for several weeks reveal that these neurons exhibit at least three patterns of spontaneous electrical activity (Malouf and Gruol, Neurosci. Absts, 1984). We have now used intracellular recordings to identify the mechanisms generating the spontaneously activity and to characterize the development of these mechanisms during HPN maturation in culture. Intracellular recordings, in agreement with extracellular observations, demonstrated that the expression of spontaneous electrical activity develops slowly over the first two weeks in culture. During this time, action potentials (AP's) or post synaptic potentials (PSP's) are rarely recorded. The reasons for this low spontaneous activity are not presently known, but the HPNs are capable of producing APs in response to either depolarizing current injections or application of glutamate. Furthermore, repetitive depolarizations which elicit AP's result in the influx of large numbers of PSP's, presumably through recurrent pathways, indicating that these cells are synaptically coupled by the second week in culture. One possible explanation is that expression of spontaneous activity depends on the development of endogenously generated activity, such as the type attributed to CA3 HPNs, which in turn excites the other HPNs. The existence and temporal development of endogenous activity in the cultured HPNs is currently under investigation. Extracellular recordings demonstrated that by the third week in culture most cells exhibit some form of spontaneous activity. While a few cells fire in a random pattern of single spikes, greater than 80% of the HPNs display a bursting type of firing pattern. The burst patterns can be divided into two types. One type is a simple burst pattern consisting of repetitive clusters of 3-8 single spikes. The second type is characterized by prolonged bursts (20-50 spikes) comprised of smaller (2-6 spike) bursts. Intracellular recording revealed a fundamental difference between the two bursting patterns. While spikes are usually associated with a volley of PSP's in both patterns, spikes are elicited from PSP's which rise and return to the baseline after each spike in the simple pattern. In the complex pattern, however, bursts of spikes ride atop a general membrane depolarization of 2-5 mV. These data suggest that the two bursting patterns may result from different synaptic and/or endogenous mechanisms. Identification and analysis of the mechanisms which generate these patterns should aid in our understanding of the cellular and synaptic physiology of HPNs. (Supported by NIAAA 06420 and 07456)

249.12 CAFFEINE-INDUCED CHANGES IN TTX SENSITIVE SLOW DEPOLARIZATIONS IN CA1 PYRAMIDAL NEURONS. K. Baker* and B.A. MacVicar, Dept. of Medical Physiology, University of Calgary, Calgary, Alberta T2N 4N1, Canada.

Intracellular calcium is implicated in regulating many cellular properties. Caffeine induces intracellular calcium release in neurons and elicits a slow depolarization. We have examined the effects of caffeine on slow depolarizations in hippocampal neurons which may be controlled by the release of intracellular calcium.

Intracellular recordings were obtained from CA1 pyramidal neurons in rat hippocampal slices with microelectrodes (100-120 mΩ) filled with 2 M K acetate. Brain slices were maintained at 33° and were superfused at 1 ml/min. Extracellular application of caffeine (5 mM) in normal saline caused epileptiform bursting in CA1 pyramidal neurons. This action could result from increased synaptic transmission and enhanced calcium spiking. We therefore examined caffeine's actions when intracellular calcium release would be the only effect, ie. after blocking synaptic transmission and calcium spiking. Cells were impaled in control solutions initially, then solutions containing low calcium (0.1 mM) and cadmium (2 mM) were perfused. This was observed to block synaptic transmission and calcium spikes. After the recordings were stable in cadmium, caffeine was perfused and in most cells there was a 10-20 mV slow depolarization often with superimposed rhythmic depolarizations. This slow depolarization did not occur in low sodium solutions. The threshold was determined by observing the onset of the slow depolarization during a ramp current injection. After the threshold was observed to be stable in low calcium-cadmium solution, caffeine was introduced. In five stable recordings following the addition of caffeine (5 mM) the cells depolarized 11.6 mV from 69 ± 1.4 mV (± S.D.) to 57.4 ± 2.9 mV and the threshold for the slow depolarization changed from 66.2 ± 1.9 mV to 75.4 ± 1.7 mV. In all five cells the slow depolarization was subsequently blocked by TTX (1 mM). Therefore caffeine effectively reduced the threshold for the TTX sensitive slow depolarization. This action could be the result of intracellular calcium release which suggests that the slow inward $Na^+$ current may be regulated by intracellular calcium. Alternatively the caffeine could directly effect the slow inward current.

249.13 EXCITATORY EFFECTS OF DELTA-9-TETRAHYDROCANNABINOL ON HIPPOCAMPAL NEURONES RECORDED IN VITRO S.A. Deadwyler R.E.Hampson and G.A. Marlow. (Spon:S.Stwertka) Bowman Gray School of Medicine, Winston-Salem, N.C. 27103.

Previous extracellular studies of the effects delta-9-Tetrahydrocannabinol (THC) on the hippocampus have suggested a biphasic dose response relationship. Extremely low doses of this compound were found to increase the excitability of CA1 cells in the hippocampal slice, while higher doses decreased excitability (Foy et. al. Brain Res Bull 1982). Recent studies in cat spinal motorneurones have indicated that delta-9-THC increases excitability by enhancing EPSPs and decreasing IPSPs. These changes were associated with a concomitant increase in membrane resistance (Turkanis and Karler Brain Res 1983). We have investigated whether or not similar cellular and synaptic changes are responsible for the reported effects of delta-9-THC in the hippocampus.

Intracellular recordings were made from 44 neurones in the CA1 region of the rat hippocampal slice preparation. Slices were maintained in two different types of incubation chambers and drug delivery was by three different techniques in order to maximize the capability of discerning the direct effects of delta-9-THC: microdrop application of THC ($10^{-4}$M) to the surface of the slice in a static chamber ; superfusion with THC ($10^{-7}$ to $10^{-4}$M); or bolus injections of THC ($9.5x10^{-3}$M) into the line of a flow chamber. THC was dispersed by sonification and administered in a suspension of pluronic F68 detergent (concentration in medium 0.18-0.56mM). The two prominent effects of THC application at all dose levels was an increase in excitability as indicated by 1) membrane depolarization and induced or increased spontaneous firing, and 2) increased discharge to intracellular depolarizing current pulses (60-70% of cells tested). In addition these changes were accompanied by an increase in firing threshold. Membrane resistance was increased in those cells which showed increased spontaneous discharge. The Schaffer collateral elicited EPSP-IPSP sequence was differentially affected by low vs high doses of THC. In 20% of the cells tested application of THC resulted in no change or a decrease in excitability. Many of the cellular and synaptic effects of THC were duplicated by application of carbachol (80 uM) to the bathing medium of cells which recovered from prior exposure to THC (Cole and Nicoll Brain Res. 1984). The results confirm the findings of previous investigations by demonstrating that delta-9-THC produces excitatory changes in CNS neurones.

249.14 **INHIBITORY POTENTIALS DECREASE PREFERENTIALLY INWARD RECTIFYING CURRENTS IN RAT AND HUMAN CORTICAL NEURONS MAINTAINED "IN VITRO"** V.Tancredi*,M.Avoli and N.Agopyan* (SPON: S.Gauthier). Montreal Neurological Institute and Department of Neurology & Neurosurgery, McGill University, Montréal, Québec, H3A 2B4, Canada.

In several different neuronal systems (e.g. motoneurons) the inhibitory action of post-synaptic potentials derive from a combination of hyperpolarization and shunting of EPSPs. We analyzed further this aspect in cortical neurons in slices of the rat hippocampus and somatosensory region. Similar experiments were also carried out in neurons in slices of "normal" (i.e. non-epileptic) neocortex (2nd temporal gyrus) taken during surgery for brain tumor. Intracellular (presumably intrasomatic) recordings were performed with K-acetate or KCl filled pipettes placed in the stratum pyramidale of the CA1 subfield, or deep layers (5th, upper 6th) of the rat or human neocortex. Extracellular focal stimulation was achieved with sharpened monopolar tungsten electrodes positioned in the stratum radiatum of hippocampal slices and in the underlying white matter or within the layers of neocortical slices.

Stimulus induced responses in recordings performed with Kacetate filled microelectrodes were composed of an EPSP-IPSP succession in the hippocampus and of a mainly depolarizing potential in rat and human neocortex. In the latter cases, however, an IPSP was disclosed by decreasing the resting membrane potential (Vm) by 5-10mV. Also, when KCl microelectrodes were employed this component of the stimulus induced response was sensitive to $Cl^-$ injections. Both the hippocampal and the neocortical IPSPs were capable of reducing and abolishing the occurrence of action potentials evoked by depolarizing intracellular pulses, an effect which resulted from the hyperpolarizing trend (when present) and the increase in membrane conductance (gm). Thus, when hyperpolarizing and subthreshold depolarizing intracellular pulses were injected before and after the stimulus, a large increase in gm was associated with the IPSP. The gm increase was greater for voltage responses in the depolarizing direction than those in the hyperpolarizing one. This feature was: (i) observed in rat hippocampal and neocortical cells as well as human neocortical neurons; (ii) present in both neurons recorded with KCl and K-acetate microelectrodes and (iii) detected in the latter cases even at a Vm close to the equilibrium potential for the hyperpolarization.

These finding suggest that cortical IPSPs affect preferentially (voltage dependent) inward currents which are particularly pronounced in both rat and human cortical "in vitro" neurons. Also such a mechanism might shunt EPSPs without decreasing to the same extent summating hyperpolarizing potentials.

249.15 AN IN VITRO BRAIN SLICE PREPARATION TO STUDY CHOLINERGIC NUCLEI OF THE BASAL FOREBRAIN (Ch1-Ch4). W.H. Griffith and R.T. Matthews. Departments of Medical Pharmacol. and Toxicol. and Medical Anatomy, College of Medicine, Texas A&M Univ., College Station, TX 77843

An in vitro brain slice preparation from guinea pigs and rats has been developed to study the anatomy, physiology and pharmacology of neurons within specific nuclei of the basal forebrain. These nuclei include the medial septum (Ch1), vertical limb of the diagonal band (Ch2), horizontal limb of the diagonal band (Ch3) and the nucleus basalis (Ch4). These nuclei contain both cholinergic and non-cholinergic cell bodies that send projections to the neocortex and hippocampus. Degeneration of neurons within these nuclei have been implicated in progressive dementias, including senile dementia of the Alzheimer's type (SDAT).

Coronal serial sections of the forebrain (400-500 µm) were cut using a Vibratome tissue slicer. Slices were transferred to a holding chamber, warmed (34-35°C) and oxygenated with 95% $O_2$, 5% $CO_2$. A single slice was later transferred to a recording chamber, held completely submerged and continually perfused with a physiological solution. Intracellular and extracellular recordings were made from neurons in all four nuclei. Based on extracellularly recorded spontaneous firing patterns in the Ch1-Ch3 areas, two populations of cells were observed, either burst-firing (40%) or rhythmically-firing cells (60%, N=20). Both cell types were excited by bath application of bethanechol or carbachol ($10^{-6}$-$10^{-4}$ M, 66% of the cells responding, N=6). Intracellular recordings also revealed spontaneous activity, including both epsps and action potentials. However, the burst-firing pattern was not observed intracellularly (N=25). Neurons in the Ch1-Ch2 region exhibited stable resting membrane potentials (-60 to -80 mV), high input resistances (50-200 MΩ) and fast (~2 ms duration) TTX-sensitive action potentials (70-100 mV). One significant difference between cells was the duration of the post-spike afterhyperpolarization (AHP). Both long duration ( ~200 ms) and short duration (<20 ms) AHPs could be recorded in different cell types. Orthodromic epsps, and action potentials could be recorded in Ch2/Ch3 cells following focal stimulation close to the recording site or placement of the bipolar stimulatory electrode some distance away in the medial septum, suggesting the presence of intact synaptic circuits between Ch1, Ch2 and Ch3 in this slice preparation. In summary, preliminary electrophysiological identification of these neurons suggests more than one cell type may be present in these nuclei. Future experiments will be directed towards extending this characterization to cholinergic and non-cholinergic neurons.

## POSTSYNAPTIC MECHANISMS III

250.1 PHORBOL ESTERS BLOCK THE RESPONSE OF RAT HIPPOCAMPAL PYRAMIDAL NEURONS TO BACLOFEN. B. E. Alger, J. M. Baraban and S. H. Snyder, Dept. Physiol. Univ. MD. Sch. Med., Baltimore, MD. 21201 and Dept. Neurosci., Johns Hopkins Univ. Sch. Med., Baltimore, MD. 21205.

We have recently reported that bath-application of active phorbol esters selectively blocks a component of the synaptically evoked potential recorded in rat hippocampal pyramidal cells in the slice preparation (Proc. Natl. Acad. Sci., USA, 82:2538, 1985). This component, the late hyperpolarizing potential (LHP), appears to be a potassium-dependent synaptic potential, however the neurotransmitter responsible has not yet been identified. If the phorbol ester-induced antagonism of the LHP is a postsynaptic effect, then phorbol esters can be used to screen potential neurotransmitter candidates. Recent suggestions that the LHP might be mediated by the bicuculline-insensitive $GABA_B$ receptor, prompted us to begin this screening by examining the response to baclofen, a specific agonist of this receptor.

Intracellular recordings were made from hippocampal pyramidal cells in vitro and the LHP and responses to bath-applied baclofen (25 - 100 uM for 30 - 60 seconds) studied. Under these conditions baclofen produces a 5-10 mV hyperpolarization which is associated with a 15 - 35 % decrease in input resistance. Full recovery occurs in 10 minutes.

Following recording of responses in the control saline, a saline containing phorbol 12, 13 diacetate (PDA), 1 uM, was perfused. Baclofen (plus PDA) was reapplied at intervals. PDA consistently reduces the hyperpolarization and conductance increase of the baclofen response 50-90%, depending upon the dose involved and duration of application. Both effects are reversible. The block of the LHP can also be attributed to a block of its conductance mechanism and not to a shift in its reversal potential. Maximal antagonism of the baclofen response is not seen until the depressant effect of PDA on the LHP is well-established; roughly 20-30 minutes after PDA is first applied. As previously reported, phorbol esters depolarize the neuronal membrane slightly (3- 8 mV) and cause an increase (≤20 %) in input resistance. Accordingly we tested the effects of baclofen both at the new "resting" potential, and after cells were repolarized to the original resting potential with current injection. The block was seen under both conditions.

Our data are not incompatible with the hypothesis that GABA, acting at the $GABA_B$ receptor, is the LHP transmitter, however the specificity of the phorbol ester antagonism for baclofen, as against other transmitter candidates, is still under investigation.

250.2 GUANINE NUCLEOTIDES STIMULATE PHOSPHOLIPASE C HYDROLYSIS OF PHOSPHATIDYLINOSITOL 4,5-BISPHOSPHATE IN RAT CORTICAL MEMBRANES. R.A. Gonzales and F.T. Crews. Dept. of Pharmacology, University of Florida Medical School, Gainesville, FL 32610.

Inositol phospholipid hydrolysis has been suggested to be the initial step in a signal cascade-amplifier system for many neurotransmitters in the CNS. Agonist stimulation of the receptor activates a phospholipase C which hydrolyzes membrane inositides and leads to the production of diacylglycerol and inositol phosphates. We have investigated the possible involvement of guanine nucleotides as part of the transduction system from agonist-receptor complex to activated phospholipase C. Rat cerebral cortical membranes were prepared from slices which had been incubated with [$^3$H]inositol to label inositides. Slices were homogenized gently with a glass-glass homogenizer in Krebs-Ringer-EDTA buffer and the homogenate was centrifuged at 1000xg for 20 min. The resulting pellet was then resuspended in 20 mM Tris, repelleted, and washed again with Tris. Gpp(NH)p addition to membranes stimulated the production of [$^3$H]inositol phosphates from the labelled membranes. The $ED_{50}$ was approximately 30 µM with a maximal effect at 100 µM. A time course study indicated that the reaction was maximal at a time of 2 min. Separation of the individual inositol phosphates which were formed by stimulation with 100 µM Gpp(NH)p showed that inositol trisphosphate formation was increased by 30-fold. Inositol bisphosphate and inositol 1-phosphate were also increased. Gpp(NH)p did not stimulate the hydrolysis of [$^3$H]phosphorylcholine from [$^3$H]phosphatidylcholine. The Gpp(NH)p effect on inositide hydrolysis was not dependent upon $Ca^{2+}$ except at concentrations above 100 µM. $Ca^{2+}$ alone stimulated [$^3$H]inositol phosphate production up to 100 µM. Higher calcium concentration inhibited the response. $Mg^{2+}$ by itself inhibited the nonstimulated production of inositol phosphates but had no effect on the Gpp(NH)p response. GTP, GDP, and GMP had smaller stimulatory effects than Gpp(NH)p. The lack of effect of App(NH)p and dibutryl cAMP suggests that the stimulation of phospholipase C hydrolysis of inositides is specific for guanine nucleotides. Previous studies have characterized a $Ca^{2+}$ dependent phosphoinositide phosphodiesterase. Our finding that Gpp(NH)p stimulated hydrolysis is not calcium dependent suggests the presence of another enzyme or that guanine nucleotides alter the calicum dependence of this phosphodiesterase. In any case, these results suggest that phosphatidylinositol 4,5-bisphosphate hydrolysis by a phospholipase C is specifically stimulated by guanine nucleotides and that a guanine nucleotide binding site may be involved in receptor stimulated inositide hydrolysis in brain. (Supported by NIAAA AA06069).

250.3 PHOSPHOPROTEIN REGULATION BY CYCLIC AMP AND BY PHORBOL ESTERS IN CORTICOTROPH TUMOR CELLS. J.F. Bishop, J.M. Farah, Jr., J. Patel, and T.L. O'Donohue. Experimental Therapeutics Branch, NINCDS, and Neurochemistry Branch, NIMH, NIH, Bethesda, MD 20205.

The role of protein phosphorylation in the regulation of cellular functions such as the synthesis, processing and secretion of biologically active proteins and peptides is a major current research focus. Although the mechanisms are unclear, it has been suggested that specific phosphoproteins are involved in neurohormone release and in the regulation of neurohormone gene expression. Stimulation of anterior pituitary corticotroph tumor cells (AtT-20/D16-16) with analogues of cyclic adenosine monophosphate (cAMP) or with 12-O-tetradecanoyl-phorbol-13-acetate (TPA) results in the dose-dependent release of pro-opiomelanocortin (POMC)-derived peptides (ACTH, β-lipotropin, β-endorphin). Since cAMP and TPA exert their pharmacological actions by activating different protein kinase systems--the cAMP dependent protein kinase (PKA) and the protein kinase C (PKC) systems, respectively--neurohormone release and precursor synthesis may be regulated by common or by different phosphoproteins. The present experiments were designed to identify and compare protein kinase substrates responsive to cAMP and toTPA in the cytosolic fraction of AtT-20 cells. AtT-20 cells were loaded with $^{32}$P-orthophosphate in a phosphate-free buffer, rinsed, and dibutyryl cAMP (1 mM), TPA (150 nM) or control solutions were added. After a five minute incubation period, the cells were homogenized and the cytosolic fractions were collected following a low speed centrifugation step. TCA precipitable proteins were then analyzed by two dimensional gel electrophoresis and quantitated by densitometry.

Stimulation of AtT-20 cells with dibutyryl cAMP resulted in a moderate increase in $^{32}$P-incorporation by an approximately 87 kd protein with a pI of about 4.8-5.0, as well as a moderate decrease in $^{32}$P-incorporation by a pair of proteins of approximately 19 kd with pIs of about 6.6-6.8. In response to stimulation with TPA, several cytosolic proteins exhibited increases in $^{32}$P-incorporation including profound increases in a 39 kd protein with a pI of about 5.0 and profound increases in the same pair of 19 kd proteins that were dephosphorylated by dibutyryl cAMP stimulation. In addition, the 87 kd protein that was moderately phosphorylated in response to dibutyryl cAMP was profoundly phosphorylated by TPA. Prominent decreases in $^{32}$P-incorporation induced by TPA were exhibited by two proteins of about 33 and 67 kd, with pIs of about 4.6-4.8. The results of these experiments demonstrate that activation of second messenger systems linked to the PKA and the PKC systems can induce alterations in the phosphorylation states of both distinct and shared phosphoproteins.

250.4 PROTEIN PHOSPHORYLATION BY PROTEIN KINASE C IN THE CELL-FREE SYSTEM OF RAT AORTA. T. Nakaki*, B.C. Wise, D.-M. Chuang and E. Costa (SPON: J.L. Meek). Lab. Preclin. Pharmacol., NIMH, St. Elizabeths Hospital, Washington, D.C. 20032.

In rat aorta, 5-HT elicits smooth muscle contraction through activation of 5-HT$_2$ receptors. We reported that the 5-HT$_2$ receptors differentially regulate the activity of a voltage-dependent $Ca^{2+}$ channel and phospholipase C in the process of rat aorta contraction. Moreover, we suggested that diacylglycerol, a metabolite of phosphoinositide which activates protein kinase C might play an important role in mediating tonic component of the 5-HT-induced contraction of rat aorta. To test this hypothesis, we carried out the phosphorylation study if there are substrate proteins for protein kinase C in rat aorta.

Male rats were decapitated and 3 cm segments of thoracic aorta were excised, adhered fat and connective tissue were removed and the aortic segments were incubated for 1 hr at 37$^0$C in a calcium-free Krebs Ringer bicarbonate buffer. The tunica intima was removed by scraping several times with a razor blade. The supernatnat after centrifugation at 100,000 x g was used for the phosphorylation study. The reactions were carried out at 30$^0$C for varying times and were terminated by the addition of sodium dodecyl sulfate (SDS)-stop solution The samples were subjected to SDS-polyacrylamide gel electrophoresis and autoradiography.

Addition of 1 mM $Ca^{2+}$ caused an increase in phosphorylation of several proteins. These include 16-, 20-, 36-, 45-, 48-, 60-, 92.5-kilodalton proteins. Among these proteins, the addition of phosphatidylserine plus $Ca^{2+}$ further increased the phosphorylation of proteins of molecular weight (in kilodalton), 16, 20 and 92.5. In the absence of $Ca^{2+}$, phosphatidylserine failed to increase protein phosphorylation.

Slight differences in a time course of phosphorylation of those proteins were noted. Net increases in phosphorylation of 20 and 92.5 kilodalton is the most evident at 20 sec, while that of 16 kilodalton was the most obvious at 60 sec.

We have also examined the effects of 12-O-tetradecanoylphorbbol-13-acetate (TPA) and 1,2-diolein which are activators of protein kinase C and the biologically inactive analogue 4 -phorbol-12,13-didecanoate (4 PDD). TPA and 1,2-diolein, but not 4 PDD, increased protein phosphorylaton of molecular weight 20, 88 and 92.5 kilodaltons.

In conclusion, consistent with our previous hypothesis, in rat aorta we could identify substrate proteins for protein kinase C, which might be activated after 5-HT$_2$ receptor stmulation.

250.5 INOSITOL TRISPHOSPHATE INJECTIONS AND IMAGING OF THE CALCIUM INDICATOR FURA-2 IN MOLLUSCAN NEURONS. L.Fink*, J.A.Connor, J.A.Strong and L.K.Kaczmarek. Depts. Pharmacology and Physiology, Yale Univ. Sch. of Med., New Haven, CT 06510 and Bell Laboratories, Murray Hill, NJ 07974.

Inositol trisphosphate (IP3) has been proposed as a second messenger that controls the release of intracellular calcium ions in a variety of cell types. We have begun to investigate the effects of IP3 on the electrical properties of the peptidergic bag cell neurons of Aplysia. Bag cell neurons in primary culture were impaled with two microelectrodes, one containing inositol trisphosphate solution (0.8 mM in 0.6M KCl) and the other containing 3M KCl for voltage recording. Brief pressure injection of IP3 into bag cell neurons reproducibly hyperpolarized the membrane potential for approximately 60 seconds. This was accompanied by a 20% reduction in input resistance that recovered with the same time course as the membrane potential. The peak amplitude of the IP3 induced hyperpolarizations was 20 to 30 mV. IP3 injection was also observed to reduce the amplitude of action potentials evoked by depolarizing currents, recovery taking place within one minute of injection. Control injections of either KCl or myo-inositol had no effect on membrane potential, input resistance, or size of action potentials.

Because these effects of IP3 are consistent with the activation of a calcium dependent potassium current, we have begun to measure changes in intracellular calcium ion concentrations in these isolated neurons. Bag cell neurons, growing on #1 cover slips, were labeled in a loading solution containing 5uM fura-2 for 1 hr. They were then incubated in artificial seawater at 26 to 28 °C for at least 2 hrs in order to de-esterify the indicator. Fluorescence (475-525 nm) of single bag cell neurons was measured with a CCD-based imaging system (see Connor, these abstracts). Localized calcium concentrations were estimated from the ratio of images taken at 340 and 380 nm excitation. In resting cells growth cones and somatic blebs often showed higher calcium concentrations than the central soma. Stimulation via a microelectrode resulted in markedly higher calcium concentrations. These changes also showed regional localization. It will be of interest to determine whether manipulation of second messenger systems, including IP3, produces changes in the calcium signal or its localization in these neurons.

250.6 IONOPHORE A23187 AND VANADATE AS PROBES FOR $CA^{2+}$ STORES INVOLVED IN THE ACh-AND INOSITOL-1,4,5-TRISPHOSPHATE-EVOKED Cl-CURRENTS IN XENOPUS OOCYTES. B. Gillo*, I. Lotan*, R. Boton and Y. Lass. Department of Physiology and Pharmacology, Sackler School of Medicine, Tel-Aviv University Ramat-Aviv 69978, Israel.

The muscarinic responses in Xenopus oocytes consists of a transient and a long-lasting inward $Cl^-$ currents followed by an outward $K^+$ current. We have previously shown (Dascal,N., B.Gillo and Y.Lass, J. Physiol, in press, 1985) that the biphasic Cl current is mediated by an increase in the intracellular free Ca concentration, released from intracellular stores; intracellular Ca and inositol-1,4,5-trisphosphate (InsP$_3$;oron, Y., N.Dascal, E.Nadler and M.Lupu, Nature, 313:141-143,1985) injection mimic the muscarinic Cl current. In the present study we show that in Xenopus oocytes, pretreated with ionophore A23187, a dose dependent Cl current followed by an outward current are evoked upon raising external Ca concentration. The Cl current amplitude is reproducible during 40 min following the inophore application. Depletion of Ca stores by application of the ionophore in Ca-free solution, inhibits the acetylcholine reponse as well as the response to intracellular injecton of InsP$_3$; the transient Cl current being more sensitive to Ca depletion. Exposing the oocyte to orthovanadate in Ca free solution for 30 min. blocks both the acetycholine- and the InsP$_3$ - induced Cl currents. We suggest that Ca mediating the muscarinic Cl current in Xenopus oocytes is mobilized from intracellular store, probably the endoplasmic reticulum, by InsP$_3$.

250.7 **CALMODULIN-DEPENDENT PHOSPHATASE OF PC-12 PHEOCHROMOCYTOMA, C-6 GLIOMA, AND $GH_3$ PITUITARY ADENOMA CELL LINES.** L. Farber, F. Iannetta*, T. Kirby* and D. J. Wolff*. Department of Pharmacology, UMDNJ-Rutgers Medical School, Piscataway, NJ 088854.

Extracts of rat pheochromocytoma (PC-12), glioma (C-6), and pituitary adenoma ($GH_3$) cells depleted of endogenous calmodulin by DEAE-cellulose chromatography have been subjected to chromatography on immobilized calmodulin. Proteins eluted selectively at submicromolar $Ca^{2+}$ concentrations maintained with EGTA were found in each case to catalyze a calmodulin-stimulated dephosphorylation of myelin basic protein. Analysis of calmodulin-binding proteins by sucrose density centrifugation revealed that phosphatase activities exhibited sedimentation coefficients of 4.45, 4.23, and 4.20 for proteins derived from C-6, $GH_3$, and PC-12 cells respectively. Bovine brain calmodulin-dependent phosphatase, widely called calcineurin, exhibited a sedimentation coefficient of 4.63.

Polyclonal antibodies to bovine brain calcineurin in its native state, to the urea-dissociated A (62,000 $M_r$) subunit, and to the urea-dissociated B (16,000 $M_r$) subunit have been prepared in rabbits in our laboratory. These antibodies have been purified by chromatography on immobilized antigen. The affinity-purified antibodies have been examined for specificity by a Western blotting procedure. Antibodies derived from native calcineurin-injected animals showed reactivity to peptides of 62,000; 32,000; and 16,000 daltons. Antibodies derived from calcineurin A-injected animals showed reactivity to peptides of 62,000 and 32,000 daltons, while antibodies from calcineurin B-injected animals reacted with a single peptide of 16,000 daltons. Examination of calmodulin-binding proteins from PC-12, C-6, and $GH_3$ cells using antibodies directed against calcineurin B revealed cross reactivity with a peptide of 16,000 daltons.

These experiments support the contention that each of these cell lines contains a calmodulin regulated phosphatase homologous physically, kinetically, and immunologically to bovine brain calcineurin.

250.8 **REGIONAL DISTRIBUTION OF CALMODULIN-DEPENDENT PHOSPHATASE (CALCINEURIN) ACTIVITY IN RAT BRAIN.** E. Chung, M.Dvorozniak*, H.C. Li*, and M.H. Van Woert, Departments of Neurology, Biochemistry and Pharmacology, Mount Sinai School of Medicine, New York, NY 10029

Calcineurin, a major calmodulin binding protein found in the brain, possesses a calmodulin-dependent phosphatase activity towards phosphoproteins as well as nonprotein phosphosters such as p-nitrophenyl phosphate (PNPP). (Li,H.C. J. Biol. Chem. 259:8801, 1984). Calcineurin has been previously shown to be highly concentrated in the bovine striatum by radioimmunoassay. In the present study we have investigated the regional distribution of the PNP phosphatase activity of calcinineurin in the rat brain. Brain tissue was homogenized in 0.1 mM EGTA (pH 7.0) containing protease inhibitors, centrifuged 28,000 g for 20 min. and an aliquot of supernatant was incubated for 20 min at 30°C in 50 mM Tris HCl (pH7.4), 0.5 mM $NiCL_2$, 20 mM PNPP, and where applicable 0.1 mM $CaCl_2$, 0.3 uM calmodulin (CM) and 0.1 mM trifluoperazine (TFP).

It should be noted that TFP specifically abolishes the CM-activated phosphatase activity of calcineurin and $Ni^{2+}$ can serve as an activator for phosphatases in general.

PHOSPHATASE ACTIVITY
(nmoles PNP released/mg/min)

| | I EGTA | II $Ca^{2}$,CM,$Ni^{2+}$,TFP | III $Ca^{2+}$,CM,$Ni^{2+}$ |
|---|---|---|---|
| Striatum | 9.9±0.7 | 17.9±1.2 | 33.5±2.4 |
| Hippocampus | 7.6±0.5 | 15.1±0.6 | 25.1±1.3 |
| Cerebral Cortex | 11.6±0.6 | 17.1±0.6 | 27.5±1.4 |
| Midbrain | 10.7±0.6 | 9.4±0.2 | 12.5±0.4 |
| Hypothalamus | 13.7±0.7 | 16.3±1.2 | 17.4±0.9 |
| Cerebellum | 14.4±0.4 | 19.6±0.5 | 18.3±0.9 |
| Medulla | 11.0±1.0 | 14.3±1.4 | 14.8±0.9 |
| Spinal Cord | 9.3±0.6 | 11.7±0.7 | 10.5±0.6 |

Each value is the Mean + SE of 6 rats.

Basal phosphatase activity was measured in the presence of 1 mM EGTA and the values ranged from 7.6 (hippocampus) to 14.4 (cerebellum) nmoles PNP/mg/min. CM dependent phosphatase (calcineurin) activity (ColumnIII-Column II) was highest in the striatum. Hippocampus and cerebral cortex also exhibited high activity while the midbrain and hypothalamus had minimal activity.

The effect of destruction of nigro-striatal input by 6-hydroxydopamine and kainic acid lesion of the striatum on striatal calmodulin-dependent phosphatase activity will be described.

250.9 EXCITATORY POSTSYNAPTIC CURRENT (EPSC) OF THE SPINAL MOTONEURON. M. Kuno & S. Matsuura*. Dept. of Physiol., Osaka City Univ. Med. Sch., Osaka 545, Japan.

Dorsal root (DR) fibers and lateral column (LC) fibers have been suggested to contact on the different sites of the frog motoneuron on the basis of different time courses of the excitatory postsynaptic potentials (EPSPs). We applied voltage clamp technique to analyze the property of EPSCs induced by DR and LC stimulation and compared the response patterns between the EPSCs.

Frog spinal cord was isolated and intra-arterially perfused with oxygenated Ringer solution. The lumbar motoneuron was impaled by two separate microelectrodes filled with 4M K-acetate, of which tip distance was adjusted to 15-30 μm by using a microelectrode holder. After checking the impalement of two electrodes into the cell by injecting depolarizing current from either electrode and recording membrane potential (MP) by the other electrode, the MP was clamped at various levels between -130 and +60 mV. Monosynaptic and polysynaptic responses were evoked by LC and DR stimulation, respectively and the stimulus intensity was usually adjusted to produce almost the same size EPSPs.

In the successful recordings of the responses, the rise time of LC-EPSC estimated between 10-90 % of the amplitude was 2.8 ± 1.7 msec and 3.9 ± 2.5 msec for DR-EPSC. The mean time constant in the decay phase was 10.9 msec for LC-EPSC and 17.3 msec for DR-EPSC, when MP was clamped at the resting membrane potential level of the cell. The time courses were influenced by the level of holding potential: The EPSC rose and decayed faster at hyperpolarized holding potential than at the depolarized and resting MP levels. Reversal potential for the LC-EPSC was almost the same level as that for DR-EPSC in many cells. When spontaneous unit (miniature) EPSCs were recorded, the rise time and decay time were alittle faster than those of the EPSCs in response to LC and DR stimulation. The time courses also became much faster at hyperpolarized holding potential. Even in cells in which spontaneous miniature EPSPs were hardly discernible before and after the voltage clamp, clear discrete occurrences of unit EPSCs were observed when the MP was clamped at the level far from the reversal potential for the LC- or DR-EPSC. The unit EPSCs were often observed about 100-200 msec after stimulus presentation and after EPSCs evoked by LC or DR stimulation decayed to the base line noise level. The reversal potentials of the unit EPSCs were apparently the same as those of the EPSCs induced by LC or DR stimulation. Current-voltage relation also showed a similar pattern between the evoked EPSCs and the unit EPSCs.

We conclude from the study that LC-EPSC and DR-EPSC show essentially the same response property except for the faster time corse of LC-EPSC relative to DR-EPSC.

250.10 AMMONIA DECREASES THE SPINAL MONOSYNAPTIC REFLEX. W. Raabe. Depts. Neurology, VA Medical Center and Univ. of Minnesota, Minneapolis, MN 55417.

Ammonia intoxication allegedly plays a role in the pathophysiology of some metabolic encephalopathies. To investigate the neurophysiological effects of ammonia, the effects of ammonium acetate ($NH_4Ac$) i.v. on the spinal monosynaptic reflex were studied in decerebrated, paralyzed and respirated cats with the spinal cord severed at $L_2$.

$NH_4Ac$ i.v., 2-4 mmol/kg, decreased the spinal monosynaptic reflex elicited by stimulation of the hamstring, gastrocnemius or peroneal nerves and recorded from the ventral root $S_1$. $NH_4Ac$ had no effect on the excitability and conduction velocities of peripheral group I fibers and α-motoneuron axons, the group I fiber spike recorded from the dorsal roots at their entry into the spinal cord and the monosynaptic motoneuron population EPSP recorded from the ventral root. Intracellular recordings from spinal motoneurons confirmed that $NH_4Ac$ i.v. does not affect the monosynaptic EPSP.

These observations suggest that ammonia intoxication decreases the reflex discharge in the ventral root by decreasing the excitability of motoneurons and/or their intraspinal axons. Since neuronal activity increases the ammonia concentration in the CNS, ammonia may play a role as a metabolic feedback modifier which dampens or prevents excessive excitation of motoneurons (and possibly other neurons).

250.11 SOME EFFECTS OF NON-UNIFORM DISTRIBUTIONS OF SYNAPTIC CONDUCTANCE INPUTS ON SPINES AS MODELED IN A CORTICAL PYRAMIDAL CELL. W.R. Holmes* and C.D. Woody (SPON: R. Pay). Depts. of Biomathematics and Biobehavioral Sciences, UCLA, Los Angeles, CA. 90024.

Non-uniform distributions of two different types of synaptic conductance inputs have been shown theoretically capable of producing non-uniform resting potentials and changes in the efficacy of postsynaptic integration in layer V cortical pyramidal cells of cats (Holmes and Woody, Soc. Neurosci. Abstr., 1984). The efficacy of synaptic inputs depended on the driving force at the synaptic sites and the electrotonic distances from the soma to the synapses. The present study examines the effects of different distributions of activated conductances on the non-uniformity of resting potentials and the efficacy of synaptic inputs (as determined by peak transient soma potential) when dendritic spines are incorporated into the dendritic cable.

To do this a passive-membrane cable model of a neuron based on a serially reconstructed, HRP-injected cortical pyramidal cell was used. Symmetry assumptions were made to efficiently model the cell with 13,820 dendritic spines. Three types of inputs were modeled. Inhibitory inputs (I) with a reversal potential of -85mV were inserted on the soma and on proximal dendrites. Excitatory inputs (E) with a reversal potential of 0mV were distributed primarily on apical spines with some on basilar spines. M-current-like inputs (M) with a reversal potential of -85mV were placed primarily on basilar spines with some also on apical spines. The effects of different levels of synaptic activity within each region were evaluated while keeping soma resting potential and cell input resistance constant. These results were compared to those obtained with uniform distributions of E and M inputs on spines with and without I input on the soma and on proximal dendrites.

With I input on the soma and on proximal dendrites and uniform E and M input on spines, resting potential varied by up to 5mV within the neuron. When the E and M inputs were non-uniformly distributed, differences of 10-30mV could be seen between the resting potential at the soma and in distal dendrites. The efficacy of distal synapses as measured by peak transient or steady-state soma potential was 2.5 times greater with some input distributions than with others. It was also found that the effects of spines could be approximated in a model without spines by decreasing specific membrane resistance and increasing specific membrane capacitance in each segment according to the amount of membrane area that was added by spines.

250.12 AN ELECTROPHYSIOLOGICAL METHOD TO LOCATE VOLTAGE-SENSITIVE MEMBRANE ON DENDRITIC STRUCTURES. R.Malinow and J.P.Miller. Department of Zoology, University of California, Berkeley, CA 94720.

The integrative properties of a neuron may depend to a large extent on the existence and exact location of dendritic voltage-sensitive membrane. We are interested in determining if voltage-sensitive channels are located on spine heads, on the dendritic shaft or both. Furthermore, if active membrane resides on spine heads, we wish to know if the spine stem resistance provides enough electrical isolation to allow for locally regenerative voltage transients in the spine heads.

We have designed an experiment to determine the precise location of active dendritic membrane, and to evaluate its effect on synaptic integration. The experiments involve intra-dendritic recordings in combination with in situ laser photo-inactivation of dendritic regions. Computer simulations using compartmental models demonstrate that this experiment should, in fact, be capable of discerning between active membrane located on spine heads and on dendritic shafts. Furthermore, if spine heads do have active membrane, then the magnitude of the spine stem resistance may be deduced from the experimental results. Preliminary experiments have demonstrated the efficacy and reproducibility of using a laser to photo-inactivate and "transect" small portions of dye-filled neurons in the hippocampal slice preparation. Intracellular recordings during the microsurgical procedure confirm the transection and demonstrate the continued viability of the neuron.

250.13 A PHYSIOLOGICAL MECHANISM FOR A HEBB SYNAPSE J.P.Miller and R.Malinow. Dept. of Zoology, University of California, Berkeley, CA. 94720

Hebb postulated that the alteration of synaptic efficacy during classical conditioning depends upon the synchronous activity of the pre- and postsynaptic neurons. We propose a physiological mechanism by which such alterations might be achieved in spiny neurons. The necessary physiological "machinery" is : 1) the existence of regenerative, voltage-dependent channels on the heads of the dendritic spines of the postsynaptic neuron, and 2) some means through which a regenerative event localized to a single spine head could produce long lasting changes in synaptic chemistry and/or ultrastructure of that spine. One specific possibility would be as follows: 1) a voltage sensitive $Ca^{++}$ conductance might be present on the spine heads, and 2) a mechanism similar to that proposed by Lynch and Baudry (Science 224, 1057-1063, 1984) may operate to increase the density of active receptors on the spine head as a function of $[Ca^{++}]$. If the voltage threshold for a regenerative $Ca^{++}$ influx were relatively high, a significant (ie. $Ca^{++}$-buffer-saturating) increase in $[Ca^{++}]$ might result only when a synaptic input to the spine head was synchronous with a depolarizing voltage transient generated at some other location in the neuron. At the head of the spine, the EPSP from the direct input would sum with the voltage transient arriving from a spike or large EPSP generated at some other location in the cell, bringing the spine head membrane above threshold for regenerative $Ca^{++}$ influx. Following such a $[Ca^{++}]$ transient in the spine head, the efficacy of subsequent synaptic inputs onto the same spine would be increased, via an increase in active receptors. Repeated pairings of synaptic input with independent voltage transients would continue to increase synaptic efficacy. Though the hypothesis is speculative, compartmental models have been used to demonstrate the feasibility of this scheme. Details of these models will be presented, and the strengths and limitations of the hypothesis will be evaluated. W. Rall and I. Segev have performed similar simulations on clusters of active spines; we thank them for their valuable comments.

251.1 A MODEL FOR IN VIVO REGULATION OF PRODYNORPHIN AND PROENKEPHALIN. J. Eberwine, J. D. Barchas and C. J. Evans. Dept. of Psychiatry and Behavioral Sciences, Stanford University, Stanford, CA 94305.

The guinea pig adrenal gland is unusual in that processing products derived from both proenkephalin and prodynorphin are present in the same medulla cells. The neuroanatomical isolation of the adrenal gland makes this organ an excellent choice for the study of the expression of these two co-localized opioid precursors at both the protein and mRNA levels. In this study we have investigated the effects of hypophysectomy and dexamethasone administration on the expression of these two opioid precursors in male Hartley Albino guinea pig adrenal glands.

Slot blots and Northern blots were utilized to characterize and quantitate the changes in mRNA levels. Peptide levels were measured in acid extracts using radioimmunoassays directed to dynorphin(1-17), dynorphin B, and α-neoendorphin (prodynorphin products), met-enk-Arg-Gly-Leu, met-enk-Arg-Phe (proenkephalin products). Dexamethasone (0.1 mcg/kg administered via i.p. injection) increased in a time-dependent fashion the levels of proenkephalin mRNA 2-fold, however no detectable increase in prodynorphin mRNA level was observed suggesting that the mRNA of these two opioid precursors are differentially regulated. A slight increase in proenkephalin derived peptides was observed with little to no change in prodynorphin derived peptides. Hypophysectomy of the animals was found to have no discernable effect on either prodynorphin or proenkephalin mRNA or peptide levels.

Supported by NIDA grant DA 01207 and NIMH grant MH 23861.

251.2 HISTAMINE IN THE RAT ADRENAL MEDULLA: IMMUNOCYTOCHEMICAL EVIDENCE FOR THE LOCATION OF HISTAMINE IN THENORADRENALINE-SECRETING ENDOCRINE CELLS. O. Häppölä*, S. Soinila, H. Päivärinta, T.H. Joh and P. Panula (SPON: O. Gandolfi). Dept. of Anatomy, University of Helsinki, SF 00170 Helsinki, Finland; and Lab Neurobiology, Cornell University Medical College, New York, New York 10021

Exogenously administered histamine results in a marked increase in both adrenal medullary and adrenal cortical secretion. There is pharmacological evidence that exogenous histamine exerts a direct action upon adrenal medullary cells and/or an indirect effect through splanchnic nerve stimulation, inducing catecholamine secretion, mainly adrenaline, from the adrenal medulla. Histamine-induced catecholamine secretion from the adrenal medulla is mediated primarily by the $H_1$ receptor. Histamine has been shown to depolarize the adrenal chromaffin cell membrane of several mammalian species. There is chemical evidence that histamine is present in the adrenal gland, while the location of histamine in the adrenal medulla is not known.

The present study was undertaken to examine the location of histamine in the rat adrenal medulla by an indirect immunofluorescence method using a specific histamine antiserum produced in rabbits. Twenty adult Sprague-Dawley rats were perfused through the left ventricle with 4% paraformaldehyde and an indirect immunofluorescence method was employed on 10 μM cryostat sections.

Histamine-immunoreactive cells, 10-20 μM in diameter, were observed in all rats studied. Most adrenal medullary cells were, however, non-reactive. No histamine-immunoreactive nerve fibers or adrenal cortical cells were detected. Mast cells were also stained, and they were easily distinguished from the adrenal medullary cells on the basis of size difference and morphology. Preabsorption with 50 μM histamine, but not with catecholamines or 5-hydroxytryptamine, completely abolished the staining. Studies of consecutive sections demonstrated that histamine-immunoreactive cell clusters showed no immunoreactivity to phenylethanolamine-N-methyltranserase, but they often showed intense immunoreactivity to dopamine-B-hydroxylase. Histamine-immunoreactive cell clusters were non-reactive to Met-Enkephalin$^5$-Arg$^6$-Phe$^7$ or 5-hydroxytryptamine.

It is concluded that the rat adrenal medulla contains non-mast cell histamine, which is located in the noradrenaline-secreting endocrine cells. It is possible that histamine is released from these cells and regulates the catecholamine secretion from the adrenal medulla.

251.3 BARIUM AND CALCIUM MEDIATE RELEASE OF CATECHOLAMINES FROM CULTURED CHROMAFFIN CELLS BY TWO DIFFERENT MECHANISMS. E. Heldman*[1], L. Raveh*[1], M.A. Levine*[2] and H.B. Pollard[2] (SPON: V. Teichberg). [1]Israel Institute for Biological Research, Ness-Ziona, Israel, and [2]Laboratory of Cell Biology and Genetics, NIADDK, NIH, Bethesda Md. 20205.

$BaCl_2$ evokes an intense secretory response when added to cultured chromaffin cells. It has been suggested that $Ba^{+2}$ may either serve as an analog to $Ca^{+2}$ or, alternatively, displace calcium from intracellular stores and thus produce the necessary intracellular environment for triggering the secretory process. We demonstrate here that $Ba^{+2}$ competes with calcium for the voltage-dependent calcium channels, but once it enters the cell, its mechanism of action is distinctly different from that of $Ca^{+2}$.

When increasing concentrations of $BaCl_2$ (0.1-3mM) were added to cultured chromaffin cells, increasing amounts of catecholamines were released depending on the $Ba^{+2}$ concentration. The kinetics of the secretion was long-lasting and resulted in depletion of up to 70% of the intracellular catecholamines. $CaCl_2$ significantly decreased the $Ba^{+2}$-induced catecholamine release. Complete inhibition of the $Ba^{+2}$-induced release was observed when the extracellular $Ca^{+2}$ to $Ba^{+2}$ ratio exceeded 2:1.

Kinetic studies with barium-133 revealed that the rate of $Ba^{+2}$ influx was also long-lasting (as for the $Ba^{+2}$-induced release) and was inhibited by extracellular $Ca^{+2}$. Nicotine (62μM) did not increase $Ba^{+2}$ influx but increased catecholamine release (in presence of 1mM $Ba^{+2}$), provided that at least 0.5mM $Ca^{+2}$ was present in the incubation medium. On the other hand, under the same conditions, 50mM KCl produced an increased $Ba^{+2}$ influx without any further increase in catecholamine release. Verapamil, high $Na^+$ (250mM), or $LaCl_3$ (2mM), compounds that block the voltage-dependent $Ca^{+2}$ influx, also blocked $Ba^{+2}$ influx as well as $Ba^{+2}$-induced catecholamine release. These data indicate that $Ba^{+2}$ enters the cell via the voltage-dependent channels and not via the nicotinic receptor-associated channels. The existance of these two types of calcium channels have previously been reported by us (E. Heldman et al, Soc. Neurosci., Vol 10, Abs 209.9, 1984).

While catecholamine release induced by nicotine, veratridine or high $K^+$ was greately inhibited by 10μM imipramine or 5μM TFP no effect of these drugs was observed on the barium-induced release. Unlike nicotine, veratridine or high $K^+$, which evoke co-secretion of catecholamines and ascorbic acid, barium did not evoke any release of ascorbic acid while producing intense secretion of catecholamines. In digitonin-treated cells, in the presence of 5mM EGTA, barium (0.1-1mM) also produced release which was further increased when $Ca^{+2}$ concentration was adjusted to 20μM.

Our data suggest that $Ba^{+2}$ and $Ca^{+2}$ compete for sites on the cell surface but within the cell they act differentially.

251.4 EXTRAADRENAL CHROMAFFIN TISSUE IN DOGS: DEVELOPMENTAL AND ULTRASTRUCTURAL CHARACTERISTICS. J.A. MASCORRO* (SPON: B. Hutchins). Department of Anatomy, Tulane University School of Medicine, New Orleans, LA 70112.

The catecholamine-containing chromaffin system consists of intra- and extraadrenal components. The extraadrenal portion may be paraaortic, paraganglion or intraganglion in position and represents a significant amount of the total system. The present work follows the development, anatomical distribution, structure and persistence of extraadrenal paraaortic chromaffin organs in dogs. Eight dogs aged 3 weeks (3), 6 weeks (2) or adult (3) were anesthesized and sacrificed by perfusion with glutaraldehyde. Their retroperitoneal tissue blocks (RTB) then were removed and immersed in a glutaraldehyde/potassium dichromate solution. This method produced a gross chromaffin reaction which clearly "mapped" the paraaortic organs and also rendered excellent preservation of the organs for morphological study. All animals demonstrated a voluminous system of "chromaffin tissue" in an extraadrenal paraaortic position. These chromated organs displayed a brown coloration, clearly visible to the unaided eye, typical of the chromaffin reaction and indicative of catecholamines. The paraaortic chromaffin bodies (PACB) were found in the midretroperitoneum and attained varying lengths. The youngest animals possessed PACB which varied from 21-35 mm in length. The 6 week dogs demonstrated PACB 20 mm and 31 mm long, respectively, while the PACB in adult animals attained lengths of 46 mm. Occasionally, single chromaffin bodies were evident elsewhere within the RTB, but the main paraaortic bodies represented the largest accumulation of extraadrenal chromaffin tissue. Histological observation showed that the paraaortic bodies were comprised of basophilic epithelial-type cells closely grouped and abundantly vascularized. Thin walled blood vessels together with connective tissue elements served to delineate the chromaffin cells into clusters. Electron microscopy corroborated these observations and confirmed the cytoplasmic presence of a multitude of dense catecholamine-like granules. Most granules exhibited homogeneously dense cores, however, certain vesicles appeared with cores which were lighter and granular. No evidence of innervation to the chromaffin cells was obtained even though much tissue was examined. It is apparent now that the extraadrenal chromaffin system in dogs is large, replete with a catecholamine-like product and persists through adulthood. It should be of paramount importance now to study this system and determine the response to stress factors which are known to cause catecholamine release from its intraadrenal chromaffin counterpart.

251.5 ULTRASTRUCTURAL DEMONSTRATION OF EXOCYTOSIS IN PERMEABILIZED ISOLATED BOVINE CHROMAFFIN CELLS. S.W. Carmichael and J.C. Brooks (SPON: J.R. Daube) Dept. of Anatomy, Mayo Clinic, Rochester, MN 55905 and Dept. Basic Sciences, Marquette University School of Dentistry, Milwaukee, WI 53233.

Exocytosis is the direct discharge of the contents of an intracellular vesicle into the extracellular space. Although there is overwhelming biochemical evidence implicating exocytosis as the primary mechanism for the secretion of catecholamines, proteins, and nucleotides from chromaffin cells, there has been a paucity of ultrastructural evidence of exocytosis. Except for studies of the hamster, transmission electron microscopic techniques have not been able to unequivocally resolve the event. We examined cultured bovine chromaffin cells using a modification of the method of Buma, et al. (Histochem. 80:247, 1984) which employs tannic acid in the culture medium. As the contents of the chromaffin vesicle are exposed to the medium, they are apparently coagulated in situ. In parallel biochemical studies it was noted that catecholamines were not measureable in the culture medium in the presence of tannic acid but could be measured when tannic acid was not present. The exposed contents appear more granular than vesicles in the interior of the cell. The process of exocytosis appears to be stopped as the contents are exposed to the tannic acid, and many images of exocytotic profiles have been captured. The plasma membrane of cells treated with tannic acid is also very distinct. Some cells were treated with the detergent saponin, which has been shown by SEM to produce holes in the plasma membrane (Brooks and Carmichael, Mikroskopie 40:347, 1983). We have demonstrated these holes by TEM. Furthermore, in saponin-treated cells that were stimulated with 100μM calcium, exocytosis was seen to occur at the intact plasma membrane and not at the holes.

This work was supported by the Mayo Foundation and NSF Grant No. 8NS-8304154.

251.6 DRUG MODIFICATION OF CATECHOLAMINE SECRETION AND THIOPHOSPHORYLATION IN PERMEABILIZED CHROMAFFIN CELLS. J.C. Brooks and M. Brooks*. Department of Basic Sciences, Marquette Univ. Sch. of Dent., Milwaukee, WI 53233.

Chromaffin cells permeabilized with saponin secrete by an exocytotic mechanism that requires exogenous calcium and has partial dependence on exogenous ATP. Replacement of ATP by the ATP analog adenosine-5'-O-(3-thiotriphosphate) (ATPγS) irreversibly thiophosphorylates cell proteins and permanently inhibits secretion. This secretory inhibition is associated primarily with the thiophosphorylation of 43 and 54 kilodalton (kda) intracellular proteins. The 43 kda protein shows a greater incorporation of $^{35}S$ from [$\gamma$-$^{35}S$]ATP in the presence of calcium. We have examined the effect of drugs which influence cellular phosphorylating systems and specific organelles on the pattern of thiophosphorylation and catecholamine secretion by permeabilized cells.

Several kinase activators and inhibitors were examined for their influence on thiophosphorylation of the 43 kda protein and catecholamine secretion. Trifluoperazine, cAMP and cGMP had no effect on stimulated catecholamine secretion. Trifluoperazine reduced total $^{35}S$ incorporation into cells but had no effect on incorporation into the 43 kda protein. Incorporation of $^{35}S$ into this protein was slightly reduced by cAMP and its inhibitor protein in the presence of calcium. Phorbol 12-myristate 13-acetate slightly enhanced catecholamine secretion with a reduction of $^{35}S$ incorporation into the 43 kda protein.

Inhibitors of cytoskeletal filaments and microtubules, cytochalasin B and colchicine, had no effect on catecholamine secretion. Similarly, several drugs known to influence chromaffin granule function had no effect on secretion. This included dicyclohexylcarbodiimide inhibition of the proton-translocating ATPase, rotenone inhibition of catecholamine uptake and atractyloside inhibition of nucleotide uptake into granules. Atractyloside, however, prevented $^{35}S$ incorporation into the 43 kda protein, suggesting a role for this protein in granule function.

251.7 REGULATION OF TYROSINE HYDROXYLASE ACTIVITY IN THE ADRENAL MEDULLA OF THE OVINE FETUS. C. Y. Cheung. Dept. of Reproductive Medicine, Univ. of Calif., San Diego School of Medicine, La Jolla, CA. 92093

In the ovine fetus, the adrenal medulla (AM) is functionally active, and secretes catecholamines at a high rate as term approaches. We have found that the ovine fetal AM contained and secreted more catecholamines than that of the adult. The present study was designed to investigate the regulation of the catecholamine biosynthetic enzyme tyrosine hydroxylase (TH) in the AM of the fetus. Ovine fetuses at 130-135 days gestation were used. The ewe was anesthetized, the fetus exteriorized, and the adrenal gland rapidly removed. The medullary tissue was homogenized in MES buffered saline and centrifuged at 49,000Xg for 1 hour. TH in the supernatant was measured using the method of Waymire et al. (Anal Biochem, 43:588, 1971). The kinetic constants of fetal TH for tyrosine, determined in the presence of excess cofactor, were Vmax= 2.9±1.0 pmol $CO_2$/min/ug protein and Km=278±130 uM. These values were significantly higher than the adult values of 1.5±0.3 pmol/min/ug and 46±3 uM. Similarly the kinetic constants of the fetal enzyme for cofactor were Vmax=5.1±1.5 pmol/min/ug and Km=174±42 uM, significantly higher than the 0.2±0.04 pmol/min/ug and 37±11 uM measured in the adult. Furthermore, the activity of fetal TH was not inducible by 100uM acetylcholine even in the presence of $CaCl_2$. These results contrasted with those seen in the adult where 100uM acetycholine stimulated TH activity by 59% in the presence of 1.5mM $CaCl_2$ ($p<0.05$). We have previously shown that prolactin and VIP could increase catecholamine release from fetal adenomedullary cells in culture. To determine whether these hormones could regulate TH activity, the fetal enzyme was incubated with 40 ug/ml ovine prolactin or $10^{-4}$M VIP for 30 minutes, and assayed for activity. Prolactin and VIP significantly increased the activity of fetal TH by 24% and 51%, resp. These results suggest that in the AM of the ovine fetus, the greater catecholamine content and release rate was associated with higher activity of the biosynthetic enzyme TH, compared to the adult. In addition, the fetal enzyme was not responsive to cholinergic stimulation while inducible by prolactin and VIP, suggesting that catecholamine synthesis in the fetal AM may be more responsive to endocrine regulation than to sympathetic neural stimulation.

251.8 GLUCOCORTICOIDS REGULATE DOPAMINE SYNTHESIS IN BOVINE ADRENAL CHROMAFFIN CELLS BY INCREASING STIMULUS-INDUCED PHOSPHORYLATION OF TYROSINE HYDROXYLASE K.L. Kelner, K.W. Brocklehurst*, H.B. Pollard and D.M. Kuhn+ Lab of Cell Biology and Genetics, NIADDK, and +Section on Biochemical Pharmacology, NHLBI, NIH, Bethesda, MD 20205.

We have previously shown that maintenance of isolated bovine adrenal chromaffin cells with glucocorticoids increases cellular dopamine levels. This is due to a glucocorticoid-induced increase in the *in situ* activity of tyrosine hydroxylase (TH). When the cells are stimulated with secretagogues, dopamine synthesis and TH activity increase in control cells, but these increases are much larger in cells that have been pretreated with glucocorticoids (Kelner, Levine, Morita and Pollard, 1985). Since secretagogues are known to increase TH activity by stimulating phosphorylation of the enzyme, which increases the affinity of TH for its cofactor, tetrahydrobiopterin, we tested whether glucocorticoid pretreatment of chromaffin cells increased stimulation-induced TH phosphorylation.

Chromaffin cells treated for 3 days with 10 μM dexamethasone were prelabeled for 90 min with $^{32}Pi$ and then exposed to various secretagogues for 2 min. Total cellular proteins were separated by SDS-PAGE and the phosphoproteins detected by autoradiography. In a parallel set of samples, TH was immunoprecipitated from cell lysates and the amount of $^{32}P$ incorporated into TH was quantitated either by SDS-PAGE, autoradiography and densitometry or by direct scintillation spectroscopy on the immunoprecipitated pellets. Glucocorticoids caused a small increase in the basal phosphorylation of TH which paralleled the increase in basal TH activity. The secretagogues, veratrine (50 μM), KCl (65 mM) and carbachol (300 μM) increased phosphorylation of TH and, as shown previously, its *in situ* activity. However, in cells pretreated with glucocorticoids, the stimulation-induced phosphorylation was markedly augmented, as was *in situ* TH activity. The correlation between glucocorticoid-induced increases in TH phosphorylation and *in situ* TH activity suggests that glucocorticoids regulate TH activity by increasing stimulation-induced phosphorylation of the enzyme.

251.9 SUPPLEMENTATION OF ADRENAL CHROMAFFIN CELLS WITH COFACTORS REQUIRED BY CATECHOLAMINE (CA) BIOSYNTHETIC ENZYMES CAN INFLUENCE CA BIOSYNTHESIS.
Robert A. Levine+, Katrina L. Kelner, and Harvey B. Pollard. Lab of Cell Biology and Genetics, NIADDK, NIH, Bethesda, MD 20205
+Current address: Lafayette Clinic, Detroit, MI 48207

Primary cultures of adrenal medullary chromaffin cells have been used to study the regulation of the enzymes involved in CA biosynthesis by their respective cofactors. The following cofactors were added to cultured chromaffin cells: 1) tetrahydrobiopterin ($BH_4$), the cofactor for tyrosine hydroxylase (TH); 2) ascorbic acid (AA), the cofactor for dopamine-B-hydroxylase (DBH), and 3) s-adenosylmethionine (SAM), the cofactor for phenylethanolamine-N-methyl transferase (PNMT). CA biosynthetic rates were determined by monitoring the incorporation of $^{14}$C-tyrosine (tyr) into intracellular CA by reverse-phase HPLC.

Incubation of cells with various concentrations of $BH_4$ for up to 2 hours in the presence of 20 uM $^{14}$C-tyr stimulated $^{14}$C-dopamine (DA) formation, which saturated at approximately 500 uM $BH_4$. However, $BH_4$ almost totally blocked the incorporation of $^{14}$C into cellular NE at this saturating concentration. AA (2 mM) alone was able to stimulate the rate of $^{14}$C incorporation into NE from $^{14}$C-tyr within the same time frame. Incubation of cells in the presence of SAM at 200uM significantly increased the rate of $^{14}$C accumulation into epinephrine. This SAM-dependent increases was seen only after much longer times (up to 6 hours)

The inhibitory effect of $BH_4$ on NE biosynthesis at higher concentrations was investigated further by incubating the cells with a combination of $BH_4$ and AA. AA (2 mM) was not able to reverse the inhibition of $BH_4$ on NE biosynthesis in the chromaffin cell model. It is possible that $BH_4$ is able to compete with AA at some site involved in the transfer of electrons to DBH within the granule. Thus, $BH_4$ may serve as a tool to probe the mechanism by which AA is coupled to DBH in NE biosynthesis. Additionally, since $BH_4$ is currently being tested in clinical trials for the treatment of certain neurological and psychiatric illnesses, it will be important to determine if during $BH_4$ therapy there is any inhibition of NE biosynthesis either in the periphery or in the central nervous system.

251.10 HISTOCHEMICAL AND BIOCHEMICAL STUDIES OF GABAERGIC SYSTEM IN THE ADRENAL MEDULLA. M. Fujimoto*, I. Hanbauer, H. Alho* and A. Guidotti. Lab.Preclin.Pharmacol,NIMH, St. Elizabeths Hosp.,Washington, D.C. and Hypertension Endocrine Br., NHLB Inst., NIH, Bethesda, MD 20205 (SPON: L.R. Steranka)

Cultured chromaffin cells of bovine adrenal medulla contain alpha-aminobutyric acid (GABA), glutamic acid decarboxylase (GAD), GABA aminotransferase, and GABA receptors. Kataoka et al. showed that nicotinic receptor stimulation releases not only catecholamines (CA), but GABA from the chromaffin cells and that GABA modulates the release of CAs (PNAS 81: 3218, 1984). Further detailed histochemical studies of adrenal glands of several mammalian species indicated that GAD immunoreactivity is present not only in the chromaffin cells but predominantly in nerve fibers. In bovine adrenal the GAD immunoreactivity is mainly located in bundles of nerve fibers, innervating the medulla. In dog adrenal a dense network of GAD positive fibers is localized in the boundary between cortex and medulla. In rat medulla, GAD immunoreactive fibers surround chromaffin cells and blood vessels. To establish the origin of fibers showing GAD positive immunoreactivity, we examined the activity of GAD in rat adrenal medulla 10 days after splanchnic nerve transsection. The enzyme activity in the denervated medulla was reduced by 10%, and GAD immunoreactive fibers were still present indicating that a large part of GAD containing fibers arriving at the medulla are not associated with the splanchnic nerve. In vivo studies with male Foxhound dogs were performed to evaluate the functional role of GABA in adrenal medulla. Drugs were injected directly to the gland by the technique described by Hilton et al. (Am.J. Physiol. 192: 525, 1958) and blood samples to measure CAs and Met$^5$-enkephalin-like immunoreactivity (ME-LIR) were obtained from the left adrenal vein. THIP ($GABA_A$ receptor agonist) increased the release of CAs and ME-LIR in parallel. Chromatographic profiles of the plasma samples on Sephadex G75 indicated that ME-LIR was associated with larger molecular forms of ME. These profiles were very similar to those of samples obtained after splanchnic nerve stimulation. Disappearance of ME might be due to the rapid degradation during the preparation of plasma samples. The release of CAs and ME-LIR was not blocked by hexamethonium, naloxone or splanchnicotomy, but was instead prevented by bicuculline. These data suggest that GABA-induced release of CA and ME-LIR were the consequence of chromaffin cell depolarization following direct stimulation of $GABA_A$ receptors located on chromaffin cell membranes. In fact, THIP ($10^{-3}$M) produced a significant release of CAs from cultured chromaffin cells providing that the $Cl^-$ concentration in the incubation medium is maintained under 50 mM.

251.11 DISTRIBUTION OF MONOAMINE OXIDASE TYPES A AND B IN THE ADRENAL GLAND. G.L. Pfeiffer* and S.W. Carmichael. Dept. of Anatomy, Mayo Clinic, Rochester, MN 55905.

Biochemical studies have shown that the chromaffin cells of the bovine adrenal medulla contain only the B type of monoamine oxidase (MAO-B) (Youdim, M.B.H., et al., Soc. Neurosci. Abstr., Vol 10, Part 2, p. 722, 1984). Furthermore, Youdim et al. showed that cells from a tumor of the rat adrenal medulla (PC12 cells) contained only the A type of the enzyme (MAO-A). In a histochemical study we have localized the enzyme in the adrenal gland of cow, man, dog, cat, and rat. For the histochemical method, tetranitroblue was used as the stain and tryptamine was the substrate. Specific inhibitors for MAO-A (clorgyline, $10^{-7}$M) and MAO-B (deprenyl, $10^{-7}$M) were used prior to and during the staining reaction. Pargyline ($10^{-2}$M), heat and substrate-free medium were used as controls, and these showed the method to be valid. Our findings confirmed that the bovine chromaffin cells contain MAO-B and endothelial cells contain MAO-A. The distribution of MAO-B activity is heterogeneous within the medulla. More activity could be seen surrounding the central vein than in peripheral parts of the medulla. Nerves within the bovine adrenal medulla and cells surrounding these nerves contain both types of MAO. The adrenal medullas of man, dog, cat, and rat were not as reactive as the cow--indicating less enzyme activity in these species. Preliminary results on human pheochromocytoma (an adrenal medulla tumor) indicate that MAO-A is predominant. Within the adrenal cortex there is a distinct zonation for the two types of MAO that varies among species. The zona glomerulosa of the cow adrenal cortex contains MAO-B whereas the zona fasciculata and zona reticularis contain MAO-A. The adrenal cortex of the other species studied contain mostly MAO-B, except the canine zona reticularis which also contains MAO-A.

251.12 DIHYDROPTERIDINE REDUCTASE IS PHOSPHORYLATED BY CYCLIC-AMP DEPENDENT PROTEIN KINASE FROM BOVINE ADRENAL MEDULLA. Keith W. Brocklehurst*, Robert A. Levine+, Kyoji Morita++, Sheldon Milstien++, and Harvey B. Pollard. Lab of Cell Biology and Genetics,NIADDK, and ++Lab of Neurochemistry, NIMH, NIH, Bethesda, MD 20205
+Current address: Lafayette Clinic, Detroit, MI 48207

Dihydropteridine reductase (DHPR) plays an integral role in biogenic amine synthesis by converting quinoid-dihydrobiopterin (q-$BH_2$) to tetrahydrobiopterin ($BH_4$). $BH_4$ is the electron donor for phenylalanine, tyrosine (TH), and tryptophan (TrpH) hydroxylases in the process of aromatic amino acid hydroxylation in various tissues. It has been thought that DHPR is normally in excess in most tissues since the majority of biopterin is present in the fully reduced, tetrahydro form ($BH_4$). Since phosphorylation appears to be a critical factor for the short-term activation of both TH and TrpH (by different mechanisms), we have investigated whether purified sheep liver DHPR could be phosphorylated by any of the known protein kinases found in adrenal medulla. A rabbit antibody to DHPR was used to examine specific incorporation of $^{32}$P into DHPR.

An adrenal medullary post-microsomal supernatant was prepared in the presence of 1 mM EGTA to be used as a source of kinases. DHPR was incubated (3 min, 37°C) in the presence of medullary supernatant, [gamma-$^{32}$P]ATP, and the following activators of protein kinases: 1) c-AMP; 2) c-GMP; 3) $Ca^{+2}$; 4) $Ca^{+2}$, calmodulin, and 5)$Ca^{+2}$, phosphatidylserine. After the reaction, aliquots were subjected to SDS-PAGE and autoradiography. Marked phosphorylation of a protein of approximately 28,000 $M_r$ corresponding to exogenous DHPR occurred only in the presence of c-AMP. Immunoprecipitation with the antibody and protein A confirmed that $^{32}$P was incorporated into DHPR. Thus, under these in vitro conditions, DHPR can be phosphorylated by a c-AMP dependent kinase, but not by protein kinases that are dependent on other activators. These studies reveal the possibility that c-AMP-dependent phosphorylation of DHPR could play a role in regulating the initial hydroxylation reactions in biogenic amine synthesis.

252.1 **EFFECTS OF UNILATERAL BRAIN DAMAGE ON THE IMMUNE SYSTEM IN MICE AND MAN.** D.M. Nance, R. Carr* and P.W. Nance*. Departments of Anatomy, Rheumatology, Physical Medicine and Rehabilitation, Dalhousie University, Halifax, Nova Scotia B3H4H7, Canada.

Based upon the effects of unilateral hypothalamic lesions we have proposed the presence of a functional brain asymmetry in the neuroendocrine control of the gonads (B.R.B. 13:651,84). Renoux et al (J. Neuroimmunol. 5:227,83) have reported that the effects of unilateral cortical ablation on T-cell function in mice depends upon which hemisphere is lesioned. We have examined the effects of left or right unilateral cortical aspiration in mice on the in vitro lymphoproliferative response of spleen cells to mitogens. Additionally, specific antibody titers in mice with unilateral cortical lesions were measured following immunization with ovalbumin. Finally, in human subjects with predominately left or right cerebral damage the in vitro response of peripheral lymphyocytes to mitogens was tested. Histologically the cortical aspirations in the mice were on average localized to a dorsomedial strip of cortex 1.2 mm wide and extended from the frontal cortex posteriorly 5.5 mm. In female mice, unilateral cortical lesions had no detectable effect on the mitogenic response of spleen lymphocytes to concanavalin A and phytohemagglutinin. Similar assays in humans indicated a tendency ($p<.072$) towards increased T-cell function in subjects with left cerebral damage. Finally, antibody titers following immunization in mice indicated a significant sex difference in titers (female>male, $p<.001$) and a tendency ($p<.078$) in both male and female mice with right cortical lesions towards reduced antibody production. The female mice with right cortex lesions had larger thymus glands than sham and right cortex lesion groups ($p<.014$). Male mice with right cortex lesions were the only group not to gain body weight during the study ($p<.024$). There was a sex difference in adrenal weight (female>male, $p<.001$) and in the female lesion groups the adrenal gland was smaller ($p<.05$) on the same side as the brain lesion relative to the contralateral side of the body. In general, these results support the possibility of a functional asymmetry in the neural control of the immune system. The direction of the changes in immune function reported here are opposite to those reported by Renoux (1983). The smaller size and dorsomedial location of the present lesions may account for these differences and suggests there may be further segregation of function between various viscero-cortical regions. Functional asymmetries in the neural control of both the endocrine and immune systems may further reflect an underlying asymmetry in the organization of the autonomic nervous system. Supported by the Medical Research Council of Canada and the Dalhousie Medical Research Foundation.

252.2 STEREOSPECIFICITY OF OPIATE IMMUNOSUPPRESSION IN RATS. F.C. Martin, Y. Shavit, G.W. Terman, R.N. Pechnick, C. Oh*, and J.C. Liebeskind. Neuroscience Program and Department of Psychology, UCLA, Los Angeles, CA 90024.

There is growing experimental evidence that both endogenous and exogenous opioids affect immune function. Our laboratory has been studying the effects of opioids on natural killer (NK) cells, lymphocytes that spontaneously recognize and kill tumor cells and are present in blood, lymph nodes, and spleen. We have demonstrated that both systemic morphine and endogenous opioids released by stress suppress NK function in rats (Y. Shavit et al., Science 223:188, 1984). More recently, we found that the suppression caused by 30 mg/kg of systemic morphine can be reproduced by giving only 20 µg intracerebroventricularly, suggesting that morphine's effect is centrally mediated.

The present study examined the stereospecificity of opiate-induced NK suppression by comparing the opiate drug levorphanol (LEV) with its inactive stereoisomer dextrorphan (DEX) in vitro and in vivo. Subjects were 12-18 week old male Fischer 344 rats. For in vivo studies, rats were given DEX or LEV (10 mg/kg, s.c.) and splenectomized 3 hrs later under anesthesia. Spleens were homogenized into single cell suspensions and these cells mixed with chromium-51 labeled YAC-1 tumor target cells. NK activity was then measured in a 4h chromium release assay. For in vitro studies, spleen cells were incubated in cell culture media containing LEV or DEX for 3 hrs at 37°C before being washed and assayed as above.

SPECIFIC NK CYTOTOXICITY (% OF SALINE CONTROL) MEAN ± 95% CI

| Dose | Dextrorphan | Levorphanol | |
|---|---|---|---|
| in vivo | | | |
| 10 mg/kg | 98±13 | 61±10 | $p < 0.001$ |
| in vitro | | | |
| 5x10-4M | 4+5 | 11+14 | NS |
| 5x10-5M | 61±28 | 58±22 | NS |
| 1x10-6M | 92±21 | 88±22 | NS |

These results indicate that LEV but not DEX suppresses NK activity in vivo. However, in vitro these drugs produced a non-stereospecific suppression apparent only at high concentrations, suggesting this effect was not mediated by binding to opiate receptors.

We conclude that the opiate alkaloids, morphine and LEV, do not suppress NK activity in vivo by acting directly upon NK cells. Rather, these results support our previous findings indicating that this effect depends upon binding to central opiate receptors. (Supported by NIH grant NS-07628).

252.3 THE STIMULATORY EFFECTS OF NERVE GROWTH FACTOR ON IN VITRO LYMPHOCYTE PROLIFERATION. L.W. Thorpe*, C. Beck* and J.R. Perez-Polo, Dept. Human Biol. Chem. and Genetics, Univ. Tex. Med. Br., Galveston, TX., 77550.

It has been shown that numerous hormones and neurophysiological agents play an important role in immunoregulation. Specific receptors for many of these substances have been demonstrated on lymphophocytes and the immunomodulatory effects of these neurohormonal agents is initiated through receptor ligand interaction. Nerve growth factor (NGF) is a neuronotrophic peptide important in the development, maintenance and regeneration of sympathetic and sensory neurons. We have recently demonstrated the existance of receptors on the surface of both human and rat lymphocytes. These findings suggest that NGF may also participate in the regulation of immune function. To test this hypothesis we examined the lymphoproliferative effects of mouse β-NGF on rat splenic cells in culture. Varying concentrations of NGF (1-20 ul/ml) were added to triplicate microtiter plate cultures and incubated for 48-120 hours. In addition, NGF (1-10 ug/ml) was also added to cultures containing Con A (1 ug/ml) and cultured for 96-120 hours. Proliferative activity was measured by [$^3$H] thymidine (Thd) incorporation. NGF had no effects on [$^3$H]Thd uptake at either 48 or 72 hours. By 96 hours of culture, NGF resulted in a significant stimulation of lymphoproliferative activity ($p<0.001$). Optimal stimulation by all concentrations of NGF was seen at 120 hours ($p<0.01$) The data are shown here in tabular form as the mean CPM±standard deviation.

| Hrs. in Culture | [NGF] ug/ml 0 | 1 | 5 | 10 | 20 |
|---|---|---|---|---|---|
| 96 | 170±28 | - | 678±88 | 935±102 | - |
| 120 | 218±60 | 435±47 | 1568±324 | 1512±211 | 1307±37 |

NGF also showed a dose dependant augmentation of Con A induced [$^3$H]Thd uptake at 120 hours.

| | CPM±SD | |
|---|---|---|
| Con A (1ug/ml) | 21656±1802 | |
| Con A+1ug/ml NGF | 31040±5692 | $p<0.05$ |
| Con A+10ug/ml NGF | 54507±5126 | $p<0.01$ |

These results suggest that, at least **in vitro**, NGF enhances the lymphoproliferative response of rat spleen cells and also is synergistic with other mitogenic stimuli. The role that NGF may play in the **in vivo** immune response remains to be elucidated. Supported by NIH Grant NS18708 and Robert Welch Grant H698.

252.4 NEURAL REGULATION OF CELLULAR IMMUNE FUNCTION IN MICE. C.A. Mullen*, J.D. Hirsch, and B. Beer. Dept. of CNS Res., Medical Research Division of American Cyanamid Co., Lederle Labs, Pearl River, NY 10965.

The central nervous system is now known to communicate anatomically and chemically with the immune system. We investigated this interaction by determining the effects of autonomic neurotransmitters on selected aspects of the murine cellular immune response. Initial experiments demonstrated that parasympathetic stimulation (PS) in vivo induced by physostigmine (250 µg/kg s.c.) caused an increase in vitro in both mitogen-provoked interleukin-1 (IL-1) and interleukin-2 (IL-2) production while sympathetic stimulation (SS) induced by norepinephrine (750 µg/kg i.p.) exerted the opposite effect. Both physostigmine and norepinephrine were administered twenty minutes prior to removal of the spleen or thymus. In addition, thymocytes and splenic lymphoblasts from parasympathetically-stimulated mice were less responsive to murine and human IL-1 and murine and rat IL-2, respectively. Based upon these results, we expanded our studies to investigate more appropriate in vitro models of cellular immunoreactivity: 1) the allogeneic mixed lymphocyte reaction (AMLR); 2) allogeneic cell-mediated cytotoxicity (CTX); and 3) natural killer cell (NK) activity. In the AMLR, the proliferation of C57BL/6 responder splenocytes to alloantigens on γ-irradiated BALB/c stimulator cells was enhanced by prior PS but reduced subsequent to SS. In contrast, both PS and SS enhanced allogeneic CTX using $^{14}$C-labeled BALB/c Con A-lymphoblasts as target cells. In addition, the enhancement by PS of allogeneic CTX was partially blocked by atropine, a muscarinic cholinergic antagonist, given to C57BL/6 mice at 10 mg/kg i.p. thirty minutes prior to the administration of physostigmine. Neither PS nor SS had any acute effects on NK activity in freshly isolated spleen cells from C57BL/6 or CBA/CA mice. NK activity was measured by a $^{51}$Cr-release assay with YAC-1 mouse lymphoma cells as targets. However, prior PS in CBA/CA mice followed by overnight culture of unfractionated spleen cells resulted in an increase in residual NK activity compared to controls which was observed in the presence or absence of the interferon-inducer, polyinosinic:cytidilic acid, a known in vitro stimulator of NK activity. These results suggest that the autonomic nervous system (ANS) may play a key role in modulating interleukin production and target cell response to these immunoregulatory proteins. The ANS may thus influence the activity of various cells involved in the cellular immune response through this mechanism. These results also imply that it is possible to exploit the potent immunoregulatory effects of the nervous system in designing drugs for a variety of therapeutic areas.

252.5 **FEVER AND NEUTROPHILIA INDUCED IN RATS FOLLOWING THE CENTRAL ADMINISTRATION OF HIGHLY PURIFIED HUMAN INTERLEUKIN-1.**
G.J. Patel*, P.C. Harrison*, V.B. Ciofalo and R.B. Faanes*. Boehringer Ingelheim Pharmaceuticals, Inc., Ridgefield, CT 06877.

**The monokine Interleukin-1 (IL-1) is one of the products of mononuclear phagocytes. It is synthesized and released from these cells in response to stimuli such as microorganisms and microbial products. IL-1 is capable of gaining access from the periphery to the thermoregulatory centers of the hypothalamus in the brain to initiate fever. Peripheral administration of IL-1/endogenous pyrogen/leukocytic endogenous mediator has been reported to produce fever and accelerate release of mature neutrophils (neutrophilia) from the bone marrow.**

**In this study, we report that direct administration of highly purified human IL-1 into the rat brain results in both fever and neutrophilia. IL-1 (1 unit), heat-inactivated IL-1 or saline (10 µl each) was administered into the third ventricle of conscious adult rats via a stereotaxically implanted guide cannula. Core temperature was measured at 30, 60, 120 and 180 min. post-treatments. Peripheral blood was collected from retro-orbital sinus 180 min. after IL-1 or saline administration for a neutrophil count.**

**IL-1 produced a highly significant increase in body temperature of rats (N=14) within 30 minutes of administration as compared to saline controls (N=15). The peak increase (mean 1.2 ± 0.07°C) was recorded at 30 min. Significant febrile response was also observed at 60, 120 and 180 min. (mean 1.1 ± 0.07; 0.82 ± 0.11; 0.75 ± 0.14°C, respectively) in IL-1 treated rats. Heat inactivated IL-1 failed to initiate fever in rats (N=5).**

**IL-1 also produced a significant increase in the number of circulating peripheral blood neutrophils (mean 3034 ± 423, N=6) as compared to saline controls (1534 ± 217, N=6). In a separate experiment, peripheral blood neutrophils were counted following the administration of half the amount of IL-1 (1/2 unit) or saline (5 µl each) into the lateral ventricle of the rat brain. In this experiment also, IL-1 produced a similar increase in the number of circulating neutrophils (mean, IL-1, 4110 ± 591 vs. saline, 1497 ± 261, N=4 each). These results suggest that purified human IL-1 is capable of producing host-defense responses such as fever and neutrophilia through a CNS mechanism.**

252.6 IMMUNOLOGICAL REACTIVITY FOLLOWING ACUTE AND CHRONIC STRESS.
S. Livnat*, J. Irwin, R. Ader, K.L. Gallo*, and H. Anisman. Univ. Rochester Sch. of Med., Rochester, NY 14642, Carleton Univ., Ottawa, Canada.

Considerable evidence suggests that psychosocial factors such as stressors can modulate immune function and resistance to disease. Stress-induced changes in the CNS resulting in altered autonomic and neuro-endocrine outflow are most likely responsible. CNS responses to stressors are influenced by both the nature of the stimulus (form, severity, chronicity, controllability) and the organism (genetics, age). It is therefore of interest to determine how these factors influence the response of the immune system to stress.

Here, we examined the effects of acute vs. chronic footshock stress on several measures of immune function in 3 strains of mice. Male mice were exposed to 1 of 3 stress conditions which we previously found to induce consistent alterations in central noradrenergic pathways: (1) 14 daily 1.1 hr sessions of intermittent inescapable footshock (Chronic stress); (2) One session of footshock (Acute stress); or (3) Exposure to the apparatus (No shock controls). One day later, mice were sacrificed and their spleens taken for measurement of lymphocyte reactivity in vitro. We examined the cytotoxic activity of natural killer (NK) cells, the proliferative responses of T and B cells, and the generation of cytotoxic T lymphocytes following stimulation.

Acute shock reduced the level of NK cell activity in CD-1 and C57BL/6 mice. In contrast, chronically stressed mice of these strains exhibited enhanced NK function. This augmented activity was depressed by fighting behavior. No significant changés in NK function were observed in DBA/2 mice. In CD-1 mice, lymphocyte proliferative and T cell cytotoxic functions were not affected by the stress regimens. Together the results of the present experiments suggest that, in addition to the well-known immunosuppressive effects of certain forms of acute stress, compensatory changes occurring under conditions of chronic stress may lead to augmentation in activity of certain cells of the immune system, depending on the strain of mice. These findings have important implications for understanding the complex relationships between stress and infectious and malignant disease.

252.7 CEREBRAL LATERALIZATION: ASSOCIATION WITH SERUM ANTIBODIES TO DNA IN SELECTIVELY BRED MOUSE LINES.
W.H. Bailey, R.L. Collins and R.G. Lahita* Institute for Basic Research in Developmental Disabilities, Staten Island, N.Y. 10314, Jackson Laboratory, Bar Harbor, ME. 04609, *Rockefeller University, N.Y., N.Y. 10021.

Lateralization of function, particularly handedness, has long been associated with cerebral asymmetry and an increased incidence of CNS-related disorders. Geschwind & Behan (1982) have reported an increased frequency of migraine, developmental learning disabilities, and immune-related disorders among strongly left-handed subjects. The latter finding is unexpected for associations of handedness with non-CNS related phenomena are rare. Geschwind & Behan explained this association by postulating that androgen exposure, controlled by MHC genes, influenced both the development of cerebral lateralization and the immune system.

We attempted to confirm this hypothesis by screening for autoantibodies to DNA in the serum of mice selectively bred for degree of handedness. Serum antibody titers to double- and single-stranded DNA (DS-DNA; SS-DNA) were measured by RIA in 68 male and female mice bred for high (HI) and low (LO) handedness or from a unselected control population (CON). Antibodies to DS- and SS-DNA were significantly greater in female than in male mice. Line differences for both antibody specifities were only evident among female mice. The ranking of antibody levels by line was LO> HET> HI. Male-female differences in antibody levels (particularly against SS-DNA) were greatest in LO line animals.

The finding that autoantibody levels were inversely related to genetically-determined differences in cerebral lateralization in mice suggests an association like that noted by Geschwind & Behan (1982) in humans. Because HI and LO line mice differ in the distribution of haplotypes within the MHC (H-2) complex (Collins et al., 1985), and because HI line mice are more 'masculinized' than low line mice (Collins, 1985) our data also support the hypothesis that MHC genes and/or gonadal steroids are important in determining associations of handedness with immune function. Supported by grants NIH GM23618 and AM04761.

252.8 DECREASED NATURAL KILLER CELL ACTIVITY IN YOUNG ADULT BASAL FOREBRAIN DAMAGED AND NORMAL AGED, RHESUS MONKEYS.
L.J. Kraus, M.B. Moss and D.L. Rosene. Depts. of Neurology and Anatomy, Boston Univ. Sch. of Med., Boston, MA 02118.

A large body of literature has demonstrated the important role of neural and endocrine influences in regulating immune function. These include studies which show that damage to specific areas of the brain result in structural and functional alterations in the immune system. We report here our preliminary findings in a study examining changes in immune function following selective brain lesions in young adult monkeys compared with normal young adult and aged monkeys. As part of a multidisciplinary study of the basal forebrain and aging in the monkey, immune measures were compared with histochemical data obtained from several of the same animals described in the present study. Bilateral lesions of the basal forebrain, involving principally the substantia innominata and nucleus basalis (SI-NB), were produced by intracerebral injection of the neurotoxin, ibotenic acid. Changes in the cholinergic system were evaluated through histochemical studies of the cholinergic marker, acetylcholinesterase (AChE) and were quantified with a scanning and integrating microdensitometer. This method has been used in our laboratory to demonstrate an age-related loss of AChE in the hippocampal formation of rats and monkeys. The immune measure was natural killer cell activity (NKCA), a component of cell mediated immune function that is important in host defense against viral illness and some neoplasms as well as in maintaining immune homeostasis. NKCA is assessed in vitro by measurement of the ability of lymphocyte effectors to lyse radiolabeled NK-sensitive target cells. We assessed NKCA activity in monkeys with ibotenic acid lesions of the SI-NB (N=4), caudate nucleus (N=2) or hippocampal formation (N=1) and in young adult (4-6 yrs, N=8) and aged (25 yrs, N=4) normal rhesus monkeys. NKCA was significantly depressed in animals with SI-NB lesions as compared with young normals ($p<0.05$). NKCA in monkeys with caudate or hippocampal damage fell within the normal range. In contrast, a significant decrease in NKCA was observed in the 4 aged monkeys and was similar to the decrease seen in animals with SI-NB damage. In the 3 monkeys with SI-NB lesions assessed for AChE activity in the hippocampus, all showed marked decreases. The pattern and extent of AChE depletion was similar in two of the animals and these same two had similar levels of NKCA. The third animal had more limited depletion of AChE loss and had slightly greater NKCA. Thus, the data suggest that cholinergic loss as a consequence of lesions of the basal forebrain or of degenerative processes in normal aging may exert a marked influence on at least one important parameter (NKCA) of immune function.

253.1 FINE STRUCTURE OF NEUROTENSIN-IMMUNOREACTIVE NEURONS IN THE CENTRAL NUCLEUS OF THE RAT AMYGDALA. S.S.W. Tay*, T.H. Williams and J.Y. Jew. Department of Anatomy, College of Medicine, University of Iowa, Iowa City, IA 52242.

An earlier immunohistochemical study (Williams, T.H. et al. In: The Amygdaloid Complex, ed. Ben-Ari, 1981) characterized distributions of several neuropeptides in the central nucleus of the rat amygdala (CNA). The heaviest concentration of neurotensin (NT)-positive reaction product was shown to be located primarily in the ventral part of the lateral subdivision, and to a lesser extent in the medial portion of the medial subdivision. The NT-immunoreactive cell bodies were localized principally in the intermediate subdivision and in the lateral part of the medial subdivision.

This light microscopic study was followed up by an electron microscopic investigation of the CNA using an avidin-biotin complex technique. Electron-dense reaction product (particles 15-25 nm in diameter) was found in cell bodies, dendrites, axons and axon terminals. In both colchicine-pretreated and untreated specimens, the perikarya and dendrites showed reaction product around profiles of rough endoplasmic reticulum, mitochondria, microtubules and vesicles, but not within their lumina. In distal dendrites, the reaction product was associated with microtubules, vesicles and postsynaptic densities.

After pretreatment with colchicine, the cytosol of NT-immunoreactive neurons contained more reaction product than the untreated material. A few NT-immunoreactive neurons showed orderly arrays of neurofilaments in their perikarya and dendrites. In cross-sections of NT-immunoreactive dendrites, the enhanced reaction product was associated with small profiles of neurotubules. In longitudinal sections of similar dendrites, the reaction product appeared to be mainly localized alongside the parallel arrays of neurotubules.

Three types of axon terminals formed synaptic contacts with NT-immunoreactive neurons in the CNA. Type A terminals contained numerous small round or oval agranular vesicles; Type B terminals were characterized by numerous pleomorphic vesicles; and Type C terminals possessed a few scattered pleomorphic vesicles. Only Type A terminals were NT-immunoreactive. All three types of terminals formed symmetrical axosomatic and asymmetrical axodendritic contacts. Type B and Type C terminals often formed synaptic glomeruli with a central NT-immunoreactive dendrite. NT-immunoreactive terminals frequently formed symmetrical axoaxonal contacts with each other as well as with non-immunoreactive Type A or Type B terminals.

This study was supported by grant NS 19578 to T.H.W.

253.2 LOCATION AND NEUROCHEMICAL CHARACTERISTICS OF NEURONS WHICH INNERVATE PENILE ERECTILE TISSUE. K. Manzanares*, N. Minorsky*, J. Kohr* and W.G. Dail. (Spon: V. Williams) Department of Anatomy, University of New Mexico, School of Medicine, Albuquerque, NM 87131.

According to classical literature, the sacral spinal cord operates through cholinergic neurons in the pelvic plexus to cause penile erection, while adrenergic neurons in the sympathetic chain prevent erection. Recent data questions whether the sacral spinal cord is the only center for penile erection and whether acetylcholine is the inhibitory substance which mediates erection. To clarify these questions, histochemical and immunohistochemical methods have been used to characterize penile neurons in the rat. A quantitative study of penile neurons, identified by dye injection into the penile crura, indicates that some 92% of the neurons in the major pelvic ganglion (MPG) are immunoreactive for vasoactive intestinal polypeptide (VIP). Ninety-five percent of the penile neurons in the MPG stain for the enzyme acetylcholinesterase (AChE), in a second group of rats. In a third group of rats, identified penile neurons in the MPG were immunostained for tyrosine hydroxylase (TH). Although TH positive principal neurons are abundant in the MPG, in a survey of over 300 neurons, none of the penile neurons stain for TH. Retrograde dye in the penile crura filled neurons in the sympathetic chain as high as the level of the diaphragm although most of the neurons occured in chain ganglia at the bifurcation of the aorta. Removal of the sympathetic chains from the diaphragm to just below the aortic bifurcation resulted in the near total elimination of adrenergic fibers in penile erectile tissue. The present study indicates that the great majority of penile neurons in the MPG are immunoreactive for VIP and have a high content of AChE. These results suggest (1) that VIP and acetylcholine may be co-localized in penile neurons in the MPG and (2) that the recently described pathway by which the hypogastric nerve innervates penile neurons in the MPG differs quantitatively rather than qualitatively from the vasodilator pathway from the sacral spinal cord. Finally, lack of staining for TH in penile neurons in the MPG and the effects of removing the chain ganglia indicate that the sympathetic chain is the major if not the sole source of the adrenergic innervation of penile erectile tissue. Supported by NIH 1R01NS19839-02 and NIH RR08139-10.

253.3 SUBSTANCE P LIKE IMMUNOREACTIVITY IN FROG SPINAL CORD. DS Adli, BM Rosenthal, RH Ho, and WLR Cruce. Neurobiology Program, Northeastern Ohio Universities College of Medicine, Rootstown, OH 44272 and Department of Anatomy, The Ohio State University, Columbus, OH 43210.

Substance P (SP) has been implicated in nociception. As a continuation of our studies on the putative roles of neuropeptides in nociceptive processing in amphibians, we examined the distribution of substance P like immunoreactivity (SPLI) in the frog spinal cord.

Adult leopard frogs (Rana pipiens) weighing 30-60gm were perfusion-fixed with Zamboni's solution. Transverse and horizontal sections of representative spinal cord levels (brachial, thoracic, and lumbar) were cut 50um thick on a vibratome or a freezing microtome. The sections were processed for the localization of SPLI by the indirect antibody peroxidase-anti-peroxidase (PAP) method of Sternberger.

Substance P like immunostaining appeared as distinct dark-brown dots and as strings of beads. These structures were interpreted to be nerve fibers and their varicosities or terminals cut in various planes of section. SPLI structures were seen throughout the gray and white matter. Small diameter SPLI fibers were seen in the dorsal root. The SPLI fibers in the ventral part of the dorsal root could be followed to Lissauer's tract. In the gray matter, dense SPLI fibers were present in an area just ventral to the central canal. In addition, a band-like SPLI region extended from the lateral edge of the gray matter to an area adjacent to the central canal. This band-like area corresponds to the region between the oval-shaped dorsal terminal field of cutaneous primary afferents and the triangular-shaped ventral terminal field of muscle primary afferents. The remaining gray matter contained a moderate density of SPLI fibers. In the white matter, SPLI fibers were densest in the dorsal part of the lateral funiculus (where Lissauer's tract is located) and the density decreased in a ventral direction. The dorsal and ventral funiculi exhibited sparse SPLI. In horizontal sections, longitudinal SPLI fibers were seen coursing in a rostrocaudal direction in the white matter. This SPLI distribution pattern is representative of all cord levels. The distribution of SPLI fibers closely matched the distribution of enkephalin like immunoreactive fibers in frog spinal cord.

253.4 CHOLINERGIC NEURONS DEMONSTRATED BY IMMUNOHISTOCHEMISTRY IN MOUSE SPINAL CORD CULTURES. E.A. Neale, G. Bruce, E. Matthew, S.W. d'Autremont*, W.L. Strauss, L.B. Hersh and P.G. Nelson. Lab. Develop. Neurobiol., NICHD, NIH, Bethesda, MD 20205 and Dept. Biochem., Univ. Texas Health Sci. Ctr., Dallas, TX 75235

A definitive morphologic marker for a given neuron type is a valuable tool for developmental and functional studies. Such a marker for mammalian cholinergic neurons in culture has not been available. A recently developed rabbit polyclonal antibody against immuno-affinity purified human placental choline acetyltransferase (ChAT) (Bruce, G., Wainer, B.H., & Hersh, L.B., J. Neurochem., in press) was used, with the biotin-avidin peroxidase technique (Vector), to visualize neurons containing this enzyme in dissociated cell cultures prepared from 13 day fetal mouse spinal cord/dorsal root ganglia. A small percentage of neurons in these cultures exhibit immunoreactivity. Pretreatment of the cultures with colchicine is not required for somatic staining. There are no stained cells when normal rabbit serum is used instead of rabbit anti-ChAT, and staining is abolished when the antibody is adsorbed to a partially (100-fold) purified preparation of rat brain ChAT.

A few of the stained neurons in each culture are large multipolar cells with axons that can be traced from the soma for long distances and numerous axonal branches that terminate in varicosities contacting other neurons. The majority of stained cells are smaller neurons with less extensive axonal arborizations. Staining above background is not detected in one week old cultures, and stained neurons are rare after two weeks in culture. By three weeks, neuronal staining is distinct. With further development in culture, the reaction product appears more intense and the morphology of stained neurons, more complex. Immunoreactive neurons are much more numerous in cultures prepared from ventral horn (Guthrie, P.B. and Brenneman, D.B., Soc. Neurosci. Abstr. 8:233, 1984) than in those from whole spinal cord. The number and morphologic features of neurons stained using anti-ChAT are similar to those stained histochemically for acetylcholinesterase.

This antibody most likely identifies cholinergic neurons. It is unclear whether our staining conditions allow for the visualization of all cholinergic neurons in these cultures.

Supported in part by NIH NS 15739 to LBH.

253.5 EARLY CHANGES IN ACETYLCHOLINESTERASE ACTIVITY AT SYNAPTIC SITES DURING DEAFFERENTATION IN SPINAL TRIGEMINAL NUCLEUS. S.H. Broderson* and L.E. Westrum. (SPON: P.D. Swanson) Depts. of Biological Structure and Neurological Surgery, Univ. of Washington, Seattle, WA 98195.

The thiocholine method of Karnovsky and Roots is being used to investigate the light and especially the electron microscopy of the acetylcholinesterase (AChE) activity in normal spinal trigeminal nuclei (STN) and at selected times after deafferenting trigeminal rhizotomies. Trigeminal rhizotomy produces abnormal physiological activity in the STN and, after appropriate survival, even spontaneous epileptiform hyperactivity. Our intent is to correlate possible alterations in AChE activity associated with this membrane dysfunction. In normal material AChE reaction product is seen extracellularly around axons, dendrites and especially terminals, including the synaptic site. At the synaptic contact, the product may fill the synaptic cleft, but more commonly is accumulated at the presynaptic membrane, occasionally in the form of irregular columns spanning the cleft. Both classes of terminals; those with round synaptic vesicles (R) and those with flattened vesicles (F) are involved. Shortly after rhizotomy (1 day), when AChE activity appears reduced throughout, some of the degenerating R terminals show disappearance of the AChE product selectively from the synaptic cleft, although it persists in adjacent areas. By seven days the few remaining, advanced degenerated R terminals now show return of AChE activity in the cleft. Also receptor sites vacated by loss of R terminals and thus reoccupied (or reinnervated) by unaltered terminals (F usually) show AChE reaction product filling the cleft except at the "active zones" (opposite focal accumulations of presynaptic vesicles). By 14 days the synaptic neuropil shows little or no evidence of degeneration and the AChE reaction product is extensively distributed around synaptic and nonsynaptic profiles. The results indicate that early loss and subsequent increased AChE activity may partly be related to changes in the synapses during degeneration and reinnervation and that the synaptic cleft region or "active zone" is involved. The observations also provide information regarding the exact membrane associations of the AChE activity at the synapse.

Supported by NIH Grants NS-20482, DE-04942 and NS-09678. LEW is an Affiliate of the CDMRC at the University of Washington.

253.6 CHOLINERGIC SYSTEMS OF THE HUMAN BRAIN STUDIED BY CHOLINE ACETYLTRANSFERASE IMMUNOHISTOCHEMISTRY K. Mizukawa*, P. L. McGeer, H. Tago*, E.G. McGeer and F. Peng. Kinsmen Laboratory of Neurological Research, Dept. of Psychiatry, Univ. of British Columbia, Vancouver, B.C. V6T 1W5, Canada.

The distribution of cholinergic neurons in human brain was determined using the choline acetyltransferase (ChAT) immunohistochemical method.

Five human brains, obtained shortly after death, were removed from the cranium and perfused through the basilar and internal carotid arteries, using an electric pump, first with 1-2 liters of ice-cold phosphate-buffered saline to wash out the blood, followed by 2-3 liters of either ice-cold Zamboni's fixative or ice-cold 4% paraformaldehyde/0.35% glutaraldehyde. The brains were sliced and the slices (1-2 cm in thickness) were post-fixed in the same fixative solution as used for perfusion for approximately 24 hrs, after which they were stored in a solution of 15% sucrose in 0.1M phosphate buffer at 4$^0$C. Frozen sections (24 µm) were cut from the brain slices and stained immunohistochemically using rabbit anti-ChAT Fab fragments, a biotinylated secondary antibody and an avidin-biotin-peroxidase (ABC) marker complex.

In the forebrain, ChAT-positive cells were observed in the caudate, putamen, nucleus accumbens, nucleus basalis of Meynert, medial septal nucleus and nuclei of the diagonal band of Broca. In the brain stem, major cholinergic cell groups were found in the motor nuclei of the cranial nerves (N.III, N.IV, N.V, N.VI, N.VII, N.IX, N.X, N.XI), nucleus ambiguus, nucleus supraspinais and nuclei parabrachialis lateralis and medialis. Minor groups of ChAT-positive cells were scattered in the nucleus cuneiformis, nucleus centralis superior, nucleus vestibularis, nucleus reticularis pontis, nucleus reticularis tegmenti pontis, nucleus gigantocellularis, nucleus olivae superioris, nucleus funiculi anterioris and lateralis, nucleus gracilis and nucleus medullae oblongata centralis.

The results are compared with those previously found in the cat (Kimura et al. J. Comp. Neurol. 200:151-201,1981) and rat using similar procedures.

253.7 CHOLINERGIC SYSTEMS OF THE HUMAN BRAIN STUDIED BY ACETYLCHOLINESTERASE HISTOCHEMISTRY. H. Tago*, P. L. McGeer K. Mizukawa* and E.G. McGeer. Kinsmen Laboratory of Neurological Research, Dept. of Psychiatry, Univ. of British Columbia, Vancouver, B.C. V6T 1W5, Canada.

A recently developed highly sensitive technique for acetylcholinesterase (AchE) has made it possible to observe clearly the distribution of this enzyme in cell bodies, dendrites and fiber tracts in human brain.

Five human brains were perfused and fixed as described in the companion abstract by Mizukawa et al. Frozen sections (24 µm) were cut from the brain slices and processed for AchE histochemistry. This method for staining free floating sections employs a peroxidase-like reactivity of products of the Karnovski and Roots' procedure in a diluted (1:100) medium. Small amounts of otherwise undetectable but highly localized reaction products are visualized by intensification using diaminobenzidine, nickel ammonium sulfate and $H_2O_2$

In control experiments, sections were incubated with eserine sulfate, DFP or BW284c51 (a specific acetylcholinesterase inhibitor). Also sections were incubated without substrate or with iso-OMPA as an inhibitor of nonspecific cholinesterase.

Careful comparison was made between neurons showing intense staining for AchE and those staining for choline acetyltransferase (ChAT) by immunohistochemistry (see companion abstract). Although AchE positive neurons were distributed in many more regions than the ChAT-positive cells, every area containing ChAT-immunoreactive neurons also contained strongly stained AchE-positive neurons. These neurons were mostly large in size (30-50 µm) and sharply outlined. They had intensely stained long processes. In a few regions (substantia nigra, locus coeruleus, hypothalamus, etc) large size neurons were found staining intensely for AchE which were completely negative for ChAT.

AChE containing axons in the cerebral cortex, hippocampus and many other regions were also observed in typical patterns of fiber tracts or in laminar arrangements.

(Supported by grants from the British Columbia Health Care Foundation, the MRC of Canada, the Mr. and Mrs. P.A. Woodward's Foundation and the B.C. Medical Services Foundation).

253.8 ANTIBODIES AGAINST HUMAN CHOLINE ACETYLTRANSFERASE: PROPERTIES AND USE FOR IMMUNOHISTOCHEMISTRY. Louis B. Hersh, Gordon Bruce and Dwight C. German, (SPON: Donnell Johns). Departments of Biochemistry, Physiology, and Psychiatry, University of Texas Health Science Center at Dallas, Dallas, Texas 75235.

The study of cholinergic neurons in human brain has become of extreme importance as these neurons appear to be selectively lost in patients with Alzheimers disease. Whereas neurons containing catecholamines or serotonin can be visualized directly using fluorescent techniques no simple method exists for visualizing neurons containing acetylcholine. Due to the non-cholinergic localization of the acetylcholine degrading enzyme acetylcholinesterase (AChE) the only specific marker for cholinergic neurons is the synthesizing enzyme choline acetyltransferase (ChAT). Over the past few years several laboratories have endeavored to purify ChAT for the production of mono-specific antisera. However, initial attempts at immunohistochemical staining in animal brains were questioned on the basis that these antibodies were not truly mono-specific. Of the 3 anti-ChAT antibodies previously used to stain human cholinergic neurones one antibody (Eng, et al. [1974] Nature 250, 243-245) has been criticised on the basis of its specificity while another antibody (Peng, et al. [1981] Neurosci. Lett. 21, 281-285) requires conversion to Fab fragments in order to achieve good staining. We report here the properties of a mono-specific anti-human ChAT antibody and its use in the immunohistochemical visualization of rat and human cholinergic neurons.

ChAT was purified to homogeneity from human placenta by immuno-affinity purification and was shown to be identical to human brain ChAT (Bruce, et al. [1985] Fed. Proc. 44, 1634). The purified human placental ChAT was used to raise polyclonal mono-specific antisera in rabbits using conventional immunization procedures. The monospecificity of the antisera was confirmed by showing its inability to react with any protein, other than ChAT, in a crude placental extract. Immunotitration of purified human placental ChAT showed the antibody to be non-inhibiting. An IgG fraction of the antibody was prepared using ion-exchange chromatography and this fraction was used for immunohistochemistry. Using standard (PAP) staining conditions cholinergic neurons were visualized in the striatium and nucleus basalis of rat brain and in the putamen and nucleus basalis of human brain. This anti-human ChAT antibody, which stains cell bodies, nerve fibres, and nerve terminals of human cholinergic neurons, will allow for further detailed studies of these neurons in normal and diseased brains.

253.9 An immunohistochemical analysis of cholinergic innervation in the cerebral cortex. F.E. Eckenstein, J. Quinn, and R.W. Baughman. Dept. of Neurobiology, Harvard Med. School, Boston, MA 02115.

Acetylcholine and other markers indicating cholinergic transmission are found in all areas of the cerebral cortex. Cholinergic cortical activity has been hypothesized to be involved in such complex mental functions as arousal and memory. Anatomical characterization of the cholinergic cortical circuitry is needed for a better understanding of the physiological role of this system.

In the rat, much of the cortical cholinergic innervation arises from large multipolar neurons in the basal forebrain. In addition intrinsic, bipolar cortical neurons also appear to be cholinergic, as judged from immunohistochemical localization of the enzyme synthesizing ACh, choline acetyltransferase (ChAT). Using immunohistochemical methods, we have analyzed the distribution of cholinergic structures throughout the cerebral cortex of the rat in detail, and have compared some of the features observed in rat with those of other species, including primates.

In rat cerebral cortex, we found the density of cholinergic terminals to be fairly constant throughout all cortical areas, except for entorhinal cortex and olfactory cortex, which show a marked increase in stained terminals. In many, but not all cortical areas, the density of ChAT-positive terminals showed a laminar distribution, and different cortical areas showed different laminar patterns of cholinergic innervation. In visual cortex, for example, a heavy band of cholinergic terminals was found at the border of layers 4 and 5; whereas layer 6 had a low density of stained terminals. Sensorimotor cortex, in contrast, had a high density of ChAT-positive terminals throughout layer 5, while layer 6 showed a moderate density. This laminar distribution of ChAT-positive terminals appears to be due to the basal forebrain projection and not to the intrinsic cholinergic cortical neurons because 1) ibotenic acid lesions of the cholinergic cell bodies in the basal forebrain abolished the laminar pattern of terminal staining in cortex and 2) terminals of the intrinsic cortical VIP/ChAT cells, visualized by staining for VIP, do not have a laminar distribution. The cholinergic basal forebrain projection to cortex was found in all species so far studied. In contrast, ChAT-positive bipolar cortical neurons were present only in rat and mouse, where they also contained vasoactive intestinal polypeptide (VIP). In rabbit, guinea pig and cat, bipolar VIP-positive neurons were present in the cerebral cortex, but these neurons did not appear to contain ChAT. Neither ChAT- nor VIP-positive neurons were found in the macaque cerebral cortex. (NIH EY03502 and ADRDA 84-1468)

253.10 Ultrastructural characterization of choline acetyltransferase containing neurons in the nucleus tractus solitrii of rat brain. D.M. Armstrong, A. Rottler* and V.M. Pickel. Dept. of Neurosciences, UCSD, LaJolla CA. 92093 & (VMP) Laboratory of Neurobiology, Dept. of Neurology, Cornell University Medical College, New York, NY 10021.

In the present study we employed the highly sensitive double peroxidase-antiperoxidase method in order to determine the distribution and ultrastructural morphology of choline acetyltransferase (ChAT) positive neurons in the nucleus tractus solitarii (NTS) of rat. ChAT is the rate limiting enzyme in the production of acetylcholine and is regarded as the most specific marker of the acetylcholine neurotransmitter system.

A well characterized antibody to ChAT (Eckenstein F. & Thoenen, H., (1982) EMBO J. 1, 363-368) was localized by immunocytochemistry in 50um Vibratome sections of rat brain fixed by vascular perfusion with a mixture of 4% paraformaldehyde and 0.2% glutaraldehyde in 0.1 M phosphate buffer.

ChAT immunoreactivity was localized to the cytoplasm of selectively labeled neuronal perikarya and dendrites. Most of the dendrites arose from ChAT-labeled neurons within the ventrally adjacent dorsal motor nucleus of the vagus (DMX). Within the NTS immunolabeled perikarya were relatively few in number, and for the most part were distributed within the caudal 2/3 of the nucleus. These neurons were only moderately labeled when compared to the ChAT-positive neurons in the DMX or hypoglossal nucleus. The labeled perikarya were typically oval and gave rise to 1 - 3 proximal processes.

As suggested by light microscopy the ultrastructural analysis of the NTS demonstrates ChAT immunoreactivity within a few perikaryon and numerous dendrites. In both instances the peroxidase reaction product was distributed throughout the cytoplasm with some selective accumulation on microtubules or around the outer rim of mitochondria. The plasma membrane of these immunolabeled neurons and dendrites often formed synapses with unlabeled presynaptic axon terminals. Although the chemical identity of these unlabeled boutons remains to be determined it is likely that at least some of them arise from peripheral afferents containing one of any number of neuropeptides (eg. substance P or enkephalin). In addition to forming classic synaptic contacts, many immunolabeled dendrites were observed in direct apposition to the basal lamina of blood vessels. Cholinergic processes have been observed innervating blood vessels within other brain regions, and thus our data indicate that a cholinergic mechanism may be important in the regulation of the cerebral microvasculature throughout many regions of the central nervous system.

Supported by NIH Grants AG-05344 & AG-05386.

253.11 THE ULTRASTRUCTURAL LOCALIZATION OF GABA-LIKE IMMUNOREACTIVITY IN THE NUCLEUS SOLITARIUS. B.E. MALEY AND K.A. HOWES*. Dept. of Anatomy, Univ. Kentucky Med. Sch., Lexington, KY 40536.

The nucleus solitarius is involved in the central regulation of cardiovascular functions. GABA, an inhibitory neurotransmitter, plays a role in this regulation, although the morphological basis for its action is not presently understood. The present study was undertaken to investigate the synaptic circuitry involving the GABA system in the nucleus solitarius.

Following fixation with a solution of 4% paraformaldehyde and 0.3% glutaraldhyde in phosphate buffer, 75 um sections of the nucleus solitarius were cut on a vibratome, incubated in GABA antiserum and processed with the peroxidase, antiperoxidase technique. The sections then were osmicated, dehydrated and embedded in Spurr's resin.

Examination of thin sections revealed GABA immunoreactivity within synaptic terminals, dendrites and neuronal cell bodies of the nucleus solitarius. The reaction product was generally present adjacent to the cytoplasmic side of membrane bound structures as well as to the membranes of the synaptic vesicles. GABA synaptic terminals, which contained numerous small clear vesicles, were distributed along the dendritic tree as well as the cell soma. The GABA terminals synapsed mainly on small to medium sized dendrites, although significant numbers of contacts were also present on large dendrites and cell bodies. On rare instances, GABA terminals were presynaptic to unlabelled axona. In addition to GABA terminals contacting unlabelled neuronal elements, GABA terminals also synapsed upon GABA immunolabelled dendrites and cell bodies. GABA immunolabelled neurons measured 8-15 um in diameter with the reaction product mainly restricted to membrane bound structures within the perikaryal cytoplasm. The GABA immunostained neurons were postsynaptic to both unlabelled and GABA immunolabelled synaptic terminals. Dendrites containing GABA immunoreactivity were characterized by reaction product associated with their microtubules, and they were postsynaptic to both labelled and unlabelled synaptic boutons.

The localization of GABA immunoreactivity in neuronal structures not only provides additional confirmation of a role for GABA in neural transmission, but also suggests a possible physiological function in the nucleus solitarius. Additionally, the presence of GABA-GABA synaptic contacts indicates a possible self-modulatory role for the GABA system. Supported by NIH HL 30702 to B.E.M.

253.12 IMMUNOCYTOCHEMICAL LOCALIZATION OF GABA IN DIENCEPHALIC AND MESENCEPHALIC NUCLEI OF THE CHICK BRAIN. W. J. Crossland and R. H. Granda*. Dept. of Anatomy, Wayne State Univ. Sch. of Med., Detroit, MI 48201.

We have identified cell bodies and axonal pathways in the chick brain using a polyclonal antibody to gamma aminobutyric acid (GABA) (Immunonuclear Corp.) visualized with an avidin-biotin-horseradish peroxidase complex (Vector Labs). All tissue sections were preincubated to remove endogenous peroxidase activity. Omitting the primary antibody abolished all stainable activity in the sections. Moreover, the antibody stained cells and presumed axonal processes in the molecular layer of the cerebellum, an observation consistent with the known morphology and distribution of GABA-containing stellate and basket cells.

There were two patterns of distribution of GABA positive cell bodies. (1) A group of nuclei containing predominately small to medium-sized cells which receive direct retinal input: lateralis anterior, ventral lateral geniculate, dorsolateralis anterior pars lateralis, ectomamillary, lentiformis mesencephali, and the stratum griseum et fibrosum superficiale of the optic tectum (primarily sublaminae a, c, and i). (2) A group of nuclei containing large and medium-sized cells which formed a band extending from the rostral thalamus to the caudal optic tectum, respectively: superior reticular nucleus pars dorsalis and ventralis, the posteroventral nucleus (tentative identification), the nucleus subpretectalis, and most caudally, the nucleus isthmi pars magnocellularis. In addition, GABA-positive cells were found in the nucleus mesencephalicus lateralis pars dorsalis of the midbrain, the preoptic area, the red nucleus, and scattered in the midbrain reticular formation. Some cells within the optic tract near the ventral lateral geniculate were also labeled.

Although many of the large cells are almost unquestionably neurons, the identity of the smaller cells, particularly those found in the optic tract, is not clear. Furthermore, we have no evidence as yet that any of these cells in fact use GABA as a transmitter, although from what is known of the avian brain, and by analogy with the mammalian brain, it seems likely that GABA may play such a role.

(Supported by N.I.H. grant EY-01796 to W. J. C.)

253.13 IMMUNOHISTOCHEMICAL LOCALIZATION OF GLUTAMATE AND GLUTAMINASE IN NEURONS OF THE PONTINE NUCLEI AND ASPARTATE AND AATASE IN NEURONS OF THE INFERIOR OLIVE. A.J. Beitz, A.A. Larson, J.E. Madl*, R.A. Altschuler and M.M. Mullett*. Univ. of Minnesota, St. Paul, MN 55108 and NINCDS, Bethesda, MD 20205.

Glutamate and aspartate are putative, excitatory amino acid neurotransmitters in the central nervous system. Both glutaminase, an enzyme which converts glutamine to glutamate, and aspartate aminotransferase, an enzyme which is involved in the interconversion between glutamate and aspartate, have been proposed as markers of neurons which use excitatory amino acids as neurotransmitters. Aspartate has been proposed as the transmitter of the olivocerebellar system, while the transmitter of the pontocerebellar system is unknown. The present study utilized a monoclonal antibody against carbodimiide-fixed glutamate (CFG), a monoclonal antibody against carbodiimide-fixed aspartate (CFA) and polyclonal antisera against glutaminase and aspartate aminotransferase (AATase) to analyze the distribution of excitatory amino acids in the pontine nuclei and inferior olivary nucleus. Five rats were perfused with a solution of 5% carbodimiide and 0.5% glutaraldehyde followed by 5% glutaraldehyde for use with the monoclonal antibodies. Five additional animals were perfused with a solution of 4% paraformaldehyde and 0.1% glutaraldehyde for use with the glutaminase and AATase antisera. Fifty micrometer thick vibratome sections were cut and reacted with the primary antisera. Sections were then immunostained using the avidin-biotinylated peroxidase procedure in conjunction with diaminobenzidine and hydrogen peroxide. CFG-like, AATase-like and glutaminase-like immunoreactivity were found in neurons in all subdivisions of the pontine nuclei. Following HRP injections into the cerebellum 81% of retrogradely labelled neurons in the basilar pontine nuclei were double-labelled with CFG immunoreactivity. Both CFA-like and AATase-like immunoreactivities were evident in neurons of the inferior olive. HRP injections into the cerebellum indicated that retrogradely labelled olivary neurons also contained aspartate immunoreactivity. These results suggest that glutamate may be the major neurotransmitter of pontocerebellar fibers, while aspartate is associated with the olivocerebellar projection. Supported by NIH grants NS19208 and DE06682 to A.J.B. and NIH grant NS17407 to A.A.L.

253.14 IMMUNOCYTOCHEMICAL LOCALIZATION OF GLUTAMATE AND ASPARTATE IN THE RETINA OF THE RAT. J.E. Madl*, A.A. Larson, A.J. Beitz and R.L. Johnson*. (SPON: D. Brown) Univ. of Minnesota, St. Paul, MN 55108.

Glutamate and aspartate are putative, excitatory amino acid neurotransmitters in the retinas of vertebrates. Biochemical studies employing microdissection have found highest concentrations of these two amino acids in the inner plexiform layer (IPL) and ganglionic cell layer (GCL) of the retina. The present study utilizes monoclonal antibodies with high degrees of specificity for fixative-treated glutamate and aspartate to analyze the distribution of excitatory amino acids in the retina of the rat. In agreement with the microdissection studies, the most intense immunocytochemical staining of the retina for both aspartate and glutamate was found in the IPL and GCL. Intense staining was also seen in certain cell bodies of the inner nuclear layer (INL). Hybridomas producing monoclonal antibodies were made by fusing myeloma cells with spleen cells from Balb/c/umc mice immunized with gamma-L-glutamyl-L-glutamate (gamma-Glu-Glu) or beta-L-aspartyl-L-aspartate (beta-Asp-Asp) conjugated to keyhole limpet hemocyanin (KLH) using glutaraldehyde-borohydride. Monoclonal antibodies obtained from mice immunized with beta-Asp-Asp/KLH gave highest intensity staining of the IPL, GCL, and some cell bodies in the INL of the rat retina using an indirect immunoperoxidase technique. Similar but less intense staining of these same layers was seen using a monoclonal antibody obtained from the mice immunized with gamma-Glu-Glu-/KLH. Specificity of these monoclonal antibodies was determined by the ability of small molecules to inhibit immunocytochemical staining of the retina and by the ability of the small molecules to inhibit enzyme-linked immunoassay (ELISA) reactivity of the monoclonal antibodies for the conjugates with which the mice were immunized. One monoclonal antibody was found to react strongly on competitive inhibition ELISA with gamma-Glu-Glu and other small molecules containing glutamic acid but not with similar small molecules containing aspartate, GABA, or glutamine. Two monoclonal antibodies were found to react strongly in the competitive inhibition ELISA assay with beta-Asp-Asp and other aspartate containing small molecules but not with similar small molecules containing glutamate or GABA. Immunocytochemical staining of the retina was inhibited by the same small molecules that reacted strongly with the monoclonal antibodies in the competitive inhibition ELISA assays. Supported by NIH grants NS07367 to J.E.M., NS17407 to A.A.L. and DE06682 to A.J.B. and also NSF grant BNS 83-11214 to A.J.B.

## NEURAL BASIS OF BEHAVIOR: INTERHEMISPHERIC RELATIONS I

254.1 HEMISPHERIC ASYMMETRIES FOR A VISUAL SEARCH TASK. Jeffrey D. Lewine* and Garth Elias*. (Spons. R.W. Doty) Center for Brain Research, University of Rochester, Rochester, New York 14642.

It has often been argued that the left cerebral hemisphere acts as an analytical/serial processor while the right serves as an holistic/parallel processor. Surprisingly, few laterality studies have used tasks specifically designed to differentiate these two information processing strategies.

A visual display search task was used to access the information processing schemes of the two hemispheres. Subjects were given a single target letter to remember at the beginning of each trial. A visual probe display of 1,2,4, or 6 letters arranged vertically was then presented with equal probability $2^{\circ}$ to the left (LVF), or right (RVF) of fixation, or directly across the fixation point, for 150 msec. The subject's task was to indicate if the target letter was present or absent from the display. Ten right-handed subjects were each given a total of 1152 trials across two experimental sessions.

If visual search proceeds in a serial fashion, response time will be related to the number of items being examined. In contrast, if search proceeds in an holistic/parallel fashion, then response time should be independent of the number of display elements.

A regression analysis relating response time to the number of elements in the display was performed for each visual field of presentation x target present/absent grouping. The obtained equations were as follows:

LVF/target-present: y=453+14.9x LVF/target-absent: y=461+33x
RVF/target-present: y=484+3.0x RVF/target-absent: y=484+27x
(y=response time in msec; x=number of letters in the display)

The data obtained from LVF presentations clearly suggest the use of a serial self-terminating search strategy. In contrast, the negligible slope (3.0x) for RVF/target-present trials is indicative of a parallel search. Interestingly, the slope for RVF/target-absent trials is similar to that of LVF/target-absent trials. It is perhaps the case that when the left hemisphere fails to find the target letter present in the display, a response is delayed until the right hemisphere confirms this. The observed response-time function is thus generated by the serially processing right hemisphere despite a RVF presentation.

In summary, the two hemispheres may indeed use different information processing strategies but, in the present situation, it seems to be the right hemisphere that serves as a serial processor while the left searches this alphabetic material in an holistic fashion. Experiments are underway to explore how search strategies are affected by the use of non-linguistic stimulus materials. Also, experiments exploring the search schemes of left-handed subjects are being conducted.

254.2 TASK-INDUCED DIFFERENTIAL CORTICAL ACTIVATION PATTERNS. M.N. Mitrushina* and J.S. Stamm. Dept. of Psychology, SUNY @ Stony Brook, New York 11794.

Measures of task-dependent cortical activations were assessed by bilateral EEG recordings from frontal, temporal, parietal and occipital areas. In a preliminary study 16 cognitive tests were administered to 200 adults and factor loadings determined. Two pictorial tests, the Raven Progressive Matrices and the Space Relations Test,had the most divergent loadings on Verbal and Spatial factors, respectively. They were used in the main experiment for EEG recordings during problem solving by 22 right-handed males. Recordings were obtained for 20 trials of each task and 16-sec. trial epochs were subjected to Fast Fourier analyses. The resulting averaged intensity values for conventional EEG spectral bands and characteristic frequencies for the alpha band (8 to 13 Hz) were subjected to statistical analyses. Indices of cortical activation were compared between verbal and spatial tasks for all subjects and between subgroups of verbalizers and visualizers. Each subject was assigned to one subgroup on the basis of his performance index, derived from response speed and accuracy on the two tasks.

Results are: (1) The most pronounced EEG discriminators between the two performance subgroups are the left and right parietal and the right frontal areas; (2) The left parietal zone provides the most pronounced discrimination between the two subgroups and its major involvement is presumed to be associated with the sequential cognitive mode; (3) There were significant interactions between the left parietal and the right frontal regions; (4) The two parietal areas show characteristic frequency shifts in opposite direction for the task conditions. Corresponding activation patterns were not revealed by any other pair of homologous areas. The findings imply complex interactions among the two parietal and right frontal areas, associated with sequential and holistic strategies.

The present findings are consistent with: (1) Anatomical evidence of interconnections between inferior parietal and premotor regions; (2) The attentional-arousal model of information processing, emphasizing distinct functional specialization of the left and right parietal areas and a mediating role of the right frontal area in processing of incoming stimuli. Further research on task-dependent EEG measures should consider subjectively preferred cognitive strategies which, together with objective task demands, influence processes for problem solving and accompanying neuronal changes.

254.3 LEFT AND RIGHT HEMISPHERE CONTRIBUTIONS TO A MOTOR SEQUENCING TASK. B. Sivak* and C. L. MacKenzie (SPON:G. Renninger). Dept. Of Kinesiology, University of Waterloo, Waterloo, Ontario, Canada N2L 3G1.

The study investigates left and right hemisphere contributions in a rapid finger sequencing task. The existence of a sequencing control center in the left hemisphere is a prime interest (Kimura, 1977, 1982).

Sensory input was lateralized for 16 right-handed subjects to either the right or left hemisphere by using specially designed contact lenses which restricted input to either the left visual field of the left eye or the right visual field of the right eye. The non-participating eye was occluded. A control condition involved subjects using both eyes during testing. Subjects performed a sequence of two keypresses in response to a light stimulus with either the right or left hand in a choice reaction time paradigm. Two experimental conditions were used. In Condition A, subjects always knew which hand to use but did not know which sequence to perform. In Condition B, subjects always knew which sequence to perform but did not know which hand to use.

Reaction time results indicate that there are no significant differences between the left and right hemisphere in selecting a sequential response when there was sequence uncertainty but hand certainty nor when there was sequence certainty but hand uncertainty. Reaction time was significantly slower when subjects wore the contact lens during testing. Further, reaction time was significantly faster for all stimulus-response combinations in Condition B when compared with all the stimulus-response combinations in Condition A. Overall, subjects made fewer errors in Condition B than in Condition A.

Interfinger time results show left eye-left hand advantage when there is sequence uncertainty but hand certainty and left eye-right hand and left eye-left hand disadvantage when there was sequence certainty but hand uncertainty.

The reaction time results do not support the notion of a control center in the left hemisphere for selection of components of a two element sequential keypress prior to movement initiation for both hands. However, the interfinger time results indicate that there are differences in the processing ability of the left and right hemispheres in a sequencing task after movement initiation.

254.4 THE RELATIONSHIP BETWEEN INPUT INTERFERENCE AND OUTPUT INTERFERENCE MEASURES OF LANGUAGE LATERALIZATION. Richard S. Lewis, Donna L. Orsini and Paul Satz*. Neuropsychiatric Inst., UCLA, Los Angeles, CA 90024.

Various experimental procedures have been used to infer hemispheric language representation in normal individuals. These methods include input interference tasks, such as dichotic listening and visual half-field, and output interference tasks,such as concurrent finger tapping and speaking. Kinsbourne [In J.B. Hellige's (Ed.) Cerebral Hemisphere Asymmetry, 1983] has argued that output interference tasks are more advantageous measures of laterality because output processes are more lateralized, more observable, less susceptible to attentional shifts, and less likely to yield facilitory effects. The present study investigates the relationship between input interference and output interference measures of cerebral lateralization, and their clinical utility, in a large sample of normal subjects.

One input interference laterality task, dichotic listening, and two output laterality tasks, concurrent finger tapping and speaking (dual manual-speech vocalization), and concurrent finger tapping and reading (dual manual-reading), were administered to 300 left-handed and 255 right-handed subjects (see Orsini et al., Neuropsychologia, 23, 223-232, for procedural details).

The results revealed low correlations between the input interference and output interference tasks (r = .11 for the correlation between dichotic listening and the dual manual-speech vocalization task; r = .06 for the correlation between dichotic listening and the dual manual-reading task). Furthermore, the results obtained with the dichotic listening technique more closely approximate the findings reported using the Wada and incidence of aphasia methods than either of the dual task measures. The proportion of right-handed subjects demonstrating findings suggestive of left hemisphere language dominance was 88% on dichotic listening, 63% on the dual manual-speech vocalization task, and 57% on the dual manual-reading task; for left-handers it was 76% on dichotic listening, 43% on the dual manual-speech vocalization task, and 42% on the dual manual-reading task.

These results will be discussed with reference to Kinsbourne's functional distance model (Kinsbourne, 1983) and their utility for predicting language lateralization.

254.5 VISUAL EVOKED RESPONSE ESTIMATES OF INTERHEMISPHERIC TRANSFER TIME IN HUMANS: OCCIPITAL REGION EFFECTS C. Saron*, P. D. Reiner* and R. J. Davidson* (SPON: R. Halperin) Dept. of Psychology, University of Wisconsin, Madison, WI 53706 and Dept. of Psych. SUNY Purchase, Purchase, NY 10577

Interhemispheric transfer time [IHTT] has been estimated by examining time differences between ipsilateral and contralateral responses to unilateral stimuli. Electrophysiological studies of IHTT have used evoked potential peak latency shifts and cross-lag correlations between waveforms from homologous sites as their estimates of IHTT. The purpose of this study was to compare these approaches and to examine differences in IHTT estimates recorded from two different occiptal scalp regions.

Visual evoked potentials [VEP's] to hemiretinal stimuli during a reaction time task were recorded from 12, 20 to 30 year old, right-handed males. 3.6° [V] by 3.0° [H] checkerboards were presented 2.9° to the left or right of central fixation for 10 ms with an ISI of 1.5-3.5 sec. 100 stimuli were presented to one visual field at a time. Subjects lifted their left index finger in response to each stimulus.

VEP's were derived by averaging EEG recorded from scalp sites O1, O2, O3 and O4 (2cm lateral to O1 and O2), referred to linked ears, for 200 ms following the onset of each stimulus. EOG was recorded from the external canthi, and from supraorbit to suborbit. Epochs confounded with eye movement were not averaged.

VEP latency differences between sites within a visual field [LVF or RVF], were examined separately for each region [O1/O2 or O3/O4], using a lag to maximum correlation procedure and measurements of P100 peak latencies. For the correlation procedure, a 50 ms wide window on the waveform from the contralateral pathway, was lagged 30 ms in both directions against the other waveform in 0.4 ms steps. The zero lag correlation [Or], maximum correlation [Mr] and its associated lag time were computed. This procedure was repeated 32 times with the window start position [W] increasing by 2 ms from 50 to 114 ms. The window from which data were chosen for further analysis represented the first peak in the function Mr vs. W for all W's whose Or > -0.5, Mr > 0.75 and Mr - Or > 0.05. If no peak was found, data from the criteria-meeting window with the greatest Mr was used. Peak latency measures were obtained by measuring the latency of the greatest positivity between 90 and 140 ms. Estimates of IHTT were computed by subtracting the latency of the peak from the contralateral waveform from the corresponding peak recorded from the homologous ipsilateral site.

Lag and peak latency differences were examined separately, with ANOVAs using visual field and region as factors. For both the lag and peak latency data, the ANOVA revealed no significant differences between visual fields for either region. For the lag data, a significant region effect was obtained [F(1,11)=18.11,p=.0014]. The mean (SD) lag values, across visual fields, were: O1/O2 = 7.0 (7.2) ms, [Or = 0.84 (0.09), Mr = 0.95 (.04)]; O3/O4 = 13.1 (6.7) ms, [Or = 0.51 (.44), Mr = 0.95 (0.05)]. For the latency data, a significant region effect was also obtained [F(1,11)=9.56,p=.01]. The mean (SD) peak latency differences, across visual fields were: O1/O2 = 7.9 (9.3) ms, O3/O4 = 14.5 (10.2) ms. Mean (SD) P100 peak latencies by region, averaged across visual field and hemisphere were: O1/O2 = 114.9 (6.9) ms, O3/O4 = 112.8 (5.9) ms.

These data indicate that relatively small changes in electrode sites play an important role in interpreting VEP esitimates of IHTT. However, markedly different approaches to waveform quantification have revealed similar effects. This work was supported by the March of Dimes Birth Defects Foundation and an equipment loan from Teca Corporation.

254.6 INTERHEMISPHERIC TRANSFER EXAMINED THROUGH SIMPLE REACTIONS TO LATERALIZED FLASHES OF LIGHT IN COMMISSUROROMIZED PATIENTS. J. Sergent. Montreal Neurological Institute, and Department of Psychology, McGill University, Montreal, PQ, H3A 2B4, Canada.

Simple reactions to lateralized flashes of light suggest that transmission of information between the two cerebral hemispheres is achieved at very high speed via the corpus callosum. The nature and efficiency of this transmission, however, vary as a function of the response modality, and a manual response does not yield the same pattern of results as a verbal response (Tassinari et al., Human Neurob., 2:77-85, 1983). The source of this discrepancy was further examined in complete forebrain commissurotomy patients who had to produce, in three separate experiments, either a finger, a blowing, or a verbal response to a 10-ms flash of light appearing in either the left or the right visual field. A control subject was tested in exactly the same experimental conditions, and his results conformed to the pattern typical of such experiments.

For the two patients (L.B. and N.G.), a blowing response was made equally fast to left and right field presentation, indicating that the two hemispheres of each patient could process the light equally efficiently. The finger task yielded a highly significant interaction between visual field and responding hand, and the reaction time difference between ipsilateral and contralateral responses was of the order of 30 and 50 ms for L.B. and N.G., respectively, suggesting that subcortical transfer of information is highly inefficient in the manual task compared to a transmission time of 2-3 ms through a callosal route. By contrast, the verbal task resulted in no visual field difference, even though the specialized mechanisms of the left hemisphere are required for speech production.

The results confirm that different pathways may subserve transmission of information across the hemispheres and they further suggest that a verbal response may be initiated in subcortical structures to which both hemispheres have equally efficient access before being organized within the left hemisphere.

254.7 RIGHT/LEFT PROCESSING OF PERSPECTIVE CUES FOR VISUAL DISTANCE IN COMMISSUROTOMY SUBJECTS. A. Cronin-Golomb* (SPON: B. Vermeire). Div. of Biology, Calif. Inst. of Technology, Pasadena, CA 91125

In normal subjects, a dot is perceived as smaller than its actual size if presented to the top half of a field, and larger than actual size if presented to the bottom half of the field. Four complete commissurotomy subjects (LB, NG, AA, and RY) were examined on this task. Stimuli were flashed for 150 msec to one or the other visual hemi-field, and included solid dots of three sizes corresponding to 0.3°, 0.8°, and 1.3° of visual field. Any one dot appeared in one of three positions (top, middle, or bottom) on a 6 X 7° card. Subjects were to point to that dot of the nine-choice array in free vision that was of the same size and position as the sample dot. Right hemisphere errors were found to lie in the direction of the normal illusion (chi square, $p < .01$). The effect was enhanced when a 'natural' gradient background (a plane of horizontal lines, receding toward the top of the card) was used, rather than a plain white background. By contrast, left hemisphere errors were generally perceived as smaller in the bottom and larger in the top half of the field ($p < .01$). No significant effect of background was observed.

Further, the right hemisphere of three subjects (LB, NG, and AA) more often chose the correct answer when the stimulus card represented a relatively 'natural' distance relationship (e.g., small dot at the top) than when the relationship was relatively 'unnatural' (e.g., small dot at the bottom.) The opposite effect was obtained for the left hemisphere in subjects NG and RY, for whom left hemisphere performance was better on trials involving 'unnatural' than 'natural' relationships. For both hemispheres, the results were independent of background used.

The findings suggest that the separated hemispheres may be analyzing some visual perspective cues in different ways. The right hemisphere appears to use natural perspective cues to determine the actual size and position of an object. When it does make an error, it judges objects high in the field as small, and those low in the field as large, again corresponding to the rules of constancy scaling. This result implicates the right hemisphere in the processing of perspective cues, which may in turn explain the observed right hemisphere susceptibility to those optical illusions such as the Ponzo that have been described in terms of perspective relations. The left hemisphere, on the other hand, may be using its skills as a feature extractor to seek out and process significant details in a field, such as usual perspective cues that contradict rather than conform to the rules of constancy scaling.

254.8 VISUALLY GUIDED REACHING AND GRASPING IN PATIENTS WITH UNILATERAL BRAIN DAMAGE. M. A. Goodale, M. E. Cohen*, J. D. Fisk*, and C. Routhier* (SPON: A. J. Hudson). Department of Psychology, University of Western Ontario, London, Ontario, Canada, N6A 5C2.

The spatiotemporal organization of visually guided reaching and grasping movements was studied in patients with restricted unilateral damage of either the right or the left hemisphere. All the patients were normally right handed. Strobe-shutter videotape records were made of the limb and hand as the subject reached toward and touched a small visual target (0.25 degrees) that was presented on a tangent screen either 10 or 20 degrees to the right or left of fixation. The reaction times and kinematics of the reaching movements were extracted from the videotapes by means of a computer-assisted digitizing system. All comparisons between the patient groups and control subjects were made with the hand ipsilateral to the lesion site. While patients with left-hemisphere lesions took no longer to initiate a pointing movement than age-matched control subjects, patients with right-hemisphere lesions took significantly longer than either the control subjects or patients with left-hemisphere lesions to initiate the same sort of movement. Once a movement was initiated, however, the performance of the right-hemisphere group differed little from that of the control group. In contrast, patients with left-hemisphere lesions took much longer to complete their pointing movement than either of the other two groups. The increase in the duration of the movement in the left-hemisphere patients was primarily due to prolonged period of deceleration during the final approach to the target. Both patient groups made larger terminal errors than the control group. In a second task, in which subjects were required to reach toward and grasp an object that differed in shape but not in location from trial to trial, the patients with right-hemisphere lesions took no longer than control subjects to initiate the reaching movement but took slightly longer to complete the entire sequence. Left-hemisphere patients, however, were slower both to initiate and to complete the reaching movement. These results suggest (1) that mechanisms within the right hemisphere may play an important role in determining the direction in which a particular movement should be made and (2) mechanisms within the left hemisphere participate in the selection of the appropriate configuration of motor programs necessary to achieve that particular movement.

This research was supported by Grant No. MA-7269 from the Medical Research Council of Canada to M. A. Goodale.

254.9 DISSOCIATION BETWEEN AUDITORY AND VISUAL CHOICE REACTION TIME IN THE TWO HEMISPHERES UNDER THE INFLUENCE OF ALCOHOL: E. Pöppel, Th. Steinbach*, J. Janzen* and W. Spann*. Institut für Medizinische Psychologie and Institut für Rechtsmedizin, Ludwig-Maximilians-Universität, 8 München 2, F R Germany

Alcohol appears to have a selective influence on the two hemispheres. This can be concluded on the basis of experiments in which intermodal choice reaction time (CRT) was determined. In these experiments, visual, auditory and tactile stimuli were presented in random order and the subject had to press as fast as possible one of the three appropriate buttons. Stimuli were lateralized in such a way that only (or predominantly in case of the auditory and tactile modality) the left or the right hemisphere was stimulated. Twelve male subjects participated in each of the two experiments. In case the left/right hemisphere was stimulated subjects had to use their right/left index finger for reaction. Thus, stimulation and initiation of motor response were controlled by the same hemisphere. After a baseline measurement in which at least 10 single reaction times for each modality were obtained, subjects drank beer and hard liquor in order to raise the alcohol level of the blood to a predetermined level. Blood tests showed that the left hemisphere group reached a level of 0.141 % and the right hemisphere group of 0.136 % . Then the CRT-experiment was repeated. With alcohol, tactile CRT was increased for the two hemisphere groups. With alcohol, auditory CRT was increased significantly only for the left hemisphere group. With alcohol, visual CRT was increased significantly only for the right hemisphere group. The same holds true if instead of reaction time the standard deviations of CRT are considered. In a control experiment it could be shown that auditory simple reaction time is increased both for the left and the right hemisphere group. In can be concluded that the interhemispheric dissociation between auditory and visual CRT is not due to a general slowing down of sensory processing and motor response, but that the dissociation appears to be dependent on a modality-specific influence of alcohol on a higher-order choice process.

254.10 ANALYSIS OF EEG COHERENCE DURING SPONTANEOUS RESPIRATORY SUSPENSION. A.T. Arenander, B. Lou*, W. Sheppard*, W.L. VanZandt, R.S. Hernandez and D. Krieger*. Neuroscience of Human Consciousness Research Laboratory, Maharishi International University, Fairfield, IA 52556.

Previous studies have reported a unique configuration of physiological and psychological processes which emerge during the practice of the Transcendental Meditation technique that correspond to a state of awareness without thoughts or spatio-temporal boundaries. In some subjects, this state of transcendental consciousness has been consistently correlated with extended periods (~40 sec.) of spontaneous respiratory suspension (SRS) which are separated by periods of awareness with thoughts and shallow respiratory activity (RA). We report here a detailed analysis of the EEG brain wave dynamics during RA and SRS. Our results support the concept that brain activity can display a highly coherent and simple state of functioning.

Data were obtained from a 10 lead montage, and analyzed for power and phase coherence parameters for the following frequency bands: theta, alpha 1, alpha 2, and beta 1. During the meditation period, relative fluctuations in power were similar across all bands and all leads. High ($>.90$) intrahemispheric coherence was found, with left hemisphere (LH) coherence greater than right (RH). Intrahemispheric coherence values were lower ($<.70$). Also, intrahemispheric coherence values were relatively constant regardless of the distance between scalp locations. Onset of SRS was associated with sharp increases in coherence values, with both hemispheres reaching nearly identical ceiling values.

Principal factor analysis of the coherence matrices showed that the factor structure changed with the onset of SRS, indicating simplification of EEG dynamics: 2 significant factors were typically obtained where factor 1 (LH) and factor 2 (RH) shared equal variance, all leads individually loaded $>0.9$, and the communality reached greater than 90%. Finally, complex demodulation at peak alpha 1 frequency produced nearly identical patterns of amplitude and phase fluctuations in bilateral leads during meditation. During SRS, phase activity stabilized. These results indicate that the human brain is capable of displaying a simple, stable state of neurophysiological functioning characterized by a high degree of sustained spatial and temporal integration.

254.11 LATERALIZED MEMORY DEFICITS IN PATIENTS WITH MAJOR PSYCHOPATHOLOGY COMPARED TO UNILATERAL STROKE PATIENTS. C.E. Naylor and F.B. Wood*. Section of Neuropsychology, Bowman Gray Sch. of Med., Winston-Salem, NC 27103

Based on previous research demonstrating lateralized deficits in patients with major psychopathology (see reviews; Flor-Henry, P., Ann. of N.Y. Acad. of Sci., 280: 777, 1976; Wexler, B.E., Am. J. of Psychiat., 137: 279, 1980; and Tucker, D.M., Psychol. Bull., 89, 19, 1981), patients with major depression (Dep.,N=15) and schizophrenia (Schiz.,N=15) were compared to two groups of stroke patients (25 right hemisphere lesioned (RH) patients and 40 left hemisphere lesioned (LH) patients), as well as to a sample of normals (N=50), matched for age, sex, and education. An equal distribution of frontal, central and posterior lesions was represented.

All subjects completed a series of memory tests as well as two "non-memory" tests, one visual (Porteus Mazes-PM) and one verbal (verbal fluency-FAS test). The two verbal memory tests consisted of delayed recall of a prose passage (cowboy story) and the post-distractional free recall trial of the Rey Auditory Verbal Learning Test (RAVLT). The two visual memory tests were delayed recall of a complex geometric design (Rey-Taylor figure) and a Figural Learning Test devised by us to constitute a nonverbal analogy to the RAVLT. It consists of five rehearsal trials of a list of novel shapes followed by a post-distractional free recall trial. Other tests of neuropsychological functioning were inserted to provide approximately a one hour delay between recalls.

The profile of the stroke patients revealed the expected cross-over interaction on all 6 tests, i.e. the RH patients were worse than LH patients on visual tasks while the LH patients were worse on verbal tests. The comparisons between the two lesion groups reached statistical significance on all tests except PM, which showed a similar though non-significant trend for RH patients to do worse. Both lesion groups were significantly worse than control subjects on all 6 tests indicating a generalized deficit as well.

Schiz. patients showed a profile that was statistically indistinguishable from LH patients on the four memory tests (worse than dep. on verbal memory tests) while dep. patients were statistically identical to the RH group (worse than schiz. on visual memory tests). Although the same cross-over interaction was found for the memory tests, the psychopathology groups did not differ on other tests, performing better than lesion groups. In conclusion, the commonality between schiz. and LH patients and between dep. and RH patients was observed most clearly on tests of memory functioning. The pattern of deficits in psychopathology is most similar to those found secondary to unilateral lesions which are centrally located on the anterior-posterior axis. These results suggest that the laterality hypothesis of major psychopathology may be especially relevant to the domain of memory functioning.

254.12 SEXUAL DIMORPHISM IN THE HUMAN CORPUS CALLOSUM? S. Demeter, J. Ringo, and R. W. Doty. Center for Brain Research, University of Rochester School of Medicine, Rochester, NY 14642.

The roles of "nature" and "nurture" in the determination of sex-linked differences in cognitive function have been much debated. The observation of anatomic variations in the cerebral cortical areas of men and women would bolster the arguments favoring a biological explanation. Since the corpus callosum consists largely of nerve fibers, which connect cortical areas of the two hemispheres, its morphology should reflect the presence or absence of such connections and thus serve as an indicator of this aspect of cortical structure. In a preliminary study, de Lacoste-Utamsing and Holloway (Science 216:1431-2, 1981) observed sexual dimorphism in the human corpus callosum, thus inferring sex-linked variation in cortical structure.

We have studied the corpora callosa of 19 men and 12 women obtained at autopsy and fixed in buffered formalin. The brains were weighed prior to fixation and were subsequently found to be free of significant neuropathology. Following fixation, each brain was bisected and photographed and its corpus callosum traced at a three-fold magnification. Computer-assisted planimetric measurements were made of the maximal splenial width, total callosal cross sectional area, and that of its posterior fifth, as described in the reference cited.

The maximal splenial width was observed to be the same in men and women and the cross-sectional area of the posterior fifth of the corpus callosum slightly larger in women than in men. However, this difference was not statistically significant. Moreover, three "blind" observers, provided with verbal descriptions and examples of tracings from the reference cited, failed to discriminate qualitatively between the corpora callosa of men and women at a better than chance level.

Although these observations suggest that there may, indeed, be a trend toward greater variability in the morphology of the corpus callosum between the sexes than within members of each sex, considerable caution must be exercised in attributing sex to a given brain on a morphological basis alone.

254.13 CEREBRAL ASYMMETRIES AND SEX DIFFERENCES IN HOMINOIDS. Darlene S. Horvath*, D.J. Woodward & Marie-Christine de Lacoste (SPON: D.L.O'Donoghue). Dept. Cell Biology, Univ.Texas Health Science Center, Dallas Texas, 75235

This study, which was undertaken to delineate the patterns of cortical asymmetries and sex differences in hominoids, is part of an overall research project designed (by MC de L) to investigate the phylogenetic and ontogenetic development of prosencephalic asymmetries in infrahuman anthropoid and prosimian primates, as well as in adult and fetal humans. Every 40th section (20 u in thickness) from coronal series of cerebra of Hylobates lar, Pan troglodytes and Gorilla gorilla, was photographed at the Max-Planck Inst. fur Hirnforschung (Frankfurt; Dr. H. Stephan's collection). The sections were digitized and five anatomical regions were delineated using allo- and neocortical landmarks, including the corpus callosum, hippocampus, amygdala, diencephalic nuclei and the parieto-occipital/calcarine sulci intersection, as landmarks. Regional volumes were obtained using the CARP system (fostered by DJW), SPSSx, and data transformation programs (written by M.C.deL) to interface between CARP and SPSSx.

Preliminary results suggest that patterns of asymmetry vary considerably among the hominoids. In the chimpanzee, all of the regions exclusive of the parietal association cortex (which was larger on the right side), manifested asymmetries favoring the left side. In the gorilla, the data suggest an alternate pattern of assymmetries with prerolandic cortex favoring the right side, and, conversely postrolandic cortex biased towards the left hemisphere. However, both of the pongid patterns of asymmetry in left/right regional volumes are different from the hominid pattern, although gorilla manifests closest approximation (similar results were obtained in an earlier study by Holloway and deLacoste, 1982). Furthermore, although Gorilla gorilla is one of the most sexually dimorphic pongids in terms of body and brain size, an initial analysis of the data indicates that there are only minor sex differences in gorilla prosencephalic asymmetries. While these results are only tentative, since the male brain used in this study was that of a juvenile gorilla, they are tantalizing because close relatives of the gorilla, Homo sapiens, exhibit significant sex diffferences in regional right/left hemispheric volumes.

In brief, our preliminary results suggest that in the course of evolution there may have been selective pressures on the hominid line for sex differences in cerebral asymmetry.

254.14 RIGHT/LEFT PROSENCEPHALIC ASYMMETRIES IN LEMURIDAE. M.C.de Lacoste & D.J.Woodward, Cell Bio. UTHSC, Dallas, TX 75235

Ongoing research has demonstrated that hominoid brains manifest significant regional volumetric asymmetries. In this study we computed right/left regional volumes in various Lemuridae to determine if prosimians also exhibit prosencephalic asymmmetries. Every 20th coronal section (10-20 u in thickness) of cerebra from Microcebus murinus (N=6), Cheirogaleus major (N=2), Cheirogaleus medius (N=2), Lemur albifrons fulvus (N=2), Lemur mongoz (N=1) and Lepilemur ruficaudatus (N=3) was photographed at the Max-Planck Inst. fur Hirnforschung (Frankfurt). The body and brain weights of these species respectively range from 54 to 1,400g and 1.64 to 23.3g. The sections were digitized and prosencephalic regions were demarcated on the basis of species-specific anatomical landmarks. Regional volumes were obtained by using the CARP system (fostered by DJW), SPSSX, and data transformation programs (written by M.C. de L) to interface between CARP and SPSSX.

Preliminary results have been obtained on Microcebus murinus, a noctural lemur of Madagascar. Microcebus has the most primitive brain amongst extant lemurs, with a more developed olfactory bulb and a less conspicuous frontal association cortex than that found in other lemuroid genera; but, nonetheless with a triradiate calcarine complex, deep Sylvian fissure, distinct temporal pole and parietal association cortex. Landmarks used to demarcate regions in this species included the rhinal sulcus of the archicortex, the genu of the corpus callosum, and the only two sulci of the neopallium -- the Sylvian fissure and the calcarine complex.

Accordingly, the data indicate that although visually the Microcebus brain appears far more symmetrical than that of its hominoid relatives, only the regions encompassing primary motor, somatic sensory and auditory cortex are quantitatively symmetrical (diff R/L=.09%). Data on secondary somatic sensory areas were not uniform. However, the region approximating Brodmann's areas 6 and 8 was consitently asymmetrical, albeit not always in the same direction. Furthermore, striate and peristriate areas, as defined by the retrocalcarine sulcus, exhibited pronounced asymmetry (in some cases up to 13%). In addition, it was found that the Sylvian fissure was higher on the R-side in 75% of the cases, a finding which has not yet been described in non-anthropoid primates.

In sum, evidence of hemispheric differences in prosimians with sparse association cortex suggest that anatomical asymmetries play a role early in primate brain evolution. Supported by NSF BNS 8316764 (MC de L) & Biological Humanics (DJW).

254.15 COMPLEMENTARY HEMISPHERIC SUPERIORITIES IN MONKEYS.
C. R. Hamilton and B. A. Vermeire.
Division of Biology, Caltech, Pasadena, CA 91125.

We have shown previously that rhesus monkeys have 1) a left hemispheric (LH) superiority for learning to discriminate lines of different slopes (Behav. Bran Res. 1983, **10**, 399-403) and 2) a right hemispheric (RH) superiority for learning, remembering, or generalizing discriminations of facial features of monkeys (Soc. Neurosci. Abstr. 1983, **9**, 651). We have now confirmed and extended these findings with additional subjects and tasks, and have shown that differential superiorities for spatial and facial processing exist within the same monkey.

Spatial Discriminations. A significant ($p > 0.01$) LH advantage was found for 19 split-brain monkeys when each hemisphere was taught four discriminations between pairs of lines tilted by 15°. A LH advantage was also found for learning four other visuospatial discriminations although only one of these was significant. When the results from these five visuospatial tasks were pooled for each subject the LH superiority was highly significant ($p < 0.001$). The direction of this asymmetry is opposite to that usually reported for human subjects.

Facial Discriminations. A significant RH superiority was found for 25 split-brain monkeys that differentiated photographs of monkeys' faces in eight different discriminations. The hemispheric asymmetry was evident in learning ($p < 0.02$), remembering ($p < 0.01$), and generalizing ($p < 0.02$) the discriminations. The asymmetry was largest on the measure of retention, which was made about five months after the original learning. Overall, female monkeys showed greater hemispheric differences than males. The direction of the hemispheric asymmetry is the same as that usually reported for human subjects.

Complementary Specialization. Twelve of the subjects learned both the spatial and facial discriminations which allowed a direct comparison of hemispheric differences within each of these subjects. Eight of these monkeys showed a clear-cut reversal of hemispheric dominance for the two types of tasks. Eleven of the 12 showed relative differences in the expected direction for the two tasks (spatial dominance-facial dominance); the mean of these differences was highly significant ($p < 0.001$).

These results indicate that human-like hemispheric superiorities evolved before the development of language. The popular description of hemispheric specialization in human beings as "analytic vs holistic" may not be directly applicable to monkeys because the two "holistic" tasks we tested appear to be lateralized to opposite sides of the brain.

## NEURAL BASIS OF BEHAVIOR: INTERHEMISPHERIC RELATIONS II

255.1 HISTOLOGICAL PARAMETERS IN CEREBRAL ARCHITECTONIC ASYMMETRY IN THE RAT. G.D. Rosen, F. Aboitiz*, G.F. Sherman, and A.M. Galaburda. Neurological Unit, Beth Israel Hospital and Harvard Med. School, Boston, MA 02215.

In the rat, the primary visual cortex (area 17) has been shown to exhibit absolute volume asymmetries (Sherman and Galaburda, Soc. Neurosci. Abs., 8:627, 1982). These asymmetries may be the result of side differences in cell-packing density (governed by cell size and interneuronal elements), or in total cell numbers, or both. The present experiment was designed to distinguish among these possibilities.

Nineteen (9 male and 10 female) adult Purdue-Wistar rats were perfused transcardially with formalin and their brains embedded in celloidin, sectioned coronally at 30μ, and every tenth section stained for Nissl substance. Parcellation of the entire neocortex and of area 17 of both hemispheres was performed under light microscopy. The parcellations were projected with a distortion-free projection apparatus, traced, and the volumes determined using an electronic planimeter. Cell-counts within area 17 were carried out at a 500X magnification using a rectangular reticule. For each animal, cell counts were performed on three slides (sampling from the rostral-caudal extent of the area). On each slide, neurons were counted in each of layers II-VI in two adjacent fields in both the right and left hemispheres. Thus, for each animal, 60 fields were counted. All measures were performed blind with respect to hemisphere and sex. The asymmetry coefficient (AC) was derived using the formula: $AC=(R-L)/0.5(R+L)$.

There were no sex differences, so the data were collapsed over this variable. There were significant absolute asymmetries in total cortical volume ($AC=0.016$, $t=5.83$, $df=18$, $p < 0.001$), in the volume of area 17 ($AC=0.074$, $t=5.39$, $df=18$, $p<0.001$), and in cell-packing density ($AC=0.043$, $t=9.05$, $df=18$, $p<0.001$) although there was no intercorrelation among these measures. Because there was no correlation between asymmetry in cell-packing density and area 17 volume asymmetry, it is concluded that interhemispheric differences in cell numbers, and not packing density, account for the asymmetry in the volume of area 17. Also, since total neocortical asymmetry does not predict for asymmetry in a given architectonic area such as 17, statements about structure/function relationships are not warranted from gross anatomical asymmetry data. In addition, a significant negative correlation was found between the total volume of area 17 (i.e., R+L) and the absolute volumetric asymmetry of that area ($r=-0.489$, $n=19$, $p<0.05$). Thus, brains with a smaller area 17 are more asymmetrical in that area.

We will discuss possible developmental mechanisms for anatomical asymmetry, as suggested by these results. (Supported by NIH grants 14018 and 19819).

255.2 EFFECTS OF INFANTILE HANDLING AND UNILATERAL CORTICAL LESIONS UPON SPATIAL PREFERENCE AND MAZE LEARNING IN THE RAT. A.S. Berrebi, D.A. Yutzey, S.H. Freter*, T.F. Pianta*, and V.H. Denenberg. Depts. of Biobehavioral Sciences & Psychology, Univ. of Conn., Storrs, CT 06268.

Previous research using unilateral neocortical lesions found that different behavioral responses can be obtained from rats with left (L) or right (R) cortical lesions, suggesting an underlying asymmetry in cerebral organization. Denenberg and his colleagues have also shown that extra stimulation in infancy (handling) can serve to modify the behavioral organization of the rat, often resulting in the enhancement of behavioral asymmetry (Beh. Br. Sci., 4: 1981). Additionally, Sherman et al. (Br. Res., 192: 1980) found that a left lesion (L) had greater influence upon directional preference than did a right lesion (R) in standard laboratory rats. This experiment examined the hemispheric laterality of the female Purdue-Wistar rat in a water maze of the Lashley III type.

Rats were handled or not handled during the first 20 days of life. When adult, all animals were given a unilateral decortication (L or R) or a sham lesion. They were given ample recovery time before testing began. A scaled drawing of the Lashley III maze was used to record the path taken by each animal, thereby allowing for the assessment of total, initial, and directional errors made in each of 19 trials. We only report initial and directional errors here.

While all lesioned animals made more errors in the direction ipsilateral to their lesions, L animals did so significantly more than R animals, indicating an underlying cerebral asymmetry and implicating the right hemisphere as the primary mediator of spatial preference in the rat. Furthermore, the difference in the strength of the spatial bias between L and R animals was greater in the handled animals than in the nonhandled animals throughout the test sessions.

Analyses of the learning curves found that rats with an intact right hemisphere had smoother and less variable learning curves than those with an intact left hemisphere. Also, those with the right hemisphere intact had sharper separation between their right and left directional errors than did those with an intact left hemisphere. Finally, infantile handling experience was found to interact with site of lesion.

255.3 HEMISPHERIC ASYMMETRY AND INTERACTION FOR RAT PAW USE. F. Szeligo, N. Clarke, E. Stillwell, N. deVries, and H. Wishart. Psyc. Dept., Univ. of New Brunswick, Fredericton, N.B., Canada E3B 6E4

Individual, non-human animals demonstrate strong preferences for left or right, but not the type of cross-population preferences seen for humans. The explanation seemed to be the specialization and lateralization of the human brain. However, evidence accumulates for anatomical, biochemical and functional dichotomization of animal hemispheres, without corresponding demonstration of behavioural lateralization.

The population of rats in the present study depicts the usual situation. In an unselected series, there were equivalent numbers of rats with left and right paw preferences (lp and rp, respectively). Further, the majority of these rats never made a 'normal' reach with the non-preferred paw (npp) during the period of testing reported. Given the strength of preference and the presumed presence of neural asymmetry, the equivalence of group preferences seems paradoxical. An entry into the resolution of this paradox, however, seems to be present.

Food deprived rats reached into narrow slots for pellets (Castro, A.J. Brain Res. 37: 173-185, 1972) during 10, 10 second trials/day for 10 days. Then some received damage to the anterior callosum and an additional 5 days of training.

On a 'normal' reach the rat's snout enters a slot and the preferred paw (pp) comes into the same slot; if the rat is to use its npp, the pp will retract and they will alternate reaching into the slot. Based on this type of reach there were 28 rp rats and 29 lp rats. On relatively rare occasions (although in some rats it approaches 1:1), the npp will reach simultaneously with the pp and enter a slot next to the slot occupied by the pp and head (-h). The rat, having asymmetrically oriented for a pp reach, has simultaneously maneuvered the npp into a position that leads to an off-target reach. The -h reach is usually without reward. This -h reaching was present in 15/28 rp and 6/29 lp rats. The proportions are significantly different ($Z = 2.54$, $p < .02$). Following damage to the callosum 2/15 rp rats increased the amount of -h reaching (only 3 produced any); 8/16 lp rats increased the amount of -h reaching ($Z = 2.18$, $p < .03$). More dramatically, 1/16 rp rats went from 0 to some -h; 6/14 lp rats went from 0 to some -h.

The pattern of results suggests that the consequences of neural asymmetry are evident, but only in ancillary behaviour. The pattern further suggests that the source of -h reading is the left hemisphere. The presence of -h reaching seems to represent a lower threshold in the left hemisphere for the production of behaviour such that it is produced even when conditions of environment and rat are not appropriate.

255.4 DIFFERENTIAL DISTRIBUTION OF H-2 HAPLOTYPES IN LINES OF MICE SELECTIVELY BRED FOR DEGREE OF LATERALIZATION. R. L. Collins, G. A. Carlson* and J. H. Nadeau*. Jackson Laboratory, Bar Harbor, ME 04609.

Eleven generations of bidirectional selective breeding produced two lines of mice differing markedly in degree of lateralization for hand preference (Collins, in S. D. Glick (Ed.), Cerebral Lateralization in Nonhuman Species, Academic Press, 41-70, 1985). Geschwind reported that immune disorders were clustered in left-handers, proposed this association was mediated by fetal androgen, and suggested that MHC genes controlling immune responsiveness also regulate the testosterone effect (Geschwind and Behan, PNAS 79: 5097-5100, 1982). The H-2 complex in mouse is the MHC homolog of HLA in man. If differences of lateralization are influenced by genes within or near the H-2 complex, we should expect that H-2 haplotypes will be differentially distributed between HI and LO lines of mice. Preliminary evidence confirms this pattern.

The foundation population was derived from 8 progenitor stocks: C57BL/6J, BALB/cJ, DBA/2J, LP/J, SM/J, RF/J, M. molossinus and M. castaneus. Of these, 6 differ in H-2 haplotype. Selection was stopped at G12, and lines were maintained by random mating since. Parental pairs of G24 HI and LO lines were typed for H-2 using a modified Terasaki microcytotoxicity procedure. H-2 haplotypes were distributed as follows:

| | b | d | k | wc | wm | v |
|---|---|---|---|---|---|---|
| GO | .285 | .240 | .128 | .128 | .086 | .131 |
| HI | 0 | .471 | 0 | .132 | .25 | .147 |
| LO | .546 | .030 | 0 | .01 | .172 | .242 |

Haplotypes b and d are differentially distributed in HI and LO lines, and k is absent from both. This pattern could arise by pleiotropy, by genetic linkage of target and H-2 loci, or by chance. The elimination of neutral genes by stochastic losses in finite populations with effective population size Ne = 48 would take longer on average than that observed; for b, 96 generations; for d, 86; for k, 58 (p. 431 of Crow and Kimura, An Introduction to Population Genetic Theory, Harper & Row, New York, 1970). The distribution of genetic variants of loci located elsewhere were obtained in the same mice: Aco-1 (Chr 4), Idh-1(1), Es-3(11), Gpi-1(7), Pep-3(1), Pgm-1(5), Es-10(14), and Hbb(7). Allelic frequencies for these loci did not exhibit the mirror-image pattern shown by H-2 haplotypes. Thus, the differential distribution of H-2 haplotypes between selected lines appears to be nonrandom. This suggests either that the H-2 complex itself exerts a pleiotropic influence on degree of lateralization, or that genes affecting lateralization reside at loci located near the H-2 complex on Chromosome 17. (Supported by GM 23618, GM 32461, CA 28231.)

255.5 STRESS-INDUCED CHANGES IN ROTATIONAL BEHAVIOR. J. Carlson* and S.D. Glick. Dept. of Pharmacology and Toxicology, Albany Medical College, Albany, N.Y. 12208

Previously this laboratory observed differences in cocaine-induced rotational behavior between left and right biased rats (S.D. Glick et al., Science, 221:775, 1983). Right-rotating female rats rotated much more than did left rotators while left rotating males rotated much more than right rotators. No sex or bias dependent differences were seen on rotation in response to d-amphetamine. In light of previous data suggesting that stress may modify an organism's reaction to stimulant drugs (A.J. MacLennan et al., Science, 219:1091, 1983) and other data (A.M. Thierry et al., Nature, 263:242:1976; N.E. Goeders and J.E. Smith, Science, 263:773, 1983) suggesting that stress and cocaine may influence similar neuronal systems (i.e., mesocortical dopamine), experiments were undertaken to examine alterations in rotational behavior to d-amphetamine in rats exposed to controllable or uncontrollable stress. Following an assessment of d-amphetamine induced rotational behavior (1.56 mg/kg males; 1.25 mg/kg females), male and female rats were exposed six days later to a series of 80 1 mA footshocks which were escapable with an appropriate response (controllable stress) or identical in duration and inescapable (uncontrollable stress). On the following day, each rat's rotational behavior in response to d-amphetamine was again tested as done previously. Analysis of rotational behavior, as indicated by directional preference before and after stress, revealed that, when compared to non-stressed controls, the rotational behavior of stressed animals was altered in a manner that was dependent upon pre-stress directional bias. Right rotating males showed a stress-dependent reduction in right preference with left rotating males being unaffected, and left rotating females showed a similar reduction with right rotators being unaffected. In addition, differences were noted in animals exposed to uncontrollable as opposed to controllable stress, suggesting that the opportunity to control the stress is an important variable in effecting these changes. These findings suggest that stress and cocaine share some commonality in producing lateralized changes in the CNS, that the ability to cope with stress is important in determining the magnitude of this change, and that individual differences in reactivity to stress may be determined in part by lateralized differences in CNS function (Supported by NIDA grant DA 03817).

255.6 RIGHT>LEFT ASYMMETRY IN D-2 BINDING IN FEMALE RAT STRIATUM K.L. Drew*, R.A. Lyon*, M. Titeler, and S.D. Glick. (SPON: F.L. Rice) Department of Pharmacology and Toxicology, Albany Medical College, Albany, New York 12208

Normal rats are known to rotate (turn in circles) in response to drugs (e.g., d-amphetamine) during the day and without drugs at night. Asymmetries in striatal dopamine and dopamine metabolites have been related to the directions of female rats' turning preferences. Schneider et al.(1) reported 23% more $^3$H-spiroperidol (D-2) binding in the left than in the right striatum in male rats. No behavioral data were available, however, so it was unclear if the left-right difference was, or was not, related to any functional asymmetry. The present study was conducted to determine if a left-right asymmetry in D-2 binding also occurs in female rats, and if such an asymmetry is related to individual rotational preferences.

Female rats (N=22) were tested in rotometers at night during the active portion of their diurnal cycle. Left and right striata were dissected, frozen on dry ice and stored at -70$^{o}$C. In order to quantitate the receptor densities (Bmax), independent Scatchard analyses were performed on each striatum using $^3$H-N-Methyl Spiperone ($^3$H-NMSP) for total binding and sulpiride to define non-specific binding. Six concentrations of $^3$H-NMSP were used ranging from $10^{-11}$ M to $10^{-9}$M. The final tissue concentration was 0.75 mg/ml and protein determinations were done by the method of Lowry. Kd and Bmax values were calculated using the radioligand binding program EBDA (2).

D-2 receptor densities were significantly greater in the right striatum than in the left striatum while no difference in Kd values was found. There was no relationship between rotational direction and Bmax asymmetry.

| | R | L | |
|---|---|---|---|
| Bmax(fM/mg) | 180 | 140 | p<.02 (paired t-test) |
| Kd($\times 10^{-11}$) | 11 | 10 | N.S. |

The asymmetry reported here for female rats is greater in magnitude and opposite in direction to that previously reported for male rats(1). Although the functional significance of this D-2 asymmetry is as yet unknown, such an asymmetry needs to be considered when evaluating changes after drugs or lesions. (supported by NIDA grant DA 03817 and BRSG grant SO7RR05394-23).

255.7 Differential effect of cortical versus subcortical noradrenergic lesions on lateralized spontaneous hyperactivity. Kenneth M. Saad[1,2]*, Catherine Mikat*, Timothy H. Moran[1], Robert G. Robinson[1,2]. [1]Dept. of Psychiatry and Behavioral Sciences, and the [2]Dept. of Neuroscience, The Johns Hopkins University School of Medicine.

Previous studies have demonstrated that noradrenergic lesions produced by as little as 1 ug of 6-hydroxydopamine injected into the right frontal lateral cortex of the rat will produce spontaneous hyperactivity while symmetrical lesions of the left hemisphere will not (Robinson & Stitt, Brain Res. 213:387, 1981). The present study assessed whether unilateral lesions of the subcortical noradrenergic dorsal bundle would also produce lateralized hyperactivity.

Male rats were given unilateral lesions of the noradrenergic dorsal bundle at 6.2 mm posterior to bregma 1.1 mm lateral to the midline and 6.2 mm from surface using either electrolytic (1 ma for 3.5 sec.) or 6-hydroxydopamine (6-OHDA) (2 or 4 ug in 1 ul solution injected at 0.33 ul/min). Seven days preoperatively and 30 day intervals by postoperatively spontaneous activity was measured at 24 hour running wheel revolutions or alternatively at once per week intervals over the 12 hour dark cycle open field activity was measured (total distance travelled) in computerized chambers with infrared detectors (Omnitech Electronics, Columbus, Ohio). There were no significant differences in spontaneous activity using photocell chambers or running wheels between right or left lesion animals with either electrolytic or 6-hydroxydopamine lesions. The lesion animals, however, were significantly more active than controls ($F_{1,23} = 4.76$ $p < .05$ electrolytic $F_{1,23} =$ , $p < .05$ 4 ug 6-OHDA). Biochemical measurement of norepinephrine concentrations following electrolytic lesions demonstrated significant ipsilateral depletions of norepinephrine in the frontal and posterior cortex ($F_{2,42} = 5.9$ $p < .01$ frontal; $F_{2,42} = 5.4$ $p < .01$ posterior). There was a significant increase in ipsilateral vs.contralateral NE concentrations in the locus coeruleus ($F_{2,42} = 4.5$ $p < .05$). The biochemical results of the 6-OHDA lesions are in process and will be presented at the meeting. These findings indicate that unilateral noradrenergic lesions of the dorsal bundle produce symmetrical effects on spontaneous activity. This is in contrast to the effect of cortical noradrenergic lesions. Thus, subcortical noradrenergic lesions may have different physiological effects on the cortex than cortical noradrenergic lesions. These data might also suggest that left hemisphere cortical injury may produce an inhibitory effect on activity.

255.8 INTERHEMISPHERIC COORDINATION OF BIRD SONG. H. Williams* (SPON: J.A. Paton). Rockefeller University, Millbrook, NY 12545.

In song birds, vocalization is controlled by a chain of telencephalic nuclei, NIf → HVc → RA; RA projects to the motor neurons innervating the vocal organ, the syrinx, which provides two independent sound sources (Nottebohm et al., JCN, 207:344, 1982). Each half of the syrinx is innervated by the ipsilateral NXIIts (tracheosyringeal nerve). Cutting one nerve or lesioning one HVc grossly distorts certain syllables or notes while leaving the remainder of the song intact (177:229, 1971; Nottebohm et al., JCN, 165:457, 1976). Single-pulse microstimulation of either HVc elicits a volley only in the ipsilateral NXIIts (Paton and Manogue, JCN, 212:329, 1982). These results strongly suggest that each hemisphere independently controls a certain portion of the bird's song (Nottebohm & Nottebohm, J. Comp. Physiol., 108:171, 1976). Yet the notes and syllables which make up bird song are delivered with exquisitely coordinated timing.

One possible mechanism for interhemispheric coordination would be contralateral projections to the forebrain song nuclei, perhaps via the anterior commissure (birds do not have a corpus callosum). However, HRP injections into RA, HVc, and NIf failed to backfill any neurons in the contralateral half of the brain.

The two known non-auditory inputs to NIf, HVc and RA are MAN and uva. Microstimulation of MAN, a magnocellular nucleus of the anterior forebrain, evokes responses only in the ipsilateral HVc and RA. Therefore, MAN cannot play a role in interhemispheric communication. Uva is a small thalamic nucleus projecting to the ipsilateral NIf and HVc and the contralateral uva, and receiving inputs from laryngeal motor neurons (Nottebohm et al., JCN, 207: 344, 1982). Microstimulation of uva elicits firing in the ipsilateral HVc, followed by a volley in the ipsilateral NXIIts. The conduction times are appropriate for an uva → NIf → HVc → RA → NXIIts pathway. Stimulating uva also evokes a response in the contralateral HVc and NXIIts, with latencies 3-5 ms longer than those recorded ipsilaterally. The difference in latency suggests that firing in uva excites the cells in the contralateral uva, in turn exciting cells in the nuclei of the contralateral song system. This hypothesis was confirmed by the finding that, after the contralateral uva was lesioned, uva stimulation elicited responses only in the ipsilateral HVc and NXIIts.

Thus, uva seems to provide the only direct non-auditory bilateral input to the song system. If the projection to uva from the laryngeal motor neurons carries information on the state of the air passage in the larynx, the inputs to HVc and NIf from the linked uvas would allow the song control nuclei in each hemisphere to synchronize their activity with the pattern of airflow in the vocal tract - thus coordinating the patterns of syringeal muscle contraction and breath control to yield complex but ordered song.

255.9 INTERHEMISPHERIC TRANSFER OF VISUAL DISCRIMINATION IN PIGEONS WITH UNILATERAL THALAMIC LESION. T.Shimizu,S. Watanabe,W.Hodos and B.Bessette. Dept. of Psychology, Univ. Maryland,College Park,MD 20742.

Interhemispheric transfer of monocularly learned discrimination was studied in pigeons with unilateral thalamic lesion. The pigeon has two visual systems,i.e., the thalamo-fugal pathway and the tecto-fugal pathway. At the level of thalamus,OPT is a relay in the former pathway and nucleus rotundus is a relay in the latter pathway. Selective lesion of these two structures was made after monocular learning and interocular transfer of the learning was examined.

METHOD

The experimental chamber was an operant chamber with two pecking keys on which discriminative stimuli were displayed by a carousel projector. Two groups of pigeons were monocularly trained on intensity,color and pattern discriminations. Following completion of discrimination training,unilateral electrolytic lesion of OPT or nucleus rotundus was made stereotactically. One group received the lesion in the trained hemisphere(contralateral to the trained eye),and the other group received the lesion in the untrained hemisphere. After 7 days of postoperative recovery period,both groups were retrained on the same task with the previously untrained eye to examine the interhemispheric transfer of learning. After behavioral experiment,the brains of the birds were histologically examined under the microscope to reconstruct the lesions. The birds without any damage in the visual system were used as control animal.

RESULTS

The OPT lesion,in either hemisphere,had no effect on interhemsipheric transfer,whereas,the lesion of the nucleus rotundus in the trained hemisphere produced a deficit in transfer. The rotundal lesion in the untrained hemisphere also yielded a deficit in transfer.

CONCLUSION

These results suggest 1) the tecto-fugal pathway has a cruicial role in interhemispheic transfer of visual discrimination in pigeons,and 2) formation of unilateral memory storage by monocular learning.

256.1 ADRENERGIC ANTAGONISTS: ATTENUATION OF MEMORY FACILITATION. D.B. Sternberg and J.L. McGaugh. Center for the Neurobiology of Learning and Memory and the Department of Psychobiology, University of California, Irvine, CA 92717.

Previous research indicates that, retention of many types of training tasks is enhanced by post-training administration of epinephrine and that the memory-enhancing effect of epinephrine is blocked by propranolol, a β-adrenergic antagonist, administered prior to training. The present study examined the effect of several α- and β-adrenergic antagonists administered prior to training to determine whether the effects of post-training administration are selectively attenuated by β-adrenergic antagonists.

Male Charles River Sprague-Dawley rats (60-90 days old) were trained in a one-trial inhibitory (passive) avoidance task. Animals were water-deprived and maintained at 85-90% of their original weights. Animals received a total of five pre-training sessions over a three day period. Animals were pre-trained to go to the dark end of the training apparatus to drink water. On the training day, thirty minutes prior to training, animals received an i.p. injection of either an α1-adrenergic antagonist, prazosin, α2-adrenergic antagonist, yohimbine, α1- and α2-adrenergic antagonist, phentolamine, a β1-adrenergic antagonist, atenolol, β2-adrenergic antagonist, zinterol, β1- and β2-adrenergic antagonist, propranolol, or the α1- and α2, β1- and β2-adrenergic antagonist medraxolol or saline. During training, the animals received relatively low footshock (350 μA, 0.7 sec) after drinking for 10 secs. Immediately following training the animals received a s.c. injection of epinephrine or saline. Twenty-four hours later, the animals were tested for retention by measuring their latency to lick. The retention performance of animals given pre-training saline injections and post-training epinephrine injections was significantly higher than that of saline control animals. Animals which received pre-training injections of any of the adrenergic blocking agents and post-training epinephrine or saline had retention scores comparable to those of the saline controls.

These findings indicate that the retention enhancing effects of post-training epinephrine are blocked by a wide variety of α- and β-antagonists.

256.2 THE INVOLVEMENT OF CALCIUM, GLUTAMATE, AND PROTEIN SYNTHESIS IN SHORT- AND LONG-TERM WORKING MEMORIES OF THE RAT. S. J. Y. Mizumori, V. Channon*, M. R. Rosenzweig, and E. L. Bennett. Department of Psychology, Univ. of Calif., Berkeley CA 94720.

Previous experiments suggest working memory of rats trained in a radial maze can be discussed in terms of short- and long-term temporal components. Long-term working memory (LTWM) was found to be susceptible to disruption by the protein synthesis inhibitor, anisomycin (Mizumori et al., Behav. Neurosci., 99: 220, 1985). Experiment 1 of this study examined the neuropharmacological nature of the short-term component to working memory (STWM). Experiment 2 addressed the issue of whether LTWM in a radial maze involves protein synthesis either because items are to be remembered over a relatively long period of time, or because the radial maze is a relatively complex task requiring storage of large amounts of information.

For Experiment 1, rats were trained to criterion on a 12-arm radial maze with 240-min delays imposed between choices 6 and 7. On test days, one of the following drugs was injected into ventral hippocampus (via chronic indwelling cannulae) 30 min before choice 1: saline (SAL), 40 mM $LaCl_3$ (a calcium uptake inhibitor), 1 M glutamate (GLU), or 302 mM anisomycin (ANI). Rats were tested after 0-, 2-, 8-, or 15-min delays. Both $LaCl_3$ and GLU injections resulted im impaired choice accuracy, regardless of the length of the delay interval ($p < .05$). ANI injection did not affect performance when 0- or 2-min delays were used; significant impairment was found following 8- or 15-min delays. Together, these data support the hypothesis that working memory involves at least two temporal components--the short-term component may involve changes in calcium uptake and the glutaminergic system, while the long-term component involves protein synthesis.

If ANI impaired LTWM in the radial maze because proteins were important for holding information over relatively long periods of time, then ANI should also impair LTWM in a simpler 2-choice spatial task--delayed alternation (DA). On the other hand, if protein synthesis was necessary because the radial maze is a complex task, then ANI might not impair choice accuracy after long delays for rats trained in the DA task. Experiment 2 showed that ANI impaired working memory in a DA task, but only when delay intervals of 8-min or longer were used. ANI had no effect on memory following 2-min delays. Thus, the temporal course of development of ANI-induced amnesia was the same for both radial maze and DA tasks. This suggests protein synthesis is important for working memory when items are to be remembered for a relatively long period of time, and may be less related to the number of items to be remembered.

256.3 THE INVOLVEMENT OF CALCIUM, GLUTAMATE, AND PROTEIN SYNTHESIS IN AVOIDANCE LEARNING IN MICE. D. H. Sakai*, S. J. Y. Mizumori, M. R. Rosenzweig, and E. L. Bennett. Department of Psychology, Univ. of Calif., Berkeley, CA 94720.

Results of different approaches to the study of the chemical basis of learning (e.g., invertebrate models, long-term synaptic enhancement [LTE], and avian conditioning) suggest that behavioral learning may involve changes in calcium regulation and the glutaminergic system. However, systematic analysis of the role of these chemical systems in mammalian behavioral learning has not been done. Here we tested the effects of agonists and antagonists to the calcium and glutamate systems on mouse avoidance learning. Furthermore, attempts were made to prevent amnesia by simultaneous injection of calcium or glutamate agonists and antagonists. Finally, an assessment of the behavioral effects of anisomycin (ANI--a protein synthesis inhibitor) was included for comparison, since based on earlier reports, ANI is known to impair memory for avoidance learning in mammals.

One of the following agents was injected into dorsal hippocampus of mice 45 min before one-way active avoidance training: saline (SAL), $LaCl_3$ (a calcium uptake inhibitor), γ D-glutamylglycine (γDGG--a glutamate receptor antagonist), $CaCl_2$, glutamate (GLU), ANI, or a combination of $LaCl_3$ + $CaCl_2$ or GLU ∓ γDGG. Retention tests were conducted 2 days after training.

Both $LaCl_3$ (40 mM) and GLU (1 M) produced significant amnesia. Test scores of mice injected with $CaCl_2$ (20, 40, or 60 mM) or γDGG (0.1 or 0.5 mM) did not differ from SAL-injected controls. 40 mM $CaCl_2$ prevented the amnesic effect of $LaCl_3$, but 20 or 60 mM $CaCl_2$ did not. When γDGG and GLU were injected simultaneously, test scores were intermediate between those of SAL- and GLU-treated mice. It appears that γDGG, in the doses employed, only partially prevented GLU-induced amnesia. ANI (604 mM) treatment rendered mice amnesic at test.

The behavioral effects of $LaCl_3$, ANI, and $CaCl_2$ were in accord with conclusions drawn from experiments on Aplysia, LTE or avian conditioning. Results of GLU or γDGG injections support the findings of avian conditioning experiments but not LTE experiments. Possible interpretations of this discrepancy will be discussed.

256.4 GLYCOGENOLYSIS AS A MODULATOR OF MEMORY STORAGE. J.L. Hall*and P.E. Gold. Dept. Psychology, University of Virginia, Charlottesville, VA 22901.

Peripheral epinephrine (EPI), released from the adrenal medulla, is a major component of those systems which regulate the storage of new information. Posttraining injections of EPI enhance later retention performance in a variety of tasks and circulating EPI levels predict later retention performance. Furthermore, the effects of many treatments on memory are blocked in animals pretreated with peripherally administered adrenergic antagonists. The present studies evaluate the possibility that EPI effects on memory may be the result of the hormone's action on the liver to induce glycogenolysis.

Rats were trained in a one-trial passive (inhibitory) avoidance task using a relatively mild footshock (0.7 ma, 0.5 sec). Immediately after training, the animals received an injection of glucose (GLU; 0.01-10 mg/kg), EPI (0.1 mg/kg) or saline. On the test trial 24 hr later, animals which received EPI or GLU (0.1 and 1 mg/kg) had significantly higher retention scores. Injections delayed by 1 hr after training had no effect on later performance. Thus, GLU injections retroactively enhanced memory storage. In contrast to the results obtained with EPI and other memory-impairing and -enhancing treatments, pretraining injections of adrenergic antagonists, did not attenuate the effects of GLU on memory. Thus, glucose appears to represent a step in memory modulation subsequent to EPI release.

Further studies used animals with chronic tail artery catheters from which plasma samples could be taken at several times after training and drug treatment. The plasma samples were assayed for GLU using a colorimetric hexokinase procedure. The results indicated that plasma GLU levels were increased significantly above basal values for up to 30 min after footshock training. Injections of GLU or EPI at doses which enhance memory also resulted in increases in plasma GLU levels for at least 30 min.

These results suggest that the following series of events may be important in regulating memory storage for avoidance training. Footshock results in release of EPI, controlled by splanchnic afferents to the adrenal medulla and EPI, in turn, releases hepatic GLU stores which then modulate memory storage. Thus, GLU availability may regulate central neuronal changes by controlling the substrate necessary for intermediary metabolism in neurons. This conclusion is consistent with evidence that brain pyruvate dehydrogenase, an enzyme at a critical point in GLU utilization, is activated after training experiences comparable to those used here (e.g., Morgan and Routtenberg, Science, 1981, 214, 470-471).

256.5 AVERSIVE EFFECTS OF LITHIUM MAY BE MEDIATED BY NEUROHYPOPHYSEAL HORMONES. E.F. O'Connor, S.W.T.Cheng* and W.G. North.* Dept. of Physiology, Dartmouth Medical School, Hanover, NH 03755

Vasopressin (AVP) appears to facilitate memory processing and learning either directly or as a consequence of its action in arousal. Several researchers have suggested that AVP's actions on behavior and physiology should be compared with those changes induced by Lithium salts (Li), which are known aversive agents and like AVP also stimulate learning and memory. In our study we examined changes in blood pressure (MAP) and in plasma levels of AVP and oxytocin associated neurophysins (NPs) in response to intra peritoneal injection of lithium chloride at 3.0 and 1.5 mEq/kg Bwt., doses which are used in behavioral studies and which approximate therapeutic levels. Control animals received .9% NaCl in an equivalent volume (.1ml/100g Bwt.). Blood pressure increases were induced by both doses of LiCl but not after saline. Both doses of LiCl also significantly increased plasma osmolality ($p<.05$), plasma Li($p<.001$), and plasma concentration of both AVP- and OT- associated neurophysins ($p<.001$).

Increases in AVP-NP were correlated with pOsm ($r=.75, p<.05$) and pLi ($r=.88, p<.001$). Comparisons of the two neurophysins suggests that in the first 10 minutes after injectin, plasma OT-NP levels increases rapidly and at 20 minutes begin to decline. In contrast, AVP-NP levels increase more slowly but continue to increase steadily for at least 60 minutes following bolus injection of LiCl. Since NPs provide an index of the function of AVP and OT neurons our results suggest that vasopressin and oxytocin are released in response to i.p. LiCl. Thus AVP and OT or their metabolites may be important in the mediatino of LiCl aversive effects or conversely, that the release of these hormones may directly mediate Li effects on learning.

256.6 EFFECTS OF PRE- VS. POST-TRAINING INJECTION OF ANISOMYCIN ON MEMORY FOR A NOVEL ACTIVE AVOIDANCE TASK. S. Benloucif, M.R. Rosenzweig, E.L. Bennett. Dept. of Psychology, Univ. of California, Berkeley, CA 94720.

Experiments with the protein synthesis inhibitor anisomycin (ANI) in this novel active avoidance task indicate greater effectiveness of ANI when administered after training than prior to training. Other tasks have consistently shown a greater effect with pre-training injections. This work examines the effect of the injection procedure on ANI induced amnesia in a Wall Jump (WJ) task.

The WJ is a 10 X 32 X 21 cm plexiglas box with a dividing door and floor shock grid. The 3 escape compartment walls are lined with wire mesh. Charles River male CD1 mice (50 to 90 days) received 3 training and 10 test trials. Trials consisted of 10 sec adaptation in the start compartment, then simultaneous opening of the door and start of a buzzer, followed 5 sec later by mild footshock (.30 mA). A correct response consisted of avoiding the shock by climbing onto the wire mesh. Test trials were conducted at 1, 4, or 7 days. Mice were injected with 120 mg/kg ANI subcutaneously (SC) or 160 µg ANI into the hippocampus (IC) following Metofane anesthesia. Control mice were injected with equal volumes of saline (.01 ml/gm body wt SC or .5 µl per hemisphere IC). The mean number of avoidances at test was compared by analysis of variance. Results shown are significant at the .05 level or beyond.

Table of Results

| injection times pre | post | injection type | no. experiments showing impairment |
|---|---|---|---|
| single injection | | | |
| 15' | | SC | 1 of 3 |
| | 15' | SC | 3 of 3 |
| 45' | | IC | 0 of 1 |
| | immed | IC | 1 of 1 |
| double injection | | | |
| 15' ANI | 15' sal | SC | 0 of 1 |
| 15' sal | 15' ANI | SC | 0 of 1 |

A single post-training injection of ANI, either SC or IC, consistently impaired performance at test (4 of 4 expts.). A single pre-training injection impaired performance in only 1 of 4 expts. The series of double injections (to date incomplete) supports the hypothesis of an interaction of injection procedure and amnesic effect of ANI. Two possible explanations for the results are these: (1) Giving injections prior to training may impair acquisition in this task, obscuring an effect of ANI. (2) An injection given after training may increase the efficacy of ANI, causing amnesia for this task. Further work will test the two hypotheses.

256.7 FAILURE OF NOOTROPICS TO MODULATE SEPTOHIPPOCAMPAL NEURONS IN THE RAT. M.F.Piercey and G.D.Vogelsang, CNS Research, The Upjohn Company, Kalamazoo, MI 49001.

High affinity choline uptake in the hippocampus has been reported to be stimulated by the nootropics piracetam (Sethy, 1983, Neurosci. Abs. 9:429) and pramiracetam (Pugsley, Poschel, Downs, Shih & Gluckman, 1983, Psychopharm. Bull. 19:721). This effect might be explained by an increase in firing rates of cholinergic neurons projecting to the hippocampus; higher firing rates would cause choline uptake to increase in response to the high demand for new synthesis of acetylcholine. Increases in firing rates of these cholinergic neurons could be responsible for the memory enhancement properties of nootropics since both acetylcholine and the hippocampus have been implicated as being important in memory function.

Using microelectrode recordings in urethane-anesthetized rats, we have now directly studied the effects of nootropics on firing rates of neurons projecting to the hippocampus from its major cholinergic input in the medial septum. Septohippocampal neurons were identified by constant short latency all-or-none responses to antidromic stimulation of the fimbria. Such cells followed the antidromic stimulus faithfully at high frequencies. Spontaneous impulses from these cells "collided" with evoked impulses, confirming that the cells were truly projecting to the hippocampus. A separate group of septal neurons was orthodromically (synaptically) excited by fimbrial stimulation. Histological recovery of dye spots left at the ends of the experiments revealed that antidromically invaded cells were located in the medial septum. Orthodromically activated cells were almost always in the lateral septum.

Piracetam and pramiracetam were tested for their effects on identified septohippocampal neurons. Although a wide variety of doses were tested and observations made over fairly long time periods, neither nootropic agent affected the firing rates of septohippocampal neurons.

The results suggest that the effects on choline uptake may be due to something other than increases in firing rates of cholinergic neurons.

256.8 OPERANT CONDITIONING OF HIPPOCAMPAL NEURONS: CHLORPROMAZINE BLOCKS REINFORCING ACTIONS OF DOPAMINE. *L. Stein and J. D. Belluzzi.* Department of Pharmacology, College of Medicine, University of California at Irvine, Irvine, CA 92717.

Although great efforts have been made to identify neurons that may deliver reward messages, the neurons or neuronal organizations that may receive such messages have been given little consideration. We have assumed that individual neurons may be organizational units whose behavior is capable of positive reinforcement. Operant conditioning of individual CA1 cellular activity in slices of hippocampus, using local applications of dopamine as reinforcement, has been reported (Belluzzi and Stein, 1983). Here we report blockade of such cellular operant conditioning by the dopamine antagonist chlorpromazine (CPZ). A single-barrelled glass micropipette for simultaneous recording and pressure injection was filled with dopamine (1 mM in 165 mM saline) and aimed at spontaneously active pyramidal cells in the CA1 layer of hippocampal slices. The neuronal response for reinforcement was a burst of relatively fast activity. To be eligible for reinforcement, such "bursts" had to contain a minimum number of spikes; this minimum number was individually established for each neuron studied so that, prior to operant conditioning, reinforceable "bursts" occurred at a rate of approximately 5 per minute. For reinforcement, the pressure injector was activated for 10-80 ms immediately after each "burst" to deliver a 10 µ-diameter droplet of drug to the cell. As shown in the Figure, neurons reinforced with dopamine exhibited significantly more "bursts" than controls reinforced with saline. When chlorpromazine (1 mM) was added to the dopamine solution (DA + CPZ), the reinforcing action of dopamine was abolished and the rate of "bursts" was suppressed below the saline control. On the other hand, neurons that received chlorpromazine alone (CPZ) exhibited the same number of "bursts" as those that had received saline. These results replicate our earlier reports of single-unit operant conditioning, and furthermore suggest that the reinforcing action of dopamine, which can be antagonized by CPZ in these experiments, is mediated at dopamine receptors.

256.9 RETARDATION OF CR ACQUISITION BY L-PIA: ANTAGONISM BY CAFFEINE AND THEOPHYLLINE. L. Winsky, J. A. Harvey and I. Gormezano, Psychology Department, The University of Iowa, Iowa City, IA 52242.

The adenosine receptor agonist $N^6$-(L-phenylisopropyl)adenosine (L-PIA) retards acquisition of the classically conditioned nictitating membrane response (NMR) of rabbits (Winsky et al., 1984, Soc. Neurosci. Abstr., 10, 793). The agonist activity of L-PIA has been associated with activation of $A_1$ adenosine receptors that produce decreases in brain levels of cAMP. This study examined the ability of the adenosine receptor antagonists caffeine and theophylline to block the effect of L-PIA on conditioned response (CR) acquisition in order to determine whether this effect of L-PIA is mediated by adenosine receptors. Rabbits received a subcutaneous injection of vehicle, caffeine (0.3 mmol/kg), or theophylline (0.2 mmol/kg) followed by vehicle or L-PIA (5.0 µmol/kg) prior to each of 10 days of acquisition training. Each daily (60 min) session consisted of 30 tone CS-shock UCS and 30 light CS-shock UCS pairings. Both caffeine and theophylline blocked the retardation produced by L-PIA as indicated by percent CRs, NMR onset latencies, and the number of trials required to attain the criteria of 10 consecutive CRs.

Caffeine and theophylline have been shown to inhibit brain phosphodiesterase in addition to blocking adenosine receptors. Thus, either or both of these actions may have produced a block of the L-PIA effect on acquisition. Since both of these effects of caffeine and theophylline would reverse the decreases in cAMP produced by L-PIA, we conclude that L-PIA retards CR acquisition by decreasing cAMP.

256.10 EFFECT OF SP AND ITS FRAGMENTS ON MONOAMINE METABOLISM AND PASSIVE AVOIDANCE RETENTION. M. Pelleymounter, Q. Fischer*, K. Schlesinger*, M. Hall* and J. Stewart. Dept. Psych., Univ. Colo., Boulder, CO 80309 and Dept. Biochem., Univ. Colo. Schl. Med., Denver, CO 80262.

Several studies have shown that substance P (SP) enhances retention of avoidance learning paradigms in rodents, whether it is administered peripherally or intracerebroventricularly (icv). Recent work has also demonstrated that SP-induced memory enhancement is accompanied by increased striatal DOPAC/DA 1 hr after administration and training and increased nigral 5HIAA/5HT as late as 24 hr after injection and training. Since both behavioral and biochemical responses to SP can be detected many hours after SP administration (and probable enzymatic degradation), it has been suggested that the effects of SP may be mediated by fragments of the peptide rather than the complete molecule. There is evidence that central injections of N- or C-terminal fragments have distinct, and often opposing, behavioral effects. We have tested the effects of icv administration of SP, its N-terminal (1-7) fragment (SP-N), and its C-terminal (<E-SP [7-11]) fragment (SP-C), on passive avoidance retention and metabolite/monoamine ratios in the medial prefrontal cortex (MPC), striatum (STR), substantia nigra (SN), and raphe nucleus (R).

Polyethylene guide cannulae were implanted into the lateral ventricles of male Swiss-Webster mice. SP (1µg), SP-N (100 ng), SP-C (1µg) or phosphate-buffered saline (PBS) was injected into the ventricles in a volume of 5µl. One hr later, one group of mice was sacrificed and MPC, STR, SN, and R were dissected from frozen brain, using the tissue punch technique of Palkovits (Brain Res., 59:449, 1973). Brain punches were homogenized in 0.1N perchloric acid. Monoamine and metabolite levels were measured with reverse phase HPLC-ECD. The remaining group of mice was trained for a passive avoidance task. These animals were placed in a brightly-lit start-box, and latency to enter a darkened area of the apparatus was measured. Upon entry into the darkened area, mice were given a 0.4 mA, 5 sec footshock. They were immediately injected (icv) with SP, its fragments or PBS at the same doses used for the biochemical tests. Twenty-four hours later, latency to enter the darkened area was again measured. Retention was defined as Day 2 - Day 1 latency.

The only difference in monoamine/metabolite ratios was found in nigral 5HIAA/5HT, where SP-N and SP-C had opposing effects, with SP-N increasing 5HIAA/5HT over both SP and SP-C. SP-C significantly decreased 5HIAA/HT in comparison to PBS. SP-N also enhanced passive avoidance retention significantly better than did SP, SP-C, or PBS. These data support the idea that SP fragments (in particular the N-terminal fragment) may mediate the biochemical changes necessary to bring about some of the central effects of SP administration, such as enhanced retention of passive avoidance behavior.

256.11 EVIDENCE FOR A FUNCTIONAL INTERACTION BETWEEN SEROTONERGIC AND CHOLINERGIC MECHANISMS IN MEMORY RETRIEVAL. S.-O. Ögren*[1], W.S. Stone[2,3] and H.J. Altman[3] (SPON: E. Schoener). [1]Astra Läkemedel AB, S-151 85 Södertälje, Sweden; [2]Dept. of Psychology, Wayne State Univ., Detroit, MI 48202; and [3]Lafayette Clinic, Detroit, MI 48207.

Recent evidence suggests that there may be an interaction between the cholinergic (ACh) and serotonergic (5-HT) nervous systems. Alaproclate (ALAP), a 5-HT reuptake inhibitor, has been shown to potentiate the tremor induced by oxotremorine (OXO), a muscarinic ACh agonist, in mice. Both neurotransmitter systems are also believed to play a significant role in the processes underlying learning and memory. Previous studies from this laboratory have shown that independent administration of OXO or ALAP can enhance retrieval of a previously learned avoidance habit when administered shortly before retention testing. The purpose of the present study was to determine if a ACh X 5-HT interaction can also be demonstrated with respect to memory. Three experiments were conducted. The behavioral task used throughout was a standard two-compartment passive-avoidance apparatus in which the mice were tested for retention of the original avoidance habit 24 hrs. later. All drugs were administered i.p. either 30 or 60 min. prior to the retention test. In Experiment 1 the dose dependent effects of ALAP and OXO were assessed relative to saline injected controls. All drugs were administered 30 min. prior to the retention test. The results reaffirmed previous observations that OXO or ALAP significantly enhance retrieval of a previously learned avoidance habit in a dose-dependent fashion. In Experiment 2 we attempted to determine whether combined administration of OXO+ALAP would also enhance memory and if so what difference, if any, might be seen in the nature of the dose response curves. The results indicated that combined OXO+ALAP does enhance memory and that the entire dose response curve shifts significantly to the left. Finally, in Experiment 3 an attempt was made to block the memory enhancement induced by either OXO, ALAP, or OXO+ALAP. Previous studies from this laboratory have shown that the memory enhancement induced by ALAP is selectively blocked by quipazine (QUIP), while that induced by OXO is blocked by scopolamine (SCOP). However, the enhancement induced by ALAP is not antagonized by SCOP, and the enhancement induced by OXO is not blocked by QUIP. Therefore, in Experiment 3 animals were treated with either ALAP, OXO OR OXO+ALAP, and were pretreated with either SCOP or QUIP. Their performance during the retention test was then assessed. The results indicate that: QUIP blocked ALAP alone but had no effect on either OXO or the OXO+ALAP combination while SCOP blocked the effects of OXO alone but had only a slight effect on the performance of the ALAP or OXO+ALAP groups of animals. The results of the present study are taken as preliminary evidence for a functional interaction between the ACh and 5-HT nervous systems in memory retrieval.

256.12 FACILITATION OF DISCRIMINATION LEARNING IN THE RAT FOLLOWING CYTOTOXIC LESIONS OF THE SEROTONERGIC NERVOUS SYSTEM. H.J. Altman[1], H.J. Normile[1]* and S-O Ögren[2]* [1]Lafayette Clinic, Detroit, MI 48207, [2]Astra Läkemedel AB, S-151 85 Södertälje, Sweden.

Recent experimental evidence suggests that serotonin (5-HT) plays an important role in the processes underlying learning and memory. These suggestions are partly based on the results of animal studies which have shown that acute elevations of 5-HT activity on or about the time of behavioral assessment impaired learning. However, a complicated relation appears to exist between 5-HT depletion and learning and/or memory. For example, depletion of 5-HT by synthesis inhibitors or by cytotoxic or electrolytic lesions has been shown to either facilitate, impair or have no effect on the performance of animals in aversively motivated tasks. Several factors are likely to be responsible for these variable results including the nature of the behavioral task (e.g. passive avoidance, one- or two-way active avoidance), the methods employed to reduce 5-HT activity (e.g. p-chlorophenylalanine, indoleamine neurotoxins, electrolytic lesions) and/or the route of administration (e.g. central, peripheral). Moreover, the effects of 5-HT depletion on the performance of animals in positively reinforced tasks has not been examined. The purpose of the present study was, therefore, to determine what effects cytotoxic lesions of the 5-HTergic nervous system might have on a rat's ability to acquire a positively reinforced complex spatial discrimination (Stone 14-Unit T-maze). Lesions were made with the cytotoxin p-chloroamphetamine (PCA) which has been shown to have a long-term neurotoxic action on 5-HT neurons. The specificity of the PCA-induced effect was assessed by pretreating PCA-injected rats with the selective 5-HT reuptake blocker norzimeldine (NZIM). Four groups of male Sprague-Dawley rats were injected (8 and 7 days prior to the onset of behavioral assessment) as follows: Group 1 = SAL + SAL; Group 2 = SAL + PCA (2 x 10 mg/kg); Group 3 = NZIM (2 x 20 mg/kg) + SAL; Group 4 = NZIM (2 x 20 mg/kg) + PCA (2 x 10 mg/kg). The first injection preceded the second by 60 min. The rats were run 1 trial/day, 5 days/week for 5 consecutive weeks in the Stone maze using sweetened condensed milk as the reward. The total number of errors each rat made per trial was recorded. In addition, the total number of trials each animal took until it ran through the maze in one or less errors on two consecutive days (trials to criterion) was recorded. The results of this study suggest that 5-HT depletion can improve the acquisition of a spatial discrimination task. Specifically, PCA-injected rats (Group 2) made significantly fewer errors over days and required significantly fewer trials to reach criterion when compared to SAL controls (Group 1). Pretreatment with NZIM completely blocked the above effects. Surprisingly, Group 3 also exhibited significantly enhanced performance in the Stone maze.

256.13 THE EFFECTS OF SEROTONERGIC RECEPTOR BLOCKADE ON LEARNING AND MEMORY IN MICE. H.J. Normile* and H.J. Altman (Spon: J. Phillis). Lafayette Clinic, Detroit, MI 48207.

Recent experimental evidence suggests that serotonin may play an important role in the way information is processed by the brain. For example, experimental manipulations that enhance serotonergic (5-HTergic) neurotransmission have consistently been shown to interfere with the performance of animals in a variety of aversively motivated learning and memory tasks. On the other hand, the effects of lesions of the 5-HTergic nervous system are difficult to interpret mainly because seemingly complimentary experimental manipulations designed to reduce 5-HTergic activity have often produced conflicting and/or inconsistent results.

Recently, a number of highly potent and apparently selective 5-HTergic antagonists have been developed. We have previously reported that pre-test administration of pirenperone enhanced the memory of a previously learned aversive habit in mice (Normile and Altman, Neurosci. Abst. 10: 255, 1984). In contrast, Bammer (Neurosci. Biobehav. Reviews, 6: 247-296, 1982) has reported that administration of cyproheptadine (but not methysergide) prior to training impaired learning in rats. The purpose the present series of experiments was, therefore, to further assess the effects of 5-HTergic receptor blockade on learning and memory by administrating a number of 5-HTergic receptor antagonists (pirenperone, ketanserine or mianserine) either (1) prior to training, (2) following training, (3) prior to testing. The behavioral task used was a modification of the standard inhibitory avoidance paradigm (the lick-suppression task) in which thirsty mice were trained to avoid drinking from a tube by pairing shock with licks (Quartermain and Altman, Physiol. Psychol. 10: 283-292, 1982). All animals were tested 48 hours later under extinction (i.e., no shock) conditions and their latencies to complete 5 seconds of drinking recorded. Both dose- and time-dependent effects were examined.

The results of the study may be summarized as follows: Administration of each of the antagonists either following training or prior to testing resulted in a significant dose- and time-dependent elevation in the latency to complete 5 seconds of drinking at the time of testing. The elevated latencies could not be attributed to non-specific effects of the drugs on behavior as non-contingently trained mice injected with the highest dose of each drug failed to exhibit an elevation in their test latencies. On the other hand, the test performance of the mice injected with these same drugs prior to training was significantly impaired in both a dose- and time-dependent fashion. These data would appear to suggest a differential involvement of the 5-HTergic nervous sytem in the processes underlying learning and memory.

256.14 EFFECTS OF BETA-CARBOLINE-3-CARBOXYLIC ACID ETHYL ESTER ON THE RETENTION OF AVERSIVELY AND APPETITIVELY MOTIVATED TASKS IN RATS. L.J. Wichlinski, R.J. Tippy*, J.W. Hall*, S. Richmond*, R. Murray*, J. Wolfe*, D. Read*, and R.A. Jensen. Developmental Biopsychology Laboratory, Southern Illinois University, Carbondale, IL 62901.

Beta-carboline-3-carboxylate derivatives produce effects which are often directly opposite to those produced by benzodiazepines. Since benzodiazepines are well-known for their amnestic properties, we hypothesized that the beta-carboline-3-carboxylate derivative would produce an opposite effect, that is, enhancement of memory storage processes. Therefore, we investigated the effects of beta-carboline-3-carboxylic acid ethyl ester (B-CCE) on two different kinds of memory tasks in rats: an aversively motivated inhibitory avoidance task and an appetitively motivated T-maze water reward task. In the inhibitory avoidance task, male Sprague-Dawley rats (75-150 days of age) were injected i.p. with either 1.0 or 5.0 mg/kg B-CCE or saline immediately following exposure to a 0.6 mA, 1.0 sec foot shock. Three weeks later, retention was measured (600 sec ceiling). Median retention latencies were: Saline (n=19) - 466 sec; B-CCE 1.0 mg/kg (n=12) - 366 sec; B-CCE 5.0 mg/kg (n=16) -600 sec. Differences between the groups were statistically significant ($H=8.88$, $p<.02$). The latencies of the B-CCE 5.0 mg/kg group were significantly different from the saline group ($U=82.5$, $p<.05$), while the saline and B-CCE 1.0 mg/kg groups did not differ significantly from each other. The differences between the B-CCE-treated animals and controls were not due to nonspecific drug effects since in earlier pilot studies, unshocked B-CCE-treated rats (10.0 mg/kg) showed a median retention latency of 5.0 sec while shocked, B-CCE-treated rats showed a median retention latency of 600 sec.

In the appetitive task, water deprived rats 80-110 days of age were treated with either saline (n=15), B-CCE 1.0 mg/kg (n=15) or B-CCE 5.0 mg/kg (n=15) immediately following training to a criterion of three correct water-reinforced responses in the T-maze. Retention was tested 48 hr later by training the animals to a criterion of 5 correct responses. Eighty percent of the saline-injected rats entered the correct arm of the maze on the first retention test trial while 67% of the animals in each drug treatment condition did so. These differences were not statistically significant. Differences in total number of errors in the test session were also not significant ($F<1.0$). These results suggest that beta-carboline-3-carboxylate derivatives may facilitate memory storage processes for aversively but not appetitively motivated tasks in rats.

We thank the G.D. Searle Company for their donation of the B-CCE used in this research. Supported by a grant from the Office of Research, Development and Administration, Southern Illinois University at Carbondale.

256.15 REVERSAL OF AF64A-INDUCED MEMORY IMPAIRMENT BY CHOLINERGIC COMPOUNDS. A. Levy, R. Brandeis*, S. Dachir*, S. Luz*, Y. Karton*, E. Heldman*, Z. Pittel* and A. Fisher*, Israel Institute for Biological Research, Ness-Ziona, 70450, ISRAEL, and I. Hanin, University of Pittsburgh, Sch. Medicine, Pittsburgh, PA. 15213, U.S.A.

Biochemical studies have shown that intracerebroventricular injection of AF64A (3 nmoles/2ul/side) induces long-term selective reduction of choline acetyltransferase, paralleled by a significant decrease in acetylcholine (Fisher and Hanin, Ann. Rev. Pharmacol. Toxicol., in press). The cholinergic hypofunction induced by AF64A was accompanied by marked memory impairment, as demonstrated in several behavioral paradigms using rats.

In this study, attempts were made to reverse AF64A-induced cognitive impairment, using the cholinesterase inhibitor physostigmine and a selective central cholinergic agonist AF30 (Cohen and Fisher, US Patent 4,104,397, Aug. 1, 1978). Passive avoidance learning test was used, in which test-drugs were injected during the first minute post-training, followed by a retention test 24 hours later. Both physostigmine (0.06 mg/kg i.p.) and AF30 (1 mg/kg i.p.) were found to reverse the AF64A-induced memory impairment. The effects of these drugs on brain cholinergic markers were concomitantly monitored. AF64A injected rats were found to be impaired in two other memory paradigms. These two tests are: a) Eight-arm radial maze, in which drugs are injected following four free choices, and the test continued four hours later. b) Morris swimming test for three days, in which the drugs are injected following the first and the second day of training. The reversal of these behavioral impairments using the above drugs is currently under investigation.

The reversal of AF64A-induced memory impairment by cholinergic compounds strongly supports the idea that AF64A injected rats can be used: (i) to mimic the cholinergic hypofunction reported in Alzheimer's disease; (ii) in drug development studies aimed to ameliorate memory dysfunction in this disorder.

256.16 PAVLOVIAN-CONDITIONED MOTOR ACTIVITY PRODUCED BY D-AMPHETAMINE TREATMENT. P.M.Duncan and D.D. Hart*. Psychology Department, Old Dominion University, Norfolk, Va. 23508.

"Spontaneous" motor activity (SMA) responses to stimuli predicting d-amphetamine(DA) injection were investigated in a Pavlovian conditioning paradigm. Three groups of rats (doses=0,1.0,4.0mg/kg) were given IP injections on 6 alternate days, 30 min after being placed in a distinctive environment (Lafayette activity detectors), and remained there for an additional 30 min. SMA counts, indicative of locomotion, vigorous grooming and stereotyped behavior, were recorded at 10-min intervals both pre and post-inj. Pre-inj SMA was recorded in order to monitor acquisition of conditioned responses (CR) to the test apparatus as indicated by daily changes in SMA. On day 7 (test day) all rats received IP saline inj for measurement of CR to the injection procedure. Non-associative drug-produced SMA effects were controlled by DA inj given saline-grp rats 1 hr after being removed from the conditioning apparatus each day.

Mean Total SMA counts during 30-min pre/post injection periods

| Cond. Day | 1 | 2 | ....6 | Test Day |
|---|---|---|---|---|
| Sal Grp,n=12 | 1225/550 | 860/750 | 805/650 | 815/450 |
| DA 1 mg,n= 9 | 1030/1650 | 1180/2425 | 920/3150 | 860/750 |
| DA 4 mg,n= 9 | 960/3900 | 1060/3600 | 910/4200 | 630/1020 |

Significant($p<.05$) pre-inj differences occurred only in the 4 mg group,which increased in activity from cond days 1 to 2. Post-inj SMA increased significantly from cond day 1-6 in the 1 mg group. Test day post-saline inj SMA was greater in both drugged groups than in saline controls (combined drugged grps vs. saline grp, $p<.05$). Test day post-inj differences between the 2 drugged groups were not significant.

These results indicate that Pavlovian conditioning to place/apparatus stimuli occurred during the first cond day, especially in the high-dose grp. Subsequently, the injection procedure apparently gained most of the predictive power, since no pre-inj CR's were seen on the following cond days. CR's to injection-related stimuli were seen in both drugged groups on the test day, and were in the same direction, rather than compensatory to drug-produced responses. Visual observation suggested that these CR's consisted of locomotion, grooming, and (in the high-dose group) some amphetamine-stereotyped behavior.

256.17 DIAZEPAM (VALIUM) BLOCKS REFERENCE MEMORY, BUT NOT WORKING MEMORY, OF A RADIAL MAZE TASK. Mauro Caudarella and Robert Hough*. Dept. of Psychology, Queen's University, Kingston, Ont., Canada K7L 3N6.

Caudarella and others have shown that diazepam has impressive anterograde amnestic effects in aversively motivated, one-trial learning tasks: immediate "working" memory is unimpared but information held briefly in working memory apparently cannot be stored permanently while the animals are under the effects of diazepam; however, information already in long-term memory can be retrieved normally. Furthermore, the amnesia was not found to be "state-dependent". The fact that diazepam inhibits hippocampal circuits suggest that the hippocampus is involved in the long-term storage of information. On the other hand, some studies (e.g. Olton & Pappas, Neuropsychologia, 1979, 17, 669) have suggested that the hippocampus is involved only in working memory and not "reference" (long-term) memory in a radial arm maze. Even if diazepam's amnestic effects are not mediated principally by hippocampal circuits, it is clear that inhibition of the hippocampus by diazepam does not disrupt working memory. However, because aversively motivated one-trial tasks may represent a special case, the present experiment tested the effect of diazepam administered during acquisition on subsequent retention of a spatial discrimination problem using food reward presented in only 4 of the 8 arms (a random set for each rat) of a radial maze raised 50 cm off the floor. Four groups (n=7) of male Wistar rats were trained at 80% body weight to run the radial maze with a minimum of errors. An "error" was considered to be any "useless" entry into an arm that did not lead to food reward; errors can be of two types: first entries into a never baited arm constitute errors of reference memory while re-entries into a baited arm (now empty because the animal picked up the food some seconds before) or unbaited arm (still empty) constitute errors of working memory. 1) One group of rats received 1 mg/kg Valium Injectable® (DZ) 20 min. before each acquisition session (max. 10 min.) and, after a 3-day break, the proprietary vehicle (V) 20 min. before a single retention test with the same 4 arms baited. The other 3 groups completed a standard 2x2 design to check for "state-dependency": 2) acquisition-V, retention-V; 3) acquisition-DZ, retention-DZ; 4) acquisition-V, retention-DZ.
RESULTS: A. Working Memory Errors (max. 4). There were no significant differences (Mann-Whitney U, p>.1) among the 4 groups during the retention session. Thus, working memory was not impaired by diazepam. There were also no significant differences among the 4 groups in number of trials to criterion during the acquisition sessions. B. Reference Memory Errors (no max.; time limit-10 min.). Of all pairwise comparisons only one difference was significant in the retention test--group 1 vs. group 2; that is, only the rats that had received diazepam during acquisition showed significantly poorer retention, and furthermore, this memory deficit was not "state-dependent". Thus benzodiazepine receptors seem to be involved in the formation of long-term reference memory rather than immediate working memory.

## HUMAN BEHAVIORAL NEUROBIOLOGY I

257.1 THE MIND-BODY PROBLEM AS SUBSETS OF THE STRUCTURE-ACTIVITY RELATIONSHIP. B. E. Morton, Dept. of Biochemistry and Biophysics, University of Hawaii School of Medicine, Honolulu, HI 96822.

Much of neuroscience research deals both with physical structures and the activities of such structures. However, the important difference between the material properties of a structure, and its kinetic and thermodynamic properties (activities) has not been widely appreciated.

Biochemists, thinking that the mechanism of action of enzymes would be clarified if their structure could be determined, have now completely resolved the atomic structure of many such proteins. Yet, information about atomic positions in an unknown protein does not even permit the prediction that the molecule is an enzyme, much less what its catalytic activity might be.

Clearly in the case of enzymes, static physical structure is different than the dynamic kinetic and thermodynamic properties resulting from the action of such a structure. Yet, the activity of an enzyme is directly tied and exquisitely sensitive to perturbations in enzyme structural conformation. A lethal point mutation, for instance, which results in the substitution of only one amino acid out of the hundreds in the primary structure of an enzyme can totally eliminate catalytic activity.

At higher and lower structural levels in the universe similar relationships between structure and activity exist. Thus, at the levels of supramolecular assemblies, subcellular organelles, cells, tissues, organs, organisms, various groups of organisms, etc., activities exist that are absolutely dependent upon structure at that level, but like enzyme kinetics, are evanescent, matter-energy transformations.

At the level of the brain, such activities encompass what has been labeled as mind. The structural dependence of mind upon brain integrity is abundantly illustrated by the consequences of cerebral accidents or by the administration of psychoactive drugs. At the organism level, this structure-based activity is called life.

Therefore, just as enzyme structure vs. enzyme activity is a subset of the structure-activity relationship, so the mind-body problem is a misnomer that can be seen to represent subsets (at two different levels, ie., brain-mind and body-life) of the same structure-activity relationship.

The mind-body problem originated from the failure of body and brain structural data to account for mind. This anciently led to the creation of extracorporeal, supernatural solutions. Recently, more accurate understanding of the fundamental differences between structure and activity has permitted the solution of the mind-body problem as subsets of the structure-activity relationship.

257.2 A DISTINCT SPEECH PRODUCTION DEFICIT FOLLOWING DAMAGE TO THE LEFT SUPPLEMENTARY MOTOR AREA: EVIDENCE FROM TRANSCORTICAL MOTOR APHASIA. P.W.Schönle, Dept. of Clinical Neurophysiology, Center for Neurological Medicine, University of Göttingen, D-3400 Göttingen, West Germany

Several reports indicate participation of the supplementary motor area in speech production: 1) Penfield and Roberts (1959) have shown that electrical stimulation in and around the region of the supplementary motor cortex in man may result in arrest of ongoing speech or initiation of repetitive involuntary vocalizations. 2) Surgical ablation of the supplementary motor area produces transient speech disturbances with difficulty in initiating speech, anomia or mutism (Erickson and Wodsey, 1951).
3) Left anterior cerebral artery infarction involving the supplementary motor area leads to transcortical motor aphasia characterised by an absence of spontaneous speech, difficulty in initiating speech, near normal repetition and preserved auditory comprehension.

In the present study four patients with transcortical motor aphasia following damage to the left supplementary motor area were examined to delineate the level of their speech production deficit. Four patients with anomic aphasia, matched for sex and age, served as controls. The ability to name line drawings was taken as a baseline measure of speech production. Two experiments were designed to tap distinct levels of processing in speech production. In the first experiment subjects had to select pictures which were related semantically. In the second experiment pictures had to be selected whose names were related phonemically (pictures of homophones, e.g. yoke/yolk, or pictures of rhymes, e.g. bear/chair).

While patients with transcortical motor aphasia showed a severe deficit in overt speech production as indexed by picture naming, their ability to identify pictures with respect to semantic and phonemic relatedness was well preserved. The finding of intact phonemic knowledge about a given word in face of a severe speech production deficit indicates a distinct processing deficit at the level of translation of linguistic information into speech motor programs.

257.3 MULTIUNIT NEURONAL RESPONSES IN THE HUMAN MEDIAL TEMPORAL LOBE DURING A VERBAL RECENT MEMORY TASK. G. Heit, M.E. Smith, E. Halgren.
Brain Research Institute, UCLA; VA Southwest Regional Epilepsy Center, Los Angeles, CA 90024

Damage to the human Medial Temporal Lobe (MTL: hippocampus, parahippocampal gyrus, and amygdala) has been shown in clinical studies to lead to deficits in recent memory, while remote semantic memory is normal. Previous studies in our laboratory (Smith et al, 1984, Soc. Neurosci. Abs. 10:846) demonstrated that stimulus familiarity has profound effects on MTL field potentials evoked to words. These results prompted the current investigation of multiunit neuronal responses during verbal recent memory, face recognition, word/nonword discrimination, and object naming tasks. Subjects were instructed to keypress to targets consisting of either repeated or novel stimuli (recognition memory task), or to words rather than nonwords (lexical decision). In the naming task, the subject verbally responded with the name of a object portrayed in a line drawing. Electrode (40u fine wire) implantation and site selection were dictated on clinical grounds for the surgical management of medically intractable partial complex epilepsy.

The principal finding was that in contrast to the simultaneous recorded field-potentials cell firing in all areas was controlled primarly by overt behavioral responses. Cell-firing was largely insensitive to stimulus familiarity (novel vs repeat), stimulus type (verbal/nonverbal or meaningful/nonsensical), or task conditions (recent episodic vs remote semantic memory, namimg) Of the 38 units recorded, 29 demonstrated this firing correlate. Some units were excited for 100-250 msec beginning 200-500 msec before the keypress. Other units were activated both before and after, or entirely after the keypress for a period of 200 to 600 msec. The later responses had onset latencies of 50-100 msec post keypress. Brief (200 msec) inhibition followed by an equal period of excitation, or a long period (500 msec) of inhibition entirely following the behavioral response, were also observed.

These firing-patterns usually occured in trials with a behavioral output. However excitation or inhibition was occasionally seen in trials with no behavioral response. This excitation or inhibition was usually earlier in onset, briefer in duration, and smaller in amplitude then that occuring in trials with an overt behavioral response. Thus, although unit-firing occured predominately in those trials with keypress, sufficient firing occured during other trials to suggest that response-selection or decision-making rather than motor response per se is the essential behavioral correlate.

257.4 EVOKED POTENTIALS DURING LINGUISTIC PROTOTYPE FORMATION. J. G. Banghart* and R.M. Vardaris. Dept. of Psychology, Kent State University, Kent, OH 44242.

Previous studies of evoked potentials (EP's) during concept formation have yielded inconsistent results. Stuss and Picton (1978) failed to find EP's that were associated with different phases of learning. Peters et al., (1977) and Wilson et al. (1973), however found an overall increase in P300 amplitude over the course of learning. Wilson et al. attributed this change to increasing decision-confidence on the part of the Subjects (Ss).

For the present investigation, 10 right-handed male volunteers were first pre-trained on a paired-associates (PA) task to label nonsense syllables by pressing buttons.Then electrodes were applied to Pz, T3, and Oz. EP's were collected from these sites while Ss learned to categorize pseudo-random dot patterns as instances of a prototype pattern. After 90 trials, the prototypes were added to the list but no category names were supplied for them. As a control procedure, novel nonprototypes also were introduced. The EP's were averaged off-line. Trials containing eye-movement artifacts were not included.

Amplitudes and latencies were analyzed for P3(1) and P3(2) (post-stimulus positive peaks from 200-300msec and 300-400msec respectively). The following results were obtained (p .05). For P3(1)there were amplitude differences between correct instances and misclassified instances early in training, as well as between late misclassified instances and non-instances (controls). In addition there were corresponding latency differences between these response types. P3(2) amplitudes were greater for nonprototypes than for prototypes late in learning. Non-prototypes also had longer latencies early in training than prototypes late in training. Additional analyses will determine whether there are differences in these parameters for the three electrode sites.

It appears that P3(2) amplitude and latency were related to detection of prototype dot patterns in our study. In addition there were learning effects on P3(2). This late positive complex may index cogntive processing during the formation of prototypes.

257.5 SENSORY EVOKED EYEBLINK: ARTIFACT OR SIGNAL. M. R. Blackburn, L. J. Trejo* and G. W. Lewis. Navy Personnel Research and Development Center, San Diego, CA 92152.

Rejection of evoked potential (EP) records contaminated by obvious eyeblinks may not entirely solve the problem of eyeblink artifacts. Even when eyeblinks do not occur, signals with similar latency and polarity are present in the EPs. These signals may arise from small eye movements associated with eyeblinks, but may also occur alone when eyeblinks are suppressed. Our strategy was to compare EP trials that either included or were free from eyeblinks. Five subjects were presented with a simultaneous 90 dB (I) 1000 Hz tone (10 ms) and 10 ms 80 ftL checkerboard at 1 meter, repeatedly over 30 trials with a random ISI averaging 4 s. The EEG was recorded from frontal, parietal, and central sites for 1000 ms pre-and 1000 ms post-stim. Although subjects were instructed to suppress eyeblinks, they often blinked involuntarily following stimulation. Single trials were edited for eyeblinks (Fp1-Cz). We inferred eyeblinks from the presence of a positive transient in the post-stimulus EEG that was greater than twice the maximum peak-to-peak amplitude of the pre-stim activity (20-40 μv). Trials free of eyeblinks were identified by the absence of a positive transient exceeding the pre-stim peak-to-peak amplitude. Eyeblink trials were averaged and compared with an equal number of eyeblink-free trials that occurred in close temporal proximity to the eyeblink trials. We found that most involuntary eyeblink potentials occurred within a narrow window centered about 100 ms post-stim. These potentials were recorded at all sites when referenced to the ipsilateral ear. In the parietal to Cz derivation, EP waveforms from trials with and without eyeblinks were similar. In particular, both types contained the sharp transient positive peak with the latency characteristic of the eyeblink, and a negative deflection at about 200 ms. The possibility that small eye movements contribute to these potentials in the absence of eyelid closures cannot be excluded. Averaged power spectra of the pre-stim epochs showed that eyeblinks were preceded by less alpha activity than non-eyeblink trials. Thus, higher states of cortical arousal appear to exist during eyeblink trials than during non-eyeblink trials.

257.6 EVIDENCE FOR PRECORTICAL GATING DURING SELECTIVE ATTENTION IN HUMANS. M. Oakley*, R. G. Eason, R. Moore* & S. Conder* Dept. of Psychology, U. of N. Carolina, Greensboro, N. C. 27412.

Both behavioral (Posner, et al., In Pick, (Ed). Erlbaum, Assoc., 1977) and electrophysiological data (Eason, B. Psychon. Soc., 1984) suggest that when one selectively attends to a location in space where a task relevant stimulus is expected to appear, neural pathways are biased such that impulses are preferentially transmitted over them. Whether the biasing occurs at a precortical or cortical level, or both, remains unresolved. Eason and assoc. (Physiol. Psych., 1983; B. Psychon. Soc., 1984) have reported that selective attention to specific locations alters neural activity in the visual pathways at the level of the retina. They interpreted their findings as evidence for attention-induced precortical gating in humans. Lukas (Int. J. Neurosci., 1981) has reported similar effects at the level of the cochlear nucleus for the auditory system. Hillyard and assoc., however, have been unable to find evidence for precortical gating in either of these sensory modalities (Hillyard & Kutas, Ann. Rev. Psychol., 1983; Mangun, et al., Neurosci. Abstr., 1984).

In view of continuing uncertainty over whether precortical gating occurs in humans, we have conducted further studies bearing on this issue. Using the same paradigm as in previous studies wherein subjects responded to target stimuli appearing at a given spatial location in the right or left visual field, we were able to modulate the amplitude of short-latency components of scalp-recorded VERs as a function of the spatial attention manipulation (Oakley & Eason, EPA Proc. & Abstr., 1985). The earliest attention-sensitive component, most clearly manifested at frontal scalp locations, had onset-offset latencies of approx. 30-60 msec. Deflections with onset-offset latencies of 60-110 and 110-150 msec. also were affected at frontal as well as at more posterior scalp locations. Based on latency data obtained from single unit recordings from monkeys (Wurtz & Assoc., Nat. Eye Inst.) and cats (Baker, et al., J. Neurophysiol., 1969), it seems probable that the 30-60 msec. component, and perhaps also the 60-110 msec. component, constitutes a far-field recording of precortical activity.

We presently are conducting further studies in an effort to corroborate and extend these results. Data have been obtained from four subjects while working under the instruction to make either a finger lift response or an eye saccade to the location at which the target stimulus appears in the relevant visual field. Based on VERs obtained from $Fp_2$ and $F_4$ over eight sessions involving a total of 6400 flash presentations per subject, three of four subjects have shown an enhanced negativity in the 20-70 msec. range when a given spatial location is attended. These data provide further evidence for precortical gating during selective attention to specific spatial locations.

257.7 BRAIN PERFUSION IN SCHIZOPHRENIA: A DYNAMIC CT STUDY. T.W. Kruckeberg[1], E.M. Burns[1], H.A. Nasrallah[2], M.H. Kathol[3], S.M. Chapman[4].
[1]College of Nursing, University of Iowa, [2]Department of Psychiatry, Ohio State University, Columbus, OH 43210, [3]Department of Radiology, University of Iowa Hospitals & Clinics, [4]Department of Psychiatry, Veterans Administration Hospital, Iowa City, IA, 52242 USA.

Dynamic brain scans were performed on ten consenting right-handed males (mean age 36 years) fulfilling DSM III criteria for chronic schizophrenia using a Picker 1200SX CT scanner. Subjects had a drug wash-out for 10-14 days prior to scanning.

A series of 30 rapid-sequence scans of a pre-selected transverse brain section (15 degrees from the canthomeatal line) were obtained, 24 of which followed the injection via a mechanical injector of 32ml of Hypaque 75 (at a rate of 8ml per sec). Graphs of changes in brain density over time in ten bilateral brain regions were generated by computer.

Peak contrast-enhanced density, arterial mean transit time (AMTT), capillary mean transit time (CMTT) and corrected capillary mean transit time (CCMTT) were examined for right-left differences and any anterior posterior (AP) gradient changes. Asymmetry of peak contrast-enhanced density was detected in the right versus left middle temporal cortex, cerebellum and cerebellar vermis. Either a flattened or hyper-posterior AP gradient was observed in all of the subjects. Fifty percent of the sample manifested prolonged CCMTT in one or more brain regions. Evaluation of these findings relative to brain perfusion will be discussed.

This work was supported by NIH grant MH38514 and VA Hospital, Iowa City, Iowa.

257.8 PATTERNS OF MEMORY FAILURE AFTER SCOPOLAMINE TREATMENT: IMPLICATIONS FOR CHOLINERGIC HYPOTHESES OF DEMENTIA. D.S. Janowsky, W.W. Beatty and N. Butters. VA Medical Center and Department of Psychiatry, UCSD School of Medicine, San Diego, CA 92093

Severe loss of both anterograde and retrograde memory is characteristic of both Huntington's disease (HD) and Alzheimer's disease (AD). In both forms of dementia, marked loss of cholinergic neurons (in the caudate nucleus and the basal forebrain respectively) constitute an important feature of the neuropathology. Since scopolamine treatment in normal subjects interferes with new learning and retards retrieval of information from semantic memory on verbal fluency tests, it has been proposed that scopolamine provides a useful drug model of the memory disturbance in AD (Bartus, et al., 1982) or HD (Caine, et al., 1981). Although the memory deficits in AD and HD appear grossly similar on recall tests, there are marked differences in the pattern of memory failure. Specifically, AD patients exhibit a marked tendency to make perseverative responses, but HD patients do not. The use of recognition procedures differentially improves memory performance in HD but not in AD, although both groups of patients make more false positive responses. If scopolamine provides a useful model of memory loss in dementia, then the pattern of memory failure after scopolamine should mimic that seen in AD or HD.

To test this idea we compared the effects of 0.5 mg scopolamine, 0.1-0.2 mg glycopyrrolate (a peripherally active anticholinergic), or saline on the performance of healthy male volunteers (Age: 20-32 years) on a battery of memory tests. Treatments were given in a counterbalanced order using a within-subjects design. Scopolamine (but not glycopyrrolate) retarded recall and tended to impair recognition of a 14-word list, but the rate of false positive errors was not affected. Scopolamine (but not glycopyrrolate) also impaired recall on the Brown-Peterson short term memory test, but the proportion of perseverative errors was not altered. Neither scopolamine nor glycopyrrolate affected verbal fluency or learning on a symbol-digit paired associate task. Performance on all of these measures is seriously disturbed in HD and AD.

Although scopolamine does impair memory, the pattern of memory failure after drug treatment in the dose used does not mimic that seen in HD or AD. Hence, this pharmacological agent may not provide as useful a model of memory loss in these forms of dementia as previously believed. The present results are not supportive of the hypothesis that the loss of central muscarinic circuits are fundamental to the memory disturbances of HD and AD.

257.9 MULTI-CHANNEL EEG COHERENCE ANALYSES DURING A CONTINUOUS MOTOR TASK. M.R.Ford*, D.K.Dekker* and J.W.Goethe* (SPON: R.B.Wallace) Research Department, Institute of Living, Hartford, CT 06106.

EEG coherence (COH), based on autospectral and cross-spectral calculations, is a frequency-specific, phase independent, linear index of the degree of coupling of two periodic phenomena. Previous reports from our laboratory (Scammon, M.E., Beh. Res. Meth. Inst., 13:517, 1981) suggest that high COH between two brain regions implies a functional connectivity between them, where one region is driving the other, or where both are being driven by a third source. Given that there is increased involvement of frontal, premotor and sensorimotor cortex during consciously directed movement, we proposed to investigate correlative changes in COH recorded from left and right prefrontal, premotor, sensorimotor and parietal regions during continuous movement conditions. Fourteen right-handed women (ages 18-39; $\bar{x}$ = 26.7 years) were instructed to alternate continuously between fist clenching and finger extension of the right hand, left hand, both hands, or neither hand (rest condition) in a counter-balanced sequence (4 one-minute trials for each condition; 16 total minutes). One minute each of intentional eye movement (EOG) and intentional facial muscle tension (EMG) were recorded for artifact assessment and control. Eight channels of eyes-closed EEG were recorded from $F_{p2}$, $F_3$, $F_4$, $C_3$, $C_4$, $P_3$ and $P_4$, each referenced to the ipsilateral earlobe. FFT spectral power analyses (POW) were conducted (sampling rate = 128 points/second; PDP-11/23) on 8 EEG channels, and COH analyses (percentage of seconds/minute in which COH $\geq$ .80) were performed on 16 pairs of leads: 4 interhemispheric, 6 intrahemispheric (left), and 6 intrahemispheric (right). One Hertz ($H_z$) interval data were combined to form frequency bands of 9-12$H_z$, 13-17$H_z$, and 18-31$H_z$ (slower frequencies were not analyzed due to the high probability of artifact contamination). Results show consistent and frequently significant increases in 9-12 $H_z$ COH during all movement comparisons except those recorded from parietal regions. Absolute POW levels in the 9-12$H_z$ band were unchanged from resting levels over all subjects; however, low-POW subjects showed consistent and significant increases in 9-12$H_z$ POW during movement, while high-POW subjects showed decreases in 9-12$H_z$ POW. Significant, though less consistent lateralized effects were observed. Significant increases in 13-17$H_z$ and 18-31$H_z$ COH were found only in premotor and sensorimotor regions. POW was unchanged for both "beta" bands. Results were independent from EOG, EMG, or SMR (sensorimotor rhythm) influences, and the COH increases were not present in adjacent parietal regions. The results strongly suggest that COH, especially in the 9-10$H_z$ range, is integrally involved in the execution of a continuous motor task, and support the contention that COH may represent the electrophysiological correlate of functional connectivity, or communication, among brain regions.

257.10 PRESERVED ENCODING CAPACITY IN PATIENTS WITH HUNTINGTON'S DISEASE. N. Butters and W.W. Beatty. VA Medical Center and Department of Psychiatry, UCSD School of Medicine, San Diego, CA 92161.

Huntington's Disease (HD) is a genetically transmitted basal ganglia disorder characterized by involuntary choreiform movements and a progressive dementia. Among the earliest and most prominent signs of the HD patients' dementia are anterograde and retrograde memory deficits. Some studies concerned with the cognitive processes underlying the HD patients' memory deficiencies have emphasized failures in encoding whereas others have concluded that failures in retrieval play a primary role.

To re-examine encoding in HD we studied 12 patients and 12 controls that were closely matched in age, gender and education. In the first experiment subjects learned a 14-word list containing 7 highly imageable words and 7 words that were difficult to image. Controls displayed superior immediate and delayed recall and better delayed recognition, but both groups remembered more highly imageable words. The magnitude of this effect was comparable for HD patients and controls and evident even on the first recall trial. In the second experiment using the same subjects we examined the buildup of proactive interference (PI) and its release following a taxonomic shift. Controls recalled more words than did HD patients, but both groups exhibited comparable release from PI. These findings demonstrate that encoding capacity is relatively well preserved in HD. Hence encoding deficits are not likely to be a major source of defective memory in this disorder.

257.11 EVENT-RELATED BRAIN POTENTIALS REVEAL PROCESSING GRADIENTS DURING VISUAL-SPATIAL SELECTIVE ATTENTION IN MAN. G.R. Mangun* and S.A. Hillyard. Department of Neurosciences, UCSD, La Jolla, CA 92093.

Selective attention to a region of the visual field has been likened to a "spotlight" that facilitates the processing of stimuli falling within its boundaries. Recent work suggests that spatial attention is not focussed upon a particular region in a discrete all or none fashion, but rather falls off continuously as a function of distance from the attended locus (i.e., a spatial gradient of attention). The possibility that spatial attention produces facilitated processing of stimuli in the vicinity of an actively attended location can be investigated using event-related brain potentials (ERPs). ERPs have been used to demonstrate electrophysiological correlates of selective attention and allow analysis of the processing of both relevant and irrelevant events. We investigated the spatial distribution of attentional gradients using ERPs to index the processing of irrelevant probe stimuli at varying distances from the attended locus.

Subjects viewed a video display that presented rectangular flashes at multiple locations in the visual fields. For each stimulus in one half-field, another stimulus was located in the mirror image location in the opposite half-field. The stimuli flashed one at a time, in random order, with ISIs ranging between 300-600 msec. Subjects attended to one stimulus location during each experimental run in order to detect infrequent target flashes that appeared at that location 15% of the time. ERPs for each of the flashing stimuli were recorded bilaterally from multiple scalp sites.

Selective visual-spatial attention was evident as an enhancement of the N170 and N270 components over frontal, central, parietal and occipital scalp sites for the attended stimuli as compared to when they were inattended (i.e., during attention to the homologous location in the opposite field). Gradient effects on ERP amplitudes were evident for unattended, irrelevant probe stimuli that were located in spatial proximity to the attended stimuli. Depending upon the stimulus configuration, the gradient effects were seen as enhancements of the P110, N190 and P250 components of the ERP to the probe stimuli.

The results are interpreted as supporting a continuous gradient structure in visual-spatial attention rather than a discrete spotlight.

257.12 SINGLE NEURON ACTIVITY IN THE HUMAN TEMPORAL LOBE: I.LISTENING AND SPEAKING. by O. Creutzfeldt*, G. A. Ojemann and E. Lettich*(SPON: A. A. Ward Jr.). Dept. of Neurol. Surgery, Univ. of Washington, Seattle, WA. 98195 and Dept. of Neurobiol., Max-Planck-Institute of Biophysical Chemistry, Göttingen, West Germany.

We have recorded single and multiple unit activity (with lacquer insulated tungsten microelectrodes) from various locations in the temporal lobe of consenting awake human subjects during epilepsy surgery. Recordings were restricted to regions which would subsequently be resected.

The patients listened to 20 multi-syllable words each preceded by a 1000Hz pulse. During a subsequent presentation they had to repeat each word. In the right and left superior temporal gyrus, below the face area, neuron activation occurred throughout the word sound, but sometimes was restricted to the second part of a composed word (e.g. airplane) with less activation to single multi-syllable words (e.g. alligator). Other neurons showed little or no activation during the word presentation but strong activation when the patient repeated the word. Activation during listening or speaking were typically accompanied by a surface negative potential in the averaged ECoG. In the middle temporal gyrus a few neurons also showed a strong activation during word repetition or a variable activation during the preceding word presentation. But most neurons there showed a strong suppression during listening and/or the word repetition. This suppression was typically accompanied by a broad surface positive potential in the averaged ECoG, on which a negative wave may be superimposed if neurons in this region were excited during the word repetition phase. All neurons responded only a little to a 1000Hz beep alone or to abrupt or continuous noises in the operating room. No speech related activity was found in the inferior temporal gyrus recordings.

These findings demonstrate that activity related to speech perception and production can be recorded in the superior and middle temporal gyri of both hemispheres outside the primary auditory cortex and the typical language areas. The activity may be specifically related to certain parts of a word with semantic significance.

257.13 SINGLE NEURON ACTIVITY IN THE HUMAN TEMPORAL LOBE: II.: NAMING, READING, MEMORY, FACE AND FIGURE MATCHING. G. Ojemann, O. Creutzfeldt* and E. Lettich*. Dept. of Neurol. Surgery, Univ. of Washington, Seattle, WA. 98195 and Dept. of Neurobiol., Max-Planck-Institue of Biophysical Chemistry, Gottingen, West Germany.

Single and multiple neuron activity was recorded during epilepsy surgery from temporal cortex (that was subsequently resected) of consenting awake patients while the patient performed various visually presented cognitive tasks.

Recordings from the left hemisphere were made during naming, reading and verbal memory tasks, with spatial matching tasks using the same items as controls. In the left superior and middle temporal gyri, neurons showed activation during several measures of silent and overt object naming and word reading compared to the spatial task controls. The same neurons also showed changes during speaking and listening to words (activation or suppression). In left inferior and middle temporal gyri an enhancement of neuron activity was observed during verbal memory input (silent naming of an object to be remembered) and with the reading task during which the memory was stored, while activity was reduced during silent or overt naming and reading that were not part of a memory task as well as during the spatial task controls. Neuronal responses were variable between trials, but in one example this response variability was related to a concomitant variability of performance. Inferior temporal neurons did not change during speaking and listening.

Recordings from the right hemisphere were made during face and figure matching, naming and labeling of facial emotional expressions. In the right superior and middle temporal gyri neurons were activated during matching tasks, compared to the other tasks; on occasion this activation was greater for face than complex figure matching. Some of these neurons also showed changes during speaking and listening.

The functional relationship of recording sites to the same tasks was independently established by electrical stimulation mapping. In some, but not all instances, maximal neuronal firing increases occurred during those tasks related to the recording site by stimulation mapping, including cases with changes during both mapping and recording related to input to verbal memory and face matching. Our findings suggest that neurons in various portions of temporal lobe may be differentially involved in silent and overt naming and reading, memory acquisition and spatial matching tasks.

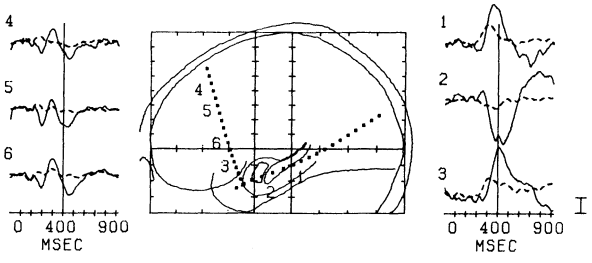
257.14 A POSSIBLE FRONTAL LOBE CONTRIBUTION TO SCALP P300. C.C. Wood and G. McCarthy, VA Medical Center, West Haven, CT and Yale University School of Medicine, New Haven, CT 06516

Human intracranial recordings provide an important source of evidence concerning the generators of P300 and other scalp ERPs. To date the only intracranial concomitants of scalp P300 with voltage gradients suggesting local origin have been reported in medial temporal lobe structures, in particular the hippocampus and amygdala (Halgren et al., Science, 1980, 210: 803-805; McCarthy et al., Soc. Neurosci. Abs., 1982, 8: 976; Wood et al., Ann. N.Y. Acad. Sci., 1984, 425: 681-721). Here we describe task-related ERPs recorded from locations throughout the human frontal lobe that could also contribute to scalp P300.

ERPs were recorded from as many as 8 18-contact depth probes in patients undergoing evaluation for possible epilepsy surgery. Subjects performed a series of two-choice categorization tasks in which stimuli occurred randomly with probabilities of .8 and .2 and subjects counted occurrences from the infrequent stimulus category. In different tasks, the stimuli to be categorized were auditory, somatosensory, or visual.

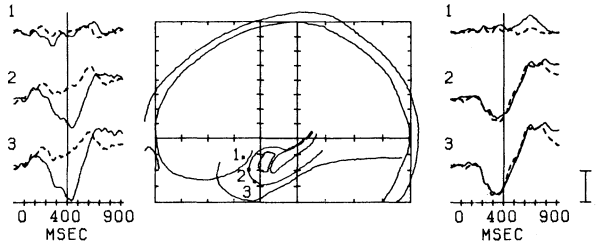
At locations in the medial temporal lobe, the previously reported ERP concomitants of P300 were obtained: A positivity posterior to the hippocampus, a sharp negativity in or near the hippocampus, and a positivity anteriorly in the region of the amygdala (4-6 in Fig; solid lines are ERPs for counted soft clicks, P=.2; dotted lines are ERPs for loud clicks, P=.8; cal: 50uV; positive up). In the frontal lobe a diffusely distributed negative-positive-negative sequence was obtained which began earlier than but overlapped with the temporal lobe activity (1-3 in Fig.). In some patients, the frontal potentials inverted across frontal cortex, suggesting a frontal cortex origin for at least part of the frontal activity. These data emphasize the likelihood of multiple generators of scalp P300.



257.15 HUMAN INTRACRANIAL ERPs DURING LEXICAL DECISION. G. McCarthy, C.C. Wood and S. Bentin, VA Medical Center, West Haven, CT and Yale University School of Medicine, New Haven, CT 06516

We have recently described intracranial event-related potentials (ERPs) recorded from the medial temporal lobe during sentence processing in humans (McCarthy and Wood, Soc. Neurosci. Abs., 1984, 10: 847). Large negative potentials with peak latencies of about 400-500 msec were obtained from electrodes in the region of the amygdala to sentence endings that were semantically anomalous, but not to normal sentence endings. We now report that potentials of similar polarity, latency, and intracranial distribution are obtained during a lexical decision task. The task was identical to that described by Bentin et al. (Electroenceph. Clin. Neurophys., 1985, 60: 343-355): 240 words and 240 nonwords were randomly presented one word per trial and subjects were required to indicate whether each stimulus was a word or not. Nine patients were studied, each of whom had chronic implanted electrodes for evaluation of possible neurosurgery to relieve intractable epilepsy.

The figure compares waveform morphology and intracranial distribution of the negative ERPs in the anomalous sentence (left) and lexical decision tasks (right). In the sentence task, anomalous endings (solid) elicited a large negativity in the vicinity of the amygdala which was absent for normal endings (dashed). In the lexical decision task, both nonword (dashed) and word stimuli (solid) elicited potentials with similar morphology and distribution to those in the sentence task. Thus, lexical decision and anomalous sentence tasks appear to elicit similar activity in the anterior medial temporal lobe. Whether such activity differs for primed and unprimed words is currently being investigated. (Calibration: 50 uV, positive upwards).



## SPINAL CORD AND BRAINSTEM III

258.1 2-DEOXYGLUCOSE UPTAKE IN THE CERVICAL CORD OF THALAMIC CATS DURING FORELIMB STEPPING ON A MOTOR-DRIVEN TREADMILL. M. Shimamura*, V.R. Edgerton, I. Kogure* and T. Fuwa* (SPON: F. Zajac). Dept. of Neurophysiology, Tokyo Metro. Inst. for Neurosci., Tokyo 183 Japan, and Dept. of Kinesiology, UCLA, Los Angeles, CA 90024.

Tracer amounts of [$^{14}$C]-2-deoxy-D-glucose (2-DG) were infused to detect areas of the cervical cord involved in forelimb stepping in thalamic and low spinal cats. Under ether anesthesia, cats were transected at stereotaxic A12 level and Th10 segment. Immediately after transection ether was withdrawn. Approximately one hour later, 100μCi/kg of 2-DG was infused into the jugular vein and one of three procedures were followed: 3 cats stepped on a motor-driven treadmill, 3 were placed on the treadmill with the belt stationary (extensor rigidity), and 2 were anesthetized with sodium pentobarbital. In all experiments 45 minutes elapsed between the time of injection of 2-DG and when cardiac arrest was induced by KCI injection, after which the brain and spinal cord were quickly removed and frozen in 2-methybutane cooled with dry ice. Frozen sections, 60μm thick, were cut, placed on glass slides, air dried, and placed on x-ray film. The film was processed after about seven days of exposure. Optical densities of the autoradiograms corresponding to specific anatomical structures at about C2 and C7 were determined. For anatomical localization, autoradiograms were compared with counterstrained histological sections. Forelimb stepping led to a discrete region of increased 2-DG uptake dorsomedially in the dorsal horn, predominantly in Rexed's laminae II-IV and in intermediate zone VII. A less marked increase in labeling was observed in the white matter at C6-C7 segments. The ventrolateral and dorsolateral funiculus exhibited slightly higher 2-DG uptake than the dorsomedial and ventromedial funiculi in both stepping and rigid cats. The ratio of uptake in the gray and white matter in C7 was considerably higher in stepping than in rigid cats. A less substantial difference between the gray and white mattter was noted at C2. The 2-DG uptake rate in anesthetized cats was lower at both C2 and C7 than in either the rigid or stepping cats. The most distinctive difference in all cats was the greater uptake around the outer rim than the more central regions of the dorsal horn. This contrast was the highest in the rigid and stepping cats. The regions of elevated 2-DG uptake may have been due to increased afferent discharges of the forelimb and its ascending volleys as well as to descending input from the brainstem.

258.2 ELECTROPHYSIOLOGICAL CHARACTERISTICS OF LONG-LOOP REFLEX COMPONENTS IN LEG MUSCLES IN MAN DURING VOLITIONAL, POSTURAL AND GAIT ACTIVITY V. Deletis,* M. R. Dimitrijevic, A. M. Sherwood, Dept. of Clinical Neurophysiology, The Institute for Rehabilitation and Research and the Dept. of Rehabilitation, Baylor College of Medicine, Houston, TX 77030

Electrical stimulation of the median nerve at the wrist has been shown to generate segmental and long-loop reflex responses. Stimulation of the superficial radial nerve at the wrist generated only long-loop reflex responses. However, these responses to stimulation of either nerve were present in healthy subjects only when accompanied by concomitant volitional activity of the involved muscle (Eisen et al., EEG clin Neurophysiol 59:205-213, 1984). The size of the long-loop reflex response can be increased by performing dynamic, skillful movements instead of applying steady, sustained activity during stimulation (Conrad and Aschoff, EEG clin Neurophysiol. 42:107-116, 1977). Initial findings were interpreted to mean that the long-loop reflex response is mediated via the spino-bulbospinal pathway while later results suggested the importance of the spino-corticospinal pathway.

We studied the effects of various maneuvers on segmental and long-loop reflex components recorded from leg muscles in healthy adult subjects. These reflexes were elicited by peroneal nerve stimulation together with tonic volitional activation of the involved muscle or repetitive movement of the ankle while in the sitting position. We also studied these reflexes in the standing position, activating the involved muscle by standing on the heels, through postural disturbances, or walking in place while stimulating. We were able to modify the segmental reflex response in the lower extremities through the use of these maneuvers, but we were not able to modify the long-loop reflex systematically, as has been found in the upper extremity. In light of the proposed mechanisms of the long-loop reflex in the upper extremity, one might expect to find similar reflex characteristics in the lower extremities. However we did not find selective facilitation of the long-loop reflex component in the lower extremity. Further studies are needed to clarify the differences between upper and lower extremity responses, which may in turn yield new insights into the mechanisms involved in the long-loop reflexes.

258.3 RHYTHMIC DEPOLARIZATIONS OF LUMBO-SACRAL AND CERVICAL DORSAL ROOTS DURING FICTIVE LOCOMOTION IN THE CAT. R. Dubuc, J. -M. Cabelguen* and S. Rossignol. Centre de recherche en sciences neurologiques, Département de physiologie, Université de Montréal, Montréal, Québec, Canada H3C 3J7.

During locomotion, the reflex responses to cutaneous input are subjected to phasic amplitude modulation. There are several levels at which such modulation could occur, the first of which is the primary afferent terminals themselves. Fifteen cats were decorticated under methohexital sodium anaesthesia (10 mg/Kg) and paralysed. Muscle nerves of either the hind- or the forelimbs were recorded during fictive locomotion. Proximal stumps of cut dorsal roots were recorded in a pool of warm paraffin oil. Dorsal root potentials (DRPs) showed clear fluctuations at the periodicity of the locomotor cycle as reported by Bayev and Kostyuk (Neurosci., 7, 1982, 1401-1409). However, no DC shifts were observed at the onset or offset of the locomotion bouts. Typically, the cervical or lumbo-sacral DRPs showed two peaks of depolarization per cycle. For instance, in the lumbar cord, the first depolarization peak (N1) occurred near the maximum of flexor activity (Sartorius lateralis) whilst the second (N2) appeared at the maximum of activity in the extensor muscle nerve (Semimembranosus anterior). Following each depolarization peak, there was a sharp trough of hyperpolarization. The first one (P1) appeared after the onset of extensor activity at a time wich could correspond to foot contact in a walking cat with similar cycle durations. The second (P2) occurred near the onset of flexor activity; this time relationship with the flexor activity strongly suggests a relation to foot lift-off. Analyses showed that the N1 and P1 components are related to flexor activity since, as the flexor burst, they do not vary with changes in cycle duration. On the other hand, N2 and P2 showed a strong correlation with the latter, suggesting that they are related to the extensor activity. It was also clear that the two depolarization peaks in the DRPs were related to the ipsilateral cycle and therefore, that N2 was not a reflection of the contralateral flexion. It was of interest to find in those preparations that many units in cut dorsal root filaments showed rhythmic discharges at the periodicity of the step cycle. Moreover, several such units showed antidromic discharges at phases of the step cycle corresponding to N1 or N2. It thus appears that the locomotor network exerts complex presynaptic effects on the primary afferent terminals which are reflected by two distinct periods of depolarization per step cycle. However, because DRPs represent presynaptic events occurring in several types of afferents, it is not yet possible to establish their relationship with the modulation of specific cutaneous reflex pathways. (Supported by the Canadian MRC).

258.4 FEATURES OF ENTRAINMENT OF SPINAL PATTERN GENERATORS FOR LOCOMOTOR ACTIVITY IN THE LAMPREY. A.D. McClellan & K.A. Sigvardt, Dept. of Physiology & Biophysics, Univ. of Iowa, Iowa City, IA and Dept. of Neurology, Univ. of Cal.-Davis, VAMC, Martinez, CA.

Central pattern generators (CPGs) in the in vitro lamprey spinal cord generate "fictive" swimming motor patterns. Mechanosensitive elements within the spinal cord are sensitive to movement of the spinal cord/notochord (Grillner, McClellan & Sigvardt, 1982; Grillner, Williams & Lagerback, 1984) and rhythmic bending of the notochord can entrain the burst pattern (Grillner, McClellan & Perrett, 1981). The intraspinal mechanosensitive edge cells, which are located in the lateral white matter, are thought to mediate the entrainment effect on the CPGs. We did a series of experiments to determine the characteristics of this movement-related feedback and how this feedback is distributed to the CPGs.

The spinal cord/notochord was dissected from adult silver lampreys, Ichthyomyzon unicuspis. A 20-30 segment piece was pinned down in the recording dish, usually with the caudal few segments free and attached to a pen motor which moved the end of the cord from side-to-side, mimicking movements that would occur during swimming. Swimming motor activity was elicited by bath application of 0.25-1.0 mM D-glutamate and motor activity was recorded from ventral roots. The dorsal roots were usually cut.

During entrainment at different frequencies, the burst duration and phase lag plots versus rhythm frequency were similar to those observed during actual swimming. Imposed step movements activated mechanosensitive elements, reset the swimming rhythm, and depressed ipsilateral or enhanced contralateral ventral root bursts. Increasing the amplitude of rhythmic imposed movements resulted in a gradual increase in the range of frequencies over which entrainment was effective.

In a low calcium Ringers solution, imposed lateral bending elicited ascending and descending activity in lateral spinal fascicles as far away as 12-24 segments from the point of bending. If the portion of spinal cord caudal to and including the point of bending was bathed in either a normal or low calcium Ringers solution, entrainment of the locomotor rhythm in more rostral segments was blocked even though activity from the mechanosensitive elements was still reaching these rostral segments. This is consistent with the finding that either complete medial or lateral lesions of the spinal cord rostral to the point of bending did not abolish entrainment; entrainment occurs locally and is distributed to other segments through the spinal coordinating system. However, entrainment was blocked by stripping away the most lateral part of the spinal cord in the region of bending, a procedure which undoubtedly destroys many of the local edge cells.

258.5 **THE ROLE OF HIP MUSCLES DURING PAW-SHAKE RESPONSE.** **M.G. Hoy, R.F. Zernicke and J.L. Smith. Department of Kinesiology, UCLA, CA 90024.**

**During paw-shake response (PSR), characteristic muscle activity and joint oscillations occur at hip, knee, and ankle. Previously we reported on muscle and inertial moments during PSR for the knee and ankle joints (Hoy *et al.*, Neurosci. Abstr. 9:63, 1983), and now we have formulated three-segment rigid-body equations of motion and quantified hip joint kinetics during PSR steady-state cycles to understand the role of hip muscles and inertial moments in the control of PSR limb dynamics.**

**PSRs were elicited in four adult spinal cats by applying tape to the hindpaw, and limb motions were filmed (200 f/s). Raw data were smoothed with a cubic spline (Zernicke *et al.*, Res. Q. 47:9-19, 1976) and differentiated to obtain hindlimb kinematics. The thigh, leg, and paw were modeled as a planar, three-segment rigid-body system. Body segment parameters were obtained (Hoy & Zernicke, J. Biomech. 18:49-60, 1985), and kinetic equations of motion were formulated using Newtonian mechanics to yield hip, knee, and ankle joint moments. Gluteus medius (GM), biceps femoris (BF), and iliopsoas (IP) were chronically implanted with bipolar electrodes; EMG data were synchronized with kinematic and kinetic data.**

**The hip joint oscillated in-phase with the knee, and out-of-phase with the ankle during steady-state cycles. Both extensors (GM and BF) were active at the end of hip flexion and the start of extension, while IP was active during late hip extension and early flexion. The extensor muscle moment peaked (-250±13 mNm) subsequent to GM activity, and the flexor muscle moment peaked (501±125 mNm) near the end of IP bursts. Muscle moments counteracted large interactive moments, particularly those due to leg and paw angular acceleration; however, asymmetry existed in the pattern of inertial loading. Generally, during extension, segmental interactive moments peaked simultaneously but in opposite directions, reducing their net effect, while during flexion, peaks were desynchronized, requiring a prolonged flexor muscle moment to control thigh acceleration. The influence of thigh motion on knee and ankle joint dynamics was relatively small.**

**In contrast to the ankle, but similar to the knee, inertial moments were significant at the hip, and hip muscle moments counteracted interactive moments due to distal segment accelerations. Unlike knee and ankle dynamics, hip flexor muscle moments typically exceeded extensor muscle moments in duration and magnitude, suggesting a differential role for hip flexors and extensors in stabilizing hip oscillations and maintaining hindlimb position during PSR. Supported by NIH grant NS19864.**

258.6 DIFFERENTIAL CONTROL OF ANKLE AND KNEE MUSCLES WITH INTERSEGMENTAL PERTURBATIONS OF THE LIMB DURING PAW SHAKING. G. Koshland, E. Cox*, and J.L. Smith. Lab. Neuromotor Control, Dept. Kinesiology, UCLA, CA 90024.

Previous work in this laboratory (Hoy, et al. Neurosci. Abst. 1984) indicated differential control of ankle and knee muscle activity during the paw-shake response (PSR). Patterns of ankle muscle moment matched patterns of paw angular acceleration, while knee muscle moments counteracted inertial moments, particularly those generated by paw dynamics. These results led to our hypothesis that perturbation of limb dynamics would have greater effect on knee than on ankle muscle activity. We tested this hypothesis by assessing EMG patterns of PSRs elicited in hindlimbs perturbed by joint immobilization.

PSRs of 3 cats, spinalized at T-12, were studied under 4 or more conditions: 1 joint was immobilized (H, K, A), 2 joints (H-K, K-A), or three joints (H-K-A). PSRs were elicited by wrapping tape around the paw, and joints were immobilized with plaster casts. Cycle periods, burst durations, and intralimb synergies were assessed from EMG of representative flexor and extensor muscles.

With ankle joint immobilized (A, K-A) or with hip cast alone (H), reciprocal activity of ankle flexor (TA) and extensor (LG) muscles was preserved. Knee extensor (VL) and flexor (BF) activity, however, was variable with inconsistent onsets, low amplitude, and missing bursts. These results are consistent with our hypothesis.

Under other conditions (K, H-K, and H-K-A), however, reciprocal activity of flexor and extensor muscles at all joints was disrupted as all muscles cocontracted at a frequency of 8-10 Hz with burst durations of 40-60 ms. These results, not predicted by the hypothesis, suggest that ankle muscle activity may be influenced by the posture or dynamics of proximal segments.

It is striking, however, how similar the cocontraction pattern is to that described for shivering, another cyclic hindlimb behavior proposed to be centrally generated (Stuart, etal. Amer. J. Phys. Med. 45: 1966). This unexpected result suggests that shivering rather than the paw-shake synergy may have been elicited under some of our testing conditions. If common unit-burst generators (c.f., Grillner 1981) in the lumbosacral cord may be configured to control either behavior, it is possible that the state of the limb determines which is triggered. Supported by NIH grant NS 16984.

258.7 **INTRALIMB KINETICS DURING PAW SHAKES WITH DISRUPTED KNEE MOTION**

T.J. Hart*, E.M. Cox*, M.G. Hoy, J.L. Smith and R.F. Zernicke.
Department of Kinesiology, UCLA, Los Angeles, CA 90024

**The paw-shake response (PSR) occurs in both normal and spinal cats, and in contrast to the strict alternation of the flexor/extensor muscle synergies of scratching and locomotion, the PSR has a mixed synergy with the vastus lateralis being coactive with tibialis anterior (Koshland & Smith, Neurosci. Abstr. 9:63, 1983). Kinetic analyses of the PSR (Hoy et al., J. Neurophysiol., Submitted) demonstrate that at the ankle joint, the muscle moment is highly correlated with the net joint moment, while at the knee the muscle moment is counterbalanced by inertial moments. Hence, it is predicted that the control of muscle moments is distinctly different at the knee and ankle joints during the PSR. In our current study, we altered the inertial characteristics of the cat hindpaw to investigate the mutability of muscle synergies and hindlimb intersegmental dynamics during the PSR.**

**PSRs were studied in adult spinal cats (T-12 transection) after weights (28 and 46 g) were attached to the proximal part of the paw. PSRs were elicited by wrapping tape around the paw, and EMG recordings of knee and ankle flexors and extensors were synchronized with kinematic data digitized from high speed cine film (200 f/s). The methods of Hoy and Zernicke (J. Biomech., 18:49-60, 1985) were used to determine paw and leg kinetics. EMG responses of the lateral gastrocnemius, tibialis anterior, vastus lateralis, and biceps femoris were recorded.**

**Weights had no significant influence on the average cycle periods, EMG onset latencies, burst durations, or on the number of paw shake cycles elicited. Angular kinematics of the weighted PSR movement demonstrated ankle and hip excursions similar to the unweighted shakes of the spinal cat, but knee movement, was disrupted as angular excursions were irregular and greatly reduced. In comparison to the unweighted PSR, the addition of mass to the paw resulted in a slight increase in the net and muscle moments at the ankle. At the knee, several factors contributed to a near-zero net moment, including a reduction of inertial terms except for an increased component due to paw angular acceleration that was effectively counterbalanced by the knee muscle moment.**

**Adding up to 46g to the cat's paw did not alter the neuromuscular patterns of the PSR; however, knee motions were markedly changed. Alterations in knee motions were not due to compensatory adjustments in the neural program, rather they emerged because of the interplay among the muscular and inertial moments that control the PSR. Supported by NIH grant NS19864.**

258.8 ACTIVITY OF RETICULAR FORMATION NEURONS DURING ACOUSTIC STARTLE IN BEHAVING CATS.

S. S. Suzuki and J. M. Siegel. V.A. Med. Ctr., Sepulveda, CA 91343 and Dept. of Psychiatry, UCLA Sch. of Med., Los Angeles, CA 90024.

In intact animals an intense acoustic stimulus elicits a startle reflex involving a phasic contraction of skeletal muscles in the whole body. Although previous lesion studies implicated the reticular formation (RF), particularly nucleus reticularis pontis caudalis (NRPC), as a critical structure mediating acoustic startle in mammals, no detailed data have been available on the activity of RF neurons during actual startle in these animals. In order to examine the role of RF neurons in startle, we have recorded RF unit activity during acoustic startle in behaving cats.

Adult female cats were implanted with mechanical microdrives containing movable bundles of 32 μm microwires into the medial ponto-medullary RF as well as EMG electrodes into three major neck muscles (splenius, biventer cervicis, complexus) bilaterally. Furthermore, three pairs of bipolar stimulating electrodes were chronically implanted into cervical cord (C2) and/or lumber cord (L1) in order to antidromically identify reticulospinal neurons. The activity of each isolated unit was observed systematically during various movements and sensory stimulation to determine its sensorimotor correlates. Unit and EMG responses to startle-inducing clicks or tone bursts (60-100 dB) were averaged by a computer.

The results may be summarized as follows. (1) Average neck EMG data indicated that the neck startle response had an onset latency of 6.5-8 ms and a duration of 5-15 ms. (2) Among the RF neurons which responded to startling stimuli, the response latency varied from 3.5 ms to more than 30 ms. Short-latency ( $\leq$ 7 ms) cells tended to cluster in NRPC. (3) Most of the responsive cells had motor correlates (neck flexion, facial movements, etc.) compatible or associated with startle. (4) Some of the antidromically identified reticulospinal cells had fast conduction velocities (about 100 m/s), short acoustic latencies (3.5-7 ms), and neck movement correlates.

In conclusion, these data support our hypothesis that certain fast-conducting reticulospinal cells normally related to neck movement act as relay neurons for the neck component of acoustic startle.

258.9 THE ROLE OF THE LOWER BRAINSTEM IN THE CONTROL OF RHYTHMICAL JAW MOVEMENTS IN THE GUINEA PIG.

S.H. Chandler, L.J. Goldberg and M. Tal. Dept. of Kinesiology and the Brain Research Institute, Univ. of Calif. at Los Angeles, Los Angeles, CA 90024.

It has been established that the basic rhythmical component of locomotion, respiration and mastication is produced by central neural networks (CPGs) which are strongly influenced by peripheral mechanisms. Based on anatomical and electrophysiological data from various laboratories the rhythmical jaw movements (RJMs) which can be induced by repetitive stimulation of the masticatory cortex in various animal species are produced by a masticatory CPG located in the brainstem. The precise location and neuronal elements which comprise this CPG have not been established. Furthermore, during RJMs the opener and closer muscles are alternately activated bilaterally. The question then arises as to whether there exists one CPG distributed between both halves of the brainstem or two functionally indepenent oscillators each residing in one half of the brainstem which are normally coupled during RJMs. The purpose of the present study was to determine in the anesthetized guinea pig with the technique of brainstem transections the elements of the lower brainstem which are essential for the occurrence of cortically induced RJMs and to what extent the integrity of both halves of the lower brainstem is critical for RJM production and bilateral activity in the jaw opener muscles.

Male albino guinea pigs were anesthetized and prepared for EMG recording from both left and right digastric muscles (jaw openers). Stimulating electrodes where inserted into both the right and left masticatory cortex to induce RJMs. The surface of the brainstem was exposed by suction ablation of the overlying cerebellum. Both midline transections and left hemisections of the lower brainstem starting at the obex were performed with a retractable fine wire knife. It was found that midline transections which extended from the obex to the rostral 1/3 of the Inferior Olivary Nucleus (I.O.) specifically abolished the ipsilateral digastric response to the repetitive cortical stimulus while leaving the rhythmical contralateral digastric response unaffected. Transections which extended between the rostral I.O and the Trigeminal motor nucleus (Mot V) completely abolished RJMs and both the ipsilateral and contralateral digastric response to the cortical stimulus. Left brainstem hemisections at the rostral I.O. and extending 2mm lateral to the midline were sufficient to abolish RJMs to stimulation of the right cortex. Under these conditions stimulation of the left cortex was capable of eliciting rhythmical activity only in the right digastric. Lesion which extended 1mm lateral to the midline which included the Nucleus Reticularis Gigantocellularis had minimal effects on RJMs. Hemisections rostral to Mot V abolished RJMs to stimulation of the left cortex but had relatively minor effects on RJMs induced by stimulation of the right cortex. Hemisections which spared the ventral quadrant rostral to Mot V had minimal effects on RJMs induced by stimulation of either left or right cortex.

These data demonstrate that the cortex of one side activates a CPG network residing in the contralateral brainstem which then coordinates bilateral digastric activity. It is suggested that the Parvocellular Reticular Formation between the I.O and Mot V contains either the CPG or output neurons of the CPG for RJMs in the guinea pig. This project was supported by NIDR-DE 06193.

258.10 LUMBAR AXIAL MUSCLE ACTIVITY IS CORRELATED WITH ELECTROENCEPHALOGRAM AROUSAL.

J. Sullivan*, S. Schwartz-Giblin and D. Pfaff (SPON: M. Schwanzel-Fukuda). The Rockefeller University, New York, New York 10021.

Under urethane anesthesia (1.2-1.4 gm/kg), rat axial motor units exhibit variable levels of spontaneous activity. The EMG activity of lateral longissimus (LL) muscle can be increased or evoked in periods of silence by stimulation of the pudendal nerve (PN) (Cohen, Soc. Neurosci. Abstr., 316: 15, 1983). We have investigated the relationship between EEG arousal, and spontaneous and evoked EMG activity, in LL of adult female Sprague-Dawley rats. LL was exposed from vertebral levels L2 through L6. Multi-unit EMG recordings were obtained with a pair of longitudinally inserted 3 cm long teflon-coated 125 μm tungsten wires bared for 1 mm at 3 points along their length. The PN was stimulated with trains of 3 or 4 pulses repeated at 2-3 Hz. Individual pulses: 200 μs duration, at 667 Hz. Stimulus currents: 50-150 μA. The EEG was recorded between two screws placed in the frontal and parietal skull bones, ipsilaterally. In 5 rats, clear and abrupt changes in EEG and spontaneous activity were analyzed. 78% (215/277) of all changes in spontaneous activity of LL EMG (active to silent or vice versa) occurred within 20 s of changes in EEG state (synchronous to desynchronous or vice versa). 76% (215/284) of all changes in EEG state occurred within 20 s of changes in spontaneous activity. Where changes in spontaneous muscle activity were associated with changes in EEG, increased muscle activity always was accompanied by EEG desynchronization, and decreased muscle activity always was accompanied by EEG synchronization. In 11 rats, PN stimulation often desynchronized the EEG within 5 s, as did tail or ear pinch. In 87% (40/46) of the cases where the PN stimulus desynchronized EEG in the absence of spontaneous LL EMG, the stimulus also evoked EMG unit activity. In these cases, unit activity was never evoked prior to EEG desynchronization. In the 15 cases where EEG was not desynchronized by the stimulus, EMG units were not evoked. In 96% (53/55) of the cases where the stimulus was applied during the desynchronous phase of the EEG, unit activity was evoked, maintained or increased by PN stimulation. Stimulation of the nucleus gigantocellularis of the medullary reticular formation is known to desynchronize EEG (Moruzzi and Magoun, 1949), and has been shown to evoke lumbar axial muscle responses at brief latencies (Femano et al., Am. J. Physiol., 246: 1984). Individual gigantocellular neurons of rat project caudally to the spinal cord and rostrally to the intralaminar nuclei of the thalamus (Scheibel and Scheibel, in Reticular Formation of the Brain, 1958). Thus, reticular activation upon pudendal nerve stimulation could facilitate subsequent lumbar axial motoneuron responses to this stimulation. (Supported by PHS Grant HD 13795).

258.11 ELECTROPHYSIOLOGY OF MOTONEURONS IN THE SPINAL NUCLEUS OF THE BULBOCAVERNOSUS IN THE RAT. W.F. Collins, III, Dept. Obstetrics and Gynecology, Yale University School of Medicine, New Haven, CT 06510.

Striated penile muscles are important for the expression of penile reflexes in male rats (Sachs, J. Reprod. Fert. 66: 433-443, 1982). The motoneurons (MN) which innervate two of these muscles, the levator ani (LA) and the bulbocavernosus, are located in the spinal nucleus of the bulbocavernosus (SNB) (Breedlove and Arnold, Science 210: 564-566, 1980). The electrophysiology of SNB MNs was examined in adult (250-400g), anesthetized (Ketamine and Xylazine; 90 and 10 mg/Kg IM respectively plus maintenance doses) male Sprague-Dawley rats using in vivo intracellular recording techniques. The left LA muscle nerve (LLAN) and dorsal penile nerve (LDPN) were isolated and placed on bipolar platinum electrodes for stimulation. In 3 experiments, right and left ventral roots (L6) were also placed on stimulating electrodes. Glass micropipettes (3M KCl; 20-50MΩ) were advanced through the dorsal column (exposed by a laminectomy (T13-S1)) to penetrate SNB MNs. The present study includes SNB MNs identified antidromically following stimulation of the LLAN as well as following stimulation of ventral root L6. The antidromic action potentials were of normal configuration as compared to those of cat hindlimb MNs and were followed by a delayed depolarization (DD) and an afterhyperpolarization (AHP). Conduction velocity was determined (conduction distance/latency) for 30 MNs and ranged from 25 to 48 m/s (mean 33.2 +/- 0.24 (SE)). SNB MN rheobase was measured as the minimun depolarizing current (50 ms duration) required to generate an action potential and ranged from 1.4 to 9 nA (mean 3.8 +/- 0.18 (SE); n = 12). SNB MN input resistance was calculated from the slope of the I-V curve using hyperpolarizing current injection and ranged from 1.4 to 2.8 MΩ (n = 3). Synaptic input to SNB MNs was examined using stimulation of the LLAN and the LDPN. Reducing the stimulus intensity applied to the LLAN to below threshold for antidromic activation of the impaled MN revealed in several cases a graded monosynaptic (by latency measurements) EPSP. In most cases, LDPN stimulation resulted in a mixed, polysynaptic (by latency measurements) EPSP/IPSP. SNB MNs on the right side of the spinal cord (identified by stimulation of the right L6 ventral root) also responded to LDPN stimulation with synaptic potentials of similar configuration and latency. The presence of LDPN input to contralateral SNB MNs could result from contralateral projection of DPN afferents (Nunez et al., Neurosci. Abstr., 9, 1983) or contralaterally projecting SNB MN dendrites (Rose and Collins, Brain Res., in press).

Support for this work was provided by NIH NS21875 and a grant from the Amyotrophic Lateral Sclerosis Society of America.

258.12 CATECHOLAMINE INNERVATION OF DENDRITE BUNDLES IN THE LUMBOSACRAL SPINAL CORD OF THE RAT. Anderson, W.J.[∓], D.L. Bellinger[+] and D.L. Felten[+]. Indiana Univ., Sch. of Med., Terre Haute Ctr. for Med. Ed., Terre Haute, IN[∓]; Dept. of Anat., Univ. of Rochester, Sch. of Med., Rochester, NY[+].

Anderson et. al. (1974) and Kerns and Peters (1974) described the morphology of 2 discrete dendrite bundles, one medial (MDB) and one lateral (LDB), in the 6th lumbar segment of the rat spinal cord. In this study, we examined these bundles and their catecholamine (CA) innervation using Golgi-Cox impregnation, fluorescence histochemistry for localization of CAs and acetylcholinesterase staining. Analysis of Golgi-Cox impregnated horizontal sections of MDB and LDB revealed fine varicose profiles that were similar to fluorescent CA fibers in size and appearance. These profiles descended in the anterior and lateral funiculi, then turned transversely, and entered the bundles at right angles. These fine varicose fibers then coursed horizontally, parallel to and sometimes in close apposition with, dendrites that formed the bundles.

CA histofluorescence of horizontal sections demonstrated a high density of varicosities within the MDB and LDB. These fluorescent fibers resembled the profiles seen in Golgi-Cox impregnated sections, as noted above. CA fibers entered the bundles perpendicular to the horizontally-oriented dendrites, and then turned rostrally or caudally to course adjacent to the dendrites. Varicosities formed pericellular rings around the motoneurons contributing to the bundles, and ran in linear arrays adjacent to the primary dendrites. The neuropil surrounding these dendrite bundles was innervated only sparsely by CA fibers, suggesting that the abundant innervation of the lumbosacral bundles is selective. A similar selective dense innervation of spinal cord dendrite bundles was noted in the cervical bundles of the rat (Bellinger et. al., Brain Res. Bulletin, in press). Alternate sections stained for specific acetylcholinesterase (AChE) demonstrated AChE-positive motoneurons and their dendrites within the bundles, and confirmed the apposition of CA varicosities with AChE-positive elements of the MDB and LDB.

The function of lumbosacral dendrite bundles remains unclear. Scheibel and Scheibel (1970) suggested that they may facilitate reciprocal activity of hindlimb muscles involved in stepping, walking and weightbearing. McKenna and Nadelhaft (1984) suggested that these bundles may subserve an excretory function in rats, as well as a possible sexual role in males. Dendrite bundles provide an ideal substrate for integration of synaptic inputs to interacting groups of homonymous and antagonist motoneurons. The presence of CA fibers adjacent to dendrites and perikarya within these bundles suggests that coordination of participating motoneurons may be regulated in part by supraspinal influences from the descending CA systems.

258.13 MORPHOLOGY OF SYNAPSES CONTACTING DISTAL DENDRITES OF NECK MUSCLE MOTONEURONS. P.K. Rose and M. Neuber*. Department of Physiology, Queen's University, Kingston, Ontario, Canada, K7L 3N6.

Much of the surface area available for synaptic contact on motoneurons is located on the dendritic tree. Indeed, a recent quantitative analysis of motoneurons innervating neck and shoulder muscles has shown that the surface areas of their dendritic trees constitute approximately 99% of the somato-dendritic surface area. Over 25% of the dendritic surface area is located more than 1,000 um from the cell body. These results emphasize the potential importance of the distal dendritic tree for the reception of synaptic inputs. Little is known however, about the morphology and density of synapses on the distal dendrites of motoneurons.

In the present experiments, neck muscle motoneurons were antidromically identified and intracellularly stained with HRP. The complete dendritic tree of one motoneuron was reconstructed from serial sections imbedded in Araldite. One group of rostrally projecting dendrites, 850 to 1,400 um from the cell body were subsequently examined at the electron microscopic level. HRP labelled dendrites were easily distinguished from the surrounding neuropil by the dense accumulation of the HRP reaction product in the cytoplasm. Each dendrite was identified by matching the location of HRP profiles seen in 0.3 um toluidene blue stained sections with the reconstructed dendritic tree.

A characteristic feature of distal dendrites is the relative paucity of synaptic contacts. Only 18% of the dendritic perimeter was contacted by boutons. The remaining membrane was enveloped by glia. Two types of synapses were identified. One contained spherical vesicles and the other contained pleomorphic or flattened vesicles. Many synapses were partially enveloped by the dendrite. Partial reconstructions using serial sections indicated that some of these synapses fitted into a trough along the dendritic shaft and thus, substantially increased the contact zone of the synapse. A preliminary examination of synapses on the cell body and proximal dendrites of two other motoneurons did not shown this specialization. Moreover, synaptic density on proximal dendrites was higher.

These studies indicate that distal dendrites of dorsal neck muscle motoneurons receive synaptic contacts. However, the density of synaptic contacts is low. If the activity of neighbouring synapses on distal dendrites and proximal dendrites is similiar, the loss of current along the dendritic path due to shunting would be less distally. Thus, the low density of synaptic contacts could significantly improve the efficacy of transmission from distal dendritic sites to the cell body. (Supported by the MRC of Canada.)

258.14 SYNAPTIC CONTACTS ON TWO POPULATIONS OF CERVICAL MOTORNEURONS IN A TURTLE, Pseudemys scripta. M.B.L. Yeow* & E.H. Peterson. Depts. of Zoology and Basic Science, Ohio University, Athens, OH 45701.

In the cryptodyran turtle, P. scripta, two populations of motorneurons (MNs) supply the cervical musculature: (1) ventral nucleus cells innervate neck muscles in a musculotopic pattern; and (2) medial nucleus cells are invariant in position (dorsomedial grey/white margin), extend dendrites into the contralateral spinal cord, and may mediate head and neck displacements in the mid-sagittal plane (Yeow and Peterson, '85a, '85b, J. Comp. Neurol., in press). Some but not all neck muscles are dually innervated by both populations of MNs. As a first step in examining the afferent circuitry of these MNs we have characterized the ultrastructure of synaptic boutons contacting ventral and medial nucleus MNs. Data were taken from spinal segment C3; each MN was sampled at 5um increments through the soma and horizontally oriented dendrites.

We have observed at least seven types of boutons contacting cervical MNs (Conradi, '69). Type S boutons bear clear, round vesicles (31-58nm) and asymmetric membrane densities. The mean length of apposition is 1.3um; variations in size, vesicle density, and ultrastructural characteristics suggest that there may be more than one morphological population of S bouton. Type F boutons bear pleiomorphic vesicles (up to 18x36nm) and thin symmetrical membrane densities ($\bar{X}$ appos. length=1.5um). M boutons resemble large S contacts ($\bar{X}$ appos. length=1.6um; vesicles 31-50um) and bear small P boutons on their convex surfaces. T boutons ($\bar{X}$ appos. length=1.7um) bear clear, round vesicles and postsynaptic dense bodies. C boutons are large ($\bar{X}$ appos. length=2um) with clear, round vesicles and a subsynaptic cistern. G boutons contain dense core vesicles (50-77nm); $\bar{X}$ appos. length= 1.3um).

The number of boutons per square um (synaptic density; Koziol & Tuckwell, '78, Br. Res. 150:617-624) was calculated for each bouton type observed in contact with MN soma, proximal, and distal dendrites. On both ventral and medial nucleus cells, the density of S and F type boutons is markedly higher than that of all other types, especially on dendrites. The density of F boutons is highest on proximal dendrites (.08 boutons/sq.um; soma-.04; distal dendrites-.03), while S bouton density increases with distance from the cell body (.03; proximal dendrites-.07; distal dendrites-.11). Ventral and medial nucleus cells differ in the relative densities of S and F type contacts: on all parts of the MN membrane, the density of S type contacts is higher on ventral nucleus cells whereas F type boutons are more dense on medial nucleus MNs. In addition, medially projecting dendrites of medial nucleus cells form chemical synapses with dendrites of unknown origin. These data suggest that ventral and medial nucleus MNs are under different patterns of synaptic drive; thus dually innervated cervical muscles may be controlled via two functionally distinct systems of motorneurons.

259.1 Effects of substance P (SP) and SP fragments on brain amine metabolism as determined by HPLC with electrochemical detection. M.E. Hall*, P. DeArmey*, M. Pelleymounter and J.M. Stewart. Dept. of Biochem., Univ. Colo. Health Sci. Ctr., Denver, and Dept. of Psychol., Univ. of Colo., Boulder, Colo.

Intraventricular (ICV) injections of substance P (SP) enhance spontaneous motor behaviors, such as hindlimb rearing and grooming, in rats (Rondeau, D., et al. Pharm. Biochem. Behav., 9: 769-775, 1978) and mice (Hall, M. and Stewart, J., Soc. Neurosci. Abstr., 10: 172, 1984). In rats, enhancement of rearing and grooming is thought to be mediated by SP's action on brain dopamine systems (Iversen, S., Substance P in the Nervous System, Pitman, 1982, 307-324). We have examined the effects, in mice, of ICV SP on levels of NE, DA, DOPAC, 5 HT and 5 HIAA in whole brain and in specific brain areas at various times after injection.

Brain tissue from peptide or vehicle-treated mice was homogenized in perchloric acid and a filtered supernatant subjected to reverse-phase HPLC on a C-18 column. Amines were quantified by a BAS electrochemical detector (+0.7V potential) and a Shimadzu integrator. Specific brain areas were removed by tissue punch from coronal sections (500 µm) of fresh frozen (-70° C) brain. Results (N=8-10/group) were analyzed by analysis of variance.

One microgram of SP (ICV) significantly alters motor behavior within 5 min. Five min. after such an injection, whole brain levels of NE and 5HT were significantly reduced. These effects were restricted to the mid- and hindbrain areas. SP also produced a significant increase in the DOPAC-to-DA ratio, suggesting an increase in DA metabolism, in the substantia nigra (SN). One hour after injection, DA was elevated and 5HT was reduced in the SN, while 5HT was also reduced in the caudate and the nucleus accumbens. A significant decrease in the 5HIAA-to-5HT ratio was observed in prefrontal cortex at 1 hr. At 24 hr. post injection, 5HT and DA were elevated in the caudate and the 5HIAA-to-5HT ratio was elevated in SN.

Amino (N-) and carboxy (C-) terminal fragments of SP have been shown to exert opposite effects on some motor behaviors (Hall & Stewart, ibid). The effects of N- and C-terminal fragments on brain amine levels were therefore examined. Opposite effects of these peptides on brain amine levels were also observed. For example, the N-terminal heptapeptide significantly increased, while the C-terminal hexapeptide significantly reduced, the 5HIAA-to-5HT ratio in the SN 1 hr. after injection.

These and other results will be presented, and discussed with regard to their possible causal relationship(s) to the effects of these peptides on motor behavior.

259.2 NEUROMEDIN N MIMICS THE ACTION OF NEUROTENSIN IN THE VENTRAL TEGMENTAL AREA BUT NOT IN THE NUCLEUS ACCUMBENS. P.W. Kalivas* and R. Richardson-Carlson* (SPON: R.C. Speth). Dept. of VCAPP, Washington State University, Pullman, WA 99164

Upon injection into the central nervous system of rodents neurotensin (NT) has been shown to produce many "neuroleptic-like" effects, including blockade of the motor stimulant effect of intra-accumbens injection with dopamine (DA). Paradoxically, injection with NT into the ventral tegmental area (VTA) produces an increase in mesolimbic DA turnover and corresponding behavioral hyperactivity. Neuromedin N (NN) was recently characterized in porcine spinal cord as a hexapeptide having a four amino acid homology with the C-terminus of NT. Since the six amino acid fragment of NT that contains the C-terminus demonstrates equivalent biological activity to the parent compound, we examined whether NN has biological activity in some of the centrally-mediated effects of NT.

Male S.D. rats were implanted with chronic bilateral injection cannulae over the VTA or nucleus accumbens. One week after surgery, either NN, NT or sterile saline vehicle was microinjected into the VTA at various doses in 0.2 µl/side over 60 sec. After injection the rats were placed in a photocell apparatus and motor activity monitored for 120 min. NN produced a significant increase in motor activity with a threshold dose between 0.03 and 0.1 nmole/side. The threshold dose for NT was between 0.33 and 1.0 nmole/side. To determine if NN was also more potent at increasing mesolimbic DA turnover, rats were given intra-VTA injection with saline or 0.33 nmole/side of either NN or NT, decapitated 60 min later, and DA and its metabolites were measured in the nucleus accumbens using HPLC-EC. At this dose, both NN and NT produced an equivalent increase in the levels of DA metabolites. In a second study, either NT, NM, NM + DA, NT + DA or saline was injected into the nucleus accumbens in a volume of 0.5 µl/side over 60 sec. Following injection, the rats were placed in a photocell apparatus. At a dose of 1.0 nmole/side, NT completely abolished the effect of DA (30 µg/side), while the equivalent dose of NN was totally ineffective.

These data show that NN produces a similar effect to NT in the VTA, but does not share the "neuroleptic-like" qualities of NT in the nucleus accumbens. While these data are suggestive of separate receptors for NN and NT in the brain, we are currently characterizing the NN receptor to directly evaluate this hypothesis.

259.3 DISSOCIATION OF TOLERANCE AND DEPENDEENCE TO MORPHINE: A POSSIBLE ROLE FOR CHOLECYSTOKININ. P.Sacerdote*, P.Mantegazza*; L.C.Rovati*, and A.E.Panerai. Dept. Pharmacology, Chemotherapy and Medical Toxicology, School of Medicine, Univ. of Milano, 20129 Milano, Italy. (Spon. L.M.Vicentini)

Proglumide, a cholecystokinin receptor antagonist, potentiates morphine induced analgesia, and reverses tolerance to morphine experimentally induced in the rat by means of short term (14 hrs/6 days) parenteral treatment with the opiate.

In the present study we looked at the effects of the concomitant administration of morphine and proglumide on the development of tolerance during long term administration of the opiate, similarly to what happens in clinical practice.

Moreover, we looked at the effects of proglumide on the development of dependence.

Drugs were administered either orally dissolved in drinking water, parenterally or orally.

Under all experimental conditions the concomitant administration of morphine and proglumide inhibited the development of tolerance to the analgesic effect of the opiate.

However, proglumide did not prevent the withdrawal syndrome induced by the administration of naloxone as evaluated by either graded (e.g. wet dog shakes, self stimulation, writhing), quantal (e.g. diarrhea, teeth chattering, irritability to touch) signs, and body weight decrease.

Our data induce to confirm the hypotheses that a cholecystokinin like peptide might play a role in the development of tolerance to morphine and that proglumide might induce the effects we showed through an inhibition of cholecystokinin.

In order to further evaluate these possibilities, studies are in progress with other substances that show in in vivo and in vit studies a cholecystokinin antagonistic activity 500/600 folds that of proglumide.

Acknowledgements

We thank Rotta labs., Monza, Italy for proglumide and otheer anticholecystokinin compounds.

259.4 EFFECT OF PENTYLENETETRAZOL (PTZ) KINDLED SEIZURES ON TRH LEVELS IN SPECIFIC AREAS OF THE RAT BRAIN. M.J. Kubek and S.L. Morzorati. The Regenstrief Institute and Departments of Anatomy and Psychiatry, Indiana University School of Medicine, Indianapolis, IN 46223.

Thyrotropin-releasing hormone (TRH) has been demonstrated to exist in extrahypothalamic sites where it may function as a neurotransmitter and/or neuromodulator. Recent studies in our laboratory have shown TRH to be elevated in specific limbic and cortical structures from 2 to 12 days after generalized seizures were induced by either electrical kindling (Neurosci. Abstr., 9:485, 1983) or electroconvulsive shock (ECS) (Life Sci., 36:315-320, 1985 and this meeting). The pattern of TRH elevation seen following kindling is similar to that observed with ECS. In order to extend these studies and to rule out a possible direct electrical effect on TRH, the present investigation examined the effect of chemical kindling on the TRH response. Male Wistar rats (250-270g) were injected once daily with a subconvulsant dose of PTZ (20mg/kg; ip). An animal was considered fully kindled after having stage-5 seizures on 3 consecutive days. This process took 20 +/- 4 days. A control group was treated identically with saline. After kindling, controls and experimentals were injected with either saline or PTZ (20 mg/kg) once a month for 6 months. The last treatment was given 48hrs prior to decapitation and the kindled subjects had stage-5 seizures within 30 min. Brains were removed, quickly dissected into 8 regions and frozen on dry ice. Tissues were extracted with HAc and TRH was quantitated by a specific and sensitive radioimmunoassay. TRH content was expressed as pg/mg wet weight (mean +/- SEM). Of the regions thus far examined, chemical kindling induced a marked increase in TRH in the Amygdala (40.85 +/- 2.2 vs 66.21 +/- 6.6; $p < 0.005$) and a 6-fold elevation in the Pyriform Ctx. (6.52 +/- 0.93 vs 30.36 +/- 2.79; $p<0.001$). These preliminary results are consistent with those seen with electrical kindling and ECS and thus rule out a possible direct electrical effect on the TRH response to seizures. These data further support the concept that endogenous TRH may be involved in the pathophysiology of epilepsy. Supported by the Veterans Administration Research Service and NIADDK AM-28260 (M.J.K.).

259.5 **EFFECT OF INHIBITORS OF MEMBRANE-BOUND METALLOENDOPEPTIDASE "ENKEPHALINASE" ON NEURONAL ACTIVITY IN THE SUBSTANTIA NIGRA OF THE RAT.** M.J.Bier*, J.Goldfarb, M Orlowski and S.Wilk.Depts.of Pharmacology and The Neurobiology Program*,Mt.Sinai School of Medicine, New York, NY 10029.

In rat brain the highest concentrations of substance P (SP) and enkephalins (ENK) are found respectively in the caudato-putamen (CP) and globus pallidus. A major target of this peptidergic outflow is the substantia nigra (SN).The metallo-endopeptidase (EC 3.4.24.11), has its highest activity in the SN and CP and was shown to be identical with the enzyme commonly refered to as "enkephalinase" (Almenoff,J. et.al.BBRC 120: 206,1981).The metalloendopeptidase degrades both ENK and SP and has a higher affinity for SP than for ENK. Inhibition of EC 3.4.-24.11 terminates the hydrolysis of SP in a preparation of striatal synaptosomal membranes (Fulcher,I.et.al. Biochem.J.203:519, 1982). Several specific inhibitors of the enzyme have been synthesized including N-(1-(R,S)-carboxy-3-phenylpropyl)-Phe-pAB (PP) and N-(1-(R,S)-carboxy-2-phenylethyl)-Phe-pAB (PE)(Almenoff,J.and Orlowski,M.Biochem.,22:590,1983). We used these inhibitors in vivo to explore their effects on the electrical activity of cells in the SN.

Male Sprague-Dawley rats, anesthetized with urethane, were secured stereotaxically for recording. Electrical stimulation of the left CP at, or rostral to, the anterior commissure was used to evoke responses in the SN. Extracellular recordings were made ipsilateral to the stimulus in both the SN compacta (SNc) and the SN reticulata (SNr). Inhibitors were infused into the right lateral ventricle at a rate of 1uM in 10min.

Responses evoked in the SN were either excitatory, mixed excitatory/inhibitory, or purely inhibitory. The cells which showed an excitatory component (+) responded to the inhibitor treatment with an increase in their spontaneous firing frequency 15-50% above baseline. Those cells whose evoked responses were inhibitory (-) evinced no response to the inhibitors. Similar results were obtained with PE($Ki=3.9x10^{-7}$) and PP($Ki=3.7x10^{-7}$). Both SNc and SNr cells responded to the drugs. Maximum firing frequency was observed 15-20 min after termination of the infusion. The inhibitors did not induce any unusual patterning in the SN units.

Inhibitors of the enzyme prolyl-endopeptidase (Wilk,S.Life Sci. 33:2149,1983),a cytosolic enzyme which also degrades SP in vitro, did not affect the firing of (+) or (-) cells in any reproducible manner.

These results are consistant with the idea that the membrane bound metalloendopeptidase is involved in regulating the activity of an excitatory peptide in the SN.

Supported by grants AM-25377,NS-17392 and MH-00350

259.6 CORTICOTROPIN RELEASING FACTOR (CRF): CENTRAL NERVOUS SYSTEM (CNS) SITE OF ACTION. M.R. Brown. Clayton Foundation Laboratories for Peptide Biology, The Salk Institute, La Jolla, CA 92037

CRF administered to rats by either intraventricular or intracisternal routes elevates plasma concentrations of epinephrine and norepinephrine and increases mean arterial pressure and heart rate. Based on the existing knowledge of CRF-like peptide and receptor distribution in the brain and of the CNS areas suspected to be involved in the regulation of the autonomic nervous system, studies have been performed to identify the CNS site(s) of action of CRF to increase plasma concentrations of epinephrine and norepinephrine. Experiments were performed in conscious rats equipped with right atrial and brain ventricular and parenchymal cannulae (28 gauge). Peptide or vehicle was administered in 100 nl volumes over 30 seconds. Cannulae placements were determined histologically. A dose response to CRF administered into the third ventricle demonstrated that 200 pmoles of peptide elicited a significant submaximal elevation of plasma concentrations of epinephrine and norepinephrine. CRF (200 pmoles) administered into the lateral, third and fourth ventricles or cisterna magnum produced similar elevations of plasma catecholamines. CRF (200 pmoles) was microinjected into more than 100 different brain areas; no correlation was found between the magnitude of the elevation of plasma catecholamines following CRF injection and the reported distribution density of CRF-like peptides and receptors in these areas. Significant elevations of plasma concentrations of catecholamines were observed in animals with injections of CRF into brain areas beginning rostrally at the anterior hypothalamus extending caudally into the brain stem; no sites within this zone appeared more responsive than another to CRF administration. The magnitude of elevation of plasma catecholamines following CRF injection into various brain areas did not depend on the proximity to surrounding ventricular structures.

The results of this study support the concept that CRF acts through brain receptors ranging through a long rostral-caudal extent. Although brain areas were identified to be unresponsive to CRF e.g. striate cortex, caudate-putamen, olfactory bulb and peoptic and septal areas, no apparent single site of action of CRF could be determined.

259.7 **5β-METABOLITES OF PROGESTERONE STIMULATE LHRH RELEASE FROM THE RAT HYPOTHALAMUS SUPERFUSED IN VITRO.** K.Kim, O.Park* and V.D. Ramirez. Department of Physiology and Biophysics, University of Illinois, Urbana, IL 61801.

Previous works using prepuberal ovariectomized, estradiol-primed (OVX+E) rats have shown that progesterone can stimulate LHRH release from in vitro hypothalamic preparations.

The present study examined the effect of 5β-metabolites of progesterone on in vitro LHRH release from hypothalamic fragments from OVX+E adult rats. The hypothalamic fragments including preoptic area, suprachiasmatic nucleus, anterior hypothalamic area and mediobasal hypothalamus (POA-SCN-MBH) were placed in a superfusion chamber (one unit/chamber) and superfused with modified Krebs-Ringer phosphate medium (pH 7.40). After 1-hr equilibration period, perfusate samples were collected on ice at 10 minute intervals for 3 to 3.5 hrs. Progesterone, pregnanolone and epipregnanolone were infused in either an intermittent (10-min on, 20-min off) or continuous mode. LHRH concentrations were determined by a sensitive and specific radioimmunoassay. Intermittent infusion of progesterone (10 ng/ml but not 1 ng/ml) stimulated in vitro LHRH release. Interestingly, much lower doses of pregnanolone (0.01 mg/ml) also stimulated in vitro LHRH release when infused in an intermittent mode. This release was characterized by two distinct peaks with the initial peak triggered approximately one hr following infusion. Mean LHRH release (X±SE, n=5) induced by an intermittent infusion of pregnanolone was significantly ($<0.05$) higher than its preinfusion values and that of control group (1.56±.21 vs .80±.04 and .87±.07 pg/10 min). In contrast, continuous infusion of pregnanolone did not evoke in vitro LHRH release, but rather decreased it. Similar results were observed when epipregnanolone, another 5β-metabolite, was infused in an intermittent mode.

These data clearly demonstrated that intermittent, but not continuous infusion of 5β-metabolites of progesterone are highly effective in stimulating in vitro LHRH release from hypothalamic fragments of OVX+E primed adult rats, within an order of potency approximately 1000-fold greater than progesterone. These results suggest that 5β-metabolites of progesterone are important signals in controlling the neural LHRH apparatus.

259.8 CENTRAL THYROTROPIN-RELEASING HORMONE INDUCES SYSTEMIC HYPOGLYCEMIA IN MICE. S. Amir, A.I. Rivkind* and M. Harel*. Dept. of Isotope Research, Weizmann Institute of Science, 76100 Rehovot, Israel.

Thyrotropin-releasing hormone (TRH, pGlo-His-Pro-$NH_2$), injected centrally, has profound and varied autonomic effects which are independent of its endocrine functions. For example, central TRH increases blood pressure, heart rate and respiratory rate, stimulates gastric acid secretion and enhances gastro-intestinal motor activity. In rats, central TRH also elicits systemic hyperglycemia which is mediated by release of adrenal medullary catecholamines and pancreatic glucagon. In the present study, intracerebroventricular (ICV) microinjection of TRH (1-10 µg) in mice produced powerful long lasting (> 3h) hypoglycemia as well as antagonized the rise in plasma glucose produced by systemic injection of epinephrine (50 µg), glucagon (50 µg), 2-deoxyglucose (500 mg/kg), apomorphine (5 mg/kg), clonidine (0.25 mg/kg) or morphine (5 mg/kg). The insulin-like hypoglycemic effect of central TRH could be reproduced by ICV injection of acid TRH (pGlu-His-Pro-OH, 10 µg), a metabolite of TRH lacking hypophysiotropic influences, as well as by the neuroactive TRH analog, γ-butyrolactone-γ-carbonyl-His-Pro-$NH_2$ (DN-1417, 10 µg), but not by another TRH metabolite, cyclo [His-Pro] (1-10 µg) or two structurally related peptides, pGlu-His-Gly-$NH_2$ and pGlu-His-Trp (1-10 µg). The centrally-mediated hypoglycemic effect of TRH was blocked by pretreatment with the muscarinic cholinergic antagonist atropine methyl bromide (1 mg/kg S.C.), which selectively inhibits peripheral parasympathetic activity or by the administration of the cytotoxic compound alloxan (100 mg/kg), which destroys insulin producing beta cells in the pancreas. Disruption of sympathetic effector mechanisms by pretreatment with the ganglionic blocker chlorisondamine chloride (10 mg/kg) or the adrenergic receptor antagonists phentolamine and propranolol (10 mg/kg) had no effect on the hypoglycemic response to central TRH. The results indicate that in mice TRH acts in the brain to elicit a cholinergic (parasympathetic)-mediated insulin-dependent glucoregulatory response which can diminish the normal plasma glucose concentrations as well as antagonize the hyperglycemia produced by compounds that stimulate endogenous glucose production. The results support the concept that TRH in the brain may play a role in the central regulation of glucose homeostasis.

259.9 INTRACISTERNALLY ADMINISTERED OXYTOCIN PRODUCES HYPERTHERMIA AND ANALGESIA IN MICE. G.A. Mason*, J.D. Caldwell*, O.H. Hatley*, D.A. Stanley*, A.J. Prange, Jr. and C.A. Pedersen. (SPON: M.A. Lipton) Biological Sciences Research Center, Department of Psychiatry and the Neurobiology Curriculum, University of North Carolina at Chapel Hill, NC 27514

Both elevated colonic temperatures and increased analgesic responses were observed in adult male Swiss Webster mice 30 min after intracisternal (I.C.) administration of oxytocin (OXY).

For thermoregulatory studies, Mice were acclimated for one hr in individual Plexiglas cages without bedding at an ambient temperature of 22°C. They were injected with OXY and/or equimolar amounts of neurotensin (NT), bombesin (BOM), arginine vasopressin (AVP) or the 0.9% saline vehicle. Colonic temperatures were recorded at 0, 30, 60, 90 and 120 min postinjection. A dose of 1 or 4 μg of OXY significantly ($p < 0.01$) increased colonic temperature after 30 min (Dunnett's T versus vehicle = 3.7 and 4.3 for 1 and 4 μg, respectively, d.f. = 12). Simultaneous I.C. administration of 2 μg OXY also significantly ($p < 0.05$) attenuated the hypothermia produced at 30 or 60 min by equimolar amounts of NT or BOM (Tukey's Test for Multiple Comparisons). The temperature effects of OXY (4 μg) and an equimolar dose of AVP (which also produced a hyperthermic response) were not additive when the two peptides were given simultaneously. An intraperitoneal (I.P.) injection of indomethacin (5 mg/kg) failed to block the hyperthermic response of OXY (1 μg), thereby indicating that the effect was not dependent on release of prostaglandins.

Centrally administered OXY also produced a positive response in the hot plate analgesia test. Mice were placed on an enclosed copper plate set at a temperature of 52.5 ± 0.5°C, and the time elapsed before the animals jumped or licked their paws was recorded. Animals were removed after such responses or after 30 sec if they had not responded. Each mouse was tested just prior to peptide administration and at 30, 60, 90 and 120 min postinjection. OXY (1 or 4 μg) produced a significant ($p < 0.05$) analgesic response at 30 min (Tukey's Test for Multiple Comparisons). This response was not blocked by naloxone (5 mg/kg) administered I.P. 30 min before I.C. OXY.

259.10 Thymosin stimulates hormone secretion from AtT20 mouse corticotropic tumor cells. J.M.Farah, Jr., J.F.Bishop, J.P. McGillis, N.R. Hall, A.L. Goldstein* and T.L.O'Donohue. Experimental Therapeutics Branch, NINCDS, NIH Bethesda, MD 20205 and Department of Biochemistry, George Washington University School of Medicine, Washington, DC 20037

A number of neuroendocrine regulators are known to govern the secretion of pro-opiomelanocortin (POMC) peptides (e.g., ACTH and β-endorphin) from corticotrophs of the anterior pituitary. Recently, thymosin fraction 5 (TSN-5), a family of thymic peptides, was found to activate the pituitary-adrenocortical axis in primates as determined by its ability to elevate blood levels of immunoreactive ACTH, β-endorphin and cortisol (Healy et al, 1983, Science 222:1353). In order to determine if TSN-5's ability to increase POMC secretion is mediated through direct stimulation of corticotrophs, we studied the effects of TSN-5 on secretion of immunoreactive β-endorphin (iβ-E) by the AtT-20 mouse corticotrophic tumor.

AtT20/D16-16 cells were grown in Dulbecco's Modified Eagle's Medium fortified with fetal bovine serum and antibiotics. Levels of iβ-E in release medium was measured by radioimmunoassay using a rabbit antiserum (C-55) provided by Dr. Gregory Mueller which detects β-E and its immediate precursor, β-lipotropin, equally well. Release of iβ-E was increased relative to control within 15 min after exposing AtT-20 cells to 200 μg/ml of TSN-5 (4.4 ± 0.5 vs 3.1 ± 0.1 ng/ml, mean ± SEM, n=6) and elevated release was observed up to 4 hrs after treating the cells with TSN-5. Under present conditions, doses of TSN-5 between 0.06 and 60 μg/ml had no effect on basal secretion of iβ-E nor on release evoked by moderate (1 nM) to high doses (0.1 μM) of rat corticotropin releasing factor (CRF). TSN-5 (600 μg/ml) and CRF (0.1 μM) separately increased release of iβ-E to 148% and 221%, respectively, of control levels (16.5 ± 1.7 ng/ml in 4 hrs, n=7) and together evoked an additive increase in hormone release. The additive effects of doses of TSN-5 and CRF which alone cause near maximal secretion of hormone indicate that actions of TSN-5 may occur by mechanisms independent of cyclic adenosine monophosphate, the second messenger which mediates CRF stimulation of corticotrophic cells. The present results are consistent with recent findings that TSN-5 stimulates ACTH release in primary cultures of rodent anterior pituitary (McGillis et al, 1985, Fed Proc 44: 3428A) and, together, suggest that a thymic derivative may join the list of substances with releasing activity on corticotrophs. The identity of the active peptide(s) in TSN-5 and its mechanism for stimulating POMC secretion in the mouse corticotrophic tumor is presently under investigation.

259.11 CENTRAL EFFECTS OF AN ANTISERUM AND AN ANTAGONIST TO SUBSTANCE P ON GONADOTROPIN, AND PROLACTIN SECRETION IN THE RAT. Carl W. Skelley, W. Les Dees and Gerald P. Kozlowski. Department of Physiology, University of Texas Health Science Center at Dallas, Dallas, Tx 75235.

Intraventricular administration of substance P (SP) to laboratory animals has been shown to cause an increase (Vijayan and McCann, Endo., 105:64, 1979) or a decrease (Eckstein et al., Neuroendo., 31:338, 1980) in serum LH with no change in serum FSH levels. Additionally, reports have been conflicting as to whether an intraventricular injection of SP causes an increase (Vijayan and McCann, Endo., 105:64, 1979) or has no effect (Chihara et al., Endo., 102:281, 1978; Maeda and Frohman, Endo., 103:1903, 1978) on PRL secretion. SP-analogues having antagonistic properties, as well as antisera to SP have been widely used in the evaluation of possible roles of this peptide in physiology. If indeed these substances are truly antagonists, then their experimental use could provide additional information to aid in determining whether or not SP plays a central physiological role with regard to gonadotropin and PRL secretion. In this regard, we have studied the central effects of both of these substances on gonadotropin and prolactin (PRL) secretion using castrated male rats. A lateral ventricular injection of an analogue to SP having antagonistic properties caused significantly lower serum LH levels without altering serum FSH and PRL when compared to saline-injected controls. Similarly, a lateral ventricular injection of anti-SP also resulted in significantly lower levels of LH when compared to control animals injected with normal rabbit serum. Additionally, no changes were observed in the levels of serum FSH and PRL as a result of the anti-SP injection. These results support the hypothesis that SP may have a central stimulatory action on LH secretion, but not on FSH and PRL secretion.

259.12 MULTIPLE FACTORS REGULATE THE RELEASE OF ATRIAL NATRIURETIC PEPTIDES FROM THE CARDIAC ATRIA. N. Zamir,* R.L. Eskay,* M. Haass,* J.R. Dave,* H. Keiser,* and Z. Zukowska-Grojec.* (SPON: J.W. Bigbee) Lab. of Clin. Science, NIMH; Lab. of Clin. Studies, DIR., NIAAA; Hypertension-Endocrine Branch, NHLBI; NINCDS; N.I.H., Bethesda, Md. 20205. U.S.A.

Evidence suggests that the mammalian atrium is an endocrine organ that may be involved in the control of blood pressure and extracellular fluid volume. A group of peptides, which appear to be associated with atrial-specific secretory granules, have potent natriuretic, diuretic and smooth muscle relaxant activities. These atrial peptides are termed atrial natriuretic peptides (ANPs), and have been shown to be derived from a common precursor. The results of several studies suggest a hormonal role for the ANPs. Utilizing an antiserum which recognizes rat alpha-ANP (3-28) alpha-ANP(5-28), alpha-ANP(5-27) and alpha-ANP(5-25) on an equimolar basis, we have determined immunoreactive (IR) levels of ANPs in rat plasma. Blood samples were obtained from conscious, unrestrained rats with indwelling arterial catheters and aliquots of plasma were extracted for ANPs with approximately an 80% recovery. Characterization of IR-ANPs present in extracted plasma by high performance liquid chromatography revealed two major peaks. The elution profile of these peaks suggests that they correspond to alpha-ANP (3-28) and alpha-ANP (5-28). Basal plasma concentrations of IR-ANPs in male Sprague-Dawley rats were 125 ± 12 pg/ml (Mean ± SEM, N=6). Acute volume load (intravenous infusion of 20 ml of 5% glucose/kg body weight over 1 min.) increased IR-ANPs 5-6 fold in plasma within 2 minutes. Similarly, infusion of 1 ml of hypertonic saline (3mEq NaCl) over 2 min. increased plasma levels of IR-ANPs 5-6 fold within 2 minutes. Ganglionic blockade with chlorisondamine, (10 mg/kg, IV) resulted in a 2-3 fold increase in plasma ANPs within 15 minutes. Our findings indicate that distension of the atria and osmotic stimulus enhance the release of ANPs and that the neural integrity of the heart is important for ANPs release from the cardiac atrium.

259.13 DECREASED CENTRAL ANGIOTENSINERGIC AMINOPEPTIDASE ACTIVITY IN SPONTANEOUSLY HYPERTENSIVE RATS. J.W. Wright, T. M. Woods*, D.L. Rochelle*, S. J. King* and J.W. Harding. Departments of Psychology and Veterinary and Comparative Anatomy, Pharmacology and Physiology, Washington State University, Pullman, WA 99164-4830.

Intracerebroventricular injections of angiotensin antagonists are differentially effective at lowering blood pressure in spontaneously hypertensive (SH) rats as compared with Wistar-Kyoto (WKY) control rats (Ganten et al., 1975; Phillips, 1980, 1983; Phillips et al., 1975; Sweet et al., 1977). And stroke prone SH rats reveal increased electrophysiological sensitivity to centrally applied angiotensin II (AII; Schnelling and Felix, 1983), and a greatly prolonged response of subfornical organ neurons in SH rats to microiontophoretically applied AII (Felix, personal communication).

Recent studies from our laboratory have also indicated enhanced and prolonged pressor responsiveness of SH rats to intracerebroventricularly applied AII and angiotensin III (AIII), consistent with the notion that SH rats are more sensitive to intracerebroventricular angiotensins. Additional rats were prepared with intracerebroventricular cannulas and were injected with [$^{125}$I]AII or [$^{125}$I]AIII and their brains were microwave irradiated to stop peptidase activity at intervals ranging from 5 through 60 seconds. The SH rats were found to have longer angiotensin survival times compared with WKY and Sprague-Dawley control animals as determined by High Performance Liquid Chromatography analyses suggesting an impairment in the ability of ventricular membrane-bound peptidases to metabolize angiotensin. Membrane-bound peptidases were implicated because incubation of these ligands in freshly collected cerebrospinal fluid from SH, WKY and Sprague-Dawley rats resulted in nondifferential delayed metabolism with approximately 91 and 52% of the [$^{125}$I]AII and [$^{125}$I]AIII respectively, remaining intact after 90 minutes at 37° C. In addition the supersensitivity of intracerebroventricularly injected angiotensins was observed to increase following pretreatment with the nonspecific aminopeptidase inhibitor, bestatin, in members of all three strains.

These results support the hypothesis that SH rats may have a dysfunction of angiotensin receptor associated peptidases which is evidenced as an impairment in angiotensin signal termination, thus resulting in sustained elevations in blood pressure.

Supported by NIH Grant HO2550, the American Heart Association, and the American Heart Association of Washington.

259.14 PRESSOR EFFECTS OF PERIPHERALLY INFUSED ANGIOTENSIN II AND III IN THE CONSCIOUS RABBIT. M. J. Sullivan, R. H. Abhold, J. W. Harding and J. W. Wright. Departments of Psychology and Veterinary Comparative Anatomy, Pharmacology, and Physiology, Washington State University, Pullman, WA 99164.

Binding studies utilizing [$^{125}$I] AII and AIII reveal a distribution of receptors in the rabbit brain similar to that seen in primates (Wright, Sullivan, Peterson and Harding, in prep). The majority of sites bind [$^{125}$I] AIII; relatively few AII sites are seen. These observations suggested that the rabbit might be an appropriate primate model as opposed to the rat which has proportionately more AII binding in the brain.

In the present study, mature male New Zealand rabbits were adapted to a restrainer daily for two weeks and were next accustomed to the insertion of an infusion needle in the marginal ear vein and a second needle in the central ear artery of the opposite ear for monitering blood pressure. Comparisons were made of pressor responses to 5 min of peripherally infused doses of AII and AIII. Doses of 1 and 10 pmol/kg/min AII and AIII were equipotent and had minimal effect on mean arterial blood pressure (MAP). At doses of 100 pmol/kg/min, AIII yielded 52% the pressor activity of AII. Radioimmunoassay (RIA) of angiotensins levels in blood samples taken during infusion of 100 pmol/kg/min AIII indicated 53% as much angiotensin as during infusion of an equimolar dose of AII. The antibody used in the RIA was cross reactive between AII and AIII and values represent the combined levels of the two peptides. During infusions of 500 pmol/kg/min, AIII yielded 64% the pressor response and 67% the plasma angiotensin level seen during infusion of AII. The half-life of AII is nine seconds as is the half-life of AIII. Since AII is converted to AIII, it has an effective half-life of 18 seconds, while aminopeptidases cleave AIII to an inactive form. Therefore during an infusion of AII, more ligand is available to interact with receptors. Our results suggest that AIII is at least as potent as AII with regard to pressor responses.

| Infusant | | Maximum Pressor Response from Baseline (mm Hg) | Plasma angiotensin (pg/ml) |
|---|---|---|---|
| 100 pmol/kg/min | AII | 24.6 | 117.7 |
| | AIII | 12.9 | 62.6 |
| 500 pmol/kg/min | AII | 44.7 | 287.5 |
| | AIII | 28.4 | 191.3 |

259.15 CARDIOVASCULAR EFFECTS OF CALCITONIN GENE-RELATED PEPTIDE IN THE PITHED RAT: COMPARISON WITH SUBSTANCE P. M. Haass*, I.J. Kopin, D.M. Jacobowitz, Z. Zukowska-Grojec* and G. Skofitsch*. Sec. of Pharmacology, NINCDS; Lab. of Clinical Science, NIMH, NIH, Bethesda, MD 20205.

Alternative processing of the primary transcript of the rat calcitonin gene has resulted in a novel 37 amino acid peptide, calcitonin-gene related peptide (CGRP). Immunohistochemical studies have shown that CGRP is located in central and peripheral nerve endings especially of primary sensory neurons. CGRP-staining was also observed in thin fibers associated with the smooth muscle of blood vessels and with the heart. Recently we found that CGRP coexists with substance P (SP) in cell bodies of sensory neurons of the trigeminal and the dorsal root ganglia. Since CGRP affects cardiovascular function in conscious rats, we compared the vasodepressor and the plasma extravasating activities of CGRP with those of SP in pithed vagotomized ratsto evaluate direct cardiac and vascular effects without interference of centrally mediated circulatory reflexes. Systemic administration of CGRP (0.1-10.0 μg/kg) evoked a dose-dependent, long-lasting vasodilation with a peak effect after 1 minute. High doses of CGRP also caused a tachycardiac response which was not blocked by pretreatment with the beta-adrenoceptor antagonist, propranolol (2 mg/kg, i.v.), suggesting a direct positive chronotropic action of CGRP. No significant change in heart rate was observed following SP administration (0.1-10.0 μg/kg, i.v.). For any given dose duration and degree of the hypertensive effect of SP was much smaller than that of CGRP. After either CGRP or SP, there was a more pronounced decrease in mean arterial pressure (MAP) after elevation of the basal blood pressure levels by constant infusion of phenylephrine (3 μg/kg/min.,i.v.):

| | (n) | dose (μg/kg) | MAP ± SEM (mm Hg) C | 1 min | 3 min |
|---|---|---|---|---|---|
| CGRP | (7) | 0.3 | 103.1 ± 3.8 | 92.9 ± 2.6* | 100.6 ± 2.7 |
| | | 1.0 | 104.9 ± 3.4 | 76.1 ± 3.5** | 90.6 ± 3.4* |
| | | 3.0 | 109.0 ± 2.4 | 71.0 ± 4.0*** | 83.7 ± 4.8** |
| SP | (7) | 0.3 | 111.1 ± 6.1 | 111.4 ± 5.0 | 111.7 ± 4.8 |
| | | 1.0 | 103.9 ± 4.1 | 90.1 ± 4.0* | 101.6 ± 4.1 |
| | | 3.0 | 108.3 ± 3.1 | 89.0 ± 3.6* | 97.7 ± 2.5 |

(*$p < 0.05$, **$p < 0.005$, ***$p < 0.001$ compared to respective C.)

Plasma extravasation was measured by the Evans blue technique. CGRP (30 μg/kg, i.v.) showed only a 4-6 fold increase in plasma extravasation whereas equimolar doses of SP (10 μg/kg, i.v.) caused a 20-30 fold increase in plasma extravasation (nasal mucosa, conjunctiva, ureter, trachea). In conclusion, at equimolar doses CGRP is 10 times more potent than SP in producing vasodilatation whereas it causes only a modest plasma extravasation compared to SP.

259.16 CARDIOVASCULAR EFFECTS PRODUCED BY MICROINJECTIONS OF ATRIAL NATRIURETIC FACTOR (ANF) INTO THE AV3V REGION OF THE RAT BRAIN. M. A. Sills and D. M. Jacobowitz. Laboratory of Clinical Science, NIMH, Bethesda, MD 20205.

During the past few years, increased attention has focused on a new class of peptides referred to as atrial natriuretic factor (ANF), which was initially discovered in extracts from atrial tissue. Studies have shown that ANF possesses potent natriuretic and diuretic activity. In addition, ANF produces vasodilatation resulting in decreased blood pressure. Recent studies have reported that ANF-containing neurons exist in rat brain (Neuroendocrinology, 40: 92, 1985). Of particular interest was the finding that the greatest density of cells was located in the anteroventral third ventricle (AV3V) area of the brain. This region of the brain is currently thought to play a major role in blood pressure regulation, fluid and electrolyte balance. Based on these findings, we were interested in examining the effect of microinjections of ANF into the AV3V region of the brain to determine whether it may play a role in cardiovascular regulation.

In the present study, 50-100 nanoliters of saline or atriopeptin III (2-40 pmol) was injected into the rostral portion of the preoptic suprachiasmatic nucleus (posc) using a double-barreled glass micropipette. Rats were initially injected with saline, followed by ANF 30 minutes later. The results indicate that injections of 2 or 4 pmol of ANF elicit a modest rise in systolic and diastolic pressures, and a small increase in heart rate (HR). Specifically, 4 pmol ANF produced significantly greater effects than saline on systolic, diastolic and mean arterial blood pressures (BP). These values were increased over baseline values by 16 ± 2 (14%), 10 ± 2 (14%), and 12 ± 2 (14%) mm Hg, respectively, by ANF. HR was moderately increased by 26 ± 6 (7%) beats per minute (bpm) by this concentration of ANF. In contrast to these results, higher concentrations of ANF (20-40 pmol) produced substantial increases in both BP and HR. Injection of 20 pmol of ANF into the posc produced significantly greater effects than saline on systolic, pulse and mean arterial pressures, as well as on HR. These values were increased with respect to baseline values by 18 ± 3 mm Hg (15%), 12 ± 3 mm Hg (25%), 10 ± 1 mm Hg (12%), and 74 ± 10 (22%) bpm, respectively, by ANF. Injections of 50-100 nl of saline into the posc produced no significant change in either BP or HR. The onset of effects on BP and HR produced by ANF was seen 30-60 min after injection. Peak effects were usually observed approximately 90-120 min after onset, and the duration of the effect was 3-4 h, after which time values returned to baseline. In conclusion, these studies provide evidence for a functional role of ANF in the AV3V area of the brain, and lends support to the idea that it may play an important role in central cardiovascular regulatory mechanisms.

260.1 FURTHER PURIFICATION AND CHARACTERIZATION OF BOVINE DOPAMINE ($D_2$) RECEPTORS. Jai Ramwani* and Ram K. Mishra. Depts. of Psychiatry & Neurosciences, McMaster University, Hamilton, Ontario, L8N 3Z5. (Sponsored by Sandra Witelson.)

Using haloperidol-linked affinity sepharose gel, we reported our preliminary findings on the purification of dopamine ($D_2$) receptors (Fed. Proc. 41, 1325, 1982).

In this communication, we now report further purification to 2000 fold, and detailed characterization of the purified dopamine ($D_2$) receptors.

Bovine striatal crude mitochondrial-microsomal $P_2$-$P_3$ membrane preparation was solubilized by 0.25% cholic acid - 1M NaCl (final concentration) in .05 M Tris, 1 mM EDTA and 0.1 mM Dithiothretol buffer (pH 7.4) as described earlier (Prog. Neuro. Psycho. Pharmacol. and Biol. Psychiat. 7, 769, 1983).

Haloperidol was convalently linked to epoxy-activated sepharose CL-6B in dimethylformamide. Solubilized receptors were passed slowly at 4-6 ml/hr. over the Hal-linked sepharose. Bound receptors were eluted with 100 nM spiroperidol in 50 mM Tris 1 mM EDTA buffer containing .02% cholic acid. Bovine phospholipids were added to the eluting buffer to prevent receptor denaturation. Eluting agent was separated by concentrating the eluent through Amicon CF25 cones and passing over the G-25 column.

Affinity eluted receptors exhibited dopamine ($D_2$) receptor characteristics. Pharmacologically, purified receptors revealed similar affinity and specificity as membrane-bound $D_2$ receptors.

Scatchard analysis showed the $K_D$ value of 0.5 nM and $IC_{50}$ values for different agents were comparable to the membrane-bound receptor (Table below).

EFFECT OF VARIOUS AGENTS ON $^3$H-SPIROPERIDOL BINDING

| Agents | Membrane Receptor | Solubilized Receptor $IC_{50}$ nM | Affinity Purified $IC_{50}$ nM |
|---|---|---|---|
| Spiroperidol | 1.00 | 0.84 | 0.70 |
| D-Butaclamol | 4.00 | 3.99 | 9.66 |
| Haloperidol | 10.75 | 7.00 | 24.0 |

The $IC_{50}$ values (conc. of drugs that inhibits 50% of the $^3$H-spiroperidol binding) were obtained by using 7 different concentrations of drugs ($10^{-10}$ - $10^{-4}$ M) and were calculated by log probit analysis.

Proteins in the solubilized and purified receptor were estimated by the Bio-Rad method.

(Supported by MRC Canada and Ontario Mental Health Foundation.)

260.2 SUBCELLULAR LOCALIZATION OF THE SCH23390 RECEPTOR: DISSOCIATION FROM DOPAMINE-STIMULATED ADENYLATE CYCLASE. D.W.Schulz, E.J.Stanford*, and R.B.Mailman. Depts. Pharmacology and Psychiatry, Univ. North Carolina Sch. of Med., Chapel Hill, NC 27514.

The compound SCH23390 has generated great experimental interest because it is potent as both a $D_1$ dopamine receptor antagonist and an inhibitor of motor behaviors caused by dopamine agonists. Since such behaviors previously had been linked to activation of $D_2$ dopamine receptors, it is important to determine if the behavioral effects of SCH23390 are mediated by a direct action at $D_1$ sites, an indirect modulation of $D_2$ sites, or an interaction with a population of receptors which is not linked to adenylate cyclase activation. In order to investigate these possibilities, we have performed subcellular fractionation studies using rat caudate-putamen, and analyzed the distribution of the specific binding of [$^3$H]-SCH23390.

Initial experiments utilized the methods of Laduron et al. (J. Neurochem., 41:84, 1983). Freshly dissected striatal tissue was separated into 5 fractions: nuclear (N), heavy (M) and light (L) mitochondrial, microsomal (P), and supernatant (S). Markers used to assess the purity of M, L, P, and S were: cytochrome oxidase, [$^3$H]-dopamine uptake, 5'-nucleotidase, and dopamine presence, respectively. Assays for [$^3$H]-SCH23390 and [$^3$H]-spiperone binding and for dopamine stimulation of adenylate cyclase were performed for each fraction.

[$^3$H]-SCH23390 binding was present in all particulate fractions, and was greatest in the microsomal fraction. However, dopamine-stimulated adenylate cyclase activity was concentrated most heavily in the mitochondrial fractions. Interestingly, the distribution of [$^3$H]-SCH23390 binding closely paralleled that of [$^3$H]-spiperone. Additional experiments employing isopycnic centrifugation in continuous sucrose gradients were carried out in order to further resolve these distribution profiles.

These data provide preliminary evidence that there may be a component of [$^3$H]-SCH23390 binding which does not coincide with the dopamine receptor that is linked with adenylate cyclase activation. In addition, findings from these studies will be used to develop strategies for purifying the SCH23390 receptor.

260.3 PHOTOAFFINITY LABELING AND PURIFICATION OF THE RAT STRIATAL D-2 DA RECEPTOR. J.Y. Lew*, E. Meller*, and M. Goldstein, Department of Psychiatry, New York University Medical Center, New York, NY, 10016.

The photoaffinity probe $^3$H-7 Azido-fluphenazine ($^3$H-AF) was used to label rat striatal DA receptors. Striatal membranes were incubated with 10 nM $^3$H-AF and the mixture was irradiated with a high pressure Hg lamp. The unreacted material was removed by washing the membranes with Tris-HCl buffer, pH 7.7, and the photolabeled membrane bound proteins were solubilized and purified. The $^3$H-AF photolabeled membrane bound proteins were solubilized with 10 mM CHAPSO and adsorbed on a wheat germ agglutinin (WGA) agarose column. The glycoproteins were eluted from the column with 0.2 M N-Acetyl glucosamin and subsequently electrophoresed on a 6%/SDS-polyacrylamide gel. Photolabeling with $^3$H-AF resulted in the covalent incorporation of the probe into several minor and one major peptide band with a molecular weight of approximately 92,000. Incubation of the striatal membranes with the irreversible DA receptor antagonist, EEDQ ($5 \times 10^{-4}$M) prevented the covalent labeling with $^3$H-AF of this peptide. The incubation of the membrane with $5 \times 10^{-4}$M (±) sulpride protected the DA receptors from inactivation by EEDQ ($5 \times 10^{-4}$M) and restored the covalent labeling of the 92,000 peptide with $^3$H-AF. These results indicate that the $^3$H-AF labeled peptide with the molecular weight of 92,000 represents a sub-unit of the D-2 DA receptors.

260.4 PROPERTIES OF $^3$H-N-METHYL SPIPERONE BINDING TO HUMAN AND RAT $D_2$ AND 5-$HT_2$ RECEPTORS IN VITRO

M. Titeler, R.A. Lyon, J.J. Frost, H.N. Wagner, D.F. Wong, R.F. Dannals, J.M. Links, P.J. Whitehouse and M.J. Kuhar. Dept. Pharmacol. Toxicol., Albany Medical College, Albany, New York 12208. Johns Hopkins Med. Inst., Depts. of Nuclear Medicine, Neuroscience, Psychiatry, and the Addiction Res. Ctr., Balt., MD 21205

N-methyl-spiperone (NMSP), containing $^{11}$C, has been successfully used as a Positron Emission Tomography ligand in humans (1). The signal detected in human caudate and putamen has been identified as primarily due to a $D_2$ receptor interaction and the signal detected due to a $D_2$ receptor interaction and the signal in the frontal cortex has been identified as primarily due to a 5-$HT_2$ receptor interaction. The study to be presented was designed and executed to obtain detailed information on the molecular interaction between N-methyl-spiperone and brain $D_2$ and 5-$HT_2$ receptors. As the half-life of $^{11}$C renders it difficult to use for detailed in vitro studies, a tritiated form of N-methyl-spiperone was synthesized (New England Nuclear).

Rat striatal, rat frontal cortex, human caudate, and human frontal cortex homogenates were prepared in a buffer of 50 mM Tris-HCl, pH 7.4 at 37°C. In the rat striatal and human caudate tissue saturation and kinetic studies were performed in the same buffer plus 140 mM NaCl; the NaCl was used because sulpiride ($10^{-5}$M) was used to define specific binding to $D_2$ receptors and sulpiride is a sodium dependent ligand (2). In rat and human frontal cortex tissue $10^{-5}$M cinanserin was used to define specific binding to 5-$HT_2$ receptors; evidence will be presented confirming the 5-$HT_2$ receptor specificity of this signal in both the rat and human tissues. Table one displays the preliminary equilibrium dissociation constants and kinetic rate constants for $^3$H-N-methyl-spiperone binding to $D_2$ and 5-$HT_2$ receptors.

| | $B_{max}$ | $K_d$ | $k_{on}$ | $k_{off}$ |
|---|---|---|---|---|
| | | $D_2$ | | |
| Rat | 14.4 pmol/g | 0.09nM | $1.71 \times 10^9$ | $1.20 \times 10^{-1}$ |
| Human | 5.0 pmol/g | 0.05nM | | |
| | | 5-$HT_2$ | | |
| Rat | 12.4 pmol/g | 0.24nM | $1.26 \times 10^9$ | $1.47 \times 10^{-1}$ |
| Human | 5.7 pmol/g | 0.26nM | | |

Data from completed saturation and kinetic studies as well as detailed pharmacological analysis of the $^3$H-NMSP signal in rat and human tissues will be presented.

260.5 AGE AND DOPAMINE $D_1$ AND $D_2$ RECEPTORS IN HUMAN BRAIN.

Natalie H. BZOWEJ* and Philip SEEMAN. Dept. of Pharmacology, University of Toronto, Toronto, Canada M5S 1A8.

Older people exhibit spontaneous oral dyskinesias which may stem from changes in their brain dopamine receptor densities. Different findings, however, have been reported for the relation between age and the density of $D_2$ dopamine receptors in human brain. Severson et al. (1982) found a fall of 2.5% per decade in two series of human caudate nuclei (N=13;N=13), but no such fall in a third series of caudates (N=17) or in 3 series of human putamens. Wong et al. (1984) found less binding of a single dose of $^{11}$C-N-methylspiperone in males over 40 yrs. Seeman et al. (1984) found little relation between age and $D_2$ density. Thus, we extended our series for $D_2$ densities and also measured $D_1$ densities.

The $D_1$ receptor density ($B_{max}$) was measured by receptor-saturation-type experiments using a range of 100 to 4000 pM $^3$H-Schering-23390 (Seeman et al., 1985). The $D_2$ density was measured using 10 to 1000 pM $^3$H-spiperone. The $B_{max}$ values were determined by Scatchard analysis. Non-specific binding for $D_1$ and $D_2$ was defined as that binding inhibited by 1 uM (+)-butaclamol.

The $B_{max}$ values (pmoles/gm wet tissue) were:

| AGE, | $D_2$ | | $D_1$ |
|---|---|---|---|
| years | Caudate | Putamen | Striatum |
| <40 | 12.2 N=10 | 12.3 N=9 | 14.5 N=9 |
| 40-69 | 10.5 N=35 | 10.9 N=35 | 12.2 N=14 |
| ≥70 | 10.0 N=36 | 13.0 N=36 | 12.1 N=11 |

We found that the $D_2$ dopamine receptor densities were constant with age in both caudate and putamen. No difference existed between males and females. $D_1$ receptors in striatum were also constant with age. (Supported by the Ont. Ment. Health Fdn.)

260.6 **QUANTITATIVE AUTORADIOGRAPHY REVEALS THAT DOPAMINE (D-2) RECEPTORS ARE LOCATED ON NEURONS INTRINSIC TO THE CAUDATE-PUTAMEN.**

**J.N. Joyce and J.F. Marshall. Dept. of Psychobiology, Univ. California Irvine, Irvine, CA 92717.**

**As part of our investigations of the lateral to medial gradient of D-2 receptors in the rat caudate-putamen (CPU) (Joyce, J.N. et al. Brain Res., 1985), we used quantitative autoradiography to determine the density of [$^3$H]spiroperidol sites in rat CPU after unilateral injection (90 nmol/0.5 µl, 15 min) of quinolinic acid (QA) into this structure or after ablation of neocortical regions. Rats were sacrificed at 7 or 21 days postoperatively, and brains sectioned and processed for [$^3$H]spiroperidol (0.1 - 1.0 nM, 100 Ci/mmol, Amersham) binding to thin sections in the presence of 40 nM ketanserin with or without 1 µM (+)-butaclamol. The tissue and a set of $^3$H-standards were apposed to $^3$H-sensitive film for 1-3 weeks. Autoradiographs were digitized, linearized and the density of specific [$^3$H]spiroperidol binding read from regions of CPU with the aid of an image processor (Altar, C.A. et al. Neurosci. Meth., 100:173, 1984). Quantification of the zone of QA-induced cell loss was achieved by acetylcholinesterase (AChE) histochemistry (following DFP treatment) and thionin staining of adjacent sections. At the site of total loss of large AChE-positive neurons D-2 sites were decreased by as much as 94% by 21 days post-op. The affinity of [$^3$H]spiroperidol for the sites was unchanged in the QA-injected CPU. In other animals, given ablations of specific neocortical fields (medial prefrontal, motor, somatosensory) or of the entire parietal-frontal cortex of one hemisphere, sections were processed for quantitative autoradiography, scraped off for scintillation counting, or thionin-stained. Analysis of the 21 day post-op tissue showed that unless there was accompanying damage to the CPU, there was no loss of D-2 sites in the CPU. The two sets of results lead to the hypothesis that D-2 sites are primarily located on neurons intrinsic to the CPU, and are not localized to neocortical afferents. Values for the regional density of D-2 sites correlate very highly with regional CAT activity and high-affinity choline uptake (Joyce, J.N. and J.F. Marshall Neurosci. Lett., 53:127, 1985), suggesting a preferential relationship of this dopamine receptor with striatal cholinergic neurons.**

260.7 KINETIC MODELING OF THE BINDING OF NEUROLEPTIC DRUGS TO BRAIN RECEPTORS DETERMINED BY POSITRON EMISSION TOMOGRAPHY.

J. Logan*, A. P. Wolf*, and C. D. Arnett (SPON: L. Giron). Department of Chemistry, Brookhaven National Laboratory, Upton, NY 11973.

From positron emission tomography (PET) studies with appropriately labeled neuroleptics, the distribution of radionuclides in various brain structures can be followed over a period of several hours. This allows an in vivo determination of the kinetics of the binding of these drugs to neuroleptic receptors. The application of specific models to these data provides information about the kinetic constants associated with the binding of drug to receptor. We have modeled data from PET studies using $^{18}$F-labeled spiroperidol, benperidol and N-methylspiroperidol in the baboon and N-methylspiroperidol in humans.

The parameters governing the uptake and loss of drug were determined from regions with few or no receptors, such as the cerebellum, and from baboon experiments in which specific receptor binding was blocked by pretreatment with the potent neuroleptic (+)-butaclamol.

Frequent arterial blood sampling, along with measurement of the fraction of plasma radioactivity due to unmetabolized radioligand, allowed an accurate assessment of the input function for brain radioactivity in these studies. Without this correction for metabolism, the model overestimated cerebellar activities for times greater than 30 min after injection. The simplest model used for receptor-containing regions was a single-site model. While this model was capable of describing the major part of the activity over the course of the experiment, in several cases it underestimated activity for times less than 2 h after injection. This suggests that the binding process may be more complex than can be represented by a single-site receptor model. From computer simulation studies we have shown that receptor concentrations can be determined by two experiments, one at a high specific activity radioligand, which defines the upper limit of the ligand distribution curve, and a second experiment at a lower specific activity radioligand such that the ligand distribution curve is between that of the high specific activity case and that characteristic of brain regions with few or no receptors. PET baboon studies using radioligand at low specific activity have demonstrated the feasibility of this approach to determining receptor concentrations in vivo.

260.8 INVESTIGATION OF INHIBITORY POTENCIES OF VARIOUS PSYCHOTROPIC DRUGS ON D-1 AND D-2 DOPAMINE RECEPTORS

T. Kazawa* M. Mikuni., S. Matsubara*and I. Yamashita*( SPON : T. Nabeshima ) Dept. of Psychiatry, Hokkaido Univ., Schl. of Med., Sapporo, Japan

We investigated inhibitory effects of various psychotropic drugs on two different dopamine receptors, D-1 and D-2, using receptor binding assay and (-)-apomorphine induced stereotypy. Clinical potencies and laboratory behavioral effects have so far been evaluated mainly in terms of D-2 receptor, but very little of D-1 receptor. The present studies were therefore focussed on D-1 receptor.

In binding study, we determined $IC_{50}$ values of drugs on D-1 and D-2, using $^3$H-cis-flupenthixol and $^3$H-spiperone bindings in rat striatum. SCH23390, cis-flupenthixol and fluphenazine showed high affinities for D-1 receptor ( $IC_{50}$ 0.9nM, 0.6nM, 4nM respectively ), other phenothiazine derivatives and amoxapine showed moderate affinities ( perphenazine,30nM, chlorpromazine,50nM, thioridazine,39 nM, amoxapine,63nM ). But butyrophenone derivatives and YM-09151-2 indicated markedly low affinities for D-1 receptor ( spiperone,560 nM, moperone,300nM, haloperidol,140nM, YM-09151-2,1800nM ) in contrast with high affinities for D-2 receptor ( spiperone,0.16nM, moperone,6.3nM, haloperidol,3.2nM, YM-09151-2,0.14nM ). SCH23390 was kindly gifted from Dr. A. Bennet.

Recently, Goldman and Kebabian ( Mol.Pharmacol.,1983 ) reported that (-)-apomorphine stimulates both D-1 and D-2 receptors, whereas (+)-apomorphine blocks those receptors. They also showed that the affinity of (-)-apomorphine toward D-2 receptor was much greater than that toward D-1 receptor. Until now most behavioral tests with apomorphine in rat have been done using relatively small dose of (±)-apomorphine. We therefore investigated whether or not the stereotypies induced by high dose of (-)-apomorphine in rat related with D-1 receptor.

Continuous stereotypic biting or licking was induced constantly in rat by 10mg/kg (-)-apomorphine(i.p.). Fluphenazine, perphenazine and haloperidol had widely different inhibitory effects as shown in the table, although these drugs had similar affinities for D-2 and these penetration rates into CNS were thought to be not largely different from the data of cataleptogenetic effects. The differences were more marked when scopolamine(2mg/kg i.p.) was given concomitantly. And D-1 selective antagonist, SCH23390, showed potent inhibitory effect. These results suggest the possibility that the stereotypies induced by high dose of (-)-apomorphine are mediated through dopamine receptors containing D-1.

| | APO-stereotypy without scopo. $ED_{50}$(95% CL) umol/kg i.p. | APO-stereotypy with scopo. $ED_{50}$(95% CL) umol/kg i.p. |
|---|---|---|
| fluphenazine | 0.28 ( 0.18 - 0.43 ) | 1.35 ( 0.92 - 1.98 ) |
| perphenazine | 3.8 ( 2.7 - 5.3 ) | 13.0 ( 10.4 - 16.3 ) |
| haloperidol | 3.9 ( 3.4 - 4.3 ) | 28.0 ( 20.7 - 37.8 ) |
| SCH23390 | 1.2 ( 0.95 - 1.6 ) | 2.0 ( 1.48 - 2.7 ) |

260.9 DIFFERENCES IN MIDBRAIN DOPAMINE CELL AUTORECEPTOR SENSITIVITY IN GENETIC MOUSE STRAINS. B.S. Walker, D.C. German and M.K. Sanghera, Depts. of Psychiat. and Physiol., U. of Texas Health Sci. Cntr., Dallas, TX. 75235.

Genetically inbred strains of mice have been found to possess differing numbers of (a) midbrain dopamine (DA) neurons (Fink & Reis, Brain Res., 222:335-345, 1981) and (b) postsynaptic DA-D2 receptors in striatal and limbic regions (Helmeste & Seeman, Psychiat. Res., 7:351-359, 1982). In our laboratory, we have been examining the anatomy, electrophysiology and pharmacology of midbrain DA neurons in the BALB/c and CBA mouse strains. We have reported differences in midbrain DA cell densities, DA turnover rates in the caudate and nucleus accumbens (German et al., Neurosci. Abstr., 9:1150, 1983), and dopamine neuronal firing rates (Sanghera & German, Neurosci. Abstr., 10:950, 1984) in these mouse strains.

The purpose of the present study was to compare the sensitivity of DA cell body autoreceptors in mice which contain different numbers of midbrain DA neurons. Extracellular single cell recordings were made from DA neurons in the substantia nigra zona compacta (nucleus A9) and the ventral tegmental area (nucleus A10) in chloral hydrate anesthetized BALB/c and CBA mice. Recording sites were marked by the iontophoretic ejection of Fast Green dye from the glass recording micropipettes. A total of 20 single DA neurons were recorded from A9 and A10 areas in the two strains. As previously reported, DA cells in the CBA fired significantly faster than in the BALB/c, (4.1 ± 0.4 vs. 2.6 ± 0.5 impulses/sec). Intravenous administration of the DA agonist apomorphine (APO; 0.5-4.0 µg/kg) inhibited DA neuronal activity in both strains and this inhibition could be reversed with low doses of the DA antagonist, haloperidol (0.1 mg/kg). However, DA neurons in the BALB/c mice were significantly more sensitive to low doses of APO (0.5-1.0 µg/kg) than the CBA mice, irrespective of differences in baseline firing rates. At higher doses, DA cells in both strains were equally sensitive to the inhibitory effects of APO.

In conclusion, we find that: (1) firing rates of DA neurons in the A9/A10 regions are higher in the CBA strain than in the BALB/c; (2) DA cell body autoreceptors in mice are considerably more sensitive to APO when compared to rat autoreceptors ($ID_{50}$ for mice = 3.0 µg/kg vs. 9.3 µg/kg for rat); and (3) in the CBA mice, which have fewer DA neurons and higher baseline firing rates, DA neurons have less sensitive cell body autoreceptors than in the BALB/c mice. Research supported by NIMH grants MH-30546 and MH-39699.

260.10 CHARACTERIZATION OF D2 DOPAMINE RECEPTORS IN THE MEDIAL FRONTAL CORTEX OF THE RAT. A.J. MACLENNAN*, A. JAKUBOVIC AND H.C. FIBIGER. Div. of Neurol. Sci., Dept. of Psychiat., U.B.C., Vancouver, B.C. Canada V6T 1W5.

The demonstration of a dopaminergic projection innervating the frontal cortex (FC) has led to many anatomical, electrophysiological, biochemical and behavioral studies of this system. Much of the biochemical and behavioral work has indicated that the FC dopamine (DA) system is functionally distinct from subcortical DA systems. Additionally, research has implicated the FC DA system in the pathology of some forms of schizophrenia. However, characterization of D2 DA receptors in the FC has been impeded by methodological difficulties associated with the small number of potential D2 binding sites in this area. In the present study these problems were attenuated by employing a low concentration of [$^3$H]-spiperone (25pM), by occluding serotonin (5-HT) receptors with 10nM ketanserin in each incubation, by using only the DA innervated area of the medial frontal cortex (MFC), and by reducing the variability associated with nonspecific and filter binding. In competition studies the specific binding (defined by 10µM (-)-sulpiride) displayed the characteristics of D2 receptors. Phentolamine, naloxone, baclofen, atropine and clonazepam were ineffective in the nM range. (-)-sulpiride was more potent than (+)-sulpiride. DA was more potent than 5-HT or norepinephrine. The specific binding was inhibited with nM concentrations of neuroleptics. The potencies of the neuroleptics correlated with their in-vivo potencies as antipsychotics as well as antagonists of DA-related behaviors. The potencies of all drugs tested with MFC tissue correlated with their potencies in an identical assay using the striatum (Str). Apomorphine was exceptional in that it inhibited MFC binding more than Str binding. This suggests that there may be proportionally more "D2 high" sites in the MFC compared to the Str.

Supported by MRC Program Grant 0023. A.J.M. is an MRC Student.

260.11 CHARACTERIZATION OF DOPAMINE RECEPTORS ON CULTURED NEURONS FROM VENTRAL MESENCEPHALON OF MOUSE E.J. Heyer, E. Chung, M. Van Woert, and J. Parise*. Department of Neurology, Mount Sinai School of Medicine, New York, New York 10029.

Primary dissociated cell (PDC) cultures of ventral mesencephalon (VM) from mouse were prepared as a model to study dopamine actions. In vivo, dopaminergic neurons are located in substantia nigra zona compacta, as well as in ventral tegmental area. In substantia nigra zona compacta dopamine is released from dopaminergic neuron dendrites. In this study we have characterized the dopamine receptor subtype found on cells in these cultures by determining whether there is dopamine stimulated adenylate cyclase activity present (mediated by the D-1 receptor) and whether the high affinity D-2 antagonist spiroperidol binds to cultured cells (mediated by the D-2 receptor if no dopamine stimulated adenylate cyclase is present).

PDC cultures of VM and PDC cultures of spinal cord were prepared from 12-14 day old fetal mice. Dopamine stimulated adenylate cyclase activity was determined by measuring the formation of $^{32}$P-cAMP from $^{32}$P-ATP in cells grown in PDC cultures of VM and in adult female mouse striatum. $^3$H-spiroperidol (1 nM) receptor binding and $^3$H-flupenthioxol (1 nM) receptor binding were performed on homogenized cells removed from 35 mm culture dishes of VM or spinal cord cultures by incubating with 1mM EDTA for 5 minutes; subsequently calcium chloride (5mM) was added back. Butaclamol (10uM) or 5-hydroxytryptamine (5-HT) (10uM) was used to determine nonspecific binding.

Dopamine (5uM) failed to stimulate adenylate cyclase activity in cells from PDC cultures of VM, whereas this concentration of dopamine produced stimulation of adenylate cyclase by 55% in adult mouse striatal tissue. Therefore, the D-1 receptor subtype associated with adenylate cyclase is not present in cells from VM. Binding was specific for a dopamine receptor site and was not contaminated by a serotonin receptor site since butaclamol but not 5-HT displaced $^3$H-spiroperidol binding. The D-2 receptor antagonist spiroperidol bound with high affinity to cells from PDC cultures of VM but not to cells of PDC cultures of spinal cord, a region in the intact animal where little to no dopamine receptor binding is expected. Therefore, cells from cultured VM have D-2 receptors. D-3 receptors which also fail to activate adenylate cyclase but bind flupenthixol with high affinity and spiroperidol with low affinity are not present in cultured VM since there was no flupenthixol binding in these cultures. Spiroperidol binding increased with age reaching a maximum at three to four weeks in culture and remained constant for at least twelve weeks. Scatchard and Hill analysis performed on cells grown in culture for at least three weeks showed $K_D$ of 1.22 nM, $B_{max}$ of 66.8 fmole/mg of protein and Hill coefficient of 1.0.

In summary, PDC cultures of VM are a useful model to study the action of the D-2 dopamine receptor subtype.

Supported in part by grants from NINCDS Clinical Center for Research in Parkinson's and Allied Diseases (NS11631-10), NINCDS Teacher-Investigator Development Award (NS00657) to EJH, and Basil O'Connor Starter Research Grant No. 5-442 from March of Dimes Birth Defects Foundation to EJH.

260.12 INHIBITION OF $K^+$-STIMULATED [$^3$H]DOPAMINE (DA) AND [$^{14}$C]ACETYLCHOLINE (ACH) RELEASE BY THE PUTATIVE DA AUTORECEPTOR AGONIST, B-HT 920. C.J. Schmidt*, A. Lobur, and W. Lovenberg. (SPON: F. Porreca). Section on Biochem. Pharmacol., NHLBI, NIH, Bethesda, MD 20205.

Results from a number of recent studies suggest that the azepine derivative, B-HT 920 (2-amino-6-allyl-5,6,7,8-tetrahydro-4 H-thiazolo-[4,5-d]-azepine dihydrochloride), behaves as a dopamine (DA) agonist with a high selectivity for the DA autoreceptor in vivo. Behavioral (Anden et al., N-S Arch. Pharmacol. 321:100, 1982) and neurochemical (Anden et al., J. Neurol. Trans. 58:143, 1983) studies have shown B-HT 920 to be a potent inhibitor of DA turnover by a mechanism which is sensitive to haloperidol. However, even high doses of the drug do not elicit increased locomotor activity or stereotypy (Brown and Mitchell, Proc. Brit. Pharmacol. Soc. Abst. p. 155, 1984). The presynaptic selectivity of B-HT 920 was examined by dual label experiments using rat neostriatal slices incubated with [$^3$H]DA and [$^{14}$C-methyl]choline to preload DA and ACh terminals respectively. Slices mounted on nichrome screens were serially transferred through a sequence of LS vials containing Kreb's-Ringer bicarbonate buffer (KRB). Release during the 5-min incubation in each vial was determined by liquid scintillation counting. The effect of B-HT 920 on the release of labeled DA and ACh as evoked by 20 mM $K^+$/KRB was taken as an indication of the activation of presynaptic and postsynaptic DA receptors, respectively. B-HT 920 inhibited the $K^+$-stimulated release of both transmitters in a concentration-dependent manner in the µmolar range. This effect of B-HT 920 was totally blocked by the active (+) isomer of the DA antagonist, butaclamol, while the (-) isomer was without effect. The selective $D_2$ blocker, sulpiride, also antagonisted B-HT 920's inhibition of [$^3$H]DA and [$^{14}$C]ACh release. In contrast, tolazoline, an alpha adrenoceptor blocking agent, did not block the effect of B-HT 920. B-HT 933, a structural analogue of B-HT 920 reported to lack DA autoreceptor affinity in in vivo models, was without effect on the $K^+$-stimulated release of either [$^3$H]DA or [$^{14}$C]ACh. B-HT 920 was without effect on the $K^+$-stimulated release of [$^3$H]5HT from the same slices from which it inhibited the release of [$^{14}$C]ACh. The results show that B-HT 920 selectively inhibits the release of both [$^3$H]DA and [$^{14}$C]ACh in vitro, specifically by activation of DA receptors, probably of the $D_2$ subtype. Since these results indicate an activation of postsynaptic DA receptors by B-HT 920 in vitro, further studies may be required to elucidate its mechanism of action in the intact animal.

260.13 RESTORATION OF DOPAMINERGIC INHIBITION OF CHOLINERGIC FUNCTION AFTER PARTIAL DAMAGE TO THE NIGROSTRIATAL BUNDLE. R.G. MacKenzie, M.K. Stachowiak, E.M. Stricker, and M.J. Zigmond. Dept. of Biological Sciences, Center for Neurosciences, Univ. of Pittsburgh, Pittsburgh, PA 15260.

While acute, pharmacological disruption of transmission at dopamine (DA) synapses in brain causes akinesia, after permanent lesions of DA systems only the near-total loss of DA elicits such behavioral dysfunctions. Moreover, when these deficits occur they usually are transient. To examine this phenomenon, we have studied the effects of destroying DA neurons on the capacity of endogenous DA to inhibit acetylcholine (ACh) release in striatum of adult male rats.

Striatal slices were preincubated in Krebs bicarbonate buffer with 50 nM [$^3$H]-choline, washed with buffer containing $10^{-5}$M hemicholinium, and then superfused with that buffer for 60 min at 0.2 ml/min, after which collection of 5-min fractions was begun. Slices were stimulated via platinum mesh electrodes with biphasic square-wave pulses (8 Hz, 2.5 msec duration, 20 mA) for 1 min beginning at 25 min ($S_1$) and 75 min ($S_2$) and $CA^{2+}$-dependent, fractional release of [$^3$H]-ACh was measured. Under control conditions, [$^3$H]-ACh release at $S_1$ and $S_2$ were the same ($S_1/S_2$, 0.96 $\pm$ 0.06, n=16). Addition of $10^{-6}$ M of the DA antagonist (S)-sulpiride beginning at 40 min increased $S_2/S_1$ to 2.02 $\pm$ 0.09 (n=27), consistent with previous suggestions that endogenous DA exerts an inhibitory influence on ACh release. When slices were taken from rats treated 3 days earlier with 6-hydroxydopamine (250 ug, ivt.) the effects of sulpiride were decreased ($S_2/S_1$, 1.41 $\pm$ 0.13, n=4) if the depletions were >80%. In contrast, when lesions were less severe (50-70% depletion of DA) the effects of sulpiride were the same as in control slices ($S_2/S_1$, 2.05 $\pm$ 0.15, n=4). Moreover, when animals with the more extensive lesions were given 2 months to recover from surgery, even those with DA depletions of 90% exhibited normal inhibition of ACh by endogenous DA ($S_2/S_1$, 2.27 $\pm$ 0.19, n=6). In a separate experiment, the density of striatal DA receptors was measured using [$^3$H]-spiperone 2 months post-lesion. An increase in D2 sites was observed only in animals exhibiting a DA depletion of 80% or greater. Collectively, these observations parallel our previous behavioral findings and suggest that there is a large capacity for increased DA function in striatum. Some of this reserve capacity may arise from the immediate decrease of DA reuptake after degeneration of DA terminals and the enhanced release of DA from the spared terminals. When those reserves are exhausted, additional adaptive responses such as receptor up-regulation may be recruited. (Supported by NS 19608.)

260.14 17β-ESTRADIOL AT A PHYSIOLOGICAL DOSE ACUTELY INCREASES RAT BRAIN DOPAMINE TURNOVER. T. Di Paolo[1], C. Rouillard*[2] and P. Bédard[2], [1]School of Pharmacy, Laval Univ., Quebec G1K 7P4 and Dept. of Molecular Endocrinology, Laval Univ. Hosp. Center, Quebec G1V 4G2; [2]Neurobiology Lab., Dept. of Anatomy, Laval Univ., Quebec G1J 1Z4, Canada.

We have investigated the effect of an acute physiological dose of 17β-estradiol on dopamine (DA) metabolism in the rat striatum and nucleus accumbens. Plasma 17β-estradiol and prolactin concentrations were measured by specific radioimmunoassays while brain dopamine and its metabolites were assayed by HPLC with electrochemical detection. One injection of 17β-estradiol (30 ng s.c.) to ovariectomized rats leads to a significant elevation of this steroid concentration in the plasma after 15 min with a peak at 30 min and a return to control values at 45 min while plasma prolactin concentrations are not significantly modified. This concentration of 17β-estradiol leads to a rapid surge of about 100 pg/ml of plasma estradiol concentrations and is similar to the proestrus blood estradiol peak which is in the order of 50 pg/ml. Striatal dopamine concentrations remained essentially unchanged following the estradiol injection while the dopamine metabolites dihydroxyphenylacetic acid (DOPAC) and homovanillic acid (HVA) and dopamine turnover as estimated with the ratios DOPAC/DA and HVA/DA are elevated 30 min after the steroid injection. A similar effect of the estrogen injection is observed in the nucleus accumbens where dopamine concentrations are unchanged while dopamine turnover is increased 30 min after the steroid injection. Increased dopamine turnover in the striatum and nucleus accumbens occurs in coincidence with peak plasma 17β-estradiol concentrations. Striatal dopamine receptor affinity ($K_D$) and density (Bmax) assayed with [$^3$H]spiperone binding remain unchanged following the injection of 30 ng of estradiol. In ovariectomized rats with a unilateral lesion of the entopeduncular nucleus, the same dose of 17β-estradiol induces a postural deviation to the lesioned side with a maximum at 30 min. These results suggest that very small doses of estradiol are able to increase dopamine turnover. This effect is seen within minutes and is relatively short. It is probably non-genomic, presynaptic and is similar to the effect of a small dose of a dopamine releasing agent. Supported by the Medical Research Council of Canada.

260.15 TRITIATED AGONIST BINDING TO A HIGH AFFINITY DOPAMINE RECEPTOR IN THE BOVINE RETINA. J.M. Ackerman* and M.E. Gnegy. University of Michigan, Ann Arbor, MI 48109.

Our previous studies suggested that light could regulate dopamine (DA)-sensitive adenylate cyclase activity in the retina (J. Neurochem., 42:1632, 1984). To further investigate the regulation of DA receptor activity in retina, we are developing an assay to measure DA receptor binding in the bovine retina using [$^3$H]DA and standard filter binding techniques. Our studies demonstrate that saturable, specific binding of [$^3$H]DA exists in retinal membrane preparations. Maximum binding occurs within forty-five minutes at 22°C, and the level of specific binding is 75%. Scatchard analysis of [$^3$H]DA demonstrates the presence of a high affinity binding site having a $K_d$ of 8.3nM and a $B_{max}$ of 690fmoles/mg protein. In addition, a low affinity component of binding is present with unestimable parameters due to high nonspecific binding.

We have measured competition by various DA agonists and antagonists for [$^3$H]DA binding sites, such as DA, ADTN, cis-flupenthixol, fluphenazine and butaclamol. The relative potencies for DA antagonists in competing for binding correlates with their ability to inhibit DA-stimulated adenylate cyclase. We have demonstrated stereospecificity of binding by competition experiments with the (+) and (-) isomers of butaclamol. The (+) isomer, which is a potent inhibitor of DA-stimulated adenylate cyclase, inhibits [$^3$H] DA binding with an $IC_{50}$ of 225nM while the (-) isomer, which is inactive, did not effectively inhibit [$^3$H]DA binding. Additional studies demonstrate that the dose-response curve for [$^3$H]DA binding in the retina displays a shift to the right by GppNHp, a non-hydrolyzable analog of GTP. This suggests the presence of a receptor linked to adenylate cyclase. The $IC_{50}$ for DA increases from 4.6 to 9.1nM and the total binding of [$^3$H]DA decreases more than two-fold in the presence of 50uM GppNHp.

In conclusion, we have demonstrated agonist binding to DA receptors in the retina with a high level of specific binding. Competition experiments with dopaminergic drugs indicate that binding is selective for DA receptors and that the binding is stereospecific. The evidence suggests that [$^3$H]DA binds to a high affinity D-1 dopamine receptor. In addition, it appears that binding occurs to a physiologically relevant receptor as evidenced by a decrease in receptor affinity in the presence of guanyl nucleotide.

260.16 DOPAMINE-D2 RECEPTORS LOCATED ON PHOTORECEPTOR MEMBRANES COUPLE TO A PERTUSSIS- AND CHOLERA-TOXIN-SENSITIVE GTP-BINDING PROTEIN. M. R. Brann* and C. Jelsema*(SPON: P. St. John) Lab of Cell Biology, NIMH, Bethesda, MD 20205.

Neuroleptic agents exert their therapeutic efficacy by binding to dopamine(DA)-D2 receptors(R). For all forebrain structures, the density of DAergic innervation correlates with the density of D2 Rs. In the retina, light induces the synthesis and release of DA in neurons which are located in anatomical register with photoreceptors(PR). In PRs, light activates the enzyme cGMP-dependent-phosphodiesterase(PDE) by bleaching rhodopsin, which subsequently couples to a GTP-binding protein(transducin) that is sensitive to both pertussis(Pt)- and cholera(Ct)-toxin.

We have found that [$^3$H]spiperone binds to saturable sites on PR membranes isolated from bovine retina, exhibiting a $K_D$ 0.2 nM and a $B_{max}$ 1 pmole/mg protein when nonspecific binding is defined with (-)sulpiride(SUL). These sites are displaced by nM concentrations of apomorphine(APO), SUL and (+)butaclamol, but not by (-)butaclamol, prazocin and mainserin. These sites are identical to D2 Rs observed in other tissues under similar assay conditions. The density of D2 Rs correlates with the concentration of rhodopsin in several preparations of retinal membranes.

Ct- and Pt-toxin catalyze the ADP ribosylation of a 40 kDa protein in crude retinal- and PR-membranes. Both toxins also decrease the affinity of APO for the D2 R by the same magnitude as GTP and GppNHp. GTP and GppNHp have no effect on the affinity of APO for D2 Rs after toxin-treatment. Since transducin is abundant in PR membranes, and is sensitive to both Ct- and Pt-toxin, these data suggest that D2 Rs couple to the same GTP-binding protein as rhodopsin. This conclusion is supported by our observation that APO activates PDE in a manner which is blocked by SUL and (+)butaclamol (see abs. C. L. Jelsema, Y. Ishihara and M. R. Brann).

260.17 D-1 DOPAMINE (DA) RECEPTOR-MEDIATED RELEASE OF $^{3}$H-ACETYLCHOLINE (ACH) FROM RABBIT RETINA IN VITRO. J.G. Hensler and M.L. Dubocovich. Dept. Pharmacol., Northwestern Univ. Med. School, Chicago, IL 60611.

Two pharmacologically distinct dopamine (DA) receptor subtypes are found in the vertebrate retina: The D-1 DA receptor, linked to the activation of adenylate cyclase, and the D-2 DA autoreceptor, which inhibits the calcium-dependent release of DA via a negative feedback mechanism mediated by the neurotransmitter itself. The D-2 DA receptor is activated by nanomolar concentrations of DA and DA agonists such as pergolide, while activation of adenylate cyclase through D-1 DA receptors requires micromolar concentrations (Kebabian & Calne, Nature, 277, 93, 1979; Dubocovich & Weiner, J. Pharmacol. Exp. Ther., 219, 701, 1981; J. Pharmacol. Exp. Ther., in press). We report here the effect of DA and DA agonists on the release of ACh from rabbit retina. Retina pieces were labeled in vitro with $^{3}$H-choline (S. A.: 80 Ci/mmol) and superfused with Krebs' solution (1.3 mM calcium) containing hemicholinium-3 (10 uM). Samples of the superfusate were collected in 4-min fractions after the spontaneous outflow of tritium had leveled off. The release of tritium, expressed as percent of total tissue radioactivity released above spontaneous levels, was evoked by exposure to the DA agonists for one 8-min period (S). In the presence of the D-2 DA receptor antagonist S-sulpiride (1 uM), DA (1 uM -1 mM) evoked the release of tritium in a concentration-dependent manner. All other DA agonists were tested in the absence of S-sulpiride. The concentration of agonist necessary to induce 0.5% release of tritium was for pergolide, 0.2 uM; for DA, 14 uM; for R-SKF 38393, 16 uM; for LY 181990, 71 uM. Omission of calcium from the superfusion medium prevented the agonist-evoked release of tritium. The S-isomer of the selective D-1 DA receptor agonist SKF 38393 was significantly less potent to induce tritium release than the R-isomer. LY 181990, the stereoisomer of the selective D-2 DA receptor agonist LY 171555, did not inhibit the release of DA through D-2 autoreceptor activation, but evoked ACh release in a concentration dependent manner. The DA receptor antagonist alpha-flupenthixol (1 uM) antagonized the calcium-dependent release of ACh induced by pergolide. Beta-flupenthixol was significantly less potent. The selective D-1 DA receptor antagonist SCH 23390 (1 uM) antagonized the release of tritium evoked by DA. Release of ACh was also evoked by forskolin (10 uM, 30 min) suggesting the involvement of adenylate cyclase activation in this release process. These results suggest that in the rabbit retina activation of a stereoselective receptor with pharmacological characteristics of D-1 DA receptors induces calcium-dependent release of ACh, possibly through a cAMP-mediated process. USPHS grants EY 04788 and MH 09215.

260.18 EVIDENCE FOR A ROLE OF D-1 RECEPTOR STIMULATION IN THE GENERATION OF EEG ACTIVITY AND AROUSAL. Ongini,M.G. Caporali* and M. Massotti. Dept. of Pharmacology, Istituto Superiore di Sanità, Viale Regina Elena, 299 - 00161 Rome, Italy.

In the attempt to clarify the functional role of D-1 receptors, we studied the effects of the D-1 receptor agonist SKF 38393 on the EEG activity in the rabbit. Selectivity of action was assessed by studying the interaction with the D-1 antagonist SCH 23390 and the D-2 antagonist (-)-sulpiride. Investigation was then extended to the effects of apomorphine, a potent D-2 agonist with weak activity at D-1 receptors.

Adult male rabbits were implanted with electrodes for recording of EEG activity. SKF 38393 was injected at 1.25-10 mg/kg iv. The time spent in EEG desynchronization, as evidenced by low-amplitude fast frequency waves, was evaluated for 60 min after injection. SKF 38393 dose-dependently produced EEG desynchronization associated with arousal. No signs of stereotyped behaviors were observed. These effects were prevented by SCH 23390 (0.003-0.01 mg/kg iv), but not by (-)-sulpiride (25 mg/kg iv). Similar results were also obtained in the rat thus confirming that SKF 38393 specifically induces a dose-dependent increase of arousal Apomorphine, at the dose of 1 mg/kg iv, also induced EEG desynchronization. As observed for SKF 38393, the effects on the EEG were prevented by the same doses of SCH 23390, but not by (-)-sulpiride.

These results provide evidence that stimulation of D-1 receptors by SKF 38393 induces EEG desynchronization and arousal. Thus, it seems likely a functional role of D-1 receptors in the generation of EEG activity related with the state of arousal. The data indicate that also the effects on the EEG induced by high doses of apomorphine may be attributed to D-1 receptor stimulation.

## DEVELOPMENT AND PLASTICITY II: AGING

261.1 IMPAIRED SURVIVAL AND GROWTH OF FETAL SEPTAL NEURONS IN THE AGED CNS. J.P. Vicedomini, G.H. Jackson*, S.T. DeKosky and S.W. Scheff. Depts. of Anatomy and Neurology, Lexington, VA and Univ. of Kentucky Medical Center and Sanders-Brown Research Center on Aging, Lexington, KY 40536.

Lesion-induced neuronal plasticity diminishes with increasing age. The reduction may reflect changes in the growth capacity of the neurons and/or changes in the ability of the aged CNS to provide the appropriate supportive milieu. Tissue transplantion techniques may help to specify the nature of diminished reactive growth in the aged CNS. Fetal tissue transplanted into neonates or young adults survives and integrates with the host CNS. If the aged CNS provides the appropriate milieu for reactive growth then transplanted fetal tissue should integrate with the CNS of aged subjects as well as it does with young adults. If the milieu is not supportive the two age groups should show very different survival and integrative capacities.

Unilateral transection of the fimbria-fornix (FF) eliminates cholinergic innervation of the hippocampal formation (HF) as evidenced by a reduction in AChE staining. Fetal septal tissue transplantation restores AChE staining with the same laminar pattern exhibited by the native cholinergic fibers. Entorhinal cortex (ERC) ablations produce alterations in AChE staining; when combined with the FF lesion in transplant animals, an ERC lesion results in an intensification of cholinergic reinnervation which is host specific.

Sixteen young and nine aged F344 rats were subjected to ablation of the FF and ipsilateral ablation of the ERC. Six to eight days following surgery fetal septal neurons (E16-19) were transplanted into the FF cavity. Thirty days after donor tissue grafting, young and aged host animals were studied using AChE histochemistry and retrograde transport (HRP) techniques.

Transplanted fetal septal neurons survived and provided AChE positive fibers to septal and ERC denervated laminae. Ingrowth was more frequently observed in young vs aged adult hosts (69% vs 22% respectively). In the younger hosts, the density and rostro-caudal extent of transplant fiber ingrowth was greater than in the aged hosts. Injections of HRP into the reinnervated zones of the HF resulted in neuronal labeling confined to transplanted septal neurons. Our results show that in each host age group transplanted fetal septal cholinergic neurons can direct their afferents into cholinergic denervated lamina. However, relative to young adults, aged hosts are impaired in their ability to provide a milieu favorable for the transplanted fetal neurons. (Supported by NIH grants NS21541, AG05119, NS00444, AG00084 and the V.A. Medical Research Service)

261.2 DECREASE IN SIZE OF ACETYLCHOLINESTERASE-POSITIVE BASAL FOREBRAIN CELL BODIES IN C57B1/6 MICE BETWEEN 7 AND 53 MONTHS OF AGE. J. Hornberger*, D.G. Flood, T.H. McNeill and P.D. Coleman (SPON: R. Joynt). Departments of Anatomy and Neurology, University of Rochester, Rochester, NY 14642.

We have previously reported stability of numbers of acetylcholinesterase-positive basal forebrain neurons in mice between 15 and 53 months. We here extend the finding of stability of cell numbers to 7 month old mice and report that there is, however, a progressive decline in cell size from 7 to 53 months. Seven 7 month-old, 8 fifteen month-old and 5 fifty-three month-old C57B1/6 mice were obtained from the NIA colony at Charles River Breeding Laboratories. The mice were injected with 2 mg/kg diisopropylfluorophosphate (DFP) in sesame oil 4 hours prior to sacrifice. They were anaesthetized and perfused with mixed aldehydes. The brains were removed and Vibratome sections cut at 20 um. Sections were stained for acetylcholinesterase by the method of Karnovsky and Roots (1964) as modified by El Badawi and Schenk (1967). Tetraisopropyl-pyrophosphoramide was included in the incubation medium to inhibit non-specific cholinesterase. Slides were coded and AChE-positive cells were counted and measured in the medial septum, nucleus of the diagonal band (vertical and horizontal bands), magnocellular preoptic nucleus and nucleus basalis of Meynert. Cells were counted in every third section. Cell sizes were determined by tracing outlines of cell bodies onto the X-Y tablet of an Apple II Plus computer, which then computed the areas of neuronal profiles. Neuron numbers did not change with age in any of the regions examined. Mean neuronal area showed a statistically significant decline with age in all regions examined. The average decrease in area from 7 to 53 months ranged from 6% in the medial septum-diagonal band complex to 15% in the nucleus basalis. The decrease in cell size reported here represents a cellular change which is not associated in the near term with cell death, but which may be associated with declines in the synthetic capacities of these cholinergic neurons.

Supported by grants AG 1121 and AG 0268 from the National Institutes on Aging.

261.3 AGE-RELATED CHANGES IN ANDROGEN RECEPTOR LEVELS IN RAT CRANIAL NERVE NUCLEI AND MUSCLES. W.H.A. Yu and M.Y. McGinnis*, Department of Anatomy, Mount Sinai School of Medicine of the City University of New York, New York, NY 10029.

In a previous study we have demonstrated the presence of high affinity cytosolic androgen receptors in motor nuclei of the hypoglossal and facial nerves and in the tongue muscles of adult rats (Soc. Neurosci. Abst. 10:901). In the present study we have examined whether cytosolic androgen receptor levels in these tissues change with aging. Young and old male Fischer 344 rats (4 and 20 months of age, respectively) were orchidectomized under anesthesia 2-3 days prior to sacrifice. Tissues from hypoglossal, facial, and cochlear nuclei were excised under a stereomicroscope. Tongue, masseter, and levator ani muscles were removed and dissected free of extraneous tissue. Pituitaries and the combined tissues from hypothalamus, preoptic area, and amygdala (HPA), that have been previously reported to show age-related changes in steroid receptor concentrations, were assayed simultaneously for comparison. The levels of androgen receptors in the cytosol of tissue samples, pooled from 4-5 rats, were determined by an in vitro binding assay, using $^{3}$H-R1881 as ligand, and expressed as fmoles/mg protein. In old rats there was a significant reduction in the number of cytosolic androgen receptors in all the cranial nerve nuclei examined. The most severe decrease occurred in the cochlear nuclei in which the receptor levels were reduced to only one tenth of the values seen in young rats. In the hypoglossal and facial nuclei, the levels of androgen receptors were reduced to one half of the values of young rats. In contrast, there were no age-related changes in the levels of androgen receptors in HPA or in any of the three muscles examined. The pituitaries of old rats showed a 2-fold increase in cytosolic androgen receptorgs compared to young rats. The decrement in androgen receptor concentration in old rats may render neurons in these cranial nerve nuclei less responsive to steroid hormone regulation and may contribute to an age-related decline in function.

Supported in part by NSF grant BNS 83-12685. Fischer rats were pvovided by the National Institute on Aging.

261.4 MORPHOLOGICAL AND NEUROPHYSIOLOGICAL ANALYSES OF NEURONS IN THE NUCLEUS BASALIS OF MEYNERT OF THE CAT. R.L. Lloyd, R.S. Fisher, C.D. Hull, N.A. Buchwald and M.S. Levine. Mental Retardation Research Center, UCLA School of Medicine, 760 Westwood Plaza, Los Angeles, CA 90024.

These studies were designed to assess some of the morphological and neurophysiological characteristics of neurons in the nucleus basalis of Meynert (NbM) in the cat. In the first experiment retrograde labeling methods were used to demonstrate the distribution of NbM neurons projecting to frontal neocortex. Lectin-bound horseradish peroxidase (HRP) was pressure injected into precruciate cortex of 6 cats. In NbM and the globus pallidus (GP) medium- and large-sized neurons were labeled with the HRP indicating that these neurons projected to the neocortex. In both areas neurons had polymorphic somata with an average cross sectional area of 286 $\pm$ 12 $\mu m^2$. There were no differences between somatic areas of retrogradely filled NbM or GP neurons. Pallidocortical neurons were most prevalent ventrally near the rostral half of the anterior commissure. NbM neurons were distributed widely across the medio-lateral and anterior-posterior extent of the nucleus. Neurophysiological experiments were performed on 5 additional adult cats. Extracellular recordings were made from 69 neurons in NbM and GP. Recording sites were chosen on the basis of the anatomical results indicating the location in NbM and GP of neurons projecting to pericruciate cortex. Responses of NbM and GP neurons to electrical stimulation of precruciate gyrus, postcruciate gyrus and caudate nucleus were determined. Most cells responded to stimulation of caudate and cortex. In both NbM and GP 84% (49/58) of the neurons responded to caudate stimulation, 62% (21/34) to precruciate cortical stimulation and 55% (21/38) to postcruciate cortical stimulation. More than half of the responding neurons displayed initially inhibitory response (57% (28/49) for caudate stimulation and 69% (29/42) for cortical stimulation). Proportionately more responses to caudate stimulation were initially excitatory (43% (21/49)) than responses to cortical stimulation (31% (13/42)). NbM or GP neurons that were antidromically activated by cortical stimulation were not encountered frequently. When such neurons were identified average latency to the antidromic spike was about 10 msec. These neurons also responded orthodromically to cortical and caudate stimulation. Analysis of spontaneous firing patterns indicated that most NbM and GP neurons were either rapidly firing (mean interspike intervals <200 msec; 25% (13/52)) or displayed relatively slow rates (mean interspike intervals >1000 msec; 42% (22/52)). These results indicate that NbM neurons project to neocortex and receive inputs from caudate nucleus and pericruciate neocortex. Supported by USPHS Grants AG 01558 and HD 05958.

261.5 NEUROPHYSIOLOGICAL CHANGES IN CAUDATE NUCLEUS NEURONS IN AGED CATS. M.S. Levine, R. L. Lloyd, C.D. Hull, N.A. Buchwald. Mental Retardation Research Center, UCLA School of Medicine, 760 Westwood Plaza, Los Angeles, California 90024.

These studies were designed to assess some of the neurophysiological changes in caudate nucleus (Cd) neurons in cats over 10 yrs of age. Extracellular single unit recordings were made from the head of the Cd in "acutely" prepared locally anesthetized cats. To date, we have recorded and compared data from 110 neurons in 5 aged cats (11-16 yrs) with data from 122 neurons in 7 adult cats (1-3 yrs). The ability of Cd neurons to respond to stimulation of monosynaptic inputs from precruciate cortex (Cx) and substantia nigra (SN) was determined. In adult cats 81% (89/110) of Cd neurons responded to Cx stimulation and 72% (58/81) responded to SN stimulation. In aged cats there was a decrease in the proportion of neurons responding to SN stimulation (63% (44/70)). The proportion of neurons responding to Cx stimulation remained relatively unchanged (79% (65/82)). Types of responses that were evoked in both adult and aged cats were similar and consisted of either excitation (increase in frequency of occurrence of action potentials), excitation followed by inhibition of action potentials or inhibition alone without preceding excitation. The proportion of time each type of response was evoked in the aged animals when either Cx or SN was stimulated was altered. In adult cats Cx stimulation evoked initially excitatory responses 74% of the time (66/89) while in aged cats excitatory responses occurred 63% (41/65) of the time. When SN was stimulated this decrease in initial excitation was greater (65% (38/58) in adults vs 32% (14/44) in aged cats). In all aged animals but not in adults stimulation thresholds were higher for evoking excitatory responses than were thresholds for evoking inhibitory responses. There was a tendency for more shorter latency responses to occur in the aged animals. In order to assess synaptic security the ability of Cd neurons to respond to iterative stimulation was determined. Distributions of the minimum intervals necessary to evoke two excitatory responses were constructed. There was a marked increase in the proportion of longer intervals in the aged animals indicating that the neuron's ability to respond to iterative stimuli was decreased. These findings provide evidence for decreasing excitability and synaptic security in Cd neurons in aged cats. Furthermore, they indicate that there are functional changes in Cd neurons during aging that parallel some of the morphological changes that we have previously described (Levine et al. Neurosc. Abst. 10, 1984, 451). Supported by USPHS Grants AG 01558, HD 05958.

261.6 EFFECTS OF AGE ON PAIRED PULSE INHIBITION AND POTENTIATION IN CA1 OF THE RAT HIPPOCAMPUS. J. F. Ott, B. E. Hunter and D. W. Walker. Dept. of Neuroscience, Univ. of Florida Coll. of Med. and V. A. Medical Center, Gainesville, FL 32610.

This study was conducted as part of an ongoing project to understand the effects of feed forward (FFI) and recurrent inhibition (RI) in the CA1 of the rat hippocampus. To help dissociate FFI from RI effects, paired-pulse stimulation was delivered to CA1 in either orthodromic/orthodromic (O/O) or antidromic/orthodromic (A/O) pairs. To evaluate age effects on O/O and A/O pairs, in vivo experiments were conducted in 10 month old (Y) or 25-27 month old (O) male Fischer 344 (F-344) rats.

Concentric bipolar electrodes were placed in stratum radiatum at the CA1-CA2 border for orthodromic stimulation and in the alveus for antidromic stimulation. Glass micropipettes were positioned in stratum oriens or radiatum to record EPSP or population spike (PS) responses. To allow comparison between animals, percentages of PS maximum or EPSP at PS threshold were used rather than absolute amplitudes. Orthodromic condition pulse intensities of 25% and 75% of the PS maximum were used as were the current intensity at the PS threshold and 25%, 50% and 75% of the EPSP at PS threshold. Antidromic condition current intensities were either 25% and 75% of the antidromic PS maximum. Test pulse current intensities were either 25% of the PS maximum or 50% of EPSP at PS threshold. Interpulse intervals ranged from 20-3000 msec.

Results from F-344 rats are similar to those we obtained from Long Evans (LE) hooded rats (Roger, C.J., et al., Soc. for Neurosci. Abstr. 10:305.7 1984). Little difference between strains was seen with A/O stimulation. However, when using O/O stimulation, the potentiation of the test pulse was less in F-344 rats, particularly at higher conditioning pulse amplitudes. As in LE rats, inhibition produced by A/O stimulation increased with increasing A/O conditioning pulse amplitude. A/O inhibition was slightly greater in Y animals. O/O stimulation produced potentiation that at higher conditioning pulse amplitudes was obscured by an initial inhibition. This inhibition increased in magnitude and duration with increasing conditioning pulse amplitude and was greater in Y animals, particularly at the higher conditioning pulse amplitudes. The potentiation seen with O/O stimulation increased with increasing subthreshold condtioning pulse amplitudes to reach a maximum when the conditioning pulse amplitude was 75% of EPSP at PS threshold. As the conditioning pulse amplitude was increased further, maximum potentiation decreased. This was true for both Y and O animals, however, potentiation was much greater in O animals. Age differences were much more prominent in the O/O than A/O paired pulse series. Preliminary analysis of these data suggest that FFI is more affected by age than is RI.

261.7 THE HYPERPOLARIZING DENDRITIC GABA RESPONSE OF THE RAT CA1 HIPPOCAMPAL PYRAMIDAL NEURON DECREASES WITH AGE.
M.F. Davies, T.J. Blaxter* and P.L. Carlen. Playfair Neuroscience Unit, Toronto Western Hospital; Addiction Research Foundation Clinical Institute; Depts. of Medicine and Physiology, University of Toronto, Toronto, Ontario, M5T 2S8.

Pressure application of GABA onto the hippocampal CA1 pyramidal cell causes a hyperpolarizing response in the somatic region and a depolarization (D-DEPOL) in the dendritic region which are both apparently mediated by chloride. Recently a dendritic hyperpolarizing response (D-HYPER) which seems to be due to an increase in calcium dependent K conductance ($gK_{Ca}$) has been described (Blaxter et al., Soc. Neurosci. Abstr., Vol 10, Part 1, p. 203, 1984).

We compared the mid stratum radiatum dendritic GABA response in slices taken from young (6-8 months) and old (25-30 months) Fisher-344 rats. Various amounts of GABA ($10^{-2}$M) were pressure applied into the mid stratum radiatum area of the impaled cell. There was no statistical difference in the resting membrane potential or input resistance between old and young neurons. The total duration of the GABA response was similar although old cells showed more variability. The amplitude of the D-HYPER phase was significantly less in the aged cells ($P<0.05$) but the duration was not significantly different. The amplitude of D-DEPOL phase was similar although the responses of the young cells were shorter, probably due to the greater strength of the underlying D-HYPER. This would indicate that the GABA activated $gK_{Ca}$ in the dendrites is lower in aged animals which might be due to an underlying change in the intracellular calcium regulatory processes.

261.8 NEURONAL INVOLUTION IN FETAL NEOPALLIAL TRANSPLANTS ISOLATED WITHIN PERIPHERAL NERVES OF ADULT RATS.
L.C. Doering and A.J. Aguayo. The Neurosciences Unit, Montreal General Hospital and McGill University, Montreal, Quebec, Canada. H3G 1A4.

Embryonic E12-13 rat neopallium was dissected, mechanically disaggregated, plated on poly-L-lysine coated tissue culture flasks and grown in a modified Eagle's minimal essential medium. After 3 to 7 days these cells were treated with trypsin, washed and centrifuged in preparation for transplantation into isolated segments of transected sciatic nerves of adult Lewis rats. An incision was made in the epineurium and 250,000 to 500,000 cultured progenitor cells were introduced into the isolated nerve segment. To minimize reinnervation of these transplants the severed ends of the transected nerves were tied off and separated from each other. Neuronal transplants were examined by electron microscopy, immunocytochemistry and morphometry at time periods ranging from 1-3 months (Group A) and 11-12 months (Group B) after grafting.

While neurons in Group A grafts survived and differentiated as described previously (Doering and Aguayo, Soc.Neurosci.Abstr.,10: 49,1984), we observed several different changes in long standing neuronal implants in Group B rats. The main alterations consisted of an intense immunostaining of the neuronal somata by RT97, an antibody directed against the 200 kD neurofilament (NF) protein subunit. The same method predominantly stained axons and dendrites of neurons in Group A grafts . Several other features of neuronal involution were evident at the ultrastructural level: nerve cell nuclei were dense and shrunken (decreased nuclear area), ellipsoid in shape (decreased form factor), contained inclusions (filamentous intranuclear rodlets) and were surrounded by a thin cytoplasmic rim. The neuropil contained accumulations of intermediate filaments, degenerating neuronal processes and many dense and multivesicular bodies. Such morphologic abnormalities were not observed in Group A rats, in cerebral cortices from the host animals nor in the brains of 1 year old rats.

These observations suggest that transplants of rat embryonic cortical neurons isolated in peripheral nerves for long time periods undergo certain involutional changes reminiscent of those described in the brains of aged animals (J.E. Johnson and J. Miquel, Mech. of Ageing & Develop. 3:203, 1974; K.R. Brizzee et al., Aging 7:515, 1978; J.P. Brion et al. Acta Neuropathol.58: 107, 1982; MB. T. Buschmann and A. LaVelle, Neurobiol. of Aging 4:197, 1983). The unusual environmental conditions and deficient afferent and efferent connections of these nerve cell grafts may accelerate involutional processes.

261.9 CALCIUM IN THE SPINE APPARATUS OF DENDRITIC SPINES IN THE DENTATE FASCIA VARIES WITH AGE.
K. Cullen-Dockstader* and E. Fifkova (SPON: A.C. Bekoff). Dept. Psych., Univ. Colorado, Boulder, CO 80309.

Using the pyroantimonate precipitation technique, we have demonstrated $Ca^{2+}$ deposits in the spine apparatus (SA) in dendritic spines (Fifkova, et al., Brain Res. 266:163, 1983). The spine apparatus is connected with the smooth endoplasmic reticulum (SER) of the dendrite, and the SER in general is considered to be a calcium sequestering site. The reported experiments were undertaken to study $Ca^{2+}$ precipitates in the SA in relation to age. Male rats (Fischer 344) ages 3, 9, 24, and 30 months (4 animals per age group) were perfused for electron microscopy and treated for $Ca^{2+}$ cytochemistry. Instead of pyroantimonate we have used oxalate as a primary precipitating agent and pyroantimonate as a secondary one to enhance the contrast of the $Ca^{2+}$ oxalate deposits. In order to minimize the possible method-related artifacts, groups of 4 rats (one from each age group) were perfused and treated at the same time. Spines were scored in the middle and distal thirds of the dentate molecular layers since here they receive a homogeneous input from the entorhinal cortex. Spines were scored as to the presence of the SA and the $Ca^{2+}$ deposits there, and the data were expressed as a percentage of the total number of the encountered spines. For each age group 3,000 spines were scored. A steady decline in the presence of deposits in the SA was observed between the 3, 9, and 24 months - 16.7%, 14.4%, and 11.6%, respectively. While this decline was not significant between the 3 and 9 months groups, it was significant between these groups and the 24 months group, respectively. Given that between these ages there was no significant decline in the presence of the SA in spines, these results may indicate a decreased capacity of the spine apparatus to sequester calcium with age, a conclusion which is in line with the suggested age-related alteration of $Ca^{2+}$ homeostasis (Landfield and Pitler, Sci. 226:1089, 1984). However, in the 30 months group, there was a significant increase of spines with deposits in the SA (18.1%) as compared to 24 and 9 months. Such a result could be related to the loss of spines observed in this region (Geinisman, et al., Anat. Rec. 187:586, 1977). Given that in the 30 months group there is also a significant increase of spines with SA, the spine loss, if it were related to the present data, would have to include specifically spines without the SA. However, the presented results could also be explained by a compensatory growth of the remaining spines with SA.

261.10 Regional Analysis of Rat Brain Proteins During Senescence
J.W. Cosgrove, J.R. Atack, and S.I. Rapoport Lab. of Neuroscience, NIA, NIH, Bethesda, MD 20205

Previous studies in this laboratory have demonstrated that the overall in vitro protein synthetic capacity of extracts of whole brain of male Fischer-344 rats is age-invariant between young (3-4 months) and old (32-34 months) animals (Cosgrove, J.W. and Rapoport, S.I: Soc. Neurosci. Abstracts 10: 131.16, 1984). Thus, there appears to be no major age-related alteration in the ability to synthesize brain proteins in the male Fischer-344 rat. However, it is possible that, where as in vitro synthetic capacity is unaltered during senescence, abnormal proteins accumulate in the brain due to an increase in in vivo translational errors associated with the aging process. These errors would be manifested as alterations in either the molecular weight of proteins due to inaccurate translation, or as changes in the isoelectric point of proteins due to amino acid substitutions resulting from translational errors. Such changes would not be detected in a study of overall protein synthetic capacity. However, use of the two dimensional gel electrophoresis method in conjunction with either standard protein dye or highly sensitive silver stain detection techniques would provide a means of investigating possible increases in translational errors.

We sampled 11 different regions of the central nervous system of the male Fischer-344 rat between 4 and 30 months of age, including several areas which reportedly show significant age-related changes in cell morphology. Our data indicate that the most abundant brain proteins are expressed at approximately equal levels in the 11 brain regions. Furthermore, the expression of these major proteins is age-invariant. These results agree with a previous study which found no major alterations in proteins in the superior cervical ganglion of the male Fischer-344 rat up to 24 months of age (Wilson et al., Gerontology, 24: 426, 1978). In contrast to the major proteins, a number of the less abundant (but still detectable) brain proteins show region-related differences in the level of their expression at 4 months of age. In addition, preliminary results indicate that the level of expression of several of these proteins is altered in relation to age. Interestingly, the altered expression as a function of age is region specific. Thus, a particular brain protein may have a constant level of expression with age in one brain region, but the same protein may display an age-related alteration in the level of expression in another brain region. These data provide no support for the theory that there is a major accumulation of translational errors or of abnormal proteins in the brains of male Fischer-344 rats in relation to age. However, they do indicate that there is region-specific regulation of expression of a number of brain proteins and that during senescence there may be differential control mechanisms which operate in some brain regions but not in others.

261.11 EFFECTS OF AGING ON ATP-DEPENDENT $CA^{2+}$ TRANSPORT IN BRAIN SYNAPTIC MEMBRANES. M. L. Michaelis and E. Le Cluyse*. Center for Biomedical Research, University of Kansas, Lawrence, KS 66046.

Synaptic plasma membranes contain two $Ca^{2+}$ transporting systems which help to maintain low free intraneuronal $Ca^{2+}$ concentrations, a $Na^{+}$-dependent $Ca^{2+}$ antiporter and a ($Ca^{+}$ + $Mg^{2+}$)-ATPase which pumps $Ca^{2+}$ to the extracellular environment. We have recently observed that aging affects the activity of both of these systems in synaptic membranes obtained from Fisher 344 rats. The affinity of the $Na^{+}$-$Ca^{2+}$ antiporter for $Ca^{2+}$ is decreased in aged animals. The $V_{max}$ of the $Ca^{2+}$-activated ATPase was also slightly decreased in 24-vs 8-month old animals. More recently we have been examining the kinetic characteristics of the ATP-driven $Ca^{2+}$-transport in very highly purified synaptic plasma membranes and the influence of aging on this activity. This transport system is dependent on the presence of $Mg^{2+}$ ($K_{0.5} \approx 55$ µm) and requires the hydrolysis of ATP ($K_m \approx 20$ µM), as non-hydrolyzable ATP analogs will not support $Ca^{2+}$ transport. Possible age-dependent alterations in the activity of this pump have been examined in highly purified membranes from the brains of 7-8 and 23-24-month old Fisher 344 rats. Incubations were carried out in a medium containing membrane protein (≈ 20 µg),100 µM ATP, 50 µM $MgCl_2$, and various concentrations of $CaCl_2$ ranging from .05 µM - 1.0 µM; with 0.2 µM CDTA to buffer the final free $Ca^{2+}$, $Mg^{2+}$, and ATP concentrations. Under these conditions we have found small differences in the kinetic characteristics of the $Ca^{2+}$ transport system between the two age groups. Computer fitting of the data to the Michaelis-Menten equation revealed a decrease in the affinity for $Ca^{2+}$ in the 24-month ($K_M$ = 2.6 µM) compared to the 8-month old animals ($K_M$ = 1.8 µM). However, the $V_{max}$ values obtained from the $Ca^{2+}$ curves for the two groups of animals indicated that the aged animals had an increased maximal transport capacity. It is conceivable that some alteration in the composition of the synaptic membranes has led to a decreased affinity for $Ca^{2+}$, but that the overall transport capacity of the synaptic junctional membranes at high $Ca^{2+}$ concentrations is maintained. Studies are underway to probe the possibility that the aging process leads to changes in the membrane lipid composition which then alters the activity of membrane proteins. 261.12 BRAIN CALCIUM-DEPENDENT PROTEASES, NEURONAL STABILITY, AND AGING: AN HYPOTHESIS. M. Baudry, J. Larson* and G. Lynch, Center for the Neurobiology of Learning and Memory, U.C. Irvine, CA 92717 U.S.A.

Current ideas about the causes of brain aging fail to account for three well-known aspects of the phenomenon: (1) aging is associated with neuronal atrophy and degeneration, (2) since maximum life-span varies by orders of magnitude across the mammals, brain aging presumably progresses at different rates in different species, and (3) the neuropathology associated with aging does not occur with equal intensity in all brain regions and cell types.

We now advance a cellular hypothesis that provides at least a partial explanation for these three features of brain aging. Specifically, we suggest that variations in the activity and/or amount of calcium-activated proteases ("calpains") dictate the rate at which pathology develops in brain with age. Calpain exists in two forms, distinguished by their threshold for activation by calcium; both forms of the enzyme are found associated with soluble and membrane fractions in brain. These enzymes degrade certain cytoskeletal proteins as well as proteins that cross-link cytoskeletal elements with each other or the plasma membrane. Several lines of evidence implicate calpains in the breakdown of the cytoskeleton as well as in muscular and neuronal degeneration. Thus these enzymes provide a plausible candidate for the causes of age-related neuropathology. Maximum life-span in mammals is highly correlated with brain size according to the formula: life span = K (brain size)$^{+0.3}$ ; bats provide a singular exception to this equation in that they live much longer than would be predicted from brain size. We have found that soluble calpain activity is negatively correlated with brain size across orders of mammals according to the formula: calpain activity = K (brain size)$^{-0.4}$, and that bats have anomalously low levels of calpain activity. Combining these points, we find that calpain activity is almost linearly (and negatively) related to maximum life span and thus presumably to the rate of brain aging. Finally, recent immunocytochemical experiments have shown that calpain is not evenly distributed throughout the brain and that it is found in high concentrations in a number of areas and cell types known to be at risk in aging (e.g. subiculum, cerebellar Purkinje cells, large neurons in cerebral cortex).

Thus calpains are linked to degeneration, co-vary with aging rate, and show at least some association with the loci of age-related neuropathology. We propose that calpain activity determines the pace at which cytoskeletal and structural elements of brain cells are broken down and replaced, and that this process, possibly coupled with progressive deterioration of intracellular calcium buffering, is responsible for the gradual appearance of irreversible damage over the course of aging.

261.13 VESICLE MOBILIZATION AND DEPLETION DURING FREQUENCY POTENTIATION AND DEPRESSION IN THE HIPPOCAMPUS OF AGED AND YOUNG RATS. M.D. Applegate* and P.W. Landfield, Dept. of Physiol. & Pharmacol., Bowman Gray Sch. of Medicine, Winston-Salem, NC 27103.

Although studies in peripheral and invertebrate systems suggest that vesicle mobilization and depletion are correlated with synaptic potentiation and depression, respectively, it is not clear whether a similar relationship is seen in mammalian brain. Moreover, except for one preliminary study, there have been no investigations of vesicle density and concurrent electrophysiology in a monosynaptic brain system. The present studies were therefore undertaken to determine whether vesicle mobilization and depression are correlated with synaptic potentiation and depression in brain. In addition, since previous studies have found a deficit in the amplitude of potentiation and increased synaptic depression in the hippocampus of aged rats during repetitive stimulation, we conducted experiments on vesicle distribution in both aged and young rats before and during a stimulation train.

Stimulating electrodes were placed in the Schaffer-commissural system of field CA1 in the hippocampus of 13 young and 11 aged rats. Recording electrodes were placed in the somal layer of CA1 and population spike responses were recorded. After control responses were obtained, the Schaffer-commissural fibers were stimulated at 10 Hz and at 150% of the voltage necessary to elicit a population spike. Stimulated animals were intracardially perfused with a mixed aldehyde solution after either 45 sec or 8-9 min of stimulation. Control animals were implanted with electrodes but not stimulated. After standard preparation, electron micrographs were shot according to a programmed sequence throughout a strictly defined zone in the region of densest Schaffer-commissural termination on CA1 apical dendrites. Synapses were analyzed for vesicle density and for density of the local vesicle population (LVP - vesicles within the region adjacent to the active synaptic zone).

In both young and aged rats 45 sec stimulation increased the proportion of vesicles near the synapse, while 8-9 min of stimulation was associated with depletion of vesicles. The degree of potentiation or depression of the population spike was correlated with the degree of vesicle redistribution to the active zone or with the degree of depletion, respectively, across individual animals. As a group, aged rats exhibited significantly less mobilization (redistribution) of vesicles at 45 sec and greater depletion after 8-9 min of stimulation.

The results indicate that the relationship between synaptic structure and physiology seen in central systems is similar to that seen in peripheral systems, and that the age-related deficit in hippocampal synaptic physiology may be related to reduced mobilization and/or recycling of synaptic vesicles. (Supported by AG 04542)

261.14 AGE-RELATED CHANGES IN CHOLINERGIC ENZYMES AND MUSCARINIC BINDING SITES IN RAT BRAIN. J.E. Springer, R. Loy, and M. Tayrien*. Dept. of Anatomy, University of Rochester Medical Center, Rochester, NY. 14642.

In the animal and human aging literature there is conflicting evidence with respect to age-related changes in cholinergic muscarinic receptor binding sites. In the present study we used quantitative receptor autoradiography and radiochemical assays to measure possible age-related changes in cholinergic muscarinic binding and choline acetyltransferase (ChAT) and acetylcholinesterase (AChE) activities in young and aged rat brain. A total of 9 young (12 mo) and 9 aged (40 mo) rats were decapitated and the brains bisected. For assay of enzyme activities, six brain tissues were dissected from one hemisphere of each brain: nucleus basalis, medial septum/diagonal band, entorhinal and frontal cortex, dentate gyrus, and Ammon's horn/subiculum. Tissues were homogenized in 10 ml cold water/gm wet weight and triplicate samples assayed for ChAT, using (14C)-acetyl CoA, and for AChE using (14C)-acetylcholine chloride. For autoradiographic analysis, adjacent 20 um sections were preincubated in buffer, and then incubated in 2.0nM [3H]QNB (S.A. 77 Ci/mM), with or without 1 uM atropine, at 25C for 90 min. Sections were briefly washed and rapidly dried prior to exposure for 6 days to LKB Ultrofilm. Following developing, autoradiographs were analyzed using the ARIA program developed for densitometric analysis with the Nikon Magiscan. Regional specific binding was determined for the subiculum, CA1, CA3, dentate gyrus and hilus subregions of the hippocampal formation. Relative optical densities (normalized rank order) was also determined for these regions relative to whole hippocampus.

As reported by others, we find a drop in both ChAT (38%) and AChE (28%) in the septum, and a 46% drop in ChAT activity in the nucleus basalis of aged rats. Activity of both enzymes in frontal and entorhinal cortex and dentate gyrus is equivalent in young and aged brains. By contrast with dentate gyrus, the activities in Ammon's horn/subiculum of ChAT and AChE are 24% and 38% lower, respectively in the aged brains. At all dorsal hippocampal levels in the autoradiographic analysis, specific binding is no different in the aged and control animals, and is relatively constant through the dorsal levels measured. However, at the more temporal levels of the hippocampus, specific binding is higher in the dentate gyrus (25%), CA1 (27%), and subiculum (40%) in the aged brains. These findings indicate that in aged rat hippocampus, there may exist a compensatory muscarinic receptor mechanism which is responding to changes in cholinergic activity, especially in Ammon's horn and subicular regions.

Supported by NS-20288 (RL) and AG-T32107 (JS).

261.15 AGE-CORRELATED DENDRITIC CHANGES IN MEDIUM SPINY STRIATAL NEURONS OF THE C57BL/6NNIA MOUSE. T.H. McNeill, L. Koek*, S. Brown*, and J. Rafols. Dept. of Neurology, Univ. of Rochester, Rochester, NY 14642; Dept. of Anatomy, Wayne State Univ., Detroit, MI 48201.

Alterations in neurotransmitter systems of the basal ganglia have been postulated to contribute to a disruption of motor function and balance associated with advancing age. Previous biochemical studies in rodent and human brain have reported age-related declines in a number of biologically active substances in the striatum and the substantia nigra, decreases in the number of dopaminergic and cholinergic binding sites in the striatum, and age-correlated morphological changes in dopaminergic neurons of the midbrain. Since it is known that medium spiny neurons (MS) are a principal target population for nigrostriatal dopamine fibers, we undertook a study to examine the question as to whether striatal MS target neurons undergo compensatory dendritic growth or regression with age in response to possible degeneration of neighboring and/or afferent projecting neurons.

For our study, five mouse brains from each of six age groups (3, 6, 10, 20, 25 and 30 mos) were prepared by the Golgi Cox method. Qualitative examination of the striatum showed that MS neurons had oval shaped cell bodies with several primary dendrites emerging from their soma. Primary dendrites lack spines with the density of the spines reaching a maximum on terminal or next to terminal segments. In general, MS neurons in the caudal striatum had larger dendritic profiles than MS neurons at a more rostral level. Data collection at both a rostral and caudal anatomical level of the striatum show that while there was regression in the dendritic processes of some MS neurons, dendrites of other MS neurons remain unchanged or enlarged. Quantitative examination of dendritic profiles showed that between 3 and 10 months of age, there was an overall loss of total dendritic length in MS neurons, primarily in terminal segments, followed by an increase in dendritic length between 10 and 30 months of age. Total dendritic length in aged mice (30 mos) was not statistically different from young adults (3 or 3 mos). Of interest is that the onset of dendritic "growth" at 10 months is paralleled by the initialization of morphological changes in DA neurons of the SN. These data suggest that while there is no comprehensive change in overall dendritic length or total number of dendritic segments in MS neurons between young and old mice, MS neurons of the striatum represent a dynamic population of growing and regressing cells. Our data also support the concept that with normal aging there are two populations of MS neurons in the striatum. One population is characterized by shrinking dendritic profiles and may be dying, while the other group of surviving neurons show normal or even expanding dendrites with age.

261.16 DENDRITES OF THE SUBICULUM IN HUMAN AGING AND ALZHEIMER'S DISEASE. D.G. Flood, M.A. Tovey* and P.D. Coleman. Depts. of Neurology and Anatomy, Univ. of Rochester Sch. of Med. & Dent., Rochester, NY 14642.

In addition to studying dendrites of layer II pyramidal neurons of parahippocampal gyrus, dentate gyrus granule cells, and hippocampal pyramidal cells in normal human aging and in Alzheimer's disease, we have extended our studies to the subiculum, the major source of efferents from the hippocampus. From over ninety cases obtained at autopsy, five subjects were assigned to each of the following four groups: 1) normal middle-aged adults (ave. age = 51 yr.), 2) normal old adults (ave. age 73 yr.), 3) normal very old adults (ave. age = 90 yr.), and 4) senile dementia of the Alzheimer's type (ave. age = 76 yr.). All cases were free from significant neurological or psychiatric disorders, except the cases in the latter group had a well-documented history of late stage Alzheimer's disease. All cases were also free from significant neuropathology at autopsy, except that cases in the latter group had abundant senile plaques and/or neurofibrillary tangles in the hippocampus and adjacent neocortex. Pyramidal neurons of the superficial layer of the subiculum were randomly selected for analysis from coded 200 um thick sections of tissue prepared by the Golgi Cox method. The groups did not differ significantly in post-mortem time which averaged 12.8 hrs. Preliminary data suggest that unlike previous findings in other regions of the hippocampus which showed age-related dendritic growth, the neurons in the subiculum show age-related decline in both lengths and numbers of segments. Cases with Alzheimer's disease could be grouped into two categories on the basis of the dendritic measures. The first group showed marked declines in dendritic extent, particularly in the apical dendritic tree. The second group of Alzheimer's cases had dendritic measures which were similar to normals of the same age. Supported by NIH grants AG 02680, AG 01121 and AG 03644, and by the Univ. of Rochester Center on Aging.

261.17 A COMBINED GOLGI HIGH VOLTAGE-E.M. STUDY OF DENDRITE TIPS IN OLFACTORY BULB IN AGING SPRAGUE-DAWLEY RAT. A.A. Carboni, Jr.*, M. del Cerro and P.D. Coleman (SPON: J. Albano). Department of Anatomy, University of Rochester, Rochester, NY 14642.

A variety of studies have described region, species, and age-specific growth of dendrites in the brains of aging animals, including human. Usually, this is reported as growth and, in some cases, branching of terminal dendrites. An important question arising from these observations is whether the newly formed dendritic surface at and near the tips of terminal dendrites forms synaptic contact with the surrounding neuropil. Hinds and McNelly (1977) described growth of dendritic material of the olfactory bulb mitral cells of aged Sprague-Dawley rats. We conducted a Golgi high voltage-e.m. study of the same cell type in the same strain to determine whether the tips of growing mitral cell dendrites formed synaptic contact with the surrounding neuropil. Olfactory bulbs were prepared by a technique in which neurons are Golgi-impregnated (Valverde, 1970), sectioned at 150 microns and gold toned (Fairen et al., 1977). The sections were then embedded in plastic for dendritic quantification at the light microscopic level. Following this quantification the terminal regions of individual dendritic segments were cut from the 150 micron section, re-embedded and re-sectioned serially at 1 micron. The serial 1 micron sections were then examined with the high voltage electron microscope to determine the density of synapses at the presumed newly formed region near dendritic terminations.

Supported by grant AG 1121 from the National Institute on Aging. Use of the AEI EM7 Mkll 1.2 MV high voltage electron microscope of the New York State Department of Health and the assistance of Dr. M.J. Song is gratefully acknowledged.

261.18 AN INEXPENSIVE PC BASED SYSTEM FOR QUANTIFICATION OF NEURONAL PROCESSES. A. Moyer*, V. Moyer* and P.D. Coleman (SPON: V. Laties). Department of Anatomy, University of Rochester, Rochester, NY 14642.

We have developed a system for quantification of neuronal processes based on an IBM PC computer and a GTCO graphics tablet that is used to quantify dendritic extent in two or three dimensions. In the most simple use of this system for 2-D quantification, a tracing of the dendritic tree of a single cell is placed on the graphics tablet. Calibration information is entered. The cell body may be entered. Dendritic segments are then entered by moving a cursor along the drawn dendrite. The operator signals each branch point and ending to the computer. The operator indicates whether an ending was the result of sectioning. The computer automatically orders dendritic segments in both somatofugal and somatopetal ordering systems and signals unfilled branch points on its display of the dendritic tree as entered by the operator. When analyzing pyramidal neurons, the system provides separate analysis of the basal tree, apical shaft, oblique dendrites and terminal tuft of the apical tree.

Three dimensional quantification requires the addition of: (1) provision for mixing a video image of the microscope field with the computer graphics display and (2) one stepping motor driver with stepping motor attached to the fine focus control of a microscope. The stepping motor driver uses information from the serial port of the computer to determine the desired focus changes. The operator moves a computer-generated cursor display along a dendrite displayed in the mixed video image produced by this system and signals desired moves of the calibrated focusing stepping motor to the computer. Information about these moves is retained by the computer to provide the third dimension. Both the two and the three dimensional systems provide information about segment numbers and lengths as a function of both somatofugal and somatopetal ordering. A Sholl concentric circles (spheres) analysis is also provided.

This system represents a considerable departure from a highly automated system developed previously in this laboratory. However, the greater degree of operator control over the pace of the system makes this new version much more tolerable to the operator. Software and hardware specifications are available.

261.19 ANTIGENIC SPECIFICITY IS NOT ASSOCIATED WITH ANTI-BRAIN ANTIBODIES IN SERUM FROM HUMANS TO 91 YEARS OLD. K. Leary and P.D. Coleman (SPON: R. Emerson). Department of Anatomy, University of Rochester, Rochester, NY 14642.

Age-related increase in brain reactive antibodies (BRA) has been reported in a number of studies. We examined the specificity for brain of BRA in human serum from subjects of varying ages. We obtained serum from 40 individuals from 8 months to 91 years old. BRA were assessed in frozen sections of young, middle aged and old human superior frontal gyrus by an indirect fluorescent antibody technique in which intensity of fluorescence was determined. Reactions were labelled using FITC conjugated anti-human IgG F(ab')2. Prior to primary incubation aliquots of serum from each person were untreated, or preincubated with 2% gamma globulin free human albumin or with brain homogenate. As a fourth treatment 20 randomly chosen serum samples underwent pepsin digestion and dialysis to cleave the F(ab')2 and Fc portions of the IgG molecule. All slides were read using a Nikon Optiphot fluorescence microscope with a digital microphotometer attachment. A dichroic filter in the photometer beam path blocked lipofuscin fluorescence, and a variable diaphragm allowed determination of fluorescence intensity from a small portion of a single neuron or from the entire field. Fluorescence intensities were measured with a 40x objective. All readings were taken in layer II.

Microphotometer data from single cells and from full fields indicated no significant change in serum binding to brain with increasing age regradless of pre-treatment of the serum. Pre-absorption with brain reduced (but did not emliminate) binding more than any of the other pretreatments. The binding remaining after preabsorption with brain appears to be attributable to non-specific binding.

Supported by grant AG 1121 from the National Institute on Aging.

261.20 RECOVERY OF VISUAL FIELDS IN MONKEYS DURING CHRONIC DOSING WITH METHYL MERCURY. V. Moyer* and P.D. Coleman (SPON: B. Weiss). Department of Anatomy, University of Rochester, Rochester, NY 14642.

We are conducting studies of chronic methyl mercury produced loss of neurons in monkey visual cortex and the dendritic extent of the surviving neighboring neurons. Visual field defects were used as a behavioral measure of the effect of mercury dosing. Eight juvenile (28-33 months old) Macaca fascicularis monkeys were fitted with occluding contact lenses and trained to monocularly fixate a point straight ahead and then detect and reach for a small marshmallow brought slowly into the visual field from the periphery at one of 8 locations around a perimetry apparatus. Visual fields were tested twice a week. When stable visual fields had been obtained for two weeks, chronic dosing with oral methyl mercury in grape juice was started for six randomly selected monkeys. An initial loading dose of 200 ug/kg body weight of methyl mercury was given twice a week until the blood level of total mercury reached approximately 2 ug/ml of blood. This took an average of seven weeks. Thereafter biweekly dosing was adjusted to maintain total mercury levels near 2 ug/ml blood. Blood levels were sampled biweekly.

Dosing and visual field testing continued for over one year. Dosing of two monkeys was stopped during the resulting visual field loss. These two animals showed rapid recovery of visual fields after the cessation of dosing. Visual field loss was expressed as total degrees of field loss summed over the 8 locations tested. There were major individual differences among monkeys in both the timing and the extent of the visual field loss. The onset of the loss came between 2 and 11 weeks after the start of dosing, with the peak loss coming 10 to 19 weeks after the start of dosing. The peak total degrees lost ranged from 50 to 265. During this time all monkeys showed recovery of visual fields to near pre-dosing levels.

This finding of consistent recovery of function during and after chronic administration of methyl mercury to a primate is unusual in that chronic human methyl mercury poisoning is usually considered to produce long-term visual field deficits. Our findings are, however, in agreement with the data of Merigan, et al. (1983) for chronically exposed monkeys.

## ENDOCRINE CONTROL OF DEVELOPMENT II

262.1 ACTION OF CORTICOIDS UPON DEVELOPMENT OF ELECTRICAL PROPERTIES IN CULTURED CHICH EMBRYOS BRAIN NEURONES. Beatriz-Fuentes Pardo, Leticia Verdugo-Díaz*, Pedro N. Velázquez*, Marta C. Romano*. Deptos. Fisiología e Histología, Facultad de Medicina, División de Investigación, UNAM.70250. CINVESTAV. México, D. F.

Progressive changes in both passive and active electrical properties in cultured chick embryos brain neurones were recorded from the 3th to the 12th day of development. The effects of corticosterone application in unique doses to 24 h old cultured were also studied. The main results are: a) in corticoid pretreated cells the membrane resting potential recorded at 3th or 6th day of culture showed a significant increment with respect to control, b) the resistance, capacitance and time constant were systematically modified along the twelve days of culture, and the corticoids pretreated cells reached earlier the final values of these parameters than control cells, c) in control cultures the height and frequency of spikes reached values similar to adult neurones around the 9th day; corticoid pretreated cells often showed these values around the 6th day of culture, d) microscopical observations of both control and pretreated cells showed no significant differences in somal size of neurones along development. Suggesting that corticoids act upon differentiation of metabolic and enzimatic processes involved in cellular electrical properties.

262.2 EXTRINSIC CONTROL OF SULFATIDE AND CEREBROSIDE SYNTHESIS IN ISOLATED RAT NEONATAL OLIGODENDROCYTES. R.P. Saneto, M.C. Cardwell,* L.H. Rome,* and J. de Vellis, MRRC, UCLA, Los Angeles CA 90024.

The formation and maintenance of myelin by oligodendrocytes has been known for over sixty years. However, what factors control these processes remain largely obscure. Recently we developed a serumless chemically defined medium that induced proliferation of isolated oligodendrocytes (Proc. Natl. Acad. Sci. (USA) May 10 issue, in press). Immunocytochemical detection indicated that the components of the oligodendrocyte defined medium (ODM) insulin, transferrin and pituitary fibroblast growth factor, induced the expression of myelin basic protein without a concomittant increase in galactocerebroside (GC). This suggests that expression of these two myelination-associated events are to some degree separately controlled. When either triiodothyronine ($T_3$) or both hydrocortisone (HC) and dibutryl cyclic AMP (dbcAMP) were added to ODM, the extent and intensity of GC staining per culture increased significantly. Neither HC or dbcAMP added separately had an effect. Hormonal effects on the synthesis of both GC and sulfatide were measured biochemically by incubation with ($^3$H)palmitate. Cultures were labelled for 24 h and incorporation into GC and sulfatide was determined after alkaline methanolysis by TLC with purified standards. After 5 days of exposure to 15 nM $T_3$ or 1 uM HC and 1 mM dbcAMP, the synthesis of both GC and sulfatide was significantly increased. $T_3$ induced an equal effect on both GC and sulfatide, increasing the amount of synthesis 150% over control cultures. Together HC and dbcAMP were found to increase the synthesis of the myelin glycolipids to different degrees; GC synthesis was increased 100% and sulfatide synthesis 130% over control cultures. These data indicate that $T_3$ and HC and dbcAMP together, can stimulate GC and sulfatide synthesis in isolated neonatal oligodendrocytes. 262.3 TESTOSTERONE INCREASES CELL NUMBERS IN ORGANOTYPIC CULTURES OF FETAL MOUSE SPINAL CORD. K.F. Hauser and C.D. Toran-Allerand. Ctr. Reprod. Sci., and Depts. of Neurol., and of Anat. and Cell Biol., Columbia Univ., New York, NY 10032.

Developmental exposure to androgens is responsible for the appearance of a sexually dimorphic androgen receptor-containing motor nucleus in the spinal cord of the male rat (Breedlove and Arnold, Sci., 210: 564, 1980) and mouse (Hauser and Toran-Allerand, unpublished). In order to characterize the developmental role of androgen on androgen receptor containing neurons and to distinguish it from the contributions of the neuromuscular effector unit, we have studied the effect of testosterone on motoneuron numbers in cultures of all lumbo-sacral levels of the spinal cord, using [3H]-thymidine autoradiography. Mice were mated for a single 45 min. period (7:30-8:15 AM) and checked for sperm plugs immediately thereafter (E-0). On E-10, pregnant mice received two, 250uCi i.p. injections of [3H]-thymidine at 8:00 AM and 12:00 PM. On E12, which precedes a normally occuring period of mouse lumbar motoneuron death (Lance-Jones, Dev. Brain Res., 4: 473, 1980), individual spinal cord segments L1-6 and S1 were removed with their attached dorsal root ganglia. Explants were exposed twice weekly to the steroid-deficient, serum containing medium standard for our laboratory, which was additionally supplemented with muscle extract (5%), 9-day chick embryo extract (5%), and NGF (100ng/ml). Two embryos were taken from each pregnant female; explants from 1 embryo were treated with testosterone (20ng/ml), while those from the second served as controls. After 35 days in vitro, explants were fixed in 10% neutral formalin, and 6um paraffin sections were processed for autoradiograpy. Cells with a distinct nucleolus, and 20 or more silver grains (heavily labeled) were counted from every third section at a magnification of X640.

Preliminary counts indicate that testosterone significantly increased the number of heavily labeled cells at all levels using the $t$ statistic for paired observations ($P<0.05$). Autoradiograms of 3 mice injected on E-10 and killed when adults showed that the most heavily labeled cells were motoneurons. The results suggest that, despite the presence of muscle extract, testosterone per se exerted an additional specific neuronotrophic effect on the pre-explantation labeled motoneurons, probably by enhancing cell survival, or (less likely) by enhancing cell differentiation and/or inhibiting further proliferation. Since comparable spinal cord cultures are unable to aromatize androgens to estrogens (Hauser et al., in preparation), these findings suggest that the observed effect occurs throughout the lumbo-sacral cord and is directly mediated in part by testosterone. (Supported by NIH, NIMH, and the Whitehall Foundation).

262.4 AXONAL DEVELOPMENT IN NORMAL AND HYPOTHYROID RAT CEREBELLAR CORTEX. C. Gravel*, N. Leclerc*, A.V. Plioplys* and R. Hawkes* (SPON: R.F. Estable-Puig) Laboratory of Neurobiology, Laval University, Quebec, Canada G1J 1Z4.

We are using monoclonal antibodies to investigate the effects of hypothyroidism on axonal development in rat cerebellar cortex. Two monoclonal antibodies raised against synaptosomal plasma membranes have been used to follow axonal development in an interneuron (basket cell) and a projection neuron (Purkinje cell). MabN210 recognizes the high molecular weight subunit of neurofilaments and gives exclusively axonal staining in the cerebellar cortex. MabMIT-23 recognizes a neuron-specific mitochondrial determinant and stains all adult neuronal classes, including the axons (Hawkes et al. Cell 28: 253, 1982). The immunocytochemical staining patterns of the antibodies were compared on two groups of developing rats, normal controls and a group rendered hypothyroid with 6-n-propyl-2-thiouracil. Animals were studied through the first postnatal month. The expression of the 210Kd antigen is severely suppressed in hypothyroid animals. In normal rats, immunoreactivity first appears at P12 and attains adult levels at P15. By contrast, there is little of no mabN210-immunoreactivity at P15 in hypothyroid animals. By contrast, the levels of MabMit-23 were little affected. MabMIT-23 and mabN210 both reveal a novel feature of Purkinje cell axonal development: the transient presence of focal axonal swellings. Swellings are seen in both normal and hypothyroid animals but the timecourse is protracted in the latter group. [Supported by grants from MRC Canada and Fonds de recherche en paralysie cérébrale].

262.5 **NEONATAL HYPOTHYROIDISM PREVENTS NATURALLY OCCURRING CELL DEATH IN THE SUPERIOR CERVICAL GANGLION OF THE RAT.** P. Beaston-Wimmer* and A.J. Smolen (SPON: T.J. Cunningham). Dept. of Anatomy, Med. Coll. of Pa./E.P.P.I. Division, Philadelphia, PA. 19129.

Ganglion neurons in the rat superior cervical sympathetic ganglion (SCG) undergo naturally occurring death during the first two postnatal weeks, resulting in the loss of approximately one third of the neurons present at birth. It is generally thought that regulation of neuronal survival during this period depends exclusively on interactions of the developing neurons with their targets, and in the case of sympathetic neurons, with the well-defined target trophic substance, nerve growth factor. However, recent studies have shown that the factors which regulate neuronal survival in vivo are more complex than was previously assumed. For example, it is now known that when neonatal rats are exposed to increased levels of circulating gonadal steroids during the first two postnatal weeks, most of the naturally occurring neuronal death is prevented. Even the normal differences in levels of circulating steroids in neonatal male and female rats is sufficient to result in reduced neuron death in males.

We have recently begun to investigate the importance of thyroid hormone in the development of the sympathetic nervous system. In several regions of the nervous system, abnormal levels of thyroid hormone during the neonatal critical period are known to alter various aspects of development. In the sympathetic nervous system, experimental hyperthyroidism was shown to accelerate maturation of neurotransmission temporarily, while hypothyroidism delayed maturation. In the present study, we produced experimental hypothyroidism by treating newborn rats with daily subcutaneous injections of propylthiouracil (PTU). Littermates received injections of vehicle only. The injection regimen was continued until postnatal day 15, which marks the end of the period of naturally occurring neuron death. In vehicle injected male rats, there were 27,400 $\pm$ 2,011 neurons in the SCG, compared with 33,800 $\pm$ 1,830 in PTU treated animals. Thus, PTU treated rats had 23% more neurons in their SCGs than did control rats. One possible explanation for this finding is that experimental hypothyroidism delays the onset of neuron death. Alternatively, there may be interaction between thyroid hormone and the gonadal steroids. Further experiments are needed to examine these hypotheses.

262.6 ENHANCED MYELINATION OF RAT BRAIN FOLLOWING ADRENALECTOMY. V.L. Friedrich, Jr., K.R. Fairman and J.S. Meyer. Dept. of Biobehavioral Sci., Univ. of Connecticut, Storrs, CT 06268 and Dept. of Psychology, Univ. of Massachusetts, Amherst, MA 01003.

Removal of the adrenal glands from rat pups causes increases in brain weight and in brain content of myelin, isolated by subcellular factionation, and of the myelin-related enzyme 2':3'-cyclic nucleotide phosphohydrolase (Meyer and Fairman, Dev. Brain Res. 17:1-9). The present study was undertaken to verify and characterize the increased myelin content morphometrically.

The adrenal glands of five Sprague-Dawley rat pups were surgically removed at 11 days after birth; five controls were sham operated (laparotomy without adrenalectomy). Animals were sacrificed at 63 days after birth and processed for electron microscopy. Optic nerve was sectioned transverse to its axis, and corpus callosum was cut sagittally, at the midline. Myelin area fraction was determined by point hit counting of randomly placed electron micrographs, and total myelin as the product of myelin area fraction and tract cross sectional area. The number of lamellae and circumference of randomly selected myelinated axons were also determined.

Multivariate analysis of variance showed a significant overall effect of adrenalectomy ($p=.008$), with changes in myelin per tract cross section ($p=.005$), tract area ($p=.008$) and number of lamellae per myelinated axon ($p=.001$).

The total area of myelin per whole tract cross section was increased 24% in the optic nerve and 14% in the corpus callosum of adrenalectomized animals. The number of lamellae per myelinated axon was increased 10% in both tracts. By contrast, the myelin area fraction was unaffected by adrenalectomy.

Regression analysis relating the number of myelin lamellae to axon circumference showed no effect of adrenalectomy, suggesting that the increased number of lamellae in the myelin sheaths of adrenalectomized animals may be caused by an increase in the size of the axons. Analysis of variance also suggested ($p=.07$) increased size of myelinated axons after adrenalectomy.

The present results are consistent with our previous studies and indicate that adrenalectomy increases the amount of myelin, defined morphologically, in fiber tracts of brain. This effect is expressed at least in part as an increase in the thickness of individual myelin sheaths, a change which may reflect increased axonal size. While the mechanisms of action and cellular targets remain to be determined, these results support the notion that adrenal hormones regulate neural development and that early removal of the adrenal glands stimulates the formation of myelin.

262.7 EARLY ADRENALECTOMY PROMOTES BRAIN CELL PROLIFERATION IN RATS. R. Yehuda*, K.R. Fairman*, and J.S. Meyer. Division of Neuroscience and Behavior, Department of Psychology, University of Massachusetts, Amherst, MA 01003

Previous studies in our laboratory have shown that adrenalectomizing rats on day 11 of life leads to an enhancement of subsequent brain growth which is due to at least 2 factors: increased myelination and elevated brain DNA content. The present experiments were designed to determine whether brain cell proliferation is stimulated following early adrenalectomy, and more specifically to assess the time course, regional specificity, and hormonal reversibility of such stimulation. Rats were either adrenalectomized or sham-operated on day 11 postnatal. Two, 7, or 14 days following surgery, subjects were injected s.c. with ($^3$H)thymidine and then sacrificed 1 h later. Brains were removed and dissected into cerebral cortex, hippocampus, midbrain-diencephalon, and cerebellum. DNA in each sample was extracted, assayed, and counted to determine thymidine incorporation as an index of mitotic activity. Increases in DNA labeling (specific activity) were observed in all brain areas of ADX animals, the effect being similar at each time point. To correct for possible group differences in availability of the labeled precursor, results were also expressed in terms of specific activity divided by the radioactivity in the acid-soluble fraction (i.e., relative specific radioactivity). Adrenalectomy also resulted in significant changes in this measure. The effect of glucocorticoid replacement on the rate of cell proliferation was examined in a second experiment in which pups were implanted with Alzet osmotic minipumps (1 ul/h pumping rate) containing either 1.25 or 2.5 mg/ml corticosterone sodium succinate or saline vehicle. One week of corticosterone treatment reversed the effects of adrenalectomy on both specific and relative specific activity in all brain regions and in a dose-dependent manner. We are currently investigating the effects of adrenalectomy on thymidine kinase activity as an independent measure of cell division. Overall, these results indicate that day-11 adrenalectomy leads to a prolonged stimulation of brain cell proliferation in areas where cell formation at this time is exclusively glial (i.e., cerebral cortex and midbrain-diencephalon) as well as in areas where postnatal neurogenesis is known to occur (cerebellum and hippocampus). We hypothesize that this stimulation results from the removal of a tonic inhibitory influence exerted by circulating glucocorticoids in the normal intact animal.

This research was supported by NSF grant BNS-8118073, BRSG grant RR-07048, and a Healey Endowment Award from the University of Massachusetts.

262.8 EFFECTS OF ADRENALECTOMY ON REGIONAL CNS DEVELOPMENT. T. L. Thomas* and L. D. Devenport (SPON: J. T. Braggio). Department of Psychology, University of Oklahoma, Norman, OK 73019.

Adrenalectomy (ADX) increases gross brain weight (Devenport, 1979) by removing endogenous glucocorticoids, not mineralocorticoids or medullary hormones (Devenport & Devenport, in press). This study sought to determine if the brain growth is general or limited to specific regions.

Thirty day old female rats were bilaterally ADX or sham operated under ether anesthesia. Following a 24 hr recovery period in heated units, the rats were housed in pairs for approximately 7 days, then housed individually. They were sacrificed after a total of 45 post-operative days by sodium pentobarbital overdose. Following perfusion with "instant processing" formalin, brains were removed, prepared uniformly, and stored in 10% buffered formalin for 24 hr. After coding for blind analysis forebrains were weighed and frozen in tissue-tek frozen embedding medium. Sections taken for this study conformed to selected representations found in Paxinos & Watson (1982). These hydrated coronal and saggital samples were slide mounted with coverslip and enlarged with a projection microscope for measurement.

Of the variety of structures and areas examined, the parietal and occipital cortices exhibited significant thickening, and the thalamus underwent significant widening in the ADX rats. No other areas or fiber tracts were significantly differentiated across groups. We also observed a trend toward diminished within-group variation in structure size in ADXs. This trend achieved statistical significance in the case of thalamus (-4.3mm Bregma) and septal area (-0.3mm Bregma) width.

The results indicate that the brain growth stimulated by ADX is regionally specific. Only a small trend for general growth was observed. Instead, the major effect was upon thalamus and neocortex. Decreased within-group variability was observed and adds to the commonalities between ADX- and environmental enrichment-induced brain growth (Cummins, et al, 1977). Both procedures seem to decrease the variability of brain size and to increase cortical thickness. While the fine structural basis of the ADX-induced growth is presently under investigation, our failure to find significant thickening of heavily myelinated fiber tracts suggests that it is not myelination, at least of our selected structures, that lies at the basis of the growth.

262.9 IS MEDIAL PREOPTIC OPIATE RECEPTOR ONTOGENY ANDROGEN OR ESTROGEN DEPENDENT? R. P. Hammer, Jr. Dept. of Anatomy and Reproductive Biology, University of Hawaii School of Medicine, Honolulu, Hawaii 96822.

The opiate receptor content of the rat medial preoptic area (MPOA) exhibits sexual dimorphism and varies across the estrous cycle in adults (Hammer, Brain Res., 308: 172). Moreover, a dense concentration of opiate receptors develops in the MPOA shortly after birth in females. However, this early receptor development is prevented in females by daily postnatal testosterone administration, and it is fostered in males by neonatal gonadectomy (Hammer, Brain Res., in press). Since estrogen is present even in neonatal brains due to aromitization of androgen to form estrogen, MPOA opiate receptor ontogeny could be dependent on interaction with either of these steroid hormone subclasses.

To elucidate this interaction, film autoradiographs of [$^3$H]naloxone binding in brain sections from five-day old (postnatal day 6 [D6]) male and female rats were examined. Males had been injected subcutaneously on postnatal day 2 with 100 µg of the estrogen antagonist, tamoxifen, in 50 µl sesame oil. Females received daily injections of 250 µg of dihydrotestosterone (DHT), a non-aromatizable androgen compound, in 25 µl sesame oil. Control animals received the same doses of vehicle on the same schedule as experimental animals. Oil-treated females had significantly greater MPOA opiate receptor labeling than all other groups. A dense concentration of MPOA opiate receptors developed in oil-treated females, but not in oil-treated males. Also, DHT prevented the formation of a dense MPOA opiate receptor concentration in females and tamoxifen did not allow its formation in males.

These results further substantiate the importance of sex hormones on MPOA opiate receptor ontogeny during the early, postnatal critical period. When administered during this period, androgen alone is enough to prevent MPOA opiate receptor development; furthermore, blockade of estrogen receptors does not alter this androgen-induced effect. Therefore, it would seem that inhibition of MPOA opiate receptor development is a complex phenomenon not dependent solely on estrogen receptor interaction, rather more dependent on the influence of compounds on androgen receptors. Ongoing studies using androgen receptor blockers should confirm the androgen dependence of this effect.

262.10 DETECTION OF A SOMATOMEDIN -C RELATED mRNA IN RAT BRAIN. P.K. Lund*, B.M. Moats-Staats*, M. Hynes, E. Hoyt*, T. Verdoorn*, V.K.M. Han*, A.J. D'Ercole*, M. Jansen*$^{\pm}$, L. Van den Brande*$^{\pm}$ and J.J. Van Wyk*. School of Medicine, University of North Carolina, Chapel Hill, 27514 and Dept. Pediatrics, State University of Utrecht, The Netherlands.(SPON:R.Dingledine)

Somatomedins or insulin-like growth factors (Sm/IGF) are peptide mitogens thought to be involved in fetal and post-natal growth. Recent evidence indicated the presence of somatomedins in mammalian brain ( Binoux et al, FEBS Lett. 124, 178, 1981; Sara et al., Acta Physiol. Scand. 115, 467, 1982;. ) and suggested that human brain contains predominantly IGF-II rather than Sm-C ( Haselbacher et al, PNAS 82, 2153, 1985). We investigated the production of Sm-C encoding mRNAs in fetal and newborn rat brain to determine whether there was de novo synthesis of Sm-C. Poly (A) RNA from16 to 20 day embryonic, newborn,14 day old and adult rats was size fractionated on agarose gels, transferred to nylon membranes and hybridized with a $^{32}$ P labelled cDNA probe encoding human pro-Sm-C (Jansen et al, Nature 306, 609,1983) A mRNA of 1.75 kilobases (kb) was present in brain poly (A) RNA at all time points investigated except adult, and was more abundant in brain from fetal and newborn animals than14 day old animals These data indicate that rat brain synthesizes a mRNA encoding a protein related to Sm-C and that this protein may be implicated in growth and development of rat brain. Soares et al (Nucleic Acids Res. 13, 1119, 1985) detected a 1.75kb mRNA in neonatal rat brain, by hybridization to a short cDNA probe which showed partial homology to 5' untranslated region and signal peptide coding sequences of rat IGF-II mRNA. This mRNA did not hybridize to cDNA sequences encoding the IGF-II sequence. The precise structure of the 1.75 Kb rat brain mRNA remains to be determined by sequencing of cDNAs However, the mRNA appears to share sequences common to human Sm-C and rat IGF-II mRNAs and may represent the rat Sm-C mRNA or a mRNA encoding an as yet uncharacterized growth factor.

262.11 THE EFFECTS OF ACTH AND PREDNISOLONE ON ELECTROSHOCK SEIZURES, DEVELOPMENT, AND BRAIN WATER AND ELECTROLYTE CONTENTS OF NEWBORN RATS. T. Honda, H.S. White, S.Y. Chow, J.W. Kemp, D.M. Woodbury (SPON: P.R. Burgess). Dept. of Physiol. Univ. of Utah, S.L.C., UT 84108.

ACTH and prednisolone (PSL) have been used for the treatment of infantile spasms. Cortisol has been reported to produce biphasic effects on brain excitability which are age-dependent (Vernadakis and Woodbury, J.P.E.T., 139:110, 1963). The present investigation attempts to identify specific biochemical effects of these agents on the brains of neonatal rats that correlate with their anticonvulsant activities.

Neonatal rat pups were administered either 0.9% saline (2.5 ul/gm body wt.), ACTH (0.5 mg/kg, s.c.) or PSL (2.5 mg/kg, s.c.) on postnatal days 0-3, or 4-7, or 8-11. On postnatal day 15, each animal received an electroshock stimulus (50 mA for 0.2 sec at 60 Hz), through corneal electrodes. Their response to this stimulus was graded as follows: 1 (running seizure), 1.5 (running plus opisthotonus), 2 (forelimb clonus). These were averaged and compared with controls that received only saline. On the 16th postnatal day, under ether anesthesia, blood and CSF were collected for determination of electrolytes ($Na^+$, $K^+$ and $Cl^-$), animals were then sacrificed and the brain dissected out. Cerebral cortex, cerebellum and brain stem tissues were analysed for water and electrolyte contents.

Results suggest that brain excitability as measured by electroshock stimulus was decreased by pretreatment of animals with ACTH or PSL on days 0-7, but was increased by delaying treatment until postnatal days 8-11. CNS development as estimated by eye opening appeared to be enhanced by treatment with ACTH or PSL given on days 0-3 or days 4-7. On postnatal day 14, eyes were open in 90% of animals receiving ACTH on days 0-3, and 83% of animals treated with PSL on days 0-3. This compares with 44% in control animals. In those animals treated between days 4-7, eyes were open in 40% of the controls, 75% of ACTH group, and 100% of the PSL group. Cerebellar water content was reduced by treatment with ACTH on days 4-7 and 8-11. Treatment with PSL on days 4-7 reduced the water content of the cerebral cortex, cerebellum and brain stem. In contrast, when treatment with PSL was delayed until 8-11 days, no change in water content was observed. Reductions in brainstem sodium (12%) and chloride (21%) were observed following treatment with PSL between days 0-3. A decrease in chloride (10%) was also observed in the cortex of animals treated with PSL on postnatal days 4-7. In addition, PSL (4-7 days) increased the cerebral cortex potassium content. No change in tissue electrolyte content was observed following treatment with ACTH. These results suggest that treatment with ACTH or PSL early in development is more effective in producing an anticonvulsant effect than if treatment is witheld until later in development. We are presently attempting to correlate the above reported changes in water and electrolyte contents with the activities of the transport enzymes $Na^+/K^+$-ATPase and $HCO_3^-$-ATPase. These data will provide useful information pertaining to the effects of ACTH and PSL on brain excitability and their use in the therapy of infantile spasms.

262.12 POSTNATAL DEVELOPMENT OF 'SMOOTH' AND 'SPINY' LHRH CELLS: EFFECT OF NEONATAL GONADECTOMY. S.Wray and H.Gainer. Laboratory of Neurochemistry and Neuroimmunology, National Institute of Child Health and Human Development, Bethesda, MD 20205.

Two distinct morphological luteinizing hormone releasing hormone (LHRH) cell types have been previously identified in male and female rats; smooth LHRH cells (sLHRH) and irregular LHRH cells with spinelike processes (iLHRH). The number of iLHRH cells increases postnatally, stabilizing shortly after puberty, suggesting that new synaptic inputs to LHRH cells may be important for the timing and maintenance of reproductive maturation. Gonadal steroids affect LHRH secretion and are critical for reproductive function. This study examines whether gonadal steroids influence the development of smooth and/or irregular LHRH cell types.

One to 2 days post-parturition, 3 male and 3 female Sprague-Dawley rat pups were bilaterally gonadectomized. After surgery, animals were placed under a warming lamp until active and then returned to their mother and left undisturbed for 8 days, after which body weights of gonadectomized and control pups were recorded daily. All animals showed a steady gain in body weight. Pups were weaned and separated according to genotypic sex on postnatal (pn) day 25. At pn days 50-71, animals were anesthetized and perfused with saline followed by 4% paraformaldehyde/0.2% picric acid in 0.1M sodium cacodylate buffer (pH 7.4) with or without 0.15% glutaraldehyde. Consecutive vibratome sections (50 um) were taken from the olfactory peduncles caudally through the median eminence. Tissue sections were blocked in normal goat serum (10%,1hr) and immunocytochemically processed for LHRH. For light microscopy, sections were incubated in LR-5 antiserum (Gift from Drs. Benoit and Guilleman) diluted 1:20,000 in 0.4% triton X for 24 hrs., followed by an avidin-biotin-horseradish peroxidase procedure (Vectastain). For electron microscopy, sections were reacted as above, but no triton X was used. After visualization of LHRH neurons, sections were rinsed in buffer, trimmed, placed in 1% $OsO_4$ (1/2- 1 hr at room temp), dehydrated and embedded in LR White. Silver sections were placed on Formvar-coated slot grids and counterstained with uranyl acetate and lead citrate.

The total LHRH cell number (between 1050-1300 immunoreactive LHRH cells), and distribution of LHRH cells and fibers were unaffected by neonatal gonadectomy. The percentages of sLHRH cells and iLHRH cells in control and gonadectomized animals were identical. Therefore, removal of gonadal steroids in the neonate did not prevent the pn development of the LHRH cell population. Possible alterations in synaptic inputs to sLHRH cells and iLHRH cells after neonatal gonadectomy are currently being examined by immunocytochemical methods at the electron-microscopic level.

## REGIONAL LOCALIZATION OF RECEPTORS AND TRANSMITTERS II

263.1 THE ONTOGENETIC DEVELOPMENT OF 5-$HT_1$ RECEPTORS IN THE RAT BRAIN: AN AUTORADIOGRAPHICAL STUDY. T. Glaser*, M. Rath*, J. Traber*, K. Zilles*† and A. Schleicher*†, (SPON: F.-K. Pierau) Department of Neurobiology, Troponwerke, D-5000 Cologne 80, FRG and †Anatomical Institute, Univ. of Cologne, D-5000 Cologne 80, FRG.

The densities of serotonin$_1$ (5-$HT_1$) binding sites in various cortical regions of the rat brain at various stages of postnatal development were studied by means of quantitative autoradiography.

In all regions studied, the increase in binding site density between the first postnatal day and adult age was sigmoidal. This increase in the various regions showed a marked heterochrony. Binding sites developed earlier in neocortex than in allocortex. 50% of the adult binding site density was reached in the following order: motor cortex (day 9) > primary somatosensory cortex (d 10) > prefrontal cortex (d 12) > hippocampal formation (d 14-20). It is very interesting that there was also a heterochrony found within the hippocampal formation, with the fascia dentata having the fastet and the $CA_1$ region the slowest increase in receptor density. Adult values of recognition site numbers in the various cortical areas were also reached at different ages. The highest number of 5-$HT_1$ binding sites was found in the dorsal subiculum, the lowest in the primary somatosensory cortex. Radioligand saturation experiments using whole brain membranes corroborated the autoradiographical findings.

The results demonstrate a systematic developmental direction from iso - to allocortical areas.

263.2 MULTIPLE SEROTONIN RECEPTORS IN THE HUMAN BRAIN: CHARACTERIZATION, MAPPING AND EFFECTS OF DISEASE. J.M. Palacios[1], A. Pazos[1*], D. Hoyer[1*] and A. Probst[2*]. [1]Preclinical Research, Sandoz Ltd. and [2]Dept. Pathology, University of Basle, Basle Switzerland.

We have studied the pharmacological properties and the anatomical localization of the proposed subtypes of 5-HT receptors (5$HT_{1A,1B,1C}$ and 5-$HT_2$) by both membrane binding assays and quantitative autoradiographic studies, using labeled ligands selective for the different binding sites. These ligands included $^3$H-5-HT (5-$HT_1$ sites), $^3$H-8-hydroxy-2-(NN-dipropylamino)-tetraline (8-OH-DPAT) (5-$HT_{1A}$), $^{125}$I-cyanopindolol (5-$HT_{1B}$), $^3$H-LSD (5-$HT_{1A,1C}$, 5-$HT_2$), $^3$H-mesulergine (5-$HT_{1C}$) and $^3$H-ketanserin (5-$HT_2$).

Both, similarities and differences were found in the pharmacology and distribution of the 5-HT sites in the human brain, when compared to the rat brain. The affinities of different compounds for 5-$HT_{1A}$ sites in the human were similar to those previously found in the rat. The anatomical distribution of these 5-$HT_{1A}$ sites in the human brain was also similar, in general terms, to that seen in the rat, the hippocampus, raphé nuclei, amygdaloid complex and several cortical fields being enriched in these sites. However, some differences were found; for instance, the dentate gyrus, which is the part of the hippocampal formation presenting the highest density of 5-$HT_{1A}$ binding sites in the rat, only contained a moderate density of specific binding in the human. The 5-$HT_{1C}$ receptor sites in the human brain presented a pharmacological profile similar to that found in the rat, although a certain decrease in the affinity of all the drugs tested was observed. Like in the rat and pig, the human choroid plexuses contained high density of 5-$HT_{1C}$ sites. The species differences were much more marked in the case of 5-$HT_{1B}$ and 5-$HT_2$ sites, where important changes in the pharmacological properties between rat and human brain were found. For example, $^3$H-mesulergine, which label 5-$HT_2$ receptors in the rat, did not recognize them in the human brain. Other substances showing high affinity for 5-$HT_2$ sites in the rat brain were less effective when tested in the human. Regarding the anatomical distribution of these 5-$HT_2$ receptors in the human brain, the different cortical fields, including the frontal, temporal, parietal, visual, cingulate and entorhinal areas, were the most enriched regions. The human mammillary bodies also presented relevant densities of 5-$HT_2$ sites.

Finally, a comparation between the distribution and pharmacology of the different 5-HT sites in the normal brain and that in cases of senile dementia Alzheimer type and Parkinson's disease will be presented.

263.3 **QUANTITATIVE AUTORADIOGRAPHIC LOCALIZATION OF NEUROTRANSMITTER BINDING SITES IN AMYOTROPHIC LATERAL SCLEROSIS.** S. Manaker, C.H. Rhodes, C.M. Wieczorek* and A. Winokur. Departments of Psychiatry, Pharmacology and Pathology, University of Pennsylvania School of Medicine, Philadelphia, PA 19104.

We used quantitative autoradiography to localize neurotransmitter receptors and uptake sites in spinal cords from three non-neurological controls and three patients with ALS. We examined the densities of TRH receptors with 10 nM ($^3$H)-methyl-TRH, β-adrenergic receptors with 150 pM ($^{125}$I)-iodopindolol, norepinephrine uptake sites with 2 nM ($^3$H)-desmethylimipramine, muscarinic receptors with 2 nM ($^3$H)-quinuclidinyl benzilate, and choline uptake sites with 40 nM ($^3$H)-hemicholinium-3. Sequential sections from cervical, thoracic, lumbar and sacral spinal cord were used for total and non-specific binding for each ligand.

Large decreases in the density of TRH receptors were found in Lamina IX of ALS spinal cords. In thoracic spinal cord, the density of TRH receptors was reduced by 80% (ALS, 16 ± 6 fmol/mg P; control, 82 ± 15 fmol/mg P). Smaller reductions were noted in cervical (ALS, 28 ± 11 fmol/mg P; control, 58 ± 11 fmol/mg P) and lumbar (ALS, 14 ± 10 fmol/mg P; control, 43 ± 6 fmol/mg P) spinal cords. In contrast to TRH receptors, muscarinic receptor densities appeared to be diminished throughout the ventral horn of ALS spinal cord. In Lamina IX, muscarinic receptors were decreased in concentration by 56% in the cervical cord (ALS, 217 ± 26 fmol/mg P; control, 495 ± 63 fmol/mg P) and 68% in the lumbar cord (ALS, 200 ± 30 fmol/mg P; control, 626 ± 116 fmol/mg P). Reductions of 66% and 67% were observed in sacral and thoracic ALS cords, respectively. In the remaining laminae of the ventral horn, decreases in muscarinic receptor densities ranged from only 30% in the thoracic cord (ALS, 161 ± 18 fmol/mg P; control, 229 ± 12 fmol/mg P) to over 60% in sacral cord (ALS, 145 ± 43 fmol/mg P; control, 360 ± 71 fmol/mg P). No alterations in β-adrenergic receptors, noradrenergic uptake sites, or choline uptake sites were noted in adjacent sections of ALS spinal cords.

These data replicate some previous findings in the literature. However, this is the first report, to our knowledge, of normal levels of noradrenergic and choline uptake sites in ALS tissues. Since we simultaneously assayed several neurotransmitter binding sites in sequential sections from the same block of tissue, it is clear that in Lamina IX of the ventral horn, specific depletion of some neurotransmitter binding sites occurs in ALS while other binding sites remain intact. That depletion of both TRH receptors and muscarinic receptors occurs in ALS may reflect an aspect of the pathophysiology of the disease, rather than non-specific loss of receptors localized on degenerating motor neurons. (Supported by NIMH RSDA MH00044 and NIH NS18332 to AW, MSTP NIH 5-T32-GM07170 to SM, NIH 2-T32-NS07064 to CHR and NIH NS19597 and NS20006 and fellowships from the Sloan Foundation and the Klingenstein Fund).

263.4 **AUTORADIOGRAPHIC LOCALIZATION OF BETA-ADRENERGIC RECEPTORS IN HUMAN BRAIN.** G. Reznikoff,* S. Manaker, C.H. Rhodes, A. Winokur and T.C. Rainbow. Departments of Psychiatry, Pharmacology and Pathology, University of Pennsylvania School of Medicine, Philadelphia, PA 19104.

Little information is currently available on the localization of noradrenergic systems in the nuclei and subregions of the human central nervous system (CNS). We have employed the technique of quantitative autoradiography to examine the distribution of β-adrenergic receptors in post-mortem human brain. None of our subjects died as a result of psychiatric, neurologic or endocrine disease. The radioligand used, ($^{125}$I)-iodopindolol (IPIN), bound with an appropriate affinity to post-mortem hippocampus ($K_d$ = 93 ± 30 pM). In addition, the potency of l-propranolol ($IC_{50}$ = 1.1 ± 0.7, N = 3) was 50-fold greater than the potency of d-propranolol ($IC_{50}$ = 50.8 ± 19.1, N = 3) at inhibiting ($^{125}$I)-IPIN binding in hippocampus. These pharmacologic data suggest that our autoradiograhic technique detects authentic β-receptors in post-mortem human tissues.

Highest concentrations of β-receptors (> 50 fmol/mg protein) were found within all subfields of the hippocampus, and high to moderate concentrations were observed in the cerebellum. The thalamic nuclei, basal ganglia, midbrain and amygdala contained moderate densities of β-receptors (25-50 fmol/mg P). All areas of the cerebral cortex, including frontal, cingulate, insular and temporal cortices, were also moderately labeled by ($^{125}$I)-IPIN. In addition, the individual layers of the cerebral cortex were homogeneously labeled in moderate densities. The hypothalamus contained low levels of β-receptors (< 25 fmol/mg P), which were comparable to the β-receptor levels noted in white matter.

The autoradiographic distribution of β-receptors differs from the regional β-receptor densities reported from homogenate binding studies, which reported moderate densities of hippocampal β-receptors, probably reflecting dissection artifacts. The dense concentration of β-receptors in the human hippocampus may suggest functions for NE in the human CNS, including effects on neuroendocrine regulation and memory processing. The distribution of β-receptors in human brain also differs from the β-receptor distribution observed in rat brain. For example, the superficial layers of rat cerebral cortex are heavily labeled by ($^{125}$I)-IPIN, with large differences observed between β-receptor densities in different cortical regions (PNAS 81: 1585, 1984). No such variation existed in human brain, suggesting that β-receptors may play a relatively minor role in cortical functions. (Supported by MSTP NIH 5-T32-GM07170 to SM, NIH 2-T32-NS07064 to CHR, NIMH RSDA MH00044 and NIH NS 18332 to AW, and NIH NS19597 and NS20006 and fellowships from the Sloan Foundation and the Klingenstein Fund to TCR).

263.5 **AUTORADIOGRAPHIC LOCALIZATION OF THYROTROPIN-RELEASING HORMONE (TRH) RECEPTORS IN HUMAN BRAIN.** A. Winokur, S. Manaker, A. Eichen,* C.H. Rhodes and T.C. Rainbow. Departments of Psychiatry, Pharmacology and Pathology, University of Pennsylvania School of Medicine, Philadelphia, PA 19104.

Thyrotropin-releasing hormone (TRH) exerts many effects upon central nervous system (CNS) function. We have utilized the technique of quantitative autoradiography to anatomically localize specific receptors for TRH in post-mortem human brain. None of our subjects died as a result of psychiatric, neurologic or endocrine disease. The radioligand used, ($^3$H)-3-methyl-his$^2$-TRH (($^3$H)MeTRH), bound with similar affinity to post-mortem human pituitary gland ($K_d$ = 9.5 ± 1.4 nM) as to post-mortem amygdala ($K_d$ = 9.6 ± 2.0 nM). In addition, unlabeled MeTRH was 10- to 20-fold more potent than TRH at inhibiting ($^3$H)-MeTRH binding. These data suggest that our autoradiographic technique detects authentic TRH receptors in post-mortem human tissues.

An animal model was used to show that post-mortem decay causes little alteration in TRH receptor densities. We quantified TRH receptor concentrations in 18 different structures from the septal and amydgaloid regions of 24-hr post-mortem rat brain, and compared these values to our previously reported (J. Neurosci. 5:167, 1985) concentrations in freshly sacrificed rats. Only small increases and decreases in TRH receptor concentrations were observed, and more importantly, the relative distribution of TRH receptors was maintained ($r_s$ = 0.9195; $p < 0.001$).

Within human brain, high concentrations of TRH receptors (200-400 fmol/mg protein) were localized throughout the amygdala, including the cortical, basal and lateral nuclei, and also within the stratum oriens of the hippocampus. Low levels of TRH receptors (< 50 fmol/mg protein) were localized within the other layers and subfields of the hippocampus, as well as within all areas of cortex, basal ganglia, and diencephalon.

While a few non-hypophysiotropic actions of TRH on human CNS function are known, this distribution of TRH receptors may be consistent with possible sites of action of TRH in human brain. More importantly, the discrete localization of TRH receptors provides a neuroanatomical template for focusing investigations into the effects of TRH on the human CNS. (Supported by NIMH RSDA MH00044 and NIH NS18332 to AW, MSTP NIH 5-T32-GM07170 to SM, NIH 2-T32-NS07064 to CHR and NIH NS19597 and NS20006 and fellowships from the Sloan Foundation and the Klingenstein Fund to TCR.)

263.6 MODULATION OF HYPOTHALAMIC PROGESTIN RECEPTOR LEVELS BY THE NORADRENERGIC SYSTEM IS SPECIFIC TO THE VENTROMEDIAL NUCLEUS. J. Thornton, B. Nock , B. McEwen and H. Feder. Institute of Animal Behavior, Rutgers University, Newark, NJ 07102 and Rockefeller University, New York, NY 10021.

Progesterone is involved in both the induction of sexual behavior and gonadotropin surges in female guinea pigs. Progesterone appears to act through high affinity, specific intracellular receptors which are highly concentrated in the hypothalamus/preoptic area and are induced by estradiol. The noradrenergic system modulates the level of estradiol-induced cytosolic progestin receptors in hypothalamus. Treatment with the α1 antagonists phenoxybenzamine or prazosin or with the dopamine β-hydroxylase inhibitor U-14624 decreases the number of cytosolic progestin receptors (CPRs; Nock et al, Brain Res., 207:371, 1981; Nock and Feder, Brain Res., 310:77, 1984). The present experiment was designed to more precisely localize where within the hypothalamus noradrenergic (NA) function affects cytosol progestin receptors. Ovariectomized adult guinea pigs were given three daily injections of 20μg estradiol-17β benzoate (EB). Twenty four hours later, females were injected s.c. with either 5mg/kg prazosin HCL in 25% propylene glycol vehicle or the vehicle alone. Six hours later, females were anesthetized, perfused with 10% DMSO and brains were removed and frozen. Coronal sections (300μm thick) were cut and areas were dissected by the method of Palkovits (Brain Res., 59: 499, 1973). Cytosols from microdissected areas were assayed for cytosolic progestin receptors with 0.6nM [3H]R5020 (a synthetic progestin) ± 100 fold excess unlabelled R5020. Tissue from 1-3 females was pooled per sample, N=7-16 samples per area. When hypothalamic areas were examined, it appeared that the decrease in estradiol-induced CPRs in whole hypothalamus is due to a selective decrease in the ventromedial nucleus (VMN). Prazosin resulted in VMN CPR levels of 22.4±1.3 fmoles/mg which is significantly decreased compared to the level of 32.2±4.0 fmoles/mg seen in vehicle treated females. Prazosin did not decrease CPR levels in the periventricular area (PVE) of the anterior hypothalamic nucleus (praz=31.2±6.3, veh=24.2±5.4), the PVE of the ventromedial hypothalamus (praz=40.5±10.3, veh=37.9±9.1), the anterior hypothalamic nucleus (praz=12.8±2.2, veh=12.4±1.4) nor the arcuate-median eminence (praz=185.3±12.2, veh=201.2±11.4). Consistent with other reports, prazosin did not significantly decrease CPR levels in any preoptic areas examined. This was true for both the medial preoptic area and the periventricular preoptic area. In sum, the α1 antagonist prazosin caused a selective decrease in estradiol-induced CPRs in the ventromedial nucleus of the hypothalamus. Because lordosis induced by estradiol and progesterone is also blocked by α1 antagonists it is possible that the noradrenergic system acts at the VMN to modulate both CPR number and lordosis responsiveness.

263.7 HIPPOCAMPAL BETA$_1$-ADRENERGIC RECEPTORS: EVIDENCE FOR LOCALIZATION ON DENTATE GRANULE CELLS. J.K. Tayyeb*, D. Lorton and J.N. Davis (SPON: A.D. Roses). VA Med. Ctr. and Depts. of Med. (Neurology) and Pharmacol., Duke Univ., Durham, NC 27705.

$B_1$-adrenergic receptors have a specific topography in the hippocampus, being found in the hilus and molecular layer of the dentate gyrus. The cell type which possesses the $B_1$-receptor is not known. We have hypothesized that these receptors are located on dentate granule cells. To test this hypothesis we have injected colchicine, a selective neurotoxin which preferentially destroys granule cells, into the hippocampus and used quantitative in vitro receptor autoradiography to study alterations in $B_1$-receptor levels.

Colchicine (0.25 ul, of 2.5 ug colchicine in saline) was injected unilaterally into the ventral hippocampus of adult male Sprague-Dawley rats. Two weeks after the injection, the rats were sacrificed and the brains processed for $B_1$-receptor autoradiography using [$^{125}$I]-cyanopindolol and the specific $B_2$ antagonist ICI 118,551. Densitometric readings were made in $CA_1$, $CA_3$, the molecular layer of the dentate gyrus, and the subiculum. The molecular and granule cell layer widths were measured in cresyl violet stained sections.

Relatively high levels of $B_1$-receptors were located in $CA_1$, $CA_3$, the molecular layer of the dentate gyrus and the subiculum on the control side. Colchicine injection resulted in a loss of granule cells in the dentate gyrus without damage to the pyramidal cells. On the injected side, a decrease in density of $B_1$-receptors in the molecular layer and $CA_3$ corresponded to a decrease in molecular and granule cell layer widths across all sections suggesting that dentate granule cells have $B_1$-receptors located on their dendritic and axonal projections. An unexpected decrease in density of $B_1$-receptors was found in $CA_1$ and subiculum and was not associated with the decrease in of granule cell or molecular layer width. We believe the decrease in subicular receptor density to be the result of transynaptic events, but cannot exclude the possibility that colchicine has biochemical effects on subicular cells without producing histological evidence of damage.

263.8 DETERMINATION OF 12-14 BIOGENIC AMINES IN BRAIN TISSUE DURING A SINGLE HPLC RUN OF 20 MINUTES WITHOUT PRIOR CLEAN-UP OF SAMPLES M.G. Hadfield and N. Narasimhachari. Neurochemistry Research Laboratory, Dept. of Pathology and Psychopharmacology Research Laboratory, Dept. of Psychiatry, Medical College of Virginia, Virginia Commonwealth University, Richmond, Virginia 23298

High performance liquid chromatography with electrochemical detection (HPLC-Ec) is now the method of choice for quantitating biogenic amines and their metabolites in brain tissues. But in many solvent systems (mobile phases) reported in the literature, either the number of compounds that can be measured in limited, the run is prolonged if all metabolites are measured or the sensitivity is low without sample clean-up.

We have now developed a solvent system consisting of 0.1 M citric acid, 0.06% diethylamine, 0.05 mM $Na_2EDTA$, 200 mg/l 1-heptansulfonic acid and 3% acetonitrile at pH 2.5. With this solvent system and a 25 cm, 5µM ODS column, we can separate and analyze 12-14 biogenic amines and their neutral and acid metabolites during a single run lasting less than twenty minutes. The amines and metabolites include: norepinephrine (NE), 4-hydroxy-3-methoxyphenylglycol (MHPG), normetanephrine (NM) and metanephrine (MN); dopamine (DA), 3,4-dihydroxyphenylacetic acid (DOPAC), 4-hydroxy-3-methoxyphenyl-acetic acid (HVA) and 3-methoxytyramine (3-MT); serotonin (5-HT), 5-hydroxyindole-3-acetic acid (5-HIAA) and 5-hydroxytryptophol (5-HTL). L-3, 4-dihydroxyphenylalanine (DOPA), 5-hydroxy-L-tryptophan (5-HTP) and epinephrine (EPI) can also be measured. We have used isoproterenol (IP) and 5-hydroxyindole (5-HI) as two internal standards for catechols and indoles respectively and both these are separated from the endogenous compounds. The brain tissue from the rat or mouse is homogenized with 5% perchloric acid (PCA) containing the desired internal standards (20 ng/ml). The homogenate is centrifuged at 5000 r.p.m. for 5 min and 50 µl of the clear supernatant is injected into the HPLC system.

One of the major advantages of the present system is the ability to quantitate MHPG which is distinctly separated from the solvent front. This is a problem in many solvent systems since MHPG elutes close to the solvent front and tends to be obscured by it. Further, this system provides quantitation of all metabolites of interest in biogenic amine metabolism thus providing increased amounts of data from each brain region analyzed. The sensitivity is in the picogram range thus making it possible to measure minor metabolites in any given tissue sample weighing 1-10 mg.

263.9 DIFFERENTIAL ALTERATIONS IN DOPAMINERGIC MARKERS IN THE BASAL FOREBRAIN AND STRIATUM OF RATS WITH 6-OHDA-LESIONS OF THE SUBSTANTIA NIGRA. C.Geula* and J.T. Slevin.Veterans Administration Medical Center and the Depts. of Neurology and Pharmacology and the Sanders-Brown Research Center on Aging, University of Kentucky, Lexington, Kentucky 40536

The aggregate from several laboratories suggests the presence of dopamine (DA), HVA and DOPAC (metabolic derivatives of DA), and DA receptors in the basal forebrain (substantia inominata, SI) of rats and primates including humans (nucleus basalis of Meynert, nbM). The present study investigates the source of the DA synaptic markers found in this region.

Sprague-Dawley rats were anesthetized and 8 ug of 6-hydroxydopamine was unilaterally injected in the substantia nigra pars compacta (SNc). After a week, the animals were sacrificed and striatal levels of dopamine and its metabolites were measured by high pressure liquid chromatography with electrochemical detection. The striatal dopamine level on the lesioned side was significantly decreased (-78%) compared with the nonlesioned side. The dopamine level was also significantly but more modestly decreased in the SI ipsilateral to the SNc lesion (-48%). DOPAC was significantly lower in the striatum and not detected in the SI (detection limits, 20pg) of the lesioned side. As documented from several laboratories, striatal $D_2$ receptor density on the lesioned side increased to 123% of control. In contrast, there was no change in ipsilateral $D_2$ receptor density in the SI of lesioned rats (-8%).

These data demonstrate that a lesion in the SNc leads to a decrease in DA levels in the ipsilateral SI without a concurrent denervation supersensitivity, in contrast to the well-documented receptor changes of the striatum which have been reproduced here. These findings suggest that the decrease in DA levels observed in the nbM of patient's with Alzheimer's disease may be due to partial destruction of DA nbM afferent projections from the SNc.

Supported in part by the VA Research Service, NINCDS (TIDA 00732) and NIA (1 T32 AG0084-01A1).

263.10 EFFECTS OF PCPA ON INDOLE CONCENTRATIONS IN BRAINSTEM AND SPINAL CORD TERMINALS. J.L. Steinman, S.M. Carlton, G. Hillman*, B. Haber and W.D. Willis. Marine Biomed. Inst. and Depts. Pharmacology and Physiology & Biophysics, Univ. Texas Medical Branch, Galveston, TX 77550.

Administration of para-chlorophenylalanine (PCPA) to inactivate the 5-HT rate limiting enzyme tryptophan hydroxylase produces profound reductions in indole concentrations in spinal cord samples. However, the depletion of 5-HT was less pronounced in nu. raphe magnus (NRM) and ventral cord as compared to nu. raphe pallidus (NRP) and dorsal cord, respectively. The present studies assessed whether regional changes in 5-HT after PCPA can be attributed to selective reduction in terminal structures.

5-HT in terminals was assessed with two approaches. First, 40 µm sections of brainstem (BS) and spinal cord (SC) from PCPA treated (600 mg/kg, IP for 3 days) or control rats were immunohistochemically (IHC) stained for 5-HT. Photographs were taken of NRM (directly dorsal to NRP), lamina II (dorsal) or lamina VIII (ventral) of lumbar cord through a microscope (40X). Negatives were viewed through a camera attached to a Grinnell image analysis system interfaced to a Masscomp MC500 computer. Images were digitized and analyzed with a program that identified only terminal structures. Pixels comprising nerve terminals were identified on the basis of their brightness as compared to neighboring pixels; axons, cell bodies and motoneurons were eliminated. The number of pixels (#-pix) falling within a brightness window was counted for each image and data grouped according to drug treatment. The #-pix representing IHC-stained terminals in NRM was reduced from control values by 46% after PCPA. The #-pix in lamina II was reduced by 69% and in lamina VIII by 49%. The overall analysis suggests that PCPA produced a greater reduction of 5-HT immunoreactive terminals in dorsal cord as compared to terminals impinging upon cells in NRM or on ventral horn motoneurons.

The second approach taken was to measure the concentration of 5-HT in synaptosomal fractions from BS and SC. Rats were pretreated with 400 mg/kg PCPA and sacrificed by decapitation. Tissue pooled from 2-4 rats/group was subjected to subcellular fractionation according to Whitaker et al. (1964). Aliquots of each fraction were taken for analysis of indoles and catecholamines using HPLC with a 3µ C18 column and coulometric (ESA) electrochemical detection. The 5-HT content of the crude P2 fraction was taken to represent synaptosomal 5-HT. PCPA differentially reduced 5-HT content of the BS fraction by 75% and SC fraction by 83% with parallel changes in 5-HIAA. These data corroborate the differential effects of PCPA on IHC stained terminals in NRM and SC. Conflicting effects of PCPA in behavioral or electrophysiological paradigms may be due to alterations at particular terminal sites.

Supported by NIH grants NS11255, NS09743, NS17696 and NS07022.

263.11 SPINAL CORD SUBSTANCE P RECEPTORS ARE PRESENT ON AUTONOMIC AND SOMATIC MOTOR NEURONS: STUDIES WITH SUICIDE TRANSPORT, MEDULLARY LESIONS AND NEUROTOXINS. C.J. Helke*, C.G. Charlton and R.G. Wiley. Uniformed Services Univ. of the Health Sciences, Bethesda MD 20814 and Vanderbilt Univ., Nashville, TN 37202.

Substance P (SP) receptors are present in spinal cord nuclei that contain motor neurons innervating somatic muscles or autonomic ganglia (J. Neurosci., in press). Our previous study (Brain Res. 328:190, 1985), using suicide transport of ricin combined with receptor autoradiography of $^{125}$I-Bolton Hunter-labeled SP, showed that in certain medullary nuclei SP receptors are present on motor neurons. In the current study, the cellular location of the SP binding sites in the intermediolateral cell column (IML), the phrenic motor nucleus, and the lateral part of the lumbar ventral horn (site of sciatic motor neurons) was investigated.

Two weeks after a unilateral injection of ricin into the superior cervical ganglion (SCG) of adult rats, SP binding and cholinesterase-stained neurons were reduced in the IML. Unilateral electrolytic lesions of ventral medullary SP neurons (which decrease SP content in the IML) do not alter the density of SP binding in the IML. Likewise, 6-hydroxydopamine and 5,7-dihydroxytryptamine which reduce the norepinephrine and serotonin contents of the spinal cord, do not reduce the SP binding in the IML. Whereas ricin injected into the SCG destroyed the preganglionic motor neurons and also altered the SP binding, the reduction of SP, norepinephrine and serotonin innervation to the IML failed to reduce binding. This suggests that the SP receptors are located postsynaptically on preganglionic neurons rather than presynaptically on SP (autoreceptors), or monoamine neurons.

Unilateral injections of ricin into the phrenic nerve resulted in the unilateral destruction of phrenic motor neurons in the cervical spinal cord and caused a marked reduction in the SP binding in the nucleus. Likewise, sciatic nerve injections of ricin caused a loss of associated motor neurons in the lateral portion of the ventral horn of the lumbar spinal cord and a reduction in the SP binding. Ricin-induced destruction of neurons is not always associated with a loss of SP binding sites. Sciatic nerve injections also destroyed afferent nerves of the associated dorsal root ganglia and increased the density of SP binding in the dorsal horn.

These data show that SP receptors are present on somatic and autonomic motor neurons of the spinal cord. Other tachykinin peptides such as substance K, neuromedin K, and eledoisin are not discretely localized in areas which contain spinal cord autonomic and somatic motor neurons (Buck et al., this meeting). (Supported by NIH Grant #NS-19317 to C.H. and VA Merit Review Grant to R.W.)

263.12 SUBSTANCE P RECEPTORS SHOW DEVELOPMENTAL CHANGES IN THE RAT: AN ONTOGENY STUDY. C.G. Charlton* and C.J. Helke, Uniformed Services Univ. of the Health Sciences, Bethesda, Maryland 20814.

Receptors for the polypeptide, substance P (SP), have been mapped and characterized in the spinal cord of rats. High density receptors occurred in sensory, autonomic and somatic motor nuclei in adult rats. Functional studies show a role for SP in sensory, autonomic and motor controls. These functions show postnatal developmental changes, which if mediated by SP, suggest that the receptors for the peptide may also undergo postnatal changes. This hypothesis was tested by using light microscopic autoradiography and membrane homogenate binding of $^{125}$I-Bolton-Hunter SP ($^{125}$I-BH-SP) to study SP receptors in the spinal cord of rats of different ages.

In cervico-thoracic segments of rat spinal cord, the autoradiograms showed that specific binding of $^{125}$I-BH-SP occurred exclusively in the grey matter and that mean binding varies inversely to age. In pups, up to about 15 days old, binding sites were generally diffusely distributed over the grey matter, and become progressively more defined in specific nuclei as the rats matured. The age-related binding was confirmed in membrane homogenate binding study of whole spinal cord, which showed that the ratio for the concentration (cpm/mg protein) of specific binding was 88: 12: 3: 1 for rats 11 (26gm), 38 (145gm), 90 (329gm) and 260 (553gm) days old. The ratio for the specific binding to the spinal cord (not corrected for tissue weight) for the same group of rats, was 22: 8: 3: 1. These data showed that SP receptors decreased as a function of age, and that the decrease in concentration was not entirely due to increases in protein.

These findings may represent a new avenue in the study of geratology, and developmental biology and in diseases e.g. sudden infant death syndrome (SIDS). Interestingly, the phrenic (respiratory) motor nucleus receives a bulbospinal SP projection and contains SP receptors. Recently, it has been shown that SP is elevated in the medulla of SIDS victims (Bergstrom et al., Brain Res. 323: 279-285, 1985). (Supported by NIH grant # NS-19317).

263.13 AUTORADIOGRAPHIC LOCALIZATION OF BOMBESIN BINDING SITES WITHIN THE GASTROINTESTINAL TRACT. Timothy H. Moran, Terry W. Moody, Michael S. Goldrich*, Paul H. Robinson and Paul R. McHugh. Department of Psychiatry, The Johns Hopkins University School of Medicine, Baltimore, MD 21205, Department of Biochemistry, The George Washington School of Medicine and Health Sciences, Washington, D.C. 20037.

Bombesin (BN) is a tetradecapeptide with biological activity in both the gastrointestinal (GI) tract and brain. Peripherally administered bombesin has been demonstrated to inhibit food intake and this action of BN appears to be peripherally mediated. In order to identify candidate target sites at which BN could exert this effect, the distribution of BN binding sites was mapped in the stomach and small intestine by *in vitro* autoradiography.

Binding sites for BN were labelled with $^{125}$I Tyr$^{4}$ BN. Binding was carried out on 25u slide mounted tissue sections taken from the fundus, antrum, pylorus, duodenum and ileum. Binding conditions were similar to those demonstrated to provide high affinity binding to brain sections with specific binding of 80-85%. Tissue sections were incubated for 60 min at 22°C in 10 mM HEPES, pH 7.4, 130 mM NaCl, 4.7 mM KCl, 5 mM MgCl2, 1mM EGTA, 0.5% bovine serum albumin, 0.07 mM bacitracin and 3nM $^{125}$I BN in the presence or absence of 1 uM unlabeled BN. Incubations were followed by two consecutive 4-min washes in buffer at 4°C. Slides were dried and apposed to LKB H$^{3}$ Ultrofilm to obtain autoradiographic images.

The greatest density of binding was found in the gastric fundus. Binding was also present in the proximal gastric antrum and in the duodenum and ileum. In all cases binding appears to be limited to the neural plexus within these tissues and is not found in either the mucosal or muscular layers. No binding was found within the pyloric sphincter. This pattern of binding sites is clearly differentiated from that of cholecystokinin (CCK), another peptide which inhibits food intake. CCK receptors are exclusively localized to the circular muscle layer of the pyloric sphincter in adult rats. The differential distribution of BN and CCK binding sites within the GI tract suggests that CCK and BN exert their effects on food intake through different sites of action.

264.1 MULTIPLE, LONG-RANGE FOCAL COLLATERALIZATION OF SINGLE CORTICO-CORTICAL AXONS IN MONKEY SENSORY-MOTOR CORTEX. J. DeFelipe*, M. Conley and E. G. Jones. Department of Anatomy, University of California, Irvine, CA 92717.

Vertical (interlaminar) connectivity dominates thinking on the intrinsic organization of the cerebral cortex. Horizontal (intralaminar) connectivity also exists and axoplasmic transport studies reveal inter- and intra-areal connections terminating in multiple dissociated clusters of axonal arborizations which arise from similarly dissociated patches of pyramidal neurons. We sought to determine whether individual cortico-cortical axons terminate in multiple focussed interareal and intraareal arborizations corresponding to the patches.

We made small iontophoretic or pressure injections of horseradish peroxidase (HRP) in the white matter just beneath area 3b or 5. We then reconstructed retrogradely labeled pyramidal cells in which axons and collaterals could be traced from somata for distances of up to 6 mm.

The cell bodies of the cells were located in layer III of areas 4, 3a, 3b, 1, 2, or 5. The axon descended vertically towards the white matter and during the initial trajectory the axon measured 1-1.5 μm but at a distance of 20-30 μm from the cell body where the axon become myelinated it measured 2-5 μm. Collaterals of the main descending axons were of two kinds: one was very thin and within a few microns devolved into terminal branches with small boutons terminaux; the others were major, myelinated collaterals which had long horizontal or oblique trajectories traversing several cytoarchitectonic areas. There were two distinctive characteristics of the major collaterals: first the long trajectory (sometimes over 800 μm) over which they gave off no branches; second, several terminal branches arising from widely separated parts of the parent collateral and even from different major collaterals of the same cell could converge on the same cortical focus, giving rise to dense patches of terminations mainly in layers II-IV. Single cells were observed that had one to three terminal patches in their own cytoarchitectonic area as well as one or more patches in one to four of the other areas, the connectivity between areas following previously established rules (Jones et al. J. Comp. Neurol. 181: 291, 1978).

The present results indicate a highly specific spread of connections in the horizontal dimension of the primate sensory-motor cortex formed by single axons and which contrasts with the pattern of equally specific vertical connections formed by certain populations of pyramidal and non pyramidal cells. (Supported by Grants Numbers NS 21377, NS 507072 and F05 two 3156 from the NIH, USPHS).

264.2 EXPANSION OF THE S-I CORTICAL AREA ACTIVATED BY SAPHENOUS NERVE INPUTS IN RATS AFTER DESTRUCTION OF SCIATIC NEURONS WITH THE LECTIN RICIN. J. T. Wall, R. G. Wiley, and C. G. Cusick. Depts. of Psychology and Neurology (VAMC), Vanderbilt University, Nashville, TN 37240.

When the hindpaw skin of an adult rat is partially deafferented by mid-thigh sciatic nerve section, regions of S-I cortex usually representing sciatic inputs become responsive to hindpaw zones which remain innervated by the saphenous nerve (J. Neurosci., 4, 1984, 1499). Since the cell bodies and central processes of primary sensory neurons commonly survive distal nerve section, it is possible this enlargement in the saphenous projection system is actively modulated by some signal from sectioned sciatic neurons. In the present study, we attempted to eliminate sciatic neurons to evaluate what effect removal of primary sensory neurons and possible active signal release has on the size of the cortical projection of saphenous inputs.

Dorsal root ganglion neurons of adult rats were destroyed as a result of retrograde transport of the toxic lectin ricin from mid-thigh injections of the sciatic nerve. Previous anatomical studies indicate such injections produce a severe loss of cell bodies in dorsal root ganglia associated with the sciatic nerve (Soc. Neurosci. Abstr. 9, 1983, 298). After ricin injection, maps of the S-I hindpaw representation were made from neurophysiological recordings and compared to hindpaw maps from normal and sciatic-sectioned rats.

The results indicate the cortical projection area of saphenous inputs in rats that had ricin injections 6-101 days before mapping ($\bar{x}$ = .57 mm$^2$) is: larger than the saphenous area of normal rats ($\bar{x}$ = .14 mm$^2$; $t(15) = 10.44$; $p < .001$), and not statistically different from the saphenous area of rats whose sciatic nerves were sectioned and ligated 4-91 days before mapping ($\bar{x}$ = .45 mm$^2$; $t(11) = 2.02$; $p > .05$). In addition, plots of the size of the saphenous area as a function of time after ricin injection or section are similar. Thus, the spatial and temporal features of adjustment in the size of the cortical projection of saphenous inputs appear comparable after section of sciatic processes and after loss of sciatic neurons.

Although it is recognized that injury of one part of the nervous system commonly leads to organizational adjustments in related circuits which survive damage, there is little understanding of the factors controlling such adjustments. The present findings suggest primary sciatic neurons do not actively modulate size adjustments in the cortical projection system of neighboring saphenous inputs during the first 100 days after sciatic injury.

264.3 MORPHOLOGY AND ULTRASTRUCTURE OF TERMINATIONS FROM SINGLE CORTICOSPINAL TRACT AXONS ARISING FROM SENSORIMOTOR CORTEX IN THE CAT. E.J. Casale*, A.M. Kavookjian*, A.R. Light (SPON: D. McIlwain). Department of Physiology, UNC-Chapel Hill, Chapel Hill, NC 27514

Little is known concerning the laminar collateral distribution and synaptic ultrastructure of single, corticospinal tract (CST) axons. In the present experiments, single CST axons arising from sensory cortex were impaled with micropipettes filled with 4-10% horseradish peroxidase (HRP), near their termination within the lumbar enlargement in chloralose-anesthetized cats. Axons were positively identified as corticospinal by their ability to "follow" electrical stimulation of the cortex at 300 Hz with minimal (<0.1ms) latency shifts.

Conduction velocities ranged from 9-112 m/sec with a mean of 37 m/sec. Typically, individual CST axons activated via natural stimulation responded to brush or tap of the entire leg, foot, and tail contralateral to its origin in the cortex. Occasionally units had spontaneous activity. Intraaxonally stained fibers displayed wide variation with respect to the amount of collateralization within the gray matter, their mediolateral and rostrocaudal extent, and their laminar distribution. Overall, however, boutons were found mainly in laminae III through VII.

Boutons of one fiber were analyzed at the EM level. Both boutons en passant and boutons terminaux were found within laminae III, IV, and V. Most boutons were large and glomerular-shaped with preterminal axons myelinated as far as the glomerulus. Asymmetrical contacts were made with many dendritic spines. Occasionally contacts were made on large dendritic shafts, but no axo-axonic or axo-somatic contacts were found. Vesicles were mostly round (40nm diameter) and clear, except for the occasional presence of a few large dense-core vesicles (85nm diameter).

These data indicate that CST axons, as well as primary afferent axons, may terminate within the dorsal horn as glomeruli.

264.4 SYNAPTIC CONNECTIVITY OF THALAMOCORTICAL AXON TERMINALS WITH SPINY STELLATE NEURONS IN MOUSE SmI CORTEX. G. Benshalom* and E. L. White. (SPON: N. Vardi). Unit of Morphology, Faculty of Health Sciences, Ben-Gurion University of the Negev, Beer Sheva 84105, Israel.

The distribution of thalamocortical (TC) synaptic connections with spiny stellate cells in layer IV of the barrel region in mouse primary somatosensory cortex, was examined in 7 three month-old, male CD/1 mice. TC afferents were labeled by lesion induced degeneration, which, in previous studies, had been shown to label reliably all TC synapses in mouse barrel cortex. Golgi impregnated/gold-toned spiny stellate cells were identified with the light microscope prior to thin sectioning. Analyses of 7 spiny stellate cell dendrites from 7 different neurons showed them to form most of their synapses with their dendritic spines rather than with their shafts. The relatively few synapses on dendritic shafts were about evenly divided between symmetrical and asymmetrical types; spinous synapses were primarily of the asymmetrical type. From 13 to 23% of all asymmetrical synapses with spiny stellate cell dendrites were with TC axon terminals and these were located mostly on spine heads. Spines forming TC synapses were irregularly distributed along the entire lengths of the dendrites, except for their proximal segments which bore few spines. These results show that spiny stellate cell dendrites form a relatively high proportion of TC synapses as compared with other types of neurons in mouse SmI cortex, implying that spiny stellate cells are strongly influenced by TC synaptic input. Moreover, the efficacy of spinous synapses may be enhanced by active membrane properties of the spine head. Thus the possibility exists that by virtue of their spines, thalamic input may influence layer IV spiny stellate cells to an even greater extent than would be predicted merely by the distribution of TC synapses.

264.5 PROJECTIONS OF THE MEDIAL PORTION OF THE POSTERIOR THALAMIC NUCLEAR GROUP (POM) TO THE SOMATOSENSORY CORTEX OF THE RAT. K.A.Koralek*, K.F.Jensen and H.P.Killackey*. (SPON: L.Ide) Dept. of Psychobio., Univ. of Calif., Irvine, CA 92717.

In the somatosensory cortex of the rat two cytoarchitectonic zones can be distinguished. The granular zone has a well developed layer IV and receives clustered projections from the ventral posterior nucleus (VP). The dysgranular zone has a poorly developed layer IV and has been described as receiving sparse thalamic input. The present study focuses on the projections of POM to somatosensory cortex.

Adult Sprague Dawley rats were injected with .1 to .5 microliters of WGA-HRP into the dysgranular zones. The animals were perfused after a 12 to 24 hour survival period. Coronal sections were processed with TMB. Additional rats were injected with .25 to .75 microliters of WGA-HRP into either POM or VP. The cerebral hemispheres were flattened, sectioned tangentially and processed with TMB.

Injections into the dysgranular zone result in extensive retrograde labeling in POM. The bulk of labelled cells are located in the anterolateral aspect of POM bordering on the dorsal and medial borders of VP. Injections of WGA-HRP into POM produces different patterns of label in the dysgranular and granular zones. The anterograde label was heaviest in the dysgranular zone. In some cases, a uniform dense label filled a substantial portion of the dysgranular zone adjacent to the barrel field. This area was devoid of anterograde label following large injections of WGA-HRP into VP. In the adjacent granular zone, injections of POM resulted in sparse label distributed in a grid-like pattern complementing the pattern of anterograde label from VP. This distribution of label is open to two interpretations. It may reflect either direct afferents from POM or collaterals arising from corticothalamic projection neurons projecting to POM from somatosensory cortex.

These results indicate that POM is a major source of thalamic input to the dysgranular zone. We interpret this finding as evidence that POM and VP project differentially to the rodent somatosensory cortex.

264.6 AT WHAT LEVELS OF THE SOMATOSENSORY SYSTEM DOES MI CORTEX STIMULATION MODULATE CUTANEOUS SENSORY TRANSMISSION IN THE RAT? S.E. Knowles, H.-C. Shin and J.K. Chapin. U. of Texas Health Sci. Cntr., Dallas Tx. 75235.

We have used standardized electrical stimulation parameters in the forelimb area of MI cortex to test motor cortical modulation of cutaneous sensory responses in the following somatosensory relays: cuneate nucleus, VPL thalamus, and SI cortex (granular and infragranular layers.) In 36 ketamine anesthetized rats (200-250 gm) a narrow (.1 mm diam) bipolar concentric stimulating electrode was driven to a depth of 1700 uM into a standard location in the MI cortical forelimb area (2.0 mm anterior to bregma, 3.5 mm lateral to midline). The same stimulation parameters (single 1.0 msec pulses; 50 uAmp constant current) were used for all experiments. These currents were lower than thresholds for producing forelimb movement (average about 100 uA). This MI stimulation was used as the conditioning (C) stimulus in a condition-test (C-T) paradigm in which the test (T) stimulus was standardized mechanical vibration of digit #2 of the contralateral forepaw. Post-stimulus histograms were used to quantitate the responses to these C and T stimuli delivered at different C-T intervals.

In the cuneate nucleus, direct responses to the MI cortical stimulation were rare ( <10% of animals). However, in about 50% of recorded cells the C-stimulation (in MI cortex) caused a moderate inhibition of responses to T-stimulation (on forepaw). This inhibition mainly occurred at longer C-T intervals ( >25 msec). Most cells in the cutaneous forepaw area of the VPL thalamus were similar to those in the cuneate in that they did not respond directly to the MI cortical stimulation, but their responses to paw vibration were moderately inhibited by C-stimulation at relatively long C-T intervals. A few cells, however, especially those in VPL locations representing more proximal limb, or head areas, did respond to the MI stimulation. These exhibited a more powerful, and shorter latency C-stimulus induced inhibition of responses to T-stimulation (of appropriate skin areas). Similar C-T interaction studies were carried out during microelectrode penetrations through the layers of the SI cortical forepaw area (2-3 mm away from the stimulating electrode in MI cortex). Very few neurons in the granular or supragranular layers responded directly to the MI stimulation, but in the infragranular layers both ortho- and antidromic responses were common. These infragranular cells were much more strongly inhibited by C-stimulation at short (10-25 msec) C-T intervals. In conclusion, the MI cortex appears to exert stronger effects on somatosensory transmission within the SI cortex than at lower relays. Supported by grants NS18041, AA0390, and the Biological Humanics Foundation.

264.7 MORPHO-FUNCTIONAL CORRELATION ON N. RETICULARIS THALAMI NEURONS:AN INTRACELLULAR AND HRP STUDY IN RAT'S THALAMIC SLICES. R. Spreafico*, M. De Curtis*,C. Frassoni*,G. Avanzini*(SPON: European Neuroscience Association) Dept. of Neurophysiology - Ist. Neurologico "C. Besta" - 20133 Milano (Italy).

Aim of the present work is to investigate the intrinsic organization of n. Reticularis thalami (Re) by means of a combined anatomical and physiological study using intracellular recording and HRP injection of single neurons. 20 experiments were performed on horizontal slices (300-400 μm thick) of rat thalamus incubated in vitro. Glass micropipettes filled with $K^+$ acetate (4M) or with a 4% Horseradish Peroxidase (HRP) solution in 0.2 M KCl were employed for intracellular recording and intracellular injection of the enzyme. Resistances of microelectrodes were 40-80 MΩ and 80-150 MΩ respectively. Recording electrodes were positioned in the n. Re. Recorded cells were identified physiologically by orthodromic stimulation of internal capsule and ortho- or antidromic activation from the thalamus using tungsten stimulating electrodes. After the physiological study, HRP was intracellularly injected through the recording micropipette by means of positive pulses (2-3 nA, 10 msec in duration, 50 Hz for 2-3 minutes). Two hours after injections, slices were immersed in phosphate buffer solution containing mixed aldehydes for 2 hours and then transferred in a 30% sucrose phosphate buffered solution. After fixation slices were cut in 100 μm thick frozen sections and processed for HRP visualization. Camera lucida drawings were performed on serial sections in order to reconstruct HRP injected neurons.

25 out of 40 impaled neurons were orthodromically activated by both I.C. and thalamic stimulation and showed similar membrane characteristics. Twelve neurons were also labelled by HRP and camera lucida reconstructed. Pericarya of these cells were generally fusiform with dendrites arborizing mainly in the anteroposterior extent of the nucleus. Few spines were visible. The axons of labelled neurons were reconstructed for long distance in different thalamic nuclei. In few instances axon collaterals emerging from the proximal portion were observed to ramifie within the Re.

The results suggest the existence of a subpopulation of Re projecting neurons subserving also intrinsic local circuitry.

264.8 INTRACORTICAL AND THALAMIC CONNECTIONS OF SMI FOREPAW CORTEX OF THE RACCOON. G.S. Doetsch, K.W. Johnston*, G.P. Standage and C.-S. Lin. Depts. of Surg. (Neurosurg.), Physiol. and Anat., Med. Coll. Ga., Augusta, GA 30912 and Dept. of Anat. Duke Univ., Durham, NC 27710.

Our previous electrophysiological studies have shown that denervation of a forepaw digit in the adult raccoon causes neurons within the deprived portion of SmI cortex to develop "new" receptive fields (RFs) on digits adjacent to the denervation site. Because some of these changes occur within 24 hours, we suggest that they reflect the unmasking of pre-existing anatomical connections.

To test this notion, the intracortical and thalamic connectivity of SmI cortical digit zones was examined in adult raccoons using the horseradish peroxidase (HRP) tracer method. Injections of 50% HRP (.01-.3 ul) were made into the crown of a specific gyrus representing digit 2, 3, 4 or 5. After 48 hours, each animal was perfused intracardially with saline followed by an aldehyde mixture, and the brain was processed for HRP histochemistry. The locations of retrogradely-labeled neurons and orthogradely-labeled axon terminals in the thalamus and SmI cortex were plotted.

The gyral crown of each SmI cortical digit zone was found to have specific reciprocal thalamic connections with a distinct crescent-shaped lamella of neurons extending rostrocaudally through the lateral part of VPL. The regions containing labeled thalamocortical relay neurons and corticothalamic terminals overlapped extensively. Neurons within adjacent lamellae were not labeled, consistent with the finding by Rasmusson (1985) that, in the raccoon, VPL relay neurons project their axons to only one cortical digit area with no collaterals to neighboring areas.

In contrast, the SmI cortical digit zones themselves were found to be interconnected by local cortico-cortical circuits. The gyral crown of a given zone was reciprocally connected with small clusters of neurons located in the fundus of one or both sulci demarcating that gyrus and separating it from adjacent digit zones. The cells were confined mainly to layer VI, while the axon terminals were located primarily in layers III-IV and VI. Shorter reciprocal connections were found with other neuronal clusters located within the crown or sulcal banks of that same gyrus. These cells and axon terminals were present mainly in layers II-IV and VI. Thus, a given digit zone can receive input from neighboring digit areas via neurons located in the sulcal regions demarcating that zone.

The action of these cortico-cortical connections may largely account for the unmasking of "new" RFs following denervation. Projections from adjoining digit zones to the intervening sulcal region could account for the convergent functional properties of neurons located in that region. Input from the sulcal regions may then explain why the crown of a reactivated digit zone develops convergent properties similar to those of normal sulcal regions.

(Supported in part by NSF grant BNS-8419035.)

264.9 QUANTIFICATION OF THALAMOCORTICAL AND CORTICOCORTICAL AXON TERMINALS USING PHA-L IMMUNOHISTOCHEMISTRY. E. L. White and A. Keller*. Unit of Morphology, Faculty of Health Sciences, Ben Gurion University, Beer Sheva, Israel

Phaseolus vulgaris leuco-agglutinin (PHA-L) was injected iontophoretically into the vibrissal area of either the ventrobasal thalamus or of the ipsilateral SII area in CD/1 mice. After perfusion, cortex ipsilateral to the injection site was sectioned and reacted with biotinylated anti-PHA, with an avidin-biotin-horseradish peroxidase complex and then with diaminobenzidine to demonstrate the horseradish peroxidase. The result of this procedure was to label thalamocortical (TC) and corticocortical axons and their terminals with a reaction product visible with both the light and electron microscopes. Results of the TC study confirmed previous findings that TC axon terminals form about 20% of the asymmetrical synapses in layer IV of mouse barrel cortex. This suggests that the anterograde PHA-L method can provide accurate information on the numbers and types of synapses involving identified axon terminals. In addition, because preterminal axon segments remain intact and are labeled, it should be possible to use the anterograde PHA-L method to determine how many synapses are made by a single axon, and further, how many axons contact individual postsynaptic elements. However, it cannot be excluded that some PHA-L labeled terminals are collaterals of cells labeled by the retrograde transport of the lectin. Therefore, as a further check on the efficacy of PHA-L as an anterograde label, we compared results using PHA-L with results of combining HRP injections and lesions at a single site. The latter approach enables afferents, identified by lesion induced degeneration, to be differentiated from collaterals labeled by the retrograde transport of HRP. Results of lesion/injections at sites in thalamus and SII will be presented. Supported by N.I.H. # NS 20149-02, BSF # 3201/83.

264.10 SPATIOTEMPORAL RESPONSE PROPERTIES OF SOMATOSENSORY NEURONS IN THE PERIPHERY AND SI CORTEX OF THE MONKEY MEASURED WITH SCANNED, VARIABLY SPACED DOT ARRAYS. J.R. Phillips*, K.O. Johnson, K.H. Fasman, S.S. Hsiao*. (SPON: A.B. Schwartz) Bard Laboratories, Dept. Neuroscience and Dept. Biomedical Eng., The Johns Hopkins University Sch. Medicine, Baltimore, Md. 21205.

The spatial and temporal resolution of peripheral and cortical neurons was investigated using plastic surfaces composed of arrays of raised dots with center-to-center spacing varying from 0.9 to 6.2 mm and dot diameters ranging from 0.4 to 1.2 mm. The dot heights were 0.6 mm. In the peripheral experiments, monkeys (M. mulatta) were anesthetized with sodium pentobarbital and action potentials were recorded from single afferent axons. In the cortical experiments the monkeys were alert and performing a behavioral task that was unrelated to the tactual stimuli. Their hands were restrained in an apparatus that allowed stimuli to be applied to the distal pads of the fingers. The dot patterns were swept across the finger pads repeatedly in such a manner that the receptive field scanned the entire surface in successive sweeps. When mapped onto the coordinates of the stimulus surface, the action potential patterns provide a direct display of the spatiotemporal resolution of the neuron.

Neurons studied in this way showed greater resolution than has been reported previously for similar patterns. The minimum center-to-center dot spacing resolved by peripheral slowly adapting afferent fibers ranged from 1.1 mm for the most sensitive fiber to 2.4 mm for the least sensitive fiber. The comparable range for quickly adapting cutaneous afferents was 1.8 to 3.4 mm. Pacinian afferents had responses that could not be easily classified; individual dots at even the largest spacings were not resolved, but these responses were not entirely unstructured. Scanning velocity (20-100 mm/sec) had little, if any, effect on the resolution of peripheral afferents. Likewise, dot diameter had relatively little effect on the maximum resolution of the peripheral afferents. Cortical neurons studied in SI cortex, predominantly in area 1, varied greatly in their capacity to resolve these stimulus patterns with minimum resolved dot spacing ranging from 1.1 to 6.0 mm. The most sensitive cortical neuron (a neuron with a sustained response to steady cutaneous deformation) was as sensitive to spatial detail as the most sensitive peripheral afferents. The small population of cortical neurons studied using a range of scanning velocities showed a mild loss of spatial resolution with increased scanning velocity. Supported by NIH Grants NS18787 and GM07057.

264.11 NEURAL REPRESENTATION OF EMBOSSED LETTERS IN PERIPHERAL MECHANORECEPTIVE AFFERENTS AND SOMATOSENSORY CORTEX OF THE AWAKE MONKEY. S.S. Hsiao, K.H. Fasman, J.R. Phillips*, and K.O. Johnson. Bard Laboratories, Dept. Neuroscience and Dept. Biomedical Eng., The Johns Hopkins University Sch. Medicine, Baltimore, MD. 21205.

The human capacity for tactual spatial pattern recognition has previously been investigated in psychophysical experiments using embossed letters of the alphabet with heights ranging from 3.0 to 8.0 mm. The experiments reported here employ the same stimuli and are aimed at studying the neural representation of letters and the transformations effected in the ascending somatosensory pathways. The experiments fall into two categories. In the peripheral experiments, recordings were made from single afferent axons of monkeys (M. mulatta) anesthetized with sodium pentobarbital. In the cortical experiments, recordings were made from neurons located in SI cortex of alert monkeys performing a behavioral task unrelated to the test stimuli.

The stimuli consisted of 3 full alphabets (2.0, 4.5, and 6.5 mm high) and a set of 10 A's and S's ranging in height from 2.0 to 10.8 mm. The letters were swept repeatedly across the finger pads, in such a manner that the receptive field scanned the entire surface in successive sweeps. When mapped onto the coordinates of the stimulus surface, the action potential patterns provide a direct display of the neurons' spatiotemporal responses to the embossed patterns. The peripheral slowly adapting (SA) afferents resolved 6.5 and 4.5 mm alphabets quite effectively, but at 2.0 mm the representation was markedly degraded. Quickly adapting (QA) afferents required patterns about 50% larger for their spatial resolution to equal that of the SA afferents. However, a large number of the 4.5 mm letters could be recognized from QA spatiotemporal responses, suggesting that these afferents may play some role in tactile spatial pattern recognition. Changes in scanning velocity (from 20 to 40 mm/sec) had no effect on the spatial response patterns of the SA's and had a minor effect on the response patterns of some QA afferents. The Pacinian afferents resolved the patterns poorly and we infer that they play no role in tactile spatial pattern recognition.

Neurons studied in SI cortex, predominantly area 1, yield spatiotemporal responses that are different from those seen in the periphery. In most cases it is not possible to identify the stimulus by simple visual inspection of the neuronal responses. This is so even for cortical neurons that resolve periodic spatial patterns as effectively as the most sensitive peripheral SA afferents. Supported by NIH Grants NS18787 and GM07057.

264.12 ROUGHNESS PERCEPTION: A PSYCHOPHYSICAL AND NEUROPHYSIOLOGICAL INVESTIGATION. K.H. Fasman, S. Hsiao*, J.R. Phillips*, and K.O. Johnson. Bard Laboratories, Dept. Neuroscience and Dept. Biomedical Eng., The Johns Hopkins University Sch. Medicine, Baltimore, MD. 21205.

The neural mechanisms underlying tactile roughness perception were investigated using 18 plastic surfaces composed of arrays of raised dots. Three dot diameters (0.4, 0.8, and 1.2 mm) and six center-to-center spacings (1.3, 2.4, 3.2, 4.3, 5.2, 6.2 mm) were used. In the psychophysical experiment subjects explored each surface with the pad of the index finger, using whatever force and velocity seemed most appropriate, and reported their subjective estimate of roughness. The surfaces were presented in random order and hidden from view. Normalized roughness estimate versus dot spacing reached a maximum at 3.2 mm and then fell again at larger dot spacings, i.e. the surfaces began to be perceived as smoother at greater dot separations. The effect of dot diameter was much more pronounced at small dot spacings than at larger spacings. At the smallest dot spacing, 1.3 mm, the medium and small dot diameters produced roughness estimates that were 2.5 and 6 times greater than the estimates for the largest dot diameter. At large dot spacings, 3.2 mm and above, dot diameter had little effect, although increasing dot diameter still reduced the subjective estimates slightly.

The same stimuli were repeatedly scanned across the receptive fields of macaque peripheral mechanoreceptive afferents (slowly adapting (SA), quickly adapting (QA) and Pacinian (PC)). The responses of the SA and QA afferents were spatially and temporally modulated for all dot spacings of 2.4 mm and greater. At the smallest dot spacing (1.3 mm) some of the the SA afferents were modulated effectively. The Pacinian afferents produced very complex responses which were clearly patterned but not at the fundamental spatial and temporal frequencies of the stimulus. It is clear that subjective reports of roughness were not related to any simple aspect of the spatial or temporal patterning in the afferent discharge. Surfaces producing equal reports of subjective roughness, e.g. 0.4 mm dots at 1.3 mm spacing and 0.8 mm dots at 6.2 mm spacing, produced very different spatial and temporal neural response patterns in all of the afferents. However, mean impulse rate in all of the afferent populations behaved in the same general manner as did subjective roughness, rising with increasing dot spacing to a maximum value and then falling. Supported by NIH Grants NS18787 and GM07057.

264.13 MECHANICALLY DRIVEN TRIGEMINAL EVOKED POTENTIALS IN CAT. Steven M. Barlow and Kevin Spangler*. Orofacial Physiology Laboratory, Boys Town National Institute, Omaha, NE 68131.

Afferent information derived from cutaneous mechanoreceptors distributed around joints and within areas of skin which undergo conformational changes associated with movement is thought to play an important role in providing feedback for developing and maintaining ongoing fine motor control. The purpose of the present study was to examine the response characteristics of the trigeminal system in cat to natural stimulation.

Short latency brain stem (far field) and cortical (early near-field) potentials were evoked by mechanical stimulation of the perioral face region and recorded epidurally over the primary sensorimotor cortex and directly from more caudal structures in the trigeminal lemniscal pathway, including the venteroposteromedial nucleus of the thalamus. Experiments were performed on adult cats positioned in a stereotaxic frame. They were anesthetized with nembutal and tracheostomized. Body temperature was monitored and maintained within resting levels. Monophasic displacements, with peak to peak rise times of approximately 5 milliseconds, were applied to the nonglabrous surfaces of the upper lip using a specially designed linear motor having a probe contact area of 0.125 $cm^2$. Stimulus amplitude ranged from 25 to 1000 microns. Multi-channel recording of far-field potentials were differential using Ag/AgCl ball macro-electrodes (0.5 mm tip diameter) for extradural recordings and platinum multiunit electrodes (50 micron tip diameter) for depth recorded potentials. Amplified signals and motor synchronization pulses were digitally signal averaged. The location of recording sites and extent of lesions were determined by histologic examination of stained serial sections through the damaged tissues.

Surface recorded cortical (early near-field) and brain stem (far-field) potentials were adequately evoked by the application of mechanical stimuli to the upper lip. Although more complex in waveform morphology, the mechanically driven trigeminal somatosensory evoked potentials (TSEP) obtained in the present study are similar to those recorded in response to direct electrical stimulation of the mental nerve (Dong, W.K., Brain Res., 233: 205-210, 1982). Additionally, the latencies and amplitudes of individual components of the mechanically driven TSEP varied systematically with the rate and amplitude of stimulation.

264.14 SIMULATIONS OF A SPATIO-TEMPORAL MODEL FOR CORTICAL 2-DG PATTERNS. C. E. Smith* and D. G. Kelly* (SPON: B. L. Whitsel) Dept. of Statistics, Biomathematics Program, North Carolina State University, Raleigh, NC 27695 and Dept. of Mathematics, Univ. of North Carolina, Chapel Hill, NC 27514.

Recent labelling techniques, such as 2-deoxyglucose (2-DG), are beginning to provide insight into the spatial pattern of cortical activity. The amount of labelling incorporated is usually assumed to be directly related to the cummulative neuroelectric activity of the labelled neurons. Here we present simulated two dimensional patterns of firing rates (cortical activity) at a series of successive time intervals, e.g. 20, from a neural network model that emphasizes the modular nature of cortical processing (Szentagothai, J. Rev. Physiol., Biochem. Pharm., 98: 11-94, 1983). The goal of the modelling effort is to examine a variety of excitatory and inhibitory connection patterns between cortical columns and sub-columns and determine classes that produce steady-state patterns similar to those seen in 2-DG experiments. The specific application is to mammalian primary somatosensory cortex. To provide a greater degree of resolution than that of a cortical column (300 x 300 u), we use as our basic unit a cortical square of 150 x 150 microns. For each unit in a 2-D matrix, e.g. 52 x 52 units, excitatory and inhibitory connections to other units are assigned weights, reflect that unit's contribution to changes in the designated unit's average firing rate. For example, a connection pattern of a unit to its 48 nearest neighbors are specified. In addition to inputs from neighboring units, the 2-D matrix also receives a separate set of two dimensional inputs, called the input pattern and representing intraunit connections. The weighted inputs are summed and input to a sigmoidal function to incorporate firing rate saturation and zero clipping. For small signal analysis, the sigmoidal function is disregarded and methods of two dimensional signal processing are used.

For a fixed spatial input pattern, e.g. a 2-D ascending staircase, various connection patterns among units were examined. Center surround connections can produce edge enhancement, corner enhancement, peak detection, and damned temporal oscillations for different parameter values. Moving spatial input patterns were also examined as were altering connection weights due to level of activity (adaptive spatial filtering). The use of the model is intended to be a pragmatic one. First determine several connection pattern parameters that give the desired steady state solution patterns for a given spatial input pattern, then predict the response to different input patterns and pharmacological manipulation of connection parameters, e.g. remove a type of inhibitory synapse. (Supported by ONR Contracts: N00014-85-K-0105 and N00014-83-K-0387).

## OPIOIDS: PHYSIOLOGICAL STUDIES II

265.1 A NON-OPIOID MECHANISM AT THE LEVEL OF THE SENSORIMOTOR CORTEX MEDIATES THE ANTICONVULSANT EFFECT OF OPIATES IN THE RABBIT. M. Massotti and M.G. Spillantini* Laboratorio di Farmacologia, Istituto Superiore di Sanità, 00161, Roma, Italy.

Using various animal models of experimental seizures, data have been provided indicating an anticonvulsant effects of opiate agonists. In the rabbit, the convulsant effect due to the injection of penicillin (150 U.) into the sensorimotor cortex is prevented by administration of morphine (0.2-1 mg/kg iv) and cyclazocine (0.05-3 mg/kg iv). Naloxone, at doses (5-20 mg/kg iv) that per se slightly potentiate the convulsions due to penicillin, fails to antagonize the effect of morphine and cyclazocine (Massotti et al., Br. Res. 310: 201, 1984). On the contrary, it has been recently found that minute doses of naloxone (1-50 ug/kg iv) also display an anticonvulsant effect. The effects of the morphine and naloxone can be differentiated on the basis of the different EEG patterns of antagonism observed. While morphine inhibits the transmission of the ictal event, naloxone mainly inhibits the primary focus. Both are inhibited by cyclazocine, a mixed agonist-antagonist (manuscript in preparation).

On the basis of these results, it was worthwhile to study the effects of morphine, cyclazocine and naloxone injected directly into the sensorimotor cortex (ic). The three opiates were injected in a volume of 20 ul 5 min before penicillin (150 U. in 20 ul) in the same site. As shown in the table, the opiates reduce the incidence of the convulsions due to penicillin (150 U.).

| Drugs | pmoles ic x animal | C/T | Values x convulsant animal N. seizures | Total seizures time |
|---|---|---|---|---|
| Saline 20 ul | | 7/8 | 13.3 | 13.8 |
| Naloxone | 0.3 | 2/6 | 2.0 | 1.6 |
| Cyclazocine | 0.5 | 1/6 | 17.0 | 23.6 |
| Morphine | 60 | 4/9 | 6.1 | 2.5 |

C=N° animals showing convulsions T=N° animals treated

Moreover, in animals showing convulsions after naloxone and morphine, both the number of seizures and the total seizure time were also reduced. Unlike the effects observed after iv injection, no difference was observed among the three opiates in the EEG pattern of antagonism.

In conclusion, present data would suggest that in the sensorimotor cortex of the rabbit a non-opioid mechanism mediates the anticonvulsant effect of opiates.

265.2 THE EFFECT OF IMMUNOSUPPRESSION AND OPIATES UPON THE VISUAL EVOKED RESPONSES OF CORTICAL AND SUBCORTICAL STRUCTURES. N. Dafny, P. Dougherty* and N.R. Pellis*. Department of Neurobiology and Anatomy, and the Department of Surgery, University of Texas Medical School, Houston, Texas 77030.

Previous studies from this laboratory demonstrated that immuno-modulating agents (α-interferon, cyclosporine A, cyclophosphamide and cortisol) attenuate opiate withdrawal suggesting a possible involvement of the immune system in opiate dependence. More recently, we demonstrated that destruction of the immune system by irradiation also alters the behavioral properties of addiction. The present study was undertaken to determine if visual evoked responses (VER) are altered in three brain regions following destruction of the immune system and if the morphine effects on the VER remain intact after ablation of the immune system. Whole body irradiation to 500 rads selectively ablates the immune system. Irradiation was performed at either 2 hours prior to morphine exposure (pellet implantation), or at 2 hr prior to naloxone injection. VER were recorded from eighteen freely behaving male Sprague-Dawley rats previously were implanted under anesthesia with permanent electrodes. The brain regions chosen were as follows: The superior colliculus (SC) as a control region; the visual cortex (VCx) for a region of higher integrative activity; and the ventromedial hypothalamus (VMH) due to reports demonstrating its interaction with the immune system. The VER's were obtained at 2 hr and 72 hrs following irradiation; as well as 6 days and 9 days post-irradiation to observe any possible subtle alterations not detected at the earlier times. VER's in the SC remained unchanged for the entire time course. The majority of the VER recorded from the VCx remained unchanged at 2 hrs, post irradiation. However, at 3, 6 and 9 days the amplitude of the VER was potentiated. The VER recorded from the VMH was altered at all time points studied. The changes in the VMH and the VCx usually affect the $N_2$ and $P_3$ components of the VER. Finally, the VER following morphine treatments of the irradiated animals were differed from that obtained from intact morphine naive animals. In conclusion, the doses of irradiation used had no destructive effect upon the electrical activity of the CNS as assessed by the VER obtained in the superior colliculus (SC) However, the VER in those CNS areas that have some immune interaction as well as affecting immune function were altered. Moreover, the morphine effects on VER in immunosuppressed animals were differed than those observed in intact animals. These results further support our previous indications of CNS-immune system interaction.

265.3 KAPPA OPIATE MODULATION OF THYROID STIMULATING HORMONE (TSH) RELEASE IN THE RAT. S. Iyengar and P.L. Wood, Neuroscience Research, Pharmaceuticals Division, CIBA-GEIGY Corporation, Summit, NJ 07901.

In rats acute administration of morphine or leu-enkephalin results in decreased TSH secretion (Lomax et al. Neuroendocrinology, 6:146, 1970; Bruni et al. Life Sci., 21:461, 1977; May et al. Horm. Metab. Res., 11:30, 1979). Multiple opiate receptors have been implicated in the release of some pituitary hormones (Pechnick et al. J. Pharmacol. Exp. Ther., 232:163, 170, 1985). However, their role in the release of TSH has not been well characterized.

The effect of various opiates, more specifically kappa opiates, on basal TSH release was studied in the male rat. Plasma TSH was measured (by RIA, using a NIADDK kit) 60 min after acute systemic injections of the drugs. Mu and delta opiates (morphine 16 mg/kg i.p. and DADLE 2 µg i.c.v.) caused significant decreases in plasma TSH, confirming the results of the above workers. These effects were antagonized by naloxone (5 mg/kg i.p. injected twice at 6 min prior to and 30 min after drug) and Win 44441-3 (5 mg/kg i.p. at 10 min prior to drug). Naloxone (2 and 5 mg/kg i.p.) and Win 44441-3 (2 and 5 mg/kg i.p.) by themselves did not have any effect on TSH. The kappa agonists, (-) bremazocine (0.1 and 1 mg/kg), MR 2034 (4 and 16 mg/kg) and U 50488H (8 and 16 mg/kg) caused very significant decreases in TSH (levels were 19 - 25% of controls) that were partially or fully reversed by the antagonists. This response was attenuated in animals made tolerant to U 50488H and challenged with an acute injection of the drug (tolerance was achieved by injecting the drug in ascending order of 10, 15, 23, 34, 55 and 71 mg/kg i.p. every 12 hr). U 50488H had no effect on hypophysectomized animals. Tifluadom, a kappa agonist, also inhibited TSH release significantly.

Thus, 1) Multiple opiate receptors have an inhibitory effect on TSH release, 2) kappa opiates modulate basal TSH release, 3) these studies present evidence for kappa opiate action on yet another pituitary hormone and 4) endogenous kappa opiates may be important mediators of hypothalamic function.

265.4 KAPPA AND MU OPIOID RECEPTOR AGONISTS HAVE DIFFERENT MOTIVATIONAL PROPERTIES AS REVEALED BY PLACE AND TASTE PREFERENCE CONDITIONING R.F. Mucha, M.J. Millan* and A. Herz*. Dept. Neuropharmacol., Max-Planck-Institute for Psychiatry, 8033 Planegg, F.R. Germany, and Addiction Research Foundation, Toronto M5S 2S1, Canada.

Whether the selective activation of individual types of opioid receptors has different motivational effects is not known. Therefore, agonists selective for the kappa and the mu opioid receptor were tested in classically conditioned preference procedures. Such methods give rats a choice between a stimulus paired with drug injections and another paired with vehicle; rats typically prefer stimuli paired with appetitive reinforcers and avoid those paired with aversive stimuli.

Two stimuli, unbiased, place and taste conditioning procedures were used. Naive rats were run on only one method, using three SC injections of drug or vehicle during training and no injections during testing. The kappa agonists produced conditioned aversions: Taste aversions were produced by racemic mixtures of ethylketazocine, tifluadom, and U50-488 and active isomers (+) tifluadom, (-) bremazocine, and Mr 2034. The corresponding inactive isomers either produced no effect or were less potent. Place aversions were produced by U50-488 and (-) bremazocine, but not by (+) bremazocine nor by any of the other kappa receptor agonists tested with the taste procedure. Although naloxone also produces conditioned aversions (place), these were attenuated by arcuate nucleus lesions while the aversions seen with kappa agonists were not. The mu agonists produced conditioned preferences. Place preferences were produced by morphine, fentanyl, and sufentanil. Taste preferences were produced by low doses of these substances; at high doses the taste preferences were absent or replaced by aversions. Inactive isomers, (+) morphine and dextrorphan, did not produce any conditioned preferences, but they did produce conditioned taste aversions.

Therefore, with systemic administration of drug, activation of kappa opioid receptors has aversive properties and activation of mu receptors, appetitive reinforcing effects. This may have implications for understanding the mechanisms of motivation produced by opioid analgesics.

265.5 ELECTROPHYSIOLOGICAL CHANGES IN SUBSTANTIA NIGRA AFTER DYNORPHIN ADMINISTRATION. A. Lavin* and M. Garcia-Munoz. Centro de Investigaciones en Fisiología Celular, U.N.A.M., P. O. Box 70-600, 04510 Mexico, D.F.

High concentrations of Dynorphin (Dyn) have been measured in the reticular part of the substancia nigra (SNR) (Palkovitz, M. et al, Neuropeptides, 4:193,1984). Recently Dyn cells have been observed in the striatum of cat and rat (Chesselet, M.F. and Graybiel, A.M., Life Sci., 33:37,1983; Zamir, N. et al, Nature, 307:643,1984). The origin and course of the Dyn-containing striatonigral fibres seem to be similar to those containing GABA and Substance P. When injected into SNR, Dyn causes a dose-dependent contralateral rotation which is partially inhibited by naloxone (Herrera-Marchitz, M. et al, Eur. J. Pharmacol.,102: 231,1984). The present experiments were designed to explore the electrophysiological changes induced in SNR by local administration of Dyn. The experiments were performed on 34 male Wistar rats (250-260 g), acutely prepared under Halothane anesthesia. The rats were tracheotomized, fixed to the stereotaxic apparatus and maintained at a constant temperature (37°C). For i.v. injection of naloxone the femoral vein was cannulated. Extracellular potentials were recorded with glass microelectrodes (14-18 Mohms). Dyn was administered by pressure ejection (Picospritzer, 5-20 psi/50 msec) from a glass pipette. Dyn (1-9 Sigma, 50 pM, pH 7.0) and naloxone hydrochloride (DuPont 2.0 mg/kg i.p. or 0.2 mg/kg i.v.) were dissolved in 0.9% saline. Tyrosyl-3,5-(N)-3H-Dyn (1-9, Amersham) was administered in the course of some experiments; radioactivity was determined by liquid scintillation counting.

Twenty-one out of 32 cells recorded in SNR (70%) showed a decrease in firing rate after Dyn administration. Radioactively labelled Dyn was administered in 12 experiments in order to verify the administration of the drug. Radioactivity (486±564 cpm above blank) was observed in 10 of the 12 experiments (83%); 8 cells were in SNR. In 6 experiments once the response to Dyn was observed, naloxone was administered. In every ocassion naloxone antagonized the effect of Dyn, and in most cases it increased firing rate and decreased spike amplitude. In 13 experiments where naloxone was not administered, the duration of the response to Dyn was found to be 6.0±4.5 min. Ten cells were also recorded in SNC; 8 did not respond and 2 were excited.

The results of the present investigation indicate that Dyn exerts an inhibitory effect on SNR neurons which appears to be pharmacologically specific since it is reversed by naloxone.

This experiment was partially supported by a gran from CONACyT, PNCCBNA 001888.

265.6 ENKEPHALIN-INDUCED SEIZURES : µ OR δ ?. O.Carter Snead, III, Department of Pediatrics and The Neuroscience Program, University of Alabama at Birmingham, Birmingham, Alabama.

Leucine-enkephalin (LE) and morphine (M) are two opiate compounds which interact with opiate receptors in a specific and saturable manner. Morphine is thought to have a high affinity for µ receptors and to exert its analgesic effect via this opiate receptor subtype while leucine-enkephalin has high affinity for the δ receptor. Both LE and M produce seizures which, although similar in some ways, differ in terms of naloxone dose response and morphology (Snead & Bearden, Neuropharmacology 21: 1137, 1982). This raises the question as to whether δ receptors (Frenk, Brain Res. Rev. 6:197, 1983), µ receptors, or both are involved in the seizures produced by these compounds.

This question has been approached by examining the ontogeny of the EEG and behavioral response to the δ agonist Tyr-D-Ser-Gly-Phe-Leu-Thr (DSLET), as well as D-Ala$^2$-D-Leucine$^5$-enkephalin (DADL). Until recently methodologic difficulties have precluded careful depth recordings and the use of convulsants (e.g. peptides) that do not cross the blood brain barrier in the developing animal. However, using a recently developed technique, rat pups ranging from 1 hour to 84 days of age were implanted with intraventricular cannulae and cortical and hippocampal electrodes (Snead and Stephens, Exper. Neurol. 82:249, 1983). Varying amounts of DSLET or DADL were then administered intracerebroventricularly. (icv). Once a baseline response was obtained, the experiment was repeated in animals pretreated with either naloxone or the specific δ antagonist ICI 154,129. The response of adult animals treated with the latter drug plus leucine-enkephalin was also determined.

DSLET produced spikes and behavioral seizures in adult animals similar to those seen with LE or M. However the ontogeny of DSLET-induced seizures was different from that seen with DADL, LE, M, or the specific µ agent morphiceptin (Snead, Epilepsia 25:662, 1984). DSLET seizures were blocked by both naloxone and ICI 154,129 but LE seizures were blocked only by naloxone.

These data suggest that LE-induced seizures are not δ-specific but may require both µ and δ receptors to manifest themselves.

265.7 PREPUBERTAL DEVELOPMENT OF OPIATE BINDING SITES IN RABBIT BRAIN: CORRELATION WITH LH RELEASE. M. Wilkinson and E.V. YoungLai*. Dept. of Obstetrics and Gynecology, McMaster University, Hamilton, Ontario, Canada, L8N 3Z5.

Hypothalamic opiate peptides may provide an important component of the physiological regulation of puberty. Most studies have been performed in the rat and little is known with respect to the female rabbit. We have recently described the occurrence of a major peak of LH secretion in the immature female rabbit (7th Intl. Congr. Endocr. p. 1555, 1984). This occurs at approximately 35-50 days after birth; puberty normally occurs at about 100 days. In preliminary studies designed to investigate the influence of endogenous opiates on LH release in the rabbit we have quantified the binding of [$^3$H]naloxone (NAL; S.A. 51 Ci/mmole) to opiatergic sites in mediobasal hypothalamus (MBH) and cerebral cortex. Binding assays were performed on brain slices (350μm) as previously described (Brain Res. Bull. 13, 481, 1984). Tissue was obtained from rabbits aged 1, 29, 40, 51 and 100 days. [$^3$H]NAL binding was characterized in cortical slices and was shown to be reversible, stereospecific, saturable, of high affinity and thermolabile. Saturation binding curves were analysed by the method of Zivin & Waud (Life Sci. 30, 1407, 1982). $B_{max}$ values in MBH increased from birth (808±86 cpm/mg tissue; counting efficiency 48%) to a peak at 40 days (3431±358 cpm/mg tissue) after which they declined to 1865±210 (51 days) and 2155±202 cpm/mg at 100 days. In cerebral cortex binding was lower than in MBH (birth: 293±30 cpm/mg) and reached near maximum values by day 29 (838±149 cpm/mg tissue). Receptor numbers did not decline with further maturation. The $K_d$ value, particularly in MBH, showed a similar pattern of change i.e. at birth binding was of high affinity (0.89±0.17 nM) which declined to 3.70±0.50 at day 40 but increased again by day 51 (1.50±0.30 nM).

The major prepubertal peak of LH, which occurs around 35-50 days after birth, appears to correlate with a shift in MBH opiate binding to a lower affinity, higher capacity binding site. Whether this corresponds to a change in the ability of naloxone to release LH remains to be determined.

Financial support was from the Canadian MRC.

265.8 EFFECTS OF β-ENDORPHIN ON ORNITHINE DECARBOXYLASE ACTIVITY: A POSSIBLE ROLE FOR ENDOGENOUS OPIATES IN REGULATION OF TISSUE GROWTH. J.V. Bartolome*, C. Kuhn and S.M. Schanberg*. Dept. of Pharmacology, Duke University Medical Center, Durham, N.C. 27710.

A considerable body of evidence now exists indicating that opiates might participate in growth processes, particularly in the modulation of brain growth. The question remains as to which of the endogenous opiate peptide systems are involved in perinatal regulation of growth processes. The current study examines the effects of β-endorphin on ornithine decarboxylase (ODC) activity in 6 and 25 day-old rats. ODC catalyzes the initial step in the synthesis of polyamines, intracellular messengers which regulate macromolecule synthesis during replication, differentiation and growth (Heby, O., Differentiation, 19: 1, 1981; Pegg, A.E. and McCann, P.P., Am. J. Physiol., 243: C212, 1982). Previous studies have shown that alterations in ODC levels are invariably associated with deficits in tissue maturation and/or function (Slotkin, T.A., Life Sci., 24: 1623, 1979). In the present study, we have shown that intracisternal (i.c.) administration of β-endorphin (1 μg) markedly reduced brain ODC activity in 6 and 25 day-old rats. This ODC response was essentially uniform across brain regions including cerebellum, brainstem + midbrain and cerebral cortex. The inhibitory action of β-endorphin on brain ODC suggest that this endogenous opiate might act as a growth inhibitory factor during perinatal development. Since it has been reported that endogenous opiates might also play an important role in the regulation of growth of peripheral tissues, the effects of β-endorphin on heart, liver and kidney ODC were also investigated. The i.c. administration of β-endorphin resulted in a marked reduction in ODC activity in all three peripheral tissues. In contrast to the inhibitory actions of centrally administered β-endorphin, subcutaneous administration of β-endorphin increased ODC activity in the heart and liver, while no significant changes were observed in kidney ODC. Thus, the reduced tissue ODC levels observed in animals given β-endorphin i.c. appears to be mediated by central effects of β-endorphin. The results from this study demonstrate that β-endorphin can modulate growth-related processes such as ODC and the polyamines, which are necessary for tissue growth and development. (Supported by USPHS Grant No. 2 RO1 MH13688 and RSA Grant No. 2 KO5 MH06489).

265.9 **PROTECTION FROM CEREBRAL ISCHEMIA BY U-50488, A SPECIFIC KAPPA OPIOID ANALGESIC AGENT.** A.H.Tang* and R.C.Silvia* and A.Salvatierra. CNS Research, The Upjohn Company, Kalamazoo, MI 49001.

The kappa opioid receptor agonists have a number of pharmacological properties (e.g. analgesic, sedative, anticonvulsant, diuretic). Because of the implication of opioid receptor mechanism in stroke (e.g. Faden, Stroke 15:575, 1984), we investigated the effects of U-50488, a specific kappa opioid receptor agonist (VonVoigtlander et al., J. Pharmacol. exp. Ther. 224:7, 1983), in several models of experimental cerebral ischemia.

Mongolian gerbils were anesthetized with 2% halothane and the common carotid arteries were occluded bilaterally for 7 or 15 minutes. Seven-minute bilateral carotid occlusion (BCO) produced behavioral hyperactivity 24 hours later (Tang et al., Soc. Neurosci. Abst. 10:126, 1984). There was also selective degeneration of pyramidal neurons in the dorsal hippocampus when examined one week later (Kirino, Brain Res. 239:57,1982). Pretreatment with U-50488E (30 mg/kg i.p.) 30 min prior to BCO protected the gerbils from the post-ischemia behavioral abnormality and prevented neuronal degeneration in the hippocampus. The protective effect on hyperactivity was shared by two other kappa agonists (ethylketocyclazocine and bremazocine), but was partially reversed by the simultaneous administration of naloxone (3 mg/kg). Naloxone (10 mg/kg) given alone had no protective effect. BCO for 15 minutes in gerbils resulted in death for the majority of animals within one week. Pretreatment with U-50488E significantly reduced mortality from 15 minutes of BCO.

BCO in rats of the Fischer 344 strain under brief halothane anesthesia for surgery produced marked cerebral edema in the forebrain within the first few hours. Reperfusion at the end of 4 hours BCO was followed by rapid deterioration and death. Pretreatment with U-50488H (10-30 mg/kg) prior to BCO completely prevented the development of cerebral edema and protected the rats from the lethal effects of BCO in this model. A therapeutic potential for U-50488 in stroke is indicated.

265.10 EFFECTS OF CYCLAZOCINE ON RAT CEREBELLAR PURKINJE NEURONS: COMPARISON WITH PHENCYCLIDINE. M.B. Kim*, K.C.H. Pang*, R. Freedman* and M.R. Palmer. Departments of Pharmacology and Psychiatry, University of Colorado Health Sciences Center 4200 E. 9th Ave., Denver CO 80262 and Denver Veterans Administration Hospital Medical Research Service 1055 Clermont, Denver CO 80220.

Cyclazocine is a benzomorphan which, in addition to more classical opiate properties, binds to the sigma opiate receptor site. Recently, it has been suggested that the sigma opiate receptor is identical to the binding site responsible for the actions of phencyclidine (PCP). Since the electrophysiological actions of PCP have already been demonstrated on rat cerebellar Purkinje neurons, the effects of cyclazocine were also studied in this system with the goal of comparing the electrophysiological effects of cyclazocine to those of PCP. Cyclazocine inhibited the spontaneous firing rates of Purkinje neurons. These responses were stereospecific and qualitatively appeared similar to the effects of PCP. Antipsychotic drugs, haloperidol and fluphenazine, partially antagonized the actions of cyclazocine, suggesting a catecholaminergic involvement similar to the mechanism proposed for PCP. Unlike PCP, on the other hand, the effects of cyclazocine were also partially reversed by the opiate antagonist, naloxone. Taken together, these results suggest that in the rat cerebellum cyclazocine may be interacting with at least two receptor mechanisms: a naloxone-sensitive opiate site, and a naloxone-insensitive site which might involve catecholaminergic mediation similar to the PCP mechanism of action. The naloxone-sensitive effects of cyclazocine, however, may be related to an interaction of the drug with kappa receptors rather than with the more clasical mu or delta opiate mechanisms.

This work was supported in part by USPHS grants AA-05915 and DA-02429. K.P. is a predoctoral fellow (USPHS HD-07072).

265.11 IS INTRATHECAL DYNORPHIN A KAPPA LIGAND IN RATS? C.W. Stevens and T.L. Yaksh*, Departments of Neurosurgical Research and Pharmacology, Mayo Clinic, Rochester, MN 55905.

Opioids produce their effects by an interaction with specific receptors which are classified on the basis of in vivo and in vitro bioassays into subtypes described as mu, delta, and kappa opiate receptors. Previous work in rats chronically implanted with intrathecal catheters has shown that spinally administered delta ligands (e.g. D-Ala$^2$-D-Leu$^5$-enkephalin) inhibit cutaneous, thermally-evoked responses (hot plate, HP; tail flick, TF) and are inactive against visceral, chemical stimuli (writhing test, WT); kappa ligands (e.g. U50488H) are potent on WT but inactive on HP/TF whereas mu ligands (e.g. morphine) are active on all three measures (Schmauss and Yaksh, JPET 228:1-12, 1984).

Numerous in vitro bioassays have established dynorphin A(1-17) and its shorter sequences as potent kappa ligands (see Chavkin et al., Science 215:413, 1982), however in vivo administration has produced controversial results. In an attempt to assess the putative kappa activity of dynorphin A(1-17) and its shorter sequences in vivo, we have examined their effect after intrathecal delivery in rats. We find that dynorphin A(1-17) and (1-13) produced severe motor dysfunction characterized by total loss of hindlimb tonus at doses as low as 10 and 3 nmol/rat, respectively. This motor dysfunction was also produced by dynorphin A(3-13), which is inactive at kappa sites, and was not affected by systemic naloxone (3 mg/kg). Dynorphin A(1-17) and (1-13) at doses below those which produce motor dysfunction had no effect on HP, TF or WT. Dynorphin A(1-7), (1-8), (1-9), and (1-10) had no effect on HP or TF at 30 nmol; and no effect on WT with doses as high as 100 nmol/rat. In contrast, the kappa agonist U50488H (10 nmol) was potent on WT, showed no activity on HP or TF, and produced no motor dysfunction with doses as high as 100 nmol.

| | Minimum Effective Dose (nmol) | | | | | | |
|---|---|---|---|---|---|---|---|
| Dynorphin A Sequence | (1-7) | (1-8) | (1-9) | (1-10) | (1-13) | (1-17) | (3-13) |
| Motor Dysfunction | >100 | >100 | >100 | >100 | 3 | 10 | 30 |

No effect of dynorphin A sequences on HP, TF, or WT at doses just below those producing motor dysfunction.

We conclude that the potent in vitro kappa activity of dynorphin A may not be reflected after in vivo intrathecal administration in rats. Additionally, the motor dysfunction which is seen after intrathecal delivery of the longer chain dynorphins does not appear to be mediated by opiate receptors. (Supported by Grant DA-02110.)

265.12 ELECTROPHYSIOLOGICAL AND BIOCHEMICAL STUDY OF THE ANTAGONISM OF PCP ACTION BY METAPHIT IN RAT CEREBELLAR PURKINJE NEURONS. Y. Wang*, M.R. Palmer, R. Freedman*, M.V. Mattson*, R.A. Lessor*, M.F. Rafferty*, K.C. Rice*, A.E. Jacobson* and B.J. Hoffer, Depts. of Pharmacology and Psychiatry, Univ. of Colo. Health Sci. Cntr., Denver, Colorado 80262; Laboratory of Chemistry, Inst. of Arthritis, Diabetes and Kidney Diseases, NIH, Bethesda, Maryland 20205; and Medical Research Service, Denver Vet. Admin. Med. Cntr., Denver, Colorado 80220.

Recent biochemical reports have shown that metaphit (1-(1-(3-isothiocyanatophenyl) cyclohexyl) piperidine) irreversibly antagonizes about 50% of the PCP receptors in rat hippocampus and striatum. In view of our previous work showing a stereospecific, and therefore presumably receptor mediated, depression of rat cerebellar Purkinje (P) neuron discharge by PCP, we investigated the actions of metaphit in this brain area. Metaphit, applied locally by micro pressure-ejection, irreversibly antagonized PCP-induced slowing of P cells in 19 of 20 neurons tested. This antagonism began 5-20 minutes after metaphit application and lasted up to 90 minutes, the longest time point studied. Metaphit also had a transient direct depressant action. Application of sufficient drug to elicit a marked depressant response was a necessary prerequisite for the subsequent blockade of PCP effects. Little or no antagonism of norepinephrine or GABA-induced inhibitions by metaphit was seen in cells where PCP effects were blocked. Since PCP is an indirect noradrenergic agonist in cerebellum, this finding suggests that the blockade of response is at the noradrenergic nerve terminal, rather than at postsynaptic receptors of P cells. In correlative biochemical studies on cerebellum, metaphit completely inactivated PCP receptors, measured by radioligand binding, in 4 of 6 animals. In the remaining animals, 64% and 32% of the PCP receptors were blocked. We postulate that metaphit is a mixed PCP agonist-antagonist which causes a potent and irreversable pharmacological blockade of PCP actions. This evidence suggests that metaphit could become a useful tool in electrophysiological and biochemical studies of PCP receptor-mediated events.

265.13 DIURNAL CHANGES IN THE OPIATERGIC CONTROL OF LH RELEASE IN PREPUBERTAL RATS ARE ASSOCIATED WITH DIURNAL VARIATIONS IN HYPOTHALAMIC BUT NOT CORTICAL [3H]-NALOXONE BINDING SITES. W. Jacobson* and M. Wilkinson (SPON: K.B. Ruf). Dept. Physiol. Biophys., Dalhousie Univ., Halifax, Canada B3H 4H7.

Endogenous opiates exert a tonic inhibitory influence on LH release in the rat. The degree of this inhibition is known to change as the animal matures. In addition, sex differences exist as to the degree of inhibitory activity exerted by the opiatergic system at any point in development. It has been demonstrated that in the prepubertal female rat, a clear diurnal variation exists in the LH response to opiate receptor blockade with the opiate antagonist naloxone, the response being maximal in the morning and reaching a nadir in the late afternoon. We present here the results of experiments performed to determine whether this diurnal variation in naloxone responsiveness is the reflection of similar changes in the hypothalamic complement of opiate receptors. Binding studies were performed with saturating concentrations (10 nM) of [3H]-naloxone (NAL) on fresh 400μ thick slices of rat mediobasal hypothalamus (HYP) or cortex (CX) obtained at 0700, 1000, 1300 and 1600 hrs (Method: Brain Res. Bull. 13: 481, 1984). Over this time frame, a clear decrease was seen in the amount of NAL bound to HYP slices (7 am, 27±2 vs 4 pm, 18.1±2.2 fm/mg) but not CX slices (7 am, 10.6±1.1 vs 4 pm, 9.5±1.7 fm/mg) in 26 day old females. There was no change in NAL binding to either HYP (25.4±1.9 vs 25.2±1.2 fm/mg) or CX (11.6±1.2 vs 10±1 fm/mg) slices from 26 day old males over the same time frame. A similar pattern was observed in 30 day old females, with HYP binding dropping steadily over the day, (7 am, 18.5±1.4 vs 4 pm, 7.6±0.8 fm/mg) and CX binding remaining unchanged (7 am, 13.1±0.8 vs 4 pm, 13.3±2.4 fm/mg). In males of this age, however, while CX binding did not show any variation over the period studied, a decrease in HYP binding was apparent by 10 am and persisted through the late afternoon. In 15 day old animals, a somewhat less pronounced decrease in HYP NAL binding was seen in the males, while females showed a transient early afternoon decrease of approximately 50% which returned to early am values by 4 pm. In neither sex did CX binding vary. At 9 days of age, the only tissue in which NAL binding varied over the day was male HYP which showed a decrease from a 7 am high of 20.3±2 to a 4 pm low of 7.2±0.9 fm/mg. These observations may provide a neural substrate for the diurnal variations in responsiveness of LH release to opiatergic influence which is seen in prepubertal rats.

265.14 ANTINOCICEPTIVE EFFECTS OF MU AND DELTA OPIOID RECEPTOR LIGANDS IN THE RAT PERIAQUEDUCTAL GRAY MATTER (PAG) AND MEDULLARY RETICULAR FORMATION (MRF) AS STUDIED BY THE MICROINJECTION TECHNIQUE. T.S. Jensen* and T.L. Yaksh* (SPON: B.F. Westmoreland). Gentofte Hospital, Denmark and Mayo Clinic, Rochester, MN U.S.A.

In rats stereotaxically implanted with microinjection (MI) cannula in either the PAG or the medial/paramedial MRF, microinjection (0.5 μl) of morphine (MOR), sufentanil (SUF), D-Ala$^2$-D-Leu$^5$-enkephalin (DADL) or D-Ser$^2$-Thr$^6$-leucine enkephalin (DSTLE) produced dose-dependent elevations in the response latency on tail flick and hot plate tests. Both mu (MOR and SUF) and delta (DADL and DSTLE) opioid receptor ligands produced a maximal elevation in the supraspinally mediated hot plate response when administered into either the PAG or the MRF. Similarly, mu and delta receptor ligands produced maximum elevations in the spinally mediated tail flick response when microinjected into the PAG. In contrast, delta, but not mu, receptor agonists produced a total blockade of the tail flick response following administration into the MRF. MI of mu (MOR) or delta (DADL) agonists into the PAG or the MRF also inhibition of the visceral chemical evoked writhing response. Systematic examination of the effects of intracerebral naloxone administered into the same site as the opioid ligand revealed a dose-dependent (0.3-5.6 nmol) antagonism of the effects produced by both DADL and MOR. At each dose of naloxone, the magnitude of the inhibition was greater with morphine than DADL on both the hot plate and tail flick. These observations suggest that mu and delta opioid receptor linked systems within the MRF but not the PAG produce their antinociceptive effects by discriminable mechanisms with a differential action on spinopetal versus supraspinally organized modulatory systems.

| MI Site | Tail Flick | Hot Plate |
|---|---|---|
| PAG | | |
| MOR | 3.1 ± 0.01$^+$ | 2.9 ± 0.01$^+$ |
| SUF | 0.2 ± 0.02 | 0.2 ± 0.02 |
| DADL | 0.7 ± 0.05 | 0.5 ± 0.02 |
| DSTLE | 1.4 ± 0.06 | 2.7 ± 0.5 |
| MRF | | |
| MOR | -* | 3.5 ± 0.7 |
| SUF | -* | 0.2 ± 0.01 |
| DADL | 0.1 ± 1.8 | 0.1 ± 1.9 |
| DSTLE | 1.4 ± 0.3 | 1.2 ± 0.2 |

*Submaximal elevation of tail flick latency following intracerebral opioid administration. $^+ED_{50}$ nM.

265.15 ROLE OF HIPPOCAMPUS IN RAT SHAKING BEHAVIOR. J.D. Connor and B.P. Damiano. Dept. Pharmacology, Hershey Medical Center, Pennsylvania State Univ., College of Medicine, Hershey, PA 17033.

Head shaking behavior has been reported after electrical stimulation of the hippocampal interstitium. The likelihood of current spread from the sites of stimulation has made it difficult to evaluate the extent to which hippocampal cell types actually participate in the response. Our approaches to this issue include: 1) stimulation in awake, unrestrained rats of a synaptic input (perforant path) into the dentate gyrus while monitoring shake behavior and evoked potentials; 2) prelesions of CA3 pyramidal cells to study the need for hippocampal output in the shake response; 3) various drug treatments that evoke shakes in conjunction with field potentials and lesions.

Entorhinal (perforant path) stimulation (1-10 Hz; single, twin or trains of stimuli) in conscious rats caused 5-15 shakes in 2-3 min (higher frequencies caused more shakes). Epileptiform activity in the dentate gyrus was not required for shakes to occur. Stimulation of granule cells directly via the recording electrode elicited responses similar to those produced by entorhinal stimuli. Granule cell discharge as evidenced by a population spike was necessary for shaking responses to occur. Rats with relatively pronounced lesions of CA3 pyramidal cells (kainic acid, 350 ng, bilaterally icv) did not develop shakes with any of the stimulation paradigms. Thus, it appears that entorhinal stimuli cause shakes by activating granule cells which, in turn, initiate hippocampal output.

Met- or leu-enkephalin (200 µg icv) caused shaking behavior (~ 10 shakes/10 min), and epileptiform activity (repetitive spontaneous population spikes and afterdischarges). The enkephalins also decreased granule cell recurrent inhibition, as measured by the twin-pulse technique. Enkephalin disinhibition preceded the epileptiform discharges and shaking behavior, and was prevented by naloxone (10 mg/kg i.p.). Naloxone also blocked shake production. Prior kainic acid treatment blocked enkephalin shakes, but not the depression of recurrent inhibition.

Classical "wet dog shakes" evoked by naloxone in morphine-dependent rats were not associated with changes in granule cell evoked potentials, nor were they affected by kainate pretreatments. Results similar to those produced with morphine abstinence were also obtained with TRH (1 µg icv), a potent shake inducer.

The overall conclusions: 1) synaptic activation of excitatory pathways into and out of the hippocampus causes shaking behavior; 2) some shake inducers (icv enkephalins) act through hippocampal mechanisms; 3) shakes caused by icv TRH or morphine withdrawal apparently require CNS areas other than the hippocampus for their generation or modulation.

265.16 ANGIOTENSIN-CONVERTING ENZYME INHIBITORS POTENTIATE THE ANALGESIC ACTIVITY OF [MET]-ENKEPHALIN-ARG$^6$-PHE$^7$ BY INHIBITING ITS DEGRADATION IN MOUSE BRAIN. B.S. Barbaz, W. Autry* and J.A. Norman, Neuroscience/Cardiopulmonary Research, Research Department, Pharmaceuticals Division, CIBA-GEIGY Corporation, Summit, NJ 07901

The degradation of the enkephalin-containing heptapeptide Tyr-Gly-Gly-Phe-Met-Arg-Phe (YGGFMRF) was investigated by incubating the peptide with synaptic membranes from mouse brain. The degradation products were derivatized with 4-dimethylaminoazobenzene-4'-isothiocyanate (DABITC) and analyzed by HPLC and by amino-terminal analysis. The incubation of YGGFMRF with synaptic membranes yielded YGGFM and RF as the degradation products. This dipeptidyl-carboxypeptidase activity could be potently inhibited by MK-422 and captopril, inhibitors of the angiotensin-converting enzyme, with $IC_{50}$ values of 8 nM and 95 nM, respectively. The "enkephalinase A" inhibitor, thiorphan, weakly inhibited this dipeptidyl-carboxy-peptidase activity with an $IC_{50}$ value greater than 1 µM.

YGGFMRF, MK-422, captopril and thiorphan all produced a dose-dependent elevation of mouse jump latencies in the hot plate test when administered intracerebroventricularly. However, when sub-analgesic doses of the inhibitor were concomitantly administered intracerebroventricularly with a sub-analgesic dose of the hepta-peptide YGGFMRF, only the angiotensin-converting enzyme inhibitors, MK-422 and captopril, potentiated in the analgesic response of this peptide. These results provide in vitro and in vivo evidence that in the mouse brain, the angiotensin-converting enzyme is the primary enzyme involved in the proteolytic degradation of the hepta-peptide YGGFMRF.

265.17 ENHANCEMENT OF TRYPTAMINE TURNOVER IN MOUSE BRAIN BY MORPHINE ADMINISTRATION. Alice A. Larson. Dept. Veterinary Biology, University of Minnesota, St. Paul, MN 55108.

While tryptamine (TA), a trace indoleamine, is present in the brain, its function in this tissue remains unclear. TA has a rapid turnover rate and is sensitive to changes in the activity of monoamine oxidase. While the spinal C-fiber reflex is inhibited by 5-hydroxytryptophan, a serotonin precursor, it is enhanced by administration of TA (Bell and Martin, JPET 196,373,1976). We have previously reported an enhanced rate of response to the noxious thermal stimulus of the tail-flick assay after intrathecal injection of TA in rats (Larson, Brain Res, 265:109, 1983). More recently, Harrison and Christian (Neurobiology of the Trace Amines, 249, 1983) have found that isolation-induced stress elevates the concentration of TA in brain and adrenal tissue of rats. As TA is thus implicated in pain- and stress-related activities, the purpose of the present investigation is to examine the effect of opiate analgesics on the concentration and turnover of TA in the brain. Endogenous TA was extracted from mouse whole brain homogenates using ethyl acetate, purified using Bio-Rex 70 cation exchange columns and analyzed on an isocratic HPLC system consisting of a C18 reverse phase column and fluorescence detection. The injection of 100 mg/kg of morphine sulfate i.p. 3 hr before sacrifice, or implantation of a 75 mg morphine pellet 72 hr prior to sacrifice did not significantly alter the concentration of endogenous TA. However the turnover of TA in whole brain, as measured by TA accumulation 60 min after administration of pargyline HCl, increases after coadministration of 100 mg/kg of morphine with pargyline compared to pargyline-treated controls. Implantation of one 75 mg morphine pellet at either 48 or 72 hr prior to pargyline also resulted in an enhanced rate of TA accumulation compared to placebo-implanted control mice. Morphine has been found to enhance the activity of a variety of putative neurotransmitters thought to be involved in analgesia, e.g. serotonin and norepinephrine. The present data indicate that both acute and chronic morphine treatment also appear to enhance the metabolism of TA, a trace amine which has been shown to facilitate pain-reflex activity. The enhancement of tryptaminergic activity after morphine treatment may thus be a factor in the development of tolerance to opiate analgesia. This work was supported by NIH Grant NS17407.

265.18 BRAIN SITES OF STEROID-OPIATE INTERACTION IN THE CONTROL OF LUTEINIZING-HORMONE SECRETION IN THE MINIATURE PIG. N. Parvizi*. (SPON:W. Reinhardt). Institut für Tierzucht und Tierverhalten (FAL), Mariensee, 3057 Neustadt 1, F.R.G.

The present study was conduced to study the central sites of action of leu-enkephalin (leu-E) and met-enkephalin (Met-E) on LH-secretion and to determine the steroid-enkephalin interaction.

Twenty adult ovariectomized miniature pigs were bilaterally provided with stainless steel tubings (22 G) bearing a 28 G exchangeable innertubing in amygdala (AMY) and mediobasal hypothalamus (MBH). One week after this surgery and 5 days prior to the beginning of the experiment (EXP) a silastic catheter was inserted into the left jugular vein. All surgeries were performed under stresnil-hypnodil (Jansen, Düsseldorf, FRG) anesthesia. In 3-day intervals, the animals received following treatments: EXP. I:(7 animals)30 ng leu-E or 1 µl saline (0.7 %; solvent) were microinjected (mic) into the AMY, MBH or AMY & MBH. Blood samples (2 ml) were withdrawn from 90 min before to 180 min after the mic in 10 min intervals. Plasma samples were stored at -20° C until LH was measured. One day was asigned as control blood sampling without any mic. EXP. II:(7 animals) was similar to EXP. I except that Met-E was microinjected. EXP. III: the animals (n =6) were microinjected with 3 ng estradiol-17ß (E2) or 30 ng testosterone (T) into the MBH. 180 min thereafter they received a mic of 30 ng Met-E in the same site of MBH. Blood was taken as in EXP.I. In all three experiments each animal received each treatment.

Leu-E decreased plasma LH-levels significantly ($p < 0.01$; ANOVA) when it was given into the AMY & MBH. Microinjection of Met-E into the AMY, MBH or MBH & AMY has no significant effects on LH-secretion. However, there was a pronunced interaction between Met-E and steroids. Microinjection of Met-E 180 min after microinjection of E2 or T results in plasma LH-values which are 30 % and 26 % the levels after the microinjection of E2 and T respectively.

The data indicate that (a) leu-enkephalin may modify the LH-secretion independent of gonadal steroids. Its effect can be brought about by mechanisms involving AMY and MBH. (b) Met-enkephalin amplifies the MBH mediated feedback control of gonadal steroids on LH-secretion.

The work was supported by the German Research Foundation (DFG).

265.19 SUCROSE INHIBITS DISTRESS VOCALIZATIONS AND ELEVATES PAIN THRESHHOLDS IN 10-DAY-OLD RATS: MEDIATION BY ENDOGENOUS OPIOIDS. E.M. Blass, E. Fitzgerald*, and P. Kehoe. Dept. of Psychology, Johns Hopkins University, Baltimore, MD 21218.

The discoveries that: 1) neonatal altricial rats can taste and respond to a variety of substances and, 2) endogenous opioid systems appear to be behaviorally functional in 10-day-old rats led us to evaluate interactions between pleasure, psychological and physiological stress. In one experiment, either 3.5% or 11.5% sucrose or distilled water was infused through jaw cannulae into the mouths of Day 10 pups that were separated from their mothers but group-housed as a litter. Infusions were preceeded by intraperitoneal injections of isotonic saline or naltrexone (0.5 mg/kg b.w.). Paw-lift latencies (PLL) from a 48° C hot-plate were determined either 1 or 3 min after termination of sucrose infusions.

In a second experiment, individually housed rats received through the indwelling jaw cannula infusions of 7.5% or 11.5% sucrose or milk. The number of distress vocalizations (DVs) caused by the isolation was recorded on a minute-by-minute basis for experimental and control isolated pups. Additional groups of rats were so treated following naltrexone injections.

Sucrose infusions markedly elevated PLL of group-housed rats. Latencies increased from 9.2 sec in water-infused animals to 16.1 and 21 sec for rats receiving 3.5% and 11.5% sucrose infusions, respectively. Naltrexone injections reversed the effect as PLL were reduced to control levels. Thus, sucrose infusions very quickly elevated pain threshhold, as inferred by PLL, in non-stressed, group-housed 10-day-old rats.

Infusions of sucrose or milk attenuated the frequency of DVs in isolated rats from a mean of 266 DVs in 5 min to 50, 147 and 112 DVs for 7.5% and 11.5% sucrose and milk, respectively. Naltrexone injections reversed this trend elevating the number of DVs to 223, 280 and 324 DVs per 5 min period for 7.5% sucrose, 11.5% sucrose and milk, respectively. Taken together, these results demonstrate interactions between putative pleasure and pain systems in 10-day-old albino rats. Moreover reversability by naltrexone suggests an opioid-like mediation of these phenomena.

These studies were supported by Research Grant AM18560 and Research Scientist Award MH00524 to E.M.B. and an NIH Predoctoral Fellowship to P.K., MH09211.

265.20 OPIOID MEDIATION OF SEPARATION DISTRESS IN 10-DAY-OLD RATS. P.Kehoe and E.M.Blass, Dept. of Psychology, Johns Hopkins Univ. Baltimore, Md. 21218

The present study demonstrates the relationship between distress vocalizations (DVs), analgesia and opioid activity in 10-day-old rats separated from their dam for as few as 5 min. The experimental paradigm consisted of individually isolating 10-day-old pups for 5 min, during which time ultrasonic cries were recorded. The physiological response to the isolation stress was assessed by a hot-plate technique developed to establish a reliable method of measuring neonatal rats' responsiveness to nociception. The number of DVs 5 min and paw lift latencies (PLL) provided the dependent measures. Five groups of pups were studied in the first experiment. Pups tested on the hot-plate immediately after removal from the nest had a mean withdrawal latency of 9s. Rats isolated for 5 min had a latency of 15s and emitted 300 DVs, similar to saline pretreated pups (15s and 320 DVs). Pups that received naltrexone injections prior to isolation emitted 630 DVs during the isolation and exhibited remarkably short PLLs (6s). In contrast, pups pretreated with morphine had a 22s PLL and were relatively quiet (22DVs). Thus, naltrexone increased pain sensitivity and ultrasounds while morphine resulted in the opposite effects.

To determine whether the opioid mediation of these 2 behaviors is central in origin, we replicated the above experiment with solutions administered intracerebroventricularly (ICV) 90 min prior to isolation. Involvement of the endorphinergic system in isolation-stress behaviors was also assessed by pretreating a group with beta-endorphin antibodies (ICV). In general, central injections mimic findings obtained with peripheral treatments. Those isolated for 5 min after no injection or an ICV injection of saline had a mean PLL of 17.9 and 18.2s and emitted 280 and 320 DVs respectively. Morphine given intracranially caused pups to exhibit a withdrawal latency of 30s with 54 DVs. In contrast, naltrexone-injected pups had a PLL of 10.5 and emitted more DVs than any other group (480). Pups administered beta-endorphin antibodies also withdrew from the heat faster than the saline or no-injection control pups (12.3s) but interestingly did not differ statistically from these groups in their DVs (337).

These studies implicate central opioid systems in the modulation of neonatal isolation-induced stress and its expression in ultrasonic calls and reduced pain sensitivity. The beta-endorphin peptide may, in fact, be partially responsible for isolation-induced responses since antibody treatment significantly reduced heat withdrawal latencies relative to untreated isolates but did not significantly change the number of emitted cries.

## SPROUTING AND SPROUTING MECHANISMS

266.1 EFFECTS OF GM1 GANGLIOSIDES ON CHOLINERGIC ENZYMES AND Na-K-ATPase IN THE HIPPOCAMPUS AFTER FIMBRIA-FORNIX TRANSECTION IN RATS. B. Fass, J.J. Ramirez*, S.P. Mahadik & S.E. Karpiak. Psych. Dept., Clark Univ.,Worcester,MA; Neurosurg. Dept., Univ. Virginia Med.Sch; Div. Neurosci., NYSPI, Columbia Univ. Med. Ctr., New York,NY.

To assess whether exogenous gangliosides accelerate the onset of lesion-induced sprouting in the hippocampus (HPC), we evaluated the effects of GM1 treatments on HPC cholinergic enzymes (AChE and ChAT) and Na-K-ATPase (a neuronal plasma membrane marker) after unilateral transection of the fimbria-fornix (FF). Previous research showed that histochemical staining for AChE is intensified and biochemical measures of AChE and ChAT are increased beginning some time between 14-30 days after transection (Gage et al., 1983). These enzyme changes evidently reflect sprouting by a ventral cholinergic afferent to the HPC (Gage et al., 1984).

In the present study, male albino rats (250-400g) were injected with GM1 (10mg/kg,IP) on the day before surgery, the day of surgery and every third day thereafter. The rats were killed at 14 or 18 days after transection, in order to evaluate whether the treatments promoted the onset of cholinergic sprouting in the HPC. AChE staining was virtually eliminated in the ipsilateral HPC, and optical density measures of residual staining were identical for GM1-treated and untreated rats. Biochemical measures of AChE and ChAT were obtained from additional rats killed at 19 days after transection. Enzyme activity was significantly reduced ($p<.001$) in the ipsilateral HPC relative to the contralateral side. Such reductions were greater in GM1-treated rats than in untreated controls ($p<.001$). By contrast, Na-K-ATPase activity in the ipsilateral HPC was increased (+19.2%) in GM1-treated rats and decreased (-18.9%) in untreated controls, relative to the opposite side.

Since AChE and ChAT were not enhanced at 14-19 days after transection in GM1-treated rats, it appears that the treatments did not accelerate cholinergic sprouting in the HPC. This result is consistent with our previous finding that cholinergic sprouting in the dentate gyrus after unilateral entorhinal lesions is not enhanced by ganglioside treatments (Fass & Ramirez, 1984). The observed reductions in AChE and ChAT may signify more rapid removal of degenerating axons, which could be advantageous for terminal growth at later time points. The increased levels of Na-K-ATPase might indicate that GM1 enhances sprouting by noncholinergic fibers in the HPC, and/or "stabilizes" membranes in the HPC (Karpiak, 1983; Karpiak & Mahadik, 1984). It remains to be determined whether these changes reflect a direct effect on enzyme levels/activities per se, or whether GM1 treatments affect the total number of enzyme-containing synapses in the denervated HPC.

266.2 TIME COURSE OF CHANGES IN HISTOCHEMICAL STAINING FOR GLUCOSE-6-PHOSPHATE DEHYDROGENASE (G-6-PDH) IN THE LATERAL SEPTUM AFTER FIMBRIA-FORNIX TRANSECTIONS. D. Stein and B. Fass. Psychol. Dept., Clark Univ., Worcester, MA 01610

Hippocampal efferents project to the lateral septal nucleus (LS) via the fimbria and dorsal fornix (1). Unilateral transections of this pathway denervate the LS and induce sprouting by surviving inputs (2). Sprouting in the LS has been shown to begin at about 6 days posttransection (DPT), proceed maximally until about 25 DPT, and continue until about 120 DPT (3).

In order to assess whether denervation and subsequent reinnervation might affect cellular metabolism, we evaluated the effects of unilateral fimbria-fornix transections on G-6-PDH activity in the LS. Denervation has been found to exert detrimental effects on neuronal metabolism, including reductions in succinate dehydrogenase activity, uptake of 2-deoxyglucose, and incorporation of protein precursor (4,5,6). We were interested in studying G-6-PDH in a model system where lesion-induced sprouting occurs, because previous research showed that the activity of this oxidative enzyme increases during axonal regeneration (7).

Adult male albino rats (300-400g) survived for 2,4,6,8,10,14,18, or 30 DPT and their brains were processed for G-6-PDH histochemistry (after 8). The intensity of staining in the denervated LS was measured with a densitometer and compared with the intensity in the contralateral (control) LS. At 2 DPT, staining was reduced to 61% (±5.2 SEM) of the control value, and at 4 DPT it was 67% (±2.4). The intensity returned to control values by 14 DPT. Thus, metabolic activity in the LS (as reflected by G-6-PDH staining) is dramatically reduced after denervation, and a recovery of activity occurs at the time when reinnervation proceeds maximally (3). The recovery of staining may be due to G-6-PDH within sprouting axons, or it may reflect changes within the denervated/reinnervated neuropil of the LS.

This research was supported by FIDIA contract CS-185-84 (D. Stein). We thank R. O'Connell for use of the densitometer (supported by NINCDS grant NS14453).

266.3 EMBRYONIC HIPPOCAMPAL TRANSPLANTS INDUCE COLLATERAL AXONAL SPROUTING FROM UNINJURED CHOLINERGIC SEPTAL AXONS Lawrence F. Kromer Dept. of Anatomy & Neurobiology, University of Vermont, Burlington, VT 05405

Prior studies demonstrate that embryonic hippocampal transplants are innervated by regenerating cholinergic septal axons when they are permitted to fuse with the lesioned surface of the septum in an adult recipient (Kromer et al., 1980, Brain Res. 210:153-172). However, it is uncertain whether uninjured cholinergic axons located in the fornix-fimbria are capable of sprouting collateral axons which can innervate a hippocampal transplant if their normal projection to the host hippocampus is intact.

In the present experiments, adult rats received aspiration lesions of the cingulate and parietal cortices overlying the fornix-fimbria at its site of attachment to the posterior septum. A piece of embryonic hippocampus (embryonic day 14-15) was placed on the dorsal surface of the uninjured fornix-fimbria. After a survival period of up to three months the specimens were processed for Acetylcholinesterase (AChE) histochemistry and fast blue retrograde fluorescence tracing in order to determine whether the hippocampal transplants received a cholinergic input. In these experiments the hippocampal transplants formed extensive attachments to the dorsal surface of the host fornix-fimbria and received a dense AChE-positive fiber ingrowth that was directly traced to AChE fibers originating in the fornix-fimbria. In these specimens the normal cholinergic septal-hippocampal projection within the fornix-fimbria appeared to be intact since the host hippocampus possessed a normal pattern and density of AChE fibers. Injections of fast blue into the transplants resulted in the retrograde labeling of neurons in both the medial septum and diagonal band regions.

The present results provide preliminary evidence that embryonic hippocampal transplants are capable of stimulating collateral axonal sprouting from uninjured cholinergic axons in the fornix-fimbria of an adult recipient. Experiments are currently in progress to determine the percentage and distribution of septal neurons that innervate both the transplant and the host hippocampus. This will be accomplished by identifying double labeled septal neurons following the injection of different retrograde fluorescent tracers into the host hippocampus and transplant. (Supported by NIH grant #NS18126)

266.4 SPROUTING OF SEROTONERGIC AXONS IN THE AREA DENTATA AFTER LESIONS OF THE MEDIAN RAPHE NUCLEUS. J.H. Haring. Dept. of Anatomy, St. Louis Univ. Sch. of Med., St. Louis, MO 63104.

The serotonergic (5-HT) innervation of the area dentata (AD) arises from neurons of both the dorsal (DRN) and median (MRN) raphe nuclei, however, the MRN is the primary source of 5-HT fibers, particularly to the dorsal AD. The present immmunocytochemical study has examined the sprouting response of 5-HT axons remaining in the dorsal AD after electrolytic or 5,7-dihydroxytryptamine lesions of the MRN.

In the dorsal AD of unlesioned rats, the distribution of 5-HT immunopositive terminals is most dense beneath the stratum granulosum. Also, a sparse plexus of 5-HT fibers and varicosities is seen in the hilar region and in the stratum moleculare. Two weeks after lesions of the MRN, a severe reduction in the 5-HT innervation is observed in all subsectors of the dorsal AD. Six weeks after MRN lesion, reinnervation appears to be taking place although the density of 5-HT fibers remains less than normal. The hallmark of this 5-HT axon proliferation is the presence of large fibers which originate in the dense 5-HT band of stratum lacunosum moleculare and cross the hippocampal fissure to collateralize and reinnervate stratum moleculare, the region subjacent to stratum granulosum and the hilar region. These studies also suggest that a denervation threshold may exist for the induction of 5-HT axon sprouting. Lesions which result in near total destruction of the MRN induce the appearance of large reactive 5-HT axons. These reactive fibers are less common when fewer MRN neurons are destroyed. Instead, the proliferating axons appear as tangles of 5-HT fibers which expand to fill vacancies adjacent to their normal terminal domaine. These 5-HT tangles have also been observed in the supragranular region of the AD which normally receives little or no 5-HT input. Current qualitative estimates indicate that at least 30-50% cell death must occur in the MRN before the induction of 5-HT axon proliferation will occur.

Long-term anatomical studies of the proliferation of 5-HT fibers after MRN lesion, as well as correlative functional studies using behavioral and electrophysiological methods are being conducted.

266.5 THE RELATIONSHIP BETWEEN DOPAMINE DEPLETION AND SEROTONIN HYPERINNERVATION IN THE RAT CAUDATE FOLLOWING NEONATAL 6-OHDA TREATMENT.
Towle*, A.C., Mueller, R.A., Lauder, J.M., Breese, G.R. Departments of Anatony, Anesthesiology, Pharmacology and Biological Science Research Center, University of North Carolina, Chapel Hill, N.C., 27514. (SPON:H.Krebs)

Recently, 6-OHDA treatment of neonatal rats has been shown to lead to an increase in the serotonin content of the caudate nucleus. Similar treatment of adult rats does not result in any change of serotonin content. To gain some insight into the mechanism for this hyperinnervation, we sought to investigate the effects of partial depletions of dopaminergic (DA) neurons and fibers on the serotonin innervation of the caudate.

Rat pups were treated on day 5 with either 100, 50, or 25µg 6-OHDA (i.c.v.) and sacrificed 2 months later. Biochemical measurement of the caudate showed that the drug reduced DA levels by 98.3, 80.1, and 72.5% respectively. Serotonin content was increased in the caudate by 45% at the 100µg 6-OHDA and was not significantly changed by the lower doses. Quantitative immunocytochemical analysis was performed to determine if the biochemical changes were reflected by an alteration of nerve terminal density. Rats were perfused with 4% paraformaldehyde, and 10 micron paraffin sections were cut through the caudate and stained for tyrosine hydroxylase (TH) or serotonin immunoreactivity. The number of terminals intersecting the sides of a 0.25mm$^2$ box were counted at 40x. After neonatal 6-OHDA treatment, the density of TH nerve terminals decreased from 237 intersections/mm (saline) to 5.7* (100µg), 55.2* (50µg), and 73.2* (25µg). The serotonergic terminal density was: 18.3 (saline), 45.3* (100µg 6-OHDA), 26.4 (50µg), 24.6 (25µg) (*$p < .05$). The anatomical evidence confirms the biochemical data and suggests that the increased serotonin is due to an increase of terminal density. The observation that incomplete denervation of TH containing neurons does not lead to a partial hyperinnervation indicates that simple competition between DA and serotonergic nerve terminals can not explain the 6-OHDA induced hyperinnervation. Rather the caudate must be virtually depleted of DA before the serotonergic hyperinnervation can occur.

266.6 RECOVERY OF NOREPINEPHRINE (NE) TERMINALS IN SPINAL CORD FOLLOWING NEONATAL 6-HYDROXYDOPAMINE (6-OHDA). K.E. Simmons* and D.J. Jones. (SPON: M.S. Albin). Depts. of Pharmacology and Anesthesiology, The University of Texas Health Science Center, San Antonio, TX 78284

Previous studies in adult rats have demonstrated that destruction of spinal cord norepinephrine (NE) terminals with 6-hydroxydopamine (6-OHDA) produces hindlimb flexor reflex (HFR) hyperresponsiveness. This hyperreflexia also occurs, in time, following transection of the spinal cord and has been attributed to supersensitivity of receptors within the circuitry of the motor reflex arc. In contrast to these results in adult animals, 6-OHDA-induced destruction of spinal NE terminals in neonatal animals does not produce HFR hyperresponsiveness when measured on postnatal day (PND) 15, which is prior to maturation of spinal pre- and postsynaptic NE elements. On PND 45, after neonatal 6-OHDA, HFR hyperresponsiveness was present suggesting that the expression of denervation-induced hyperreflexia requires the maturation of spinal NE postsynaptic receptors.

The present work extended the above studies to evaluate the response of presynaptic neuron activity by measuring the high affinity uptake of $^3$H-NE in upper and lower spinal cord segments from control rats and those treated at birth with 6-OHDA (PND 1 and 2; 100 mg/kg, SubQ). In addition, spinal cords were transected in groups of control or 6-OHDA treated rats on PND 15 (TX-15) or PND 45 (TX-45). These TX animals were maintained until PND 60 at which time they were sacrificed and upper (above TX) and lower (below TX) $^3$H-NE uptake measured. As expected, $^3$H-NE uptake was reduced over 75% in lower cord in adult rats with spinal cords transected on PND 45 (TX-45). However, no difference was noted in upper and lower cord of TX-15 rats suggesting recovery of terminals in the lower cord by the PND 60 sacrifice date. A 75-80% decrease in $^3$H-NE uptake was present in upper and lower cord segments in control, 6-OHDA treated rats sacrificed on PND 60 without TX. Transection of the cord on PND 45 did not alter the depletion produced by the neonatal 6-OHDA since a 60-70% decrease in $^3$H-NE uptake in upper and lower segments was present. In the TX-15, 6-OHDA group, upper cord $^3$H-NE uptake was not different from the TX-45, 6-OHDA group. However, lower cord uptake was similar to the TX-15 control group in which uptake was identical to non-treated controls. These results suggest that following neonatal 6-OHDA, transection of the spinal cord prior to maturation of spinal NE systems induces "sprouting" of the remaining NE fibers to reestablish NE terminal function.

266.7 SYMPATHETIC INNERVATION OF THE RAT PINEAL GLAND: OVERLAP OF INNERVATION BY THE TWO INTERNAL CAROTID NERVES (ICN) AND SPROUTING FOLLOWING UNILATERAL DENERVATION. J. R. Lingappa and R. E. Zigmond, Dept. of Pharmacology, Harvard Medical School, Boston, MA 02115.

The rat pineal gland receives sympathetic innervation, via the right and left ICN, from neurons whose cell bodies are located in the two superior cervical ganglia. Using quantitative fluorescence microscopy, we have examined the density and distribution of fluorescent profiles in the pineal gland after lesions of the ICN. 10 μm sections of pineal glands were stained using a glyoxylic acid method. Photographs of a portion of every 10th section were analyzed using a grid overlay to determine the density of fluorescent processes. 32 h after sectioning both ICN, by which time the lesioned fibers have degenerated, the density of fluorescent profiles was 3% of that seen in sham-operated controls. 32 h after sectioning one ICN (uniICNx), the density was decreased to 56% of the sham value. Analysis of montages of whole sections indicated that the the magnitude of the decrease following uniICNx was similar in the right and left halves of the sections. Thus the results suggest that each ICN innervates both sides of the pineal gland equally. Zigmond et al. have proposed that the decrease in the nocturnal activity of the enzyme N-acetyltransferase (NAT) that is found on the first night after uniICNx, but not on the second night, is caused by varicosities of the lesioned neurons taking up norepinephrine released by the intact neurons (PNAS 78: 3959, 1981; J. Neurosci. 5: 142, 1985). (NAT is involved in the synthesis of the pineal hormone melatonin.) In order for such "heteroneuronal uptake" to occur (i.e., for terminals of one ICN to take up transmitter released by terminals of the other ICN), the terminal fields of the two ICN must overlap. The anatomical findings presented here suggest the existence of such an overlap.

Sections of pineal glands were also analyzed at longer times after uniICNx. Two weeks after the lesion, the density of fluorescent profiles had increased to 92% of the control value. When the contralateral ICN was cut 2 weeks after the original uniICNx and pineals were removed 32 h later, the density decreased to 2% of the sham value, indicating that all of the increase in fluorescent profiles following uniICNx originates from sprouting of the contralateral ICN and not from regeneration of the lesioned ICN or sprouting and ingrowth of other adrenergic neurons. Interestingly, although nocturnal pineal NAT activity is inhibited 9 h after uniICNx, it is restored to normal by 32h (see references above), that is, before significant sprouting has occurred. It remains to be determined whether the sprouting is important for the restoration of other aspects of normal pineal function. This work was supported by USPHS grants NS 17512 and MH 00162.

266.8 ALTERATIONS IN THE SEROTONERGIC PROJECTIONS TO STRIATUM AFTER DOPAMINE-DEPLETING BRAIN LESIONS IN INFANT OR ADULT RATS. A.M. Snyder, M.J. Zigmond, and R.D. Lund. Dept. of Anatomy and Cell Biology and Center for Neuroscience, University of Pittsburgh, Pittsburgh, PA 15261.

It has previously been shown that 6-hydroxydopamine (6-HDA) administered to neonatal rat pups so as to produce a near-total destruction of central dopaminergic (DA) neurons results in an increase in the serotonin (5-HT) content of striatum (Stachowiak, et al., Brain Res., 291: 164-167, 1984). Recently, it has been shown that these biochemical changes are accompanied by an increase in the density of 5-HT-immunoreactive fibers in striatum (Mailman, et al., Soc. Neurosci. Abs., 9: 932, 1983), as well as an increase in the number of raphe neurons labelled after HRP injection into striatum (Kaul, et al., Soc. Neurosci. Abs., 10: 1021, 1984). We have now combined immunocytochemistry and retrograde labelling to study this sprouting response in infant- and adult-lesioned rats.

Intraventricular 6-HDA injections in 3 day old rats resulted in the near-total absence of tyrosine hydroxylase-immunoreactive processes in striatum 2-5 months later. A marked increase in the density of 5-HT-immunoreactive fibers was seen in rostral striatum, in confirmation of previous biochemical findings (Stachowiak, et al., 1984). Using retrograde tracing with horseradish peroxidase (HRP) or rhodamine-labelled microspheres, we observed a 40-220% increase in the number of cells in the raphe that projected to the rostral striatum. Subsequent immunocytochemical processing indicated that at least 80-90% of the HRP-labelled cells in the raphe were 5-HT-positive.

Animals given 6-HDA as adults showed no increase in 5-HT-immunoreactive terminals in striatum. In addition, no increase in the number of labelled raphe cells was observed in these animals when HRP was injected into rostral striatum 12-30 days post-lesion, although when HRP injections were made in adult animals 6-12 days post-lesion, an increase in the number of labelled cells was seen. This latter effect may have been due to abortive sprouting, an acute lesion-induced hyperactivity of 5-HT neurons resulting in their taking up more HRP, or a nonspecific effect of 6-HDA treatment.

Our results indicate that deprivation of DA input to the striatum of infant rats leads to a marked and persistent increase in serotonergic raphe projections to rostral striatum, whereas the same manipulation in adult rats only causes a transient appearance of enhanced raphe-striatal labelling. 266.9 SPROUTING OF AN INTACT, UNDAMAGED NEURON: PUTATIVE ROLE FOR CHANGES IN BLOOD OSMOLARITY. D.J. Maetzold and A.G.M. Bulloch. Dept. Med. Physiol., Univ. of Calgary, Alberta, T2N 4N1, Canada.

The freshwater pulmonate Helisoma has been used in a number of studies aimed at elucidating the regulation of sprouting and the formation of electrical synapses. It has been shown that some forms of stress evoke sprouting from a pair of intact buccal ganglia neurons, R5 and L5. Of the stress conditions examined, those involving loss of body fluids, i.e., body wall incision and estivation, were found to evoke sprouting. Furthermore, the observed sprouting followed a particular pattern. A sprouted cell was found to extend a process across the buccal commissure and towards the arborization of the contralateral neuron 5. The current study was undertaken to examine the possible effect of osmoregulatory responses upon neuronal morphology.

Snails were placed in 250ml beakers containing hyperosmotic pond water (20% artificial seawater). Snails were examined at Day 0, 12 Hr., Day 1, 2, 3. Buccal ganglia were dissected, cells R5 and L5 were injected with Lucifer Yellow CH and fixed within 2 hours and prepared for whole mount fluorescence microscopy.

Examination of the neurons R5 and L5 showed that sprouting was maximal (27%) at Day 1. This is in contrast to the earlier study which found a maximal sprouting frequency at Day 3 in response to body incision. The time course of sprouting frequency in stressed animals was as follows: 12hrs.-13%; Day 1-27%; Day 2-12%; and Day 3-11%. The sprout in response to hyperosmotic pond water was similar to that observed in response to injury or estivation. That is, the sprouted cell extended a process across the buccal commissure towards the arborization of the contralateral neuron 5.

In conclusion, the present study supports the hypothesis that sprouting can occur in response to changes in blood osmolarity. This study, however, does not distinquish between the possibilities that the observed sprouting is a direct response to changes in osmolarity or is due to actions of the accompanying change in hormonal balance.

266.10 PHEOCHROMOCYTOMA PC12 CELL LINE - A LIGHT, SCANNING AND TRANSMISSION ELECTRON MICROSCOPIC STUDY. M.A.England*, M.Gupta and M.F.D.Notter (SPON: E.D.Caine). Depts. of Anatomy, University of Leicester Medical School*, Leicester, U.K. and University of Rochester School of Medicine, Rochester, NY 14642, U.S.A.

Pheochromocytomas are tumors of adrenal medulla with characteristics of immature and adult chromaffin cells. PC12 is a single cell clonal line of these tumor cells and offers a great advantage in understanding the surface and chemical characteristics of these cells in vitro - when actively dividing, and when rendered amitotic. It has been well established that these cells respond to nerve growth factor (NGF) in culture by extending neurites. The present studies were undertaken to investigate the neuronal properties of PC12 cells from a rat clone at the light and electron microscopic level when exposed to (a) antimitotic agents alone, (b) NGF, and (c) a combination of antimitotic agents and NGF. The cells were grown in monolayer cultures on collagen-coated plastic petri-dishes or glass cover-slips. The cultures were divided into four groups - (i) untreated controls, (ii) treated with the antimitotic agents mitomycin C/5-Bromodeoxyuridine(BUdR), (iii) NGF, and (iv) a combination of mitomycin C/BUdR and NGF. At the end of the culture period, the cells from all these groups were processed for fluorescence histochemistry using sucrose-potassium phosphate-glyoxylic acid (SPG) method of de la Torre, scanning and transmission electron microscopy. Growth curves were also plotted after counting cells over a 11 day culture period in the four groups. Our results show that the untreated cells continued to divide and remained unchanged morphologically. NGF treatmant alone inhibited growth during the first few days after treatment but then cells resumed division. Treatment with the antimitotic agents alone inhibited cell division while the cells extended small neurites. The combination of antimitotic agents and NGF inhibited growth while the cells extended longer neurites. With all the treatments the cells showed bright green histofluorescence, indicating the prescence of catecholamines. The results of these studies will be presented at a greater detail.

Supported by grant NS 19711.

266.11 ANTIBODIES TO NERVE GROWTH FACTOR DIFFERENTIALLY AFFECT DORSAL ROOT GANGLION NEURONS IN VIVO. C.E. Hulsebosch, J.R. Perez-Polo+ and R.E. Coggeshall. Marine Biomedical Institute, +Human Biological Chemistry and Genetics, University of Texas Medical Branch, Galveston, TX 77550.

We previously reported a 10-15% increase in unmyelinated dorsal root axons ipsilateral to spinal denervations produced by spinal hemisection or unilateral sectioning of neighboring dorsal roots. This increase in axon number we interpret as sprouting of centrally projecting sensory neurons. In an effort to manipulate the sprouting, 7S mouse submaxillary nerve growth factor (NGF) was presented in excess or endogenous NGF removed by administration of rabbit antibodies to purified beta-NGF (ANTI-NGF). The excess NGF had no noticeable effect. By contrast, ANTI-NGF treatment (3µ l whole rabbit sera/gm.), in hemisected animals increased the number of unmyelinated dorsal root axons by 7% on the operated side and 50% on the unoperated side.

The present study is designed to pursue these findings. Neonatal rats were given daily injections of ANTI-NGF from birth to one month and compared to untreated 1 month old littermates as controls. Below is a table of the means from 8 specimens of the number of myelinated (MY) and unmyelinated (UN) axons in the T4 dorsal roots and the number of neurons in the T4 dorsal root ganglia (DRG) of both groups.

| | ANTI-NGF | CONTROL |
|---|---|---|
| MY | 1595 | 1356 |
| UN | 5944 | 4097 |
| DRG | 3900 | 5884 |

These data show a statistically significant increase in unmyelinated axons ($p<.0001$) and a statistically significant decrease in DRG neuron number ($p<.0001$) in the ANTI-NGF rats. These data indicate that blocking endogenous levels of NGF differentially affects the neuron population in the DRG. Approximately 34% of the neurons require NGF for survival and die if this requirement is not met. The neurons which do survive in the NGF deprived environment sprout even more vigorously than those experiencing surgical denervation.

266.12 **ARE POLYAMINES INVOLVED IN COLLATERAL SPROUTING?** **C.L. Hix and J.N. Davis. Veterans Administration Medical Center and Dept. of Pharmacology, Duke University, Durham, NC 27705.**

**After removing the input from the entorhinal cortex to the dentate gyrus of the hippocampal formation, many of the other fibers projecting to this area expand their innervation. We have been using the sprouting of cholinergic fibers from the medial septum after a unilateral entorhinal cortex lesion to study the role of polyamines in initiating collateral sprouting. We measured septal ornithine decarboxylase (ODC) activity, the first step in the biosynthesis of the polyamines putrescine, spermidine, and spermine, after entorhinal lesions and determined the extent of sprouting in animals pretreated with α-difluoromethylornithine (DFMO), an irreversible inhibitor of ODC.**

**In the first experiment, male Sprague-Dawley rats received either a unilateral entorhinal cortex lesion or a sham lesion. At various times after the operation, the activity of ODC in the septum was determined. In the second experiment, rats received daily injections of either 0.9% saline or 1 g/kg DFMO in saline for two weeks. A unilateral entorhinal cortex lesion was then made, and the drug treatment continued for an additional two weeks. Rats were sacrificed by perfusing with formalin, and adjacent sections through the hippocampus were stained for either acetylcholinesterase activity (Koelle) or the presence of degenerating nerve terminals (Gallyas silver stain).**

**The results are consistent with the hypothesis that polyamines are not involved in collateral sprouting. We found no differences in ODC activity between sham operated and lesioned animals. Furthermore, DFMO pretreatment did lower brain and renal ODC activity but did not alter the pattern of degeneration or sprouting. Experiments to confirm that the levels of polyamines were lowered by the DFMO pretreatment are currently underway. These data are the first studies of the role of the polyamines in collateral sprouting. Collateral sprouting occurs in uninjured neurons. By contrast, polyamines have been implicated in neuronal responses to injury and in neuronal development. These data suggest that polyamines may be part of the growth and repair processes, but may not play a role in neurite extension, axonal guidance, and neuronal target recognition.**

**(This material is based upon work supported by a National Science Foundation Graduate Fellowship, the V.A., and NS06233.)**

266.13 **INDUCTION OF A NEURITE-PROMOTING FACTOR THAT MAY BE INVOLVED IN THE IN VIVO REACTIVE SPROUTING RESPONSE TO BRAIN INJURY.** D.L. Needels, M. Nieto-Sampedro, and C.W. Cotman. Dept. of Psychobiology, University of California, Irvine, CA, 92717.

In response to partial denervation of a CNS structure, the spared fibers sprout into the deafferented zone. We report here the induction following brain injury or deafferentation of a novel neurite-promoting factor (NPF) that may be responsible for this reactive sprouting response.

A quantitative bioassay was devised in order to measure NPF levels in brain extracts. Purified ciliary ganglion neurons cultured in the presence of high levels of KCl survived for 24 hours, but did not produce neurites. When an extract of rat brain was included in the culture medium, the percentage of neurons with neurites increased in a dose-dependent manner. Quantitative titers were estimated from the dose-response curves.

Brain NPF activity increased several-fold over basal levels following ablation of the entorhinal/occipital cortex. The time course of this response to injury was determined by measuring the activity in tissue surrounding the wound cavity at various times post lesion. The NPF levels reached a maximum between 9 and 15 days post lesion, and subsequently decreased. The rise in neurite-promoting activity closely paralled reactive axon sprouting in vivo. To test whether denervation alone could induce NPF's, we compared NPF levels in hippocampus before and 12 days after electrolytic ablation of the entorhinal cortex. Neurite-promoting activity increased 3.5 fold in the deafferented hippocampus of young adult rats, but did not increase in aged animals. The delay in reactive sprouting in aged animals may be due to a diminished induction of NPF's following denervation.

The injury-induced (but not the basal) activity was sensitive to freezing and thawing, but was reactivated in the presence of thioglycerol or mercaptoethanol. Moreover, all neurite-promoting activity was blocked by treatment with N-ethyl maleimide. These data suggest the presence of a molecule containing an easily oxidized sulfhydryl group that is essential for the neurite-promoting activity in injured-brain extracts. The brain NPF's are probably proteins (based on inactivation by heat or trypsin), but are different from laminin, nerve growth factor, and polyornithine-bindable NPF's.

In conclusion, we describe the induction following brain injury of a protein that may cause reactive sprouting in vivo. Its properties distinguish it from all other reported neurite-promoting factors.

266.14 THE EFFECTS OF 4-AMINOPYRIDINE AND STRYCHNINE ON RAT SPINAL CORD REORGANIZATION FOLLOWING SCIATIC NERVE LESION. H. Markus* and B. Pomeranz. (SPON: C. THOMPSON). Dept. of Zoology, University of Toronto, Toronto, ONT., CANADA M5S 1A1.

In a previous study (Markus, H. et al., Brain Res., 296: 27, 1984) we investigated the changes that occurred in the rat spinal cord following peripheral nerve lesion. Immediately after sciatic nerve lesion, dorsal horn cells in the lumbar cord (L4 and L5) were deafferented and did not respond to mechanical stimulation of the hindlimb. 21 days after sciatic nerve lesion these deafferented dorsal horn cells responded to mechanical stimulation of the hindlimb. However these responses were not elicited by cutaneous stimulation of their normal hindlimb receptive fields but by cutaneous stimulation of areas of the hindlimb outside their normal receptive fields.

In this study we investigated the time course of dorsal horn reorganization. We observed that the deafferented dorsal horn cells did not respond to mechanical stimulation of the hindlimb during the first two weeks after sciatic nerve lesion. However 2 weeks after the lesion was made the deafferented dorsal horn cells began to respond to mechanical stimulation of the hindlimb.

These results indicate that following peripheral nerve lesions new connections are produced in the spinal cord. Other investigators (Rodin B.E. et al., J. Comp. Neurol., 215: 187, 1983; Seltzer Z. and Devor M., Brain Res., 306: 31, 1984) have shown that new connections in the spinal cord are not due to collateral sprouting but to strengthening of pre-existing but ineffective pathways. To determine whether the appearance of novel receptive fields following chronic sciatic nerve lesion was due to the strengthening of these latent synapses we attempted to activate these ineffective pathways in the acutely lesioned animal by administration of chemicals (4-aminopyridine, strychnine) which facilitate synaptic transmission. Preliminary studies indicate that these chemicals do not consistently cause the appearance of novel receptive fields in the acutely denervated animal.

266.15 PARTIAL DENERVATION OF THE FROG SARTORIUS CAUSES ENHANCED TRANSMITTER RELEASE AT SURVIVING JUNCTIONS.
A.D. Grinnell, Dept. of Physiology and Jerry Lewis Neuromuscular Research Center, UCLA, Los Angeles, CA 90024

Partial denervation of skeletal muscle has long been known to result in terminal and nodal sprouting from surviving axons. This is generally felt to represent a response to signals generated by the denervated muscle and/or degenerating nerve products (Brown, Holland & Hopkins, Ann. Rev. Neurosci., 4:17-42, 1981). In both frogs (Rotshenker, J. Physiol., 292:535-547, 1979) and mammals (Rotshenker & Tal, J. Physiol., 360:387-396, 1985), sprouting from intact motor axons has also been reported following axotomy of contralateral homologous motoneurons. That this sprouting occurs earlier for proximal than for distal contralateral axotomy suggests that it is in response to a signal transmitted between neurons in the spinal cord. In frogs, it has also been shown that contralateral axotomy leads to a long-lasting increase in transmitter release from intact sartorius nerve terminals (Herrera & Grinnell, Nature 291:495-497, 1981). It seems likely that the two contralateral responses are related. If both increased transmitter release and sprouting can be triggered by interaction between homologous motoneuron pools lying on opposite sides of the spinal cord, it might be predicted that similar signals would operate even more strongly within a single motoneuron pool. Thus sprouting in a partially denervated muscle might also be associated with increased transmitter release from intact axons.

To test this hypothesis, frog sartorius nerves were partially sectioned 0.5-1 cm from the point of entry into the muscle, and synaptic strength measured at periods up to two weeks later (prior to reinnervation by sectioned axons.) There is a sharp increase in mean synaptic strength which is evident as early as 6 days after nerve section. The magnitude of the enhancement in synaptic strength is inversely proportional to the number of motor units left intact in the muscle. In this preparation, the increase in release efficacy appears to precede sprouting. It is not yet clear whether this effect on synaptic strength is due to peripheral signals, to transneuronal interaction between axotomized and intact motoneurons, or to altered activity patterns.

266.16 EFFECT OF EXPANSION OF MOTOR NEURON TERMINAL FIELD ON ACETYLCHOLINE RELEASE. S. Rochel and N. Robbins, Case Western Reserve University, School of Medicine, Cleveland, Ohio 44106.

Herrera and Grinnell (Nature 287, 649 (1980) have reported that transmitter release from frog motor nerve terminals increased when the motor unit size was reduced. Testing the essumption that this relation is reciprocal, we have studied the reverse situation by generating 5 fold increase of the motor unit size.

The efficacy of evoked acetylcholine release was studied in mouse soleus muscle motor nerve terminals at varying intervals after partial denervation produced by L5 nerve section.

Two to four days after section of ventral root nerve L-5, only 2-6 motor units of the normal 21 remained intact, and indirect stimulation evoked only 8-15% of the direct twitch tension.

Indirect twitch tension almost completely recovered between 28 and 50 days after nerve section. However, twitch under lower Ca (0.5mM) and high Mg (1.9mM) was reduced 2 to 3 times compared to contralateral controls. This indicated reduction of evoked transmitter release.

Two subpopulations of nerve terminals evolved in the recovering partially denervated muscles, as observed by intracellular direct measurement of quantal content in 0.4mM Ca, 2.75mM Mg. The quantal content of the first population was greater than contralateral control at earlier times (28-50 days) and equal to control at a later time (90 days). The second population had lower quantal content than control at all times, and probably consisted of newly sprouted terminals, since it was associated with low mepp frequency and slower impulse conduction.

Thus, when the terminal field of the motor units expands 3-5 fold, the efficiency of evoked ACH release is reduced in the sprouted terminals, even 90 days after nerve section. This reduction of efficiency may establish the upper limit for motor unit sprouting. The transient increase of transmitter release in non denervated terminals may reflect either increased axonal transport of synaptic components or greater excitatory drive.

266.17 THE ROLE OF MUSCLE FIBER INACTIVITY ON MOTONEURON SPROUTING. M.M. Wines*, S.A. Spector, S.P. Carter*, M.L. TeVrucht*, and M.S. Letinsky. Ahmanson Laboratory of Neurobiology, Jerry Lewis Neuromuscular Research Center, University of California, Los Angeles, CA 90024.

Motoneurons supplying striated muscles in amphibians and mammals are seen to sprout unmyelinated outgrowths from nodes of Ranvier and endplate arborizations following a variety of experimental perturbations. Muscle fiber inactivity produced by intramuscular injection of botulinum toxin or $\alpha$-bungarotoxin, or following nerve block with tetrodotoxin results in prolific amounts of motoneuron sprouting. Since each of these substances alters the physiological status of either the axon or its associated muscle fiber, it is unclear if the inactivity produced is the definitive stimulus to sprouting.

In a recent study by del Castillo and Escalona de Motta (J. Cell Biol. 78:782, 1978) the topical application of formamide was seen to selectively eliminate muscle fiber contractile activity without altering presynaptic release mechanisms or myofiber electrical activity. Given these qualities, following formamide application motoneuron sprouting can be assessed in an environment devoid of muscle contractile activity in which the physiological state of the neuromuscular junction has not been altered.

The cutaneous pectoris muscle (CP) of adult frogs (Rana pipiens) was unilaterally exposed to 4M formamide for an initial incubation of 15 minutes. This produced complete paralysis of the CP muscle for 4-5 days. With repeated exposure to formamide it was possible to block all muscle fiber activity up to 28 days. Prior to each application the muscle was stimulated indirectly to ensure that complete inactivity had been maintained. Visualization of the nerve terminals was accomplished by staining with tetranitroblue tetrazolium. The morphology of the presynaptic neurites remained unchanged until day 19, afterwhich moderate amounts of terminal sprouting were noted. The frequency of this terminal sprouting from synaptic arborizations increased with time, whereas nodal sprouting was never observed.

The induction of motoneuron sprouting by formamide is interesting in that it is initiated over a much longer time course as compared to the onset of sprouting following the application of other neurotoxins (e.g., 4-6 days after botulinum toxin). It appears that CP motoneurons have the inherent ability to sprout well before day 19 as significant amounts of terminal sprouting was observed as early as 7 days following partial denervation of this muscle. The disparity between the onset of sprouting after formamide versus other toxins suggests that inactivity alone is not the immediate cue responsible for sprouting, and may further suggest that motoneuron sprouting following each of these methods is the response to two or more distincty different stimuli.

266.18 LONG-TERM SURVIVAL OF THE ISOLATED GOLDFISH MAUTHNER AXON. S.J. Zottoli, L.E. Marek, M.A. Agostini and S.L. Strittmatter. Department of Biology, Williams College, Williamstown, MA 01267.

CNS axons of certain invertebrates, when isolated from their somata, are known to survive both morphologically and physiologically for extended periods of time. These isolated segments can play an important role in the regenerative process, providing pathways along which regenerating axons find their targets. Although morphological studies have indicated survival of isolated axonal segments of vertebrate CNS neurons, no physiological studies have been reported. Utilizing the goldfish Mauthner cells (M-cells), we report morphological and physiological survival of isolated axons for at least 2 months.

Fish 8.5 to 11.5 cm in body length were maintained between 13.5-15.0°C and kept on a 12 hr light-dark cycle. The M-axons were injured by crushing the brain at the spinomedullary level. For morphological studies, the brains and spinal cords of 7 fish were fixed and processed for electron microscopy at postoperative intervals from 27-95 days. The M-axons were studied in spinal cord segments 3.5 cm distal to the M-cell somata, since the M-axon diameter decreased in a proximodistal direction in the 5 control fish studied. The wound site was sectioned to confirm M-axon injury. For electrophysiological studies, KCl electrodes (3-10MΩ) were used to intracellularly stimulate M-axon distal segments and muscle activity was recorded with a pair of stainless steel wires placed in the mid-trunk region of the fish. Lucifer yellow was injected into the distal segments to confirm that the M-axons had been severed.

M-axons appeared "normal" on EM examination for up to 77 postoperative days. The area of the M-axon sheath did not change during this interval as compared to controls. Between 87-95 postoperative days, the M-axons had degenerated with only myelin debris to mark their former position. Intracellular stimulation of 7 M-axons in 5 fish between 47-62 postoperative days resulted in ipsilateral EMGs in all cases.

Thus, M-axons survive up to 77 days after separation from their somata and are able to conduct action potentials and initiate muscle activity for at least 62 days. The mechanisms for survival and the role of these isolated segments may play in the regenerative process of the M-cell or any other CNS neuron are currently not known. However, the accessibility of the M-axon provides a unique opportunity to answer such questions.

267.1 OCTOPUSES AND SQUIDS FOR DEVELOPMENTAL STUDIES NOW AVAILABLE THROUGH LABORATORY CULTURE. J.W. Forsythe* and R.T. Hanlon* (SPON: P.M. Adams). Marine Biomed. Inst., Univ. Texas Med. Br., Galveston, TX 77550.

Cephalopod molluscs are advanced invertebrates that have been used extensively by the biomedical research community, particularly in Europe. Unpredictable availability of live animals has limited their use in the U.S., but we have recently cultured 5 species of Octopus (Hanlon, R.T. and Forsythe, J.W., Lab. Anim. Sci. 35:33, 1985) and the squids Loligo forbesi and L. opalescens (Yang, W.T. et al., Aquaculture 31:77, 1983) through the life cycle (cycles range 6-15 months). In vivo and developmental studies are now possible. Cephalopods are the only invertebrates possessing both a closed circulatory system and a highly vascularized brain in which the lobes are separate, rendering them good comparative models to vertebrates. Examples of recent experimental uses include: the glial blood-brain barrier; photo-transduction in the vertebrate-like eye; morphogenesis, pattern formation and regeneration of neurally controlled chromatophores in the skin; and aging (single breeding with optic gland hormone initiating both maturation and senescence). Octopuses are quite hardy, easily transportable, and can be maintained at inland aquaria. They are particularly useful in learning and memory experiments (even hatchlings are adaptable to training paradigms), they have short- and long-term memory stores, they narcotize easily and can withstand operations. Squids are renowned for their giant axons and giant synapses, which are models for nerve transmission, axonal transport and cell membrane biophysics. Synaptic transmission at the neuromuscular junction of the squid chromatophore organ is also being actively studied (Florey, E. et al., Comp. Biochem. Physiol., in press). Recent development of a semi-intact squid preparation lasting up to 4 hours (Dubas, F. et al., J. Exp. Biol., in press) will enhance future physiological experimentation. Ontogenetic studies have not been possible until now, but limited numbers of laboratory-cultured squids and octopuses are now available to selected researchers.

267.2 SEROTONIN-MEDIATED CHANGES IN SENSORY INPUT TO THE JUVENILE CRAYFISH ESCAPE RESPONSE CIRCUIT: DIFFERENCES CORRELATED WITH REARING CONDITIONS. R.A.Fricke, Dept. of Anatomy, Emory University School of Medicine, Atlanta, GA 30322.

Serotonin has been found to produce a variety of effects in Crustacea. In the periphery, serotonin increases transmitter release at certain neuromuscular junctions (Glusman and Kravitz, J. Physiol., 325:233, 1982), while in the CNS it increases the firing rates of postural flexor motoneurons (Livingston et al., Science, 208:76, 1980) and suppresses sensory transmission in the escape response circuit (Glanzman and Krasne, J. Neurosci., 3: 2263, 1983).

We recently found that escape responses of juvenile crayfish are not inhibited by restraint (Fricke and McDonald, unpublished). In adult crayfish restraint decisively inhibits escape tailflips (Krasne and Wine, J. Exp. Biol., 63:433, 1984). To determine if the absence of restraint-induced inhibition in juveniles reflects the delayed development of postsynaptic serotonergic mechanisms, I have recorded sensory EPSPs in an escape command cell, the lateral giant interneuron, using animals having a body length of 1-2 cm. Serotonin superfused over the semi-intact juvenile nervous system at concentrations of $10^{-4}$ to $10^{-3}$M produced a variety of effects on sensory EPSPs triggered by electrical stimulation of abdominal ganglion 2nd roots. In 5 cases EPSPs were inhibited (% reduction = 45.5% ± 14.5% SD). This is qualitatively similar to previous observations in adults. On the other hand, EPSPs were substantially augmented (% increase = 93.8% ± 36.3 SD) in 4 other cases, and in 1 case EPSPs were not significantly changed during exposure to serotonin, but showed marked augmentation (44% ± 25%) after returning to normal crayfish Ringer. EPSPs recorded from different segmental lateral giants of any one animal were similarly affected by serotonin.

This unusual serotonin-mediated augmentation of sensory input to the escape circuit was accompanied by inhibition of spontaneous activity in postural flexor motoneurons recorded extracellularly from abdominal ganglion superficial 3rd roots. Thus, there appears to be a coordinated reversal of serotonin actions that affects locomotor and postural systems of the crayfish abdomen. Although the cause of these changes is uncertain, there was a strong correlation between the social environment in which animals were maintained and the cellular actions of serotonin. Augmented responses were seen in animals (4 of 5) that were maintained individually in small (4" x 4") plastic containers, whereas inhibition was seen in most animals that had been maintained communally (5-25 animals), in larger (7" x 13") plastic containers.

267.3 ENVIRONMENTAL REGULATION OF BEHAVIORAL DEVELOPMENT IN THE CRAYFISH. R. Toler* and R.A. Fricke (SPON: P. Lennard). Dept. of Anatomy, Emory Univ. Sch. of Med., Atlanta, GA 30322.

During early postembryonic development crayfish pass through a stage during which characteristic modulations of adult escape behavior are not evident. It has been proposed that early inflexibility of escape behavior depends on the existence of a strong monosynaptic sensory input to the escape command cell (the lateral giant interneuron) and that command cell growth results in the partial decoupling of this electrotonic synaptic connection (Fricke, Br. Res. 332:139, 1984). To further explore the relationship between growth of the lateral giant interneuron (LG) and the development of escape response plasticity we have: (1) determined more precisely the stage at which escape plasticity appears; and (2) characterized lateral giant growth changes during the course of postembryonic development.

We manipulated the growth rates of siblings by subdividing broods and raising these groups at two different temperatures (18.2-19.8° C) and by varying the frequency of feeding (1/week and 3/week). We found that plasticity of escape behavior (habituation and restraint-induced inhibition) appeared when crayfish reached a body length of 3-4 cm, regardless of their age.

We used intracellular injections of horseradish peroxidase and standard histological techniques to characterize lateral giant growth during postembryonic development. We also measured conduction velocity and input resistance as additional indices of lateral giant size. In the smallest animals studied (1-2 cm) LG has a very simple and compact dendritic arbor, axon diameter is less than 10 µm and input resistance is 10-20 x $10^6$ ohms. At maturity, LG axon diameter is 90-100 µm, the dendritic tree is more complex (e.g. more higher order branches) and input resistance is 100-500 x $10^5$ ohms. Initially the increase in LG size and complexity parallels overall body growth. Parameters reflecting LG growth, however, plateau beginning when crayfish reach a body length of 3-4 cm, the point at which behavioral plasticity is first noticed. This substantial increase in LG size and the matching decrease in LG input resistance are compatible with the hypothesis that partial decoupling of electrotonic sensory inputs results from an increased postsynaptic electrical load that is unmatched by an increase in monosynaptic sensory connections.

267.4 CENTRAL PROJECTIONS OF PERIPHERAL SENSORY CELLS LACKING FUNCTIONAL ACTIVITY IN DROSOPHILA MOSAICS. M. G. Burg and C.-F. Wu. Dept. of Biology, Univ. of Iowa, Iowa City, IA 52242.

Two temperature-sensitive paralytic mutations of Drosophila, $para^{tsl}$ and $nap^{ts}$, are implicated in affecting sodium currents, blocking axonal conduction at high temperatures. The $para^{tsl}$ $nap^{ts}$ double mutants are completely lethal even at 17°C (Nature 286:184, 1980). Previous results showed that it is possible to produce small-patch mosaics containing a single double mutant bristle sensory cell. Behavioral studies confirmed that the $para^{tsl}$ $nap^{ts}$ sensory cell is non-functional at all temperatures tested (17-25°C), while the rest of the nervous system functions normally. Further EM examination of the non-functional $para^{tsl}$ $nap^{ts}$ sensory cell showed normal mechanoreceptor ultrastructure (Soc. Neurosci. Abstr. 10:513, 1984).

It is interesting to know whether lack of activity may affect pathfinding and formation of central projections of these sensory cells. We examined the morphology of the identified bristle sensory cells located on the dorsal mesothorax using the cobalt backfilling technique. Backfilling showed that each identified cell had a characteristic projection pattern, with only minor variations occurring between flies. Results demonstrated that $para^{tsl}$ $nap^{ts}$ non-functional sensory cells follow a normal pathway, project into the proper region of the thoracic ganglia, and form branching patterns typical of normal sensory cells. Moreover, no major differences were found between the central projection patterns of $para^{tsl}$ $nap^{ts}$ sensory cells when compared to the contralateral control projections within the same fly. Therefore, functional activity appears to have no direct effect on the pathfinding and arborization of projections of these sensory cells. Supported by NIH grants NS 00675, NS 18500, and a grant from Searle Scholars Program to C.-F. Wu, and by NIH Pre-doctoral Genetics Traineeship GM 07091 to MGB.

267.5 ALTERED DEVELOPMENT OF THE DROSOPHILA GIANT FIBER PATHWAY IN THE TEMPERATURE-SENSITIVE MUTANT SHIBIRE: CONTROL BY TIMING OF HEAT-PULSE. M.R. Hummon and W.J. Costello. Dept. Zool. and Biomed. Sci./Col. Osteo. Med., Ohio Univ., Athens, OH 45701.

The giant fiber (GF) pathway in Drosophila can be investigated by stimulating the brain and recording from target muscles in the thorax. Minimum latencies of 0.81 msec for TTM (jump muscle) and 1.25 msec for DLM (wing depressors) indicate GF activation in wild-type (Tanouye & Wyman, 1980, J. Neurophys. 44:405). Minimum latencies of shibire (shi) flies reared at the permissive temperature (18-22C) were 0.97 msec for TTM (9 flies, n=20) and 1.45 msec for DLM (9 flies, n=24). Shi flies exposed to 6h heat-pulse (HP) of 30C during early pupal development show heat-sensitive periods and anomalous cuticular development (Poodry, et al., 1973, Devel. Biol. 32:373); as well, the GF motor system is altered by a fusion of the 6 DLM fibers into 3 (Costello & Salkoff, 1983, Neurosci. Abstr. 9: 832) and by disruption of the PSI (peripherally synapsing interneuron) connection to DLM motor axons (Hummon & Costello, 1984, Neurosci. Abstr. 10:1032).

To examine the existence of critical periods of development in GF pathway components, shi flies reared at 22C were given HP at 1-66h of pupariation (~1-44h @ 25C). Minimum latencies for DLM were higher ($\alpha < 0.05$) in all HP groups with survivors (HP onset 16-66h; HP @ ≤15h was lethal) and synchrony of right and left DLM was usually absent. Minimum latencies as high as 1.82 msec were measured (HP @ 18,36,38h). Minimum latencies for TTM were occasionally higher ($\alpha < 0.05$) than non-HP for test groups with HP <48h.

Morphology was investigated with serial 5 μm sections for light microscopy and selected serial thin-sections for TEM. Wild-type morphology of the GF pathway (King & Wyman, 1980, J. Neurocyt. 9: 753) occurs in non-HP shi flies, with GF extending past the cross-over of PSI in the mesothoracic ganglion to reach the TTMn, and PSI readily detectible in the peripheral nerve, PDMN. Flies with HP onset at 16-18h lack a prominent PSI cross-over in CNS, lack GF extending past this area, and lack well-defined PSI in PDMN. PDMN in such flies has a higher number (~200) of small axons (diameter, 0.2-0.3 μm) than in non-HP or HP @ 66h flies (~100). Morphology of flies with HP onset at 66h is variable; 2 of 3 studied showed normal 6 DLM and 1 of 3 had entirely normal PSI morphology in CNS and PDMN. PSI cross-over was not clearly identifiable in 2 flies; only one had any trace of PSI in PDMN. It is possible that this period of development is close to the endpoint of GF pathway development.

GF pathway components and target muscles are differentially altered as a function of timing of HP. These differences may be a function of their differential timing in development. Thus, shi will permit us to investigate the critical periods of development of neuronal components and targets and interactions necessary for proper pathway formation.

267.6 DEVELOPMENT OF GIANT FIBER PATHWAY COMPONENTS IN DROSOPHILA: POSSIBLE INVOLVEMENT OF COATED VESICLES. W.J. Costello and M.R. Hummon. Dept. Zool. and Biomed. Sci./Col. Osteo. Med., Ohio Univ., Athens, OH 45701.

Because of its genetic repertoire, Drosophila melanogaster can be used to great advantage in studying development. We have been engaged in looking at the development of components of the giant fiber (GF) pathway by using the temperature-sensitive mutant shibire (shi). When exposed to non-permissive temperatures (<28C), shi flies become paralyzed due to a failure in synaptic transmission. Recent work (Costello & Salkoff, 1982, Neurosci. Abstr. 8: 494; Kosaka & Ikeda, 1983, J. Cell. Biol. 97:499) has indicated that the shi defect is in the recycling of membranes, specifically the "pinch-off" mechanism in endocytosis.

We have found that by heat-pulsing (HP) shi pupae at particular stages of development, various anomalies in the GF pathway are induced. These anomalies can occur in neurons and muscles alike. Thus, we can 1) prevent normal GF connectivity to targets in the CNS such as TTMn (jump muscle motoneuron), 2) prevent the PSI (peripherally synapsing interneuron) from forming its normal pathway out a peripheral nerve (PDMN), 3) affect normal connectivity of PSI with the motor axons of the DLM (wing depressor muscle), 4)prevent normal boundary formation of the DLM such that the muscle consists of 3 fused muscle fibers instead of the normal 6 muscle fibers (Costello & Salkoff, 1983, Neurosci. Abstr. 9:832; Hummon & Costello, 1984, Neurosci. Abstr. 10;1032; 1985, Neurosci. Abstr. 11: in press; in preparation).

During initial formation, these components interact with each other. For example, in the early pupa, such interactions are readily seen to occur between adult myocytes and larval muscles serving as their end targets. Adult myocytes send out many fingers which connect with and project into the larval muscles. Many transient junctions are also formed between the myocytes and larval muscle and between nerves and larval muscle. As well, numerous coated vesicles/pits are present in the larval muscle, forming opposite myocytes or nerve. These coated structure are prevalent only during this period, which corresponds to the same period at which a HP would prevent normal boundary formation in the DLM. Before or after this critical period, such structures are absent.

Coated vesicles are an indicator of receptor-mediated endocytosis and play a role in intercellular trafficking of molecules. Since the shi defect is affecting such membrane recycling processes, we can disrupt normal development arbitrarily with HP. By disrupting this process during critical periods of development, normal formation of the GF pathway components is prevented. It thus seems likely that the coated vesicles are playing a role in disseminating molecular information to developing/degenerating cells regarding pathfinding and target interaction.

267.7 THE DEVELOPMENT OF SEXUALLY DIMORPHIC NEURONS IN THE GENITAL DISC OF DROSOPHILA MELANOGASTER. B. J. Taylor*and W. A. Harris. (SPON: G. L. Harris). Biology Dept., UCSD, La Jolla CA 92093.

In order to ask how genes known to control sexual differentiation in Drosophila melanogaster, act on sexually dimorphic neurons, we have begun to characterize the development, differentiation, and central projection patterns of sensory neurons derived from the genital disc. Horseradish peroxidase (HRP) fills of adult flies show distinct central projections in the abdominal ganglion for female versus male bristles. Antibodies raised against HRP ($\alpha$-HRP) appear to bind specifically to a cell surface marker expressed soon after differentiation (Jan & Jan, 1982). Using a monoclonal $\alpha$-HRP antibody (provided by Yuh Nung Jan), we have stained genital discs from male and female larvae and pupae.

The genital disc is bilaterally symmetrical and contains the separate primordium for the female and male genitalia and a single anal primordium. Depending on the chromosomal sex of the tissue, only one of the genital primordia develops and the anal primordium undergoes either male or female differentiation. In genital discs from either sex, the first neurons to become immunoreactive are found around pupariation in the sexually expressed genital primordium but not in the repressed primordium. In the male, the first neurons are associated with the presumptive lateral plate and clasper regions of the disc. Neurons associated with the anal plates appear by 4-8 hours after pupariation. In the female, the first neurons appear to be associated with the internal genital primordium and slightly later neurons are found in the external genital primordium and presumptive anal plate region. Thus, while the first neurons have the same temporal onset of differentiation in the two sexes, the location of the neurons are in sexually dimorphic regions of the genital disc.

Several genes affect the differentiation of sexually dimorphic somatic tissues. Mutations in two of these sex-determining genes tra, transformer, and tra-2, transformer-2, convert a chromosomally female fly into a male one. The normal $tra^+$ and $tra\text{-}2^+$ gene products are needed throughout the development of sexually dimorphic tissues for the proper differentiation of female characteristics. A temperature sensitive mutation of the tra-2 locus has made it possible to separate the decisions for the number of bristles from their morphology (Belote & Baker, 1982). We are extending this analysis to the sensory neurons found in the genital disc and analysing the role that tra and tra-2 play in neuronal differentiation.

267.8 DEVELOPMENT OF HOMOLOGOUS SEROTONERGIC NEURONS IN OPISTHOBRANCH MOLLUSKS. A.J. Longley (SPON: P. Grant). Pacific Sciences Institute, Box 835, Friday Harbor, WA 98250, and Friday Harbor Labs.

Gastropod mollusks possess neurons which are uniquely identifiable; some of these cells have been recognized as homologous in several orders. I have examined patterns of serotonergic (5HT) neurons in Phidiana (Hermissenda) crassicornis and several related opisthobranchs using an antibody specific for serotonin in ganglion wholemounts. Using the same antibody (also in wholemount), I have followed the development of 5HT neurons in Phidiana and some of its relatives.

In adult Phidiana, Aeolidia papillosa, Armina californica, and Tritonia diomedea, the homology of several neurons was clearly indicated by shared transmitter, location, and axon distribution. The serotonergic giant cerebral neuron (GCN), with axon branches in the lip nerve, buccal ganglion, and buccal nerves, was present in all species examined. In addition to this well characterized neuron, an unpaired left pedal neuron, with the principal branch of its axon in the left pleural nerve, was also found in each species. This neuron appears to be LPdl, identified as 5HT containing in Tritonia (Audesirk et al., Comp. Biochem. Physiol. 62C:87-91, 1979). In Hermissenda, the axon branching and soma location of this neuron correspond to that of LPdl studied by Jerussi and Alkon (J.Neurophysiol. 46:659-671, 1981). 5HT containing somata are absent from the buccal and pleural ganglia.

During development, in very early veligers of Phidiana, 5HT immunoreactivity is first seen in fine, varicose axons in the region of the central ganglia before the somata for these axons have appeared. The GCN somata appear at the time of statocyst formation. At this stage, each GCN extends a varicose axon toward the velar lobes and across the midline at the velum, suggesting that the GCN's innervate the velar lobes before they are lost at metamorphosis. By metamorphosis, serotonergic processes have extensively innervated the region of the buccal ganglion and LPdl can be seen extending its axon in a loop, apparently through the pleural ganglion. The smaller serotonergic cerebral and pedal neurons of the adult are not yet visualized with the antibody shortly after metamorphosis. Early development of 5HT neurons has also been followed in Aeolidia and Melibe leonina; in all species, the GCN's appear at the same stage and extend axons toward the velum and across the midline.

The similarity of early development of these homologous neurons indicates that the developmental mechanisms which give rise to these neurons have been conserved. Currently, other antibodies are being used to distinguish other metabolic classes of nerve cells in adults (RD Longley and AJ Longley, Neurosci. Abst., 1985) and during development of related species. It is now feasible to compare, at the cellular level, evolutionary differences in nervous system development.

267.9 HOT AND COLD SHOCKS PERTURB THE SYNAPTIC ORGANISATION OF FLY PHOTORECEPTOR TERMINALS. A. Frohlich and I.A. Meinertzhagen, Department of Psychology, Dalhousie Univ., Halifax, N.S., Canada

The rules governing synapse formation between identified neurons of the lamina, the first optic neuropile of the fly's compound eye, have been investigated further with special reference to the synapses of the photoreceptor terminals. Six receptor terminals (R1-6) provide input to a cartridge, the unit module of the lamina. Each receptor forms a population of equivalent, uniform synaptic contacts. At each contact an invariable combination of four postsynaptic elements is assembled. These are: two monopolar interneurons (L1, L2) and, at proximal depths, two processes of an amacrine cell. In order to test the combinatorial rules of assembly of these elements we have perturbed the developing visual system, so as to affect the availability of postsynaptic elements.

Flies, Musca domestica, were subjected to cold or hot pulses (5h at 4°C; 1h at 37°C) during the first half of normal pupal development at 20°C, before synaptogenesis occurs. The flies were prepared for electron microscopy at emergence. Survey montages and series of 40-100 sections were analysed. The effects were qualitatively similar for hot and cold pulses, and also for exposure at different developmental stages. They included: in the retina, the frequent loss of R7 and less frequent loss of one or more cells R1-6; in the lamina, the less orderly arrangement of elements, greater variability in cartridge receptor terminal complement and occasional supernumerary postsynaptic cells. We have examined in detail several cartridges with such augmented composition, including one "mega"-cartridge with 4 L1, 2 L2 and 14 receptor cells (the latter are distinguishable ultrastructurally, while L2 is distinguished from L1 by its feedback synapses upon R1-6). The analysis reveals that all receptor terminals are equivalent in the formation of gap junctions and synapses. Rules of postsynaptic combination are strictly adhered to. L1 always pairs with L2 as two elements of a synapse. Receptor terminals may form synapses with more than one L1 or L2, while one L1 may pair with more than one L2 at different synapses, and vice versa. It therefore seems that cartridge affiliation plays no role in synaptogenesis. Rather, neuron classes only must be recognised, all neurons of a given class being equivalent. The results simply the existence of neuronal class labels but the absence of cartridge labels at the time of synapse formation.

Supported by NIH grant EY-03592.

267.10 METAMORPHOSIS OF A CPG: REUSE AND SUBSEQUENT MODULATION OF THE LARVAL ECDYSIS MOTOR PROGRAM FOR THE GENERATION OF ADULT-SPECIFIC ECLOSION BEHAVIOR. K.A. Mesce and J.W. Truman. Dept. of Zoology, Univ. of Washington, Seattle, WA 98195.

Metamorphosis of the hawkmoth, Manduca sexta, is marked by dramatic changes in both body morphology and neuronal organization. Many of these neuronal changes underlie stage-specific behaviors such as crawling in the larva, the defensive gin-trap response in the pupa, and flight in the adult. Ecdysis behavior, or the shedding of the old cuticle, is one behavior, however, that persists throughout metamorphosis and is periodically expressed as the insect molts from one stage to the next. Larval, pupal, and adult ecdyses are all triggered by the same neuropeptide, eclosion hormone, which acts on the CNS to evoke the respective motor patterns. Previous work (Weeks & Truman, 1984, J. Comp. Physiol. 155:407) showed that the larval ecdysis behavior involves an anterior-directed, peristaltic wave of contractions accompanied by the transient retraction of segmental prolegs as each segment is drawn forward. At the pupal stage, the behavior appeared quite different because the prolegs were absent, however, the motor pattern generated by the pupal CNS was essentially identical to that seen in larvae, including the firing phase of motor units that formerly controlled the prolegs.

The major movements shown by the adult during its ecdysis involve a rapid retraction of the abdominal segments in a metachronous fashion followed by their extension coupled with wing muscle contractions. These movements are very different from those shown by larvae and pupae and suggested that the larval CPG was dismantled during metamorphosis and a new one constructed for the adult stage. However, when descending inputs to the adult abdominal ganglia were blocked, the abdomen lapsed into a motor pattern which was identical (on both behavioral and electrophysiological criteria) to that shown at larval ecdysis. Thus, the larval ecdysis CPG appears to be conserved through metamorphosis whereupon new descending inputs modulate the output of this CPG to produce the different behavior displayed by the intact adult. Various aspects of this modulation will be discussed.

267.11 MONOCLONAL ANTIBODIES AGAINST THE SEXUALLY DIMORPHIC OLFACTORY SYSTEM OF *MANDUCA SEXTA*. A. Hishinuma†, S. Hockfield§, R. McKay§, and J.G. Hildebrand†. †Dept. Biol. Sci., Columbia Univ., New York, NY 10027, and §Cold Spring Harbor Lab.,Cold Spring Harbor, NY 11724.

Olfactory receptor cells in the antenna of the sphinx moth *Manduca sexta* send their axons through the antennal nerve (AN) into the ipsilateral antennal lobe (AL) of the brain. The primary olfactory fibers terminate in the neuropil within glomeruli, where they make synaptic contacts with AL neurons. Among other classes of sensory cells, receptors specialized to respond to the sex pheromone of the conspecific female moth are present exclusively in male antennae. The axons of these sexually dimorphic olfactory cells all project to a male-specific neuropil region in the AL, the macroglomerular complex (MGC), where they make synapses with male-specific AL neurons. Axons of mechanosensory neurons at the base of the antenna in both sexes join the intracranial segment of the AN and project into the brain.

As part of continuing studies of the functional organization and postembryonic development of the antennal sensory pathways in *Manduca*, and of the molecular basis of neuronal diversity, we have generated monoclonal antibodies (MAbs) against the male system. Mice were immunized with homogenates of ALs and intracranial segments of ANs from adult male moths, and supernatant media from cultures of hybridoma cells prepared by standard methods were screened immunohistochemically on sections of male ALs. Of the interesting hybridoma lines we have successfully cloned, five secrete MAbs that are cell type-specific, including a male olfactory-specific MAb.

*Olfactory-Specific Antibody* (OSA) stains olfactory receptor cells in both males and females. Cell bodies, dendrites, and axons of the primary olfactory neurons stain with OSA, but no other elements in the brain, subesophageal ganglion, or prothoracic ganglion bind this MAb. Using electron-microscopic immunocytochemistry (EMI) with HRP-conjugated secondary antibody, we have shown that OSA recognizes a surface antigen on olfactory cells and their axons. Axons of OSA-immunoreactive cells are fasciculated together in the AN. *Male Olfactory-Specific Antibody* (MOSA) stains cell bodies, dendrites, and axons of a subset of receptor cells in males but *not* in females. In the AL, MOSA labels the male-specific MGC but not the "ordinary" glomeruli common to both male and female ALs. *Mechanosensory Antibody* stains the antennal mechanosensory fibers but not the primary olfactory axons. *Glial-Specific Antibody* selectively stains glia in the AN and AL, as well as glia elsewhere in the CNS. *Synapse-Specific Antibody* (SSA) stains glomeruli (the sites of all known synapses in the AL) but not other AL regions lacking synapses. EMI shows that SSA reacts with some but not all synaptic terminals in glomeruli, suggesting that these labeled terminals are contributed by a subpopulation of AL neurons. Current efforts aim to characterize the antigens of these MAbs and to explore their expression during adult development.

267.12 CONTRIBUTIONS OF SENSORY AXONS AND CENTRAL NEURONS TO THE DEVELOPMENT OF GLOMERULI IN THE ANTENNAL LOBES OF *MANDUCA SEXTA*. K.S. Kent* and J.G. Hildebrand. Dept. Biol. Sci., Columbia Univ., NY, NY 10027.

As part of our continuing studies of the postembryonic development of the antennal lobes (ALs) in the brain of *Manduca sexta*, we have examined the projections of primary sensory axons and the morphology of central neurons, which normally have arborizations in the glomeruli of the AL, under conditions in which the sensory axons are prevented from reaching their normal target sites or reach them via atypical routes.

Sensory axons from the labial "pit organ" (LPO) project into the subesophageal ganglion (SEG), forming two tracts that bifurcate and project bilaterally to a single glomerulus (LPOG) in each AL [Harrow et al., *Soc. Neurosci. Abstr. 9*:216, 1983]. Antennal sensory axons enter the AL and project to all of the other glomeruli. Our methods of anterograde staining of afferents with cobalt reveal no antennal sensory projections to the LPOG. To examine the intrinsic capacity of sensory fibers to form discrete knots resembling glomeruli, we prevented antennal or LPO axons from reaching the AL by cutting the antennal nerve, removing the brain, or cutting the circumesophageal connectives prior to the ingrowth of adult sensory axons. Antennal fibers formed a neuroma in the head, and axons from the labial palps were restricted to the SEG. To test the ability of sensory axons to seek their normal targets and to examine the specificity of the axons for particular target sites, we redirected antennal or labial axons by severing the antennal nerve or transplanting the anlage of the labial palp to the antennal socket on the head. Antennal axons often entered the brain via an atypical route, and axons from the labial palp entered the brain without traversing their normal tracts in the SEG. Finally, to study the capacity of central neurons to form discrete glomerular arborizations in the AL in the absence of normal sensory inputs, we removed anlagen of the antennae or labial palps prior to metamorphosis.

Our findings show that: (a) afferent axons from the antenna and the LPO form knot-like terminal projections even when prevented from reaching their targets in the AL; (b) sensory axons can reach their target sites in the AL via alternate routes and remain specific for their respective target sites; (c) sensory fibers can project to target sites of their contralateral counterparts if prevented from reaching their normal ipsilateral targets or forced to grow into the contralateral side of the brain; and (d) central neurons deprived of sensory input maintain dense arborizations in "protoglomerular" regions of neuropil in the deafferented AL that correspond to, but are less regular and discrete than, normal glomeruli. Thus we believe that afferent axons and central neurons develop certain characteristic morphological profiles independently of the presence of each other. The development of discrete, fully formed glomeruli in the AL, however, depends upon interactions between sensory axons and central neurons.

267.13 EARLY EVENTS IN THE DEVELOPMENT OF THE ANTENNAL LOBES OF THE BRAIN OF THE MOTH MANDUCA SEXTA. Leslie P. Tolbert. Dept. of Anatomy, Georgetown Univ. School of Medicine, Washington, DC 20007.

The antennal system of the moth Manduca sexta arises and develops during postembryonic development and offers an accessible system in which to study cellular morphogenesis and synaptogenesis. As shown by Sanes and Hildebrand (Dev. Biol. 51:282 & 300), the antennal imaginal disk everts at the onset of metamorphic adult development, and sensory neurons are born. The sensory neurons extend axons to innervate the forming antennal lobes (ALs) of the brain. A previous study of the histological development of the AL and of the maturation of AL synapses during the latter half of adult development (Tolbert et al., J. Neurosci. 3:1158) indicated that many important cellular events occur during the first half of development. The current study focuses on the early development, with the long-term goal of understanding the developmental interactions between the antennal sensory neurons and the neurons and glial cells of the AL.

The mature AL comprises two clusters of AL-neuron cell bodies, and a central area of large, criss-crossing neurites surrounded by an array of dense, compact glomeruli, where the synaptic interactions between antennal sensory axons and AL neurons occur. Glomeruli are separated from each other by almost-complete envelopes of glial processes. On day 2 of the 18 days of metamorphosis, before the earliest antennal sensory axons have reached the AL, the lobe is a mound of light-microscopically homogeneous neuropil, ringed by a tightly packed layer of glial cell bodies and surrounded by cell bodies of AL neurons. As sensory axons begin to reach the AL, the outer region of neuropil becomes dense and compact. A few glial processes begin to infiltrate the condensed neuropil. By day 5, glial cells form irregular septa subdividing the condensed neuropil into regions that by day 6 are light-microscopically identifiable glomeruli. In our earlier study, we had found the first evidence of synapses at day 6; the synapses had small, weakly staining membrane-associated densities and a small number of vesicles in the presynaptic element, and thus looked immature. With improved ultrastructural preservation, I now find clear examples of synapses as early as day 2. The synapses look like mature synapses, with darkly staining membrane-associated densities and hundreds of vesicles in the presynaptic element. Since the synapses appear before the influx of antennal sensory axons, they are presumed to be between AL neurons. I am presently looking at the initial formation as well as the ultimate fate of these synapses in both normal ALs and ALs that are never allowed to receive antennal sensory axons.

These findings indicate that the AL is more highly differentiated at early stages than previously recognized.

267.14 IMMUNOCYTOCHEMICAL REACTIVITY OF NEURONS IN WILD-TYPE AND MUTANT C. ELEGANS TO ANTISERA AGAINST GABA, SEROTONIN, AND CCK. S. McIntire* and R. Horvitz (SPON: E. Wolinsky), Dept. of Biology, MIT, Cambridge, MA 02139.

The nematode Caenorhabditis elegans is unique in that the complete cell lineage from fertilized egg to adult has been determined and found to be essentially invariant among individuals. This organism's small size (1 mm) and rapid life cycle (4 days) have facilitated extensive genetic analyses. Furthermore, the morphology and connectivity of each of the 302 neurons in the adult have been determined from reconstructions from electron micrographs of serial sections. We have identified reactivity of certain neurons in C. elegans to antisera raised against GABA (gamma-aminobutyric acid), 5-HT (serotonin), and CCK(cholecystokinin). We have identified behavioral mutants abnormal in anti-GABA staining patterns; these mutants define eight genes involved in neurotransmitter expression and/or neuronal morphogenesis.

The antibody to GABA stains the ventral and dorsal nerve cords, a series of commissures, and 19 cell bodies of the ventral nervous system. The number and locations of these cells and processes indicate that they are the DD and VD motorneurons. A set of four neurons, possibly the RME motorneurons, located immediately anterior to the nerve ring also stain. Additional putative GABAnergic neurons are present in the heads and tails of both hermaphrodites and males.

The antibody to 5-HT labels the HSN motorneurons, the pharyngeal NSM neurosecretory motorneurons, a set of six male-specific ventral cord motorneurons (either CA3-CA8 or CP3-CP8), as well as other unidentified neurons in the heads of both hermaphrodites and males and the tails of males.

The antibody to the neuroactive peptide CCK labels cells that have been tentatively identified as the hermaphrodite-specific VC motorneurons and the male-specific CA3-CA8 or CP3-CP8 motorneurons. The male-specific CEM sensory neurons as well as several additional unidentified neurons in the head and tail also appear to stain.

By screening existing "uncoordinated" mutant strains for abnormalities in staining patterns with anti-GABA antisera, we have identified eight genes that can affect GABA expression, the positions of GABAnergic cell bodies, and/or the growth of GABAnergic axonal processes.

267.15 LOW TEMPERATURE REVERSIBLE NERVE BLOCK INITIATES CLAW TRANSFORMATION IN ALPHEID SHRIMPS. DeF. Mellon and G. Cox*, Dept. of Biology, Univ. of Virginia, Charlottesville, VA 22901.

Alpheid shrimps (snapping shrimps) exhibit remarkable morphological plasticity in that the asymmetry of the first pair of thoracic legs can be reversed in adult animals (Wilson, E.B., Biol. Bull. 4: 197, 1907; Darby, H.H., Pub. Carnegie Inst. Wash. No. 435: 347, 1934). Assymetry reversal is normally triggered by loss of the larger "snapper" claw, and it involves transformation of the remaining, smaller "pincer" claw into a snapper, and the concomitant regeneration of a new pincer at the site of the original snapper. We have shown previously that transformation of the pincer can also be triggered by severing both nerve trunks in the existing snapper claw (Mellon, DeF., Stephens, P.J., Nature, 272: 246, 1978). This leads to a situation of symmetry, with snapper claws on both sides. We now report that pincer transformation is also triggered by maintaining the snapper claw at ambient temperature below 6°C for a period of 5-6 days. At this temperature, nerve impulse activity is blocked and thus constitutes a possible causative agent in the onset of transformation. We currently lack sufficient data to determine whether, at these ambient temperatures, axoplasmic transport is also blocked.

When both claws are surgically removed at the same time, both regenerates reproduce their original condition. We are now cooling the pincer claw for periods of 5-6 days following snapper removal. The results will indicate whether cold-blocked nerve in an otherwise transforming animal can influence the expression of claw type on the opposite side. These studies will be important in elucidating the trophic mechanism by which peripheral nerve controls claw type in crustaceans.

267.16 MUSCLE FIBER TRANSFORMATION IN SNAPPING SHRIMP:EVIDENCE FOR FIBER DEGENERATION. K.M.Mearow and C.K.Govind, Dept. of Zool., Scarborough Campus, University of Toronto, West Hill, Ontario. M1C 1A4

The dimorphic claws of the adult snapping shrimp (Alpheus sp.) exhibit an interesting plasticity, in that if the major snapper claw is autotomized the remaining minor pincer claw will transform into a snapper. In the pristine state, the pincer closer muscle is composed of a central band of fast fibers sandwiched by slow, while the snapper muscle has all slow fibers. During claw reversal, the pincer fast fibers gradually transform to slow, on the basis of sarcomere length (Stephens and Mellon, 1979, J.Comp.Physiol. 132:97).

We wished to determine the time course of transformation of another muscle fiber property, i.e., the myofibrillar ATPase activity, using enzyme histochemistry. Thus, snapping shrimp were induced to autotomize the major and then at appropriate periods later, the transforming claw was removed and examined histochemically.

Our results suggest that the fast fibers degenerate, rather than change to slow during claw reversal. At several days prior to the first molt after autotomy, there was still a distinct band of fast fibers in the transforming pincer. However, by the second molt, the fast fiber band had completely disappeared, although the space where it had been was still evident. By three molts there was no longer any space left and the muscle was completely slow. The disappearance of the fast fiber band suggested muscle degeneration during the intermolt between the first and second molts. In order to confirm this, the transforming muscle was examined with EM. The central region showed the presence of some rather abnormal appearing fibers. These were in various states of disorganization, ranging from areas with intact short sarcomeres to total loss of fibrillar integrity; phagocytic cells were also seen. These disrupted fibers observed with their attachments to the central tendon were adjacent to normal appearing long sarcomere fibers. Further EM examination of transforming claws is being carried out to determine the time course of the fast fiber loss. However, on the basis of present results, it would appear that fiber degeneration and replacement, rather than fiber transformation, occurs during claw reversal in snapping shrimp.

267.17 ROLE OF NERVE IN DETERMINING CONTRACTILE PROTEIN ISOFORM EXPRESSION IN CRUSTACEAN MUSCLE. M.M. Quigley*, G. Cox* and DeF. Mellon, Jr. Dept. of Biol., University of Virginia, Charlottesville, VA 22901.

Differentiation of muscle fibers into mature fast and slow forms involves selection of appropriate contractile protein isotypes. It is known that in vertebrates nerve activity has a profound effect in determining myofibrillar protein expression. In contrast to most vertebrate muscle, adult crustacean fibers exhibit polyneuronal innervation, often with both phasic and tonic axons supplying a single fiber. How this heterogeneous innervation influences gene expression in its target muscle fiber is not known. The main claw closer muscles ($Cl_1$) of the snapping shrimp, Alpheus, offer a unique system for investigating neural influences in crustacean muscle fibers. The first thoracic legs consist of a large snapper claw and a smaller pincer. The main closer muscle of the snapper is composed entirely of slow fibers, while the pincer $Cl_1$ contains both fast and intermediate fibers. Two exciter and two inhibitor axons distribute terminals in different combinatons to the muscle fiber population in each claw. It has been shown previously that the pincer $Cl_1$ contains a single TnT isoform which can be distinguished from snapper TnT by SDS-polyacrylamide gel electrophoresis. We have used this difference to test the role of nerve in initiation of the quasi-developmental transformation of the pincer claw into a snapper. If claw transformation is hormonally regulated, then it may be expected that the process could occur in the absence of an intact nerve supply to pincer $Cl_1$. To test this idea efferent axons to pincer $Cl_1$ were cut during claw transformation. After two molts TnT isoform expression was assayed in the closer muscles of experimental animals and compared to that of normally transforming animals. The results indicate that an intact nerve supply to the transforming claw is necessary to see a change in TnT expression.

To further investigate the role of nerve in determining isoform expression we have raised monoclonal antibodies against myosin purified from slow muscle (snapper closer). Four antibodies have been identified which show differential reaction with myosin from fast and slow muscles. Characterization with ELISA, a western blotting of high resolution-low percentage acrylamide gels and immunocytochemistry now allow us to conclude that there is a minimum of five MHC isoforms in Alpheus striated muscle. It is our goal to use these highly specific markers to correlate protein isoform expression with the patterns of innervation seen in the claw closer muscles.

267.18 MONOCLONAL ANTIBODIES THAT DISTINGUISH AMONG AXON TERMINALS OF IDENTIFIED MOTOR NEURONS IN THE COCKROACH. J.L. Denburg, R.T. Caldwell*, J.A Morrison*, Biology Deptartment, Univ. of Iowa, Iowa City, IA 52242

In the nervous system of the cockroach, Periplaneta americana there are identified motor neurons that have the ability to selectively reinnervate their target leg muscles following axotomy. It was previously demonstrated that among the set of 6 coxal depressor muscles (CDMs) studied in detail each muscle innervated by different motor neurons could be distinguished by its cell surface glycoproteins. The question addressed in this study is whether there are detectable molecular differences among the identified motor neurons. Hybridoma techniques are ideal for these studies.

Mice were inocculated with thoracic ganglia of adult insects and hybridomas were produced by the usual procedures. Supernatants of hybridoma cultures were screened for monoclonal antibody (MAb) binding to frozen sections of thoracic ganglia and leg muscle. The extensive branching of the motor neuron axon within the muscle and the multi-terminal nature of the innervation ensured that every section through a muscle would contain many neuronal processes.

These procedures enabled the isolation of 28 MAbs that selectively bind to sections of ganglia and to nerve branches within sections of muscle. Most of these MAbs bind with equal intensity to nerve branches in all of the CDMs. However, of particular interest are two MAbs that selectively bind to axon terminals in some of the muscles and not others.

MAb 6E7 binds to axon terminals in only 2 of the 6 CDMs. From the known pattern of innervation of these muscles, this would indicate that these axons are from inhibitory neurons or from the dorsal unpaired median cells which modulate contraction of these muscles. MAb 1216E10 binds to axon terminals only in those 4 of the 6 CDMs that receive innervation from motor neuron $D_S$. The absence of binding of either of these MAbs to neuronal somata makes it difficult to definitively identify the neuron synthesizing the antigen. However, the neuronal location of these antigens is indicated by the loss of MAb binding to sections of muscle that had been maintained in a denervated state for two weeks. The antigens of both MAbs are membrane-bound and their localization can be observed in whole mounts of muscles. This enables the visualization of all the axon terminals in each of the muscles.

These results indicate that there are molecular differences between axon terminals of identified motor neurons that undergo a specific cell recognition process when reinnervating muscles during axonal regeneration. (Funded by NIH grant NS 14295)

267.19 A MUTANT DROSOPHILA MOTOR NEURON: ANATOMY AND REDUCED HRP UPTAKE. D.H. Baird and M.S. Hillis*. Department of Biology, Yale University, New Haven, CT 06511.

We are studying the giant fiber (GF) pathway in mutant and wild-type flies to approach the question of synaptic specificity. We have further characterized a motorneuron of the pathway, the tergotrochanteral ("jump") muscle motor neuron (TTMMN), using HRP. A tungsten needle is dipped in concentrated HRP solution, and inserted through the dorsal insertion of the TTM. The histological procedures used to stain the HRP containing neuron are a modified version of those used by Koto (1983, Ph.D. Thesis, Yale). We concur with Koto's findings, concerning the anatomy within the ganglion, of the wild-type adult TTMMN. Peripherally, the TTMMN enters the muscle at a point about 1/3 of the TTM's length (ventral to dorsal). Before the axon enters, it forks. Both branches extend among the muscle fibers (one dorsally, one ventrally) and bifurcate further. Near the ganglion midline, the medial branch (MB) of the cell usually curves anteriorly overlapping the distal bend of the GF axon. Nomarski optics were used to visualize the GF.

Thomas and Wyman (1984, J. Neurosci. 4:530-538) isolated two non-jumping mutants, pas and ben which disrupt the GF-TTMMN synapse. We find in pas flies that the distal portion of the MB is reduced in length and/or diameter compared to wild-type. This finding is especially interesting considering that the synapse between GF and TTMMN (made by this branch, King and Wyman, 1980, J. Neurocytol. 9:753-770) is physiologically abnormal in pas flies (Thomas and Wyman, 1984). Pas flies carrying a chromosome deficient for the pas locus [Df(pas)] show reduced HRP staining in both the percentage of animals with stained TTMMNs, and the intensity of staining. 50% (n=34) of the flies of the genotype pas/Df(pas) showed the entire TTMMN stained while 92% (n=50) of wild-type TTMMNs stained completely. Because we see even, rather than granular staining, we believe HRP diffuses into this neuron through damaged endings as opposed to uptake in vesicles. It is possible that there is a general reduction in HRP uptake due to reduced numbers or size of neuromuscular endings. This is unlikely because of the normal muscle potentials of the TTM when its motor neuron is directly stimulated. The reduced staining may be due to reduced transport of HRP, either generally or only in the MB. The MB is less darkly stained than the PB in 4 flies carrying two different deficiencies with a small region of overlap in or near the pas locus (near polytene chromosome band 19E5). This observation suggests that reduced tranport in the MB correlates with the absence of a normal GF-TTMMN synapse in flies which may be completely deficient for the pas locus. [Support: NS-07314 to R.J. Wyman]

268.1 CHRONIC CYSTEAMINE ENHANCES ANTAGONIST-INDUCED DOPAMINE RECEPTOR SUPERSENSITIVITY. D.B. Lozovsky, D.C. Jimerson and I.J. Kopin. NINCDS and NIMH, NIH, Bethesda, MD 20205

Some recent studies suggest that enhanced prolactin secretion mediates the development of antagonist-induced dopamine (DA) receptor supersensitivity (Hruska, R.E., et al., Eur. J. Pharmacol. 65: 455, 1980; Life Sci., 30:547, 1982), whereas others have disputed this mechanism (Jenner, P. et al., Eur. J. Pharmacol. 76:31, 1981; Borison, R.L. and Diamond, B.I., Pharmacologist, 21:268, 1978; Gordon, J.H., and Diamond, B.I., J. Neurochem., 42:523, 1984). We have studied the effect of cysteamine - a potent depletor of immunoreactive pituitary and plasma prolactin - on antagonist-induced DA receptor sensitization. Rats were injected with haloperidol (1 mg/kg daily, i.p.) or domperidone (5 mg/kg, twice per day, i.p.) alone or in combination with cysteamine (50 mg/kg, twice per day, i.p.) for 21 days. The effect of cysteamine alone was also studied. Control rats received i.p. injections of vehicles. On the 24th day the rats were decapitated and striata removed and frozen. The number of DA receptors in each striatum was determined by measuring the specific binding of [$^3$H] spiperone (1.2 nm) to striatal membranes. The affinity (Kd) of the binding was calculated from Scatchard plots of the data obtained for pools of striatal membranes. In rats treated with haloperidol or with domperidone, [$^3$H]spiperone binding was significantly increased as compared to controls (31.5 ± 1.5 pmole/g tissue, 29.4 ± 0.8 pmole/g tissue and 25.1 ± 1.0 pmole/g tissue, respectively). Chronic treatment with cysteamine resulted in additional significant increases in the numbers of DA receptors (36.4 ± 0.9 pmole/g tissue and 33.3 ± 1.6 pmole/g tissue for haloperidol - and domperidone-treated rats, respectively). Cysteamine alone had no effect on [$^3$H]spiperone binding in vehicle-treated rats (23.1 ± 2.0 pmole/g tissue). None of the treatments affected Kd of the [$^3$H]spiperone binding. These results provide indirect evidence that prolactin may attenuate drug-induced sensitization of striatal DA receptor, which is consistent with results obtained in hypophysectomized rats by Gordon, J.H. and Diamond, B.I. (J. Neurochem., 42:523, 1984). Other possible mechanisms for the cysteamine effect observed in this preliminary study include an effect on tissue neuroleptic levels or an action mediated through other neuroendocrine alterations, e.g., decrease of somatostatin levels.

268.2 **AMPHETAMINE HAS MULTIPHASIC EFFECTS ON ADENYLATE CYCLASE ACTIVITY IN STRIATAL AND MESOLIMBIC RAT BRAIN REGIONS** J. M. Roberts-Lewis and M.E. Gnegy, Departments of Psychology and Pharmacology, University of Michigan, Ann Arbor, MI, 48109.

Amphetamine has complex, dose-dependent, multiphasic, effects on many measures of behavioral, electrophysiological, and dopaminergic activity. These diverse effects are thought to be partly due to differential actions of amphetamine on striatal and mesolimbic brain regions. In addition, a differential, dose-dependent action of amphetamine via the D1 versus D2 dopamine receptors may account for some of these effects. We have investigated the acute effects of in vivo amphetamine treatment on the D1 dopamine-sensitive adenylate cyclase system, and report here that there are biphasic and regional alterations in adenylate cyclase activity which occur in response to different doses of amphetamine.

Adult, female, Holtzman rats were treated with 1.0, 2.5, 7.5 mg/kg amphetamine, or an equal volume of saline, I.P., 30 minutes prior to decapitation. Crude membrane fractions were prepared for adenylate cyclase assay from homogenates of striatal or mesolimbic (olfactory tubercle plus nucleus accumbens) dissections. Adenylate cyclase activity was measured in response to GTP and the D1 agonist, SKF38393.

Our data indicate that striatal membranes exhibit a small but significant up-regulation of D1 mediated cyclase activity after a low dose of amphetamine (1.0 mg/kg), whereas at higher doses (2.5 or 7.5 mg/kg), a down-regulation of activity is observed. These alterations are evidenced by a 12% increase in Vmax after 1.0 mg/kg amphetamine, compared to a 26% or 16% decrease in Vmax after 2.5 or 7.5 mg/kg, respectively, relative to controls. Mesolimbic brain regions, on the other hand, exhibit a down-regulation of D1-stimulated cyclase activity at all doses of amphetamine, with the maximum response (a 38% decrease in Vmax) occuring after 2.5 mg/kg amphetamine.

These results may be correlated with the multiphasic behavioral, electrophysiological, and biochemical effects of amphetamine that have previously been reported, suggesting a link between the regulation of adenylate cyclase activity and other responses which occur following acute amphetamine treatment.

Supported by NIMH grant 36044-04.

268.3 BEHAVIOURAL AND BIOCHEMICAL ALTERATIONS OF STRIATAL DOPAMINE RECEPTORS FOLLOWING REPEATED L-DOPA ADMINISTRATION IN 6-HYDROXY-DOPAMINE LESIONED RATS. A.Groppetti*, F.Tirone*, C.Flauto*, E.Paratì*, A.Vescovi* and M.Parenti. Dept. of Pharmacol., Univ. of Milan and Inst.Neurol. "C.Besta", Milano, Italy.

It has been reported that prolonged administration of L-dopa can cause behavioural changes reflecting enhanced activity of dopamine (DA) receptors. However, no biochemical correlation which might explain these behavioural alterations was found.

Now we report that L-dopa, given for two weeks to rat bearing a lesion of the nigro-striatal DA fibers, induced behavioural and biochemical changes both indicative of supersensitivity of DA receptors.

The lesions were performed by injecting 6-hydroxydopamine (6-OHDA) monolaterally into the rat substantia nigra. L-dopa was administered twice a day at a dose of 25 mg/kg (plus 2.5 mg/kg carbidopa) for two weeks starting 15 days after 6-OHDA injection. Sixteen hours after last L-dopa treatment rats were tested for apomorphine (0.5 mg/kg s.c.) induced circling behaviour or killed. Adenylate cyclase (AC) was assayed in partially purified striatal membranes. Striatal contents of Met-enkephalin-like immunoreactive material (ME-IR) and substance P (SP) were also measured.

It was found that, as expected, unilateral destruction of the nigro-striatal pathway with 6-OHDA induced controlateral rotations after apomorphine injection and increased sensitivity of AC to DA stimulation.

Treatment with L-dopa did not correct the increased sensitivity of AC to DA induced by 6-OHDA but further enhanced it. Also apomorphine-induced controlateral rotations were strongly potentiated by L-dopa. This effect was antagonized by SCH-23390, a compound reported to be a preferentially inhibitor of $D_1$, receptors. Striatal levels of both ME-IR and SP were altered by L-dopa treatment.

It is suggested that repeated administration of L-dopa to rats with nigro-striatal DA fibers lesioned, can enhance behaviour mediated by apomorphine and function of striatal DA receptors coupled to AC. It may be speculated that alterations of peptidergic modulatory influences are involved in these effects.

268.4 CHANGES IN RAT STRIATAL DOPAMINE-STIMULATED ADENYLATE CYCLASE ACTIVITY FOLLOWING ACUTE AMPHETAMINE ADMINISTRATION. J.V. Barnett* and R. Kuczenski. Tennessee Neuropsychiatric Institute and Dept. of Pharmacology, Vanderbilt University School of Medicine, Nashville, TN 37232

Catecholamine receptors positively coupled to adenylate cyclase have been shown to undergo desensitization following excessive stimulation. Since amphetamine (AMPH) is known to act by releasing dopamine (DA) we chose to examine, for adaptive changes, striatal $D_1$ DA receptors which are positively coupled to adenylate cyclase. Doses of AMPH were chosen for their contrasting behavioral effects: 1 mg/kg which primarily enhances locomotor activity, and 5 mg/kg which promotes intense, focused stereotypies. AMPH or saline was administered subcutaneously 45 minutes prior to sacrifice. Following decapitation the striata were rapidly removed, homogenized and assayed for adenylate cyclase activity by following the conversion of $\alpha^{32}P$ ATP to $^{32}P$ cAMP. A dose of 5 mg/kg AMPH, but not 1 mg/kg AMPH, caused a 2 fold shift to the right in the dose response curve for DA in stimulating adenylate cyclase activity when compared to saline treated animals. Basal activity or guanosine 5'-triphosphate (10-5 M), guanosine 5'-(β-γ-imido)triphosphate (10-5 M), and NaF (10 mM)-stimulated activity did not change. The time course of the apparent AMPH-mediated $D_1$ DA receptor densensitization was next addressed. Groups of animals (n=6) were administered 5 mg/kg AMPH and sacrificed at 0, 25, 90, and 180 minutes post administration. Desensitization was noted at 25 minutes while cyclase activity at 90 and 180 minutes did not differ significantly from the 0 time point. At no time point tested (25, 45, or 60 minutes) did 1 mg/kg AMPH alter DA-stimulated adenylate cyclase activity. Desensitization of the DA-stimulated adenylate cyclase was also observed at a stereotypy producing dose of methylphenidate (MEPH) (50 mg/kg at 40 minutes). These data demonstrate $D_1$ DA receptor desensitization. The lack of change in NaF-stimulated activity is consistent with homologous desensitization as described for other cyclase systems. This desensitization occurs following a stereotypy-producing dose of both AMPH and MEPH. A possible role for $D_1$ DA receptor densensitization in the onset of stereotypy is suggested. 268.5 **EFFECTS OF AN IRREVERSIBLE DOPAMINERGIC LIGAND, FLUPHENAZINE-N-MUSTARD (FNM), ON DOPAMINERGIC BEHAVIOR IN SUPERSENSITIVE MICE.** K. Thermos, J.D. Winkler*, D.B. Goodale* and B. Weiss, Department of Pharmacology, Medical College of Pennsylvania, 3300 Henry Avenue, Philadelphia, PA 19129

FNM irreversibly inhibits [$^3$H]spiroperidol binding to mouse striatal membranes both in vitro and in vivo. In vitro FNM inhibits [$^3$H]spiroperidol binding with an $IC_{50}$ of 80 nM. Preincubating FNM (250 nM) with striatal membranes, followed by extensive washing, reduced the $B_{max}$ of [$^3$H]spiroperidol by approximately 60%, indicating the irreversible nature of this ligand. In vivo administration of FNM ip to mice reduced [$^3$H]spiroperidol binding in a dose-dependent manner with an $ED_{50}$ of 2.5 umole/kg, as determined by the binding of a single concentration of spiroperidol (0.5 nM). To elucidate whether FNM binds irreversibly to [$^3$H]spiroperidol binding sites in vivo, we administered a single dose of 62 umole/kg, ip, to mice. The striatal tissue was removed two hours after injection and extensively washed. Scatchard analysis of [$^3$H]spiroperidol binding (0.1-4 nM) revealed a 50% decrease in $B_{max}$. This agrees with the in vitro evidence for the irreversibility of FNM binding. In order to determine the effects of FNM on dopaminergic function, we examined the ability of FNM administered in vivo to antagonize apomorphine-induced rotational behavior. We used mice with unilateral lesions of the striatum caused by injection of 6-hydroxydopamine using a plastic mold described by Goodale et al., (Soc. Neurosci., 1985). In these animals, acute apomorphine injection caused a consistent rotational behavior, with an $ED_{50}$ of 0.4 umole/kg, sc. FNM was able to block the rotational behavior induced by an injection of apomorphine (1 umole/kg,sc) in a dose related fashion. The $ED_{50}$ for FNM was approximately 0.8 umole/kg, ip; complete blockade occurred at 20 umole/kg, ip. A high dose of FNM (100 umole/kg, ip) completely blocked the apomorphine-induced rotation and reduced the $B_{max}$ of the lesioned striatum by 85%. Administration of a low dose of FNM (1.8 umole/kg, ip), however, caused a 90% reduction in apomorphine-induced rotation with no significant effect on the $B_{max}$ of [$^3$H]spiroperidol binding. This preliminary evidence indicates that the behavioral effects of FNM can be observed at doses that do not appear to alter [$^3$H]spiroperidol binding, suggesting that the blockade of certain dopaminergic behavioral effects by FNM may be explained by its interaction with sites besides spiroperidol binding sites. Accordingly, this irreversibly binding dopaminergic ligand may be a useful probe for identifying proteins involved in dopamine mediated behaviors. Supported by funds from the Department of Public Welfare, Commonwealth of Pennsylvania.

268.6 DECREASED DOPAMINERGIC D-2 BINDING IN THE GLOBUS PALLIDUS OF HYPERPROLACTINEMIC RATS. N.S. PILOTTE, K.A. GREGERSON and D.R. BURT. Depts. Pharmacol. and Physiol., Univ. of Maryland Sch. of Medicine, Baltimore, MD 21201.

Others have reported that striatal dopaminergic D-2 binding sites, evaluated by incubation of membranes with [$^3$H]spiperone in the presence or absence of d(+)butaclamol, slightly increase or do not change in rats made hyperprolactinemic by chronically elevated levels of estradiol or prolactin (PRL). However, spiperone (with butaclamol) occupies serotoninergic S-2 sites in the striatum as well and the presence of these additional sites may obscure differences in binding to D-2 receptors.

Cycling female rats were made hyperprolactinemic by treatment with ovine PRL (oPRL, 4 mg/kg sc, q 8 hr). Treatment was initiated on the morning of diestrus 2 and and rats were decapitated 49 hr after the first injection. Each brain was transected coronally at the anterior aspect of the optic chiasm and the globus pallidus and caudate nucleus were removed separately and homogenized. The washed resuspended membranes were incubated at 37°C with 0.4 nM [$^3$H]spiperone in the presence of absence of $10^{-6}$M d(+)butaclamol or $10^{-7}$M quinazolinedione (R43448) for 30 min. Bound ligand was separated from free by vacuum filtration through Whatman GF/B filters and washed with 12 ml ice-cold 0.15 M NaCl. The number of sites bound in the presence of R43448 was subtracted from those bound in the presence of butaclamol and represented the number of D-2 sites. Two-thirds of the sites labeled by [$^3$H]spiperone in the caudate were dopaminergic and their numbers were similar in rats treated with vehicle or oPRL (273 $\pm$ 42 and 316 $\pm$ 28 fmol/mg protein, respectively). About 50% of the sites labeled by [$^3$H]spiperone in the globus pallidus were dopaminergic in each group. However, treatment with oPRL resulted in a 50% reduction in D-2 sites in the globus pallidus compared to vehicle-treated controls (69 $\pm$ 10 and 132 $\pm$ 39 fmol/mg protein, respectively). These results are suggestive that the dopaminergic sites in the globus pallidus, which comprises about 25% of the striatum, may be hormonally sensitive whereas the remaining caudate is not.

268.7 REGULATION OF STRIATAL D2 DOPAMINE RECEPTORS. H. R. Wagner, M. Traub*, A. Reches, G. Nilaver, E. Alter*, V. Lewis, S. Fahn, E.A. Zimmerman. Depts. of Pharmacology and Neurology, Columbia Univ. Coll. of P. & S., NY, NY 10032.

Dopamine (DA) D2 receptors in rat brain up-regulate following interruption of dopaminergic function. Up-regulation is induced by denervation, transmitter depletion or receptor blockade. The mechanism underlying D2 up-regulation has been assumed to be the same regardless of the method of induction. However recent studies demonstrating haloperidol (HAL)-induced increases in the density of $^3$H-SPIP binding sites in the denervated mesolimbic area (Staunton et al., Nat.,299:72,1982) and striatum (Reches et al., Br. Res.,275:183,1983) challenge this assumption and suggest that denervation and receptor blockade affect D2 receptors through separate mechanisms. We now report that chronic administration (two weeks) of the DA depleting agent, reserpine(RES)(0.25 mg/kg, sc), to rats with unilateral 6-OHDA lesions of the substantia nigra also induces an additive increase in the density of $^3$H-SPIP striatal binding sites. Increases occur at doses of RES producing maximal increases in the density of $^3$H-SPIP binding sites in intact striata. Denervation-induced up-regulation of D2 receptors differs from drug-induced up-regulation. Additivity does not occur in intact rats treated concurrently with RES and HAL (2.0 mg/kg, ip) or with RES and the tyrosine hydroxylase inhibitor, alpha-methylparatyrosine (a-MPT) (75.0 mg/kg, ip). Additive increases in binding in denervated animals receiving RES are not mediated by a RES-induced decrease in striatal DA levels. Doses of RES above those used in our studies (0.25 mg/kg, sc) produce further decreases in striatal DA levels but no increase in the density of $^3$H-SPIP binding sites. Concurrent administration of a-MPT and RES also decreases striatal DA below levels obtained in rats receiving only RES but is without effect on $^3$H-SPIP binding. The latter findings confirm that additivity is not mediated by drug-induced decreases in the amount of residual DA. The data also show that denervation-induced up-regulation of striatal D2 binding sites differs from drug-induced up-regulation. We speculate that the unique effect of denervation on the D2 receptor may reflect the loss of a presynaptic regulatory factor.

268.8 ALTERATIONS IN THE AFFINITY OF [$^3$H]NIMODIPINE BINDING SITES IN THE BRAIN FOLLOWING CHLORPROMAZINE TREATMENT AND SUBSEQUENT WITHDRAWAL. V. Ramkumar* and E.E. El-Fakahany (SPON: G.A. Young). Dept. of Pharmacology and Toxicology, Univ. of Maryland School of Pharmacy, Baltimore, MD 21201.

The following study was undertaken to assess possible alterations at the calcium channel level in the brain following chronic chlorpromazine treatment and subsequent drug withdrawal. Male ICR mice were administered chlorpromazine orally in ground diet mixed with the drug (0.5 mg chlorpromazine/g diet. The estimated drug intake per animal with this dose was 2.5 mg/day. [$^3$H]nimodipine binding studies were performed 1 and 2 months following initiation of drug treatment and 1, 2, and 3 weeks following subsequent withdrawal after a 2 month treatment. For binding studies, brains were homogenized in 40 vol. of 50 mM Tris-Hcl buffer (pH 7.4) and crude synaptosomal membranes were prepared by differential centrifugation. The final pellet was resuspended in buffer to give a 5% homogenate (w/v). Membranes were incubated with 5-8 concentrations of [$^3$H]nimodipine (130.5 Ci/mmol, New England Nuclear, Boston, MA) in a final volume of 1 ml of Tris buffer, with 1 uM nifedipine used to define non-specific binding. Incubations were for 90 min in the dark at room temperature. Samples were then filtered under vacuum through GF/C glass fiber filters and washed 3 times with 3 ml ice-cold Tris buffer. Radioactivity was determined by liquid scintillation spectrophotometry.

Our results indicate significant increases in the affinity constant ($K_a$) of [$^3$H]nimodipine-$Ca^{++}$ channel complex with chlorpromazine treatment compared to age-matched controls. These values averaged 6.35, 10.64 and 15.87 ($nM^{-1}$) for control mice and for those treated with chlorpromazine for 1 and 2 months, respectively. Maximal binding capacity ($B_{max}$) did not show significant changes from control, averaging 185.8, 188.7 and 155.4 (fmol/mg protein) for the respective groups. Upon withdrawal of chlorpromazine a significant decrease in the $K_a$ was observed, without significant alteration in $B_{max}$. Values for $K_a$ averaged 6.67, 1.98 and 7.8 ($nM^{-1}$) following 1, 2 and 3 weeks of withdrawal, respectively, with the corresponding $B_{max}$ values of 182.4, 203.0 and 173.0 (fmol/mg protein). The implications of these findings in terms of the therapeutic and side effects of this neuroleptic drug are not clear at present. Studies presently underway, assessing the effects of chronic treatment with other neuroleptic drugs on [$^3$H]nimodipine binding, may contribute to a better understanding of these preliminary findings. (Supported in part by a grant from Miles Laboratories)

268.9 A ROLE FOR PRESYNAPTIC BLOCKADE IN THE DEVELOPMENT OF A NEUROLETIC INDUCED DOPAMINE RECEPTOR HYPERSENSITIVITY. J.K. Clopton*, W.C. Koller, J.C. Curtin and J.H. Gordon. Dept. of Pharmacology, The Chicago Medical School, N. Chicago, IL 60064 and Hines V.A. Medical Center, Chicago, IL.

Existing data suggest that two benzamide compounds metaclopromide (MET) and sulpiride (SUL) are about equally potent in terms of their ability to block postsynaptic dopamine receptors (i.e. ability to inhibit apomorphine-induced turning behavior or stereotypy). However, MET is 20 times more potent than SUL in blocking dopamine autoreceptor mediated events (i.e. apomorphine-induced hypomotility). Because of this divergence in the relative pre vs postsynaptic blocking potency , it was possible to conduct an experiment to determine what role, if any, presynaptic dopamine autoreceptors would play in the development of a neuroleptic-induced postsynaptic dopamine receptor hypersensitivity.

Male Sprague-Dawley rats received SUL (10 mg/kg/day; N=6), MET (10 mg/kg/day; N=6) or a ratio of the two (SUL/MET= 9/1 or 7/3 mg/kg/day; N=6/group) for 16 days. These experimental groups essentially hold the relative amount of postsynaptic blockade constant while varying the relative amount of presynaptic blockade. Additional groups of animals received 1 or 3 mg/kg/day of MET or 20 mg/kg/day of SUL. All experimental and control groups were tested for apomorphine-induced stereotyped behavior 6 days after the last dose of neuroleptic.

MET at a dose of 10 mg/kg/day induced a postsynaptic dopamine receptor hypersensitivity, while the same dose of SUL had no effect. However, at equal mg doses, MET is 20 times more potent than SUL at blocking dopamine autoreceptors. The results of the relative "presynaptic dopamine receptor blockade" dose response curve illustrated that increasing the level of chronic presynaptic dopamine receptor blockade results in an increased postsynaptic dopamine receptor sensitivity upon withdrawl. Since the level of postsynaptic receptor blockade was held constant it would appear that some level or proportion of presynaptic dopamine autoreceptor blockade is required before the chronic postsynaptic blockade will result in the development of a postsynaptic dopamine receptor hypersensitivity. Interestingly, it is probably the combination of pre- and postsynaptic blockade which produces this response since 3 mg/kg/day of MET alone is not effective but this dose is effective when administered with 7 mg/kg/day of SUL. Overall our preliminary results and data from the literature suggest that a blockade of the dopamine autoreceptors is required before chronic blockade of postsynaptic dopamine receptors will result in the development of a receptor hypersensitivity. Moreover, these data suggest that the presynaptic dopamine autoreceptor may be responsible for the development and maintainance of a neuroleptic-induced dopamine receptor hypersensitivity.

268.10 QUANTITATIVE AUTORADIOGRAPHIC ANALYSIS OF INCREASED [$^3$H]-SPIROPERIDOL BINDING FOLLOWING CHRONIC HALOPERIDOL TREATMENT. C.M. Paden, S. Krueger* and T.C. Rainbow[1]. Dept. of Biology, Montana State Univ., Bozeman, MT 59717 and Dept. of Pharmacology, Univ. of Pennsylvania School of Medicine, Philadelphia, PA 19104.

While the ability of chronic neuroleptic treatment to elevate dopamine (D-2) receptors in the neostriatum has been known for almost a decade (D.R. Burt et al., Science 196: 326, 1977), the limitations of membrane homogenate binding methods have made it impossible to examine this phenomenon in more anatomically discrete brain areas. New techniques in computer-assisted densitometry of film autoradiograms have recently been applied to analysis of increases in neostriatal D-2 receptors following lesions of the substantia nigra (K.A. Neve et al., Brain Res. 302: 9, 1984), indicating the potential of quantitative autoradiography for anatomically precise investigation of receptor plasticity. In order to demonstrate the applicability of this approach to drug induced alterations in D-2 binding, we have performed densitometric equilibrium binding analyses on serial sections of neostriatum from control and neuroleptic treated rats.

Adult male Holtzman rats received either vehicle, 0.5 mg/kg or 10 mg/kg haloperidol sc daily for 3 weeks. Neuroleptic treated animals displayed marked catelepsy shortly after injections. Animals were sacrificed by decapitation 6 days after cessation of drug treatment, and brains were removed and frozen on dry ice for Ultrofilm autoradiography as previously described (T.C. Rainbow et al., J. Neurosci. Methods 5: 127, 1982). Three sets of 12 serial sections were cut at different rostral-caudal levels of the neostriatum. One section of each set was incubated in one of 9 concentrations of $^3$H-spiroperidol (21 Ci/mmole, NEN) ranging from 0.064 to 1.49 nM or in one of 3 concentrations of ligand plus 1 μM + butaclamol. Incubation conditions were as described by J.M. Palacios et al., Brain Res. 213: 277, 1981. Following incubation sections were rinsed, dried and apposed to LKB Ultrofilm (T.C. Rainbow et al., ibid) for 60 days.

Initial Scatchard analyses of the most caudal series of autoradiograms using a computerized video image analysis system (Eye Com II; Spatial Data Systems) revealed that increases in saturable binding of $^3$H-spiroperidol are readily quantifiable on film autoradiograms. Maximum binding in whole striatum was increased 37% and 45% over that of controls in the low and high dose haloperidol groups, respectively. These preliminary findings indicate that computerized densitometry of film autoradioagrams should be useful in quantifying drug induced alterations in dopamine receptor binding in more restricted anatomical areas too small for analysis in homogenate binding assays.

268.11 PROLACTIN ENHANCES THE RATE OF TIME-DEPENDENT DECLINE IN CATELEPSY INDUCED BY IRREVERSIBLE NEOSTRIATAL DOPAMINE RECEPTOR BLOCKADE VIA N-ETHOXYCARBONYL-2-ETHOXY-1,2-DIHYDROQUINOLINE (EEDQ). J.A. Joseph, J. Coupet, *+L. Antonian, C.C. Loullis. Dept. of CNS, Med.Res., Lederle Labs, Pearl River, NY and +Matrix Labs, New York, NY.

Previous experiments have indicated that rats given EEDQ, a potent, irreversible D-2 receptor antagonist), exhibit catalepsy and other behavioral effects indicative of D-2 receptor blockade. In vitro receptor binding assays of striatal membranes from these animals have revealed declines in Bmax of > than 90%. These effects are time-dependent and usually disappear within one week following injection. In the present experiment, attempts were made to determine whether this time course could be altered by prolactin administration. Prolactin has been shown to induce striatal dopamine receptor up-regulation. Thus, the effects of chronic prolactin were examined on the rates of (a) reappearnace of neostriatal D-2 receptors and (b) the declines in catalepsy during the first 48 hours after EEDQ (10 mg/kg) treatment in Wistar rats. Two groups of rats were utilized. They received subcutaneous implants of Alza pumps containing either rat prolactin dissolved in saline (35.2 μg in 220 μl; infusion rate 160 ng/hr) or saline. EEDQ (10 mg/kg i.p.) was administered on day 6 following surgery. Catalepsy was assessed at 4 hrs, 24 hrs and 48 hrs after EEDQ administration by observing the length of time that the animals remained stationary with their forpaws on a horizontal rod and their hindpaws on the floor. Subgroups of saline or prolactin treated animals were sacrificed at the above timepoints and [$^3$H]spiroperidol binding determined in striatal membrane preparations from these animals and non EEDQ injected controls. Results showed that while the prolactin-treated animals exhibited greater catalepsy than saline treated animals at 4 hrs post EEDQ (X Pro 131.2 ± 10.2 sec; N = 11; SAL X 80.9 ± 23.0 sec N = 11). The prolactin treated animals showed greater recovery than saline treated animals (X Pro 11.8 ± 2.2; X sal 23.2 ± 13.9) at 24 hrs following EEDQ treatment. These findings contributed to a significant condition x time interaction in a subsequent analysis of variance ($F(1,20) = 6.1 / < .025$). At 48 hrs post EEDQ these differences were no longer apparent because all animals had recovered. Findings from the preliminary $^3$H spiroperidol binding analyses revealed that the reappearance of $D_2$ receptor binding at these time points paralleled the behavioral recovery (Sal and Pro at 4 hrs $^3$H spiroperidol binding = 0% of control; at 24 hrs Pro = 41% Sal = 20% of control; at 48 hrs 50% and 39% respectively).

268.12 CALCIUM CHANNEL AGONIST-INDUCED MURINE SEIZURES. R.C. Shelton*, J.A. Grebb and W.J. Freed. (SPON: G.N. Ko). Section on Preclinical Neurosciences, Neuropsychiatry Branch, NIMH, Saint Elizabeths Hospital, Washington, D.C. 20032.

Calcium has been implicated in both the pathophysiology of seizures and the mechanism of action of some anticonvulsants. Calcium channel inhibitors (CCI's) and agonists are potential pharmacologic probes of these relationships. We report here that the calcium channel agonist Bay K 8644 induces seizures in mice. We also report the effects of pretreatment with various CCI's and anticonvulsants on Bay K 8644-induced seizures.

**METHODS:** A total of 70 Swiss-Webster mice were used. Bay K 8644 was injected freehand intraventricularly (ICV) into restrained animals (J. Appl. Physiol., 25:319, 1968). Animals were observed for 60 min and seizures were scored for time of onset, duration and severity. Dose response experiments determined that 37.5 μg ICV was the minimum dose producing consistent seizure activity (duration = 19.3 ± 6.4 min (mean ± SEM)). The effects of CCI's and anticonvulsants on seizure activity were assessed by pretreating the animals with intraperitoneal injections of the test drugs 30 min before administering the Bay K 8644.

**RESULTS:** Bay K 8644 produces seizures in mice characterized by recurrent clonic and tonic convulsions sometimes accompanied by rigidity and self mutilation. Four different CCI's were tested for their ability to block Bay K 8644-induced seizures. Nifedipine (50 mg/kg) and verapamil (50 mg/kg) completely blocked the seizures. Diltiazem (50 mg/kg) and nifedipine (5 mg/kg) reduced the duration to 8.0 ± 3.6 min and 9.7 ± 3.7 min, respectively. These drugs also reduced the severity of the seizures. Flunarizine (50 mg/kg) did not affect the seizures. Five conventional anticonvulsants were also tested. Phenytoin (50 mg/kg) and valproate (200 mg/kg) increased the duration of seizures to 54.5 ± .69 min and 50.7 ± 2.0 min, respectively, and also increased the severity of the seizures. Carbamazepine (50 mg/kg), diazepam (5 mg/kg) and pentobarbitol (32.5 mg/kg) did not affect the seizures.

**DISCUSSION:** The most important finding is that Bay K 8644, thought to be a fairly specific calcium channel agonist, induces seizures in mice which lends additional support to studies suggesting a role of brain calcium regulation in seizures. The ability of nifedipine and verapamil to block these seizures supports their being induced by calcium channel agonist activity. CCI's previously have been reported to block metrazol-, 4-aminopyridine-, penicillin-, lesion-, and audiogenic-induced seizures in other murine models. The exacerbation of Bay K 8644-induced seizures by phenytoin is perhaps surprising in view of the report that phenytoin inhibits the binding of nitrendipine to brain memebranes (Ann. Neurol., 16:616, 1984). Further investigations with this model, however, are encouraged by a study showing beneficial clinical results in children with temporal lobe epilepsy when treated with flunarizine (Epilepsia, 25:217, 1984).

268.13 **CALCIUM CHANNEL INHIBITORS PREVENT NEUROLEPTIC-INDUCED APOMORPHINE SUPERSENSITIVITY IN MICE.** J.A. Grebb, R.C. Shelton*, and W.J. Freed. Section on Preclinical Neurosciences, Neuropsychiatry Branch, NIMH, Saint Elizabeths Hospital, Washington, D.C. 20032.

Chronic thioridazine (TDZ) treatment in animals produces less dopaminergic supersensitivity than other neuroleptics. We hypothesized that this difference is due to the potent calcium channel inhibitory effect of TDZ (Am. J. Psychiatry, 141:352, 1984). If this hypothesis were correct, the effects of TDZ would be mimicked by coadministration of calcium channel inhibitory (CCI) drugs with haloperidol (HAL), a neuroleptic without CCI activity.

**METHODS:** Swiss-Webster mice (n=163) were treated chronically (28d) with CCI's (diltiazem, nifedipine or verapamil) in two different doses (high and low) and/or HAL. Powdered CCI was mixed with powdered food, and HAL was administered in the drinking water. Following three days of drug withdrawal, mice were tested for amphetamine (AMPH)-induced locomotion and apomorphine (APO)-induced cage climbing. Data were analyzed by a one-way analysis of variance followed by a Duncan's multiple comparisons test. The null hypothesis was rejected at the .05 level.

**RESULTS:** HAL treatment alone resulted in an APO-induced cage climbing score of 46.3 ± 3.0 (mean ± SEM), and animals that received neither CCI or HAL had a score of 31.5 ± 3.2. Coadministration of high-dose diltiazem or verapamil (but not nifedipine) prevented the development of HAL-induced APO supersensitivity with scores of 22.5 ± 8.8 and 33.6 ± 7.1, respectively, with low-dose diltiazem and verapamil showing a trend in the same direction. Chronic administration of diltiazem without HAL also induced APO supersensitivity (54.0 ± 2.8). Coadministration of CCI's with HAL did not affect the development of HAL-induced AMPH supersensitivity; however, verapamil treatment alone induced AMPH supersensitivity.

**DISCUSSION:** The data support the hypothesis that coadministration of a CCI (verapamil or diltiazem, but not nifedipine) with HAL would mimick the effects of TDZ treatment alone. The differential effects among the CCI's are consistant with the finding that TDZ has diltiazem-like effects on dihydropyridine (e.g., nifedipine) binding on rat myocardial membranes (Biochem. Biophys. Res. Commun., 121:657, 1984), as well as with the hypothesis that diltiazem and verapamil share a common binding site (Proc. Natl. Acad. Sci. U.S.A., 80:860, 1983). The different results for APO and AMPH sensitivity could be explained by hypothesizing that CCI's blocked the spread of dopamine receptors to extra-synaptic regions of the neuronal membrane. The reasons for the diltiazem-induced APO supersensitivity and the verapamil-induced AMPH supersensitivity are unknown, but suggest complex and potentially important interactions between calcium channels and dopaminergic systems.

268.14 SEROTONIN TYPE 2 (S2) RECEPTOR BINDING IN MONKEY AND RAT BRAINS FOLLOWING BASAL FOREBRAIN LESIONS WITH IBOTENIC ACID. G.Wenk,K. Engisch*,L.McCall*T.Aigner,S.Mitchell,R.Struble,D.Price,M.Mishkin and D.Olton. Departments of Psychology and Neuropathology, The Johns Hopkins University, Baltimore, MD 21218 and Laboratory of Neuropsychology, NIMH, Bethesda MD 20205.

In monkeys and rats, the major source of cholinergic (CH) innervation of the neocortex and hippocampus is the nucleus basalis magnocellularis (NBM) and medial septal area (MSA). The death of CH neurons in the NBM and MSA causes reductions in cortical CH markers which correlate with the presence of dementia in humans with Alzheimer's Disease (AD) and with impaired memory in rats with basal forebrain lesions. Serotonin neurons originating in the dorsal and median raphe nuclei modulate NBM CH influence by tonically inhibiting the release of acetylcholine in the cortex and hippocampus. AD patients show a significant decrease of serotonergic receptors, serotonin and 5-HIAA levels in the cortex and hippocampus. We investigated whether the loss of CH afferents to the cortex and hippocampus in monkeys and rats correlates with changes in serotonergic innervation.

Nine male cynomologus macaques (Macaca fascicularis),3-5 kg, were divided into experimental (lesion) and control groups. Lesions of NBM and MSA were made with ibotenic acid. 10 months after surgery, the monkeys were sacrificed and bilateral samples were taken from the hippocampus and 28 cortical areas and assayed for choline acetyltransferase (ChAT) activity and S2 binding. 60 male albino rats (250-300g) were divided into experimental (NBM and MSA lesions) and control groups and sacrificed 4 months after surgery. Rat cortex and hippocampus were assayed for ChAT activity, S2 and QNB receptor binding, high affinity choline uptake (HACU) and endogenous levels of biogenic amines.

In monkeys, cortical ChAT activity decreased and S2 binding increased and were inversely correlated. The hippocampus was an exception to this pattern; ChAT activity decreased and S2 binding did not change. In rats, frontal cortical ChAT activity decreased and S2 receptor sites increased. Hippocampal ChAT decreased and S2 binding did not change. Cortical and hippocampal QNB receptor binding and norepinephrine, dopamine, and serotonin levels were not different from controls. HACU was decreased in both areas. The results suggest that non-cholinergic neurotransmitter systems may respond to the loss of cortical cholinergic afferents. Supported by USAMRDC DAMD-17-C2225, AG05146 and NS20471.

268.15 QUANTITATIVE AUTORADIOGRAPHY OF CHRONIC ANTIDEPRESSANT AND ESTROGEN TREATMENT ON SEROTONIN-2 RECEPTORS IN RAT BRAIN. C. Fischette, Dept. of Pharmacology, Hoffmann-La Roche Inc., Nutley, NJ 07110

Numerous studies using membrane fractions or homogenates of rat brain have indicated that chronic administration of all classes of antidepressant drugs lowers serotonin-2 receptors (S-2) in the forebrain. Estrogen has also been used as an effective antidepressant, and studies in the literature indicate that antidepressant-induced down-regulation of S-2 receptors does not occur in gonadectomized male or female rats unless estrogen is present. While studies using grossly dissected brain regions are valuable, the quantitative autoradiographic technique allows examination of discrete areas of the brain that were previously unavailable for study. Hence, individual nuclei and discrete layers of the cortex can be analyzed.

All groups of male and female rats were gonadectomized for 7 days prior to chronic imipramine treatment. At the time of gonadectomy, subgroups of males and females were implanted subcutaneously with silastic capsules containing 100% crystalline estradiol (1 cm exposed steroid). Imipramine or vehicle was injected i.p. once daily (10 mg/kg/day) for 21 days. Twenty-four hours after the last injection all animals were sacrificed and the brains were prepared for autoradiography of S-2 receptors. Briefly, 32µ sections of rat brain were dried and labelled with 2.0 nM $^3$H-Ketanserin (67 Ci/mmol) ± 1 µM methysergide to assess nonspecific binding. Sections were apposed to LKB Ultrofilm along with tritiated brain mash "standards". Various areas of the CNS were analyzed by computer-assisted densitometry.

As previously described, an intense layering of $^3$H-Ketanserin binding is found in frontal cortex (Fischette, C.T. and Nock, B., Soc. for Neurosci., p. 554, 1984). Middle layers of cortex bind to a great extent while outer and inner layers of cortex are only moderately labelled. Analysis of the frontal cortex indicates that down-regulation of S-2 receptors in response to estrogen + imipramine occurs in all layers, even though receptors are not homogeneously distributed in this area. Data from other relevant limbic nuclei will be presented. Specific localization of action may give us insights into the mechanism of action of antidepressant drugs.

268.16 ANTIDEPRESSANT AGENTS ALTER THE SENSITIVITY OF 5-HT RECEPTORS INVOLVED IN THERMOREGULATION. G.A. Gudelsky, J.I. Koenig, H. Jackman and H.Y. Meltzer, Univ. of Chicago, Dept. of Psychiatry and Ill. State Psychiatric Institute, Chicago, IL.

Treatment of rats with tricyclic antidepressants has been shown to reduce the number of 5-$HT_2$ binding sites without influencing the number of 5-$HT_1$ sites. On the other hand, monoamine oxidase inhibitors (MAOI) have been shown to reduce the number of both 5-$HT_2$ and 5-$HT_1$ receptors. Recently we have proposed that in the rat 5-$HT_2$ receptors mediate 5-HT agonist-induced hyperthermia while 5-$HT_1$ receptors mediate 5-HT agonist-induced hypothermia (Pharm. Biochem. Beh. 22:489, 1985). The present study was undertaken in order to determine whether the responsiveness of 5-HT receptor mechanisms involved in thermoregulation is altered after the administration of antidepressant agents. The hyperthermic response resulting from the activation of 5-$HT_2$ receptors by 6-chloro-2-(1-piperazinyl)-pyrazine (MK-212) was examined in rats 48 hrs after the administration of mianserin (10 mg/kg). Mianserin treatment produced a significant shift to the right in the dose-response relationship for MK-212-induced hyperthermia. The mianserin-induced suppression of the hyperthermic response to MK-212 was dose-related and observed 48 hrs but not 24 or 96 hrs after its administration. Mianserin treatment also diminished the increase in body temperature elicited by 5-methoxy-N,N-dimethyltryptamine (5MeODMT, 3 mg/kg). The hyperthermic response to MK-212 also was diminished 48 hrs after the administration of several other agents known to reduce the number of 5-$HT_2$ receptors, viz., pizotifen (5 mg/kg), loxapine (10 mg/kg) and methysergide (10 mg/kg). In contrast, the 5-$HT_{1A}$ receptor-mediated decrease in body temperature produced by 8-hydroxy-2-(di-n-propylamino) tetralin (8-OH-DPAT) was not altered by mianserin. Treatment of rats with the MAOI nialamide (75 mg/kg), twice daily) for 7 days significantly diminished the 5-$HT_2$ receptor-mediated increase in body temperature produced by 5MeODMT, as well as the 5-$HT_{1A}$ receptor-mediated decrease in body temperature produced by 8-OH-DPAT. The effect of chronic nialamide on MK-212-induced hyperthermia could not be studied because a single injection of nialamide attenuated the response to MK-212. It is concluded that the sensitivity of 5-$HT_2$ and 5-$HT_{1A}$ receptors involved in thermoregulation can be altered by antidepressant drugs in a manner that is consistent with data from radioligand binding studies. Thus, the administration of mianserin, loxapine, pizotifen or methysergide selectively desensitizes 5-$HT_2$ receptor mechanisms involved in hyperthermic responses, whereas nialamide reduces the responsiveness of both these receptors and 5-$HT_{1A}$ receptors involved in hypothermic responses.

Supported, in part, by USPHS MH 30,938.

268.17 COMPARISON OF SEROTONIN AGONIST AND ANTAGONIST EFFECTS ON 5-$HT_2$ BINDING SITES. M. A. Blackshear, L. L. Martin* and E. Sanders-Bush. Department of Pharmacology, Meharry Medical College, Nashville, TN; Neuroscience Res., CIBA-GEIGY Corp., Summit, NJ; and Department of Pharmacology, Vanderbilt University, School of Medicine, Nashville, TN 37208.

Previous studies have shown that acute and chronic administration of the serotonin (5-HT) antagonist, mianserin, decreases $^3$H-spiperone binding to 5-$HT_2$ sites in the frontal cortex (Arch. Pharmacol. 324, 125, 1983). Using $^3$H-ketanserin, a more specific ligand for the 5-$HT_2$ site, the present study confirms that acute mianserin causes a decrease in 5-$HT_2$ sites and further investigates the mechanism of this effect. The in vitro and in vivo effects of mianserin are compared with those of trifluoromethylphenylpiperazine (TFPP), a directly acting 5-HT agonist.

Male Sprague-Dawley rats were administered single doses of 5 mg/kg mianserin or single or repeated doses of 20 mg/kg TFPP. One day after the last injection, 5-$HT_2$ binding sites in the frontal cortex were assayed. Chronic administration of TFPP twice daily for 5 days caused a 48% decrease in the density of 5-$HT_2$ sites (Bmax = 25.7 ± 1.1 vs 13.3 ± 0.6 pmol/g for control and treated rats), with no change in $k_d$ (0.69 ± 0.04 vs 0.79 ± 0.07 nM). The adaptive change in 5-$HT_2$ sites induced by chronic TFPP treatment was similar, both qualitatively and quantitatively, to that caused by chronic mianserin treatment. However, unlike mianserin, which also decreased 5-$HT_2$ sites after a single dose, the effect of TFPP was only evident when given chronically. Mianserin and TFPP had similar in vitro effects on 5-$HT_2$ sites. Preincubation of brain membranes with either 12 nM mianserin or 0.5 uM TFPP induced an increase in the $K_d$ value with no change in the Bmax value.

Similar adaptive changes in 5-$HT_2$ sites after treatment with mianserin, which presumably binds to this site as an antagonist, and after TFPP, which is thought to bind as agonist, is not the predicted response based upon other aminergic systems. It is possible, therefore, that adaptive mechanisms in the serotonergic system differ from those in other aminergic systems or, alternatively, that the drugs used to characterize 5-HT receptor systems should be re-evaluated. (Supported by a NSF fellowship to MAB, NIH Research Grants MH-26463 and MH-34007).

268.18 METHYSERGIDE TREATMENT SELECTIVELY DECREASES SEROTONIN-2 RECEPTORS IN MOUSE CEREBRAL CORTEX. P.C. May, D.G. Morgan, D. Salo* and C.E. Finch. Andrus Gerontology Ctr., USC, Los Angeles, CA 90089.

Serotonin receptor regulation is poorly characterized when compared to the well described supersensitization of dopaminergic and beta-adrenergic receptors in response to chronic receptor blockade or denervation. To assess serotonergic receptor plasticity, young (3 mo) male C57BL/6J mice were treated with methysergide, a serotonin antagonist with central actions at both serotonin-1 (S-1) and serotonin-2 (S-2) receptors. Methysergide (0, 5, 15, 45 mg/kg body weight; n=16/dose) was administered in the drinking water for 21 days. After a 3 day drug free period, mice were sacrificed and cerebral cortex (CX), hippocampus (HC), hypothalamus (HY) and caudate nucleus (CN) were collected and frozen. S-1 binding sites were measured in HC, HY and CX by saturation analysis using 6 concentrations of ($^3$H)5-HT (0.5-16 nM) with non-specific binding estimated with 10 uM methysergide. Assays were conducted under conditions which prevented membrane peroxidation or formation of a low affinity binding site for ($^3$H)5-HT. In addition, S-2 binding sites were measured simultaneously in CX membranes using ($^3$H)-spiperone (0.25-8 nM) with 30 nM prazosin added to all tubes to occlude the alpha-adrenergic site. Ketanserin (500 nM) was used to define non-specific binding. In control animals, S-1 receptor density determined by Scatchard analysis averaged 257 ± 17, 179 ± 4, 120 ± 7 fmoles/mg protein for HC, CX and HY, respectively. Methysergide treatment had no effect on S-1 receptor density or Kd (1.2 ± 0.1 nM). In contrast, methysergide treatment unexpectedly reduced S-2 binding in the CX in a dose-dependent fashion (8%, 21% and 28% decrease for 5, 15, 45 mg/kg methysergide, respectively). The effect was specific for serotonergic S-2 sites since $^3$H-spiperone binding in the CN, which labels primarily D-2 dopamine sites, was unaffected by drug treatment. These results suggest that serotonin receptors behave in a non-classical manner in response to chronic receptor blockade with antagonist or that in vivo, methysergide may have additional pre-synaptic effects on serotonin uptake or release.

This study was supported by an NIA grant to C.E.F. (AG 03230), an NRSA Fellowship to P.C.M.(1 F32 AG 05329) and a Potamkin-Lerner Fellowship to D.G.M.

## NEURAL PLASTICITY IN ADULT ANIMALS III

269.1 GM1 GANGLIOSIDE REVERSES THE BEHAVIORAL DEFICITS FOLLOWING COLCHICINE-INDUCED GRANULE CELL LOSS IN RAT HIPPOCAMPUS. D. F. Emerich*, D. E. Schmechel* and T. J. Walsh* (SPON: R. Fanelli). NIH/NIEHS, Res. Tri. Pk, NC, 27709 and VA Medical Center, Durham, NC.

GM1 ganglioside exerts a trophic effect on damaged peripheral nerves and also promotes recovery of function following various forms of neural insult. The studies presented here examined the effects of GM1 on the behavioral and morphological alterations induced by intradentate injections of colchicine (COL). This treatment selectively destroys granule cells in tbe hippocampus and produces persistent alterations in both cognitive and motor behaviors.

Three days prior to surgery and for 25 days thereafter Fischer rats were injected i.p. with 30 mg/kg GM1 or saline (vehicle). COL (3.5 ug site) or saline was bilaterally injected into the dentate gyrus at two rostrocaudal locations. Rats injected with COL (COL-SAL) were significantly more active than the controls (SAL-SAL) 7, 14, 21 and 30, but not 39, days after surgery. In contrast, the COL group treated with GM1 (COL-GM1) exhibited a transient hyperactivity which was only evident 7 days after surgery. Thus, GM1 enhanced the rate of recovery of normal motor behavior following COL. COL also impaired retention of a passive avoidance response 14 days post treatment. The COL-SAL group had significantly shorter retention latencies 48 hrs following training, while the COL-GM1 group exhibited no deficits in this task. In a final series of studies, the COL-SAL group exhibited altered responsiveness to a variety of psychoactive drugs. They were more sensitive to (a) the motor stimulant effects of apomorphine, and (b) the analgesic effects of morphine. However, they were less sensitive to the motor activating effects of scopolamine. GM1 prevented all of these alterations in pharmacological responsiveness.

After behavioral analysis, rats were perfused with 4 % paraformaldehyde-0.1 % glutaraldehyde for histology. The COL-SAL group showed a loss of granule cells, mild ventricular dilitation, and a decrease of hippocampal volume, with relative preservation of pyramidal neurons in other subfields and basket cells in the dentate gyrus. The neural damage was present, but clearly minimized in the COL-GM1 group.

Thus, the effects of GM1 on COL-induced behavioral and morphological changes might provide a useful model system for studying neurodegenerative disorders and their treatment.

269.2 **PURIFICATION OF A KINASE C SUBSTRATE: BRAIN PHOSPHOPROTEIN F1 AND THE DISCOVERY OF AN ENDOGENOUS KINASE C INHIBITORY FACTOR.** **S.Y. Chan, K. Murakami* and A. Routtenberg. CRESAP Neuroscience Laboratory, Northwestern University, Evanston, Ill. 60201.**

**The *in vitro* phosphorylation of Protein F1 ($M_r$=47kD, pI=4.5) was selectively increased and directly related to synaptic plasticity of long-term potentiation [*Behav Neuro Biol*, (1985), 43, 3-11,]. Recent evidence using crude synaptosomal plasma membranes suggested that phosphorylation of protein F1 was stimulated in a dose-dependent manner by the additon of a partially purified kinase C (PKC) fraction [*Brain Res*, (1985), in press].**

**We have begun protein F1 purification to determine whether F1 is a substrate for protein kinase C under controlled reaction conditions. Protein F1 of high purity was isolated using an osmotically-shocked $P_2$, membrane fraction as starting material. F1 was extracted from the membrane fraction using first pH 11.5, then pH 5.5 buffer. Further purification by hydroxylapatite (HP) column eluted with 30-75mM KPi (pH 7.2), then P-100 gel filtration chromatography, yielded two bands of 67kD and 47kD in silver-stained 10% SDS gels. Isoelectrofocusing (2D gel) showed that the 47kD protein was acidic (pI=4.5), similar to the known physical properties of protein F1 in $P_2$,. This is the first demonstration that a highly purified protein F1 can be phosphorylated by the addition of a highly purified PKC (see Murakami *et al.*; this meeting). This phosphorylation was absolutely dependent on phosphatidylserine (PS, $K_a$=40ug/ml) and $Ca^{2+}$ ($K_a$=50uM). 1,2 diolein reduced the $K_a$ of free $Ca^{2+}$ for F1 phosphorylation by exogenous PKC to 10uM in the presence of PS.**

**During the isolation of protein F1, we have discovered an endogenous inhibitory factor of F1 phosphorylation. This factor could not be precipitated by 80% $(NH_4)_2SO_4$ and its activity was destroyed by trypsin (10ug/ml, 30 min. at 30°C), suggesting that it is a protein. The inhibitory factor has been partially purified using the HP column, eluted with 200-400mM KPi, pH 7.2. A 50% inhibition of F1 phosphorylation by PKC was observed using this fraction (dialysed in 50mM Tris). Similar inhibition of phosphorylation was found when exogenous histone H1 instead of F1 was used as PKC substrate. This inhibitory factor may thus be an endogenous inhibitor of kinase C and could regulate the PKC-F1 dependent synaptic plasticity. (Supported by MH 25281-12 and AFOSR 83-0335 to A.R.).**

269.3 **PHORBOL ESTER, WHICH INDUCES PROTEIN KINASE C (PKC) TRANSLOCATION TO THE MEMBRANE, PREVENTS DECAY OF LONG-TERM POTENTIATION** D. Lovinger*, P. Colley*, D.J. Linden*, K. Murakami*, and A. Routtenberg. Cresap Neurosci. Lab., Northwestern Univ., Evanston, IL 60201.

Long-term potentiation (LTP) in the hippocampal formation induces translocation of PKC activity to the membrane [*Fed Proc* (1985) 44 1421], and increases Protein F1 phosphorylation [*Behav Neural Biol* (1985) 43 3-11] as do phorbol esters and exogenous PKC [Akers et al., *Br Res* (1985) in press]. To test the hypothesis that increased PKC translocation alters LTP we compared potentiation in the hippocampus of the intact rat following local application of phorbol myristate acetate (PMA), a compound which induces PKC translocation [*Nature* (1983) 301 621-623], or 4-alpha phorbol (4AP), an inactive phorbol compound.

In urethane anesthetized rats a stimulating electrode was placed in the perforant path, and a 5-barrelled micropipette for iontophoretic application of PMA or 4AP was placed to record field potentials from the hilus of the dentate gyrus. Following drug application both low (0.2 Hz) and high (two 8 pulse trains at 400 Hz) frequency stimulation were given.

LTP exhibited less decay after PMA than after 4AP; Fig 1 shows that the PMA group retained a greater percentage of inital potentiation of population spike amplitude (SA) 30-60 min after high frequency stimulation than the 4AP group. Application of PMA did not affect responses to low frequency stimulation prior to LTP. Thus PMA alone appears incapable of inducing synaptic plasticity. PMA at 30ng/ml reduced the Ca2+ requirement for activition of purified PKC (see Murakami et al., this meeting) from $K_a$~30uM to $K_a$~2uM. PMA may act synergistically with molecular events induced by high frequency stimulation (eg. elevated intracellular calcium) to activate PKC and promote and prolong synaptic plasticity. (This work was supported by MH 25281-12, and AFOSR83-0335 to A.R).

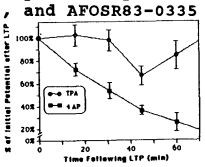

Fig 1. Decay of potentiation was calculated using the formula: (% increase in SA vs. baseline at time x)/(% increase in SA immediately following LTP). Values are means ± SEM. N=6 in both groups.

269.4 **A PHOSPHOPROTEIN (F1) DIRECTLY RELATED TO NEURAL PLASTICITY IN ADULT RAT BRAIN MAY BE IDENTICAL TO A MAJOR GROWTH CONE MEMBRANE PROTEIN (pp46).** R.B. Nelson*, A. Routtenberg, C. Hyman*, K.H. Pfenninger*. (SPON: R. Sekuler) Cresap Neuroscience Laboratory, Northwestern University, Evanston, IL, and Dept. Anatomy and Cell Biology, Columbia University P and S, New York, NY.

Protein F1 and a protein F1 kinase have been implicated in the molecular regulation of neural plasticity: F1 phosphorylation is increased in direct relation to the production of long-term potentiation [LTP; *Behav.Neur.Biol.*(1985)43:3], a physiological model for synaptic plasticity. Concomitantly, activity of a phospholipid/$Ca^{2+}$-dependent protein kinase, which phosphorylates protein F1 (Akers and Routtenberg, *Br.Res.*,in press), is translocated from cytosol to membrane [*Fed.Proc.*(1985)44:1421]. The increase in F1 phosphorylation also accompanies LTP lasting 3 days (Lovinger *et al.*,*Br.Res.*,in press).

Phosphoproteins of nerve growth cones isolated by subcellular fractionation from fetal brain ["growth cone particles"; *Cell*(1983)35:573] have recently been characterized (Katz *et al.*, *J.Neurosci.*,in press). We report here that protein F1 may be identical to pp46, a major membrane-bound growth cone phosphoprotein, on the basis of molecular mass ($M_r$ ~47kD), isoelectric point (~4.4), microheterogeneity, and phosphopeptide maps following limited proteolysis with *S. aureus* V8 protease (fragments of 23kD, 13kD, and 11kD). F1 and pp46 are both phosphorylated by a $Ca^{2+}$/calmodulin-dependent kinase. While F1 phosphorylation is stimulated by phosphatidylserine and phorbol ester (TPA), the phosphorylation of its counterpart in growth cone particles is stimulated by TPA, but by phosphatidylserine only under certain conditions.

Phosphoproteins and their kinases which are enriched in growth cones may be involved in the regulation of neurite growth in brain development. In adult brain, growth of presynaptic terminals has been observed in model systems of neural plasticity [*Science* (1972)176:191]. Thus, the fact that LTP enhances phosphorylation of a protein similar, if not identical, to one characteristically found in growth cones suggests that a common mechanism underlies both normal neurite growth and the generation of LTP. (Supported by MH25281-12 and AFOSR 83-0335 to A.R., NIH NS 21729 to K.H.P., NRS fellowship DA05254 to R.B.N., and an MDA fellowship to C.H.).

269.5 **DIRECT STIMULATION OF PROTEIN KINASE C (PKC): UNSATURATED FATTY ACIDS (OLEATE, ARACHIDONATE) ARE SUFFICIENT.** K. Murakami*, S.Y. Chan, and A. Routtenberg. Cresap Neurosci. Laboratory, Northwestern University, Evanston, IL 60201 (SPON: J.P. Rosenfeld).

Protein F1 (Mr: 47K, pI: 4.5) phosphorylation state is changed by long-term potentiation (LTP; *Behav. Neural Biol.* (1985) 43:3). F1 is a substrate of PKC (*Brain Res.* (1985) in press). LTP in hippocampus induces the translocation of PKC activity from cytosol to membrane, the active site of PKC (*Fed. Proc.* (1985) 44:1421), suggesting an important role for PKC in synaptic plasticity.

It has been shown that diacylglycerol (DAG), containing unsaturated fatty acid (UFA) in the acyl position greatly increases the affinity of PKC for $Ca^{++}$. DAG may be a second messenger for PKC activation. We have examined whether the UFA itself of DAG directly stimulates PKC. PKC was purified to apparent homogeneity (700-1000 fold) by a 4-step LC procedure: 1) DEAE-cellulose 2) AcA34 gel filtration 3) hydroxytapatite and 4) phenyl-sepharose chromatograghy. Homogeneity was confirmed by SDS gelelectophoresis.

Two unsaturated fatty acids were evaluated. Oleic acid ($18:1^{\Delta 9}$) and arachidonic acid ($20:4^{\Delta 5,8,11,14}$) directly stimulated PKC *without phospholipids* in the presence of $Ca^{++}$ at a $K_a$ of 50 uM (oleate) and 53 uM (arachindonate). $V_{max}$ for oleic acid was similar to that for phosphatidylserine (PS). In contrast to UFA, saturated fatty acid like stearic acid did not stimulate PKC. Methyl esters of UFA also had no effect on PKC activation.

PKC may be *phospholipid-sensitive* rather than phospholipid dependent since oleic or arachadonic acid alone was sufficient to activate PKC. One possible mechanism is that phospholipases release UFA from phospholipids and free UFA stimulate PKC translocation/activation directly. This is supported by the fact that oleic acid stimulates protein F1 phosphorylation using a partially purified F1 substrate (see Chan *et al.*, this meeting). Alternatively, an arachidonate and oleate at acyl position in phospholipids are actually involved in the physiological activation of PKC. These new findings suggest a potential role of oleic or arachadonic acid in synaptic plasticity. (Supported by MH 25281-12 and AFOSR 83-0335 to A.R.).

269.6 EFFECTS OF INTRACEREBROVENTRICULAR KAINIC ACID ON THE PERFORANT PATH PROJECTION TO THE RAT FASCIA DENTATA. David R. Armstrong, Debra A. Evenson* and J. Victor Nadler. Dept. Pharmacology, Duke Univ. Med. Ctr., Durham, NC 27710.

Intracerebroventricular (i.c.v.) administration of kainic acid (KA) destroys neurons of the hippocampal CA3-CA4 area, but spares dentate granule cells and cells of origin of the perforant path (PP). A previous study showed that, although PP fibers do not degenerate after bilateral i.c.v. administration of KA, nevertheless the density of PP innervation in the dentate molecular layer is transiently reduced. Dentate granule cells were suggested to shed excitatory innervation in response to destruction of the CA3-CA4 neurons to which they project. The present study was undertaken to determine whether this reversible loss of PP synapses implies a depression of PP-evoked granule cell activation.

Male rats were prepared unilaterally with an indwelling i.c.v. cannula, a bipolar stimulating electrode in the angular bundle and a microdrive mounted on the skull above the hippocampus. After a 2-wk recovery period, a tungsten recording electrode was lowered into the dentate hilus, and "input-output" curves (field EPSP vs. stimulus current and population spike vs. field EPSP) were generated. KA (1.41 nmol) was infused through the cannula and input-output curves were obtained every other day for two weeks. A separate series of animals was similarly infused with KA and prepared for electron microscopy. All subjects treated with KA developed relatively complete lesions of the ipsilateral CA3 area, with variable involvement of the ipsilateral CA4 and minimal cell death in the contralateral hippocampus.

I.c.v. infusion of KA transiently reduced the maximum amplitude of the PP-evoked field EPSP and population spike. Simultaneously, the excitability of the granule cells appeared to have increased, as suggested by a leftward shift of the population spike/EPSP curve with no comparable change in the EPSP/current relationship. These effects were maximal 2 d after the infusion and reversed by day 8. In some rats spontaneous epileptiform discharges were recorded during the postinfusion period, and the occurrence of these ictal events altered evoked synaptic activity.

Electron microscopic studies revealed that unilateral infusion of KA reduced the density of PP innervation in both ipsilateral and contralateral dentate molecular layers. This reduction appeared to be maximal (~25%) 2 d after the infusion and essentially reversed by day 8. Thus the synaptic deficit may account, in part, for transient depression of the maximal electrophysiological response. However, the destruction of target cells does not appear to act as the stimulus for these effects, since KA reduced PP synaptic density bilaterally whereas only ipsilateral granule cells were extensively deprived of their postsynaptic targets. (Supported by NIH grant NS 06233.)

269.7 INVOLVEMENT OF MUSCARINIC CHOLINERGIC RECEPTORS IN KINDLING. V. Westerberg* and M. E. Corcoran. Department of Psychology, University of Victoria, Victoria, B. C., Canada V8W 2Y2.

A previous report (Westerberg & Corcoran, Neurosci. Abstracts, 1983) indicated that the muscarinic cholinergic antagonist scopolamine slowed the rate of amygdaloid kindling in Sprague-Dawley rats. Two experiments were conducted to further investigate this finding.

In the first experiment, two weeks after implantation of electrodes, male Sprague-Dawley rats received application of unilateral amygdaloid stimulation once every 2 days. Some rats received an IP injection of scopolamine hydrobromide (1, 5, 10, or 15 mg/kg) 15 min before each stimulation, and others received 1.5 ml/kg of the distilled water vehicle. If rats failed to develop bilaterally generalized (stage 5) seizures by the cutoff of 16 afterdischarges (ADs) they were given a 14-day rest without stimulation and then rekindled without the drug. Scopolamine slowed the rate of kindling in a dose-related manner with increased doses of scopolamine resulting in increased seizure prophylaxis (control, M=11.78, SEM=1.21; 1mg/kg, M=12.33, SEM=1.34; 5mg/kg, M=20.25, SEM=3.73; 10mg/kg, M=18.22, SEM=2.05; 15mg/kg, M=22.20, SEM=2.85). Of the 36 rats treated with scopolamine, 21 failed to develop past unilateral clonic seizures by the cutoff, and required as many additional drug-free ADs to rekindle (M=11.07, SEM=2.08) as controls required for initial kindling. This suggests that scopolamine can produce a genuine prophylactic effect, in agreement with the findings of Arnold et al., (Exp. Neurol., 1973, 40, 457) with another muscarinic antagonist, atropine. Scopolamine administered to kindled rats did not affect the intensity or duration of previously kindled seizures, indicating that scopolamine does not act like an anticonvulsant.

In the second experiment Sprague-Dawley rats were treated as above except that they were given the distilled water vehicle, 10 mg/kg scopolamine hydrobromide, or 10.36 mg/kg scopolamine methyl bromide, the quaternary derivative of scopolamine that does not easily cross the blood-brain barrier. Scopolamine again slowed seizure development (control, M=10.00, SEM=1.85; scopolamine M=23.87, SEM=4.75; methyl scopolamine, M=15.20, SEM=1.66) compared to both the control and methyl scopolamine-treated rats. Methyl scopolamine-treated rats kindled at the same rate as controls. Methyl scopolamine given to kindled rats did not affect the intensity or duration of established seizures.

The present results support the hypothesis that central cholinergic or cholinoceptive neurons play an important role in the development of kindled seizures, but that once seizures have developed, cholinergic neurons are no longer involved.

269.8 CHANGES IN CENTRAL MONOAMINES AFTER AMYGDALOID KINDLING. J. Lewis*, V. Westerberg* and M. E. Corcoran (SPON: R. Skelton). Department of Psychology, University of Victoria, Victoria, B. C., Canada.

There is considerable evidence that central monoamines (MAs) can modulate the rate of kindling. Some of this evidence is correlative, with some studies finding changes in MAs after kindling and other studies finding no changes. The discrepancies between the different studies may be attributable to variations in biochemical procedures, numbers of seizures evoked, and the intervals between the last seizure and time of sacrifice. We reexamined the question by holding constant the procedures for kindling and postmortem biochemistry while varying the intervals at which rats were killed after the last seizure.

Male hooded rats received bilateral implantation of electrodes into the amygdala. Some rats were stimulated in one amygdala until 3 generalized seizures were kindled; other rats served as yoked controls and received an equal number of nonconvulsant 3-Hz stimulations. Rats were killed by cervical fracture either 2 weeks or 4 weeks after the last seizure. The brains were rapidly dissected over ice, tissue was homogenized and frozen at -196°C, and regional concentrations of MAs (and in some cases major metabolites) were later determined using HPLC with electrochemical detection.

Changes in noradrenaline (NA): We found a small but significant depletion of NA in the ipsilateral frontal cortex at 2 weeks, but this had recovered to normal values at 4 weeks. A small but significant depletion of NA was detected in contralateral hippocampus at 4 weeks; there was no corresponding change in MHPG, a major metabolite of NA. There were no other changes in NA.

Changes in dopamine (DA): There were no significant changes in DA.

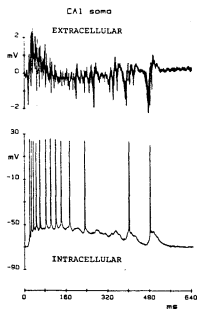
Changes in serotonin (5-HT): There were small but significant depletions of 5-HT in the contralateral hypothalamus and hippocampus at 2 weeks. The hippocampal depletion was accompanied by a comparable decline in 5-HIAA, the major metabolite of 5-HT. These changes were no longer detectable at 4 weeks, whereas a significant depletion of 5-HT was observed in the ipsilateral hippocampus at 4 weeks, accompanied by a nonsignificant increase in 5-HIAA. There was a significant increase in 5-HIAA in the ipsilateral hypothalamus, accompanied by a nonsignificant depletion of 5-HT, at 4 weeks.

We failed to replicate most previous reports of changes in MA concentrations in kindled brain. We did find some changes in MAs or metabolites, but these were not consistent across the 2 intervals. Thus the alterations in MA concentrations produced by kindling do not fall into a simple and readily interpretable pattern.

Supported by MRC and NSERC.

269.9 REDUCED INHIBITION AND EPILEPTIFORM DISCHARGES IN THE IN VITRO HIPPOCAMPUS PRODUCED BY 3-MERCAPTOPROPIONIC ACID (3-MPA). A.Stelzer*, N.T.Slater and G.ten Bruggencate. Physiology Institute, Univ. Munich, Pettenkoferstr. 12, D-8000 Munich 2, W. Germany.

The actions of many convulsant and anticonvulsant agents have been related to their ability to reduce or facilitate GABA-mediated ipsps in the hippocampus and other structures. In the present experiments we have examined the effects of the convulsant agent 3-MPA, a competitive inhibitor of the GABA synthesizing enzyme glutamic acid decarboxylase (GAD), on excitatory and inhibitory postsynaptic potentials in the guinea-pig hippocampal slice. Slices were cut on a vibrating tissue cutter and maintained at 30-33°C in Krebs Ringer of the following composition (mM): NaCl 118, KCl 3, $NaHCO_3$ 25, $NaH_2PO_4$ 1.2, $MgCl_2$ 1, $CaCl_2$ 1.5, D-glucose 11. Intra- and extracellular recordings were made in the CA1 stratum pyramidale of slices in which the CA2/3 subfield was removed by dissection.Evoked responses were produced by stimulation of both stratum radiatum and alveus. The bath application of 1 X $10^{-6}$ to 2 X $10^{-5}$M 3-MPA reversibly induced both orthodromically-evoked and spontaneous (see Fig) epileptiform discharges after exposures of 60-90 min. This concentration of 3-MPA had no significant effect on the population spike and intra- and extracellularly recorded epsp, but produced a complete abolition of both anti- and orthodromically-evoked ipsps.



This reduction of ipsps was not associated with alterations of the reversal potential or membrane conductance. Seizure discharges appeared 20-30 min after the complete blockade of ipsps. Higher doses of 3-MPA (> $10^{-4}$M), however, rapidly and reversibly reduced both epsps and ipsps within 1-2 min of application, and no seizure discharges were observed at these concentrations. The reduction of synaptic potentials in the presence of high doses of 3-MPA was associated with an increase of membrane conductance, but no significant change in membrane potential.

These results therefore demonstrate that GABA-mediated ipsps in the hippocampus can be reduced by a competitive inhibitor of GABA synthesis in a concentration range that closely corresponds to the $K_i$ for in vitro inhibition of GAD (1.8 $\mu M$[1]). Furthermore, these experiments suggest that either a considerable safety factor exists for the inhibitory control of epileptiform discharges, or the convulsant effects of 3-MPA may result from some other action of the drug.

269.10 CHRONIC DESIPRAMINE TREATMENT RETARDS THE DEVELOPMENT OF KINDLED SEIZURES FROM ENTORHINAL CORTEX IN RAT. C. Applegate* and and J.L. Burchfiel (SPON: C.T. Lombroso). The Children's Hospital, Boston, MA 02115.

Norepinephrine (NE) systems have been suggested to play an inhibitory role in the development of kindled seizures. Much of this evidence is derived from depletion studies in which the removal of NE results in a facilitation in the rate of development of generalized seizures. The chronic administration of the NE uptake inhibitor desipramine (DMI) has been shown to result in reductions in both NE beta-receptor numbers and isoproterenol-stimulated adenylate cyclase activity which endure for a period of time following drug withdrawal. We have employed chronic DMI treatment as a means of altering NE system functioning to further examine the role of NE in generalized seizure development during kindling. We predicted that this treatment would decrease beta-receptor functioning and concommitantly facilitate the rate of kindling.

Adult, male, Sprague-Dawley rats were unilaterally implanted with bipolar stimulating electrodes into the entorhinal cortex, in or near the area of the angular bundle. Following recovery, animals received intraperitoneal injections of either DMI (15mg/kg) or saline daily for 7 days. Two days following drug treatment, after-discharge (AD) thresholds were determined and kindling trials were begun. Animals received twice daily electrical stimulation (ISI > 2 hrs.) at suprathreshold (+50 - 100μA) current levels. Rats were stimulated until a minimum of 6 consecutive fully generalized seizures were elicited. It is important to note that animals were never electrically stimulated in the presence of DMI in this experimental design.

Contrary to our expectation, chronic DMI treatment significantly increased the number of stimulations required to elicit the first fully generalized seizure as well as the number of stimulations required to reach our criterion of 6 consecutive generalized seizures (median trials to criterion: DMI=110; saline=45). This effect occurred in the absence of differences in threshold current levels for the elicitation of AD's or AD durations.

These data suggest that the relationship between a down-regulated NE beta-receptor system and the development of kindled seizures is complex and may involve additional adaptive mechanisms.

269.11 KINDLING ANTAGONISM: THE EFFECTS OF NOREPINEPHRINE DEPLETION USING DIFFERENTIAL 6-OHDA REGIMENS. J.L. Burchfiel, R. Konkol* and C. Applegate*. Children's Hospital, Boston MA 02115.

The concurrent, alternate stimulation of limbic system structures can result in a relative or absolute suppression of the expression of fully generalized seizures at one or both of the stimulated sites. This is a phenomenon we have labeled "kindling antagonism" (Burchfiel, et al., Exp. Neurol., 75:479-489 (1982)). We recently have been interested in the mechanism of inhibition of seizure suppression at the antagonized site, and have begun a series of experiments aimed at defining a role for norepinephrine (NE) in the kindling antagonism phenomenon.

Male, Sprague-Dawley rats were administered 6-OHDA in two regimens designed to produce different patterns of brain NE depletion: (1) adult rats were administered 25 ug of 6-OHDA intracisternally 3 times at equally spaced intervals over 7 days, and (2) neonatal rats were administered a single intracisternal injection of 15 ug of 6-OHDA within 24 hrs of birth. Following a 14 day recovery period (regimen 1) or at maturity (regimen 2) rats were implanted with bipolar stimulating electrodes into the septal nucleus and ipsilateral entorhinal cortex and were introduced into the kindling antagonism paradigm. Following kindling, biochemical (HPLC-EC) and histochemical (glyoxylic acid) analyses were performed to assess the effect of the neurotoxin treatments.

Adult 6-OHDA treatment resulted in significant whole brain reductions in NE and almost completely eliminated the development of kindling antagonism. Neonatal treatment also resulted in forebrain reductions in NE, but produced brainstem and cerebellar increases in NE levels and hindbrain neuronal hyperinnervation. In contrast to adult treatment, neonatal treatment left the development of kindling antagonism intact. Neither 6-OHDA regimen altered the threshold for the elicitation of afterdischarges or the afterdischarge duration. In addition, neither regimen produced reductions in striatal dopamine or dopamine metabolite levels.

These results suggest an inhibitory role for NE in the expression of generalized seizures from the suppressed site in this model and further suggest the involvement of pontine, medullary and/or cerebellar circuitry in the kindling antagonism phenomenon.

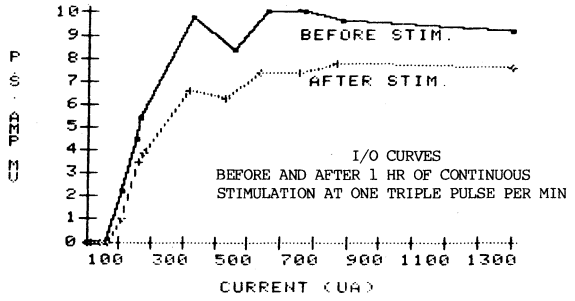
269.12 ALTERATION OF HIPPOCAMPAL DENTATE FIELD POTENTIALS ELICITED BY LOW FREQUENCY STIMULATION. J.B.Wiesner, S.J.Henriksen, and F.E.Bloom, Div. of Preclinical Neuroscience and Endocrinology, Scripps Clinic and Research Foundation, La Jolla, Ca. 92037.

Electrical stimulation of the perforant pathway of the hippocampus elicits complex "field potentials" that can be recorded from the dentate gyrus. As a part of our neuropharmacological analyses of these evoked events we have stimulated this pathway for prolonged periods of time (1-4 hrs) in halothane-anesthetized rats. Field potentials were recorded in the granule cell layer via single-barrel glass micropipets. Stimulation paradigms involved sets of single, double, or triple constant-current pulses continuously delivered to the ipsilateral angular bundle of the perforant path, at intervals ranging from 10 to 60 sec. In accordance with reports by others using both in vivo and in vitro preparations (Brain Res. 110:143,1976 and 151:623,1978), we observed that the initial PS and the subsequent potentiated PS of multi-pulse stimulations varied in amplitude over time, particularly at higher rates of stimulation (i.e. $\geq$0.1 Hz). However, we have also observed significant alterations in evoked PS amplitudes when much slower rates of stimulation were extended over long periods of time. Such alterations of PS amplitude include: (1) long-term decreases; (2) long-term increases; and (3) transient fluctuations of varying duration. Long-term decreases were a predominant effect, and were marked by a decrease of up to 60% in the maximal response in stimulus-response curves (e.g. illustrated below). The lack of stability of PS amplitude, even with very low rates of stimulation, must be an essential consideration in medium- or long-term pharmacological tests in both in vivo and in vitro hippocampal preparations. The bases of these long-term changes are under investigation. (Supported by AA 06420 and DA 03665).



269.13 OLFACTORY BULB KINDLING: EFFECTS ON FIELD POTENTIALS EVOKED IN THE OLFACTORY BULB, PYRIFORM CORTEX, DENTATE GYRUS, AND RETICULAR FORMATION. R. D. Russell and J. S. Stripling. Department of Psychology, University of Arkansas, Fayetteville, AR 72701.

This study investigated the anatomical generality of effects of olfactory bulb (OB) epileptiform afterdischarge (AD) and kindling on OB-stimulated field potentials. Male Long-Evans rats (N=17) were implanted with recording electrodes in the OB, anterior or posterior pyriform cortex (PC, a monosynaptic OB projection site), dentate gyrus (DG, a polysynaptic OB projection site), and reticular formation (RF). Rats received one of the following experimental treatments: 1) daily AD via 50 pulse/sec electrical stimulation of OB (KINDLED group, N=7); 2) daily 1 pulse/sec stimulation (SHAM group, N=5); or 3) daily acclimation to the recording chamber (nonstimulated CONTROL group, N=5). Evoked potentials (EPs) were collected from the KINDLED and SHAM subjects immediately preceding each experimental treatment and from all subjects 3 and 10 days following the last treatment.

Kindling differentially affected late components of the EPs in the OB and DG. For example, in the OB a persistent increase in a late and long duration (> 60 msec) negative wave was associated with kindling whereas an earlier positive wave was unaffected. In the DG, kindling was associated with a large (> 400%) and persistent increase in a late positive wave (30-45 msec latency) whereas an earlier positive wave (15-25 msec latency) and later negative wave were unaffected. Although quantitative differences in the PC potential were evident between anterior and posterior sites, kindling's effects were relatively homogeneous across these placements. These effects, consistent with those reported earlier (Russell and Stripling, Soc. Neurosci. Abstr. 10: 187, 1984; Brain Res., in press), included an interesting pattern of changes in the population EPSP component of the EP. Early in kindling, the population EPSP in the PC was increased in amplitude whereas it declined to baseline levels later in kindling development. In the RF, kindling was associated with an asymptotic 400% increase in the amplitude of a long-latency negative component.

In summary, OB kindling is associated with anatomically extensive plasticity which is indicative of altered responsiveness in numerous sites to synchronous activation of the OB. Some of these effects (e.g., the component-specific effect in the DG) are difficult to explain solely as a result of enhanced excitability of OB mitral cells.

269.14 BENZODIAZEPINE ANTAGONISTS AND THE AMYGDALOID KINDLED SEIZURE IN RATS. T.E. Albertson and W.F. Walby*. Dept. of Internal Medicine, Univ. of Calif., Davis, CA 95616.

The anticonvulsant effectiveness of the benzodiazepine antagonists RO15-1788 (RO), CGS-8216 (CGS), and PK-11195 (PK) disolved in DMSO were evaluated against threshold and suprathreshold stimulation in previously amygdaloid kindled male Sprague-Dawley rats. Using a double injection paradigm, the effectiveness of these three antagonists to reverse the anticonvulsant properties of 3mg/kg of diazepam were also studied in this model. Pretreatment with RO (3, 10, and 30mg/kg) reduced, though not statistically significant, the afterdischarge duration (80.5% control) and the seizure rank (3.8 compared to control of 5) at the highest dose tested after suprathreshold stimulation. Pretreatment with either CGS (3, 10, and 30mg/kg) or PK (10 and 60mg/kg) failed to consistently modify either elicited afterdischarge durations or seizure ranks. Afterdischarge thresholds were also not consistently modified by pretreatment with either of the three antagonists.

In the double injection paradigm, 3mg/kg diazepam significantly reduced both elicited afterdischarge duration and seizure rank when injected 15 minutes before or after a second injection of control DMSO (0.25cc/kg) before suprathreshold stimulation (30 minutes from first injection to stimulation). When either CGS (10mg/kg) or RO (10mg/kg) were given 15 minutes before 3mg/kg diazepam prior to stimulation, the anticonvulsant properties of diazepam were blocked. When CGS (10mg/kg) and PK (10mg/kg) were given 15 minutes after 3mg/kg diazepam, the anticonvulsant effectiveness of diazepam was not blocked. However, RO (10mg) given 15 minutes after diazepam (3mg/kg) effectively blocked the anticonvulsant properties of diazepam. Increasing the dose of PK to 60mg/kg 15 minutes after diazepam failed to block the anticonvulsant effectiveness of 3mg/kg diazepam. When 10mg/kg of CGS was given less than 10 minutes after diazepam or if the interval was held at 15 minutes after diazepam but the dose was increased to 30mg/kg of CGS, the anticonvulsant effectiveness of diazepam was blocked. Together, these data point to the lack of significant anticonvulsant effectiveness of these three benzodiazepine antagonists in the fully kindled amygdaloid model of epilepsy in the rat. Both RO and CGS have demonstrated the ability to reverse the anticonvulsant effectiveness of diazepam when given before or after diazepam dosing as long as appropriate dose and dosing intervals of CGS are used. High doses of PK failed to reverse the anticonvulsant effectiveness of diazepam when tested after diazepam dosing in this model. (Supported in part by BRS-2507RR 05684-16)

269.15 THE ASYMPTOTIC LIMITS OF LONG-TERM POTENTIATION/DEPRESSION ARE INDEPENDENTLY CONTROLLED. H.S.LOPEZ*, B.BURGER & W.B LEVY (SPON: M.Merickel).Dept. Neurosurgery, Univ. of Va. C'ville, VA 22908.

An algebraic description of synaptic modification consistent with our work at the entorhinal cortex-dentate gyrus (EC-DG) synapses is $m_i = e \cdot f(y) \cdot (x_i - cm_i)$. e represents the contribution of nonspecific inputs; f(y) refers to an integrative postsynaptic event specific at least on a cell by cell basis and probably specific to a postsynaptic dendritic domain; and $(x_i - cm_i)$ provides the specificity that allows individual modification of individual synapses. $(x_i - cm_i)$ also controls the asymptotic limits of potentiation and depression when $e \cdot f(y)$ is non-zero. The data here agree with this formulation and emphasize the individuality of synaptic modification, particularly the individuality of the asymptotic limits of synaptic modification.

The experiments resemble (1) except for tetrodotoxin injections into the EC to reduce spontaneous activity. Stimulating electrodes were placed in the angular bundles (AB). Field potentials (pEPSP) were monitored in the DG on both sides, recording a contralateral and ipsilateral pEPSP for each AB stimulation. 9 rats received 2 distinct conditioning periods (CPs) separated by a 15' test period. In both CPs, conditioning consisted of 30 trains of 8 pulses @400Hz (1 train/145s). These bilateral trains were asynchronous with the train to one AB (trailing AB) coming 3 ms after the train to the other AB (leading AB). In CP2 the asynchrony was reversed with the leading AB becoming the trailing. One hour of testing followed CP2. All test stimuli are single unilateral pulses.

With either CP the leading contralateral potentiates and the trailing one depresses, i.e. a contralateral afferent synapse potentiates and then depresses, or vice versa, over the 2 CPs. Important here are results after CP2 since both ipsilateral responses were taken to asymptotic potentiation by CP1 (after CP1, the ipsilateral pEPSP increased 63% of its preconditioning value while only 15% after CP2). After CP2 the pEPSP of the CP2-leading contralateral increased 97% of its prior value while the CP2-trailing contralateral decreased to 31% of its prior value.

Thus, by driving ipsilateral afferents to asymptotic potentiation, contralateral potentiation and depression are shown to be independent of either converging or collateral ipsilateral changes. Further, both contralateral potentiation and depression are independent of converging and collateral effects in the sense that they are not subject to the process that produces asymptotic limitations upon either group of ipsilateral afferents. These results agree with an algebraic formulation in which individual synapses are individually modifiable and the parenthetical "presynaptic term" $[(x_i - cm_i)]$ controls asymptotic changes on a synapse by synapse basis. 269.16 THE DEVELOPMENT AND DECAY OF KINDLING-INDUCED INCREASES IN PAIRED-PULSE DEPRESSION IN THE DENTATE GYRUS. M. deJonge* and R.J. Racine, Department of Psychology, McMaster University, Hamilton, Ontario, Canada L8S 4K1.

Inhibition in the hippocampal dentate gyrus (DG) of the rat has been shown to increase as a result of kindling, possibly due to an increase in benzodiazepine (Bz) receptors (Tuff et al., Brain Res. (277)1983(79). The kindling-induced increase in Bz receptors appears to be inversely related to time since the last stimulation, so it is expected that the increase in inhibition also decays over time. The present study investigated the time course, for both development and decay, of the increase in inhibition due to kindling. Rats were kindled in either the DG or in the perforant path, the main afferent pathway to the dentate gyrus. Animals in the control group received no kindling stimulation but were treated identically otherwise. Paired-pulse (P-P) and input/output (IO) measures (of responses evoked in the DG by pulses applied to the perforant path) were taken 24 hrs after the 1st epileptiform after discharge (AD) and 24 hrs after every 9 ADs (3 ADs were triggered each day, 3 hrs apart) until a Stage 5 seizure occurred. The same measures were taken again 24 hrs after the 1st and 4th Stage 5 seizure and 3, 7, 14, and 28 days after the 4th Stage 5 seizure. IO curves revealed that the population spike of the perforant path-kindled animals was potentiated at the higher intensities and depressed at the lower intensities, while DG-kindled animals showed a decrease in spike height over the whole IO curve. Spike height was back to baseline 4 weeks post kindling. Population EPSP (slope) measures in both groups were increased as a result of kindling and continued to rise during the 2 weeks after kindling was terminated. Four weeks after kindling, however, the slope measures had values similar to those observed on the day kindling was terminated. An increase in the early inhibitory component (20-50 msec), as measured by the population spike depression in the P-P experiments, was apparent after the 1st AD. After the 10th AD the late inhibitory component (200-1000 msec) was also increased. No further increase in inhibition was observed after AD 19. The increase in the late inhibitory component decayed back to baseline within 2-4 weeks post kindling while the increase in the early inhibitory component was still apparent 4 weeks post kindling. These results suggest that either the early inhibitory component increases in strength and duration, presumably due to an increase in Bz receptors, or both the early and late components potentiate and decay through independent processes as a result of kindling. In the latter case a biochemical process underlying the changes in the late component needs to be identified. A change in the GABAb receptor system is one possibility.

269.17 KINDLING INDUCES EPILEPTIFORM DISCHARGES AND A PROGRESSIVE ENHANCEMENT OF LONG-TERM POTENTIATION IN THE IN VITRO HIPPOCAMPUS. N.T.Slater, A.Stelzer* and M.Galvan*. Physiology Institute, Univ. of Munich, Pettenkoferstr. 12, D-8000 Munich 2, W.Germany.

It has been proposed that the long-term potentiation (LTP) produced by tetani of hippocampal pathways may underlie the development of epileptogenesis in the kindling model of epilepsy (see McNamara et al., Prog. Neurobiol., 15:139,1980). We have explored this hypothesis using the in vitro hippocampal slice. Guinea-pig hippocampal slices were cut with a vibrating tissue cutter and maintained at 28-32°C in Krebs Ringer of the following composition (mM): NaCl 118, KCl 3, $NaHCO_3$ 25, $NaH_2PO_4$ 1.2, $MgCl_2$ 1, $CaCl_2$ 1.5, D-glucose 11. Stimuli were applied to the stratum radiatum and evoked responses recorded intra- and extracellularly in the CA1 stratum pyramidale. At 30-32°C, repeated tetani (10-20V, 50Hz, 2s delivered 5x at 0.1Hz every 30 min) produced a progressive shift to the left of the relation between stimulus intensity and evoked postsynaptic potential, and a small increase in the maximum evoked population spike. No change in the presynaptic volley was noted. After 4-6 kindling tetani, both spontaneous and stimulus-induced epileptiform discharges appeared, which together with the enhanced orthodromic response, persisted for at least 6 hr. The development of seizure discharges, but not the enhancement of excitability, was suppressed at 28°C. Neither LTP nor the development of seizure discharges were observed when slices were kindled in the presence of the NMDA receptor antagonist ± APV (100μM), which alone had no effect on field potentials. Kindling could then be induced as in control slices after washing out APV. The application of APV to slices already kindled by 4-6 tetani did not abolish the enhanced orthodromically-evoked early potentials, but did reversibly reduce both late extracellularly-recorded afterdischarges and the intracellularly-recorded depolarizing afterpotential.

In the presence of raised Ca (2mM) and Mg (2mM), LTP was observed after the first tetanus, but no further increases of excitability nor epileptiform discharges were induced by subsequent tetani. The progressive enhancement of excitability and the development of epileptiform discharges were also observed in slices in which the CA2/3 subfield was removed by dissection, suggesting that kindling of the CA1 was not dependent on the influence of the CA2/3 'pacemaker' subfield. Measurements of membrane resistance revealed either no significant alteration, or increases following kindling, and no significant alterations of spike accomodation or after-hyperpolarizations were observed.

These results provide support for the hypothesis that repeated kindling-like tetani produce an enhancement of NMDA receptor mediated LTP which may serve as the trigger for the genesis of epileptiform discharges in the CA1 hippocampal subfield.
(Supported by Sonderforschungsbereich 220; Teilprojekt B2).

270.1 Gangliosides GM1 and GD1b ARE ANTIGENS FOR IgM M-PROTEINS IN MOTOR NEURON DISEASE. L. Freddo*, N. Latov* Columbia U., N.Y.,N.Y. 10032, R.K. Yu, Yale U., New Haven, CT.06510, P.D. Donofrio*, H.S. Greenberg*, J.W. Albers*, A.G. Alessi*, A. Leavitt*, G. Davar*, D. Keren*, U. of Michigan, Ann Arbor, MI 48103. (SPON: E.A. Zimmerman)

In patients with plasma cell dyscrasia there may be naturally occurring monoclonal antibodies or M-proteins that have autoantibody activity and cause autoimmune disease. In patients with demyelinating neuropathy and IgM M-proteins for example, the M-proteins bind to a carbohydrate determinant that is shared by MAG and by other glycoproteins and glycolipids in peripheral nerve, and they may cause the neuropathy. We recently studied a patient who resented with lower motor neuron disease and an IgM-lambda M-protein, and found that the M-protein binds to antigens in the central and peripheral nervous system.

Binding of the M-proteins to gangliosides prepared from human spinal cord or cauda equina was examined by immunostaining after separating the gangliosides on high performance thin layer chromatography plates (HPTLC). The plates were coated with polyisobutylmethacrylate in n-hexane, and immunostained with the patient's serum followed by peroxidase-conjugated antibody to human IgM and 3,3'-diaminobenzidine. The IgM immunostained two ganglioside bands in both central and peripheral nerve extracts, which co-migrated with GM1 and GD1b. Immunostaining was specific for the lambda light chain, the same as the M-protein light chain type. Incubation with liposomes containing GD1b or GM1 selectively absorbed the M-protein from the patient's serum, and the serum IgM also immunostained purified GM1 and GD1b on HPTLC plates. Binding of serum IgM to GM1 and GD1b was also tested by ELISA. Microwells were coated with the purified gangliosides, and IgM binding was detected using peroxidase-conjugated antibodies to human IgM and o-phenylenediamine as substrate. Binding of serum IgM to GM1 and GD1b was detectable at seum dilutions of greater than 1:10,000. Control sera, including from patients with IgM M-proteins and neuropathy or normal subjects did not bind to the same glycolipids.

The data suggest that the IgM M-protein in the patient's serum binds to a determinant shared by the gangliosides GM1 and GD1b. The role of the M-protein in causing the lower motor neuron disease is not yet known, but it might bind to one of the gangliosides or to a glycoprotein sharing the same determinant in motor neurons or their axons, and cause neuronal dysfunction and disease.

270.2 THE IMMUNOCYTOCHEMICAL LOCALIZATION OF FUNGI IN THE BRAIN OF AIDS PATIENTS. F. J. Denaro, Dept. of Neuropathology, H-720, UCSD Medical Center, 225 Dickinson Street, San Diego, Cal. 92103

AIDS patients are susceptible to a number of opportunistic infections (OI). Fungal infections figure predominantly among these and are a significant cause of morbidity. The CDC's projected death total for the AIDS epidemic is staggering. Yet, at this time there is no treatment for AIDS. For some time to come, the only course of action is to treat the life threatening OIs. Because an AIDS patient may suffer from many different OIs, and particularly because many of the drugs used to treat such OIs may have adverse side effects; precise diagnosis of the OI is paramount.

The microscopic examination of a buccal smear is sufficient to determine thrush. However, identification of a systemic fungal infection is more difficult. The unique identification of a fungus is not yet possible by serological or immunological means. This is in part due to the complexity of the fungal antigens.(Axelsen, N.H.,Scand. J. Immunol 5,177,1976). Biopsy material is often examined for the suspected pathogen. With this method one may culture or examine the tissue microscopically. Cultures can take time and also the possiblity of retrospective studies are limited. Microscopic examination can be diagnostic, but it also presents a number of pit falls depending on the histologic stains used. For example: The H&E stain and the Fibrin (Weigert)-Gram stains do not stain all fungal elements. If one uses the PAS, one may overlook small fungal cells. The Mucicarmine stain will stain cryptococcus but not other fungi. The GMS is excellent, but it is more involved than the PAP or ABC methods. It would be advantageous to have an immunocytochemical stain for the screening of fungus and for other immunocytochemical studies.

In this study an antibody to Candida albicans (DAKO,#B143) was tested for its immunocytochemical staining ability. This antibody has been used for quantitative immunoelectrophoresis (Axelsen, N.H.,Scand. J. Immunol 5,177,1976) but not immunocytochemistry. It was found that this antibody does indeed stain for Candida as well as staining a number of other fungi. CDC test tissue stained positively for Histoplasma and cryptococcus. Also, one of our controls for Blastomyces stained. This cross-reactivity will be discussed.

In the immunological staining of postmortem brain tissue, candida was found in a number of cortical locations. What appears to be cryptococcus was found in the striatum,cortex and cerebellum.

Acknowledgements: I thank DAKO for the immunocytochemicals and the CDC for test tissues.

270.3 THE BLOOD: BRAIN BARRIER (BBB) IN MURINE HERPES SIMPLEX VIRUS (HSV) MYELITIS: EFFECT OF HIGH DOSE $CO_2$ ON ILLNESS R. R. McKendall, W. Woo*, T. A. Kent*, Depts. of Neurology and Microbiology, University of Texas Medical Branch, Galveston, Texas 77550.

Our earlier observation that systemic antibody administration effectively reduced HSV titers in footpad but not CNS sites of infection suggested that the BBB may prevent antibody access to the CNS during the first several days after infection. To determine if increased BBB permeability would reduce the illness rate, we treated mice with antibody and high dose $CO_2$, which has been shown to reversably increase the blood: brain barrier permeability to large molecules. Preliminary work indicated that mice were able to survive 12% $CO_2$ for 1.5 hours several times a day.

Male, 4 week old mice, n=50, were infected with HSV in the footpad and divided into the following treatment groups: a) No treatment, n=10, b) 0.5cc 1:64 titer anti HSV antibody i.p. 3.5 days after infection, n=10, c) 12% $CO_2$ for 1.5 hours, 3 times per day, n=10, and d) both antibody and $CO_2$, n=10. Illness rates were assessed twice daily. In addition, two groups of 5 mice each were studied for the effect of $CO_2$ on the BBB to protein. Albumin was conjugated with Na-Flourescein and injected via a tail vein 3.5 days after HSV innoculation in both groups. In the first group, CSF and blood were obtained 2 hours later. The second group was treated with 12% $CO_2$ for 1.5 hours and CSF and blood obtained after a 2 hour circulation time.

Illness rates can be seen in Table 1. $CO_2$ reduced the illness rates. Prior treatment with antibody did not further reduce this rate. Flourescence spectrophotometric analysis of the matched CSF and blood samples indicated that $CO_2$ increased the CSF/plasma ratio by 23%.

These preliminary results indicate that high dose $CO_2$ reduced the illness rates in this mouse model of HSV myelitis. Since the presence of high titer antibody did not potentiate $CO_2$, the positive effect of $CO_2$ may not be due to increased brain levels of antibody, but may be due to either: a) increased brain levels of other immune substances, or b) direct effects of $CO_2$ on immune function or virus survival.

Table 1. Number Ill divided by Number Inoculated

| Group | No $CO_2$ | $CO_2$ |
|---|---|---|
| HSV | 6/10 | 1/10 |
| HSV + Anti HSV Ab | 5/10 | 3/10 |
| TOTALS | 11/20 | 4/20[a] |

(a) $P<.05$ vs Non-$CO_2$ treated, chi-square

270.4 LIPID CONTENT OF SWINE INFLUENZA AND OTHER VACCINES. S.W. Brostoff*, E.L. Hogan, S. Dasgupta*, J.-L. Chien*, R.E. Erwin* and K.C. Leskawa* (SPON: J. Zemp). Department of Neurology, The Medical University of South Carolina, Charleston, SC 29425

An extensive immunization program conducted in the United States in 1976 to reduce the threat of an influenza epidemic caused by a swine flu strain is reported to have been associated with an increased incidence of Guillain-Barre syndrome (GBS). To search for a causative agent, experimental allergic neuritis (EAN) has been used as an animal model, since it shares many features of GBS. There have been many studies on the roles of lipids, either alone or in combination with protein, in causing experimental demyelinating diseases. Among these are galactosylcerebroside (GalCer), gangliosides and phosphatidylserine (PS). A qualitative and quantitative study was undertaken in order to assess whether a difference in the presence of these and other lipids could be associated in a meaningful way with swine flu vaccines. Six lots of swine flu vaccines (from different manufacturers) were compared to other influenza vaccines and non-influenza vaccines (Hepatitis; Rubella; and Diphtheria, Tetanus and Purtussis).

Cholesterol content varied from 3.0 to 44.0 ug/ml vaccine, but no major differences were found between the different types of vaccines. Cholesterol esters were not detected in any of the samples, and the non-influenza vaccines had a higher content of monoglycerides.

Total phospholipid content varied from 0.012 to 0.101 umole Pi/ml vaccine, and again major differences between types were not observed. Influenza vaccines roughly paralleled normal human plasma, in terms of individual phospholipids, with phosphatidylcholine, sphingomyelin and phosphatidic acid being the major phospholipids. Appreciable amounts of phosphatidylethanolamine were found in only one swine flu vaccine. PS was not detected in any swine flu vaccines, but was present in other flu vaccines, suggesting that PS-protein complexes do not play a role in the occurence of GBS.

Similarly, this study does not support the concept that gangliosides are involved in eliciting GBS, since only two of the six swine flu vaccines showed trace amounts of ganglioside (less than 0.5 ug/ml vaccine) and all three of the non-swine flu vaccines contained ganglioside (GM3 in all cases). GalCer was found in substantial quantities in swine flu vaccines, and was absent or present in trace amounts in the non-influenza vaccines. GalCer was also found in the other influenza vaccines (non-swine flu). With the knowledge that anti-GalCer serum causes demyelination under experimental conditions, the presence of this compound in commercial vaccines does warrant further attention.

Supported in part by NIH grant NS11867.

270.5 MONOCLONAL ANTIBODIES AGAINST DIHYDROLIPOAMIDE REDUCTASE [NAD+] (LAD). E. Brownridge*, R.A.P. Kark, P. Weisz-Carrington*, and M. Beene*. From the Depts. of Neurology and Pathology, VAMC and LSUMC School of Medicine, Shreveport, LA 71130.

The mitochondrial enzyme dihydrolipoamide reductase [NAD+] (lipoamide dehydrogenase, LAD, EC 1.6.4.3) is a part of the pyruvate dehydrogenase complex. Abnormalities of LAD have been associated with several inherited diseases of the brain. It is questioned whether the enzyme changes are primary or secondary. Precise, specific antibodies could help to answer this question. To seek monoclonal anti-LAD antibodies, 5 mice were hyperimmunized with purified pig-heart LAD (Sigma). Four produced antisera. Spleen cells from two were fused with non-secreting murine myeloma cells (P3X63-AG8.653) using polyethylene glycol. About $3x10^5$ spleen-cells were placed in each of 576 culture wells and grown for two weeks in hypoxanthine-aminopterine-thymidine medium with murine peritoneal "feeder" cells. Aliquots of supernatants from each well were examined by enzyme-linked immunoabsorbance assay (ELISA) for anti-LAD activity in an assay with sequential layers of hybridoma supernatant, LAD, and rabbit polyclonal anti-LAD IgG (purified by immunoabsorbance on an LAD-Sepharose column) which was tagged with horse-radish peroxidase (HRP). The ELISA was specific for the injected purified LAD, which has been used by others to study the amino acid sequence and three-dimensional structure of the enzyme. Cells from positive wells were cloned by limiting dilution and grown in the presence of feeder cells. Production of monoclonal anti-LAD was assessed by ELISA with LAD, monoclonal hybridoma supernatant, and HRP-tagged anti-mouse IgG, a more sensitive but equally specific reaction. We isolated 23 clones. As these appear to differ in avidity for LAD, they may represent several distinct clones.

270.6 RNA VIRUS INFECTIONS OF MOUSE SENSORY NEURONS IN CULTURE. R.J.Ziegler and E.K.Stauffer Univ. of Minn. Medical School, Duluth, MN. 55812 and D.R.Carrigan Univ. of Maryland Medical School, Baltimore, MD. 21201

Several RNA viruses are known to be neurotrophic. Some of these viruses like rabies are cytolytic to neurons, while other viruses like subacute sclerosing panencephalitis (SSPE) virus are non-cytolytic to neurons. We exposed two different types of NIH Swiss mouse dorsal root ganglia (DRG) cell cultures to four RNA viruses in order to determine if non-cytolytic viral replication or viral antigen synthesis occured. Cultures displaying either of these phenomenon were examined for changes in evoked action potentials (EVAPs).

DRGs were removed from 13-day mouse fetuses and dissociated cultures of 1) purified sensory neurons or 2) glia and sensory neurons were prepared. One to two week old cultures were exposed to either mumps virus (Kilhim strain), measles virus (Edmonston strain), SSPE virus (Mantooth strain), or ecotrophic murine leukemia virus (Lake Casitis strain) and viral replication monitored at various times post-infection (pi) by standard plaque assay or the XC assay for the Lake Casitis virus. Cultures not producing infectious virus were examined for the synthesis of specific viral antigens by the indirect immuno-fluorescent technique.

Mumps virus actively replicated in the sensory neurons and caused changes in the waveform of EVAPs. Measles virus replicated at low levels in cultures infected for three days or three weeks, although the number of neurons synthesizing measles antigens increased from 1% to 50% during this time period. Some measles virus-induced changes in EVAPs were observed. SSPE virus did not replicate, produce viral antigens, or change EVAPs during a three week infection period. Neurons exposed to Lake Casitis virus gave ambiguous results. More virus was detected at later times pi, but viral envelope glycoprotein antigen was not detected in these purified neuron cultures. Similer cultures observed at three to four weeks pi contained many large multi-nucleated neurons which also contained no envelope antigen. Large numbers of glial cells which did contain antigen reappeared in the older cultures. EVAPs from the multinucleated neurons appeared normal. The multinucleated neurons may be caused by fusion from without due to the virus produced by the glial cells in the cultures. Futher investigations of the phenomenom are in progress.

270.7 EXPERIMENTAL ALLERGIC ENCEPHALOMYELITIS (EAE) IN RATS: SEVERITY OF PERIPHERAL NEURITIS CAUSED BY VARIOUS NEURAL ANTIGENS. A. M. Kelahan and M. J. Buckley*. Dept. of Neurology, Northwest. Univ. Sch. Med., Chicago, IL 60611.

EAE is an experimental form of inflammatory demyelination which results from the innoculation of a host organism, typically a rodent, with a neural antigen from a non-host species, along with an immune system potentiating adjuvant. Because the resultant pathology compares favorably to that known to occur in multiple sclerosis (MS), and because of similar immune system involvement, EAE has been regarded for years as a prime animal model of MS. However a commonly reported feature of clinical EAE in rats is peripheral neuritis, which is not known to occur in pure MS. The purpose of this study was to compare the degree of peripheral neuritis caused by the exposure of rats to one of several types of neural antigens.

The neural antigens utilized were: a) whole guinea pig spinal cord myelin basic protein (MBP); b) a synthetic encephalitogenic peptide (amino acid chain 68-84 of guinea pig spinal cord MBP); c) lymph node cells (LNC) isolated from rats previously affected with EAE and then cultured with MBP; and d) MBP-cultured LNC (as in c above) followed within 10 days by guinea pig spinal cord MBP. Sensitization was accomplished via intradermal innoculations of the hind foot pads (a and b), intravenous injections (c) or both routes of administration (d). At various times during acute clinical stages and recovery, compound motor action potentials (CAP) evoked by electrical stimulation were recorded from the caudal nerve-muscle complex. Recordings were made at normal tail temperature and during heating (14-15 $^0$C above normal) and cooling of the tail. The presence and degree of peripheral neuritis in EAE-diseased rats was defined by changes in CAP propagation velocity, amplitude and initial latency as compared to similar recordings in normal rats.

In all cases of EAE sensitised rats, significant differences in measured CAP parameters were observed only in those rats exhibiting clinical signs of motor deficits; rats which had recovered from clinical EAE were not different from normal. Of the four different neural antigen groups, rats innoculated with the synthetic peptide displayed the least involvement of peripheral nerves, as indicated by normal appearing CAPs. In the other neural antigen groups, amplitude was the most significantly affected CAP parameter: a) amplitudes at normal tail temperature tended to be reduced in size and b) amplitude decreased much faster during tail heating as compared to normal. In some rats the heat lability of CAP amplitude was so profound as to reach, and maintain, a zero level during most of the recording session; lowered blocking temperature for transmission of electrical activity has been previously defined as a hallmark indicator of peripheral nerve pathology. Other CAP parameters were only sporadically different from normal in EAE-diseased rats and were not considered as good of indicators of peripheral nerve condition as CAP amplitude.

The results of these studies demonstrate that a) EAE can occur as a relatively pure CNS disorder and b) a major encephalitogenic role of MBP may reside in a specific peptide chain of whole MBP.

270.8 THE EFFECTS OF STEROIDS AND NON-STEROIDAL ANTI-INFLAMMATORY AGENTS ON VASCULAR PERMEABILITY IN THE C6 SPHEROID IMPLANTATION GLIOMA MODEL. H. Reichman*, C. L. Farrell*, R. F. Del Maestro* (SPON: M. Rathbone). Brain Research Laboratory, Victoria Hospital, London, Ontario, N6A 4G5

Cerebral edema associated with intracranial tumours is a consequence of breakdown of the normal permeability conditions of the blood brain barrier (BBB). The intracerebral spheroid implantation technique is a good model for primary brain tumours in that it has many features that mimic the growth and behaviour of primary intracranial tumours in humans. Tumour growth and vascular permeability have been characterized in this model. Edema was localized using fluorescein-conjugated antibodies to serum albumin. We have used Evans Blue (EB) as a marker to quantitate the leakage of serum constituents from tumour vessels, and have also quantified the ultrastructural features associated with the BBB in vessels in and around the tumour. Steroid therapy with methylprednisolone and dexamethasone significantly decreased vessel permeability as has been demonstrated in other experimental models and in humans. Because these parameters have been defined and quantified, this is an excellent model for assessment of new clinical therapies on edema formation. There are complications associated with long term steroid therapy. We used this model to examine the effects of two non-steroidal anti-inflammatory agents, indomethacin and ibuprofen, on edema-associated EB leakage in this model. Indomethacin significantly reduced EB leakage whereas the effect of ibuprofen requires further investigation. This suggests that non-steroidal anti-inflammatory agents may be a possible alternative to steroid therapy of patients with brain tumours.

271.1 DETECTION OF A NEURITE PROMOTING FACTOR WITH SOME SIMILARITY TO NERVE GROWTH FACTOR IN CONDITIONED MEDIA FROM RAT PRIMARY SCHWANN CELLS AND ASTROGLIA. J. Assouline*, E. P. Bosch*, R. Lim, R. Jensen* and N. J. Pantazis. Depts. of Anatomy and Neurology, Univ. of Iowa Medical College, Iowa City, IA 52242.

For unexplained reasons, numerous types of cells in culture, synthesize nerve growth factor (NGF) and secrete it into their feeding medium (conditioned medium). We investigated the possibility that primary Schwann cells and astroglia cells synthesize NGF. Primary Schwann cell cultures were established from newborn rat sciatic nerve. Fibroblasts were eliminated by both cytosine arabinoside treatment and an immunoabsorption technique. Indirect immunofluorescence for RAN 1 (specific for Schwann cells) and Thy 1.1 (for fibroblasts) revealed that the cultures contained 95-99% Schwann cells. Astroglia cells were established from 18d fetal rat brain. Indirect immunofluorescence revealed >90% astroglia (positive for glial fibrillary acidic protein), 8% thy 1.1 positive fibroblasts and <2% galactocerebroside positive oligodendrocytes. To obtain conditioned medium (CM), the established cells were grown to confluence in serum containing medium and then were switched to a serum-free defined medium (N2). After 2-4d, the CM was collected and processed for study.

Four methods were used to detect NGF in the CM: 1. β-NGF specific radioimmunoassay (NGF-RIA) using an antibody to mouse β-NGF; 2. β-NGF radioreceptor assay (NGF-RRA) using the NGF receptor from rat pheochromocytoma cells (PC12); 3. Bioassay on chick embryo, dorsal root ganglia (DRG); 4. Bioassay on PC12 cells. The NGF-RIA detected low levels of β-NGF (14-68 pg/ml), whereas the NGF-RRA detected 10-25 fold more NGF. Since the receptor used in the NGF-RRA is derived from rat cells, this assay may be more specific for rat NGF than the NGF-RIA. In the DRG bioassay, extensive neurite outgrowth was observed for both Schwann cell and astroglia cell CM. Similar outgrowth was seen with these samples in the PC12 cell bioassay. Antibody to mouse β-NGF did not inhibit this outgrowth in either bioassay.

In conclusion, several results, including positive NGF bioassays and detection of NGF by RIA and RRA, suggest that NGF is present in both Schwann and astroglia cell CM. Since the Schwann and astroglia cells were derived from the rat, the inability of mouse β-NGF antibody to inhibit neurite outgrowth may be due to species differences in NGF. These cells may produce a novel neurite promoting factor(s) which shares the biological activity of NGF and binds to its receptor, but possesses different antigenic determinants. Further characterization is underway. (Supported by NIH grant GM28644 to N.J.P. and NSF grant BNS-8308341 and NCI grant CA31896 to R.L.).

271.2 NGF-LIKE IMMUNOREACTIVITY IN THE CENTRAL AND PERIPHERAL NERVOUS SYSTEM OF THE FETAL RAT. Å. Seiger,* C. Ayer-LeLievre,* T. Ebendal,*[1] and L. Olson* (SPON: Å. Seiger, Member ENA). Dept. of Histology, Karolinska Institute, Stockholm, Sweden, and [1]Dept. of Zoology, Uppsala Univ., Uppsala, Sweden.

The regional distribution of nerve growth factor-like immunoreactivity is described in 15-17-day rat fetuses based on immunohistochemistry using affinity-purified polyclonal antibodies against mouse submaxillary gland nerve growth factor (NGF). In CNS, immunoreactivity was seen along neural pathways, such as dorsal and ventral fascicles in the spinal cord, fascicles in formatio reticularis, commissura posterior, fasciculus retroflexus and stria terminalis. These fluorescent pathways did not show discernable individual immunoreactive nerve fibers. Positive receptor nerve cells were seen in the immature olfactory mucosa and, at fetal day 17, weakly fluorescent retinal ganglion cells were found. Afferent fiber bundles from these receptor cells contained strongly positive individual nerve fibers. Fiber bundles could be followed from retina through the optic stalk to the chiasm. Numerous strongly positive fiber fascicles were seen to converge from the olfactory mucosa and enter the olfactory bulb ventromedially. Along the dorsal surface of cerebral cortex and tectum from 15-day fetuses a system of fibrous structures appeared neuronal and varicose on longitudinal sections.

In cerebral cortex of 17-day fetuses, the superficial zone was negative, whereas material in the intermediate zone interspersed between the differentiating neurons and growing axons was strongly positive. In many peripheral sensory and autonomic ganglia the neuronal perikarya were negative but surrounded by fascicles of NGF-positive fibers. Both proximal and distal roots were strongly positive as were peripheral branches of nerve bundles in many areas, including dermis, tongue and salivary glands. We conclude that immunohistochemistry using affinity purified antibodies to NGF reveals a widespread distribution of a NGF-like material in many areas of the central and peripheral nervous system of the prenatal rat. The specificity and implications of the observations for brain growth will be discussed, particularly in relation to recent reports about the presence of messenger RNA for NGF in the mammalian brain.

271.3 SYNTHESIS OF A NERVE GROWTH FACTOR-LIKE MOLECULE BY RAT PHEOCHROMOCYTOMA CELLS IN CULTURE. I. Kim* and N.J. Pantazis. Dept. of Anatomy, Univ. of Iowa Medical College, Iowa City, IA 52242.

The PC12 cell line, cloned from a rat adrenal pheochromocytoma (Greene, L.A. and Tischler, A.S., Proc. Natl. Acad. Sci. USA, 73:2424, 1976), has been used to study the mechanism of action of nerve growth factor, NGF. In the presence of NGF, the PC12 cells will extend processes (neurites) similar to those seen when embryonic sensory and sympathetic neurons are cultured with NGF. Unlike embryonic sensory and sympathetic neurons, it is thought that the PC12 cells do not require NGF for survival. However, various types of cells in culture, including fibroblast, muscle and glia, synthesize NGF and secrete it, thereby conditioning their feeding medium. We investigated the possibility that PC12 cells have NGF in their conditioned medium.

PC12 cells, a gift from Dr. Lloyd Greene, were initially grown in RPMI-medium containing 5% fetal calf serum and 10% horse serum. In these conditions, the great majority of cells did not attach to the flask but grew in suspension. With time, increasing numbers of cells attached. At this point, the cells were divided into floating cells (PC12F) and attached cells (PC12A). To obtain conditioned media (CM), both PC12F and PC12A cells were grown to high density with serum containing medium and then were switched to a serum-free defined medium (N2).

Three methods were used to test for NGF in the concentrated CM from PC12F and PC12A cells: (1) β-NGF specific radioimmunoassay (NGF-RIA) using an antibody prepared against mouse β-NGF; (2) β-NGF radioreceptor assay (NGF-RRA) using NGF receptors on PC12F cells; (3) NGF bioassay using the PC12F cells which respond to NGF. Both NGF-RIA and NGF-RRA detected an NGF-like molecule in the concentrated CM from both the PC12F and PC12A cells. When the samples were tested in the NGF biological assay, the PC12A CM stimulated extensive fiber outgrowth, whereas the PC12F CM produced marginal fiber outgrowth. Polyclonal antibody against mouse β-NGF did not inhibit neurite outgrowth.

In conclusion, NGF-RIA and NGF-RRA suggest that an NGF-like molecule is present in PC12F and PC12A CM. This result is supported, in the case of PC12A CM, by NGF bioassay where a positive neurite outgrowth was observed. Anti-NGF antibody did not inhibit the fiber outgrowth. This may be due to species differences in NGF since the antibody was raised against mouse β-NGF while the PC12 cells are derived from rat. Further biochemical characterization of the NGF-like molecule produced by PC12 cells will determine its similarity to mouse NGF. There are numerous autocrine systems described for various growth factors. Whether or not this NGF-like molecule produced by PC12 cells can act on PC12 cells in an autocrine fashion is unknown. (Supported by NIH grant GM28644 to N.J.P.).

271.4 ENTORHINAL LESIONS RESULT IN INCREASED NEURITE-PROMOTING ACTIVITY IN MEDIUM CONDITIONED BY HIPPOCAMPAL SLICES. K.A. Crutcher and F. Collins, Dept. of Anatomy, University of Utah School of Medicine, Salt Lake City, Utah 84132.

Medial septal lesions result in increased levels of NGF-like activity in medium conditioned by exposure to hippocampal slices (Collins and Crutcher, this volume). In order to determine whether removal of other hippocampal afferent fibers would also affect such neurite-promoting activity we made unilateral electrolytic lesions of the entorhinal cortex in four adult female albino rats and unilateral injections of kainic acid (.4ug) into the hippocampal formation of four additional rats. Entorhinal lesions have been shown to result in extensive denervation of the ipsilateral dentate granule cells. Kainic acid injections result in destruction of hippocampal pyramidal cells with subsequent degeneration of contralateral (commissural) inputs to the granule cells. Slices (dentate-CA3) were prepared from the ipsilateral (entorhinal animals) and contralateral (kainic acid animals) hippocampal formation one week after the lesion and placed in culture medium for two days. Slices from control (unlesioned) animals were treated in the same way. The conditioned medium was then assayed for its effect on neurite outgrowth from explanted 9-day old chick lumbar sympathetic ganglia.

Entorhinal lesions resulted in increased neurite-promoting activity of the medium conditioned by hippocampal slices ipsilateral to the lesion when compared to medium conditioned by control slices or by slices contralateral to kainic acid injections. Preliminary results indicate that the increased neurite-promoting activity following entorhinal lesions is blocked by antibodies to NGF. These results suggest that removal of the entorhinal, but not the commissural, input to the dentate granule cells results in increased neurite-promoting activity in medium conditioned by exposure to slices of the dentate gyrus-CA3 region. A similar increase in growth activity is obtained following medial septal lesions and has been proposed to correlate with the sympathetic sprouting response observed in vivo (Collins and Crutcher, this volume). Entorhinal lesions do not result in sympathetic sprouting but do elicit proliferation of septohippocampal terminals. Commissural denervation does not evoke sprouting of either system. As a working hypothesis, we propose that the increased growth activity observed following entorhinal lesions correlates with the septo-hippocampal sprouting response. If the activity turns out to be related to NGF, this would be consistent with results obtained by other investigators demonstrating effects of NGF on septohippocampal neurons. Supported by NIH grant #NS17131.

271.5 NGF-LIKE ACTIVITY IN THE RAT HIPPOCAMPAL FORMATION: REGIONAL DISTRIBUTION AND INCREASE AFTER MEDIAL SEPTAL LESION. F. Collins and K. A. Crutcher Dept. of Anatomy, Univ. of Utah Sch. of Med., Salt Lake City, UT 84132

Sympathetic axons from nearby blood vessels grow into the hippocampal formation following a medial septal lesion that destroys the septal input to the hippocampal formation. This invasion of sympathetic axons is analogous to that observed when nerve growth factor (NGF) is injected directly into regions of the CNS. This analogy suggested that sympathetic ingrowth may result from increased NGF-like activity in the hippocampal formation after a medial septal lesion. Sympathetic ingrowth is densest in the dentate gyrus-CA3 region of the hippocampal formation, with little or no growth into the CA1 region. One would, therefore, expect the dentate-CA3 region to have the highest concentration of the putative NGF-like activity. Our experimental results support the hypothesis that there is NGF-like activity in the rat hippocampal formation, whose distribution and concentration is correlated with sympathetic sprouting after septal denervation.

Conditioned medium, prepared from slices of the dentate-CA3 and CA1 regions of the hippocampal formation, was assayed for its ability to increase neurite growth from embryonic chick sympathetic ganglia in culture. Some rats were given prior denervating medial septal, or various nondenervating control, lesions. Conditioned medium from the dentate-CA3 region contained approximately 2 fold more activity than from the CA1 region. Activity in conditioned medium from both regions of the hippocampal formation increased 1.5-2 fold within 1 week after medial septal, but not control, lesions. In conditioned medium from the dentate-CA3 region, this elevation in activity was observed even when the medial septal lesion had been given as long as 24 weeks earlier. In addition, the neurite stimulating activity in hippocampal conditioned medium was blocked by a specific, affinity purified antibody to mouse submaxillary gland NGF. These results indicate that: 1) Conditioned medium from the adult rat hippocampal formation contains an activity which is able to stimulate sympathetic neurite growth and is antigenically related to NGF. 2) The increase in this activity after a medial septal lesion and its differential distribution within the hippocampal formation correspond to the induction and pattern of sympathetic sprouting, respectively. Experiments directed at understanding the effect of other denervating lesions are described in a companion abstract (Crutcher and Collins, this volume). Supported by NIH Grant #NS 17131.

271.6 GLIAL FACTORS IN THE BRAIN. T. Amano. Dept. of Neuroscience, Lab. of Neurochemistry, Mitsubishi-Kasei Institute of Life Sciences, 11 Minamiooya, Machida-shi, Tokyo 194, Japan

Monoclonal antibodies to 2.5 S nerve growth factor (swiss webster) were produced by in vitro immunization in which BALB/C mouse spleen cells were fused with P3U1 myeloma cells. Three kinds of monoclonal antibodies were obtained. 1) Monoclonal antibodies which recognize antigenic determinants in astrocytes in the mouse and rat brain. 2) Monoclonal antibodies which recognize antigenic sites in neurons. 3) Monoclonal antibodies which had no localization in the brain. The first two groups had no biological activities which inhibit neurite outgrowth of spinal ganglion of 8-day-chick embryo. The third group had biological activities. Western blottings of extract of submaxillary glands of C57BL/6j mouse revealed exactly the same localization bands on nitrocellulose with 38,000 and 60,000 in molecular weight as with polyclonal anti-NGF. In purified preparations of NGF from mouse submaxillary gland, immunoblottings revealed one band with 14,000 in molecular weight. The third group of hybridomas which had quite similar properties to polyclonal anti-NGF, revealed clear localization in astrocytes in the brain after the stab wound in the cortex. In other experiments using secreted proteins from C6Bu1 rat glioma cells in serum-free culture for 48 hours as antigens, one of the hybridomas recognized both astrocytes and neurons in the brain. Western blottings showed quite similar pattern to monoclonal antibodies to NGF in two dimensional electrophoresis. Together with these results, we conclude that neurotrophic factor in the brain may exist in astrocytes and may be related to nerve growth factor.

271.7 **SYNERGISM BETWEEN NGF AND LAMININ IN PROMOTING SURVIVAL AND NEURITE OUTGROWTH FROM PURIFIED SENSORY NEURONS IN LOW DENSITY CULTURE.** A.I. Millaruelo*, M. Nieto-Sampedro and C.W. Cotman. Department of Psychobiology, University of California, Irvine, CA 92717.

Nerve growth factor (NGF) is known to promote survival and neurite outgrowth from explanted sensory and sympathetic ganglia in culture[1]. However, in the absence of non-neuronal cells a relatively small percentage of sensory or sympathetic neurons survive in the presence of NGF[2,3], and very few of these cells exhibit neurite outgrowth. The survival and outgrowth of neurites from sympathetic neurons in response to NGF is potentiated by the basement membrane protein laminin[3]. The present work evaluates the role of laminin, NGF and extracts of normal and injured rat brain in the survival and outgrowth of neurites from sensory neurons.

Chick embryo dorsal root ganglion (DRG) neurons, freed (90%) from non-neuronal cells, were cultured at low density (3500 cells/cm$^2$) in medium containing 10% fetal calf serum on a polylysine substrate. Under these conditions, only 5% survived for 48 h, and none put out neurites (determined at 4 h and 48 h). If the medium was supplemented with NGF (up to 50 μg/ml), survival increased to a maximum of 33% of the neurons seeded but only 18% of them bore neurites. Treatment of the growth substrate with laminin (10 μg/ml, 2 h) by itself did not increase survival, although the few surviving neurons had neurites at 48 h. The simultaneous presence of NGF and laminin dramatically enhanced (to 100% of the neurons seeded) both survival and neurite initiation and outgrowth of purified DRG neurons. Thus, endogenous laminin secreted by non-neuronal cells may play a role not only in the enhancement of neurite outgrowth from sensory neurons in response to NGF[4], but also in the survival of these neurons.

NGF and laminin also acted synergistically to promote neurite outgrowth from purified ciliary ganglion neurons. However, survival of these cells seemed to require additional neurotrophic support.

Extracts of normal and injured adult rat brain contained NGF-like survival-promoting and neurite-promoting factors for DRG neurons. The percentage of neurons with neurites increased from 31% to 75% when cultured on laminin-treated vs. untreated polylysine.

Our work highlights the importance of synergistic trophic interactions for both neuronal survival and differentiation, and emphasizes the necessity of using pure cell populations to analyze individual effects of growth factors.

271.8 INSULIN ATTENUATES NEUROTOXIC EFFECTS OF TAXOL ON VENTRAL REGIONS OF FETAL MOUSE SPINAL CORD EXPLANTS INDEPENDENT OF NGF-RESCUE OF ATTACHED DORSAL ROOT GANGLION (DRG) NEURONS. E.R. Peterson* and S.M. Crain (SPON: E.B. Masurovsky). Dept. of Neuroscience, Albert Einstein College of Medicine, Yeshiva University, Bronx, N.Y. 10461

After exposure of fetal mouse cord-DRG explants to the plant anti-tumor alkaloid, taxol, DRG neurons remain dependent on high levels of exogenous NGF for survival, long after drug withdrawal (Peterson & Crain, Science 217, 377, '82). While neurons in dorsal cord explants do not normally require a DRG input for longterm maintenance, during and after taxol exposure these cells also become more dependent on trophic factors provided by NGF-enhanced DRG neurite projections. Ventral cord neurons in these same taxol-treated explants show extensive degeneration.

In the present study, mouse cord-DRG explants (E-13) with attached DRGs were cultured in control media containing NGF (300 units/ml) for 4 days, and then exposed to taxol (1-2 um) ± insulin (20 ug/ml, bovine pancreas, Sigma) + NGF for 4 days. After taxol withdrawal, the cultures were maintained in control media with NGF ± insulin for 1-2 wks. Increased numbers of ventral cord neurons survived with insulin supplement, while in control cultures, the ventral cord tissue was more often reduced to a monolayer of glial cells. Insulin markedly attenuated the usual degeneration of taxol-treated ventral cord neurons, even when the NGF level was transiently lowered after drug withdrawal to levels that resulted in severe damage to the DRG and dorsal cord neurons. Electrophysiologic tests showed that characteristic synaptic network discharges could be generated in the ventral cord tissue "rescued" by insulin.

While development of many ventral cord neurons is essentially normal in longterm explant cultures without addition of insulin, following exposure to taxol they become dependent on insulin (or insulin-like factors), just as DRG neurons remain dependent on NGF and dorsal cord neurons become dependent on DRG neurite inputs. In the absence of these enhanced extrinsic influences, taxol exposure results in severe cytotoxic abnormalities in DRG and cord neurons. In drug-free cultures, DRG and cord neurons probably survive by utilizing small amounts of essential trophic factors present in serum/embryo-extract nutrient media or provided by supporting cells. Perhaps certain types of neurologic degenerative disorders might involve defective regulation of a putative endogenous factor with activity similar to that of taxol (Schiff et al, Nature 277, 665, '79) in specific groups of neurons (see rev. by Crain & Peterson, in Cellular & Molecular Biology of Neuronal Development, ed. I. Black, Plenum '84). (Supported by grants NS-19611 to Dr. P.S. Spencer and BNS-821847 to S.M.C.)

271.9 **LAMININ AND PYRUVATE TOGETHER SUPPORT SHORT TERM SURVIVAL OF RAT SEPTAL NEURONS IN LOW DENSITY, SERUM-FREE CULTURES.** S. K. R. Pixley and C. W. Cotman, Department of Psychobiology, U. of Cal., Irvine, CA 92717.

Laminin has neurite-promoting effects for a variety of cultured neurons and has been implicated in neurite-promotion during nervous system development and injury repair. We report here that laminin is also capable of supporting survival of central neurons maintained in culture. The survival effect is not observed in the absence of pyruvate, a trophic component of astrocyte conditioned media.

Septal neurons from embryonic day 18 rats did not survive for 24 hours when dissociated and cultured at low density in a standard serum-free medium containing the N1 supplements. However, if both laminin and pyruvate were present in the culture system, significant 24 hour cell survival was observed. Laminin supported cell survival only if it was present in the culture system during cell plating (either attached to the substrate or soluble in the medium); laminin did not support cell survival if it was added after cells had adhered to polylysine-coated culture wells. Variations in laminin concentration did not affect cell attachment or the percent of total cells that were identified as neurons. Laminin-supported neurons survived for 4 days in culture, but the cell numbers were 53% of the 24 hour values.

Laminin also acted as a neurite-promoting factor in these cultures. Significant numbers of septal neurons were capable of producing neurites, even at the lowest laminin concentrations tested. Above this baseline, the percent of neurite-bearing cells was proportional to laminin concentration. The rate of neurite initiation was also proportional to laminin concentration.

Thus, laminin promoted neuronal survival and sprouting if it was present during cell plating and if the cells had metabolic support in the form of pyruvate. No other trophic agents were required for survival.

Both neuronal process formation and neuronal death occur during development and after injury to the CNS. A variety of neurotrophic factors are present at both times and laminin may be one of them, acting as a survival promoting agent in vivo as it does in embryonic neuronal cultures.

Supported by grant MH19691 and NIH Fellowship NS07238.

271.10 GROWTH FACTORS, cAMP AND ELEVATED $K^+$ PREVENT THE DEATH OF CLONAL PC12 PHEOCHROMOCYTOMA CELLS IN SERUM-FREE MEDIUM. R.E. Rydel and L.A. Greene*, Department of Pharmacology, New York University School of Medicine, New York, NY 10016

In serum-containing medium (85% RPMI 1640, 5% fetal calf serum, 10% horse serum, and no nerve growth factor), cultures of PC12 cells show excellent viability and growth. When serum is withdrawn, 90% of the cells die within 4-6 days and 99% by 2-3 weeks. If nerve growth factor (NGF) is added at the time of serum withdrawal, the cells remain viable for at least 1 month and extend neurites (Greene, L.A., J. Cell Biol. 78:747, 1978). In the present study, we sought to determine a) if other conditions could mimic the survival properties of NGF in serum-free cultures of PC12 cells and, b) if so, whether these conditions produce other shared responses in PC12 cells.

Cultures of PC12 cells on collagen-coated dishes were washed three times with serum-free medium (RPMI 1640) and then re-fed with serum-free medium containing one of the agents listed below. Cultures were fed every other day and cell number per culture was determined after 1-3 weeks. 5 ng/ml fibroblast growth factor (FGF), 500 ng/ml insulin, 40mM $K^+$, 30μM forskolin, 0.5mM dibutyryl cAMP, and 1.0mM 8(4-chlorphenylthio)-cAMP all prevented death of PC12 cells in serum-free medium to a similar extent as that observed with 50 ng/ml NGF. Treatment with 5 ng/ml epidermal growth factor resulted in approximately half the number of surviving PC12 cells when compared with the above treatments. Dibutyryl cGMP (0.5-1.0mM), 1.0mM 8-bromo cGMP, 1.0mM sodium butyrate, phorbol myristate acetate (10nM and 1.0μM), vasoactive intestinal peptide (2.0-5000 ng/ml), arginine vasopressin (10-2500 ng/ml), 10μM dexamethasone, and platelet-derived growth factor (1 U/ml) did not promote survival of PC12 cells in serum-free medium. FGF produced stable neurites (> 3 cell diameters in length and containing growth-cone-like flattenings) after 3 days of treatment in serum-free medium. These processes appear quite distinct from those recently reported with FGF treatment of PC12 cells in serum-containing medium (Togari, et.al., J. Neurosci. 5:307, 1985). With the exception of NGF, none of the other agents caused neuritic outgrowth.

When added to serum-free cultures, all agents supporting survival shared the ability to yield rapid (< 1 hr) changes in the phosphorylation of specific cytoplasmic and nuclear proteins of PC12 cells, and induced cell flattening and spiking within 24 hours of addition. This suggests that phosphorylation may play a causative role in cellular survival and that the PC12 cell system may prove useful for studying mechanisms involved in neuronal cell death. Supported by NIH grant NS16036 and NIH predoctoral training grant GM07827.

271.11 ENHANCEMENT OF AChE ACTIVITY IN CULTURED SPINAL CORD NEURONS BY THYROTROPIN RELEASING HORMONE.
J.M. Lyles and C.L. Weill Depts. of Neurology and Anatomy, Louisiana State University Medical Center, New Orleans, LA 70112.

Recent investigations have indicated that thyrotropin releasing hormone (TRH) displays neurotrophic properties with respect to motoneurons. The process of motoneuron cell death which occurs during embryonic development accounts for the loss of approximately 50% of the motoneurons in the lateral motor column of the chick between days 6 and 10. Weill (Neurosci. Abst. 10,641(1984)) found that TRH enhances spinal cord motoneuron survival when administered in vivo. Therefore, the current study was initiated to examine the effect of TRH on acetylcholinesterase (AChE, EC 3.1.1.7), an enzyme that is specifically associated with motoneurons in cultures of embryonic chick spinal cord.

The culture system employed day 6 embryonic chick spinal cords which were trypsinized and plated in collagen coated 16 mm multiwells at a density of 2 million cells/well in complete MEM containing 10uM cytosine arabinoside C. Cultures were fed every 2 days with complete MEM (MEM with 5% chick embryo extract, 10% horse serum, 2 mM glutamine, 50 U/ml penicillin, 50 ug/ml streptomycin and 2.5 mcg/ml fungizone). Cells were harvested at 2 day intervals over an 8 day period and extracts stored in liquid nitrogen until assayed. AChE, a marker for neuronal development, was assayed according to the method of Ellman using acetylthiocholine iodide as substrate.

The results show that AChE activity increased in control cultures two fold between days 1 and 8. Similar increases with culture age were observed in cultures treated with 50 nM TRH. In the TRH treated cultures, however, AChE activity was higher at all ages examined, with levels significantly elevated ($p<0.1$) by 45%, 86% and 44% at days 4, 6 and 8, respectively. Mean AChE values (mU/mg total protein ±SEM) for duplicate samples were: day 4 control, 4.97±0.67; day 4 TRH treated, 7.20±0.11; day 6 control, 8.24±0.06; day 6 TRH treated, 15.3±2.31; day 8 control, 8.97±1.16; day 8 TRH treated, 13.0±0.05.

Depolarizing conditions in general have been shown to be neurotrophic and we found that 25mM K+ also elevated AChE levels in cultured spinal cord neurons. Hence, it appears that the peptide hormone TRH has a similar trophic effect on spinal cord neurons in culture. Other enzyme markers and parameters will be explored to characterize the neurotrophic effect of TRH further. Supported by NIH grant NS18642.

271.12 TRANSFERRIN LEVELS IN AMYOTROPHIC LATERAL SCLEROSIS AND CONTROL SERA MEASURED BY RADIOIMMUNOASSAY. M.K.N. Patel and B.W. Festoff. Dept. Neurology, V.A. Medical Center, 4801 Linwood Blvd., Kansas City, MO 64128.

Previous research from our laboratory reported that peripheral nerve extract stimulated myogenesis in chick primary cells in culture (Popiela et al.; J. Neurosci. Res. 8:547-567, 1982), and also promoted long term survival and neurite outgrowth in cultured embryonic chick spinal cord neurons (Popiela et al. Cell. Mol. Neurobiol. 4:67-77, 1984). This trophic factor was identified as transferrin.

We asked the question, could transferrin also be involved in the etiology of amyotrophic lateral sclerosis? We chose to measure serum transferrin because the pathology involved peripheral motor neurons and muscle and blood components have access to both these tissues.

Human transferrin was labeled with Iodine-125 and used in a competitive binding assay with rabbit anti-human transferrin antibodies. The antigen-antibody removal by centrifugation was enhanced by preincubation with goat anti-rabbit IgG. The pellet was counted in a gamma counter. Our results shown in Table I below indicates that statistically there is no significant difference in serum transferrin levels in ALS and controls.

271.13 INFLUENCE OF POLYPEPTIDE GROWTH FACTORS ON ACETYLCHOLINESTERASE (AChE) AND AChE MOLECULAR FRACTIONS IN ANNEURALLY CULTURED ADULT HUMAN MUSCLE

Ghislaine Gallez-Hawkins, Valerie Askanas, Edward Hawkins, W. King Engel. USC Neuromuscular Center, Los Angeles, CA, 90020

In skeletal muscle, AChE and its 16S endplate-specific molecular fraction are under neuronal influence. We have previously reported that fibroblast growth factor (FGF), epidermal growth factor (EGF), and insulin (I) increase the total number of acetylcholine receptors (AChRs) and AChR aggregation in aneurally cultured adult human muscle (Askanas et al, Neurol, 35:102, 1985). In this regard, the influence of polypeptide growth factors (PGFs) on cultured human muscle is very similar to the influence of soluble neuronal factors on cultured animal muscle. In the present study, we examined the influence of PGFs on AChE activity and AChE molecular fractions in cultured adult human muscle. Muscle cultures were established in 5 experiments, each from a different muscle biopsy. Cultures were initiated from $5x10^5$ cells/dish in 60 mm petri dishes and grown for 3 wks. In each experiment, 10 dishes were treated with combined addition of 50 ng FGF + 10 ng EGF + 10 ug insulin and 10 dishes received control medium (CM). AChE was extracted in buffer containing 1M NaCl,1% Triton X-100, and 1 mM EGTA in 10 mM Tris HCl pH 7.2. AChE was determined at 37°C by the method of Ellman et al (Biochem Pharm. 7:88, 1961) and expressed in optical density variation units 1hr at 412 nm lh. One optical density variation unit (1OD) corresponds to hydrolysis of 73.5 umol acetylthiocholine iodide, (Rieger and Vigny, J Neurochem 42:601,1984). AChE molecular fractions were characterized by sedimentation coefficients in a 5-20% sucrose gradient, using B-galactosidase as a 16S marker and alkaline phosphatase as a 6S marker. 200 ul samples were added to the gradient, which was subsequently centrifuged at 168,000 g for 16 hrs. In cultures treated with PGFs, total AChE activity was increased to 340% of the control value ($p=0.005$). However, there was virtually no difference in distribution of AChE molecular fractions between PGF-treated and control cultures. Control cultures had 62% 4S, 26% 10S, and 12% 16S, and PGF-treated cultures had 61% 4S, 28% 10S, and 11% 16S.

Our studies demonstrate: 1) the presence of end-plate-specific 16S molecular fraction of AChE in aneurally cultured human muscle; 2) significant influence of FGF+EGF+I on total AChE activity of cultured adult human muscle, without a preferential influence on the 16S molecular fraction, and 3) an action of PGFs similar to that of soluble neuronal factors, since the latter also increase total AChE without preferentially influencing the end-plate specific molecular fraction in chick cultured muscle (Siegel, Trends in Pharm. Sci. 4:131, 1983). Even though PGFs and soluble neuronal factors increase the total number of AChRs, AChR aggregation and AChE in cultured muscle, other factors and/or nerve-muscle physical contact may be necessary for preferentially influencing the 16S end-plate specific molecular fraction of AChE. 271.14 SERUM FREE, HORMONALLY-CHEMICALLY DEFINED MEDIUM FOR PRIMARY CULTURE OF HUMAN MUSCLE.

Valerie Askanas, Susan Cave, and W. King Engel.
Usc Neuromuscular Center, Los Angeles, CA, 90020

We have previously reported that addition of fibroblast growth factor (FGF), epidermal growth factor (EGF) and insulin to culture-medium containing 10% fetal calf serum (FCS) caused synergistic increase of creatine kinase and increase of total acetylcholine receptors (AChRs) and clustering of AChRs in cultured human muscle as compared to muscle cultured in non-supplemented medium (Ann. Neurol. 16:143, 1984, Neurol. 35:102, 1985). We now report that supplementation of medium with those three polypeptide growth factors and with several other components allowed establishment of a serum-free medium (SFM) in which development and maturation of adult human muscle are much better than in control medium (CM) containing10% serum. SFM is based on F14 medium (Proc.Natl. Acad. Sci. 69; 3180,1972) supplemented per 1ml with: 50 ng FGF, 10 ng EGF, 10 ug insulin, 50 ug transferrin, 10 nM dihydrotestosterone, 50 uM hydrocortisone, 5 nM estradiol, 25 pM triiodothyronine, 50 uM putrescine, 2x $10^{-4}$ units alpha-tocopherol, 1 uM leupeptine, 0.1 mM L-carnitine, 2.5 mg BSA, 15 mM (pH 7.4) Hepes buffer. Cultures were established on collagen-coated 35 mm petri dishes from trypsinized cells ($4X10^5$ cells per dish), in medium supplemented with 10% FCS + FGF+ EGF + insulin. After 24 hours, when the majority of cells were attached, this medium was replaced by SFM.

In five experiments, each from a different biopsy (total of 50 cultures), human muscle cultured for 4 weeks in SFM had 223% ($p<0.02$) increase of CK activity and 217% increase ($p<0.02$) of total AChRs compared to muscle cultured in CM. Isozymes of CK indicative of muscle maturation revealed 30% increase ($p<0.005$) of muscle (MM) band in SFM cultured muscle compared to control muscle. AChR clusters were increased 1122% ($p < 0.001$) in SFM cultured muscle compared to control muscle. In addition, spontaneous contractions were often observed in SFM-cultured muscle and very rarely in control muscle.

In summary: 1) we present the first demonstration that adult human muscle can be cultured in SFM; 2) SFM supports human muscle growth and maturation significantly better than serum-supplemented medium; 3) SFM provides an important environment in which one can selectively study the influence of various hormones and growth factors on human muscle carrying an abnormal gene.

271.15 IN VIVO EFFECT OF A NERVE EXTRACT UPON NUMBERS OF ACETYLCHOLINE RECEPTORS IN DENERVATED SKELETAL MUSCLES.

S.T. SAYERS*, J.A. MCLANE AND I.R. HELD, Neuroscience Res. Sect., V.A. Hospital, Hines, IL 60141 and Depts. of Biochemistry and of Pharmacology, Loyola Univ. of Chicago Medical Center, Maywood, IL 60153.

The appearance of new extrajunctional (exj) acetylcholine receptors (AChR) is a characteristic response of adult skeletal muscle to denervation. Although this has been shown to be due to an increase in messenger RNA's coding for AChR protein, the neural signal leading to the increased transcription of the AChR gene is not known. Apparently, however, some neural influence normally represses the synthesis of exj AChR. The objective of this study was to determine whether continual infusions of a nerve extract would retard the appearance of new AChR.

Immediately after bilateral denervation of soleus muscles in the rat hindlimb by sciatotomy, an extract of sciatic nerves (100,000xg supernatant of nerve homogenate) obtained from other rats was injected intramuscularly (20 µl of 2.0-7.1 mg protein/ml). Then mini-osmotic pumps (Alza Corp.) loaded with the same extract were implanted to release the extract directly onto the soleus muscle at a rate of 1 µl/hr for 66 hr. Contralateral solei received injections and infusions of Ringer's solution. Also, injections and infusions of liver extract (7.5 mg protein/ml) or purified transferrin (5.0 mg/ml) were performed. After denervation and infusion periods of 66 hr, the solei were dissected and divided into junctional (j) and exj regions. Triton X-100 solubilized AChR were extracted from homogenates of these muscle sections and incubated with 125I-alpha bungarotoxin (BUTX). Radioiodinated AchR were separated by Sephacryl S-200 chromatography and quantitated.

Based upon the binding of 125I-BUTX the number of j and exj AChR in the Ringer-infused denervated muscles was increased 4-5 fold. This is comparable to AChR levels observed in 66 hr denervated solei receiving no infusions. The AChR numbers in denervated solei receiving a high concentration nerve extract infusion (6.0-7.1 mg protein/ml) were reduced 58-71% and 24-57% in the j and exj regions, respectively. Infusions of transferrin or liver extract reduced the denervation induced increase of AChR <30%.

Our results show that there is an active component present in nerve extracts which prevents the increase in numbers of AChR which usually occurs after denervation. This activity is apparently present at a lower level in the non-neural liver extract. Transferrin, a known growth promoter, had only a small effect on muscle AChR number even at high concentrations. These results are consistent with the current hypothesis that axonally transported neurotrophic substances influence the synthesis of muscle AChR.

Supported by the V.A. Medical Research Service and BRSG funds from Loyola Univ. of Chicago.

272.1 CHARACTERIZATION OF NERVE GROWTH FACTOR (NGF) BINDING BY CULTURED NEURAL CREST CELLS. P. Bernd. Department of Anatomy, Mount Sinai School of Medicine of the City University of New York, New York, N.Y. 10029.

We have previously demonstrated by light microscopic radioautographic techniques that a subpopulation of cultured neural crest cells undergoing differentiation have specific NGF receptors. These cells are the likely targets of NGF during differentiation and development. This study was done to pharmacologically characterize the binding of NGF to neural crest cells (7 to 14 days past explantation). Neural crest cultures were prepared from the trunk region of 48 hr quail embryos, and subcultured after 3 to 5 days onto gelatin coated 100mm plastic Petri dishes (approximately 2 x $10^6$ cells/dish) or 16mm plastic wells (approximately 1 x $10^5$ cells/well). Cells were washed with chick embryo extract-free culture medium for 2 hr, and triturated off 100mm dishes prior to experimentation (HBSS without $Ca^{++}$ and $Mg^{++}$ and with 1mM EDTA). Neural crest cells in suspension were then exposed to varying concentrations of $^{125}$I-NGF (0.07 to 200 ng/ml, 130 cpm/pg, 1 hr, 37°C), after which 100ul aliquots were removed (approximately 100,000 cells/aliquot), layered over a 175ul cushion of 0.15M sucrose and spun (1 min, Beckman microfuge B). The tubes were then quickly frozen and the tips, containing the cell pellet, cut off. Both cell pellet and supernatant were counted in a Gamma counter. Controls included an excess of nonradioactive NGF (5 ug/ml), as well as $^{125}$I-NGF. The data indicate that $^{125}$I-NGF binding was saturable with less than 20% nonspecific binding. Scatchard analysis revealed the presence of one type (class) of receptors with a $k_d$ similar to that of the low affinity NGF binding site (approximately 3.2 nM). This was corroborated by displacement experiments ($k_d$ approximately 1.9 nM) in which cells were exposed to $^{125}$I-NGF (5 ng/ml), as well as varying concentrations of nonradioactive NGF (0 to 5 ug/ml) for 1 hr (37°C). Binding of $^{125}$I-NGF was sensitive to trypsin; only 25% specific binding remained following sequential exposure to trypsin (0.05%, 90 min) and $^{125}$I-NGF (5 ng/ml; 1 hr). Quantitation of surface-bound vs. internalized $^{125}$I-NGF by differential release of the former at low pH, high salt (0.2M acetic acid, 0.5M NaCl) revealed that 13% of the $^{125}$I-NGF was internalized following incubation for 1 hr. In addition, specific binding was determined to be about 175 cpm/ug protein. These findings indicate that differentiating neural crest cells differ in their $^{125}$I-NGF binding properties from embryonic chick sympathetic or dorsal root ganglia, known NGF targets, in that they lack a high affinity $^{125}$I-NGF binding site. This suggests that these cells, which have not terminally differentiated (i.e. cell division still continues), may express an early developmental form of the NGF receptor. Supported by grants from the NIH (#HD 17262) and the Dysautonomia Foundation.

272.2 DEVELOPMENTAL EXPRESSION OF NERVE GROWTH FACTOR RECEPTORS IN PRIMARY CULTURES OF NEURAL CREST CELLS. C.A.M. Greiner*, A.T. Lloyd*, and G. Guroff. Department of Neurology and Committee on Neurobiology, U. Chicago; Section on Growth Factors, National Institute of Child Health and Human Development, NIH, Bethesda, MD 20205.

It has been suggested that environmental factors may be involved in the phenotypic expression of neural crest cells; however, the nature and mechanism(s) of such epigenetic influences are unknown. Previous work from this laboratory (Dev. Brain Res., 7: 131, 1983) demonstrated that 5-day cultures of neural crest cells express receptors for nerve growth factor (NGF), a molecule necessary for the survival and development of various neural crest derivatives. The present study examines the expression of NGF receptors during the development of neural crest cells in vitro.

Neural crest primary cultures were established from the caudal 6-8 segments of 2-day quail embryos and maintained in α -MEM, 15% horse serum, and 10% chick embryo extract. Cultures aged 2-8 days were incubated with $^{125}$I-NGF for 1 hour at 37°C. Control cultures additionally received an excess of unlabeled NGF. NGF receptors were detected in cultures aged 4-8 days, although specific binding could occasionally be detected in 3-day cultures. The amount of binding, however, often varied considerably among cultures of the same age. Parallel cultures processed for indirect immunofluorescence revealed a subpopulation of neural crest cells that express NGF receptors. Large fluorescent aggregates were noted in 5- and 6-day cultures; similar smaller aggregates were observed in 4-day cultures. Some 3-day cultures exhibited faintly fluorescent cells; 2-day cultures were consistently nonfluorescent. Pigment cells did not appear to bind NGF.

In order to determine the magnitude of the NGF-binding population, 5-day cultures were incubated with fluorescein isothiocyanate-conjugated NGF for 24 hours at 37°C and analyzed cytofluorometrically. Preliminary results indicate that approximately 28% of neural crest cells in 5-day cultures express NGF receptors. Experiments are currently in progress using cell sorting techniques to isolate and characterize this neural crest subpopulation.

272.3 AN AUTORADIOGRAPHIC AND IMMUNOHISTOCHEMICAL DEMONSTRATION OF NERVE GROWTH FACTOR RECEPTOR-BINDING SITES IN RAT LUMBAR SPINAL CORD. E.M. Johnson, P.A. Lampe*, P.A.Osborne* and H.K.Yip. Dept. of Pharmacology, Washington Univ. Sch. of Med., St. Louis, MO 63110.

The presence of nerve growth factor (NGF) receptors on terminal processes of dorsal root ganglion (DRG) neurons was inferred by the previous demonstration of the retrograde transport of $^{125}$I-NGF from the spinal cord to the DRG. The presence and distribution of NGF binding sites in the rat lumbar spinal cord was determined using light microscopic autoradiography and immunohistochemistry. A narrow band of high density of silver grains was observed in laminae I and II of the dorsal horn after injection into spinal cord of $^{125}$I-NGF or iodinated monoclonal antibody against NGF receptor. Injection of $^{125}$I-cytochrome c or coinjection of $^{125}$I-NGF with an excess amount of unlabelled NGF produced no specific binding. The immunohistochemical results with the monoclonal antibody were consistent with the autoradiographic data. Immunoreactive neuronal processes and terminals were also localized in the superficial laminae of the dorsal horn.

Dorsal rhizotomy resulted in a complete loss of NGF receptor-binding sites in the dorsal horn, as demonstrated by both autoradiography and immunohistochemistry, indicating that these receptors are contained in primary sensory afferents.

The distribution of NGF receptor-binding sites in the rat spinal cord was similar to that observed for substance P and other neuropeptides in the cord. Our results suggest that these peptidnergic neurons also contain NGF receptors at their terminals in the superficial layers of the dorsal horn. These findings are consistent with the idea that NGF derived from the CNS is important in the development and maintenance of sensory neurons. (Supported by NIH grant NS 18071).

272.4 COMPARATIVE DYNAMICS OF RETROGRADE TRANSPORT OF NERVE GROWTH FACTOR AND HORSERADISH PEROXIDASE IN RAT LUMBAR DORSAL ROOT GANGLIA. H.K. Yip and E.M. Johnson, Dept. of Pharmacology, Washington Univ. Sch. of Med., St. Louis, MO 63110.

The dynamics of the retrograde transport of $^{125}$I-nerve growth factor (NGF) and horseradish peroxidase (HRP) in primary sensory neurons were studied in rat. After injection of $^{125}$I-NGF or HRP into crushed sciatic nerves, labelling was examined in spinal nerves, dorsal root ganglia (DRG), dorsal roots, and spinal cords. Retrograde transport of both $^{125}$I-NGF and HRP was first observed in DRG neurons 6 hr. after injection. This indicated that the rate of transport ( 7mm/hr) of these proteins was identical. Significant differences in the sizes of DRG neurons labelled by $^{125}$I-NGF were observed depending on survival time. No such difference was seen in HRP-injected animals at any given time. After HRP injection the total number of labelled neurons in the DRG was higher than after $^{125}$I-NGF injection. At six hours after the injection, 60% of all the HRP-labelled cells had a diameter greater than 25 μm; whereas 90% of all the $^{125}$I-NGF labelled cells had a diameter less than 25 μm. There was a gradual shift in the size of $^{125}$I-NGF labelled neurons towards larger diameter with longer survival times. Thus, 24 hr. after the injection 83% of the labelled cells had a diameter greater than 25 μm. The data suggest that small diameter neurons retrogradely transport and turnover NGF faster than larger diameter neurons. There was a preferential accumulation of silver grains in small DRG neurons (mean diameter 25 μm) at early survival times (4 and 8 hr.); an inverse situation (mean diameter 42 μm) occurred at late survival time (24 hr.). In contrast, the mean diameter of HRP-labelled neurons remained constant ( 30 μm) at all times after injections.

The time span of the observable accumulated HRP in the neurons is much longer than that of $^{125}$I-NGF. Transport of HRP was observed in the dorsal horn and motor neurons. There was no labelling in this area of the spinal cord after injection of $^{125}$I-NGF. Hence, the rate of degradation of the transported NGF seems to be faster than HRP and that could account for the lack of transganglionic movement of NGF.

In summary, our study has shown that different populations of DRG neurons, in terms of sizes, were retrogradely labelled by NGF at different survival times. The total number of neurons which become labelled ( 85%) appears to be the same with NGF or HRP indicating that all sensory neurons retrogradely transport NGF. These results indicating that, in contrast to HRP, observing retrogradely labelled cells at any given time after $^{125}$I-NGF injection is not representative of the whole population of neurons capable of such transport. Whether this will prove a consistent difference between "receptor-mediated" transport versus "non-specific" transport is not known. (Supported by NS 18071).

272.5 WHEAT GERM AGGLUTININ BLOCKS THE BIOLOGICAL EFFECTS OF NERVE GROWTH FACTOR ON PC12 CELLS. G.E. Landreth and C. McCutchen. Dept. of Neurology, Medical University of South Carolina, Charleston, SC 29425.

The binding of nerve growth factor (NGF) to cell surface receptors initiates a variety of effects leading to the morphological and biochemical differentiation of a clonal pheochromocytoma line, PC12. The PC12 cells possess two interconvertible populations of NGF receptors, a low affinity, rapidly dissociating class (fast receptors) and a high affinity, slowly dissociating class (slow receptors). The occupancy of slow receptors is correlated with many of the biological effects of NGF. The NGF receptor is a membrane glycoprotein possessing N-acetylglucosamine residues which will bind the lectin, wheat germ agglutinin (WGA). It has previously been demonstrated that the binding of WGA to the NGF receptor results in the quantitative conversion of fast receptors to slow receptors, the acquisition of trypsin resistance by the hormone-receptor complex, and association of the receptor with the detergent-insoluble cytoskeleton. These characteristics are similar to those exhibited by slow receptors.

Treatment of PC12 cells with WGA dramatically and reversibly inhibited the ability of NGF to elicit three distinct biological effects. NGF causes the rapid production of ruffles on the cell surface; however, pretreatment of the cells with WGA blocked any NGF-induced change in cell surface morphology. NGF treatment stimulates the phosphorylation in situ of a 250 kDa cytoskeletal protein. Pretreatment of the cells with 50 µg/ml WGA inhibited the phosphorylation of this protein. The effect was reversible on addition of 10mM N-acetylglucosamine and was not produced by other lectins. PC12 cells also respond to NGF by extending neurites. If the cells are divested of their neurites, they will regenerate these processes over 24 hrs. If the cells are replated in serum-free medium, the lectin inhibits the ability of NGF to elicit neurite outgrowth. The inhibition is half-maximal at 3µg/ml WGA. The subsequent addition of 10mM N-acetylglucosamine reverses the effect of WGA, restoring the ability of NGF to elicit neurite outgrowth. Other lectins were without effect. These data demonstrate that the WGA-induced changes in the NGF-receptor interaction reflect important changes in the ability of the receptor to transmit biological signals, abrogating the biological effects of NGF on these cells.

272.6 NERVE GROWTH FACTOR AND TPA ALTER Nsp100 PHOSPHORYLATION IN PC12 CELLS IN A SIMILAR MANNER. T. Hama* and G. Guroff (SPON: L. Neckers). Section on Growth Factors, National Institute of Child Health and Human Development, NIH, Bethesda, MD 20205.

Treatment of PC12 cells with nerve growth factor alters several phosphorylations in the cells. One which has been looked at in some detail is the phosphorylation of soluble protein called Nsp100. Treatment with nerve growth factor causes a decrease in the phosphorylation of this protein in whole cells and also in cell-free extracts prepared from treated cells (End, Tolson, Hashimoto, and Guroff, J. Biol. Chem., 285: 6549, 1983). Nsp100 and the kinase acting on it have now been separated and partially purified (Togari and Guroff, J. Biol. Chem., 260: 3804, 1985).

In an effort to trace the biochemical events underlying this alteration in phosphorylation we have inspected the action of other effectors of phosphorylation on this system. Our data indicate that treatment of PC12 cells with TPA, a tumor promoter known to act on protein kinase C, also decreases Nsp100 phosphorylation. In addition, peptide mapping indicates that the pattern of decrease in the overall phosphorylation of this protein is the same as that seen with nerve growth factor treatment. And, as with nerve growth factor, the decrease is threonine-specific. The similarity between the effects of nerve growth factor and those of TPA in this system allow speculation on the role of protein kinase C activation as an early step in the action of nerve growth factor on phosphorylation in its target cells.

272.7 DECREASED FIBROBLAST GROWTH FACTOR SENSITIVITY OF NERVE GROWTH FACTOR-TREATED PC12 CELLS. K. Fujita*, H. Kuzuya*, and G. Guroff. (SPON: J. McLaughlin). Section on Growth Factors, National Institute of Child Health and Human Development, NIH, Bethesda, MD 20205.

Nerve growth factor treatment of PC12 cells leads to morphological and biochemical differentiation and to a decrease in cell division. A concommitant of the differentiation is a (heterologous) down-regulation of receptors for epidermal growth factor. Epidermal growth factor is a mitogen for most of the cells upon which it acts and for PC12 cells as well. We have suggested that the down-regulation is part of the mechanism by which nerve growth factor causes differentiation; that is, nerve growth factor prevents the action of mitogens to which the cells normally respond.

Fibroblast growth factor also acts on PC12 cells. It produces a form of morphological differentiation, but this differentiation is different than that produced by nerve growth factor (Togari, Dickens, Kuzuya, and Guroff, J. Neurosci., 5: 307, 1985). Fibroblast growth factor is a mitogen for many of the cells on which it acts. Our data show that fibroblast growth factor is a mild stimulant of PC12 cell division as well; both DNA content and $^{3}$H-thymidine incorporation are moderately, but definitely increased by the factor. Using orinthine decarboxylase activity as a probe, we have shown that treatment of PC12 cells with nerve growth factor decreases the action fibroblast growth factor on those cells. These data suggest that nerve growth factor down-regulates the fibroblast growth factor receptor. They support the general postulate that nerve growth factor causes a down-regulation of mitogen receptors.

272.8 NERVE GROWTH FACTOR AND OTHER AGENTS MEDIATE PHOSPHORYLATION AND ACTIVATION OF TYROSINE HYDROXYLASE THROUGH MULTIPLE PHOSPHORYLATION PATHWAYS. J. Cremins*, M. McTigue* and S. Halegoua* (SPON:M.Schwartz) Dept. of Neurobiology and Behavior, SUNY at Stony Brook, Stony Brook, N.Y. 11794.

Nerve Growth Factor (NGF) and other agents rapidly stimulate different cellular kinases resulting in the phosphorylation of a number of proteins in PC12 cells (Halegoua and Patrick, Cell, 1980). In order to identify the kinases stimulated by NGF and to establish the second messenger systems involved in the generation of NGF responses, we further studied the phosphorylation and resultant change in activity of tyrosine hydroxylase (TH), a common substrate of multiple cellular kinases.

A rapid phosphorylation and activation of TH occured in PC12 cells in response to NGF, Epidermal Growth Factor (EGF), Bt$_2$cAMP, cholera toxin, $K^+$ depolarization, or phorbol ester (PMA). Examination of TH tryptic phosphopeptides analysed by two dimensional peptide mapping revealed four available sites of phosphorylation (T1-T4). Site specific phosphorylation of each of the four tryptic phosphopeptides was achieved in response to the various agents. NGF and cAMP elevation generated phosphopeptide patterns which were qualitatively the same (T1 and T3). Quantitatively, NGF resulted in a much greater phosphorylation of T3 than T1, while the reverse was true of cAMP elevation. T2 and T3 were phosphorylated in response to $K^+$ depolarization only in the presence of $Ca^{+2}$. EGF increased the phosphorylation of T3 and T4. PMA increased the phosphorylation of only peptide T3. The above data suggest the identity of NGF activated kinases as the Ca/phospholipid dependent protein kinase (C-kinase for T3), and cAMP dependent protein kinase (for T1).

In order to confirm that C-kinase is responsible for T3 phosphorylation, the following experiments were performed. Dose response using PMA indicated that it acted in the nanomolar range, comparable to its ability to activate C-kinase. Phorbol ester derivates which are unable to activate C-kinase also did not result in TH phosphorylation. A physiologically relevant activator of C-kinase, diacylglycerol, had the same effect as PMA. Inhibitors of C-kinase and cAMP dependent kinase were also used to elucidate the kinase identities involved in NGF action. Chlorpromazine and trifluoperizine, inhibitors of C-kinase, each blocked the phosphorylation of T3 but not of T1 in response to phorbol esters or NGF. These results demonstrate that the phosphorylation of T3 in response to NGF is due to C-kinase. The results using inhibitors indicate that the cAMP dependent kinase is regulated independently from C-kinase by NGF.

The above results demonstrate a molecular basis for the activation of TH by NGF and provide a framework for similar studies on other NGF actions.

272.9 EFFECT OF NERVE GROWTH FACTOR (NGF) AND SYMPATHECTOMY ON CELL SURVIVAL AND FIBER OUTGROWTH FROM SUBSTANCE P NEURONS GRAFTED IN OCULO. C. Ayer-LeLievre,* J. Kessler,[1] T. Ebendal*[2] and Å. Seiger* (SPON: W.A. Gregory). Dept. of Histology, Karolinska Institute, Stockholm, Sweden, [1]Dept. of Neurology, Albert Einstein College of Medicine, New York, and [2]Dept. of Zoology, Uppsala University, Uppsala, Sweden.

Nerve growth factor (NGF) is known to increase survival and SPLI content in late prenatal and postnatal dorsal root ganglion cells. Sympathectomy results in an increase of NGF levels in the rat iris.

Chronic injection of capsaicin (for 5 weeks) to young rats results in a disappearance of intrinsic substance P fibers. Cranial sensory (trigeminal, nodose petrous and superior-jugular) and parasympathetic (submandibular) ganglia containing substance P neurons have been transplanted from 11- to 21-day fetal to the eye chamber of capsaicin-treated rats. The outgrowth on iris of fibers from such grafted substance P neurons has been evaluated both qualitatively and quantitatively. Fetal central substance P neurons have also been grafted under the same conditions.

Grafts were treated with NGF, anti-NGF antibodies, or a saline solution as control. After a 3-week period in oculo, the NGF treatment resulted in a marked stimulation of the outgrowth of sensory substance P fibers which was not observed in untreated controls. Also, the strong NGF stimulation was selective for the sensory substance P-positive fibers as compared to sensory myelinated fibers and parasympathetic substance P-positive ones.

Sympathectomy of the host iris also resulted in an increase of substance P in fibers from grafted sensory ganglia, but the effects of sympathectomy and of NGF treatment were both quantitatively and qualitatively different.

(Supported by the Swedish MRC, NSRC, the French CNRS and the American NIH.)

272.10 EFFECTS OF NERVE GROWTH FACTOR ON GRAFTS OF CHROMAFFIN TISSUE TO THE ANTERIOR CHAMBER OF THE EYE AND TO THE BRAIN. L. Olson,* I. Strömberg,* H. Björklund,*[1] T. Ebendal,*[2] M. Herrera-Marschitz*[3] and Å. Seiger* (SPON: L. Olson, Member ENA). Depts. of Histology and [3]Pharmacology, Karolinska Institute, Stockholm, [1]Dept. of Pharmacology, Pharmacia AB, Uppsala, and [2]Dept. of Zoology, Uppsala University, Uppsala, Sweden.

The possible effect of nerve growth factor (NGF) on survival and adrenergic nerve fiber production by heterologous grafts of adult adrenal chromaffin tissue to the anterior chamber of the eye and to the dopamine-denervated striatum was studied histochemically. A considerably larger area of the host iris became innervated by nerve fibers from the chromaffin grafts if the host iris was sympathetically denervated prior to grafting. This stimulation was probably caused by an increase in NGF levels in the iris and could be further enhanced by injection of NGF into the eye chamber. This treatment also greatly enhanced the density of the newly formed adrenergic nerves. Studies now in progress using dissociated cell suspensions from adult chromaffin tissue address the question as to which cell types respond to NGF. When chromaffin grafts are implanted in the dopamine-denervated striatum they are partly able to counteract the apomorphine-induced rotational behavior in such animals. Addition of NGF increases the number of permanently surviving catecholamine-containing cells in intrastriatal chromaffin grafts. A recently devised continuous infusion technique using a subcutaneously implanted osmotic minipump connected to a dialysis fiber stereotaxically placed in striatum permits continuous infusion of NGF over a period of one month. The chromaffin grafts then form rich networks of nerve terminals in host striatum directed towards the NGF source. The reductions of apomorphine-induced rotational behavior are much larger than without NGF treatment. Chronic infusion of NGF alone or of saline does not influence the apomorphine-induced rotations. The effects of chromaffin grafts plus NGF lasts for at least one year. Antibodies against glial fibrillary acidic protein (GFA) were used to monitor glial disturbances caused by the grafting and infusion techniques. Only minor or moderate changes of nearby astrocytes were seen. 6-Hydroxydopamine used to denervate host striatum caused a permanent, but transient, panstriatal gliosis.

272.11 REGULATION OF NERVE GROWTH FACTOR (NGF) SPECIFIC MESSENGER RNA IN THE PERIPHERAL AND THE CENTRAL NERVOUS SYSTEM: R. Heumann*, S. Korsching* and H. Thoenen (SPON: H. Holländer). Dept. of Neurochemistry, Max-Planck-Institute for Psychiatry, D-8033 Martinsried,FRC.

We have developed a sensitive assay for the quantification of mRNA-NGF using cRNA-probes. An absolute quantification of mRNA-NGF was possible by adding unlabelled RNA synthesized in vitro as an internal standard to detect PNA recovery. Both NGF and its mRNA were correlated with the density of sympathetic innervation in the target organs of the sympathetic nervous system. However, while the superior cervical ganglia contained the highest levels of NGF, their mRNA was barely detectable. Thus, the high levels of NGF in sympathetic ganglia result from retrograde axonal transport rather than local synthesis.

Earlier studies in the central nervous system have shown that cholinergic magnocellular neurons are responsive to NCF. We have now found relatively high NGF and mRNA-NGF levels in the target regions innervated by these neurons (hippocampus: 1.4 ng NGF/g wet weight and 500 fg mRNA-NCF/µg poly(A)$^+$). In contrast, no mRNA-NGF was detectable in the region containing the cell bodies of these cholinergic neurons although the levels of NGF present in the same region was relatively high. These results support the concept that NGF acts also as trophic factor in the central nervous system.

Previous studies have indicated that a blockade of sympathetic axonal transport creates an increase in NCF levels in target organs. Iris cultures were therefore used to determine if this increase resulted exclusively from the inefficient removal of NGF after denervation or if innervating axons may also regulate NCF synthesis. The drastic increase of NGF-levels in cultured iris was preceeded by a mRNA-NGF increase starting at 2-3 h after explantation. Between 16 h - 24 h mRNA-NGF decreased again to a still elevated level at 48 h. The regulation in cultured iris was further investigated using inhibitors of transcription, translation or processing.

272.12 DENERVATION OF THE RAT IRIS DOES NOT INCREASE THE LEVEL OF mRNA ENCODING Beta NERVE GROWTH FACTOR. D.L. Shelton and L.F. Reichardt. Dept. Physiol. UCSF, San Francisco, CA. 94143

Beta nerve growth factor (NGF) is a protein necessary for the survival and maintenance of sympathetic and sensory neurons in vivo and in vitro. Evidence has accumulated which indicates that NGF is required at the growing tips of axons, and when present there, is bound, internalized, and retrogradely transported to the cell body. Recently it has been demonstrated that NGF is present in sympathetic target organs in vivo and that the amount of mRNA encoding for NGF (NGF mRNA) in a tisssue strongly correlates with the density of sympathetic innervation. This supports the hypothesis that NGF is produced by the target tissues of the responsive neurons.

Using the rat iris as a model target, it has been shown that the NGF content of a tissue increases dramatically after denervation or explant into culture. It is not known whether this change reflects a change in the synthetic rate of NGF, or is indicative of some change in the turnover of the molecule. In order to determine whether there is a change in synthesis controlled at the mRNA level, we have assayed the rat iris for its content of NGF mRNA after surgical and chemical denervation and after explant into culture.

Removal of the sympathetic innervation by either chemical or surgical methods has no effect on the level of NGF mRNA in the rat iris. The combined surgical removal of the sympathetic and sensory innervation also has no effect on the level of NGF mRNA in the iris. Therefore, denervation of the rat iris does not cause an increase in the content of NGF by increasing the level of NGF mRNA.

We also examined the NGF mRNA content of the rat iris after explant into culture. In this case, unlike the denervation in vivo, we did find a large, rapid increase in the NGF mRNA content of the rat iris. The increase was readily detectable within one hour, reached a maximum increase of ten to twenty fold by six to twelve hours, and was still evident after three days in culture. This increase did not reflect a general increase in the level of mRNA during explant. Although this response to explantation may be of use in understanding the normal control of NGF synthesis in vivo, it is not due to denervation. This differential effect of denervation and explantation indicates that organ culture may not be an acceptable model for denervation.

272.13 ABSENCE OF THE α AND γ SUBUNITS OF 7S NERVE GROWTH FACTOR IN DENERVATED RODENT IRIS: IMMUNOCYTOCHEMICAL STUDIES. R.A. Murphy, S. Landis+, J. Bernanke* and K. Siminoski*. Department of Anatomy and Cellular Biology and Department of Neurobiology+, Harvard Medical School, Boston, Massachusetts, 02115.

Immunocytochemical methods have been used to determine if denervated rodent iris produces nerve growth factor (NGF) in a form chemically similar to that of the 7S NGF complex in mouse submandibular glands. Irides of adult rats and mice were cultured for up to six days or sympathetically denervated by superior cervical ganglionectomy and left in situ four days. Tissues were stretched on slides and treated with rabbit antisera raised against the α, β and γ subunits of 7S NGF. Antibodies were visualized by indirect immunofluorescence. In control studies done on plastic (Poly/Bed 812) sections of mouse submandibular glands, antibodies of each of the subunits were localized to secretory granules of granular tubule cells. In rat iris, denervated 2-6 days, βNGF immunoreactivity was evident in a cellular plexus that closely resembles in distribution and morphology, nerve fibers in the normal iris, in agreement with a previous study (Rush, R.,Nature,312:364,1984). Identical staining patterns were observed in mouse iris. In neither rat nor mouse, however, did nerve-like processes stain with antibodies to the α and γ subunits nor was any other structure in the iris detectably immunoreactive for these proteins. This evidence suggests that the βNGF-like protein in denervated rodent iris is not synthesized as part of the 7S NGF complex, in contrast to mouse salivary gland. Cells in the iris also did not react with antibodies to epidermal growth factor, a protein that has been co-localized with NGF in mouse submandibular glands and in the prostate of the quinea pig.

272.14 EFFECTS OF CULTURE CONDITIONS ON THE CONCENTRATIONS OF NERVE GROWTH FACTOR (NGF) IN FIBROBLAST CELL CONDITIONED MEDIUM. M. Mowry* and N. J. Pantazis (SPON: W.W. Kaelber). Dept. of Anatomy, Univ. of Iowa Medical College, Iowa City, IA 52242

Although NGF is essential for development and maintenance of sensory and sympathetic neurons, little is known about factors which can affect NGF concentrations. Testosterone and thyroxine can increase NGF concentrations in the mouse submandibular gland. Fibroblast cells in culture synthesize NGF and secrete it into their feeding medium (conditioned medium). Isoproterenol is reported to increase NGF concentrations in fibroblasts in vitro (Schwartz, J.P. and Breakefield, X.O., Proc. Natl. Acad. Sci. USA, 77:1154, 1980). The present study examines the effects of various culture conditions on NGF concentrations in fibroblast cell conditioned medium (CM).

To test the effects of different media, confluent mouse fibroblast cells ($L_{929}$) were fed one of the following media: 1. Dulbecco's modified Eagle's medium/Ham's F12 (DMEM/F12); 2. N2 defined medium; 3. MCDB 105 defined medium. After 4d, the CM was removed, named cycle 1, and cells refed. This was repeated twice more at 6d intervals, and the CM named cycles 2 and 3, respectively. The CM was concentrated and an NGF radioimmunoassay was used to determine NGF concentrations. With DMEM/F12, the highest NGF concentrations were in the CM from cycle 1, whereas NGF concentrations in cycles 2 and 3 declined substantially. With MCDB 105, cycle 1 CM had an NGF concentration similar to cycle 1 CM obtained with DMEM/F12. In contrast to DMEM/F12, the NGF levels in cycles 2 and 3 did not drop with MCDB 105. Cells fed N2 medium had considerably lower levels of NGF in most cycles when compared to either DMEM/F12 or MCDB 105. Like DMEM/F12, the CM obtained with N2 showed a decline in NGF from cycle 1 through 3, with cycle 3 having no detectable NGF.

The effects of testosterone (10 and 1 nM), isoproterenol (100 and 10 μM) and thyroxin (10 and 1 μM) on NGF concentrations in fibroblast cell CM over three cycles were examined in DMEM/F12. Within each treatment group, cycle 1 had the greatest NGF concentration; cycles 2 and 3 had much less. When treatment groups were compared with controls (DMEM/F12 only), testosterone lowered the levels of NGF in CM from cycle 1; cycles 2 and 3 were similar between testosterone treatment and controls. In contrast, both isoproterenol and thyroxin increased NGF levels in cycles 2 and 3 respectively compared to controls. Neither agent had an effect on cycle 1.

In conclusion, MCDB 105 was best at maintaining higher levels of NGF in the CM. Testosterone, isoproterenol and thyroxin produced contrasting results; testosterone decreased NGF, whereas isoproterenol and thyroxin increased it. How these agents alter NGF levels, either by affecting NGF synthesis, degradation, or secretion, is unknown. (Supported by NIH grant GM28644 to NJP)

272.15 CARBOXYLMETHYLTRANSFERASE INHIBITORS BLOCK NERVE GROWTH FACTOR-MEDIATED INCREASE IN LEVELS OF TYROSINE HYDROXYLASE IN PRIMARY CULTURES OF BOVINE ADRENAL MEDULLARY CELLS. A. Acheson and H. Thoenen. Dept. of Neurochemistry, Max-Planck Institute for Psychiatry, 8033 Martinsried, W. Germany.

We have previously shown that primary cultures of calf chromaffin cells respond to nerve growth factor (NGF) treatment with selective increases in the levels of key catecholamine biosynthetic enzymes, including those of tyrosine hydroxylase (TH). The increase in TH levels occurs between hrs 36 and 48 of NGF exposure, and requires the continuous presence of NGF during the initial 36 hr.

It has recently been reported that several short- and long-term effects of NGF on PC12 cells, ranging from changes in membrane ruffling (minutes) to "priming" (days), can be inhibited by carboxylmethyltransferase inhibitors (Seeley et. al., JCB 98:417-426, 1984; Landreth and Rieser, JCB 100:677-683, 1985). We have examined the ability of several such inhibitors to block NGF-mediated TH increases. First, we measured the ability of these inhibitors to block the incorporation of $^{3}$H-methyl- versus $^{35}$S-methionine (met) into proteins. Cells were treated with 5'-deoxy-5'-methylthioadenosine (MTA, 3 mM), 5'-S-(2-methyl propyl) adenosine (SIBA, 1 mM), D-eritadenine (EA, 10 uM) or vehicle (DMSO) for 24 hr. Radioactive compounds were then given to the cells for 1 hr in the continued presence of the drugs. MTA and EA blocked the incorporation of $^{3}$H-methyl-met into protein by 65 and 80% respectively, while having no effect on $^{35}$S-met incorporation. SIBA blocked the incorporation of both isotopes into protein by 30%. When cells were treated with drugs for 24 hr, then left in culture in drug-free medium for an additional 24 hr, the effects of MTA and SIBA were fully reversed, whereas that of EA was only slightly reversed. Direct measurement of the formation of $^{3}$H-methyl esters via measurement of $^{3}$H-methanol formed upon alkaline hydrolysis of the protein also revealed extensive blockade of methylation after 24 hr by MTA and EA, but not by SIBA.

Cells were then treated concurrently with the inhibitors and NGF (1000 ng/ml) for 24 hr, then with NGF alone for an additional 24 hr. Under these conditions, MTA and EA blocked the NGF-mediated increase in TH levels, whereas SIBA was without effect. In addition, MTA and EA were unable to inhibit the cAMP-mediated increase in TH activity using the same drug treatment protocols, suggesting that the nature of their effects is selective. Given the apparent specificity of MTA and EA to block methylation, as well as the reversibility of MTA's effects, we conclude that methylation is important in NGF's mechanism of action for increased TH levels, and that the methylation event of importance occurs early in the process (first 24 hr).

272.16 DEVELOPMENT OF A HIGHLY SENSITIVE IMMUNOASSAY FOR MEASUREMENT OF ENDOGENOUS NGF IN PERIPHERAL AND CENTRAL NERVOUS SYSTEM OF THE ADULT RAT. G.Weskamp*, H.P.Lorez* and U.Otten (SPON: W.J.Fischli). Dept. of Pharmacology, Biocenter of the University, Basel, Hoffmann-LaRoche & Co.Ltd, Basel, Switzerland.

Nerve growth factor(NGF) is a trophic substance known to regulate the development and maintenance of function of sympathetic and sensory neurons. A sensitive enzyme-linked immunosorbent assay for NGF has been developed: Polyclonal goat antibodies against 2.5S mouseNGF were adsorbed to polystyrene multiwell plates. After adding the NGF-sample or standard solution, the second antibody, a specific monoclonal $IgG_{2a}$-antibody was applied. This antibody complex was detected with a biotin-labelled immunoglobulin to which peroxidase-coupled streptavidin was bound with high affinity. Enzyme-activity was quantified by the change in the optical density, using orthophenylenediamine as substrate. The detection limit of this assay is 0.1 pg/well corresponding to 0.004 fmol NGF.

Partial denervation of peripheral end-organs,e.g.iris, induced a significant, rapid increase in iris-NGF levels, which was followed by a prolonged hypertrophy of the remaining intact neurons, as monitored by biochemical and morphological analyses.

Determinations with this sensitive immunoassay revealed high levels of NGF in different brain regions, including the septum, hippocampus and neocortex, suggesting that NGF plays a physiological role in the functioning of the central nervous system.

Supported by the Swiss National Foundation for Scientific Research (Grant 3344-082).

272.17 ASCITES DERIVED MONOCLONAL ANTIBODIES AGAINST NERVE GROWTH FACTOR OF HUMAN ORIGIN. K. Werrbach-Perez*, C. Beck*, L.W. Thorpe* and J.R. Perez-Polo (SPON: H. Eisenberg). Dept. of Biol. Chem. And Genetics, Univ. Tx. Med. Br., Galveston, Tx. 77550.

The nerve growth factor protein, NGF, is a developmental and maintainance factor for sympathetic and sensory neurons. Although similar in many respects, there are also differences among the species of NGF that may have important consequences as to the regulation of NGF activity in vivo. NGF can be isolated as $\alpha_2\beta\gamma_2$ multimer from mouse submaxillary gland, a $\gamma\beta$ complex from snake venom or an $\alpha\beta$ complex from human term placenta. The amino acid composition, isoelectric point and molecular weight of human term placenta β-NGF is very similar to that of murine β-NGF. Also, human term placenta β-NGF can displace murine β-NGF from NGF receptors found on IAN-1 human neuroblastoma cells. The clinical significance of NGF has yet to be elucidated since potent inhibitors of NGF activity hamper the measurement of NGF activity in human sera and radioimmunoassays for NGF protein in human sera have relied on antibodies directed against mouse β-NGF. NGF of human origin, whether from term placenta or secreted by a human neurofibroma line, is antigenically indistinguishable. The goal of this project was to develop stable hybridoma clonal lines compatible with growth in ascites fluid that would secrete high affinity antibodies to human β NGF. Using a modification of in vitro immunization techniques developed by us, 454 viable hybridoma cultures were obtained after fusion with P-3 $IgG_1$, secreting mouse myeloma. Of these, after ELISA screening against human β-NGF and cloning, there were six clones that proved to be stable. Ammonium persulfate precipitate of conditioned media of all six clones was found to be active against human beta-NGF. These results were confirmed by immunoblotting and immunoprecipitation with $^{125}$I-human β-NGF. Antibodies secreted by clones PP3, 5 and 6 are $IgG_1$ while 10, 11 and 12 secrete $IgG_1$ and IgM antibodies. P-3 is an $IgG_1$ secretor; thus, both the myeloma $IgG_1$ and IgM gene from spleen are expressed and three classes of antibodies are secreted: IgG and IgG/IgM hybrid. This interpretation is consistent with immuneprecipitation results with protein A and a second antibody, protein-A combination that binds both IgG and IgM. Of these PP3 grows well in ascites fluid and is useful at dilutions of $10^5$. (Supported by NIH grant NS 18708 and Robert Welch Foundation Grant H-698).

## TRANSMITTERS IN INVERTEBRATES III

273.1 DIFFERENTIAL DISTRIBUTION OF TWO HOMOLOGOUS NEUROPEPTIDES (RPCH & AKH) IN CRAYFISH NERVOUS SYSTEM. A.J. Madsen, Jr.*, W.S. Herman* and R. Elde (SPON: G. Giesler, Jr.). Departments of Anatomy, Genetics and Cell Biology, University of Minnesota, Minneapolis, MN 55455.

Red pigment concentrating hormone (RPCH; pQLNFSPGW-$NH_2$) and adipokinetic hormone (AKH; pQLNFTPNWGT-$NH_2$) are peptides isolated from neurohemal tissues of arthropods. Because of their striking structural similarities, these peptides have been regarded as members of a family of invertebrate peptides. The present study was undertaken to determine if immunoreactivity related to each of these peptides coexists within single neurons of a representative arthropod, the crayfish, or whether neurons differentially express peptides detected by antisera selective for RPCH and AKH.

Crayfish (Orconectes immunis) brains and eyestalks were fixed by immersion in Zamboni's fluid, sectioned at 10um on a microtome-cryostat and collected on gel-coated slides. Sections were rehydrated and incubated in primary antisera directed against RPCH or AKH, or absorption control serum for 12-16 hours at 4° C. After washing the sections, fluorescein labeled goat anti-rabbit IgG was applied for 60 minutes. Sections were rinsed, counterstained with ethidium bromide and coverslipped. Previous studies using the immunoblotting technique of Larsson (1981) indicated the antisera to be selective for their respective peptides and exhibit little, if any, cross-reactivity for the heterologous peptide.

Nerve fibers and terminals containing RPCH- or AKH-immunoreactivity were abundant in many regions of the eyestalk and brain of the crayfish. Neuronal cell bodies containing RPCH- or AKH-immunoreactivity were observed throughout the eyestalk, the protocerebrum, the deutocerebrum and the tritocerebrum. Examination of serial sections indicated that individual neurons stained for either AKH-immunoreactivity or RPCH-immunoreactivity, but not both. These results strongly suggest that although RPCH and AKH share strong sequence homologies, individual neurons are dedicated to the production of either one or the other of these two peptides. The mechanisms by which the differential production of AKH and RPCH might occur are not understood, but two possibilities seem likely. Firstly, mRNA may code for separate prohormones which do not coexist in single neurons of the crayfish. Alternatively, post-translational processing of a common biosynthetic precursor may give rise to the production of one peptide at the expense of the other.

Supported by the Graduate School of the University of Minnesota and the Minnesota Medical Foundation.

273.2 INDIVIDUAL NEUROSECRETORY CELLS REGULATING CORPUS ALLATUM ACTIVITY IN THE BRAIN OF THE LOCUST SCHISTOCERCA AMERICANA. M. Zaretsky Dept. of Elect. Engr. and Comp. Sci., Univ. of California, Berkeley CA 94720.

Juvenile hormone (JH) is the principal gonadotropin for most insects. Among several effects of JH upon oogenesis, the best understood is control of production of the protein vitellogenin by the fatbody. A number of reports on several insect species indicate the neurosecretory cells (NSCs) of the brain are significantly involved in the regulation of JH synthesis and oogenesis. The number and location of the NSCs involved varies with the insect group. Both excitatory and inhibitory interactions of the NSCs with the glands that synthesize JH, the corpora allata (CA), have been reported. There is strong evidence for allatotropic hormones, both in the general control of molting and metamorphosis and in specific control of oogenesis and yolk deposition, but these have been neither isolated nor characterized. It is not known what determines the changes in the rate of JH synthesis.

The locust Schistocerca is highly advantageous as an experimental animal for the study of JH regulation. The innervation of the CA is excitatory and comes mainly from the lateral neurosecretory cells (LNSCs) of the brain. The axons of these neurons leave the brain for the corpus cardiacum (CC) by way of NCCII and pass on to the CA in NCAI. To identify the neurons of the brain that excite JH synthesis by the CA, the NCAI was back-filled with cobalt. The axons within NCAI were examined with the electron microscope. Individual NSCs of this group of neurons were filled intracellularly with Lucifer Yellow dye or horseradish peroxidase, which reveal their individual morphology. To correlate the spontaneous activity of these NSCs with the gonotrophic cycle, extracellular recordings were made from the nerve to the CA, and the activity of individual cells was monitored with intracellular electrodes.

In addition to these techniques, stimulation of individual NSCs that innervate the CA will be combined with radiochemical assays for JH [Tobe SS and Pratt GE(1975) J. exp. Biol. 62:611]. Thereby, it should be possible to identify individual NSCs that regulate JH synthesis by the CA. Of particular interest is the effect of circulating levels of JH and ecdysteroids upon the NSCs that regulate JH synthesis.

273.3 IMMUNOHISTOCHEMICAL LOCALIZATION AND PHYSIOLOGICAL ACTIONS OF TWO RELATED INSECT NEUROPEPTIDES (CC1 AND CC2) M.E. Adams, M.F. Ray*, R.K. Ho*, S.J. Kramer*, and P. Marbach*, Research Laboratories, Zoecon Corp., Palo Alto CA 94304 and Pharmaceutical Div., Sandoz Ltd., Basel, Switzerland.

Two peptide hormones occurring in a prominent neurohemal organ, the corpus cardiacum of the cockroach (Periplaneta americana) have been isolated and sequenced. They are blocked octa-peptides referred to here as "CC1": pGluValAsnPheSerProAsnTrpNH$_2$ and "CC2": pGluLeuThrPheThrProAsnTrpNH$_2$, (Scarborough, et al., PNAS 81: 5575, 1984). The identical structures have been independently reported as "M1" (CC1) and "M2" (CC2) (Witten, et al., Biochem. Biophys. Res. Comm. 124: 350, 1984) or as "Neurohormone D" (CC1) (Baumann, et al., Biomed. Biochim. Acta 43: K13, 1984). CC1 and CC2, the locust adipokinetic hormones (AKH I, II) and crustacean red pigment concentrating hormone (RPCH) comprise a family of peptides with close sequence homology. All stimulate muscle rhythmicity and modulate carbohydrate and lipid metabolism. We report here that CC1- and CC2-like immunoreactivity (CC-IR) is not confined to the corpus cardiacum, but also occurs in neurons throughout the nervous system and in nerve terminals innervating the gut, where they possibly function as neurotransmitters.

Serum antibodies were produced in rabbits against amino-terminal CC1 or CC2 conjugates to BSA. Radioimmunoassay studies conducted thus far indicate that the antisera cross-react between CC1 and CC2, but do not recognize AKH or RPCH. Immunohistochemical staining shows strong CC-IR in the corpora cardiaca, consistent with release of the peptides as circulatory neurohormones. CC-IR also occurs in neurons of the brain and segmental ganglia. Brain neurons occur in the medial and lateral pars intercerebralis and in the optic lobes. In the segmental ganglia, immunoreactive medial and lateral cell pairs as well as large medial unpaired neurons are evident. Central arborizations in the segmental ganglia occur in the ventro-medial neuropile areas typically innervated by neurosecretory cell types. The presence of CC-IR nerve terminals innervating foregut musculature suggests synaptic transmitter roles for the peptides. Application of $10^{-7}$ M CC1 or CC2 to the gut region innervated by these terminals causes rhythmic contractions and initiation of peristaltic movements.

Our studies implicate CC1 and CC2 in close-range transmitter functions as well as in hormonal roles. The cellular mechanisms underlying CC1/CC2 actions are under investigation.

273.4 IMMUNOCYTOCHEMICAL MAPPING OF PEPTIDES IN THE BRAIN AND SUBESOPHAGEAL GANGLION OF *MANDUCA SEXTA*. U. Homberg*, S.G.Hoskins, and J.G. Hildebrand (SPON: Tim Kingan). Dept. Biol. Sci., Columbia Univ., New York, NY 10027.

Neuropeptides can be detected in the insect brain not only in the neurosecretory cells of the *pars intercerebralis* but also in other regions [Duve & Thorpe, in *Insect Neurochemistry and Neurophysiology* (eds. A.B.Borkovec & T.J. Kelly), Plenum (1984); Schooneveld et al., *Gen. Comp. Endocrinol. 42*:526 (1985)]. As part of our continuing study of the distribution of putative neurotransmitters in the brain, and especially the antennal lobes, of *Manduca* [Hoskins & Hildebrand, *Soc. Neurosci. Abstr. 9*:216 (1983); Hoskins et al., *Soc. Neurosci Abstr. 10*:688 (1984)], we have investigated the distribution of immunoreactivities recognized by antisera specific for locust adipokinetic hormone (AKH), cholecystokinin (CCK), FMRFamide, glucagon, insulin, leu- and met-enkephalins, substance P, and somatostatin.

Particular sets of neurons in the *pars intercerebralis* are stained reproducibly by each of the antisera except those specific for met-enkephalin and somatostatin; those antisera reacted with none of the cells. Some of the immunoreactive neurons have arborizations in the protocerebrum and tritocerebrum and, in the case of the AKH-immunoreactive cells, axons that can be traced into the neurosecretory *corpora cardiaca*. In other parts of the brain and subesophageal ganglion, immunoreactivities related to AKH, FMRFamide, CCK, and substance P are detectable. In the optic lobes about 50 cell bodies associated with the *lobula* and *medulla* show AKH- or substance-P-like immunoreactivity. The antennal lobes exhibit 10-15 local interneurons immunoreactive to anti-AKH, a few local interneurons immunoreactive to anti-substance P, and one cell immunoreactive to anti-CCK. In the median protocerebrum several neurons showing AKH- or substance-P-like immunoreactivity can be detected in the upper division of the central body and the diffuse protocerebral lobes. The subesophageal ganglion has 2 pairs of neurons with substance-P-like immunoreactivity and 5 that stain with anti-AKH, one of which projects into the antennal lobes and further into the protocerebrum. Experiments in which alternate sections were exposed to different antisera revealed that glucagon- and CCK-like immunoreactivities are present in some of the same cells in the *pars intercerebralis*. Some but not all of the neurons stained by anti-AKH are also immunoreactive to substance P antisera and vice versa. These observations suggest that either these antisera recognize different epitopes on a single peptide or the immunoreactive cells contain more than one neuropeptide.

Supported by a research contract from the U.S. Army Research Office and, in part, by NIH grant AI-17711 and NSF grant BNS-83-12769. U.H. is a postdoctoral fellow of the Deutsche Forschungsgemeinschaft and S.G.H. is supported by a postdoctoral fellowship from NIH.

273.5 IDENTIFICATION OF APLYSIA NEURONS WITH CCK/GASTRIN-LIKE IMMUNOREACTIVITY IN WHOLEMOUNTS OF APLYSIA GANGLIA. J. K. Ono, Division of Neurosciences, Beckman Research Institute of the City of Hope, Duarte, CA, 91010.

An immunohistochemical survey of wholemounts of the CNS of the marine mollusc, Aplysia californica with antisera against the peptides cholecystokinin (CCK) and gastrin demonstrates that numerous Aplysia neurons contain CCK/gastrin-like peptides. Immunoreactive neurons were present in all ganglia except for the pleural ganglia and immunoreactive fibers were observed in the intestine. Several of these immunoreactive neurons in the buccal and cerebral ganglia are re-identifiable. By correlating physiological characteristics with immunoreactivity, buccal neurons B13 and B7, originally identified by Gardner (J. Neurophysiol., 40:349, 1977), have been shown to contain CCK/gastrin-like immunoreactivity. Radioenzymatic assays of individual neurons for acetylcholine (ACh) indicate that B13 contains significant concentrations of ACh, comparable to the levels in the previously identified cholinergic buccal neurons, B4 and B5. The cerebral A cluster neurons, originally described by Fredman and Jahan-Parwar (Brain Res., 100:209, 1975) also display CCK/gastrin-like immunoreactivity. However, application of mammalian forms of CCK and gastrin to the cerebral B cluster neurons, which are postsynaptic to the A neurons, does not elicit a conductance change comparable to the synaptic response.

Variations in the staining patterns with different antisera to CCK and gastrin were observed. Only antisera which recognize the carboxyl terminus common to both CCK and gastrin (WMDF-amide) appear to stain Aplysia neurons. Among the antisera which recognize the Aplysia form of CCK/gastrin, only one (antiserum 5135) stained neurons in the ventral lower right quadrant of the abdominal ganglion. Previously, Osborne et al. (Science, 216:409, 1982) demonstrated that the serotonergic giant cerebral neurons in another mollusc, Helix, contains a CCK-like peptide. However, the cell body of the homologous neurons in Aplysia, the metacerebral or C1 neurons, do not appear to be immunoreactive to the various antisera to CCK and gastrin.

These studies suggest that in the Aplysia CNS there may be more neurons displaying CCK/gastrin-like immunoreactivity than those that are positive for 5HT (Ono and McCaman, Neurosciences, 11:549, 1984). Moreover, the peptide may be co-localized with conventional neurotransmitter amines in certain neurons. The Aplysia form of the CCK/gastrin peptides may be similar to mammalian forms of CCK and gastrin at the caboxyl end but may differ toward the amino end. (Supported by NIH grant NS 18862)

273.6 FMRFAMIDE-LIKE SUBSTANCES IN THE SWIM MOTOR NEURONS OF THE LEECH. B. J. Norris* and R. L. Calabrese. The Biological Laboratories, Harvard Univ., Cambridge MA 02138.

The neuropeptide FMRFamide (Phe-Met-Arg-Phe-NH$_2$), first identified in molluscs (Price and Greenberg, Science 197:670-671, 1977), has been localized with immunocytochemical techniques to a distinct set of neurons in the central ganglia of the leech Hirudo medicinalis (Kuhlman et al., Neurosci. Abs. 46.2, 1984). The excitatory motor neurons that innervate the longitudinal muscles of the body wall appear to be among those that contain FMRFamide-like immunoreactivity (FLI).

We labeled identified longitudinal motor neurons with intracellular injections of Lucifer yellow and tested them for FLI using indirect immunofluorescent labeling. All identified excitatory longitudinal motor neurons on the dorsal surface of the ganglion showed FLI. Cells 5, 6, 8, 107, 108 and L labeled intensely while cells 3 and 4 labeled only faintly. A putative excitatory longitudinal motor neuron on the ventral surface of the ganglion (cell 157) did not show FLI. None of the inhibitory longitudinal motor neurons (cells 1, 2, 7, 9 and 102) showed FLI. Two motor neurons innervating the medial dorsoventral muscles also contained FLI. Cell 117, an excitatory neuron, labeled intensely and cell 101, an inhibitory neuron, labeled very faintly. We will determine the amount of FMRFamide-like substance in a single identified longitudinal motor neuron (cell L) using radioimmunoassay (Li and Calabrese, this meeting).

Our preliminary experiments show that bath applied FMRFamide at a concentration of 0.8 x 10-7 mM caused a strong contraction in longitudinal muscle. Continuing research involves characterizing the effects of applied FMRFamide on longitudinal muscle.

The major excitatory neuromuscular transmitter in the leech is acetylcholine (Wallace, J. Neurosci. 2:1108-1118, 1982), and excitatory neuromuscular transmission is blocked by curare (Kuffler, J. Comp. Physiol. 124:333-338, 1978). We will block cholinergic transmission with curare and look for residual neuromuscular effects which could be due to a FMRFamide-like peptide.

We wish to thank T. O'Donohue and W. Watson for their generous gift of anti-FMRFamide antiserum. This work is supported by NIH grant RO1 NS21232.

273.7 FMRFamide-LIKE SUBSTANCES IN THE LEECH: BIOCHEMICAL CHARACTERIZATION. C. Li and R. L. Calabrese. Biological Laboratories, Harvard University, Cambridge, MA 02138.

FMRFamide is a tetrapeptide that is present in a variety of invertebrates and vertebrates. FMRFamide-like immunoreactivity has been localized to a number of neurons and neural processes in the leech, Hirudo medicinalis (Kuhlman, Li, and Calabrese, 1985a, J. Neurosci., in press). To determine whether true FMRFamide exists in the leech, acidified methanol extracts of leech nerve cords and heart tubes were examined biochemically for FMRFamide-like substances. Using a radioimmunoassay, 8-15 pmol, 2-3.5 pmol, and 1-4 pmol of FRMFamide-like equivalents were measured per nerve cord, head brain, and heart tube extract, respectively. The inhibition of trace binding to anti-FMRFamide antibody (a kind gift from T. O'Donohue and W. Watson) by serial dilutions of synthetic FMRFamide and tissue extracts was parallel, indicating a similar affinity of synthetic FMRFamide and tissue extracts to the antibody.

Extracts of nerve cords and heart tubes were further purified on a $C_{18}$ Sep-pak cartridge for reverse phase high pressure liquid chromatography (HPLC) analysis. Five peaks containing FMRFamide-like immunoreactivity were recovered from nerve cord extracts. The majority of immunoreactivity was found in three peaks. The largest of these peaks co-eluted with synthetic FMRFamide; the other two peaks co-eluted with oxidation products of synthetic FMRFamide. Heart tube extracts contained two peaks that were FMRFamide-like immunoreactive. The major peak co-eluted with synthetic FMRFamide, and the minor peak co-eluted with one of FMRFamide's oxidation products. We are isolating the peptides for amino acid sequencing.

A pair of neurons innervating the heart, the heart modulatory neurons (HA cells), were found to contain FMRFamide-like immunoreactivity using immunocytochemical methods; in addition, the peripheral effects of bath application of FMRFamide are very similar to those effects produced by HA cells (Kuhlman, Li, and Calabrese, 1985b, J. Neurosci., in press). HA cells were isolated to quantify and analyze the FMRFamide-like immunoreactivity. 20-50 fmol of FMRFamide-like equivalents were measured per HA cell extract. HPLC analysis of cell extracts revealed two peaks of immunoreactivity, one that co-eluted with synthetic FMRFamide and one that co-eluted with an oxidation product of FMRFamide. These data support our hypothesis that HA cells use FMRFamide as their primary neurotransmitter.

273.8 IMMUNOCYTOCHEMICAL LOCALIZATION OF SEROTONIN, FMRFamide, BPP, AND $SCP_B$ IN NUDIBRANCH MOLLUSKS. Roger D. Longley* and Alison J. Longley. Pacific Sciences Institute, P.O. Box 835, Friday Harbor, WA 98250 and Friday Harbor Laboratories, Friday Harbor, WA 98250.

We have used antibodies to serotonin, FMRFamide, BPP, and $SCP_B$ in a wholemount method which allows efficient, direct visualization of the three dimensional structure of immunoreactive somata, axons, and neuropil in the nudibranch central nervous system. $SCP_B$ containing neurons were identified with a mouse monoclonal antibody marked with a rhodamine labeled second antibody, which allowed crossreactivity comparisons in the same preparation to other antibodies labeled with FITC. We tested this antibody for specificity by first filling, with lucifer yellow, visually identifiable $SCP_B$ containing neurons in the Tritonia buccal ganglia before processing with the $SCP_B$ antibody.

In the species examined [Hermissenda (Phidiana) crassicornis, Aeolidia papillosa, Armina californica, and Tritonia diomedea], strong homologies were present in soma location and axon distribution for several large neurons. The serotonergic giant cerebral neurons (GCNs) and an unpaired serotonergic left pedal neuron, apparently LPd1 in Tritonia and Hermissenda, are uniformly present. The GCNs and LPd1 can be recognized with antiserotonin antibody in developing Hermissenda (AJ Longley, Neurosci. Abstr., 1985). In each species, a large $SCP_B$ immunoreactive neuron in the cerebral ganglion, usually adjacent to the GCN, sends axons into the cerebral nerves. This neuron is especially prominent in Aeolidia. In the buccal ganglion, a large $SCP_B$ neuron with an axon in the gastroesophageal connective was seen. The gastro-esophageal ganglion also contains a large $SCP_B$ neuron with an axon in the gastric nerve. With the antibodies used, many other neurons, both large and small, could be seen for which cross species homologies were not evident. In Hermissenda, a large neuron in the right pleural ganglion, apparently the largest neuron in this ganglion, is immunoreactive to $SCP_B$, but a comparable neuron was not seen in the other species examined.

The following general observations were made. 1) BPP immunoreactive neurons crossreact with antiFMRFamide antibody. 2) Axons immunoreactive to antiFMRFamide were not seen in peripheral nerves. 3) Some FMRFamide and $SCP_B$ immunoreactive neurons crossreact. 4) The largest number of immunoreactive neurons seen contained serotonin and $SCP_B$, but there are ganglionic differences in the distribution of serotonin and $SCP_B$ containing neurons. Buccal and gastroesophageal neurons contain $SCP_B$ and a small number of $SCP_B$ neurons are in the pleural ganglia, but there are no serotonergic somata in these ganglia. Most of the serotonergic neurons are in the pedal ganglion, but there are only about two $SCP_B$ neurons in that ganglion. 5) Serotonin and $SCP_B$ containing neurons in the cerebral ganglia innervate the rhinophore ganglia with densely varicose endings.

273.9 EFFECTS OF NEUROTENSIN AND A NEUROTENSIN-RELATED PEPTIDE FROM LOBSTER ON CARDIAC FUNCTION. S.R. Kirschenbaum, C.A. Aghajanian*, C.H. Price, and R.E. Carraway*. Department of Biology, Boston University, Boston, MA 02215 and Department of Physiology, University of Massachusetts Medical Center, Worcester, MA 01605.

Many peptides isolated from vertebrates have been demonstrated in invertebrates by radioimmunoassay and immunohistochemistry although few precise structures and functions have been identified. We previously reported the occurence of neurotensin (NT)-related peptides in the heart and hepatopancreas of the lobster (Homarus americanus). The partial sequence of one of these peptides shows close sequence homology with the C-terminal region of mammalian-NT. Using mammalian NT and partially purified lobster NT we examined the role of NT in lobster cardiac function .

Heart tone, beat frequency and amplitude were recorded from an intact heart isolated from CNS inputs and perfused with saline to which cardioactive substances were added. Perfusion with $10^{-5}$ M NT for several seconds induced a dose-dependent increase in muscle tone and a decrease in beat amplitude within seconds and a delayed increase in frequency . All effects were reversible: after washout of NT, the heart returned to baseline tone and amplitude in about 3 minutes and baseline frequency in 10-15 minutes. Repeated applications resulted in reduced maximal responses indicating desensitization to NT.

Intracellular recordings from single muscle fibers were made to further examine the effect of NT on muscle. NT ($10^{-5}$ M) depolarized the resting membrane potential by 10-20 mV and decreased the magnitude of the rhythmic depolarizations. These dose-dependent responses had the same onset and washout times as responses in the intact heart. A synthetic peptide having the proposed sequence for lobster immunoreactive NT induced similiar depolarizations of the muscle membrane at concentrations of about $10^{-9}$ M.

These results suggest that the NT-like peptides demonstrated in lobster heart play a role in invertebrate cardiac function. The lobster immunoreactive NT would thus be structurally as well as functionally related to mammalian NT for which a cardiovascular regulatory role has been proposed.

273.10 PARTIAL PURIFICATION OF A POLYPEPTIDE FROM LOBSTER EYESTALKS THAT INDUCES cGMP ACCUMULATION IN LOBSTER NEUROMUSCULAR PREPARATIONS. M.F. Goy*, C.M. York*, and D. Mandelbrot* (SPON: D. Potter) Neurobiol. Dept., Harvard Med. School, Boston, MA 02115.

We are investigating the function of cyclic GMP (cGMP) at the neuromuscular junction of the lobster, Homarus americanus. Several observations suggest that this nucleotide might play a role in regulating some aspect of crustacean neuromuscular physiology: 1) lobster muscle is among the richest known sources of cGMP-dependent protein kinase, 2) the tissue contains several phosphoproteins whose state of phosphorylation can be influenced more effectively by cGMP than by cAMP, and 3) guanylate cyclase and phosphodiesterase are highly active in these preparations.

Although previous work has shown that the physiological properties of these synapses can be modulated by a number of circulating neurohormones, no factor has yet been identified in the lobster that alters muscle cGMP levels. Accordingly, we screened extracts of neural and neurosecretory structures for the ability to promote cGMP accumulation in isolated exoskeletal muscles. Extracts of the eyestalk (which includes the neurosecretory sinus gland) contain a factor that causes greater than 100-fold increases in muscle cGMP content, whereas extracts of other tissues are inactive.

The biological activity of the eyestalk factor is destroyed by boiling and by digestion with trypsin, chymotrypsin, or pronase. The factor has been carried sequentially through several purification steps, including differential centrifugation, gel filtration chromatography, ion exchange chromatography, and reverse phase chromatography, with a net purification of greater than 13,000-fold over the starting material. These procedures reveal that the factor has an apparent molecular weight of 6-10,000 daltons, an acidic isoelectric point, and hydrophobic binding characteristics. In other crustacea, a peptide with a similar molecular weight and an acidic isoelectric point (the crustacean Hyperglycemic Hormone) has been implicated in the cGMP-mediated regulation of glycogen metabolism. However, in lobsters, the hyperglycemia-inducing factor is reported to have a molecular weight of 1,500 daltons. Our long range goal is to purify the lobster eyestalk factor described here to homogeneity, compare it to the hyperglycemic hormones of other crustacea, and use it as a probe to evaluate the physiological role of cGMP at the neuromuscular junction. (Supported by NIH grant #NS 07848 to E.A. Kravitz. Lobster eyestalks were kindly donated by Legal Seafood, Boston, MA).

273.11 OCTOPAMINE- and cAMP-STIMULATED PHOSPHORYLATION OF A PROTEIN ASSOCIATED WITH PHOTORECEPTOR SOMATA IN THE LIMULUS VENTRAL EYE. S. C. Edwards* and B-A. Battelle. C. V. Whitney Laboratory, Univ. of Florida, St. Augustine, FL 32086

Efferent innervation to retinas exists in many animal species. The Limulus ventral eye provides an excellent system for studying the role of efferent innervation in visual function. Previous studies (reviewed by Battelle, TINS 7:277, 1984) have shown that in the ventral eye, the efferent fibers project specifically to the photosensitive membrane of the photoreceptors. The biogenic amine octopamine (OCT) fulfills many criteria as a neurotransmitter within these fibers. O'Day and Lisman (ARVO, 1984) showed that exogenously applied OCT increases the rate of dark adaptation of the photoreceptors. These effects were mimicked by forskolin, a nonspecific adenylate cyclase stimulator, and cAMP.

We are studying the biochemical effects of OCT on Limulus ventral photoreceptor cells. Since OCT stimulates an increase in the level of intracellular cAMP and activates adenylate cyclase in these cells (Kaupp et al., Vision Res. 11:1503, 1982), we speculated that OCT may cause changes in the phosphorylation of photoreceptor proteins. We have examined the effects of OCT on the phosphorylation of proteins in ventral eye preparations enriched in intact photoreceptor cell bodies (P-fraction) and in axon-enriched fractions which contain only few photoreceptor cell bodies (A-fraction). The fractions are maintained at 4°C in Limulus saline containing glucose for 12-18 hrs following dissection, then preincubated in the light in saline containing [32P] orthophosphate (2.3 mC/ml) for 1.5 hrs prior to experimentation. We have reported (ARVO, 1985) that subsequent exposure of P-fractions to OCT (0.2 - 2.0 uM) stimulates the phosphorylation of a protein with an apparent molecular weight of 122 ± 2.3 kD based on its mobility on SDS-PAGE and detection using autoradiography. Enhanced phosphorylation of the 122 kD protein occurred within 5 min of exposure of the tissue to OCT and was blocked when the tissue was preincubated for 10 min with 10 uM phentolamine, an OCT receptor blocker, prior to exposure to OCT (2 uM) plus phentolamine. OCT did not stimulate the phosphorylation of this protein in the A fraction.

We now report that the 122 kD protein is phosphorylated when the P-fractions are exposed for 5 min to either 10 uM 8-bromo-cAMP or 10 uM forskolin. Furthermore, this protein and proteins having approximate molecular weights of 170 and 57 kD are phosphorylated when homogenates prepared from either the P- or A-fractions are exposed to 10 uM 8-bromo-cAMP in a MOPS buffered medium (pH 7.0) containing gamma-labelled [32P] ATP, 10 mM $MgCl_2$, 1 mM EGTA, and 1 mM DTT. These results suggest that the OCT-stimulated phosphorylation of the 122 kD protein in the ventral eye is mediated by cAMP and probably involves a cAMP-dependent protein kinase. (Supported by NIH Grant #EY05724-01 and the C. V. Whitney Laboratory).

273.12 AUTORADIOGRAPHIC LOCALIZATION OF SEROTONIN RECEPTORS IN APLYSIA GANGLIA. M.J. Kadan and P.R. Hartig, Dept. of Biology, The Johns Hopkins University, Baltimore, MD 21218.

Serotonin and dopamine receptors have been identified in Aplysia by $^3$H-LSD binding to ganglia homogenates (Drummond et al., Brain Res. 184: 163-177 (1980)). We have used the sensitive serotonergic ligand $^{125}$I-LSD to study the distribution and properties of receptor sites in the Aplysia nervous system. $^{125}$I-LSD is 120 fold more sensitive than $^3$H-LSD for receptor assays, which allowed us to carry out binding studies on a single ganglion and to generate autoradiographic images of receptor distribution with 1-5 day exposures.

Ten micron frozen sections were cut from Aplysia ganglia and thaw mounted on gelatin subbed glass slides. Sections were covered with ligand solution (0.3 nM) ± competing drugs for 20 min. at 37°C, cooled, then washed 40 min. in ice cold water. Sections were blown dry under a stream of cold air and exposed to film (LKB Ultrofilm or Kodak AR10 stripping film). Binding was assessed by microdensitometry of the autoradiographic image, or by wiping sections from the slides and directly counting the radioactivity.

$^{125}$I-LSD binding to ganglia sections was saturable and stereospecific. Cinanserin, an effective serotonergic antagonist in this system, reached a plateau of displacement near 20 µM after displacing 65-75% of the bound $^{125}$I-LSD. Serotonin was the most potent agonist displacer, reaching a plateau near 100 µM. Dopamine was a weaker displacer than serotonin while epinephrine and norepinephrine showed no significant displacement at 100 µM. Interestingly, 8-OH-DPAT, a selective serotonergic ($5\text{-}HT_{1a}$) agonist appeared equal to or more potent than serotonin as a displacer.

Comparison of autoradiographic images and histologically stained sections demonstrated that the specific binding was restricted to the neuropil region. No specific labeling of the surrounding cell soma or ganglion sheath was observed. This receptor distribution matches electrophysiological data on serotonergic responses in this system. Specific labeling of the axonal processes within the sheath of the ganglia interconnective was also observed.

This study provides the first autoradiographic mapping of serotonin receptor distribution in Aplysia, demonstrating that receptor binding sites within the ganglia are localized to the neuropil region, in accord with electrophysiological data.

273.13 HISTOFLUORESCENCE OF CATECHOLAMINE-CONTAINING NEURONS IN *Drosophila*. V. Budnik*, A.M.Vallés* and K. White* (SPON: H. Epstein). Department of Biophysics and Department of Biology, Brandeis University, Waltham MA 02254.

The neurotransmitter dopamine has been identified in several invertebrates. In the fruit fly *Drosophila melanogaster*, it is possible to alter the levels of dopamine using genetic variants in the gene *Ddc* encoding the enzyme dopa decarboxylase (Wright et al., Genetics, 84: 287, 1976). As a prelude to the study of effect of dopamine concentration on neural development, we have initiated a study of catecholaminergic neurons in *Drosophila*. In order to identify dopamine containing neurons, the pattern of catecholamine containing neurons in the fly central nervous system (CNS) was determined using two histofluorescence techniques (Flanagan, J. Insect Physiol., 30: 697, 1984; Furness et al, Histochem, 57: 285, 1974). The larval CNSs were dissected and treated by either the glyoxilic acid or the paraformaldehyde-glutaraldehyde method. Both methods gave the same stereotypic pattern of stained cells. In the brain lobes, histofluorescence was observed in three bilaterally symmetrical clusters of 4 to 6 neurons each. In the ventral ganglion, a characteristic pattern of fluorescent cells was observed in a row of cells along the dorsal midline and a lateral row of ventrally located cells, consisting of a single cell per hemi-segment in the thoracic and abdominal segments. In addition, a cluster of cells is also present in the subesophageal ganglion. Comparison of the pattern of catecholaminergic neurons in the larval ganglion with serotonergic neurons shows that the two patterns are distinct (see Vallés and White, this volume). CNS of adult and of mutant larvae deficient in the gene *Ddc* were also examined. (Supported by NH grants GM 31503).

273.14 CHARACTERIZATION OF TRANSMITTER INTERACTION AND IMMUNOCYTOCHEMICAL LOCALIZATION OF GAMMA AMINOBUTYRIC ACID AT THE NEUROMUSCULAR JUNCTION OF THE CENTIPEDE Lithobius forficatus. M.E.C. Fitzgerald*†, A.A. Manthey*††, and J.F. Reger*† (SPON: R.B. Caldwell). Division of Neuroscience, Dept. of Anatomy† and Dept. of Physiology††, U.T.C.H.S., Memphis, TN 38163.

Spontaneous depolarizing and hyperpolarizing events were recorded from centipede intersegmental muscle using standard intracellular glass capillary electrodes. These events were somewhat different from miniature end-plate potentials (MEPPs), as recorded from amphibian muscle, in that they had long durations of 100ms or more with slow rise times, and the peak amplitudes of a series of events from the same recording site varied over a wide range from 0.2 to 4.0 mV (mean = 1.10 ± 0.046 (SE) mV) for both types of events. Preliminary histograms suggested quantization of amplitudes of the events.

Local perfusion of bicuculine ($10^{-5}$M, a specific gamma aminobutyric acid (GABA) receptor antagonist) resulted in depolarization and often in contraction of the muscle; in several cases, bicuculine perfusion also eliminated the hyperpolarizing events. In other experiments, perfusion of glutamate di-ethyl ester (GDEE) ($10^{-5}$M, a glutamate receptor antagonist) caused the depolarizing events to disappear. These results suggest that the spontaneous events arise from prejunctional release of GABA and glutamate respectively. Bath application of glutamate ($10^{-5}$M) initially caused depolarization of 5 to 6 mV; following this, fibers spontaneously repolarized despite continued presence of glutamate and after 30 minutes attained values of potentials 5 to 6 mV more negative than resting control values. These results suggest that desensitization of glutamate receptors may be occuring during the repolarization phase and that the hyperpolarization observed is a consequence of continued influence of spontaneous GABA release.

Although these electrophysiologic measurements thus suggest that two transmitter systems are acting on the muscle fibers, prior work (Reger and Fitzgerald, J. Submicrosco. Cytol. 13:1, 1981) had only shown one synaptic morphology. A GABA primary antibody technique was therefore employed to distinguish and localize inhibitory components on the electron microscopic level.

Supported by Sigma Xi Grant-in-aid-of-Research and U.T.C.H.S. grant BRSG-84-10. The authors express their thanks to Dr. Robert Stiles and Dr. Ranney Mize for their assistance in computer analysis and immunocytochemical procedures.

273.15 CONTRACTIONS OF COCKROACH HYPERNEURAL MUSCLE IN RESPONSE TO GLUTAMATE, PROCTOLIN, OCTOPAMINE, AND A FACTOR FROM THE PINK BOLLWORM. J. I. Moss*, and T. A. Miller* (SPON: A. E. Chalmers). Div. of Toxicology and Physiology, Dept. of Entomology, Univ. of California, Riverside, CA 92521

The cockroach (Periplaneta americana) hyperneural muscle was dissected as described by Miller and James (J. Insect Physiol., 22:981, 1976) and was found to contract in response to a 2.5 µl drop of extract from cockroach abdominal nerve cord, whole pink bollworm (Pectinophora gossypiella) pupae, house fly (Musca domestica) heads and mouse brain. Ion exchange chromatography of these extracts produced three areas of activity. Two of the areas corresponded to the elution volumes of aspartate and glutamate. The third eluted shortly after glutamate.

Of the twenty common amino acids, only glutamate and aspartate caused contraction of this muscle at concentrations at or below $1x10^{-3}$M. Octopamine, applied at $1x10^{-6}$M, caused either no response or a relaxation of the muscle. The pentapeptide, proctolin, caused contractions with a drop on threshold of about $1x10^{-11}$M. Since the third area of activity is stable to acid hydrolysis attempts, it is probably not a peptide. The maximal contractile force elicited by this material is comparable to that of glutamate, although the duration of the response to drop on assay is shorter. The contractions caused by aspartate, glutamate, and the third factor were reversibly blocked by Aranea gemma venom, while the proctolin-induced contractions were not blocked.

273.16 MECHANISMS BY WHICH OCTOPAMINE ENHANCES THE EXCITATORY JUNCTION POTENTIAL AT AN INSECT NEUROMUSCULAR JUNCTION. G. K. Fitch* and A. E. Kammer. Division of Biology, Kansas State University, Manhattan, KS 66506.

Superfusion of Manduca sexta flight muscle with octopamine, a biogenic amine, enhances the amplitude of the excitatory junction potential (EJP) made by the muscle in response to electrical stimulation of its motor neuron. In low-calcium saline, an 18-day-old pharate adult (one day from eclosion) makes a 4 mV EJP in response to motor neuron stimulation. Addition of $5 \times 10^{-6}$ M octopamine to the saline results in a 15 mV EJP. Both the normal and the enhanced EJP reach their peak about 7 ms after the EJP begins, but the enhanced EJP rises at a rate of 3.9 mV/ms whereas the normal EJP rises at a rate of 1.2 mV/ms. One possible explanation for these differences in EJP parameters is that octopamine allows more transmitter to be released from the presynaptic ending, but that the time course of transmitter release is unaffected. However, receptors for octopamine are also present on the postsynaptic cell, since superfusion of $5 \times 10^{-6}$ M octopamine results in a 7 mV hyperpolarization of the resting membrane potential of the muscle cell.

Previous work in our laboratory on 18-day-old pharate adults indicates that synaptic modulation at the neuromuscular junction (NMJ) in these developing moths may be due to both presynaptic and postsynaptic actions of octopamine, since the amplitude and frequency of miniature endplate potentials increases during the application of octopamine. To further investigate possible postsynaptic mechanisms of synaptic enhancement, glutamate, which is known to be a transmitter at some arthropod NMJs, was applied to the preparation in the presence and absence of octopamine. Glutamate alone depolarizes the muscle cell in a dose-dependent manner and is therefore probably the transmitter at this NMJ. In 18-day-old pharate adults, superfusion of $10^{-2}$ M glutamate in 20-second pulses with 15 minutes of saline superfusion between pulses to allow receptor resensitization results in depolarizations of 7 mV. Similar pulses of glutamate in the presence of $10^{-5}$ M octopamine result in 13 mV depolarizations. Thus, postsynaptic actions of octopamine nearly double the response of the muscle to a putative transmitter. Because the response of the muscle to motor nerve stimulation is more than tripled by $5 \times 10^{-6}$ M octopamine, we conclude that octopamine modulation of transmission at this immature synapse involves both presynaptic and postsynaptic mechanisms. Supported by NIH grant NS19257.

273.17 NEUROTOXIC EFFECTS OF 5,6-DIHYDROXYTRYPTAMINE IN THE CENTRAL NERVOUS SYSTEM OF THE FIDDLER CRAB, UCA PUGILATOR. G.K. Kulkarni* and M. Fingerman. Dept. of Biology, Tulane Univ., New Orleans, LA 70118.

5,6-Dihydroxytryptamine (5,6-DHT) is a selective neurotoxin producing degeneration of 5-hydroxytryptaminergic nerve terminals in the central nervous system. 5-hydroxytryptamine (5-HT) appears to function as a neurotransmitter in Uca pugilator. There is strong evidence that 5-HT has the physiological role of stimulating release of some of the hormones, such as the red pigment dispersing hormone, from the neuroendocrine complex in the eyestalk. In two hours a dose of 0.05 ml 5,6-DHT, 0.0025M, per crab induced obvious histomorphological changes in neurosecretory cells in the eyestalks, brain, and thoracic ganglion. With Mallory's triple stain three types of neurosecretory cells are readily distinguished in these structures on the basis of stainability, cell size, nuclear size, and nuclear location. We have, for convenience, designated these cells as types I, II, and III. Only cell types I and II (the two larger types) showed changes after the 5,6-DHT was injected. The size of the type I cells in the eyestalk increased, but decreased in the brain and thoracic ganglion. The nucleus of the type I cells in the brain increased, decreased in the thoracic ganglion, but did not change in the eyestalk. However, the quantity of stored neurosecretory material decreased in the type I cells of all three regions. The size of the type II cells decreased in the three centers, but the size of the nucleus in the type II cells of the brain increased whereas it decreased in the eyestalk and thoracic ganglion. Like the type I cells, the quantity of stored neurosecretory material was reduced in the type II cells of all three regions. These changes in cell types I and II presumably reflect responses to a large degree to depletion of 5-HT in the neurons that are involved in stimulation of the release of the neurohormones they produce. Concomitant with the degeneration of 5-hydroxytryptaminergic neurons that occurs after 5, 6-DHT administration is 5-HT depletion. This depletion would presumably involve release of sufficient 5-HT to stimulate neurosecretory cells that normally respond to 5-HT excitation by releasing their contained neurohormones, thus accounting for the observed decrease in stored neurosecretory material in cell types I and II. The observation that the type III cells showed no changes after the 5,6-DHT was administered is not surprising in view of the fact that in the fiddler crab 5-HT selectively produces hormone release, some hormones being released only by dopamine or norepinephrine. Also, the fact that the type III cells showed no changes is strong indication that the changes in cell types I and II were not merely nonspecific responses to a neurotoxin. Supported by NSF Grant PCM-8300064.

277 SYMPOSIUM. MOLECULAR INSIGHTS INTO GABA-RECEPTOR FUNCTION. J. F. Tallman, Yale Univ. Sch. of Med. and E. Costa, NIMH, St. Elizabeths Hosp., (Chairpersons); C. Braestrup*, Novo Industri, Denmark; H. Möhler*, Hoffmann-LaRoche, Switzerland; J. Bormann*, Max-Plank Institut at Göttingen, FRG; D. Gallager, Yale Univ. Sch. of Med.; A. Guidotti, NIMH.

Recent biochemical, electrophysiological, pharmacological and immunological experiments have provided many details about the molecular structure and function of the GABA receptor complex (Introduction-E.Costa). Current information indicates that this complex is composed of at least two nonidentical subunits and contains binding sites for GABA and drugs which interact with chloride channels. Benzodiazepines are allosteric modifiers of the GABA site and indirectly enhance the actions of GABA. The ability to interact with GABA predicts the relative agonist and antagonist properties of drugs that interact at the benzodiazepine receptor. The target size of the entire complex and individual drug binding sites has been estimated by radiation inactivation (C. Braestrup). The GABA/benzodiazepine receptor complex has been purified by affinity chromatography and monoclonal antibodies against the benzodiazepine receptor have been used to determine details of subunit structure and for immunocytochemical localization (H. Mohler). Multiple conductance states of the GABA receptor have been defined by patch clamp techniques; some of these states are stabilized by drugs (J. Bormann). Altered GABA sensitivity appears to underlie the development of benzodiazepine tolerance; tolerance is rapidly reversed by benzodiazepine antagonist treatment (D. Gallager). The properties and structure of a peptide modulator of benzodiazepine receptors found in brain which possesses anxiogenic activity in a number of behavioral tasks will be described (A. Guidotti). Future molecular approaches to the study of the GABA/benzodiazepine receptor and their implications for human studies will be discussed (J. Tallman).

278 SYMPOSIUM. EFFECTS OF BEHAVIORAL STATE AND MOTOR ACTIVITY ON SENSORY NEURONAL PROCESSING. R. Dubner, NIDR-NIH, and C. Bell, Good Samaritan Hospital (Co-Chairmen); J.C. Houk, Northwestern Univ.; M.C. Bushnell, Université de Montréal, J.M. Miller, Univ. of Michigan; D.L. Robinson, NEI-NIH; J. Fuster, UCLA.

Recent studies indicate that simple and complex behaviors in invertebrates and vertebrates modify the transmission of sensory information at different levels of the central nervous system. This symposium will examine several sensory systems in which signals are modified by motor activity and more complex aspects of behavior involving attention and memory. R. Dubner will introduce the session with an overview of the interaction of behavior and sensory processing. C. Bell will discuss how central discharges in mormyrid fish alter the sensory consequences of motor commands. J.C. Houk will report that the sensitivity of cat inferior olivary cells is attenuated during certain phases of active movement in contrast to sensory responses evoked by passive movement or by external cues. M.C. Bushnell will describe the responses of medullary dorsal horn (trigeminal nucleus caudalis) neurons to innocuous and noxious thermal stimuli in monkeys trained in a detection task. She will show how attentional factors modify the monkey's ability to detect these stimuli. J.M. Miller will report on studies of neurons at various levels in the monkey auditory system, including the cerebral cortex, and how behavioral tasks and training can dramatically alter cellular responses. D.L. Robinson will describe the visual properties of neurons in the pulvinar thalamic nuclei of the primate during behavior. He will show how responses during specific tasks are modified by changes in neurotransmitter activity and are related to attention. J. Fuster will show that neurons in the inferotemporal and frontal cortices are responsive to visual stimuli and that their discharges can be modified when a monkey performs a visual memory task. A discussion period will follow in which the participants will examine possible directions for future research in this area.

## TROPHIC INTERACTIONS I

279.1 THE EFFECT OF TRANSSYNAPTIC STIMULATION ON THE MORPHOGENESIS OF THE AMPHIBIAN MAUTHNER CELL. L.A. Goodman and P.G.Model. Dept.Neurosci., Albert Einstein Coll. Med., Bronx, NY 10461

Afferent innervation affects the properties of target neurons. During development, formation of synaptic contacts may be essential for the normal differentiation and maintenance of postsynaptic neurons. We have examined the extent to which ingrowing axons regulate the morphogenesis of a single target neuron, the Mauthner cell (M-cell). M-cells occur as a pair of large, uniquely identifiable neurons in the medulla of fish and premetamorphic amphibians. In the axolotl (Ambystoma mexicanum), M-cells are located at the level of entry of the vestibular nerve (nVIII); each receives synapses from the ipsilateral nerve as a major source of afferent input. nVIII terminals are morphologically distinctive as club endings in both the light and electron microscopes. These endings are restricted to the proximal ventral surface and branches of the M-cell lateral dendrite. Here we report on the effects of superinnervation on the growth and branching of this portion of the M-cell lateral dendrite.

Superinnervation was brought about by the unilateral implantation of an extra vestibular primordium (together with its associated nVIII ganglion) rostral to the in situ one. Surgery was performed prior to nVIII ougrowth and M-cell differentiation. The contralateral side served as a control. When the animals reached the 21mm larval stage, the ectopic nerve was labelled with horseradish peroxidase (HRP).

Subsequent LM examination of the larvae showed that both the ectopic and in situ vestibular primordia had developed into anatomically normal ears. HRP-labelled vestibular axons entered the brain at the level of nV and coursed caudad in the nVIII tract. EM analysis demonstrated labelled club endings on the appropriate region of the experimental M-cell lateral dendrite. Comparison of LM-reconstructed experimental and control M-cells revealed that superinnervated M-cells had significantly enhanced dendritic branching in the region of the lateral dendrite that normally receives vestibular input. No changes were observed in the size and shape of the M-cell soma, medial dendrite, or axon.

These results support the hypothesis that afferent input has a transsynaptic trophic effect on the morphogenesis of target neurons. Our data, together with the results of deprivation experiments (Kimmel, Develop. Biol., 55:244-259, 1977), indicate that ingrowing axons have an essential role in regulating the elaboration of a normal dendritic branching pattern by target neurons during development.

279.2 PRESYNAPTIC INFLUENCE ON POSTSYNAPTIC CHANNEL KINETICS IN FROG SYMPATHETIC NEURONS. L.M. Marshall* (SPON: D.E. Millhorn). Dept. of Physiol., Univ. of North Carolina, Chapel Hill, NC 27514

Sympathetic ganglia of the frog contain two types of principal neurons, B and C neurons, which are selectively innervated by two different classes of cholinergic preganglionic axons, B and C fibers. In both types of ganglionic neurons, the fast excitatory postsynaptic currents (EPSCs) are mediated by nicotinic ACh-gated channels. This study examined the EPSCs and ACh-gated channels of B and C neurons in normal ganglia and in ganglia where denervated B neurons were incorrectly innervated by preganglionic C fibers. The results provide evidence that the kinetic properties of postsynaptic ACh-gated channels depend on the particular class of innervating preganglionic axon.

Neurons in the 9th and 10th lumbar sympathetic ganglia of adult bullfrogs were identified according to conduction velocity and voltage clamped at -50 mV (20-22°C). In normal ganglia, the time constant for the exponential decay of the EPSCs was 5.5 ±1.1 msec for B neurons and 10.2 ±2.3 msec for C neurons (mean ±S.D.). Spectral analysis of ACh noise revealed that these different EPSC decay rates correspond to similar differences in the mean lifetime of ACh-gated channels of the B neurons (5.2 ±0.9 msec; ±S.D.) and C neurons (9.8 ±2.0 msec). This indicates that the EPSC decay is governed by the rate of channel closure.

To innervate B cells with C fibers, preganglionic B fibers were cut while the C fibers remained intact. Three weeks after surgery, B neurons were identified by antidromic conduction velocity (> 1 m/sec) and found to be innervated solely by preganglionic C fibers. These incorrectly innervated B neurons had slowly decaying EPSCs and long mean channel open times which were indistinguishable from those of normal C neurons.

B neurons maintained these slower ACh-gated channels for over three months when the surgery was repeated to prevent the return of the preganglionic B fibers. When B neurons were reinnervated by B fibers, the mean EPSC decay time was not significantly different from that of B neurons in normal ganglia. This indicates that the expression of slower ACh-gated channel kinetics in B neurons is not a consequence of reinnervation alone, but a specific response to innervation by preganglionic C fibers. (Supported by grants NS 17203 & NS 14899.)

279.3 MUSCLE FIBERS ARE REQUIRED FOR THE SELECTIVE ACCUMULATION OF CONNECTIVE TISSUE CELLS IN JUNCTIONAL REGIONS OF DENERVATED SKELETAL MUSCLES. Elizabeth A. Connor and U.J. McMahan. Dept of Neurobiology, Stanford University, Stanford, CA 94305.

Denervation of a skeletal muscle results in a selective accumulation of connective tissue cells in the former region of innervation. These connective tissue cells are structurally similar to fibroblasts. Such cells may play a crucial role in reestablishing neuromuscular function after nerve damage; connective tissue cells make and degrade extracellular matrix, and the extracellular matrix of nerve and muscle is directly involved in regeneration of the neuromuscular junction.

We have undertaken a series of studies aimed at determining the function of the connective tissue cell aggregates and learning how the accumulation of the cells is regulated. In the experiment described here we examined the role of components of the denervated neuromuscular junction--the muscle fiber, degenerating axon terminal and the Schwann cell associated with the terminal--in directing the accumulation of connective tissue cells. We damaged frog muscles in ways that caused degeneration of the muscle fibers but left intact myofiber basal lamina, the axons that innervated the muscle fibers and the Schwann cells. Regeneration of muscle fibers was prevented. One month later, when all of the original muscle fibers had been phagocytized, the axons were damaged. In the absence of muscle fibers, but in the presence of degenerating axons and Schwann cells, there was no accumulation of the connective tissue cells in the former junctional region. The usual accumulation was observed in denervated intact frog muscles and damaged frog muscles where the muscle fibers were allowed to regenerate. We conclude that neither degenerating axons nor denervated Schwann cells are sufficient to generate the connective tissue cell response to muscle denervation; on the other hand a signal provided by myofibers is required for the accumulation of cells to occur. Supported by an MDA Postdoctoral Fellowship to E.A.C. and NIH grant NS 14506.

279.4 FACTORS THAT INFLUENCE THE MAINTENANCE OF REGENERATING AXON TERMINALS AT NEUROMUSCULAR JUNCTIONS. Y.M. Yao & U.J. McMahan, Dept. of Neurobiology, Stanford Univ. Sch. Med., Stanford, Ca. 94305.

The maintenance of motor axon terminals at the neuromuscular junction in skeletal muscles of the adult frog is virtually independent of muscle fibers. Accordingly, if muscles are damaged in ways that result in degeneration and phagocytosis of muscle fibers but spare the muscle fiber basal lamina sheaths and motor axons, the axon terminals persist at synaptic sites on the sheaths for more than a year (Yao & McMahan, Soc. Neurosci. Abs., 10, 1085, 1984). On the other hand, regenerating axon terminals are highly dependent on muscle fibers for their maintenance. If axons as well as muscle fibers are damaged, the axons regrow to the original synaptic sites on the empty muscle fiber basal lamina sheaths but most terminals disappear from the synaptic sites within a few months (Sanes et al., J.C.B. 78: 1978, Yao & McMahan, Soc. Neurosci. Abs., 10, 1085, 1984).

In the study presented here, we sought to determine whether regenerating axons acquire the ability to persist in the absence of muscle fibers if they first reinnervate the muscle fibers. We crushed the nerve to the frog's cutaneous pectoris muscle. Seven to ten days after the axons had reinnervated the muscle fibers, we caused muscle fiber degeneration without damaging the axon terminals. Five months later, 65% of the synaptic sites on the empty basal lamina sheaths were still occupied by regenerating axon terminals. On the other hand, in muscles 5 months after reinnervation of empty basal lamina sheaths only 5% of the synaptic sites were occupied by axon terminals. We conclude that adult muscle fibers provide a factor or factors that enable regenerating axon terminals to persist without the muscle fibers and that this long-term stabilization effect is achieved within a few days after reinnervation.

Supported by a NRSA fellowship NS 07089 and a National Amyotrophic Lateral Sclerosis postdoctoral fellowship to Y.M.Y. and NIH grant NS 14506.

279.5 CELL MEMBRANE CONTACT REGULATES TRANSMITTER PHENOTYPIC EXPRESSION IN CULTURED SYMPATHETIC NEURONS. J.E. Adler and I.B. Black. Division of Developmental Neurology, Cornell Univ. Med. Coll., N.Y., NY 10021.

We have previously reported that high neuronal density with attendant aggregation, selectively increases expression of choline acetyltransferase (CAT) and substance P (SP) in dissociated, pure neuronal cultures of rat superior cervical sympathetic ganglia. To investigate the specific role of cell contact in selective transmitter expression, CAT activity and SP content in high density cultures were examined under various circumstances. CAT activity appeared de novo after two days in culture and rose rapidly thereafter. Similarly, SP content, detectable 6 hours after plating, doubled during the first two culture days and subsequently increased more than 10-fold. The increases closely paralleled perikaryal aggregation, suggesting that cell contact may be a critical factor. Moreover, interference with aggregation physically, by methylcellulose, or chemically, by tunicamycin, inhibited the increases in CAT activity and SP content without affecting neuronal survival. Thus, cell contact appeared to mediate the expression of CAT and rise of SP in high density neuronal cultures.

To elucidate potential molecular mechanisms and to determine whether interaction of membrane component(s) elicited the rises in CAT activity and SP content, ganglion cell membranes were added to cultures of varying densities. After three days in high density cultures, cell membranes doubled the increases in CAT and SP. Moreover, even in lower density cultures, membranes elicited the appearance of CAT activity. Our studies suggest that interaction of cell membrane components regulate phenotypic expression in aggregating neurons. We are currently defining the characteristics of this membrane factor. (Supported by NIH Grants NS 10259 and HD 12108).

279.6 THE TARGET HIPPOCAMPUS INCREASES TYROSINE HYDROXYLASE AND NE UPTAKE IN LOCUS COERULEUS IN CULTURE. C.F. Dreyfus, M.A. Gillies*, M. Goldstein and I.B. Black. Div. of Developmental Neurology, Cornell Med. Coll. New York, NY 10021 and Dept. of Psychiatry, New York Univ. Med. Center, New York, NY 10016.

To define mechanisms underlying brain development, we have been examining maturation of noradrenergic traits in the mouse locus coeruleus (l.c.) in vivo and in culture. Previous studies indicated that tyrosine hydroxylase (TH) and the specific, high-affinity norepinephrine (NE) uptake system exhibit developmental increases in culture, reflecting ontogeny in vivo. Further, depolarizing agents significantly increase TH in l.c. neurons without affecting NE uptake in the same cells, suggesting that two noradrenergic characters exhibited by the same neuron may be independently regulated.

To determine whether locus cells are similarly affected by another extracellular signal, we now examine the effects of a normal locus target, the hippocampus, on maturation of TH and NE uptake.

Locus explants were dissected from mice at embryonic day 14 (E-14) and co-cultured with either the E-18 iris or E-18 hippocampus. The iris was used as an inappropriate target control. Within 7 days, the locus elaborated TH-containing neurites which contacted the co-cultured iris or hippocampus. After 5 weeks, hippocampal-locus co-cultures exhibited a significant increase in both TH activity and NE uptake, in striking contrast to iris-locus controls. Consequently, the hippocampal target apparently influenced these two locus traits similarly.

In conclusion, our studies suggest that the specific hippocampal target regulates maturation of two NE traits associated with the same locus neurons. We are now in position to define molecular mechanisms underlying effects of extracellular stimuli on critical transmitter traits in brain cells in culture. (Supported by NIH Grant NS 20788, NSF Grant BNS80-24081 and the American Parkinson Disease Association. CFD is the recipient of a Teacher-Scientist Award from the Andrew W. Mellon Fdn.).

279.7 TROPHIC EFFECTS AND SURVIVAL OF PC12 CELL GRAFTS IN RAT BRAINS. C.B. Jaeger. Department of Physiology & Biophysics, New York University Medical Center, New York, NY 10016.

Neural transplants grown in the brain are useful for the study of numerous questions concerning neural development, plasticity, trophic influences, regeneration, and biosynthetic prostheses. One drawback of neural grafts is that they have a heterogeneous composition of various neuronal and non-neuronal cell types. To circumvent this problem the present study used grafts consisting of one cell type only, namely PC12 cells. PC12 pheochromocytoma cells may express some neuron-like characteristics such as process extension when exposed to nerve growth factor and fibroblast growth factor. Moreover, PC12 cells synthesize catecholamines, such as dopamine, and PC12 cells therefore could provide a possible biosynthetic dopamine replacement source. However, previous work showed rejection of PC12 cells when they were transplanted subcutaneously to a species other than New England Deaconess Hospital rats from which PC12 cells were originally derived.

In this study variable numbers of cultured PC12 cells were aggregated and implanted into one of the following regions of the brain: lateral ventricles, tectum, cerebral cortex, ventral forebrain. The hosts were Sprague Dawley (SD )rats ranging in age from four days to six weeks. Following sacrifice of the hosts between two weeks and two months post-transplantation, the brain tissues containing the PC12 cell graft were histologically processed for localization of enzymes and glia filaments. It was found that PC12 cell aggregate grafts survive transplantation to the brain of either immature or mature SD rats. Graft volume inceased over time as a result of continued cell division. Implanted PC12 cells exhibited immunoreactivity to antisera against tyrosine hydroxylase and aromatic amino acid decarboxylase but not phenylethanolamine n-methyltransferase, suggesting dopamine synthesis by the grafted PC12 cells. Adjacent to large fiber tracts and in deep layers of the host cortex, some of the PC12 cells grew processes. PC12 cell grafts were extensively vascularized by host-derived cerebral microvessels. Observation of the ultrastructure revealed the formation of fenestrated capillaries in PC12 cell grafts a finding which was confirmed by leakieness of the "blood graft barrier" to circulating horseradish peroxidase and Evans Blue. Grafts that were four to eight weeks old contained migrated fibrous astrocytes and in these cases the host brain bordering the PC12 cell grafts was populated by notably reactive astroglia .

The observed structural alterations of host-derived cells and some grafted PC12 cells suggest the presence of bi-directional trophic interactions between the host brain and the PC12 cells.

279.8 CORONARY PERFUSATE OF THE RAT, GUINEA PIG AND RABBIT SUPPORTS THE SURVIVAL OF EMBRYONIC SYMPATHETIC NEURONS IN CULTURE. Arun R.Wakade, John C. Prat* and Taruna D. Wakade*. Department of Pharmacology, State University of New York Downstate Med. Ctr., Brooklyn, NY 11203

Sympathetic neurons (SN) derived from peripheral ganglia of the chick embryo continue to survive and grow in culture supplemented with essential neurotrophic factors. For example, nerve growth factor (NGF) or a medium conditioned by chick embryonic heart cells is known to support the survival and induce neurite outgrowth of SN in culture (Edgar et al., Nature 289: 294, 1981). We report here another source which provides a rich supply of material that exerts a powerful effect on the survival and neurite outgrowth of SN maintained in culture.

SN were derived from 10- to 12-day-old chick embryonic paravertebral and lumbo-sacral sympathetic ganglia and plated on polyornithine-coated dishes containing F14 culture medium. Hearts obtained from adult male or female rats, guinea pigs or rabbits were perfused through aorta (Langendorf method) with a culture medium (F14) at a rate of about 2 to 7 ml/min at 37°C. The perfusate was sterilized by filtration and added to culture dishes along with insuline and transferrin (1 µg/ml each) (Wakade et al., Exp. Cell Res. 140: 79, 1982). Within minutes after the addition of the heart perfusate (HP), neurons began to show the outgrowth of neurites with prominent growth cones. After 1 to 2 hr several neurons had neurites of 2 to 3 times the size of their cell body. About 60% of the plated cells survived in culture up to 2 to 4 days in the presence of HP. These effects occurred in the absence of NGF. However, addition of NGF exaggerated the above effects, and essentially all the plated cells survived in the HP. SN surviving in the presence of HP exhibited intense neurite outgrowth, and the cell bodies appeared to be enlarged. The culture substrate treated with HP for 2 hr and then washed 2 times with saline supported the survival of neuronal cells for 2 days, even in the absence of NGF. Secondly, if the cultures were initiated first in normal culture medium containing NGF and after 2 days the medium was changed to HP plus NGF, it was found that the cells took up more $^{3}$H-norepinephrine and contained more ATP than those cells that remained in normal medium plus NGF throughout. Perfusates of rat kidney, salivary gland and the adrenal gland did not show neuron-supporting activity. Removal of both auricles, loss of cardiac activity (rate and force of contraction) and removal of $Ca^{++}$ from the perfusion medium did not abolish the survival effect of the HP.

It is concluded that adult mammalian cardiac muscle releases substances in the circulation which markedly influence the survival and morphological differentiation of SN.

(Supported by NIH Grant No. HL18601 and NSF Grant No. BNS8409685.)

279.9 PROLONGED PRODUCTION OF NEURITE PROMOTING ACTIVITY AFTER PERMANENT NERVE TRANSECTION. A.J. Windebank and J.F. Poduslo. Peripheral Nerve Center, Mayo Clinic and Mayo Foundation, Rochester, MN 55905.

Cells from previously transected rat sciatic nerve support neurite outgrowth from embryonic rat dorsal root ganglia (DRG) (Richardson and Ebendal, Brain Res. 246:57-64, 1982; Windebank and Poduslo, Neurol. 35:294, 1985). We now demonstrate that this activity depends on time of explantation after permanent transection and is not due to NGF activity.

Sciatic nerves were permanently transected (Poduslo et al, J. Neurochem. 44:388-400, 1985) and then endoneurial tissue explanted onto collagen-coated dishes at various times. After 24 hours in culture, E15 rat DRG were added either as co-culture or separately with or without NGF. Neurite outgrowth from DRG was measured on photomicrographs of replicate cultures (n=8 to 42) after 24, 48, and 90 hours. Outgrowth was linear during this period.

| Culture Conditions | Neurite outgrowth from DRG at 90 hours mm(Mean ± S.E.M.) | Significance of difference from control |
|---|---|---|
| NGF 100 mg/ml | 1.30 ± .05 | |
| No NGF | 0 ± 0 | |
| Co-culture (days post transection) | | |
| 0 | 1.16 ± .08 | NS |
| 2 | 1.12 ± .07 | NS |
| 5 | 1.00 ± .06 | < .005 |
| 7 | 1.02 ± .05 | < .025 |
| 14 | 0.57 ± .09 | < .001 |
| 35 | 0.99 ± .08 | < .01 |
| 41 | 1.33 ± .05 | NS |

This suggests a biphasic production of neurite promoting activity.

The effect was not inhibited at 7, 14, and 35 days by two anti-NGF polyclonal sera. Although the possibility of two different factors is raised by these observations, their chemical nature, the specific cells producing the factor(s), and possible subpopulations of responsive DRG neurons, are still to be identified.

279.10 CHARACTERIZATION OF THE BINDING PROPERTIES AND RETROGRADE AXONAL TRANSPORT OF A MONOCLONAL ANTIBODY DIRECTED AGAINST THE RAT NERVE GROWTH FACTOR RECEPTOR.
M.Taniuchi* and E.M.Johnson, Jr. (SPON: D.B. McDougal,Jr.) Dept. of Pharmacology, Washington Univ. Sch. of Med., St. Louis, MO 63110.

We have demonstrated in vitro and in vivo the specific binding of a monoclonal antibody to the rat nerve growth factor (NGF) receptor. Previous work had shown that this antibody (designated "192-IgG"), a product of the immunization of BALB/c mice with solubilized plasma membrane proteins of PC12 cells, does not compete with NGF for binding to the NGF receptor of PC12 cells, but instead interacts with the receptor to increase NGF binding to these cells (Chandler, C.E., L.M. Parsons, M. Hosang, and E.M. Shooter, 1984, J. Biol. Chem., 259: 6882-6889). In the present study, a solid-phase separation assay verified the specific formation of a ternary complex of 192-IgG, the NGF receptor, and NGF: $^{125}$I-labeled 192-IgG precipitated from solution only when incubated with both solubilized NGF receptor and NGF covalently linked to a solid phase (Sepharose 4B). The 192-IgG also mediated the specific precipitation of NGF receptor molecules which were either covalently coupled to $^{125}$I-labeled NGF or directly radioiodinated. Filtration assays using plasma membrane preparations of various rat tissues showed strict correlation of $^{125}$I-192-IgG and $^{125}$I-NGF binding; only membranes obtained from superior cervical ganglion (SCG) bound significant amounts of the monoclonal antibody and NGF.

Injection of $^{125}$I-192-IgG into the rat anterior eye chamber led to a specific accumulation of intact antibody molecules (as assessed by SDS-polyacrylamide gel electrophoresis) in the ipsilateral SCG, evincing the retrograde axonal transport of the monoclonal antibody from the neuronal termini, located at the iris, to the cell bodies situated in the ganglion. The time course and saturation characteristics of $^{125}$I-192-IgG retrograde transport were very similar to those previously reported for $^{125}$I-NGF transport, indicating that 192-IgG can be internalized and transported by the same mechanisms as is NGF, and suggesting that the NGF receptor itself is also retrogradely transported. Consistent with results of the in vitro binding assays, 192-IgG and NGF failed to compete for retrograde transport and were actually co-transported. Retrograde axonal transport of 192-IgG appears to be species-specific, since $^{125}$I-192-IgG was transported in the rat, but not in mice, gerbils, hamsters, or guinea pigs. These results establish monoclonal antibody 192-IgG as a specific probe for the rat NGF receptor in vitro and in vivo.

279.11 SELECTIVE DESTRUCTION OF NGF RECEPTOR-BEARING CELLS USING A HYBRID TOXIN. P.S. DiStefano, J.B. Schweitzer and E.M. Johnson, Jr. Dept. of Pharmacology, Washington Univ. Sch. of Med., St. Louis, Mo. 63110.

A hybrid toxin composed of ricin A chain and a monoclonal antibody directed against the rat NGF receptor (IgG 192) was prepared using the heterobifunctional cross-linking agent N-succinimidyl-pyridyldithio-propionate (SPDP) and purified by affinity chromatography. Characterization studies showed that the hybrid, 192-s-s-A, displaced bound $^{125}$I-192 from rat superior cervical ganglion (SCG) membranes with an IC 50 3-5 times lower than that of unconjugated 192. When incubated with cultured rat SCG neurons 192-s-s-A inhibited protein synthesis in a concentration-dependent fashion. The effect of 192-s-s-A on these neurons was reversed by coincubation with an excess of 192. The IC 50 of 192-s-s-A on protein synthesis in rat SCG neurons was 4 nM. Intact ricin and ricin A chain inhibited protein synthesis in these neurons with IC 50 values of 5 pM and 500 nM, respectively. The 192-s-s-A hybrid had no effect on mouse SCG neurons or a human melanoma cell line known to have NGF receptors. This is consistent with the ability of 192 to recognize only the rat NGF receptor. Also, 192-s-s-A did not inhibit protein synthesis in primary rat muscle cell cultures or Vero cells, which do not have cell surface receptors for NGF. 192-s-s-A was able to inhibit protein synthesis in PC12 cells but the potency was 10-100 times less in these cells compared to rat SCG neurons. Ricin and A chain were also 10-100 times less potent in PC12 cells than neurons. Rat SCG neurons exposed to 192-s-s-A lost their refractile appearance under phase optics, showed granular degeneration of neurites, and died. Thus the decreased protein synthesis caused by the hybrid toxin correlated with the morphological destruction of the neurons.

Studies in vivo indicated that $^{125}$I 192-s-s-A was retrogradely transported from the iris muscle to the superior cervical ganglion (SCG) in the rat. Transport of hybrid was blocked by an excess of 192, but not A chain. Gel electrophoresis and subsequent autoradiography of SCG extracts indicated that free A chain, as well as intact 192-s-s-A and 192, was present in the SCG. Similar results were seen in the rat dorsal root ganglion when $^{125}$I 192-s-s-A was injected into the crushed sciatic nerve. These results indicate that ricin A chain can be delivered to the cell bodies of NGF receptor-bearing cells.

192-s-s-A represents a potentially powerful tool by which to selectively destroy NGF receptor-bearing cells in vitro. The hybrid toxin may prove useful as an in vivo toxin. (Supported by a grant from the Monsanto Company).

279.12 THE USE OF MONOCLONAL ANTIBODIES DIRECTED AGAINST THE GANGLIOSIDE GM1 TO PROBE NGF-MEDIATED NEURITOGENESIS OF EMBRYONIC CHICK SENSORY GANGLIA IN VITRO. S.G. Matta*, M.M. Rapport and F.J. Roisen. Dept. of Anatomy, UMDNJ-Rutgers Medical School, Piscataway, NJ 08854 and Div. of Neuroscience, New York State Psychiatric Institute, NY, NY 10032.

Gangliosides are acidic glycosphingolipids that are prominent components of neuronal membranes and may play a major role in cell surface functions. In several neuronal cell models, an interaction between the ganglioside GM1 and nerve growth factor (NGF) has been shown to exist. To investigate the specific nature of the NGF-ganglioside interactions, we have employed five different monoclonal antibodies (mAbs) directed against GM1 (designated B6, C3, C4h2, D1 and D3) to probe NGF-mediated neuritogenesis. The survival and differentiation of embryonic chick sensory ganglia in vitro (dorsal root ganglia, DRG) are NGF-dependent. Our previous work and that of others have shown that exogenous bovine brain gangliosides potentiate these responses. The separate growth parameters of DRG studied were: 1) neurite induction, quantitated by computer-assisted measurement of neurite length and number per explant and 2) general metabolic activity, assayed by measuring levels of ornithine decarboxylase (ODC), the rate-limiting enzyme in polyamine biosynthesis. For morphologic evaluation, DRGs were dissected from 9 d embryonic White Leghorn chicks and grown for 44 h in Medium 199 + 10% FBS and 10 mg/dl gentamicin, supplemented with 10 ng/ml 2.5s NGF and 20% ascites fluid containing one of the five mAbs to GM1. Control groups were exposed to medium containing 20% ascites fluid without mAb. Image-analysis revealed that the mAbs did not produce equivalent responses. C4h2, D1 and D3 inhibited NGF-stimulated neurite length and number, whereas B6 and C3 reduced only number. Metabolic activity was assessed by incubating DRGs for 5 h in serum-free medium, supplemented with 20% mAb ascites fluid, in the presence or absence of 10 ug/ml 7s NGF. These studies demonstrated further that only mAb B6 and C4h2 inhibited the NGF-stimulated elevation of ODC. Comparison of the individual effects of the mAb on neurite length, number and ODC activity revealed that each elicited a specific response. Both B6 and C3 mAbs reduced neurite number but not length, while only B6 inhibited the NGF-mediated ODC elevation. mAb D1 resulted in the greatest reduction in neurite length and number, but did not alter ODC levels. These studies have shown that the ganglioside GM1 regulates NGF-mediated neuronal development and suggest that individual sites on the ganglioside molecule may modulate specific neurotrophic interactions. 279.13 CORRELATION BETWEEN LONG-TERM $GM_1$ GANGLIOSIDE EFFECTS ON CNS REPAIR AND NEUROTROPHIC ACTIVITY. A. Consolazione*, C. Aldinio*, D. Presti*, R. Dal Toso*, A. Leon and G. Toffano (SPON: G. Calderini). Fidia Neurobiological Research Laboratories, Abano Terme, Italy

We have already documented that chronic $GM_1$ monosialoganglioside treatment facilitates the repair of the nigro-striatal pathway in adult rats following unilateral hemitransection but not following a single unilateral intranigral injection of 6-OH-DA (Toffano, G., et al., Acta Physiol. Scand., 122:313, 1984). In this context we have recently provided evidences indicating that the lack of $GM_1$ effects in the 6-OH-DA lesioned animals may be related to differences in lesion-induced neuronotrophic (NTF) activity. Therefore it has been proposed that $GM_1$ may necessitate adequate titers of NTF induction so as to facilitate CNS repair processes (Toffano, G., et al., Soc. for Neurosci. Ann. Meeting, abst. 194.2, 1984).

As induction of neuronotrophic activity following injury has been reported to be slower in aged rats than in young adults (Needles, D.L., et al., Soc. for Neurosci. Ann. Meeting, abs. 243.14, 1983), we investigated the capability of $GM_1$ to facilitate repair in hemitransected rats of different ages. Results obtained indicate that $GM_1$ is capable of enhancing CNS repair in rats of all ages considered (2-18 months). Nevertheless, the $GM_1$ treatment protocol, necessary to obtain long-term beneficial effects in hemitransected rats, is dependent on the age of the rats, i.e. with increasing age there occurs an increasing latency in the appearance of $GM_1$ effects on striatal tyrosine-hydroxylase (TH) activity. These results further support the hypothesis that NTF molecules, although still unidentified, may indeed be essential for long-term $GM_1$ effects in vivo as in vitro (Ferrari, et al., Dev. Brain. Res., 8:215, 1983). Along this line, experiments are in progress to assay and characterize the neuronotrophic activity in the striatum and substantia nigra of hemitransected rats of different ages.

279.14 PURIFICATION AND CHARACTERIZATION OF NEURONOTROPHIC ACTIVITY FROM BOVINE CAUDATE NUCLEI: POSSIBLE MODULATION BY $GM_1$ GANGLIOSIDE. R. Dal Toso*, O. Giorgi, D. Presti*, M. Favaron*, A. Leon and G. Toffano. Fidia Neurobiological Research Laboratories, Abano Terme, Italy.

Specific extrinsically occurring neuronotrophic factors (NTF) are known to regulate cell survival and neurite outgrowth of embryonic neurons both in vivo and in vitro. Recent evidences suggest that similar or functionally equivalent activities may be operative in the adult CNS not only for the maintenance of neuronal survival and specific synaptic connections but also for the occurrence of functional neuronal repair following damage, (Nieto-Sampedro, M., et al., J. Neurosci., 3:2219, 1983). In this context we have provided evidences suggesting that long-term $GM_1$ beneficial effects on CNS repair may necessitate NTF induction and possibly occur via modulation of NTF activity in vivo as in vitro (Toffano, G., et al., Soc. for Neurosci. Ann. Meeting, abst. 194.2, 1984). To verify these hypotheses, attempts were made to detect and purify NTF(s) from extracts of the bovine caudate nuclei.

Serumless dissociated fetal mouse mesencephalic cell cultures were utilized as bioassay and the NTF activity quantified by measuring specific $^{3}$H-dopamine uptake, specific $^{14}$C-GABA uptake and neuronal cell survival with time in culture. Data obtained indicate that crude supernatant preparations (100,000 x g for 2 hrs) contain activity capable of increasing all parameters considered. Purification procedures, including Sephadex G-150 gel filtration and HPLC cationic exchange chromatography, indicate that the NTF activity is associated with a non-dializable, trypsin and heat-labile basic molecule(s). This activity is presumably not nerve growth factor (NGF) since NGF, when applied to mesencephalic cell cultures, does not modify any of the parameters considered and NGF antiserum does not decrease the extracted NTF activity.

Preliminary results indicate that similar activity occurs in crude striatal extracts from rat brain. The titers of such activity increase following injury and its effect on CNS cultured neurons is amplified by $GM_1$. Further purification and biological characterization of the reported NTF(s) is currently in progress.

280.1 REDUCTION IN 2-DEOXY-D-GLUCOSE AND COLD-WATER SWIM ANALGESIA IN AGED RATS. E. Kramer and R.J. Bodnar, Dept. of Psychology, Queens College, CUNY, Flushing, NY 11367.

Compromised coping responses, including impairments in glucose tolerance and thermoregulation occur during aging. Since acute exposure to either 2-deoxy-D-glucose (2DG) or cold-water swims (CWS) produces analgesia in young adult rats, the present study examined whether alterations in these responses occurred as a function of age. Further, to determine the relative specificity of any observed changes, aging effects upon 2DG hyperphagia and CWS hypothermia were also examined. First, separate cohorts of 4, 9, 14, 19 and 24-month old female rats received ascending doses of 2DG (0, 50, 250, 450 and 650 mg/kg, IP) with tail-flick latencies and jump thresholds assessed 30, 60 and 120 min later. Then the same rats received 2DG injections (0, 650 and 1200 mg/kg) and food intake was assessed 5 h later. Significant decreases in 2DG analgesia were observed on both the tail-flick and jump tests as a function of age with the maximal decrease observed at the highest 2DG dose. The magnitude of the effect was more robust on the tail-flick test. 2DG hyperphagia systematically decreased with age: significant hyperphagia was noted in the 4 and 9-month groups, no change in intake was noted in the 14-month group, and significant hypophagia was noted in the 19 and 24-month groups. Second, new cohorts of rats received a no swim control and a 3.5 min CWS at a water temperature of 2°C with tail-flick latencies, jump thresholds and core body temperatures assessed 30, 60 and 90 min later. CWS analgesia was eliminated in the 24-month group on both pain tests, and was attenuated in the 19-month group on the jump test. The reductions in CWS analgesia could not be attributed to concomitant changes in hypothermia since CWS hypothermia was actually more pronounced in the three older cohorts. While the decrements in 2DG analgesia appear progressively through adulthood, the decrements in CWS analgesia appear more abruptly in the aged animal. (Supported by NIH Grant AG-04425).

280.2 EFFECTS OF AGE AND GENDER ON POSTMORTEM AMINE RECEPTOR BINDING TO HUMAN FRONTAL CORTEX. J.J. Mann, P.A. McBride*, M. Stanley* and C. Petito*. Psychopharmacology Laboratory, Department of Psychiatry, Cornell University Medical College, New York, N.Y. 10021.

Amine receptor binding and monoamine oxidase (MAO) A and B kinetics were assayed in postmortem samples of human frontal cortex and head of caudate nucleus. A statistically significant positive correlation was found between age and MAO B ($r=0.6$, $p<0.01$), but not MAO A activity (Vmax). A negative correlation was found between age and the number of serotonin-2 ($5\text{-HT}_2$) binding sites in frontal cortex ($r=-0.42$, $p<0.01$). A positive correlation was found between age and beta adrenergic binding in frontal cortex ($r=0.6$, $p<0.01$). No significant age effects were seen on $5\text{-HT}_1$ receptor binding to frontal cortex or $^3$H-spiroperidol (dopamine$_2$) binding to caudate nucleus. No significant correlation with postmortem delay was found for any of these amine receptor and enzyme measures. There were no gender differences in receptor binding measures or MAO enzyme kinetics. Assay of amine receptor binding in postmortem human brain tissue appears to be a potentially valuable strategy for studying aminergic systems in psychiatric and neurological disorders when specific effects of age are taken into account. This work was supported by PHS grant #MH 40210 to Dr. Mann.

280.3 STUDIES ON CATECHOLAMINE FUNCTION AND AGING: IN VITRO UPTAKE AND EFFECTS OF COLD STRESS. H. McIntosh and T.C. Westfall. Department of Pharmacology, St. Louis University School of Medicine, St. Louis, MO 63104.

We have continued our systematic study of adrenergic function during the aging process. Present experiments have been carried out utilizing Fischer 344 rats at 2-4 months, 11-13 months, and 21-25 months to assess the effect of cold stress on urinary norepinephrine (NE) levels and in vivo tyrosine hydroxylase activity as well as to assess in vitro uptake.

For urinary NE measurements, test rats were maintained 48 hours at 4-6°C in metabolic cages after acclimating to the cages for 48 hours at 22-24°C. Control rats were kept in metabolic cages for 96 hours at 22-24°C. Urine was collected in 1 N acetic acid for the last three 24 hour periods in the cages. NE was isolated using alumina, and then measured using HPLC with electrochemical detection. There was an age related attenuation of the increase in urinary NE in response to cold stress.

One month later, in order to evaluate in vivo tyrosine hydroxylase activity, the rats were again acclimated to the metabolic cages. Then test rats were placed in precooled metabolic cages at 4-6°C for one hour prior to sacrifice. After 30 minutes in the cages, rats were injected i.p. with m-hydroxybenzylhydrazine (100 mg/kg). Control rats were injected similarly 30 minutes prior to sacrifice. Hypothalamus, striatum, and occipital cortex were dissected out and frozen immediately on dry ice. The tissue was later analyzed for dihydroxyphenylalanine (DOPA) accumulation using HPLC with electrochemical detection. In contrast to the change seen in urinary NE, DOPA accumulation in brain tissues was unaffected by age or one hour of cold stress.

Uptake studies were carried out in vitro using diced (0.3 mm x 0.3 mm) hypothalamus, occipital cortex, and striatum. Tissues were suspended in Krebs buffer, which had been oxygenated with 95%/5% $O_2/CO_2$. They were incubated at 34-36.5°C under a constant flow of $O_2/CO_2$ in a shaking water bath. After a 10 minute preincubation with or without an uptake inhibitor ($10^{-5}$ M desipramine), $^3$H-norepinephrine was added to hypothalamic and cortical samples to give a final concentration of $10^{-7}$ M. $^3$H-Dopamine was added to striatal samples preincubated with or without $10^{-5}$ M nomifensine to give a final tracer concentration of $10^{-7}$ M. The samples were then incubated an additional 7 minutes. Uptake was stopped by placing the incubation tubes in ice water. As an additional control, samples were placed in the ice bath prior to the addition of tracer. (Supported by NS16215, DA02668 and NIA.)

280.4 STRIATAL AND MESOLIMBIC DOPAMINE ($D_2$) RECEPTORS IN RAT BRAIN AS DETERMINED BY AGE, TIME AND ENVIRONMENTAL LIGHTING CONDITIONS. O. Pulido*and G. Rajakumar. Departments of Neurosciences and Psychiatry, McMaster University, Hamilton, Ontario, Canada L8N 3Z5.

Geriatric patients show a higher incidence of side effects and responsiveness to neuroleptic drugs than young individuals (Smith et al.: Aging, Vol.17, S.J. Enna et al., Eds. Raven Press, N.Y., 1981, p.231; Borchinsky, S.: Exp. Gerontol. 19:227, 1984). The clinical potency of neuroleptics correlates closely with the affinity of binding for the $D_2$ dopamine receptors (Seeman et al., Nature 261:717, 1976). We have studied the population (Bmax) and affinity (Kd) of dopamine ($D_2$) receptors by $^3$H-spiroperidol-binding in striatum and mesolimbic region (olfactory tubercle and nucleus accumbens) of young (3-month-old) and old (20-month-old) male Long Evans rats. Animals were kept under a 14L:10D lighting cycle, for 3-8 wks prior to sacrifice. Animals were decapitated at 4 or 10 hrs after lights were on and 3 or 7 hrs after lights were off. Brains were rapidly removed, dissected and frozen at -70°C until used. Direct radioligand binding with $^3$H-spiroperidol was carried out on crude membrane preparation of striatal and mesolimbic brain regions from young and old animals, following the same procedure used by Chiu et al. (Europ. J. Pharmacol. 82:243, 1982). Concentrations of 0.05 - 0.8 nM were used in the presence and absence of 1 uM (+) butaclomol to define nonspecific binding. Results indicate that age, time and lighting conditions do not significantly affect or modify the Bmax or Kd of $D_2$ receptors in the mesolimbic area. However, Bmax ($P=0.0039$, $DF=4.9$) and Kd ($P=0.045$, $DF=2.1$) of $D_2$ receptors in striatum from old animals showed a sharp increase from 3 pm (light) to 10 pm (dark) followed by a fall at 2 am (dark). The lowest values were seen during the light phase. In young animals $D_2$ receptors showed similar rhythmic patterns, but the spike at 10 pm was not statistically significant from the values observed at other times.

Striatal $^3$H-spiroperidol Binding

| | Young | | Old | |
|---|---|---|---|---|
| | 3 pm | 10 pm | 3 pm | 10 pm |
| Kd (nM) | 0.387 | 0.502 | 0.424 | 3.11 |
| Bmax (fmol/mg protein) | 196 | 246 | 164 | 474 |
