Cells were preincubated for 1 hour in a HEPES-balanced salt solution (122 mM NaCl, 4.2 mM KCl, 1.3 mM $CaCl_2$, 1.2 mM $MgSO_4$, 1.2 mM KH_2PO_4, 20 mM HEPES, 20 mM $NaHCO_3^-$, 10 mM glucose; pH 7.4) and then exposed to various concentrations of PTZ (1.0 to 10 mM) for 60 min. Under these conditions, PTZ reduced the steady-state content of $^{125}I^-$ and $^{36}Cl^-$ in cultured astrocytes in a dose-dependent manner. PTZ (10 mM) decreased the $^{125}I^-$ content from 319.9 ± 19.8 to 218.2 ± 14.3 DPM/mg protein and the $^{36}Cl^-$ content from 1407.0 ± 129.3 to 1141.6 ± 76.6 DPM/mg protein in control vs treated cells, respectively. This effect of PTZ to decrease $^{125}I^-$ and $^{36}Cl^-$ transport was attenuated when the $[Na^+]_o$ was reduced from 144 mM to 20 mM. For example, at 20 mM $[Na^+]_o$ the total $^{125}I^-$ and $^{36}Cl^-$ of control cells ($^{125}I^-$, 268.4 ± 43.3 DPM/mg protein; $^{36}Cl^-$, 1229 ± 116 DPM/mg protein) was not significantly different from that of PTZ-treated cells ($^{125}I^-$, 211.4 ± 14.3 DPM/mg protein; $^{36}Cl^-$, 1253.7 ± 74.3 DPM/mg protein). Similar results with respect to total $^{36}Cl^-$ were observed when the $[K^+]_o$ was reduced from 4.2 to 1.2 mM. PTZ (1 to 10 mM) inhibited Na^+/K^+-ATPase in a concentration-dependent manner. This action of PTZ reduced the total K^+ content of astrocytes in culture (1.20 ± 0.12 vs 0.96 ± 0.07 meq/mg protein for control vs PTZ-treated cells, respectively) and depolarized the astrocytic membrane.

The present findings demonstrate that PTZ inhibits anion transport into primary astrocytes maintained in tissue culture by blocking Na^+/K^+-mediated anion cotransport. Furthermore, PTZ inhibits Na^+/K^+-ATPase, decreases intracellular K^+, and causes membrane depolarization. Thus, in addition to its action on neurons, the data presented herein demonstrate that PTZ affects ion transport processes of astrocytes in a manner that may contribute to the convulsive action of this agent. 60.1 THE ULTRASHORT-LOOP FEEDBACK EFFECT OF CENTRALLY INJECTED GROWTH HORMONE-RELEASING FACTOR TO SUPPRESS PULSATILE GROWTH HORMONE SECRETION IS SITE SPECIFIC TO THE ARCUATE NUCLEUS. M.D. Lumpkin* (SPON: C. Colton), Department of Physiology and Biophysics, Georgetown Univ. School of Medicine, Washington, D.C. 20007

Previously it was shown that intracerebroventricular injection of growth hormone-releasing factor (GRF) would suppress GH release by a postulated mechanism of ultrashort-loop feedback whereby endogenously released or exogenously administered GRF could act as an inhibitor to the further secretion of GRF from its neurons [Endocrinology 116: 2070, 1985]. I next sought to determine whether the site at which centrally administered GRF produced this GH suppression did, in fact, correspond to the locus of GRF cell bodies in the hypothalamic arcuate nucleus (ARC) or, as another possibility, to somatostatin (SS) somata in the anterior periventricular region (PV). In order to examine this question directly in vivo, 23 gauge stainless steel cannulae were implanted stereotaxically into the bilateral ARC or bilateral PV of adult male rats. After a recovery period of 7-10 days, synthetic rat GRF (1-43, Peninsula) at a dose of 10 ng in 0.5 ul of normal saline was microinjected bilaterally over a period of 60 seconds into the ARC of conscious, unrestrained male rats through 30 gauge insertion cannulae. Microinjections into tissue sites commenced immediately after withdrawing a preinjection blood sample at 1000 h. Control animals received 0.5 ul of saline alone into these two sites. Sequential blood sampling every 15 min for 6 h between 1000 and 1600 h revealed that GRF infused into the ARC essentially abolished the 2 periods of peak releases of radioimmunoassayable GH that occurred predominantly between 1030-1130 h and 1400-1500 h in these experiments. For example, mean plasma GH $\pm$ SEM (ng/ml) at 1100 h: ARC GRF-treated (n=8), 14.6 $\pm$ 4.0 vs control (n=7), 68.0 $\pm$ 23.2 ($p<.025$). Mean plasma GH $\pm$ SEM at 1430 h: ARC GRF-treated, 13.4 $\pm$ 3.5 vs control, 135.0 $\pm$ 58.1 ($p<.025$). The overall mean for plasma GH levels between 1000-1600 h in the ARC GRF-injected group was 14.6 $\pm$ 7.4 vs 56.0 $\pm$ 9.4 ng/ml for controls ($p<.0001$). In contrast, injection of GRF into the bilateral PV produced no significant change in episodic GH secretion between 1000 and 1600 h when compared to saline-treated controls. The inhibition of pulsatile GH release by GRF injected into the ARC appeared to be specific to GH controlling elements since prolactin levels were not significantly changed. These findings suggest that the "ultrashort-loop feedback" (autoregulation) of centrally injected GRF to suppress pulsatile GH secretion is mediated to a significant degree by inhibition of neurosecretion from ARC GRF neurons rather than by stimulation of PV somatostatinergic neurons.

60.2 COEXISTENCE OF GROWTH HORMONE RELEASING FACTOR AND VASOTOCIN IN THE HYPOTHALAMO - HYPOPHYSEAL SYSTEM OF THE FROG. F. Vandesande and S. Marivoet. Lab. of Neuroendocrinology, K.U.L. Zoological Inst. B - 3000 LEUVEN (Belgium).

Rabbit anti human pancreatic growth hormone releasing factor (h.p.GRF 1-44) antisera were prepared by immunizing two rabbits with h.p.GRF 1-44 conjugated to thyroglobulin using glutaraldehyde as coupling reagent. Mouse monoclonal anti rat hypothalamic growth hormone releasing factor (r.h.GRF 1-10) antibodies were prepared using synthetic r.h.GRF 1-10 conjugated to thyroglobulin with the carbodiimide method. Two groups of adult male and female frogs (Rana temporaria) were studied. The first group was killed in January, the second in July. Serial 5 µm sections of the brains were stained using the rabbit anti h.p.GRF 1-44 antisera, mouse monoclonal anti r.h.GRF 1-10 antibodies and rabbit anti vasotocin (VT), anti mesotocin (MT), anti somatostatin (SRIF) and anti corticotrophin releasing factor (CRF) antisera in combination with a single and double PAP technique.

Single immunocytochemical staining revealed a GRF - like immunoreactivity in the magnocellular preoptic nuclei, the internal and external zone of the median eminence and in the neural lobe. No colocalisation of GRF with MT, SRIF and CRF could be detected. However, double staining with as well the polyclonal as the monoclonal anti GRF antibodies and anti VT revealed the presence of three celpopulations. The first was only positive for GRF, the second was only positive for VT and the third showed both GRF and VT - like immunoreactivity.

In the internal and external zone of the median eminence and in the neural lobe, double staining also resulted in three populations of nerve fibres. No difference between the two groups of animals was observed. Our results strongly suggest a coexistence between GRF and VT in the frog .pp

60.3 MECHANISMS OF IMPAIRED GROWTH HORMONE (GH) SECRETION IN GENETICALLY OBESE ZUCKER RATS: ROLES OF GH-RELEASING FACTOR AND SOMATOSTATIN. G.S. Tannenbaum, M. Lapointe*, W. Gurd* and J.A. Finkelstein. McGill University and Montreal Children's Hospital, Montreal, Quebec H3H 1P3, and Northeastern Ohio Universities College of Medicine, Rootstown, Ohio 45267.

Growth hormone secretion is markedly blunted in obesity; however, the mechanism(s) mediating this response remains to be elucidated. In the present study, we examined the involvement of the two hypothalamic GH-regulatory peptides, GH-releasing factor (GRF) and somatostatin (SRIF), using the genetically obese male Zucker rat. Spontaneous six-hour GH secretory profiles obtained from freely-moving chronically cannulated rats revealed a significant suppression of pulsatile GH secretion in obese (655 $\pm$ 13 gm bw) animals compared to their lean (397 $\pm$ 8 gm bw) littermates (mean 6-h plasma GH level; 4.7 $\pm$ 1.0 vs. 16.1 $\pm$ 4.1 ng/ml; $P < 0.02$). The plasma GH response to an intravenous bolus of 1 µg rGRF(1-29)NH_2 (kindly provided by Dr. P. Brazeau), administered during peak and trough periods of the GH rhythm, was significantly attenuated in obese rats at peak (87.8 $\pm$ 25.7 vs. 192.4 $\pm$ 28.9 ng/ml; $P < 0.02$) but not trough (56.1 $\pm$ 20.3 vs. 43.4 $\pm$ 12.7 ng/ml) times. Moreover, both pituitary wet weight (10.3 $\pm$ 0.46 vs. 11.9 $\pm$ 0.49 mg; $P < 0.05$) and pituitary GH concentration (29.2 $\pm$ 2.1 vs. 42.5 $\pm$ 3.3 µg/mg wet wt; $P < 0.01$) were reduced in the obese group. Measurement of hypothalamic GRF immunoreactivity using a specific radioimmunoassay for rGRF revealed a significant ($P < 0.02$) reduction in mediobasal hypothalamic GRF concentration in obese rats (30.2 $\pm$ 2.9 pg/mg wet wt) compared to lean controls (47.4 $\pm$ 5.0 pg/mg wet wt), although no significant difference was observed in hypothalamic SRIF concentration. In contrast, peripheral SRIF immunoreactive levels were significantly elevated in both the stomach (1.38 $\pm$ 0.09 vs. 1.05 $\pm$ 0.07 ng/mg wet wt; $P < 0.01$) and pancreas (0.94 $\pm$ 0.13 vs. 0.58 $\pm$ 0.06 ng/mg wet wt; $P < 0.01$) of obese rats. These results demonstrate that the genetically obese Zucker rat exhibits (1) marked impairment in both spontaneous and GRF-induced GH release, (2) significant reduction in pituitary GH concentration, (3) depressed hypothalamic GRF concentration and (4) elevated gastric and pancreatic SRIF levels. The findings suggest that the defect in pituitary GH secretion observed in obesity may be due, at least partially, to insufficient stimulation by hypothalamic GRF concomitant with exposure to increased circulating levels of SRIF.

60.4 FACILITATION BY PENTOBARBITAL OF GROWTH HORMONE SECRETION IN HAMSTERS: THE INVOLVEMENT OF ENDOGENOUS SOMATOSTATIN. K.T.Borer, Dept.of Kinesiology,Univ.of Michigan,Ann Arbor, MI 48109 and A.G. Amedor*, Dept.of Physiology, Southern Illinois Univ.,Carbondale,IL 62901.

Growth hormone (GH) release is under antagonistic influence of facilitatory GH-releasing hormone (GHRH) and of inhibitory somatostatin (SRIF). In the rat, both GHRH and SRIF appear to be released in a pulsatile manner.A SRIF pulse induces a GH trough and prevents exogenous GHRH from eliciting a GH pulse, while at the time of SRIF trough, a GHRH pulse triggers GH release (Tannenbaum & Ling, Endocrinol.,1984,115:1952). Sodium pentobarbital facilitates GH release in the rat (Howard & Martin, Endocrinol.,1971,88:497) presumably by suppressing the release of endogenous somatostatin.

We tested the hypothesis that a morning pulse of SRIF accounted for a GH trough between 0900 and 1130 h in mature female hamsters (Borer et al., Endocrinol.,1986,118:844). An intracardiac catheter was implanted through the right jugular vein 24 h before the experiment. Animals received 3 i.v. injectione: 1 ml of anti-SRIF serum or NRS at 0830 h; 0.5 ml of heparinized saline or of sodium pentobarbital (42 mg/kg) at 0945 h; and 0.3-0.4 ml of GHRH (5ng/g) or saline at 1015 h. Blood samples were collected sequentially at 5 min (first two) and at 10 min intervals (next 10) following the third injection. A blood replacement was given after each blood removal. GH determinations were made with a homologous RIA for hamster GH (Borer et al.,Neuroendocrinol.,1982,35:349). Spontaneous GH pulses were examined in CONTROL group (n=8:1.NRS, 2.saline, 3.saline). Possible presence of SRIF antagonism of GHRH was examined in GHRH group (n=7: 1.NRS, 2.saline, 3.GHRH). A possible suppression of SRIF by sodium pentobarbital was examined in B-GHRH group (n=7:1. NRS, 2.sodium pentobarbital, 3.GHRH). Finally, a possible presence of a SRIF pulse was examined in AS-GHRH group (n=7: 1.anti-SRIF serum, 2.saline, 3.GHRH).

A small GH pulse followed the third injection in control hamsters followed by a large endogenous GH pulse after 1130 h. A 3.5-times higher pulse of GH followed the third injection in GHRH group. GHRH elicited a GH pulse that was 2.4 times (AS-GHRH group) and 4.1 times (B-GHRH group) greater than in GHRH group.

We conclude that (1) SRIF is released between 0900 and 1130 h in mature female hamsters and contributes to suppression of GH release; (2) endogenous SRIF reduces the capacity of GHRH to elicit GH release at that time of day; and (3) sodium pentobarbital may facilitate GH release by suppressing SRIF release or action rather than through elicitation of endogenous GHRH release.

60.5 **HIERARCHIC CONTROL OF CALCIUM ION SIGNALLING IN SINGLE PITUITARY SOMATOTROPES: POTENT INHIBITION OF CALCIUM CHANNELS BY SOMATOSTATIN (SRIF) DOMINATES OVER GHRH-INDUCED CALCIUM MOBILIZATION.** R.W. Holl*, M.O. Thorner, G.L. Mandell*, J.A. Sullivan*, Y.N. Sinha* and D.A. Leong*. (SPON: T. Johns), Department of Internal Medicine, University of Virginia, Charlottesville, VA 22908.

The generation of intracellular signals activated by opposing (stimulatory and inhibitory) receptors can be studied together in the somatotrope. We recently described an endogenous oscillatory pattern of cytosolic calcium transients associated with spontaneous secretory activity in somatotropes (Prog. Ann. Meet. Endoc. Soc., 1987, Abstract #117). SRIF abolished this oscillatory activity and markedly inhibited GH secretion. GHRH stimulated calcium ion mobilization and promoted GH secretion. Thus SRIF and GHRH exert opposing actions in the somatotrope. The outcome of combined GHRH/SRIF treatment was determined by measuring calcium ions with the fura-2/AM method. A reverse hemolytic plaque assay (RHPA) was used to quantitate hormone secretion in single pituitary cells obtained from male Sprague-Dawley rats (125-250 gm). Spontaneous calcium oscillations were abolished, within 20 seconds, and ambient calcium levels were reduced, when calcium was withdrawn from the extracellular medium. This effect upon calcium mobilization was mimiced exactly by treatment with 1 nM SRIF, even when a source of extracellular calcium was provided, suggesting that SRIF inhibits calcium influx. Despite a 10-fold molar excess of GHRH (10 nM) over SRIF (1 nM), co-treatment with GHRH/SRIF caused cytosolic calcium levels to decrease in the same manner observed with SRIF alone. Parallel effects on GH release were measured by RHPA in the same single cells. Thus calcium mobilization is potently abolished by inhibitory input (SRIF receptor) by a mechanism that completely overrides stimulatory input (GHRH receptor). The signalling pathways for these opposing receptors must therefore converge at a common locus prior to calcium mobilization. These findings demonstrate a novel hierarchic mechanism governing opposing receptors and signal transduction in the somatotrope.

60.6 INFLUENCE OF THE GONADS ON CIRCADIAN CORTISOL SECRETION IN RHESUS MACAQUES. C.J. Smith* and R.L. Norman, Dept. of Cell Biology and Anatomy, Texas Tech University Health Sciences Center, Lubbock, Tx. 79430

Circadian/ultradian patterns of plasma cortisol were assessed in adult ovariectomized (OVX) rhesus macaques and compared with cortisol patterns in gonadally intact females during the late follicular (day 9-10) and mid-luteal (day 21-22) phases of the menstrual cycle. Beginning at 0800h, blood samples were obtained every 15 min for 24 h via an indwelling catheter. Plasma concentrations of cortisol, estrogen (E_2), and progesterone (P) were determined using specific RIAs. For purposes of data analyses, group cortisol measurements were collapsed across hourly intervals. Diurnal variations in absolute cortisol levels were analyzed separately for each group with a single-factor repeated measures ANOVA. Cortisol differences between the 3 gonadal states were evaluated using split-plot ANOVA and Tukey's t-tests. Additional estimates of change in cortisol secretion were evaluated using the relative change from the daily mean as a reference. The pulse frequency of cortisol release was determined for each subject utilizing PULSAR computer program.

A diurnal pattern of cortisol secretion was documented in all 3 groups and characterized by a progressive rise during early morning hours (0300-0600) followed by a decline of short duration and a peculiar elevation which persisted from 0900-1400 h. Within all groups, cortisol reached a nadir in the early evening hours. Significant differences between the follicular and luteal groups were not discerned. However, plasma cortisol concentrations in the OVX group were significantly depressed when levels in the gonadally intact females reached their zenith. In addition, the daily mean level of cortisol was reduced nearly 50% by OVX. When cortisol changes were assessed using the percentage change from the daily mean as an index, group differences disappeared. No statistical differences in ultradian characteristics of cortisol secretion between the 3 female groups throughout the sampling period were found.

When data in the intact female groups were combined and compared to those previously obtained from gonadally intact adult male macaques, similar 24-h patterns of cortisol secretion were documented. Surprisingly, amplitude changes in cortisol concentrations after OVX were temporally and quantitatively similar to those in orchidectomized (ORCH) males. In both sexes, circadian patterns of cortisol secretion were reduced/absent after gonadectomy. These results indicate that gonadal steroids have a significant effect on hypothalamic-pituitary-adrenocortical function.

60.7 CONSTANT LIGHT AND DARK AFFECT THE CIRCADIAN RHYTHM OF THE HYPOTHALAMIC-PITUITARY-ADRENAL AXIS. R. L. Moldow*, A. J. Kastin, M. V. Graf* and A. J. Fischman*. Seton Hall University, S. Orange, NJ 07079 and Veteran Administration Medical Center and Tulane University, School of Medicine, New Orleans, LA 70146

The effect of constant light and constant dark on the circadian rhythm of the concentrations of hypothalamic corticotropin releasing factor like immunoreactivity (CRF-LI), plasma ACTH, and corticosterone was investigated. Groups of rats were maintained under normal light-dark (LD), constant light (CL), or constant dark (CD) conditions for 10 days. Rats were then killed over a 24 hour time period and hypothalamic CRF-LI, plasma ACTH, and corticosterone concentrations were determined by RIA. Under normal light-dark conditions, hypothalamic CRF-LI concentrations exhibited significant decreases at 1700 h and 0200 h that coincided with peaks in plasma ACTH and corticosterone concentrations. In rats housed under CD conditions for 10 days, higher hypothalamic CRF-LI concentrations were detected at night than during the early part of the day. These relatively high hypothalamic CRF-LI concentrations coincided with relatively low plasma ACTH concentrations. The timing of peak plasma ACTH concentrations was slightly phase-shifted, and the amplitude was markedly attenuated compared to levels of rats housed under normal light-dark conditions. The rats exposed to CD continued to demonstrate higher plasma corticosterone concentrations in the pm than in the am. The peak in plasma corticosterone coincided with the peak in plasma ACTH concentrations; however, the amplitude was normal. In rats maintained in CL for 10 days, a decrease in hypothalamic CRF-LI concentrations at 2000 h coincided with a peak in plasma ACTH. The peak in plasma ACTH concentrations was not associated with a peak in plasma corticosterone concentrations. The rhythm of plasma corticosterone concentrations was dramatically attenuated and phase-shifted. Together, these findings indicate that alterations of normal light-dark conditions result in changes in the circadian variation in hypothalamic CRF-LI, plasma ACTH, and corticosterone levels. Changes in the circadian rhythm of plasma ACTH concentrations were related to changes in the rhythm of hypothalamic CRF-LI, but an apparent dissociation between the pituitary and adrenal rhythms was observed.

60.8 ULTRASTRUCTURAL EVIDENCE FOR CORTICOTROPIN RELEASING HORMONE (CRH) SYNAPSES WITHIN THE PARAVENTRICULAR NUCLEUS OF THE HYPOTHALAMUS (PVN) OF THE RAT. A.J. Silverman. Dept. of Anat. & Cell Biology, Columbia University, N.Y., N.Y. 10032.

Immunocytochemical studies have shown a large population of CRH neurons resides within the PVN (Swanson et al, Neuroendocrinology 36:165) and that these cells form the major if not sole source of CRH terminals on the hypophysial portal vessels (Bruhn et al, Endocrinology 114:57). We have now examined the ultrastructural characteristics of these neurons and the connections that they make within the PVN. CRH was detected in vibratome sections through the adult male rat PVN as previously reported (Hou-Yu et al, Neurosci. Absts.217.10, (86) except that the detergent was 0.02% saponin and the DAB reaction product was silver-gold intensified (Liposits, Neurosci. Lett. 31:7). In these normal animals, CRH neurons were characterized by heterochromatic nuclei which were frequently indented, an extensive Golgi apparatus and several stacks of rough endoplasmic reticulum. The antibody used reacted primarily with the numerous neurosecretory granules. These cells and their dendrites were richly innervated as has been described previously (Liposits & Paull, Peptides 6:1021). Numerous CRH positive synapses were also found within the PVN, concentrated but not confined to the periventricular zone. The presynaptic axonal elements contained, in addition to CRH positive granules, other, smaller dense core-granules and numerous clear, round 'synaptic' vesicles that accumulated in the active zone. The synapses were characterized by well defined synaptic clefts and pre and post-synaptic membrane specializations. To date the majority of CRH terminals were found on non-identified dendrites. However, as suggested by light microscopic images of CRH axonal baskets around PVN neurons (Hou-Yu, unpub.), occasional perikarya contacted by several CRH terminals have also been observed. Although most CRH axons innervated non-CRH structures within the PVN, instances of axo-somatic connections between CRH elements have also been identified. It is not known whether all the CRH terminals have their origin with the PVN but these current observations provide evidence that CRH could act locally within the hypothalamus to modulate neurosecretory or autonomic activity. (USPHS grant AM 37205).

60.9 GLUCOCORTICOID RECEPTOR IN MANGOCELLULAR NEUROSECRETORY CELLS. J.Z. Kiss[1]*, J.A.M. Van Eekelen[2]*, J.M.H.M. Reul[2]*, H.M. Westphal[3]* and E.R. de Kloet[2]* (SPON: J.-J. Dreifuss). Institute of Histology and Embryology, Univ. of Geneva Medical School, Switzerland[1], Rudolf Magnus Institute, Univ. of Utrecht, The Netherlands[2], Institute for Molecular Biology and Tumorresearch, Marburg, Federal Republic of Germany[3].

It has previously been shown, that glucocorticoids inhibit vasopressin (VP) release from the hypothalamic magnocellular system. However, the mechanism and the site of this action remained controversial. There is evidence, for example, that the effect of glucocorticoids might be mediated by increased plasma volume or by action on the peripheral osmo-receptor.

Here we report that glucocorticoid receptor (GR) in fact is present in magnocellular neurosecretory cells of the rat. In vitro ligand displacement experiment suggests that these are the type II "feed back" type receptors as defined by Reul and de Kloet (Endocrinology 1985, 117:2505). Using a monoclonal antibody against purified liver GR, immunostaining was found in magnocellular neurosecretory neurons in the SON but not in magnocellular neurons located in the paraventricular nucleus. Immunoreactive cells seem to concentrate in ventral parts of the SON where VP cells were previously shown to be located. At the ultrastructural level GR immunoreactivity has been found in the cell nucleus as well as in various cytoplasmic compartments. One to two weeks after bilateral adrenalectomy, there was a substantial decrease of immunostaining in magnocellular neurons. Administration of synthetic glucocorticoids (RU 28362 or dexamethasone) induced a robust increase in the intensity of immunostaining in cell nuclei of neurosecretory cells. The presence of GR in the SON suggest that glucocorticoids may affect vasopressin synthesis or/and secretion through direct action in magnocellular neuron.

60.10 INVOLVEMENT OF THE PARAVENTRICULAR NUCLEUS IN THE ACTH SECRETORY RESPONSE TO CENTRAL NICOTINIC CHOLINERGIC STIMULATION. S.G. Matta*, H.S. Beyer* and B.M. Sharp* (SPON: S. Nicol). Minneapolis Med. Res. Fdn. and Dept. of Med., Hennepin Cty. Med. Ctr. and Univ. of Minnesota, Mpls, MN 55415.

Nicotine is a potent stimulus for the secretion of ACTH from the pituitary in the rat. We have previously demonstrated that injection of nicotine into the hypothalamic region of the third ventricle elevated rat plasma ACTH to levels comparable to those seen when nicotine was administered iv. To identify specific brain nuclei that are involved in this central action of nicotine (N), permanent bilateral intracerebral nuclear (ICN) cannulae were used for the direct injection of nicotine into the hypothalamic paraventricular nucleus (PVN). The PVN was targeted because it contains binding sites for ^{125}I-α bungarotoxin and its neuropil contains ^{3}H-nicotine sites. On separate days, rats fitted with chronic jugular cannulae received N 0.5, 1.0 or 10.0 ug or an equivalent volume of buffer (B) into each PVN. ACTH values (pg/ml) are mean ± sem; comparisons of integrated response areas (N vs. B) were by ANOVA. Nicotine significantly elevated (B = N 0.5<N 1.0<N 10.0, p <.05) plasma ACTH, yielding peak levels similar to the maximal responses to iv or ip N:

	N	0 min	3 min	7 min	15 min
Buffer	18	25±5	27±7	33±7	43±10
N 0.5 ug	9	50±11	142±66	163±60	150±50
N 1.0 ug	15	38±7	164±51	211±76	225±78
N 10.0 ug	17	28±5	449±76	726±155	481±120

To determine whether mecamylamine (Mec) is an effective antagonist of N-induced ACTH secretion, Mec 2 mg/kg BW was delivered ip 10 min prior to N 0.25 or 1.0 mg/kg BW ip. Mec significantly inhibited the ACTH responses to both doses of N (B/B 24±6; Mec/B 31±12; B/N 1.0, 633±52; B/N 0.25, 468±79; Mec/N 1.0, 110±24*; Mec/N 0.25, 23±8*; *p<.01 compared to respective B/N). Subsequent studies with ICN Mec were conducted to determine whether the PVN mediates the effect of peripherally administered nicotine. B or Mec 10 ug were injected into PVN 10 min prior to the iv injection of saline (S) or N 0.03 mg/kg BW. Analysis of response areas (pg·min/ml) indicates that Mec effected a partial, but not significant blockade of the ACTH response to peripheral Nic: Mec/N 5904±1359; B/N 8326±1199; B/S 1855±339; Mec/S 1659±377. Thus, the PVN is directly responsive to relatively high doses of N; the activation of additional central site(s) appears to be necessary for the maximal ACTH response to peripherally administered nicotine. (Supported by NIDA DA03977)

60.11 BIOSYNTHESIS OF PRO-OPIOMELANOCORTIN IN THE RAT INTERMEDIATE PITUITARY IS GLUCOCORTICOID-SENSITIVE FOLLOWING DENERVATION. M.A. Seger*, J.A.M. van Eekelen*, J.Z. Kiss*, H.H.M. van Tol*, J.P.H.Burbach* and E.R. de Kloet* (SPON: Tj. van Wimersma Greidanus). Rudolf Magnus Institute for Pharmacology, Medical Faculty, University of Utrecht, The Netherlands.

Deafferentation of the rat anterior hypothalamus by a Halasz knife cut is known to sever also the neural input to the neural and intermediate lobes (NILs) of the pituitary gland. One week after performing the lesion in male (150-180g) rats, the animals were sacrificed and the NILs were incubated in vitro for 24h with tritiated amino acids to compare their POMC-synthesizing capacity with sham-operated controls. A general increase (2 to 4-fold vs control, $p<0.05$) of incorporation of ^{3}H into HPLC-analyzed POMC-peptides was observed, with no concommitant change in the content of the NILs. The induction of the glucocorticoid receptor (GR) in the NILs by denervation (see also Antakly, T., Science 229: 277, 1985) was visualized by immunocytochemistry. In order to test whether the induced GR was functional, the experiment was repeated in lesioned adrenalectomized (ADX) rats chronically treated with corticosterone (100 mg pellets of CORT, giving 23 ug% in plasma) and in the appropriate control groups (6 animals each). The result of the in vitro biosynthesis study showed that ADX attenuated the lesion-induced increase in POMC-peptide labelling (2 to 5-fold decrease from sham-lesioned CORT-replaced rats, $p<0.05$) and CORT-replacement reversed the effect. This suggests that IL POMC gene expression becomes sensitive to CORT after anterior hypothalamic deafferentation.

The POMC mRNA levels in the IL of rats from the 4 groups were measured by dot-blot analysis at 3 weeks post-lesion, when GR induction was maximal. The changes in IL POMC mRNA paralleled the changes in incorporation of label into POMC peptides observed in the in vitro biosynthesis study. It is concluded that:
1. anterior hypothalamic lesions induce GR in the IL which participate in the regulation of POMC gene expression;
2. CORT stimulation of GR enhances biosynthesis of POMC peptides in the IL, in contrast to its blocking role in the anterior lobe;
3. these findings may partially explain the lesion-induced increase in POMC biosynthesis.

61.1 RESERPINE TREATMENT INDUCES AN ENHANCED SENSITIVITY OF ADENYLATE CYCLASE TO DOPAMINE STIMULATION WITHOUT CHANGING THE PROPERTIES OF ^{3}H-SCH 23390 SPECIFIC BINDING. C. Missale, P. Liberini*, E. Nisoli*, M. Memo, A.Rossi, P.F. Spano. Inst. Pharm. Exp. Ther., School of Medicine, University of Brescia, Brescia, Italy and Farmitalia C. Erba, R.& D., CNS Line, Milano Italy

Behavioral studies have shown that reserpine treatment in rats causes an increased sensitivity of both D-1 and D-2 receptors to stimulation by selective agonists.

The present study shows that the DAergic behavioral supersensitivity induced by reserpine does not correlate with the kinetic properties of ^{3}H-SCH 23390 binding sites but is reflected by an enhanced activity of DA-stimulated adenylate cyclase (AC).

Male SD rats were given a single injection of reserpine (5 mg/Kg ip) and then sacrificied 2 and 20h after treatment. D1 $_{3}$DA receptor function was tested by measuring the kinetics of ^{3}H-SCH 23390 binding sites and the ability of the selective D-1 receptor agonist SKF 82526 to stimulate AC activity. We found that acute treatment with reserpine significantly increased the sensitivity of striatal AC activity to SKF 82526 stimulation. Maximally effective concentrations of SKF 82526-stimulated striatal AC activity by 100% in saline group, and 155% in striatum from rats pretreated 2h and 20h respectively with reserpine before killing. The IC-50 calculated from the dose-response curves did not differ significantly among the three groups. The function of D-1 DA recognition sites was also measured by ^{3}H-SCH 23390 binding assay. We found that 2 h and 20 h following reserpine treatment the total amount (Bmax) of H-SCH 23390 specific binding decreased by 35% with no change in the apparent dissociation constant (Kd). In a separate experiments, saturation analysis of ^{3}H-SCH 23390 specific binding to striatum from reserpine and saline treated animals were conducted after preincubating the membrane preparations with 250 nM DA. Preincubation of striatal membranes from reserpinized rats reversed the treatment-induced loss of ^{3}H-SCH 23390 binding sites, Bmax values for ^{3}H-SCH 23390 binding to striata from saline-and reserpine-treated rats were 680 fmol/mg prot and 660 fmol/mg prot, respectively. Irrespective for the mechanism by which DA preincubation reverses an apparent loss of ^{3}H-SCH 23390 binding sites, our data indicate that reserpine treatment does not alter either number or affinity of D-1 recognition sites.

61.2 **DIFFERENTIAL REGULATION OF DOPAMINE RECEPTORS IN CAUDATE-PUTAMEN AND NUCLEUS ACCUMBENS FOLLOWING CHRONIC ADMINISTRATION OF RESERPINE.**

D.L. Schambron, J.N. Joyce and P.B. Molinoff. Dept. Pharmacology, University of Pennsylvania, Philadelphia, PA, 19104.

Mapping of dopamine (DA) receptors in rat brain has indicated that D1 and D2 receptors are distributed independently (Boyson et al, J. Neurosci.6:3177, 1986). For example, the relative ratio of D1/D2 receptors in the lateral parts of the caudate-putamen (CPu) is less than in the medial CPu and nucleus accumbens septi (NAS). There also appear to be regional differences in the response to depletion of DA from the striatum (Marshall et al., this vol.) and in the response to chronic treatment with neuroletpics (Boyson et al, Soc. Neurosci. Abstr., 1986). The present experiments were designed to determine if administration of reserpine could produce selective regional changes in DA receptors or in the two principal subtypes of DA receptors.

Male, Sprague-Dawley rats (180 g at first drug treatment) were given reserpine (2.5 mg/kg I.P. first dose, 1 mg/kg s.c. thereafter) or saline (1 ml/kg) on two successive days and then at weekly intervals for two weeks (n=6) or 8 weeks (n=4). Animals were given i.p. injections of sucrose/saline for 4 days following the first injection of reserpine. After 2 weeks or 8 weeks, the animals were killed and the distribution of DA D2 ([3H]spiroperidol) and D1 ([3H]SCH 23390) receptors was determined autoradiographically.

There were regional differences in the denisty of DA receptors apparent with the short-term (2 weeks) and longer-term (2 months) experiments. After 2 weeks the density of D2 receptors had increased in all regions of the rostral CPu (lateral, central, medial; 40-60%) and NAS (90%). At more caudal levels the increase was restricted to the lateral CPu (25%). The density of D1 receptors was increased in all regions of the striatum (CPu and NAS), but the increase was significant only in the NAS (25%) within the rostral striatum and in the caudal CPu (40%).

After 2 months of reserpine treamtment the increase in the density of D2 receptors apparent after 2 weeks of treatment with reserpine had disappeared in the CPu, and had decreased in magnitude in the NAS (25% increase over saline control). Additionally, the increase in the density of D1 receptors in the CPu apparent after 2 weeks of reserpine treatment had been reversed such that the density of receptors was decreased. A 20% decrease as compared to controls was observed in all regions except the NAS, where there was a 35% increase as compared to matched controls. (USPHS GM 34781)

61.3 REPEATED ADMINISTRATION OF (-) SULPIRIDE AND SCH 23390 DIFFERENTIALLY UP-REGULATE D-1 AND D-2 DOPAMINE RECEPTOR FUNCTION IN RAT MESOSTRIATAL AREAS AND PITUITARY BUT NOT IN CORTICAL-LIMBIC BRAIN REGIONS. E. Nisoli*, M. Memo, M. Pizzi*, C. Missale, M.O. Carruba*, A. Forgione and P.F. Spano. Inst. Pharm. Exp. Ther., School of Medicine University of Brescia, Brescia, Italy

We have previously found that repeated administrations of haloperidol, a mixed D-1 and D-2 dopamine (DA) receptor antagonist, to rats for 21 days induced supersensitivity of both classes of central DA receptors. In the present study, we examined the possible functional modifications of both D-1 and D-2 DA receptor subtypes following repeated administration of DA antagonists that act selectively on a single class of DA receptors. The functional state of D-1 and D-2 DA receptors in particular was evaluated by measuring SKF 82526-stimulated and bromocriptine-inhibited adenylate cyclase activity in different brain regions of rats treated with saline, SCH 23390, or (-)sulpiride for 3 or 5 weeks. The results indicate that chronic blockade of D-1 DA receptors in striatum, nucleus accumbens, and substantia nigra by SCH 23390 induced up-regulation of the D-1 receptors without changing the functional activity of D-2 receptors. Likewise, chronic blockade of D-2 DA receptors by (-)sulpiride caused up-regulation of D-2 but not D-1 DA receptors in striatum, nucleus accumbens, substantia nigra and pituitary. We also examined the function of the DA receptor modulating striatal DA release. Treatment with either (-)sulpiride or SCH 23390 caused a decrease in the sensitivity of DA autoreceptor to inhibit DA release. SCH 23390 or (-)sulpiride did not modify the functional activity of either D-1 or D-2 DA receptors located in frontal cortex and hippocampus. In conclusion, these results indicate that chronic treatment with selective D-1 or D-2 DA receptor blockers induces a receptor-specific up-regulation which involves the DA receptors located in the nigrostriatal system and pituitary but not those in the limbic-cortical areas. These data may be of interest in understanding the development of extrapyramidal disordes following repeated administrations of neuroleptic drugs.

61.4 SELECTIVE DOWN REGULATION OF D_1 DOPAMINERGIC MEDIATED ROTATIONAL BEHAVIOR IN SUPERSENSITIVE MICE. James Winkler, Kathleen Callison*, Stephen Cass* and Benjamin Weiss, Division of Neuropsychopharmacology, Dept. of Pharmacology, Medical College of Pennsylvania/EPPI, Philadelphia, PA. 19129

Although the existence of different subtypes of dopaminergic receptors has been recognized for a number of years, it is still unclear what specific behavioral functions each of these receptors subserves. We have addressed this question by attempting to selectively down regulate D_1 or D_2 responses by administering mice selective D_1 or D_2 agonists chronically via Alzet minipumps.

Mice were initially rendered supersensitive to dopamine agonists by making unilateral 6-hydroxydopamine-induced lesions of the corpus striatum. They were then chronically implanted either with the D_1 agonist SKF 38393 or the D_2 agonist LY 171555 (Quinpirole). The concentration of drugs in the pumps were adjusted to deliver a calculated dose of 0.48 umole/hr. for SKF 38393 and 0.0625 umoles/hr. for LY 171555. Spontaneous rotational behavior as well as their response to acute challenge doses of SKF 38393 (40 umole/kg, s.c.) or LY 171555 (2.5 umole/kg, s.c.) were then determined.

Continuous exposure to SKF 38393 produced spontaneous rotations that began within one hr. after the implant. These spontaneous rotations stopped by 5 hrs. after implantation and did not reoccur throughout the two-week period of exposure. At the time spontaneous rotations ceased, the mice were totally unresponsive to an acute challenge injection of SKF 38393. This down regulation in the response to the D_1 agonist was relatively specific since no inhibition of rotational behavior was seen in response to the acute administration of LY 171555.

Mice chronically implanted with LY 171555 also showed marked spontaneous rotations beginning within one hr. after the implant. However, in contrast to the results with SKF 38393, relatively little diminution of the spontaneous rotations was seen during the two week period of exposure. Moreover, there was little change in response to acute challenges with either the D_1 or D_2 agonist.

These results suggest that D_1 and D_2 mediated events respond differently to chronic activation of their respective receptors, and demonstrate that one can produce selective and long term alterations in specific subtypes of dopaminergic receptors. Selective alterations of dopaminergic responses may provide the tools necessary for distinguishing the behaviors mediated by the different subtypes of dopaminergic receptors.

61.5 REGULATION OF MESOLIMBIC DOPAMINE RECEPTORS BY CYCLO(LEUCYL-GLYCYL). J.Z. Fields, L.R. Meyerson, J.M. Lee, F. DeLeon Jones and R.F. Ritzmann. Research Services, Hines VA Hospital, Hines, IL 60141, American Cyanamid Co., Mahwah, NJ 07430 and Olive View Medical Center, Los Angeles, CA 91342-1495.

According to the dopamine (DA) hypothesis of schizophrenia, suppression of dopaminergic (DAergic) neurotransmission in the mesolimbic DA tract should be therapeutic. Accordingly, we have been studying a family of peptides related to prolyl-leucyl-glycinamide (PLG, MIF) that appear to be capable of just such a suppression. After male Sprague-Dawley rats were pretreated on day 1 with cyclo(leucyl-glycyl)("CLG")(s.c., 8 mg/kg), there was a decrease (30 to 60%)($p<0.05$) in amphetamine (1.5 mg/kg, i.p.) induced locomotion on day 5. Activity was automatically recorded for 20 min using the radiofrequency field capability of Stoelting Electronic Activity Monitors. Under these conditions, the incidence of oral stereotypies, e.g. sniffing, was less than 1%, thus insuring that locomotion was not suppressed by stereotypic behaviors that can emerge at higher doses of DA mimetics.

Increasing the number of injections from one on day 1 to one each on days 1 to 4 did not alter the outcome. Altering CLG levels by either increasing or decreasing the dose (range 2 to 24 mg/kg) decreased the down-regulatory effect of CLG. This "inverted-U" shaped dose response curve is typical for a number of the pharmacological actions of CLG and related peptides.

At 8 mg/kg CLG there is an increase in apomorphine-induced stereotypy and an increase in the affinity and density at the higher affinity subsite observed in curves for dopamine inhibition of (^{3}H)spiroperidol binding to striatal membranes. This suggests that regulation of nigrostriatal D2 DA receptors (DA-R) may be unlike regulation of mesolimbic D2 DA-R. Hypothalamic DA-R, as measured by apomorphine-induced hypothermia and D2 DA-R, were down-regulated, the data matching effects of CLG on mesolimbic DA-R but opposite to effects on striatal DA-R.

CLG also down-regulated mesolimbic DA-R in a model of mesolimbic supersensitivity. Haloperidol (1 mg/kg, s.c.) injected daily for 21 days to male Swiss Webster mice induced a hyperlocomotion response seen following a challenge dose of apomorphine (1 mg/kg, i.p.) 48 hr following the last dose of haloperidol. Co-administration for 21 days of CLG (2 mg/kg, s.c.) completely suppressed the development of this supersensitivity.

61.6 STRESS-INDUCED ALTERATIONS IN CORTICAL SPIRODECANONE RECEPTORS. A.J. Friedhoff, H.R. Rosengarten, E.A. Stone and M. Egawa*, Dept. Psychiat., New York Univ. Sch. Med., New York, NY 10016.

Chronic stress is known to produce increases in the responsiveness of brain dopaminergic receptors. In a previous study designed to shed further light on this phenomenon we reported that chronic restraint stress alters the properties of spiroperidol binding sites (defined with (+)-butaclamol) in the cerebral cortex such that the B_{max} was increased and the K_D was reduced (Friedhoff, Rosengarten & Stone, Abstr. Soc. Neurosci. 12:192, 1986). Spiroperidol in the presence of a serotenergic antagonist, is believed to bind to both spirodecanone and D2 receptors in the cortex. Our previous study did not distinguish between these two receptors. The present study was designed therefore to determine which of these receptors is affected by stress.

Rats were subjected to repeated restraint stress (2 hrs/day for 10 days) or to control conditions (daily weighing) and were killed 15-20 hrs after the last stress. [^{3}H]Spiroperidol binding (0.1-0.8 nM) was measured in frontal cortical membranes using (+)- or (-)-butaclamol (100 nM) as the displacing agent. Specific spirodecanone receptor binding was defined as the difference between total and (-)-butaclamol-displaced spiroperidol binding and was found to comprise 10-20% of the total binding. Specific D2 receptor binding was defined as the difference between (+)- and (-)-butaclamol-displaced spiroperidol binding and was found to be 10% of the total. Because of the low amount of specific binding to these sites the data from 5 rats were pooled for each Scatchard determination. A total of 15 control and stressed rats were run.

It was found that stress caused an increased density and reduced affinity of spirodecanone receptors (B_{max} (fmol/mg prot.): control, 35.3 $\pm$ 9.4; stress, 107 $\pm$ 20.7, $p < .05$; K_D (nM): control, 0.28 $\pm$ 0.08; stress, 1.03 $\pm$ 0.18, $p = .05$). The effect of stress on cortical D2 receptors could not be assessed because the low counts obtained precluded accurate Scatchard analysis.

The above preliminary findings indicate therefore that at least part of the alteration in spiroperidol binding in the cortex after stress results from changes in spirodecanone receptors. Other authors have shown that these receptors are also increased in density in the cortex after repeated treatment with antidepressant drugs (Pol. J. Pharmacol. Pharm. 37:317, 1985). While a function for spirodecanone receptors in dopaminergic neurotransmission is still not definitely established it appears from these findings that they have a role in adaptive physiological changes in the CNS. (Supported in part by grants MH08618 and MH22768).

61.7 **BRIEF EXPOSURE TO MUSCARINIC AGONIST DECREASES MUSCARINIC RECEPTOR DENSITY IN PRIMARY CULTURES OF CORTICOSTRIATAL CELLS.** **C. Eva,[a] E. Genazzani[a] and E. Costa[b]. [a]Istituto di Farmacologia e Terapia Sperimentale, University of Turin, Italy and [b]FIDIA-Georgetown Institute for the Neurosciences, Georgetown University Medical Center, Washington, D.C. 20007.**

Regulation of muscarinic cholinergic receptors was studied in primary cultures of cerebral corticostriatal cells prepared from neonatal rats. Muscarinic recognition sites, determined by measuring the binding of the muscarinic radioligands ^{3}H-quinuclidinyl benzylate (^{3}H-QNB) and ^{3}H-N-methylscopolamine (^{3}H-NMS), were detected after 5 days of culture and markedly increased in the subsequent days, reaching a plateau at the 12th day, and decreasing thereafter. In these cultures, stimulation of muscarinic receptors by specific agonists activated two mechanisms of signal transduction: the stimulation of phosphionositide breakdown and the inhibition of adenylate cyclase. At the 10th day of culture carbachol stimulated ^{3}H-inositol-1-phosphate formation by 330% with an EC_{50} of 30 uM. Oxotremorine inhibited by 20% the forskolin-stimulated adenylate cyclase with an IC_{50} of 20 uM. Rapid receptor-mediated regulation of cell membrane surface receptors occurred upon contact with muscarinic agonists. Exposure of these cultures to 1 mM carbachol at 37°C resulted in a significant reduction in the specific binding of the hydrophobic ligand ^{3}H-NMS. The reduction was observed already after 5 min of pretreatment and increased up to 70% after 30 min. The biochemical intracellular mechanisms involved in the regulation of muscarinic cholinergic receptors and of the receptor-coupled transducer systems in these cultures will be discussed in terms of dose dependency and metabotropic mechanisms involved.

61.8 RHYTHMIC CHANGES IN RAT HYPOTHALAMIC ^{3}H-IMIPRAMINE BINDING AND 5HT UPTAKE SITES: POSSIBLE BIOCHEMICAL CORRELATE WITH ANTIDEPRESSANT ACTION. N. Brunello, A.C. Rovescalli*, M. Riva*, R. Galimberti* and G. Racagni°, Center of Neuropharmacology, University of Milan and °Institute of Pharmacology, University of Pavia, Italy.

Seasonal rhythmicity in the occurrence of acute depressive episode, as well as the therapeutic efficacy of light exposure have been documented. These observations suggest the possible involvement of the pineal gland or other biological oscillators in the pathophysiology of severe depressive illness. Therefore we have performed studies with the aim to clarify whether different light-dark cycle schedule may induce changes in the biochemical targets of antidepressants in the rat central nervous system. In particular we have investigated the effect of short day (LD 8:16) or long day (LD 14:10) photoperiods on different biochemical parameters of serotonergic neurons. A significant increase in the density of ^{3}H-imipramine (^{3}H-IMI) binding and in the Vmax of ^{3}H-5HT uptake was found in the hypothalamus of LD 8:16 with respect to LD 14:10 exposed rats. These modifications seem to be limited to serotonergic presynaptic sites, since no difference was found in the kinetic properties of postsynaptic 5HT receptors. Moreover at the moment of the sacrifice (6 hrs from the beginning of lighting), no change was found in 5HT metabolism in the hypothalami and pineals of rats exposed to the 2 different photoperiods. No analogous modification was observed, in the same conditions, in the cerebral cortex, thus indicating that a seasonal rhythm of ^{3}H-IMI binding sites and 5HT uptake possibly exists only in certain brain areas, such as the hypothalamus (which receives direct visual stimuli). A similar increase in ^{3}H-IMI binding and 5HT uptake was present in the hypothalamus of rats accustomed to a light-dark reverted cycle (DL 10:14) and sacrificed 6 hrs after the stopping of lighting in comparison to rats exposed to normal LD 14:10 cycles and sacrificed 6 hrs after the beginning of lighting. Therefore a circadian modification of the serotonergic presynaptic sites studied seem to be also present and related to dark-light exposure. Since the pineal gland of different animal species, including the rat, contains remarkable concentrations of 5-methoxytryptoline, a compound able to inhibit ^{3}H-IMI binding and 5HT uptake, the involvement of this structure in the periodic changes observed could be postulated.

61.9 **ANTIDEPRESSANT EFFECTS ON SECOND MESSENGER SYSTEMS IN RAT BRAIN: RELATIONSHIP TO EFFECTS ON RECEPTOR NUMBER AND DESENSITIZATION.** M.E.Newman and B.Lerer (SPON: H.Goldman). Jerusalem Mental Health Center, P.O.B. 140, Jerusalem, Israel.

Chronic administration of desipramine (DMI, 10 mg/kg i.p. for 3 wk) or chronic electroconvulsive shock (ECS) each resulted in a significant reduction in the degree of stimulation of cyclic AMP formation induced by noradrenaline, isoproterenol, forskolin, and the adenosine analog 2-chloro-adenosine in rat cerebral cortical slices. In cortical membrane preparations from similarly treated animals, stimulation of adenylate cyclase by GppNHp, which acts at the N protein of the enzyme, and by forskolin was increased compared to controls, while less significant increases were also obtained with manganese or sodium fluoride activation. In membranes from caudate nucleus, however, chronic DMI did not affect the degree of forskolin activation, while in cerebellar membranes an increase comparable to that seen in cortical membranes was obtained. In hippocampal membranes, forskolin-stimulated activity was increased after chronic DMI treatment, but was unaltered by chronic ECS.

These results provide partial support for the hypothesis that down-regulation of beta-adrenoceptors by chronic antidepressant treatment, an effect observed in cortex and hippocampus but not in caudate nucleus, leads in turn to increased post-receptor mediated stimulation of adenylate cyclase when membranes are prepared from these brain areas.

In cortical slices from animals which received chronic ECS, the inositol phosphate (IP_1) response to noradrenaline was increased compared to controls, but the responses to carbachol or serotonin were unchanged. The response to carbachol in hippocampal slices, however, was decreased in animals which had received chronic ECS compared to controls. Chronic DMI resulted in an increase in the noradrenaline response and a decrease in the serotonin response in cortical slices, with no change in the response to carbachol. These effects in general parallel the changes in receptor number induced by antidepressant treatment.

Chronic treatment of animals with the antimanic drug lithium (0.4% LiCl in food for 3 wk), which does not down-regulate beta-adrenoceptor number, resulted in decreased cyclic AMP responses to noradrenaline, isoproterenol and forskolin in both slice and membrane preparations from cortex. Acute LiCl in vivo (4 m eq/kg s.c. 24 hr before sacrifice) potentiated the IP_1 response to noradrenaline only, while chronic Li reduced this response but had no effect on basal IP_1 levels or the responses to other agents.

61.10 DIFFERENTIAL MODULATION OF BENZODIAZEPINE RECEPTOR BINDING BY ETHANOL IN LS AND SS MICE. LG Miller, DJ Greenblatt*, JG Barnhill*, RI Shader*. Div. Clinical Pharmacology, Tufts-New England Medical Ctr., Boston, MA 02111 and Depts. Medicine and Pharmacology, LSU Medical Ctr., New Orleans, LA 70112.

The LS and SS lines of mice were initially selected based on differential loss of the righting reflex("sleep time") in response to ethanol. Subsequent studies indicate that these lines differ in response to a wide range of hypnotics, and that alterations in GABAergic function may acount for these differences. Studies using brain membrane preparations in vitro indicated no differences in benzodiazepine receptor binding in the 2 lines. Since these techniques may not reflect binding characteristics in vivo, we examined benzodiazepine receptor binding using [3H]-Ro15-1788 binding in vivo and modulation of binding by ethanol, pentobarbital, and stress. Receptor binding was increased in LS compared to SS mice in cortex and hippocampus (cortex 850 fmol/g vs 650 fmol/g; hippocampus 986 fmol/g vs 709 fmol/g). There were no differences in binding in hypothalamus, cerebellum, or pons-medulla, and no differences in nonspecific binding in any brain region. Apparent affinity at the receptor for clonazepam was similar in LS and SS mice(IC50 21 ng/g vs 19 ng/g). Pentobarbital administration(30 mg/kg i.p.) resulted in increases in binding in all brain regions in both lines, similar to results reported with CFW mice, with a trend toward greater increases in SS compared to LS mice. Defeat stress also led to similar increases in cortex, cerebellum, and hypothalamus in both lines, with an increase also present in pons-medulla in LS mice. Administration of ethanol, 1 gm/kg i.p., with sacrifice after 1 hour, caused significant increases in binding in cortex, cerebellum, and hypothalamus of LS mice. A further increment which did not achieve significance occurred in all brain regions after administration of 2 gm/kg. In contrast, marked increases in binding occurred in all brain regions after administration of ethanol, 1 gm/kg, to SS mice. Further increases occurred in all regions after 2 gm/kg, and were significant in cortex, hypothalamus, and pons-medulla. Benzodiazepine receptor binding in vivo is increased in cortex and hippocampus in LS compared to SS mice, apparently due to an increase in receptor number. Increases in binding induced by stress and pentobarbital are similar in the two lines. After acute ethanol administration, changes in LS mice are modest compared to the substantial increases in all brain regions in SS mice. These data indicate that LS and SS mice differ both in baseline benzodiazepine receptor number and in ethanol modulation of benzodiazepine receptor binding. This finding may contribute to the differential response to ethanol in these lines.

61.11 NEUROPEPTIDE Y RECEPTORS COUPLED TO G PROTEINS: BIOCHEMICAL AND PHYSIOLOGICAL EVIDENCE. M.W. Walker* and R.J. Miller (SPON: S.P. Grossman). Univ. of Chicago, Chicago, Il 60637.

Neuropeptide Y (NPY) is a 36 amino acid neurotransmitter widely distributed throughout the central and peripheral nervous systems. NPY modulates a broad range of physiological processes, from sexual behavior to intestinal ion transport. We have previously shown that $I^{125}(Tyr^1)$-NPY binds with high affinity to receptor sites in rat brain synaptosomes. A survey of various brain regions using10 pM I^{125}-NPY revealed the greatest amount of displaceable binding in both hypothalamus (11 fmol/mg) and hippocampus (6 fmol/mg), and the lowest in cortex (2 fmol/mg) and cerebellum (1 fmol/mg). High affinity receptor sites were also seen in homogenates of dorsal root ganglion (DRG) cells cultured from neonatal rats, but not on F11 (undifferentiated and differentiated) or PC-12 (differentiated) neuronal cell lines, or on HSWP fibroblast cells.

Scatchard analysis of rat forebrain synaptosomes at 25 °C indicated the presence of two binding sites with Kd's of 30 pM (Bmax = 20 fmol/mg) and 3 nM NPY (Bmax = 300 fmol/mg). When synaptosomes were incubated for one hour with 0.1 mM GMPP(NH)P, approximately 50% of the low affinity sites were lost, suggesting that at least some of these sites are coupled to a G-protein. There was no apparent change in Kd. This seems to contrast with several other well-studied systems, such as the B-adrenergic and muscarinic receptors, in which GTP and its analogs induce a change in Kd rather than Bmax. When synaptosomes were washed free of GMPP(NH)P, resuspended into 10 uM GTP for 20 minutes, and resuspended again into standard binding buffer, the concentration of binding sites returned to control levels. The loss of binding sites is therefore reversible on a fairly rapid time scale and may reflect a shift to an extremely low affinity state which cannot be detected over the range of the binding assay.

Scatchard analysis of DRG cell homogenates similarly indicated the presence of two binding sites with Kd's of 40 pM (Bmax = 100 fmol/mg) and 5 nM NPY (Bmax = 2000 fmol/mg). When homogenates were incubated for one hour with 0.1 mM GMPP(NH)P, approximately 80% of the low affinity binding sites were lost without any apparent change in Kd, again indicating that at least some of these sites are coupled to a G-protein. Viable intact DRG cells containing metabolic concentrations of GTP would then be expected to display a low concentration of low affinity binding sites relative to membrane preparations. Indeed, Scatchard analysis of binding to intact cells revealed one major site with a Kd of 0.7 nM NPY and a binding capacity about 15% as great as that seen in homogenates (Bmax = 300 fmol/mg). Furthermore, when 0.1 nM I^{125}-NPY was competitively displaced from whole cell binding sites with unlabelled NPY, a biphasic displacement curve was obtained with IC_{50}'s of 0.3 nM (70%) and 0.4 uM NPY (30%). The data thereby suggest that GTP and analogs stabilize an extremely low affinity state of the NPY receptor.

We have demonstrated electrophysiologically that NPY inhibits inward Ca^{+2} current in DRG cells (see D. Ewald, et. al., in this volume). The effect was abolished when the cells were previously incubated with pertussis toxin, which covalently modifies Gi and Go. The inhibition was restored, however, when purified Go was added to pertussis toxin treated cells, indicating that NPY receptors must be linked to G-proteins in order to modulate current. Thus, we have shown that G-proteins modulate not only NPY receptor binding but also physiological events distal to receptor/ligand interaction in DRG cells.

62.1 **DIPS IN CROSS-CORRELOGRAMS ARE POOR INDICATORS OF INHIBITION BETWEEN ON AND OFF SYSTEMS IN CAT LATERAL GENICULATE NUCLEUS.** D. N. Mastronarde. Dept. of MCD Biology, University of Colorado, Boulder, CO 80309.

Cross-correlograms are a major tool for studying the connections between neurons. However, they can be difficult to interpret if the two cells being recorded have inputs whose activity is itself correlated. A dip in a correlogram, which is usually considered a sign that one cell inhibits the other, can be particularly ambiguous. Here, in the context of a study of inhibition between ON and OFF systems in the cat LGN, I report two reasons why the correlogram dip is a poor indicator of inhibition, and two potential solutions to this problem. I recorded overlapping retinal ganglion cell – LGN cell pairs of opposite center sign (e.g., an OFF ganglion cell and an ON LGN cell). The correlogram for such a pair generally shows that the LGN cell has a dip in firing rate after spikes from the ganglion cell. This dip does not necessarily imply that the ganglion cell inhibited the LGN cell, for two reasons. *1) Retinal correlated firing.* A similar dip appears in the correlogram between an ON and an OFF ganglion cell, which tend not to fire at about the same time. Thus, an ON LGN cell has a reduced firing rate after spikes from an OFF ganglion cell simply because the LGN cell's ON excitatory input(s) fire at a lower rate at those times. *2) Temporal summation in the LGN cell.* Retinal input spikes are less effective in firing an LGN cell, the longer the interval since the last input spike. ON ganglion cell spikes occurring for 30 to 50 ms after firings of an OFF ganglion cell do, in fact, tend to have longer interspike intervals and should thus be less effective in firing an ON LGN cell. Thus the dip in an OFF ganglion cell – ON LGN cell correlogram can be deeper and much longer than the dip in the correlogram between the OFF ganglion cell and the LGN cell's ON-center input, again without implying inhibition by the OFF ganglion cell.

One way to demonstrate inhibition is by recording simultaneously from an LGN cell, its excitatory input, and a ganglion cell of opposite sign; the analysis of one such case will be shown. Another source of evidence for inhibition may be a protracted elevation in LGN cell firing rate following a dip, which may reflect a post-inhibitory rebound. ON–OFF retinogeniculate correlograms often showed such overshoots; many overshoots appeared to be too large to arise either from inter-ganglion cell correlations or from temporal summation effects. Taking such unaccountably large overshoots as evidence for inhibition, the incidence of inhibition can be tentatively assessed for various combinations of ganglion cell and LGN cell types. In conclusion, when there is correlated firing in the afferent input, inhibition cannot be reliably detected from dips in simple correlograms; post-dip overshoots may provide an indicator for inhibition; but, more complex recordings and analysis are needed for conclusive evidence.

62.2 SHAPE AND ARRANGEMENT OF 'ON' AND 'OFF' MODULES IN CAT DORSAL LATERAL GENICULATE NUCLEUS. N. Berman, A. Naporn and B.R. Payne. Dept. of Anatomy, Medical College of Pennsylvania, Philadelphia, PA 19129 and Dept. of Anatomy, Boston University, School of Medicine, Boston, MA 02118.

On and off center neurons in the cat lateral geniculate nucleus are segregated into modules oriented parallel to projection columns, i.e. perpendicular to laminar borders (Naporn, Berman & Payne, '85). To learn more about the shape and arrangement of these modules, we made microelectrode penetrations approximately parallel to lines of projection, lines of isoelevation, or lines of isoazimuth relative to the map of the visual field in the nucleus. We also analyzed a large sample of units according to laminar location.

Although the modules have the form of columns arranged perpendicular to laminar borders, these columns appear to have sloping sides, since at the top of layer A, on cells outnumber off cells by 2.7 to 1 while at the bottom of layer A off cells outnumber on cells by 1.3 to 1. A similar result is seen in layer A1, where on cells outnumber off cells by 3.3 to 1 at the top, and only by 1.3 to 1 at the bottom. These results are in good agreement with Bowling and Wieniawa-Narkiewicz ('85). In addition, in the sample of units recorded in layers A and A1, on center cells account for 60% of the total, while in layer C, off center cells account for 66% of the total.

In tracks which travel parallel to isoelevation or isoazimuth lines, on and off center cells are arranged in alternating clusters. In layers A and A1, ON clusters are larger than OFF cluters. Along the isoelevation lines, ON clusters average 506μm in width while OFF clusters average 303μm in width. Along the isoazimuth lines, ON clusters average 281μm in width while OFF clusters average 176μm in width. These data show that both types of modules are larger along representations of isoelevation (which run mediolaterally) than along representations of isoazimuth (which run rostrocaudally). Furthermore, along these axes adjacent units (within 50μm) sometimes have receptive field centers which do not overlap. These jumps in receptive field position are commonly associated with changes in receptive field center type, suggesting that the ON and OFF modules represent discrete regions of the visual field.

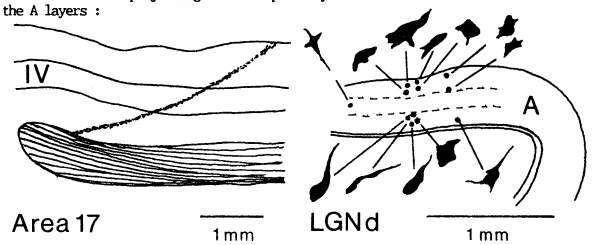
62.3 RECTILINEAR DEPOSITS OF TRANSPORTABLE LABELS : EVIDENCE FOR DEPTH DEPENDENT GENICULO-CORTICAL PROJECTIONS FROM SINGLE LAYERS IN THE LATERAL GENICULATE NUCLEUS (LGNd) OF THE CAT. Douglas B. Bowling, Department of Medical Physiology and The Lions Sight Centre, University of Calgary, Calgary, Alberta, Canada T2N 4N1.

In the A layers of the cat geniculate X, Y and On and Off signals from the retina are processed within mixed pools of cells that also serve as immediate precursors to cortical cells with new receptive field properties (e.g., orientation, direction selectivity, and ocular dominance). The sublaminar organization of the A layers as evidenced by the depth distributions of X, Y and On and Off afferents (Bowling & Michael, 1980,1984) and by X, Y and On and Off target cells (Bowling & Wieniawa-Narkiewicz, 1986) is likely to provide insight into the functional relationships between these fundamentally different visual signals and their roles in the creation of cortical receptive fields.

To examine the sublaminar and topographic features of the geniculo-cortical projection, I have developed a mechanical technique for depositing transportable labels (e.g. HRP or latex microspheres) in thin (40-100um) and continuous straight lines several millimeters in length. When made obliquely across cortical layers in area 17, the position of the label changes continuously in depth and retinotopy along the length of the deposit. Retrograde transport of the label results in an effective transformation from depth in the cortex to retinotopic position in the geniculate. Initial results support the recent finding of Humphrey et al (1985) that X-like cells projecting to the top of layer IV tend to be near the borders of the A layers :



The geniculo-cortical projections appear to reflect the sublaminar organization of the X, Y and On and Off cells in the A layers. Functional correlates of this organization are systematic differences in the amplitude and timing of X-on and X-off responses through the depths of the layers (Bowling & Wieniawa-Narkiewicz, 1987). Thus, the projections indicate that these sublaminar differences in the physiological responses to light from geniculate cells are preserved in the cortical relay and may play a role in the creation of cortical receptive field properties.

62.4 RETINOTOPIC DISTRIBUTION OF NON-LINEAR INTERACTIONS OF RETINAL AND AFFERENT EYE POSITION/MOVEMENT SIGNALS IN CAT LGN_d. R. Lal and M.J. Friedlander Neurobiology Research Center and Dept. of Physiology & Biophysics, University of Alabama at Birmingham.

In previous studies we have shown that passive eye movement in anesthetized cats affects the visual response of neurons in the dorsal lateral geniculate nucleus (LGN_d). In the present study, we quantitatively analyzed a) the relative effects of eye position/movement signals on the spontaneous and visually elicited activity of LGN_d neurons and b) the probability and relative strength of such effects with respect to retinotopy. Activity of single neurons in lamina A of the left LGN_d of anesthetized, paralyzed cats were recorded extracellularly with micropipettes. Neurons were classified as X- or Y- based on a battery of electrophysiological tests. Computer generated visual stimuli were presented through the right (contralateral) eye. Visual stimuli consisted of either drifting sinusoidal gratings at twice threshold contrast and optimal spatial and temporal frequency, or a square-wave modulated circular spot of appropriate contrast sign and size for the neuron's receptive field center at twice threshold contrast. Retinal input was prevented from the left (ipsilateral) eye by placement of an opaque contact lens and intravitreal TTX injection. The movement of the left eye was induced by complementary tension applied to the tendons of insertion of the medial and lateral retus muscles. The neuronal responses on 30-100 trials of identical visual stimuli at different eye positions or times of eye movement relative to the visual stimulus onset were collected in a randomized and interleaved fashion. Of 143 neurons for which the eye position effect was tested, 57 had a statistically significant (predominantly inhibitory) effect on visual response. None of the (35/143) neurons which were also tested for effects of eye position on spontaneous activity showed a significant effect. The ratio of the effect on visual response to the effect on spontaneous activity (non-linearity index) for most of these neurons was $\geq$ 3.0. Of 78 neurons for which the effects of eye movement were tested, 42 had significant (predominantly facilitatory) effects on visual response. However, only 9 of these neurons also had a significant effect on spontaneous activity. The non-linearity index for most of these (36/46) neurons was also $\geq$ 3.0. The magnitude (percent response change) and likelihood (percent of neurons tested which had effect) of an eye position effect increased with receptive field eccentricity while similar measures for the eye movement effect decreased with receptive field eccentricity. A model incorporating the spatial activity profile in the geniculostriate system of these effects will be presented.

62.5 **RELATIONSHIP BETWEEN RESPONSE LATENCY AND AMPLITUDE FOR GANGLION AND GENICULATE X- AND Y-CELLS IN THE CAT.** A.K. Sestokas, S. Lehmkuhle and K.E. Kratz. Dept. of Neurosurgery, University of Maryland School of Medicine, Baltimore, MD 21201; School of Optometry, University of of Missouri - St. Louis, St. Louis, MO 63121; Dept. of Anatomy, Louisiana State University Medical Center, New Orleans, LA 70112.

We have previously reported that visual response latencies of X- and Y-cells vary systematically as a function of stimulus spatial frequency and contrast (Sestokas, A.K., Vis.Res. 26:1041, 1986; Sestokas, A.K., Lehmkuhle, S. and Kratz, K.E., Vis. Res. in press). In general, shorter visual latencies are obtained with those stimuli that elicit larger responses. Hence, changes in latency as a function of stimulus condition could be due to concomitant changes in response amplitude. Alternatively, changes in latency and amplitude could be due to a direct influence of the stimulus on each of these parameters.

The purpose of this study was to examine the extent to which response latencies of ganglion and geniculate X- and Y-cells are coupled to response amplitudes. We measured the responses of ganglion and geniculate X- and Y-cells on a trial by trial basis during repeated stimulation with grating stimuli. Gratings of fixed spatial frequency and contrast were presented once per second for 100 msec in blocks of 24 trials. Stimulus spatial frequency and contrast were varied across blocks of trials. Correlations between response latencies and amplitudes calculated across stimulus conditions generally fell between -.5 and -.6 for ganglion cells, and between -.4 and -.5 for geniculate cells. Correlations between latencies and amplitudes calculated within stimulus conditions generally fell between -.2 and -.5 for all groups of cells. In general these results indicate that latency and amplitude are not tightly coupled response parameters. Therefore, for ganglion and geniculate cells, changes in visual latency that accompany changes in spatial frequency or contrast of the stimulus are not trivial consequences of response amplitude.

62.6 **FUNCTIONAL ROLE OF GABAERGIC CIRCUITRY IN THE LGN.** R.N. Holdefer, D.W. Godwin*, Y. Zhang*, and T.T. Norton. Depts. of Physiological Optics and Psychology, University of Alabama at Birmingham, Birmingham, AL 35294.

In a previous study (Holdefer et al., 1985) we described GABA-immunoreactive neurons and neuropil in the LGN of the tree shrew (Tupaia belangeri). At the ultrastructural level, labelled F2 profiles were often seen postsynaptic to retinal terminals and presynaptic to conventional dendrites.

The functional significance of GABAergic circuits was investigated with microiontophoretic application of the GABA antagonist bicuculline in the LGN of anesthetized tree shrews (NO_2/halothane). Although bicuculline increased the maintained discharge and the tonic component of the relay cells' response to briefly presented visual stimuli, there was a more significant effect on the visually driven peak firing ($p=.001$) and the duration of the phasic response ($p<.01$) of the cells.

This greater effect on visually-driven peak firing as compared to maintained discharge suggested that bicuculline application might change the signal-to-noise ratio for cells in the LGN. Receiver operating characteristic (ROC) curves were derived from interspike interval data using maintained discharge as "noise" and visually-driven activity as the "signal" (Wilson et al., submitted). Preliminary ROC curve analyses suggest that when the noise level is very low (4 cells, maintained discharge < 2.0 spikes/sec) bicuculline application can increase or decrease the discrimination of a visual signal from maintained discharge. Under moderate to high noise conditions (3 cells), bicuculline increased the detectability of a visual stimulus, and this effect was generally reversible during the postdrug control recordings from the cell.

Contrast sensitivity functions (CSFs) to a drifting, sinewave grating were also obtained before, during, and after bicuculline application. There was a significant increase in contrast sensitivity for the two lowest spatial frequencies tested (0.0625 c/deg and 0.0935 c/deg; $p<.01$) and no significant change in sensitivity at the higher spatial frequencies. CSFs taken during the postdrug condition showed that these effects were completely reversible. An analysis of the data using the difference of Gaussians model is continuing to determine whether this effect is due to changes in the surround, center, or both mechanisms.

These results demonstrate that in tree shrew, as in cat, there is some alteration of the receptive-field properties of relay cells by GABAergic processes. Our results are also consistent with a gating of visual information in which GABAergic synapses may regulate the signal-to-noise ratio in the LGN.

62.7 DENDRITIC CURRENT FLOW IN X CELLS IN THE CAT'S LATERAL GENICULATE NUCLEUS: A COMPARISON OF RELAY CELLS AND INTERNEURONS. Stewart A. Bloomfield and S. Murray Sherman, Dept. of Neurobiology & Behavior, SUNY at Stony Brook, N.Y. 11794.

Despite a large variability in dendritic architecture, relay X and Y cells in the cat's lateral geniculate nucleus are electrically compact, each having an electrotonic length (L) of about 1 (Bloomfield et al. J. Physiol. 383:653, 1987). Thus even synaptic innervation located most distally in the dendritic arbor will have a major influence on somatic and axonal responses. Geniculate interneurons have receptive field properties nearly identical to those of relay X cells, but dendritic morphology differs dramatically between these two cell types (Hamos et al. Nature 317:618, 1985). Dendrites of interneurons contain synaptic terminals in the form of clustered appendages that are both pre- and postsynaptic, and these cells also have conventional synaptic outputs from a locally ramifying axon. In addition to these morphological differences, we now describe differences in passive cable properties between relay X cells and interneurons. We made morphological measurements from 2 relay X cells and 2 interneurons after labeling them intracellularly with HRP, and we then used steady-state cable theory to determine the passive current flow from activation of a single synaptic input in their dendritic arbors.

As expected, the relay X cells were electrically compact, with L values of about 0.9. Thus even the most distal synaptic inputs will reach the soma with attenuation of only 40-50%. In addition, synaptic current applied to any segment within a single branch can propagate effectively throughout all portions of the arbor emanating from the same primary dendrite. We conclude that, for relay X cells, all synaptic information can be integrated at the soma to influence responsiveness of the axon, which represents the sole output of the cell. In contrast, the dendritic arbors of interneurons cover more than 3 electrotonic lengths. Distally generated synaptic potentials will thus be attenuated by more than 90% before reaching the soma, and attentuation less than 50% is possible only for synapses located within the proximal 1/3 of the dendritic arbor. Consequently, soma and axon responses may reflect only those inputs onto proximal dendritic shafts. Inputs onto distal dendritic shafts, as well as inputs onto clustered appendages, will have little effect on the soma, but may instead control the output of the presynaptic dendritic terminals. Furthermore, the more distally located dendritic segments may be electrically isolated from each other. Thus, much of the dendritic arbor may be comprised of autonomous functional subunits capable of both receiving and transmitting synaptic information.

62.8 STIMULATION OF THE BRAINSTEM RETICULAR FORMATION DIFFERENTIALLY AFFECTS TWO GROUPS OF X-CELLS IN THE CAT LATERAL GENICULATE NUCLEUS A.L. Humphrey. Dept. of Neurobiology, Anatomy and Cell Science, University of Pittsburgh, Pittsburgh, PA 15261.

Two physiologically distinct groups of X-cells reside in the A-laminae of the cat lateral geniculate nucleus (LGN)[1,2]. Referred to as lagged (X_L) and non-lagged (X_N) X-cells, they respond differently to a small flashing spot centered in their receptive field. At spot onset, X_N-cells give a transient discharge, while X_L-cells show a strong inhibitory dip in firing. At spot offset, cell discharge decays rapidly among X_N-cells, but many X_L-cells display a transient "offset discharge." These two groups also differ morphologically[3], and they may be differentially contacted, and thus influenced by, intrageniculate and perigeniculate (PGN) interneurons.

Inputs to the LGN from the brainstem reticular formation (BRF) facilitate retinogeniculate transmission, probably by inhibiting intrageniculate and PGN interneurons. Given the likely involvement of these interneurons with X_L- and X_N-cells, I have investigated the effects of BRF stimulation on X-cells. Electrical stimuli (10ms train of 4 pulses) were delivered to the region of the pontine reticular formation while recording extracellularly from 7 X_N-cells and 4 X_L-cells in the LGN of barbiturate anesthetized cats.

When the animal viewed a uniformly illuminated screen, stimulating the BRF alone had a strong effect on the baseline firing of X_L-cells, but not on X_N-cells. The X_L-cells responded with a strong transient discharge, which peaked at 95ms, lasted about 150ms, and attained a maximum firing level (~100sp/s) up to nine times higher than that of baseline firing. The X_N-cells gave only a negligible response to BRF stimulation alone.

When BRF stimuli preceded by 100ms the turning on of a small spot in a cell's receptive field, the two X-cell groups were also differentially affected. BRF stimulation among X_N-cells increased their discharge rates significantly above control levels throughout the period of spot onset. BRF stimulation among X_L-cells elicited a transient discharge which replaced the inhibitory dip normally seen in these cells. However, the BRF-induced transient in the X_L-cells was short-lived (~160ms); following the transient, the sustained discharge dropped to control levels and the offset discharge was unaffected.

These results indicate that X_L- and X_N-cells differ not only in their visual response properties and morphologies, but they are differentially affected by inputs from the brainstem reticular formation. Possible mechanisms underlying these differences will be considered. Supported by USPHS grant EY06459.

62.9 SUSTAINED (X) CELLS IN THE CAT LATERAL GENICULATE NUCLEUS RESPOND TO RATES OF LUMINANCE CHANGE. P. Heggelund, H.E. Karlsen*, G. Flugsrud*. Dept. of Neurophysiol., Univ. of Oslo, N-0162 Oslo, Norway.

Single cells in the lateral geniculate nucleus (LGN) respond strongly when the luminance on the receptive field is changed. We have studied how the rate of luminance change of a stationary test spot influences the response pattern of sustained (X) LGN cells. The spot size was adjusted so it approximately filled the receptive field center. The spot was surrounded by a contiguous annulus of fixed luminance (12 cd/m2). The spot luminance was modulated linearly (triangular or trapezoid luminance functions) or sinusoidally in time between 0.4 log units below to 0.4 log units above the surround luminance. Modulation frequencies between 0.1 and 400 Hz were used.

The cells responded to rate of luminance change and not to stimulus contrast. To the linear stimulus functions, in which the contrast was continuously changed, the cells responded to the constant rate of luminance change with a constant rate of action potentials at stimulus frequencies below 4 Hz. On-center cells responded when the luminance was increased, off-center cells when the luminance was decreased. This constant firing level increased monotonically with the stimulus frequency. At stimulus frequencies above 4 Hz an initial overshoot occurred. This transient became more pronounced as the frequency increased. Thus, the response gradually approached the typical pattern seen to a step function. To sinusoidal stimuli at low temporal frequencies there was a considerable negative phase shift of the response. At 1 Hz the average phase shift of the response maximum of the cells was -92 deg when the delay caused by response latency (25 deg) was subtracted.

We concluded that the X-cells perform a differentiation-like operation in the time domain. At low temporal frequencies (<4 Hz) the response approximates the first time derivative. Previous studies (e.g. Movshon et al., J. Physiol., 1978, 283, p. 101) have shown that it is at such low frequencies that most striate cortex cells operate, indicating that the LGN cell properties at such frequencies may be essential for the cortical processing. (Supported by NAVF).

62.10 **THE TEMPORAL PROPERTIES OF THE MACAQUE MAGNO AND PARVO PATHWAYS IN THE FACE OF CHANGING LEVELS OF RETINAL ILLUMINATION.** K. Purpura*, E. Kaplan and R.M. Shapley, The Rockefeller University, N.Y.,N.Y., 10021.

Psychophysical studies (deLange,1958; Kelly,1972) have demonstrated the importance of the temporal frequency of a stimulus in determining its visibility at different background levels of retinal illumination. At high temporal frequencies (for instance, 20 hz) and low spatial frequencies (1 c/deg), contrast sensitivity is proportional to background level. At low temporal frequencies (1 hz) and low spatial frequencies, contrast sensitivity does not depend on the background and is constant.

In an effort to understand the neuronal basis of these psychophysical results, we studied the magnocellular and parvocellular pathways of macaque monkeys which were anesthesized with urethane and paralyzed with flaxedil. We recorded responses of neurons in the lateral geniculate nucleus (LGN) and their retinal afferents (M and P cells) to luminance gratings at several temporal frequencies at various levels of retinal illumination. The drifting sinusoidal gratings were produced on a white CRT. Mean luminance was controlled by neutral density filters, and the monkeys were fitted with contact lenses with artificial pupils.

Our preliminary data indicate that the responses of visual neurons of both the magno and parvo pathways resemble the human psychophysical temporal frequency/light adaptation behavior. At high temporal frequencies, the contrast gains (the slope of the initial linear portions of the response-contrast functions) of these neurons varied proportionally with mean retinal illumination, while at lower frequencies the contrast gain was less influenced by the mean light level. The qualitative similarity of this behavior between parvo and magno cells is somewhat surprising given their different light adaptation behavior in general (Purpura *et al.*,1986). However, we have also examined the temporal tuning of these neurons over several light levels and found them to change in qualitatively similar ways. This suggests that the temporal properties of neurons in the parvocellular and magnocellular pathways may be established by the temporal filtering properties and light adaptation behavior of the photoreceptors or other, distal neurons.

62.11 **THE PROCESSING OF COLOR AND LUMINANCE INFORMATION IN MONKEYS: 1. PSYCHOPHYSICS.** E.R. Charles*, N.K. Logothetis, A.C. Hurlbert*, P.H. Schiller (SPON: R.Held). Dept. of Brain and Cognitive Sciences, M.I.T., Cambridge, MA

Luminance and chrominance information are thought to be separately conveyed by parallel channels in the primate visual system. Psychophysical experiments in humans show that motion, depth, and pattern perceptions are degraded at isoluminance (IL), when only chromatic cues provide contour information. These results suggest that the chrominance channel is only weakly responsive to motion, depth, and pattern cues. We report on a set of psychophysical experiments designed to study visual perception at IL in old-world monkeys, the results of which we have correlated with physiological recordings from broad-band and color-opponent cells in the monkey visual system (see abstract by Hurlbert et al. in this vol.).

We have determined IL values for four rhesus monkeys using an adaptation of the flicker photometric technique. Each monkey was trained on a visual discrimination task that required him to fixate on a central point at the start of each trial, then to saccade to a target that appeared as one of eight peripheral stimuli equidistant from the fixation point. The stimuli were checkerboard patterns in which the colors of adjacent squares were counter-flickered between red and green at a rate of 30 cps. The target differed from the non-targets only in the size of its squares. The red-green luminance ratios were varied between trials. On control tasks, the monkey discriminated between different-sized checkerboards of the same color with checkers of different luminances. All visual stimuli were generated by an Adage image processor and presented on a color monitor with linearized guns.

IL values were identified as the red-green luminance ratios at which the monkey's percentage of correct responses fell to near chance from near 100 at extreme ratios. We have compared these IL values with the red-green luminance ratios at which monkey perceptions of motion and stereoscopic depth are impaired. The results of our control tasks suggest that the low luminance contrast of the red-green IL stimuli is not responsible for the observed impairment in visual perception.

62.12 **THE PROCESSING OF COLOR AND LUMINANCE INFORMATION IN MONKEYS: 2. PHYSIOLOGY.** A.C. Hurlbert*, N.K. Logothetis, E.R. Charles, P.H. Schiller (SPON: S.Mann). Dept. of Brain and Cognitive Sciences, M.I.T., Cambridge, MA

Psychophysical experiments in humans show that at isoluminance, visual perceptions of motion, depth, and form are impaired. It has been suggested that this impairment is due to the different ways in which the primate color-opponent and broad-band channels process chrominance and luminance information. In particular, it has been proposed that at isoluminance, the broad-band channel is effectively inactivated. To test these suggestions, we have studied the physiological properties of color-opponent cells (in parvocellular LGN -- PLGN) and broad-band cells (in magnocellular LGN -- MLGN) and compared them with our psychophysical data on monkey visual perception at isoluminant (see abstract by Charles et al. in this volume).

The properties of LGN cells in anesthetized, paralyzed rhesus monkeys were studied using three methods: single-unit recordings, multiple-unit recordings, and evoked potentials. In each study, a small portion of the retina (the center of the receptive field under study) was stimulated by a red-green flickering light, generated by an LED or an Adage image processing system. Counter-flickering center-surround stimuli designed to mimic the theoretically optimal stimuli for PLGN and MLGN cells were also used. The rate of the red-green light exchange was varied from 1 to 40 Hz, and the red-green luminance ratio was systematically varied to find maximal and minimal responses at each electrode site. These optimal responses were determined by on-line computer analysis of spike frequencies.

Our results show that for most LGN cells (excluding highly color-selective cells) there is a red green luminance ratio at which an equal and minimal response occurs to each light exchange. This balanced response is generally of a lower magnitude in PLGN than in MLGN. The balancing red-green luminance ratio varied widely among cells, especially in PLGN. Thus, at the LGN level, it seems that there is no single isoluminance value for either the broad-band or color-opponent channel that correlates with our behaviorally observed effects at isoluminance.

62.13 BINOCULAR INTERACTIONS IN THE LATERAL GENICULATE NUCLEUS OF THE ALERT MONKEY. C.E. Schroeder, C.E. Tenke, M.A. Kraut*, J.C. Arezzo and H.G. Vaughan, Jr. Departments of Neuroscience and Neurology, Albert Einstein College of Medicine, Bronx, NY.[1]

It has been hypothesized that the pattern of fine lamination in the parvocellular division of the macaque lateral geniculate nucleus (LGN) may have evolved to support binocular interactions. While both excitatory and inhibitory binocular interactions in cat LGN are widely reported, studies of macaque LGN have demonstrated only weak, binocular inhibition, confined to the magnocellular laminae. In the present study we have re-evaluated this issue using procedures which allow simultaneous recording of activity in multiple laminae.

Flash-evoked field potentials and concomitant multiunit activity were recorded from LGN in 3 alert, monkeys (m. Fascicularis),using 16 channel, multicontact electrodes with contact impedances of approximately 300 kOhm (at 1000Hz) and intercontact spacing of either 75 or 150 uM. At least 2 laminae were sampled in each electrode position and responses to binocular and monocular stimulation were recorded. Prominent oscillatory potentials and multiunit responses were observed in all laminae, but both the response duration and oscillation frequency differed between parvo- and magnocellular regions. Binocular interactions were noted in every electrode penetration, and in all laminae. The most common type was binocular inhibition. One form observed was a 15-70% reduction in the peak amplitude of multiunit responses during binocular, as opposed to monocular stimulation of the dominant eye for the lamina under study. This effect was seen in all laminae, but was more prominent in magno- than in parvo-cellular layers. A second form of binocular inhibition, limited to the ipsilateral laminae in our current data, is a 10-30% reduction in multiunit activity, below its baseline level, with stimulation of the contra-lateral eye. This effect is coincident with excitatory responses in adjacent, contralaterally innervated laminae. Finally, on many occasions, we noted activity suggestive of excitatory modulation by the nondominant eye.

Our results are consistent with earlier work in that, binocular interactions were found to be more prominent in the magnocellular laminae. However, contrary to previous studies, we also observed clear binocular interactions in the parvocellular layers. In addition, the magnitude and complexity of binocular interactions were greater than previously reported, with evidence that they differ in ipsilaterally vs. contralaterally innervated laminae. These data, together with the growing body of evidence from experiments in the cat, underscore the notion that the mammalian LGN is an important site of binocular interaction.

LEARNING AND MEMORY: ANATOMY I

63.1 : CRITICAL RE-EVALUATION OF THE CONSOLIDATION HYPOTHESIS OF AMNESIA. N. J. Cohen* (SPON: F.H. Baker). Cognitive Neuropsychology Lab., Johns Hopkins University, Baltimore, MD 21218.

An early and influential view of the nature of the memory impairment in at least some forms of amnesia postulates a failure of memory consolidation. One version of this idea holds that amnesia resulting from medial temporal-lobe damage impairs processes that normally operate during the time after learning to permit the formation and/or retrieval of stable memory representations (Squire & Cohen, 1984; Squire, Cohen, & Nadel, 1985). The major pieces of evidence offered in support of this view are that medial temporal-lobe amnesia is associated with an abnormally rapid rate of forgetting and that such patients have temporally-limited retrograde amnesia (RA). The present paper reconsiders these two lines of evidence and concludes that neither provides any special support for the consolidation view.

Abnormally rapid forgetting: Extensive work with the patient H.M., profoundly amnesic since sustaining bilateral resection of medial temporal-lobe structures in 1953, failed to find rapid forgetting: Across multiple testing occasions when H.M. was given extra time to process the to-be-learned material so that his memory performance could be equated to the level of normal subjects at a time soon after learning, he showed a largely normal rate of forgetting for the material over the subsequent 3-7 days (Freed, Cohen, & Corkin, 1986). More damaging, however, is that the present paper shows that even if rapid forgetting were a reliable feature of medial temporal-lobe amnesia, it would provide no special evidence for a consolidation view of this amnesia. A simple quantitative model is offered to show how rapid forgetting could be produced equally well by an impairment in encoding, retrieval, or consolidation processes.

Temporally-limited RA. Also cited in support of the consolidation view is the existence of RA's that impair all memories acquired during the 1-3 year period prior to the onset of amnesia regardless of the content of the memories. Yet, the present paper discusses two patients whose RA's are temporally defined in the manner just described but cover time periods extending to 16 and 40 years. The graded RA's associated with Korsakoff's disease are similarly temporally defined for a period encompassing decades. Accordingly, the present paper suggests the necessity of a principled justification for the claim that the brief (or limited) temporally-defined RA reflects a disruption of consolidation processes but that the extensive form does not.

63.2 LEARNING AND FORGETTING DURING AND AFTER POSTTRAUMATIC AMNESIA IN HEAD INJURED PATIENTS. H.S. Levin, W.M. High, Jr.* and H.M. Eisenberg*. Neuropsychology Lab., Div. Neurosurgery, University of Texas Medical Branch, Galveston, TX 77550.

Following previous work implicating rapid decay of memory in a patient with bihippocampal lesions (Huppert and Piercy, Cortex, 15:385, 1979) and the postulated association between posttraumatic amnesia (PTA) and temporal lobe injury, we compared the rate of forgetting in head injured patients studied during PTA (n=13) to the retentive capacity of head trauma patients studied after resolution of PTA (n=18) and normal controls (n=18). The patients studied during PTA had more severe impairment of consciousness at the time of hospital admission and were tested after longer intervals since injury as compared to the head injured patients examined after their PTA had cleared. We modified the recognition memory procedure developed by Huppert and Piercy in which slides were presented initially for longer durations to the patients with presumed memory deficit. In contrast to the 120 color slides of pictures utilized by Huppert and Piercy, we presented 66 slides initially to the head injured patients. Total durations of presentation were 8 seconds for patients in PTA, 2 seconds for patients tested after PTA resolution and 1 to 1.5 seconds in controls. A duplicate series of these slides were divided into three sets of 22 slides (targets) for testing recognition memory at 10 minutes, 2 hours and 32 hours later. Each recognition test involved discrimination of the target slides from 22 slides which were not shown previously. Nearly one-fifth of the injured patients studied were unable to attain a criterion of initial learning (d'=2.0 or about 70% correct) over a 10 minute interval despite a prolonged exposure duration. Analysis disclosed that patients in PTA exhibited greater forgetting by 32 hours as compared to head injured patients out of PTA. Subgroups of 8 head injured patients matched according to severity of injury disclosed significant differences in forgetting at 2 hours and 32 hours despite comparable initial learning at 10 minutes following presentation.

Our findings indicate that PTA following head injury is associated with a defect in acquisition of pictorial information unless it is presented at exposure durations which exceed the times given to normal controls by a factor as great as 8. Our finding of rapid forgetting during PTA is compatible with the decay of memory exhibited by patient H.M. following bilateral hippocampal excisions. Although further investigation of head injured patients with focal lesions is indicated, our results offer preliminary support for the postulation that PTA is a form of temporal lobe memory disorder.

63.3 **MONKEY BEATS MAN IN EFFICIENCY OF MNEMONIC RETRIEVAL.** Jeffrey D. Lewine, Robert W. Doty, Sherri Provencal*, and Robert Astur*. University of Rochester, Rochester, New York, 14642.

To determine whether the temporal characteristics of mnemonic retrieval are similar in man and monkey, 4 Macacca nemestrina and 4 students were trained and tested on Sternberg's serial probe recognition task (Science, 153, 1966). Basically, subjects had to distinguish positive (target) from negative (non-target) probes as rapidly as possible, classifying them by means of differential manual responses. The probes were selected from an inventory of images of 100 multi-colored patterns. At the beginning of each test set, subjects viewed 1-6 target patterns. Each target set was then followed by several classification trials. Within a given experimental session (consisting of several test sets), a particular positive probe (+P) occurred in only one test set while a particular negative probe (-P) often occurred in two test sets. Also, patterns that served as positive probes in one session occurred as negative probes in other sessions and vice-versa. This served to insure that subjects made probe classifications based upon the relevant target information and not upon a novel vs repeat strategy, or previous pattern-response associations. The abilities of human subjects and macaques to correctly discriminate between +P and -P trials were, as measured in terms of "detectability", not significantly different [$F(1,7)=2.88$, $P>.05$], three macaques demonstrating overall detectability values equivalent to, or greater than, those of two of the human subjects! Both human and macaque subjects typically classified probes in < 600 msec, the average time required to evaluate probes increasing as a linear function of the number of relevant targets that had to be remembered. However, increasing the number of relevant targets, on average, increased probe-evaluation-time by only 8 msec/target (range 5-11 msec/target) for the monkeys but 23 msec/target (range 17-31 msec/target) for the human subjects. These values are significantly different, [$F(1,7)= 15.24$, $P<.01$]. The reaction time data suggest that, when the number of targets does not exceed the "immediate memory span", both species utilize serial strategies to access the target information, but macaques can do so at 3X the rate of man! The most parsimonious explanation is that the smaller temporal increment for macaques simply reflects shorter neural paths in a smaller brain. However, the possibility that probe evaluation by human subjects involves additional processing stages not utilized by the macaques cannot be ruled out. Nevertheless, despite the macaque's lack of the neocortical elaboration characteristic of the human brain, the data clearly demonstrate that some mnemonic processes in macaques may be more efficient than those in man. 63.4 NORMAL LEARNING SET FORMATION IN MONKEYS WITH COMBINED ABLATION OF THE AMYGDALOID COMPLEX AND HIPPOCAMPAL FORMATION. E. A. Murray. Laboratory of Neuropsychology, NIMH, Bethesda, MD 20892

Monkeys with combined ablations of the amygdaloid complex and hippocampal formation (AH) are severely impaired in both visual and tactile object recognition, and have been shown to exhibit a pattern of impaired and spared learning abilities that is similar to the pattern observed in patients with global anterograde amnesia. In an effort to understand the spared learning abilities of amnesic monkeys, monkeys with AH ablations were compared with unoperated controls on their rate of acquisition of a learning set. Since learning set formation is traditionally viewed as a relatively "advanced" function, it was hypothesized that this phenomenon would be dependent upon the medial temporal lobe limbic structures and that monkeys with AH ablations would be unable to form a learning set. To avoid penalizing the monkeys with AH ablations for their marked memory impairment, the monkeys (M. mulatta) were trained on a version of discrimination learning that had earlier been reported to yield normal scores for monkeys with AH ablations (Malamut et al., Behav. Neurosci. (1984) 98: 759-769.) All monkeys were trained on 10 consecutive sets of concurrent object discrimination problems. Each set consisted of 20 different pairs of objects, with one item of the pair arbitrarily designated as positive (baited) and the other negative (unbaited). Within a day's test session, each pair of objects was presented for discrimination, one at a time, at intervals of 20 seconds, until all 20 pairs had been used. This procedure was repeated at 24-hr. intervals with the order of the presentation of the pairs remaining constant, but the left-right position of reward following a pseudorandom order, until the monkeys reached a criterion of 90 correct responses in 100 trials. When criterion had been attained on the first 20 discriminations, the monkeys were trained in the same manner on a second set of 20 concurrent discriminations, and so on, until all 10 such sets consisting of 20 problems each had been learned.

Monkeys with AH ablations learned the first two sets of concurrent discriminations at the same rate as the controls (AH, $\bar{X}$=12.4 trials; CON, $\bar{X}$=7.8 trials), a finding that confirms the results of the earlier study by Malamut et al. Furthermore, the two groups did not differ in their rate of acquisition of the last two sets of 20 concurrent discriminations (AH, $\bar{X}$=5.1; CON, $\bar{X}$=4.7), and both groups learned the last two sets significantly faster that the first two sets (paired t-test, AH, $t=3.20$, 3df, $p<.025$; CON, $t=2.36$, 5df, $p<.05$). The results thus show that learning set formation can take place at a normal rate even in the absence of the medial temporal lobe limbic structures and therefore suggest that this process involves the retention of procedures or skills as opposed to the retention of specific facts or events.

63.5 TOPOGRAPHIC ORGANIZATION OF THE ENTORHINAL PROJECTION TO THE DENTATE GYRUS IN THE MONKEY. D.G. Amaral, M.P. Witter* and G.W. Van Hoesen. The Salk Institute, La Jolla, CA 92037, Dept. Anatomy Vrije Universiteit, Amsterdam, The Netherlands, and Univ. of Iowa, Iowa City, IA 52242.

Human clinicopathological studies and experimental primate studies have clearly indicated that the hippocampal formation plays a central role in the consolidation of sensory information into memory. It is thus of some importance to determine from which cortical regions the hippocampal formation receives its sensory inputs and how this information is conveyed to each of its distinct cytoarchitectonic fields. The monkey entorhinal cortex (EC) receives direct inputs from several polysensory associational regions of the frontal, temporal, insular and cingulate cortices. The entorhinal cortex, in turn, gives rise to the major input (the perforant pathway - PP) to the dentate gyrus which is the route through which the hippocampus proper receives most of its cortical input. The organization of the perforant pathway has been extensively studied in the cat and rat and is topographically organized such that a lateral-to-medial axis of PP origin in EC corresponds to a longitudinal or dorsal-to-ventral axis of termination in the DG. Since the topography of the primate PP has not yet been examined, we studied the organization of this pathway in two species of macaque monkeys with both retrograde and anterograde tracing techniques. Injections of retrograde tracers (WGA-HRP, Fast Blue or Diamidino Yellow) were placed at different positions along the anteroposterior extent of the DG in 10 monkeys. A cocktail of tritiated amino acids (TAA) was injected into the entorhinal cortex of 16 additional animals. Injections of retrograde tracers aimed at the most anterior portion of the DG results in a rostrocaudally oriented band of labeled cells that occupies the medial 1/3 of the EC. Injections that were placed at more posterior levels result in progressively more laterally located longitudinal zones of labeled cells. The TAA experiments confirmed this topographic organization and indicated that the pattern of PP termination in the molecular layer is not as laminated as in the rat brain. We have concluded that the origins of the projection from the entorhinal cortex to different rostrocaudal levels of the dentate gyrus are organized in obliquely oriented, longitudinal bands that more or less parallel the anterolateral-to-posteromedial axis in EC. These bands are oriented perpendicular, however, to the major axis of cytoarchitectonic differentiation of the EC and cut across most of its fields. Recent studies in the cat and monkey indicate that different regions of the entorhinal cortex receive distinct complements of afferents. Therefore, the described organization of the PP may indicate that functionally different types of information are transmitted to different levels of the DG. The bearing of this topographic organization on the function of the primate hippocampal formation will be discussed.

63.6 SUCCESSFUL PERFORMANCE BY MONKEYS WITH HIPPOCAMPAL LESIONS ON PIAGET'S A$\bar{B}$ TASK. Adele Diamond, Dept. of Psychology, Washington University, St. Louis, MO 63130, Stuart Zola-Morgan and Larry R. Squire, VA Medical Center, San Diego, CA 92161 & Dept. of Psychiatry, UCSD, La Jolla, CA 92093.

Piaget's A$\bar{B}$ task is a well-known marker of developmental change between 7½-12 months in human infants. In the task, the subject watches as a reward is hidden in 1 of 2 identical wells side by side. A brief delay follows after which the subject is allowed to reach. The reward remains in the same location until the subject is correct twice in a row; then location of reward is reversed and the procedure repeated. Human infants of 7½-9 months make "the A$\bar{B}$ error" at delays of 2-5 sec (infants 10 months or older succeed at delays this brief). Subjects making "the A$\bar{B}$ error" reach correctly at the first hiding place, or when hiding is repeated where they have just reached correctly on the previous trial. Their errors are confined to reversals and to trials where the hiding is in the same place as the previous trial and the subject was wrong on the previous trial. Performance on A$\bar{B}$ has been linked to dorsolateral prefrontal cortex by work in adult monkeys (Diamond & Goldman-Rakic, Neurosci. Absts., 1983) and infant monkeys (Diamond & Goldman-Rakic, Neurosci. Absts., 1986). E.g., monkeys with prefrontal lesions err at delays of 2-5 sec, showing the same A$\bar{B}$ error pattern as human infants.

Because interpretations of A$\bar{B}$ stress its memory requirements, we have assessed performance on A$\bar{B}$ in monkeys following damage to the hippocampus. Six cynomologus monkeys (3 with bilateral lesions of the hippocampus [H] & 3 unoperated controls [C]) were tested. All 6 monkeys performed correctly on A$\bar{B}$ at delays of 2-5 sec ($\bar{x}$ at 2 & 5 sec combined: H = 95% correct; C = 91%). At delays of 10 sec & 15 sec, performance of monkeys with hippocampal lesions progressively declined ($\bar{x}$ at 10 sec: H = 84%; C = 90%; $\bar{x}$ at 15 sec: H = 79%; C = 92%). H monkeys deteriorated equally across all types of trials; never showing the pattern of performance characteristic of human infants and of monkeys with prefrontal lesions (success on repeat trials following correct reaches; failure on reversals & on repeat trials following errors). H monkeys did have a memory impairment, as they performed poorly on Delayed Non-Match to Sample both before and after A$\bar{B}$ testing.

Accordingly, the memory impairment associated with hippocampal damage cannot explain failure on A$\bar{B}$. Prefrontal ablation but not hippocampal ablation produces errors on A$\bar{B}$ at 2-5 sec, the delays at which 7½-9 month old human infants fail. In addition, the pattern of those errors over trials does not appear to be simply a result of poor recall as H monkeys never show this pattern, even at longer delays, when their errors begin to appear. Success on A$\bar{B}$, therefore, seems to depend specifically on normal function of dorsolateral prefrontal cortex.

63.7 METABOLIC ACTIVITY IN THE THALAMUS AND MAMMILLARY BODIES OF THE MONKEY DURING SPATIAL MEMORY PERFORMANCE.
H. R. Friedman, J. Janas*, and P.S. Goldman-Rakic. Sec. Neuroanatomy, Yale Univ. Sch. Med., New Haven, CT 06515.

The 2-DG technique is unique in its capacity to provide a whole-brain record of functional activity during experimental manipulations in animals. We have been using this method to investigate the metabolic profile underlying cognitive behavior in the monkey and previously reported that specific regions of the hippocampus were activated in tasks requiring working-memory (Friedman & Goldman-Rakic, Soc. Neurosci. p. 460, 1985). We have now extended this work to several diencephalic nuclei that have been implicated in the neural circuitry of memory.

Seven male rhesus monkeys were trained on one of two spatial working-memory (WM) tasks: delayed spatial response or delayed spatial alternation, both of which require monkeys to remember specific spatial events from the preceding trials. Metabolic activity in this WM group was compared with activity in six male rhesus monkeys trained in one of two control paradigms which did not involve working-memory (the NWM group): 1) a visual pattern discrimination task which presented the same problem on every trial, or 2) a control task with similar sensory and motor components as the other tasks but with no overt mnemonic requirement.

For the final behavioral test, monkeys received an i.v. injection of ^{14}C-2-DG (100 µCi/kg) and were tested for 45 min. Local cerebral glucose utilization (LCGU) was measured using a computer based image-analysis system. Nissl-stained sections were superimposed on adjacent autoradiograph images to identify specific brain regions. A linear regression model was used to factor out individual variability in overall metabolism on the basis of the LCGU of the medial geniculate body (MGB). The mean LCGU in the MGB was nearly identical for both groups as would be expected from the fact that the white background noise was kept constant across conditions.

We examined activity in the mammillary bodies (MB), in the anteroventral (AV) and anteromedial (AM) thalamic nuclei, in the dorsal and in the ventral magnocellular (MDmc) and in the parvocellular MD (MDpc). Activity in the AV, AM, the MDpc and the ventral MDmc averaged about 15% higher in the WM group and was significantly different from the NWM group ($p<.05$). Activity in the dorsal MDmc did not significantly differ as a function of working memory. Further, no group differences were evident in the activity of the MB.

These data are congruent with previous findings which, for example, have shown that MD lesions impair performance on spatial memory tasks (Isseroff et al. Br.Res., **232**, 97-113,1982) and that MD neurons respond selectively during such tasks (Fuster & Alexander, Br.Res.,**61**,79-91). Moreover, the metabolically more active AV, AM, MDpc and the ventral MDmc all map topographically onto the very prefrontal cortical areas (Goldman-Rakic and Porrino, J comp Neurol., **242**, 535-560, 1985) that mediate behavior on the same tasks. These findings spotlight the AV, AM, the MDpc and the ventral MDmc as important components of a neural system dedicated to spatial working memory.

63.8 IMPAIRMENTS IN VISUAL SEARCH FOLLOWING DIENCEPHALIC LESIONS IN MONKEYS.
E.J. Holmes. Depts. of Psychiatry & Neuroscience, Albert Einstein College of Medicine, Bronx, N.Y. 10461.

Both the mammillary and mediodorsal nuclei of the diencephalon have been reported to be involved in memory functions in human and nonhuman primates. Lesions of these nuclei in monkeys have previously been reported to affect short-term memory capacity (Neurosci. Abstr., 1985, 11, 460) and increase susceptibility to proactive interference (Neurosci. Abstr., 1981, 7, 649). The present study was designed to investigate the effects of these lesions on visual search behavior since it was reasoned that an impairment in short-term memory may also affect "normal" search capacity.

In order to test this hypothesis, 11 cynomolgus (M. fascicularis) monkeys were trained on two different visual search tasks. Of the 11 animals, three monkeys had bilateral lesions of the mammillary nuclei, four monkeys had bilateral lesions of the mediodorsal nuclei, and four monkeys served as operated controls.

In the first task, every other foodwell in a test board containing 8 foodwells was baited. All 8 foodwells were covered either with identical white Plexiglas plaques (uncued paradigm) or with 8 plaques of different color (cued paradigm). The animal's task was to displace one of the 8 plaques on each trial until the four bits of food reward were discovered. The displaced plaques were replaced at the end of each trial with a 5-sec. intertrial interval.

In the second task, only one of the foodwells in the 8-choice test board was initially baited and covered. Once the reward was retrieved, a second foodwell was baited and covered on the next trial with the first foodwell remaining covered but not baited. After the second reward was located, a third foodwell was baited/covered and so on for each of the other foodwells (in a pseudo-random) order) with the earlier response sites remaining covered but not baited. An erroneous response to a previous reward site ended the trial, the plaque was replaced during a 5-sec. intertrial interval, and that trial was repeated. The plaques were either of different color (cued paradigm) or all painted white (uncued version).

In the first task, the monkeys with mammillary body or mediodorsal thalamic lesions did not differ from the controls in performance in either the cued or uncued paradigms. In the second task, however, the experimental animals were markedly impaired (with double the no. of errors) relative to the controls in the uncued paradigm, but again, were not impaired when color cues were used.

Thus, despite their memory handicap, monkeys with diencephalic lesions seem to be impaired in visual search only in the limited case in which the location of the reward is constantly changing and the search has to be reinitiated each time a reward site is discovered without the assistance of any salient cues. These results are consistent with previous findings of spatial/cognitive impairments in monkeys following lesions of the diencephalon.

63.9 FRONTAL AND HIPPOCAMPAL MECHANISMS IN CONDITIONAL AND NON-CONDITIONAL SPATIAL LEARNING BY MONKEYS.
D. Gaffan and S. Harrison*. Dept. Exptl. Psychol., Oxford University, Oxford OX1 3UD, England.

In the first experiment 6 monkeys (Macaca fascicularis) with fornix transection, 6 with bilateral sulcus principalis ablation, and 6 control monkeys, learned either spatial-visual conditional discriminations or visual-spatial conditional discriminations. In spatial-visual conditional discriminations the position of a pair of visual stimuli, to the monkey's left or right, indicated which of the visual stimuli was the correct (rewarded) one. In visual-spatial conditional discriminations the visual stimuli indicated, irrespective of their own spatial position, whether reward was to be found on the monkey's left, or on the right. The animals with sulcus principalis ablation were impaired in both tasks. In both tasks also, the animals with fornix transection were more severely impaired than the animals with sulcus principalis ablation. Within each of the two operated groups, the degree of impairment was equal in the two tasks, in proportion to the difficulty of the tasks for control animals.

Experiment 2 showed that neither of the operated groups was impaired in non-conditional visual learning. Experiment 3 examined non-conditional spatial learning. Here the fornix-transected group were impaired but the group with sulcus principalis ablations were normal. The contrast between impaired conditional spatial learning (Experiment 1) and unimpaired non-conditional spatial learning (Experiment 3) was significant for the group with sulcus principalis ablations, even when the impairments were assessed proportionally to task difficulty for control animals. For the fornix-transected animals the impairment in non-conditional spatial learning was as severe, in proportion to task difficulty, as the impairment in conditional spatial learning.

From these and other findings it is apparent that fornix transection produces a general impairment in learning about personal space, while sulcus principalis ablation selectively impairs conditional spatial learning. These impairments can be related, more generally, to the role of the hippocampal system in personal memory and the role of the frontal lobe in learning conditional relationships.

63.10 THE EFFECTS OF SEPARATE AND COMBINED LESIONS OF THE BED NUCLEUS OF THE STRIA TERMINALIS AND THE FORNIX ON RECOGNITION MEMORY.
R.C. Saunders and M. Mishkin. Laboratory of Neuropsychology, NIMH, Bethesda, MD 20892.

Recognition memory in monkeys is served by both an amygdalo-thalamic and a hippocampo-thalamic circuit. Lesions of either circuit alone, whether at the level of the limbic structures themselves, their efferent paths (the amygdalofugal pathways and fornix), or their thalamic targets (the magnocellular part of the medial dorsal nucleus, MDmc, and the anterior nuclei of the thalamus, AntN), result in only a mild impairment in recognition memory. By contrast, combined damage to the two limbo-thalamic circuits at any level results in a severe loss (Mishkin, Phil. Trans. R. Soc. Lond., B292:1982). The amygdala (A) and the hippocampal formation (H) have both direct and indirect routes to the thalamus. Thus, the H projects via the fornix both directly to the AntN and indirectly via the mamillary body (MB). Similarly, the A projects both directly to the MD and indirectly via the bed nucleus of the stria terminalis (BNST). Thus, the MB and the BNST appear to occupy comparable anatomical positions within the two parallel limbo-thalamic circuits. It was previously demonstrated that the MB contributes to recognition memory in the monkey. In the present investigation we sought to determine whether the BNST also contributes.

Monkeys were trained preoperatively on a visual recognition memory task (delayed nonmatching-to-sample, DNMS) requiring memory of single objects for 10 sec. After achieving the criterion of 90% correct responses in 100 trials, the monkeys received removals of the BNST alone or in combination with a fornix transection. They were retrained on the task postoperatively and then given a performance test in which their memory was tested further by increasing the delays (up to 120 sec) between the sample presentation and the retention test and by increasing the number of items to be remembered (up to 10 objects).

Scores of these monkeys were compared with scores of monkeys with fornix transection alone which had been subjects in an earlier experiment. All animals relearned DNMS without difficulty. Preliminary results on the perfomance test indicate that the animals with the BNST lesions alone, like those with fornix lesions alone perform on average at better than 92% accuracy across the increased delays and list lengths. By comparison, two animals with the combined lesion obtained an average score of only 84% on the performance test. These results are consistent with the idea that the BNST participates in recognition memory and that its function in the amygdalo-thalamic circuit could be comparable to that of the MB in the hippocampo-thalamic circuit.

64.1 EPILEPTOGENESIS PRODUCED BY REPEATED INTRAPERITONEAL ADMINISTRATIONS OF NALOXONE IN INTACT CATS. L.Rocha*, R. Gutiérrez*, F. Pellicer* and A. Fernández-Guardiola. División de Investigación en Neurociencias, Instituto Mexicano de Psiquiatría, Calz. México-Xochimilco 101, Tlalpan, C.P. 14370, México, D.F., and Facultad de Psicología, UNAM.

It has been described (Fernández-Guardiola et al., Kindling 3, Raven Press. J. Wada (Ed) pp.157, 1986) that amygdaloid kindling can be developed in a shortened fashion ("massed kindling") in "Encephale isolé" preparation and that naloxone administrations during this process shortens the time needed to produce generalized convulsive seizures (GCS) in comparison with the massed kindling alone. Naloxone administered alone, i.e. without kindling trials, was also able to produce epileptic activity; this activity was facilitated with intermittent photic stimulation (IPS) in the same preparation. In order to investigate the effects of the repeated i.p. administrations of naloxone and those of sensory stimulation in freely moving cats, we conducted experiments in 11 adult cats divided in 3 groups: a) naloxone alone group (n=3) to which 8 mg/kg of naloxone were i.p. injected every 15 minutes until the first (GCS) was produced, b) the second group (n=5) had the same naloxone schedule plus photo-acoustic stimulation (IPS: pulses of 10 µs with 1500,000 candles at 25 cm in front of the animal; acoustic stimuli: pulses of 90 ms at 4000 Hz and 95 dB) for 1 minute at 1, 3, 10, and 15 Hz after the drug administration, c) the control group (n=3) was stimulated in the same manner but 1 ml saline was i.p. injected instead. Progressive behavioral changes were found in both experimental groups that consisted of drowsiness with the first doses and subsequent doses produced myoclonias and clonic-tonic convulsive seizures without postictal relaxation in all the animals. All the animals in the naloxone alone group presented "status epilepticus". The photoacoustically stimulated experimental group developed a wide variety of behavioral manifestations that were presented more often than the naloxone alone group, but only 2 animals presented "status epilepticus". The control group did not show noticeable behavioral changes. We conclude that the repeated naloxone administrations produce behavioral changes that resemble those produced by electrical amygdaloid kindling (Goddard et al., Exp. Neurol. 25:295, 1969; Wada & Sato, Neurology 24:565, 1974) and that sensory stimulation drives and synchronizes the multisynaptic central activity in the animals under the effects of naloxone, thus facilitating the apparition of epileptic behavioral manifestations. These results suggest the inhibitory role of endogenous opioids in epileptogenesis.

64.2 ANTAGONISM OF THE ANTICONVULSANT ACTIONS OF U50,488 BY THE SELECTIVE KAPPA OPIOID RECEPTOR ANTAGONIST NOR-BINALTORPHIMINE. F.C. Tortella, E. Echevarria, J.W. Holaday, A.W. Lipowski, A.E. Takemori and P.S. Portoghese, Neuropharm. Br., Div. of N.P., Walter Reed Army Inst. Res., Washington, DC 20307 and Depts. Med. Chem. and Pharmacol., Univ. of Minnesota, Minneapolis, MN 55455.

The highly selective kappa opioid receptor analgesic, U50,488 (trans-3,4-dichloro-N-methyl-N-[2-(1-pyrrolidinyl)-cyclohexyl]-benzeneacetamide), has been shown to possess potent and efficacious anticonvulsant activity in rats (Tortella et al., JPET 237, 1986). The anticonvulsant actions of U50,488 are long-lasting, present following i.c.v. or s.c. administration, and antagonized by moderate (1.0 mg/kg) to high (10 mg/kg) doses of naloxone. This latter finding prompted the suggestion that the anticonvulsant actions of U50,488 are mediated by non-mu (probably kappa) opioid receptor subtypes. Recently, two bivalent ligands, Binaltorphamine and nor-Binaltorphamine (nor-BNI), have been reported to possess potent and selective antagonist activity for the kappa opioid binding site (Portoghese et al., Life Sci. 40, 1987). Using the supramaximal electroshock (MES) model, the purpose of the present study was to verify the kappa receptor mechanism of action for the anticonvulsant effects of U50,488 and to evaluate the in vivo selectivity of nor-BNI for kappa opioid receptors.

Male S.D. rats (225-275 g; n=10/grp) were pretreated with either saline (i.c.v. or s.c.) or the antagonist nor-BNI. Nor-BNI was administered i.c.v. (25 nmol; -30 min) or s.c. (2 mg/kg; -60 min). The rats were subsequently challenged with i.c.v. or s.c. saline (control groups), s.c. administered U50,488 (10-160 mg/kg), or i.c.v. injections of the selective mu opioid agonist DAGO (Try-D-Ala-Gly-NMe-Phe-Gly-ol)(0.275-2.2 nmol). Thirty minutes later, convulsions were induced via transauricular MES (2 sec at 60 Hz, 50 mA).

The anticonvulsant ED50's for the opioid agonists U50,488 and DAGO were 18.0 (10.7-26.9) mg/kg and 0.43 (0.23-0.81) nmol, respectively. Nor-BNI antagonized the anticonvulsant effects of U50,488, increasing the anticonvulsant ED50's for U50,488 to 42.0 (27.8-62.2) mg/kg following i.c.v., and 80.0 (41.2-155.5) mg/kg following s.c., nor-BNI pretreatment. In contrast, pretreatment with i.c.v. or s.c. nor-BNI failed to antagonize the anticonvulsant effects of DAGO (ED50's = 0.59 [0.27-1.30] and 0.69 [0.25-1.95] nmol, respectively). Importantly, nor-BNI, when given at these doses and routes of injection, had no apparent effect on overt behavior or MES convulsions.

We conclude that the anticonvulsant effects of U50,488 are mediated by kappa opioid receptors. Furthermore, Since nor-BNI antagonized the effects of the kappa selective opioid U50,488, but not those of the mu selective opioid DAGO, the results of this study have confirmed that nor-BNI represents a novel class of highly selective kappa opioid receptor antagonists.

64.3 EVIDENCE THAT OPIOID RECEPTORS MEDIATE THE ANALGESIC EFFECT OF MORPHINE INJECTED INTO THE AREA TEMPESTAS IN RATS. M.Massotti and A.D'Amore., Lab. di Farmacologia, Istituto Superiore di Sanita', 00161- Roma, Italy.

Area Tempestas is a forebrain area involved in the genesis and propagation of clonic convulsions due to bicuculline (Piredda and Gale, Nature, 317: 623, 1985) and morphine sulfate (MS) (Foote and Gale, 16th Ann.Meet., Soc.for Neurosci., Wash., D.C., 1986, Abst.n.25.6). Unilateral infusion of 0.5-20 ng/rat of MS into this area also enhances the licking reaction time to the hot plate stimulus of the contralateral forelimb in rats (Massotti, 16th Ann.Meet., Soc.for Neurosci., Wash., D.C., 1986, Abst.n.215.6). The question arises if the latter is a true analgesic effect or is related to other actions of the drug such as motor rigidity or local anesthesia.

In rats, deep cannulae were stereotaxically implanted into this area (A-P, +4.0mm from bregma; M-L, ±3.5mm from longitudinal suture; D-V, -6.5mm from dura) under pentobarbital anesthesia. Drugs were delivered at the speed rate of 60 nl/min for 2 min, then animals were tested various times after the end of the infusion. The hot plate (55.6 C) test and the test of the crossing of ipsilateral feets (Boissier and Simon, Therapie, 18:1257, 1963) were carried out to assess analgesia and catalepsy, respectively. The effects were separately recorded in right and left limbs.

Bilateral infusion of MS (20ng/rat) enhances the licking reaction time of both forelimbs (>180 sec). Subsequent unilateral infusion of naltrexone (4 ng/rat) reduces, already at the 1st min, the response in the contralateral forelimb, attaining the same values observed in intact rats (12±2 sec). In addition, unilateral infusion of chlorpromazine into this area (20-1000ng/rat) does not consistently modify the response to the hot plate stimulus.

When animals are tested for catalepsy after unilateral MS, they maintain the imposed position of the contralateral feets only (>100±20 sec) at the doses of 100 ng/rat but not after 50 ng/rat.

Present data suggest that contralateral analgesia induced by unilateral MS is an opioid-mediated phenomenon. This is confirmed by preliminary experiments showing that analgesic effect elicited by MS into this area undergoes to tolerance after a 5 days regimen of treatment.

64.4 DYNORPHIN INHIBITORY EFFECTS ON CUSPID TOOTH DENTINE-EVOKED RESPONSES RECORDED IN THE ALVEOLAR NERVE OF THE DOG. M.F. Pacheco, J.F. Fernández*, S.H. Dueñas* and J.M. Briseño*. Centro Universitario de Investigaciones Biomédicas, Universidad de Colima, Apdo. Postal 199, Colima, Col. 28000 México.

This study was undertook in order to investigate the electrophysiological mechanisms underlying the analgesic effectiveness of topically applied dynorphin observed on human dental pulp (Pacheco, M.F. and Briseño J.M., Proc. West. Pharmacol. Soc. 29: 175, 1986). In 10 pentobarbital-anesthetized dogs, three wire cuff-electrodes placed around the alveolar nerve were used to record evoked potentials elicited by electrical stimulation (50 µsec pulses) of exposed cuspid (canine) dentine. Electrical stimulation of dentine evoked compose potentials in the alveolar nerve, corresponding to discharges from both Aδ- and C-fibers (as characterized by conduction velocity measurements). Whereas the topical application of 5 µL of either saline (0.9%) or distilled water, over the exposed dentine, didn't change any parameter of the recorded potentials, the application of 5 µL of (1,2,5 or 10 mM) dynorphin 1-13 or dynorphin 1-17 produced, equipotent and dose dependent, inhibitory effects on the evoked potentials recorded. Dynorphin effects followed a temporal sequence: Aδ-fibers discharges were totally inhibited after 1-3 min of the opioid application, and recovered after 10-18 min; Activity from C-fibers was totally inhibited after 3-4 min of the peptide application, recovering after 7-10 min. The onset as well as the duration of the dynorphin effects were dependent on the dose used. These observations suggest that the deep dental analgesia elicited by dynorphin is exerted over specific receptors in dental pulp. The temporal sequence of the dynorphin inhibitory effects suggest a different location for Aδ- C-fibers, perhaps Aδ-fibers are located in dentine, and C-fibers in vascular pulp of the tooth.

64.5 **DIFFERENTIAL DEVELOPMENT OF TOLERANCE TO ANALGESIA, RESPIRATORY DEPRESSION AND HORMONE RELEASE IN A MORPHINE INFUSION MODEL.** G.S.F. Ling, R. Simantov* and G.W. Pasternak [SPON: J. Posner], Cotzias Laboratory of Neuro-Oncology, Memorial Sloan Kettering Cancer Center and Cornell U. Medical College, NY, NY 10021.

Tolerance develops to almost all of morphine's actions, including both analgesia and respiratory depression. Recent studies from our laboratory suggest that analgesia and respiratory depression are mediated through different subtypes of mu receptors: mu_1 and mu_2, respectively. Similarly, different receptors classes mediate prolactin and growth hormone release. In view of the different receptor mechanisms involved with these opiate actions, we have compared their rate of tolerance development using a continuous intravenous morphine infusion model. In the infusion model, analgesic actions peaked at approximately 2 h after which they declined due to the development of tolerance, almost reaching baseline values by 8 h. Over a series of doses (10 to 50 μg/kg/min), the peak latency demonstrated a simple dose-response relationship, increasing linearly with the log of the dose. In addition to the gradual fall in tailflick latencies with continued infusions over 8 h, analgesic tolerance was also demonstrated following bolus injections of morphine (5 mg/kg, iv). Using the bolus approach, we found that tolerance progressed with continued morphine infusions even after the infusions no longer elicted any analgesic response. Thus, the development of tolerance is not dependent upon the the continued presence of analgesia. Unlike analgesia, no significant tolerance to morphine's respiratory depressant actions, determined by arterial blood gases, was observed over 10 h at a morphine dose of 50 μg/kg/min. Previous studies have implied a mu_1 mechanism of action for prolactin, but not growth hormone release. Rats infused with morphine (25 μg/kg/min) for 8 hours demonstrated significant tolerance to analgesia and the release of prolactin, but not growth hormone. These studies suggest that the development of tolerance is related to the receptor subtype mediating the response. Tolerance develops quickly to mu_1 actions, such as analgesia and prolactin release, but far more slowly to the two non-mu_1 actions we examined, respiratory depression and growth hormone release. This differential rate of tolerance development may correspond to a lower therapeutic index of opiates in tolerant subjects. These studies also demonstate the usefulness of a continous intravenous infusion model which permits the study of any drug at any dose without the excessive fluctuations in blood levels seen with pelletting techniques.

64.6 INTERMITTENT NALOXONE ATTENUATES PHYSICAL DEPENDENCE ON METHADONE IN RHESUS MONKEYS. J.H. Krystal,* M. Walker,* G.R. Heninger, (SPON: S. Stine) Dept. Psychiatry, Yale Univ. Sch. of Medicine, New Haven, CT 06508.

Recently introduced treatment strategies for opiate dependency have suggested that opiate antagonists, such as naltrexone, or mixed agonist-antagonists, such as buprenorphine, may shorten or attenuate the opiate abstinence syndrome in patients treated with methadone. In addition, there is data from studies in monkeys and rats indicating that coadministration of opiate agonists and antagonists reduces physical dependency. In order to more fully evaluate this phenomenon in primates, the ability of intermittent opiate antagonist administration to attenuate the degree of opiate withdrawal elicited by naloxone challenge was investigated in monkeys who received daily methadone (METH) injections.

METHODS: The behavior of individually-housed rhesus monkeys (n=8) was rated daily via video, during the 20 minutes before and 40 minutes after noon injections. The baseline period consisted of a rating day without drug administration, a saline day (SAL, i.m. at noon), and a naloxone day (NAL, 0.5 mg/kg i.m. at noon). During the treatment period, monkeys received daily METH injections (2.0 mg/kg i.m.) for 14 days under 2 treatment schedules: Tx I: METH daily at 8:00 a.m. and SAL, i.m., daily at noon; Tx II: METH daily at 8:00 a.m., and SAL alternating daily with NAL (0.5 mg/kg i.m. daily at noon). Each monkey received both treatments in a balanced order separated by approximately one month. On day 15, monkeys received a single injection of NAL (0.5 mg/kg, i.m.) but not methadone.

RESULTS: Naloxone produced no behavioral signs of opiate withdrawal in opiate-naive monkeys (repeated measures ANOVA, $p = 0.4$) or in monkeys that completed Tx I or Tx II approximately one month earlier ($p = 0.4$). Naloxone challenge in monkeys receiving methadone produced behavioral signs of opiate withdrawal including retching, lying on side, "wet dog" shakes, posturing, sterotypy, body jerks and piloerection. During Tx II, naloxone elicted a mild opiate withdrawal syndrome ($p = 0.001$) after two days of methadone which did not significantly change in severity during the 7 naloxone challenges included in the 14 day treatment ($p = 0.4$). Monkeys in Tx I exhibited a more severe opioid abstinence syndrome after naloxone on day 15 which was significantly larger than the day 15 withdrawal syndrome after Tx II ($p = 0.001$) or the mild naloxone precipitated withdrawal observed during days 1-14 of Tx II ($p = 0.03$). The day 15 withdrawal syndrome after Tx II was also less severe than the mild naloxone-elicited withdrawal observed during days 1-14 of Tx II ($p = 0.04$).

DISCUSSION: Since the 1/2 life of i.m. naloxone is 1-4 hrs, while the 1/2 life of i.m. methadone is 15-24 hrs, this study provides evidence that a short intermittent blockade of opiate receptors by naloxone is sufficient to attenuate the development of physical dependency on opiates.

64.7 DIFFERENTIAL REGULATION OF AGONIST BINDING TO OPIOID RECEPTOR TYPES BY GUANYL NUCLEOTIDES: EFFECTS OF CHRONIC MORPHINE TREATMENT. L.L. Werling, S.R. Brown*, and B.M.Cox. Uniformed Services University, Bethesda, Maryland 20814-4799

We have previously reported that subsets of opioid receptors with low affinity for agonists can be identified by labeling them with [^{3}H]antagonist and measuring agonist competition over a wide range of agonist concentrations in the presence of sodium (Werling et al., Molec. Pharmacol. 30:90-95, 1986). We have now used this technique to investigate the effects of guanyl nucleotides on opioid agonist affinity at mu, delta, and kappa sites in guinea pig cortical membranes. Saturation curves for [^{3}H]diprenorphine ([^{3}H]DIP) binding to each of the three opioid receptor types in the presence and absence of GTP indicated that the affinity of antagonist for mu, delta, and kappa opioid receptors was not affected by the guanyl nucleotide. In the presence of the appropriate site-selective blocking agents, we displaced [^{3}H]DIP binding to mu receptors with Tyr-D-Ala-Gly-(Me)Phe-Glyol (DAGO), binding to delta receptors with D-Ser^2-D-Leu^5-Enkephalin-Thr (DSLET), and binding to kappa receptors with U50488H. Maximal inhibitory effects of GTP were achieved at 100 μM (added twice during the course of incubation). In the absence of GTP, DAGO displaced [^{3}H]DIP in a monophasic manner with a K_D of about 30 nM, consistent with labeling of a single site. Addition of GTP (100 μM) produced a biphasic displacement pattern, with a high affinity site of about 60 nM and a lower affinity site of about 1 - 2 μM. In cortical tissue taken from guinea pigs which had been made tolerant to morphine (1.7 mg/kg/hr for 6 days), only one affinity state of the mu receptor could be reliably identified in the presence or absence of GTP. The K_D of DAGO for this site in the absence of guanyl nucleotide was about 70 nM, and was only marginally increased in the presence of GTP. These findings suggest that in the tolerant state, guanyl nucleotides may be less capable of regulating the interaction of a mu opioid with its receptor. Two agonist affinity states of the delta receptor could be identified in the absence of any added guanyl nucleotide with K_D values for DSLET of about 5 nM and 600 nM. The proportions of sites in each state were approximately equal. In the presence of GTP, two sites were detectable with K_D values for DSLET of 26 nM and 3.2 μM, in approximately equal proportions. After chronic morphine treatment, there was no apparent change in the ability of GTP to regulate DSLET binding to delta receptors. U50488H displaced [^{3}H]DIP binding to kappa receptors with a K_D of about 15 nM in the presence or absence of added GTP. Studies are currently underway utilizing non-hydrolyzable guanyl nucleotide analogues to provide further characterization of forms of the receptor-G protein-guanyl nucleotide complex that are being labeled in our assay system. 64.8 THE EFFECTS OF CHRONIC OPIOID EXPOSURE ON THE 7315c PITUITARY CELLS: A USEFUL MODEL IN THE STUDY OF TOLERANCE. P.S. Puttfarcken and B.M. Cox. Dept. of Pharmacology, Uniformed Services University of the Health Sciences, Bethesda, MD 20814.

At least three time-dependent cellular processes appear to occur after chronic exposure of delta opiate receptor containing NG108-15 cells to opiate drugs. Law et al. (Molec. Pharmacol. 24:413-424, 1983) have demonstrated etorphine-induced desensitization of inhibition of adenylyl cyclase (AC) and opiate receptor down-regulation. An increase in AC activity above baseline levels after withdrawal of the chronically administered agonist has also been reported (Sharma et al., Proc. Natl. Acad. Sci. USA 72:590-594, 1975). Although the NG108-15 cells provide a useful model to study development of tolerance, it may be more clinically relevant to study the effects of chronic opioid exposure at the mu opioid receptor, since most addictive narcotics have preferential affinity for mu receptors. We now report the effects of chronic opioid exposure on 7315c pituitary tumor cells which contain a homogeneous population of mu opioid receptors (Puttfarcken et al., Molec. Pharmacol. 30:81-89, 1986). Opiate activation of these receptors inhibits AC. The cells (2.5 x 10^7 cells/25 ml DMEM) were plated on 75cm^2 tissue culture flasks precoated with Vitrogen 100, a sterile solution of bovine dermal collagen which facilitated cell attachment. AC activity was measured according to the method of Cote et al. (Endocrinology 110:812-819, 1982). In untreated flasks, AC activity progressively decreased. After a one-day incubation the enzyme activity could not be detected since the cells no longer remained viable. AC activity remained stable for at least 18 days when the 7315c cells were plated on Vitrogen-coated 75 cm^2 flasks. In preliminary experiments we measured the ability of the opioid agonist, D-Ala-D-Leu-Enkephalin (DADLE), to inhibit AC activity after 1-, 3-, 5-, 9-, 24-, or 48-hour exposure to 10 μM morphine compared to activity in untreated cells incubated for the same period. After approximately 5 hours of chronic morphine exposure (10 μM), DADLE was no longer able to inhibit AC activity in a dose-dependent manner. Membranes from control cells incubated in a drug-free medium did not lose their sensitivity to DADLE. [^{3}H]-Radioligand binding studies are in progress to determine if the density of opiate receptors is reduced after chronic agonist exposure in the 7315c pituitary cell. The addition of naloxone (10 μM) after 72-hour morphine exposure resulted in very little, if any, increase in AC activity above control levels after removal of morphine. This is in contrast to the 80% increase above baseline AC activity first observed by Sharma et al. (1975) in the NG108-15 cells after removal of the treatment agonist. (This grant was supported by NIDA.)

64.9 DIFFERENTIATION OF CHRONIC μ OPIOID RECEPTOR BLOCKADE AND SUPERSENSITIVITY TO MORPHINE. B.C. Yoburn and C.E. Inturrisi. Dept. of Pharmacology, Cornell Univ. Med. Coll., NY, NY 10021.

Chronic exposure to opioid antagonists produces an increase in the number of brain opioid receptors (receptor upregulation) and increases the potency of opioid agonists (supersensitivity). However, it has not been determined if blockade of morphine's actions during chronic antagonist treatment, is a critical factor in the production of supersensitivity. In the present studies, mice were implanted subcutaneously with either a low (2.0mg) or high (7.5mg) dose naltrexone (NTX) pellet for 8 days. The high dose NTX pellet produces both upregulation and supersensitivity in the mouse (Yoburn et al., J.Pharmacol.Exp.Ther., 239:132,1986). Controls were implanted with placebo pellets. Morphine analgesia was tested using the tail flick test with analgesia defined as failure to respond by 10sec (baseline latency=2-3sec). In separate groups of mice tested at 4hrs and 8 days following pellet implantation, both NTX pellets blocked the analgesic effects of a dose of morphine (24mg/kg,s.c.) that produced analgesia in 95-100% of controls. At 8 days following implantation the high dose NTX produced nearly 2.5-fold greater plasma NTX (144.1ng/ml±18.7SEM) compared to low dose NTX (67.1±9.1) as determined by RIA. In order to examine supersensitivity, separate groups of mice were implanted with placebo, or, low or high dose NTX for 8 days. The pellets were then removed and 24hrs later mice were tested for morphine analgesia (8mg/kg, s.c.). Consistent with previous results, the high dose NTX produced significant supersensitivity (71% analgesic) compared to placebo-treated controls (28% analgesic). However, the low dose NTX failed to produce a significant increase in analgesia (45% analgesic) compared to controls and produced significantly less analgesia than the high dose NTX group.

The results of these experiments indicate that blockade of morphine analgesia over an 8 day interval is not sufficient to produce supersensitivity to morphine's analgesic actions. Both low and high dose NTX implants blocked the analgesic action of morphine. However, 8 day treatment with high dose NTX increased the percent analgesic by 43% compared to controls and by 26% compared to the low dose NTX. Low dose NTX did not significantly increase morphine's analgesic potency. These findings raise the possibility that opioid antagonist-induced supersensitivity may require antagonist action not only at μ (morphine) receptors, but also at receptors that do not mediate morphine analgesia.

64.10 MECHANISMS UNDERLYING THE ACTION OF ENDOGENOUS OPIOID SYSTEMS IN NEURAL CANCER. I.S. Zagon and P.J. McLaughlin. Dept. of Anatomy, The M.S. Hershey Med. Ctr. of The Pennsylvania State University, Hershey, PA 17033.

Endogenous opioids are known to regulate oncogenic events (e.g., Science 221: 671-673, 1983), with opioids serving as trophic factors that exert an inhibitory influence on tumorigenicity. Opioid antagonist paradigms, which disturb opioid-receptor interactions, have proven particularly valuable in studies of opioids and cancer, with complete daily opioid receptor blockade (e.g., 10 mg/kg naltrexone) resulting in growth stimulation, and intermittent daily blockade (e.g., 0.1 mg/kg naltrexone) inhibiting growth. Using a murine S20Y neuroblastoma tumor model and naltrexone (NTX), we found that the mitotic index of tumors (12-15 mm diameter) from mice given a complete receptor blockade (10 mg/kg NTX) was 33% and 70% greater than control levels at 2 and 10 hr following NTX injection. Intermittent blockade (0.1 mg/kg NTX) resulted in an increase of 23% in mitotic index in contrast to controls at 2 hr, but a decrease of 25% at 10 hr; previous studies showed that receptor blockade was only effective for 4-6 hr/day in mice given 0.1 mg/kg NTX. Morphometric areal analysis of viable and necrotic tumor tissue showed no difference between control (26% viable area) and 10 mg/kg NTX mice, but a marked increase (45% viable area) was noted in mice given intermittent blockade. Radioimmunoassays revealed both β-endorphin and met-enkephalin were present in murine tumors, and were markedly elevated in tissues from both NTX groups. Met-enkephalin was detected in the cortical cytoplasm of neuroblastoma cells, but not in the nuclear region, using immunocytochemical techniques. Specific and saturable opioid receptor binding was detected in control tumor tissues for DADLE and EKC, but not for DAGO. Autoradiography experiments using ^{125}I-met-enkephalin showed a homogenous distribution in control tissues that was blocked by naloxone; densitometric measures revealed increases of 40-100% in NTX groups. Functional tests monitoring nociceptive response to a challenge with levorphanol showed a blockade during opioid antagonist presence (e.g., at 2 hr in the 0.1 NTX group) but a supersensitivity following receptor blockade (e.g., 8 hr after injection of 0.1 NTX). These results indicate neurotumors are dependent on opioids to control growth, and do so by actively regulating cell replication in an inhibitory fashion. Moreover, the mechanistic basis for antitumor effects by daily intermittent receptor blockade with opioid antagonists appears to be due to an exaggerated opioid action (e.g., mitotic inhibition), as a result of up-regulation of growth related opioids/binding sites and their interaction during the daily interval when the opioid antagonist is no longer present. Supported by NIH grants NS-20623 and NS-20500.

64.11 HUMAN NEUROBLASTOMA TRANSPLANTED INTO NUDE MICE IS REGULATED BY ENDOGENOUS OPIOID SYSTEMS. L. Nagy*, P.J. McLaughlin and I.S. Zagon (SPON: T. Lloyd). Dept. Anatomy, The M.S. Hershey Med. Ctr. of The Pennsylvania State University, Hershey, PA 17033.

Tumorigenic events associated with cancer in animals have been shown to be modulated by opioid agonists and antagonists, with the mechanism underlying this control involving endogenous opioid systems (i.e., endogenous opioids and opioid receptors). Involvement of endogenous opioid systems in human neoplasia is an important, but unanswered, question. In the present study, the role of endogenous opioid systems in human cancer was explored using an opioid antagonist paradigm and human neuroblastoma cells transplanted into nude mice. Mice were inoculated s.c. with 2.5 X 10^6 neuroblastoma (SK-N-MC) cells and separated into groups which received daily injections of either 0.1 or 10 mg/kg naltrexone (= 0.1 NTX or 10 NTX, respectively) or sterile water (= CO). The latency for appearance of a measurable tumor (5 mm or larger in diameter) in the 0.1 NTX group occurred 27% later than in control subjects (11 days), and the first death in this group occurred 33% later than in the control group (day 27). Mice inoculated with tumor cells in the 10 NTX group had an acceleration (18%) in latency time of tumor appearance. Moreover, 70% of the mice in the 10 NTX group had tumors on day 14, a time when only 10% of the CO group expressed a tumor. Forty-five days after tumor cell inoculation, only 33% of the mice in the 10 NTX group were alive, relative to 90% of the CO mice. Thus, complete blockade of endogenous opioid-receptor interaction resulted in enhanced oncogenic response, whereas intermittent blockade retarded human tumorigenesis. To determine the presence of opioid receptors in human neuroblastoma, saturation isotherms were generated utilizing 3 ligands (DAGO, DADLE, and EKC) which are prototypic for mu, delta, and kappa receptor types in neural tissues. Specific and saturable binding could only be demonstrated for DADLE and EKC. Measurements of opioid levels in tumor tissues revealed the presence of both β-endorphin and methionine-enkephalin. These studies indicate that components of endogenous opioid systems are present in a neural tumor, and are involved in the regulation of tumorigenesis. Endogenous opioids appear to function as trophic inhibitors of oncogenic events that actively control human, and animal, tumor development. The regulatory properties of opioids are mediated by opioid receptors that subserve growth-related functions.

Supported by NIH grants NS-20623 and NS-20500.

65.1 The Avian Suprachiasmatic Nucleus: Anatomical and Functional Aspects. R. B. Norgren, Jr.* and R. Silver. Dept. of Psychology, Columbia University, New York City 10027.

The suprachiasmatic nucleus is a circadian pacemaker in mammals. This has been demonstrated with a variety of methods, including lesion studies, recordings of electrical activity, transplants, glucose utilization. In birds, the function and location of the SCN is less well understood. Attempts to identify a nucleus homologous to the mammalian SCN in avian species have suggested two candidates in the anterior hypothalamus. One lies adjacent to the third ventricle. The other is in a more lateral position.

Several different methods were used to characterize these two nuclei in ring doves including retino-hypothalamic tract tracing, cytoarchitecture, immunocytochemistry, enzyme histochemistry, and deoxy-D-glucose-2-[1-^{14}C] (2-DG) labeling [in collaboration with V. Cassone]. **Retino-hypothalamic projections** were studied with intraocular injections of HRP and application of HRP to the cut end of the optic nerve. While both methods revealed a direct retinal input to the lateral hypothalamus, only the latter method suggested any retinal input to the medial hypothalamus, and this was at most very sparse. **Cytoarchitectural studies** revealed that the medial nucleus contained small, tightly packed neurons, while the lateral nucleus contained a mixed population of diffusely arranged cells. **Immunocytochemical analysis** failed to demonstrate vasoactive intestinal polypeptide or neurophysin in either nucleus. There was moderate **acetylcholinesterase staining** in the lateral nucleus and very little staining in the medial nucleus. Preliminary **^{14}C 2-DG experiments** suggested a circadian rhythm in metabolic activity in the medial nucleus.

Supported by grants MH29380 (RS) and BNS 85-19660 (VC)

65.2 ANATOMIC AND FUNCTIONAL DEVELOPMENT OF THE SUPRACHIASMATIC NUCLEI IN A MARSUPIAL. S.A. Rivkees*, C.A. Fox*, S.M. Reppert, C.D. Jacobson. Children's Service, Massachusetts General Hospital and Harvard Medical School, Boston MA 02114, and Department of Veterinary Anatomy, Iowa State University. Ames, Iowa, 50011.

Due to profound immaturity at birth, marsupials provide a unique opportunity to study the development of the circadian timing system. In contrast to rats in which a functioning circadian clock in the suprachiasmatic nuclei (SCN) develops in utero, it is likely that the SCN of marsupials develop exclusively during the postnatal period. We thus characterized the anatomic and functional development of the SCN in a pouchless marsupial, Monodelphis domestica (the grey short-tailed opossum), during the postnatal period.

The time course of SCN neurogenesis was examined using [^{3}H]thymidine autoradiography. Dams were manually restrained, and each pup in a litter was injected sc with [^{3}H]thymidine along the dorsal midline. Each litter of pups received the isotope on a different postnatal day between days 4 and 12. Pups were killed on day 30, and 6 µm coronal brain sections were processed for autoradiography. The time of appearance of the SCN as distinct nuclei was determined by light microscopic examination of Nissl stained brain sections. To define the onset of SCN functional activity, the [^{14}C]2-deoxyglucose (DG) technique was employed. Animals of specified ages were placed in constant darkness for 24 hrs prior to injection. One-half of the offspring from each litter were then injected with DG (0.1 uCi/gm) during subjective day, and the remainder were injected during subjective night. At 45 min after injection, animals were killed, and 20 µm coronal brain sections were processed for autoadiography. The relative optical density (OD) of each animal's SCN was determined.

SCN neurogenesis was completed by postnatal day 8 (0=day of birth) and the SCN were recognizable as distinct nuclei beginning on day 16. There was no day-night rhythm in SCN metabolic activity on day 16: the nuclei were metabolically active during both day and night (n=10; day relative OD 1.28±.04 (M±SEM), night OD 1.26±.07). A clear day-night rhythm in SCN metabolic activity was first observed on day 20 (n=12; day OD 1.16±.02, night OD 0.99±.01, $p<.01$). The rhythm was also apparent on day 27 (n=6; day OD 1.24±.03, night OD 0.96±.04, $p<.01$). SCN metabolic activity was very similar among the pups of each litter. Pup circadian phase was synchronous with the phase of the dam; dam circadian phase was assessed by monitoring wheel-running activity.

We conclude that in Monodelphis domestica, (1) SCN neurogenesis occurs postnatally and is complete by day 8, (2) the SCN are morphologically apparent on day 16, (3) a daily rhythm in SCN metabolic activity is present on day 20, and (4) pup circadian phase is coordinated with the circadian phase of the dam and the prevailing light-dark cycle. Supported by NIH grants HD14427 and HD16148.

65.3 THE ORIGIN, ORGANIZATION AND PROJECTIONS OF VISUAL AFFERENTS TO THE RAT HYPOTHALAMUS: IMPLICATIONS FOR THE CONTROL OF CIRCADIAN RHYTHMICITY. J.P. Card, R.P. Meade and R.Y. Moore. Medical Products Department, E.I. du Pont de Nemours and Co., Wilmington, Delaware and Neurology Department, SUNY @ Stony Brook, Stony Brook, New York.

The suprachiasmatic nucleus (SCN) of the hypothalamus receives dense and overlapping projections from the retina and the intergeniculate leaflet (IGL) of the thalamus. Each of these projections upon the SCN has been implicated in the control of circadian rhythmicity and the projection from the IGL is also distinguished by neuropeptide Y (NPY) immunoreactivity. In the present investigation we have utilized retrograde transport of fluorescent tracers (fluorogold and rhodamine labeled latex beads) combined with immunohistochemistry to gain further insight into the organization of these projections. Four different injection regimes were combined with immunohistochemical localization of either NPY or vasoactive intestinal polypeptide (VIP). These included (1) bilateral tracer injection into the SCN, (2) bilateral tracer injection into the SCN with unilateral injection of another tracer into one IGL, (3) unilateral tracer injection into one IGL and (4) injection of a different tracer into each IGL. The findings of these studies support previous observations on the organization of NPY afferents terminating in the SCN and also reveal another order of complexity in the organization of neural circuits involved in the control of circadian rhythmicity. Our findings can be summarized as follows: First, projections to the SCN from the IGL are not restricted to neurons which contain NPY. An additional group of IGL neurons, of uncharacterized chemical content, is also retrogradely labeled following SCN injections and the number of these neurons is equivalent to the number of NPY neurons which project to the SCN. Second, although a substantial number of IGL neurons project to the contralateral IGL, these neurons do not contain NPY. In some instances, a small number of these neurons are also retrogradely labeled by injection of a second tracer into the SCN. Finally, tracer injections into the IGL reveal retrogradely labeled neurons in the SCN and anterior hypothalamus which do not contain VIP immunoreactivity. Most of these neurons project to the ipsilateral IGL, but a small percentage of these cells also project to the contralateral IGL. Taken together with the fact that both the SCN and IGL receive direct projections from the retina, these findings demonstrate that the neuronal circuitry which integrates visual information in the control of circadian rhythmicity is much more complex than previously appreciated.

65.4 EVIDENCE FOR DIRECT RETINAL INPUT TO THE PARAVENTRICULAR NUCLEUS IN A PHOTOPERIODIC RODENT (MESOCRICETUS AURATUS). T.G. Youngstrom, M.L. Weiss & A.A. Nunez. Psychology Dept. and Neuroscience Prog., Michigan State Univ., E. Lansing, MI. 48824.

A retino-hypothalamic tract (RHT) with projections primarily to the suprachiasmatic nuclei (SCN) has been reported in several species (JCN 146:1, '72; Brain Res. 49:403, '73; JCN 196:155, '81). The SCN are involved in the generation of circadian rhythms and photoperiod-dependent seasonal rhythms (Physiol. Reviews 59(3):449, '79; Sci. 227:714, '85). A few fibers of the RHT continue through the SCN into the region between the SCN and paraventricular nucleus (PVN; JCN 196:155, '81; Brain Res. Bull. 17:485, '86). Cholera toxin conjugated to horseradish peroxidase (CT-HRP) has recently been shown to be a sensitive anterograde tract tracer and has been used to reexamine the retinal efferents of the rat (Neurosci. Abstr. 12:549, '86). This method has revealed RHT projections to the SCN and anterior hypothalamic area. In addition, input to the lateral hypothalamus (dorso-lateral boundary of the supraoptic nucleus (SON)) via a second route was found. Outside the hypothalamus labelled processes were reported in anterodorsal (ADT) and anteroventral thalamus (AVT), lateral geniculate nucleus and superior colliculus. In the male Syrian hamster an earlier study using intraocular injections of free HRP reported evidence of retinal input to the piriform cortex and septal area but not to the SON, ADT or AVT (JCN 196:155, '81). In this study, retinal projections to the brain of the Syrian hamster (Mesocricetus auratus) were reexamined using CT-HRP. Following a 24 hour survival period male and female Syrian hamsters were perfused and the tissue processed using a previously published procedure (J. Histochem. Cytochem. 28(11):1255, '80). Areas of the visual system previously reported to receive direct retinal input were densely labelled as was the RHT projection to the SCN. A loose bundle of RHT fibers pass dorsal through the caudal SCN into the periventricular area to form a plexus in the sub-PVN area. Some fibers proceed laterally, beneath the PVN, while a small number of fibers and presumptive terminals were located within the PVN. Dorsal to the third ventricle in or near zona incerta and nucleus reuniens labelled fibers were observed. The supraoptic nucleus (SON) and adjacent hypothalamus also contained labelled fibers. Some fibers were traced into the superficial layer of the piriform cortex. A projection from the retina to dorsal thalamus was also identified. In addition to confirming the presence of a retinal projection to the SCN of the hamster these results provide evidence of RHT input to the AHA, periventricular hypothalamus, sub-PVN area, PVN and dorsal to the PVN. This direct retinal input to the PVN may mediate acute pineal responses to light with no involvement of the SCN. Supported in part by NIMH Grant MH 37877 to AAN and NRSA Postdoctoral Grant NS 08125 to MLW.

65.5 SEASONALITY IN THE SYRIAN HAMSTER MAY INVOLVE A TEMPORAL INTERACTION OF CIRCADIAN NEUROTRANSMITTER RHYTHMS IN THE RIGHT AND LEFT SUPRACHIASMATIC NUCLEI. J.M. Wilson and A.H. Meier*. Dept. Zoology and Physiology, Louisiana State University, Baton Rouge, LA 70803-1725.

Daily injections of 5-hydroxytryptophan (5-HTP; serotonin precursor) and L-dihydroxyphenylalanine (L-DOPA; catecholamine precursor) given at the same time of day for 9 days induced scotosensitive responses (reduced gonad weights and serum gonadotropin and thyroxine concentrations) in scotorefractory hamsters maintained on short daylengths (LD 10:14) for 5 weeks. On the other hand, daily injections of L-DOPA given 12 hours after daily injections of 5-HTP for 9 days induced scotorefractory responses (increased gonad weights and serum gonadotropin and thyroxine concentrations) in scotosensitive hamsters maintained on short daylengths (LD 10:14). Thus the endogenous mechanism controlling seasonality (scotosensitivity and scotorefractoriness) in the Syrian hamster may involve two circadian systems consisting of catecholaminergic and serotonergic components that vary seasonally in their phase relations.

Inasmuch as the suprachiasmatic nuclei (SCN) have been strongly implicated as a circadian pacemaker, they may also be a site for reentrainment of circadian oscillations by 5-HTP and DOPA. Accordingly, dopamine and serotonin concentrations were determined by high performance liquid chromatography with electrochemical detection in both SCN of scotosensitive and scotorefractory male hamsters maintained on short daylengths (LD 10:14). Marked circadian rhythms of dopamine and serotonin concentrations were observed in both SCN of scotosensitive and scotorefractory hamsters. In scotosensitive hamsters, highest concentrations of both neurotransmitters occurred near the onset of light in both left and right SCN. Similarly, highest conentrations of both neurotransmitters also occurred near the onset of light in the left SCN of scotorefractory hamsters. However, peak dopamine concentrations in the right SCN occurred 12-16 hours after the onset of light and the daily peak of serotonin concentration. Thus there is a 0-hr relation between the daily peaks of serotonin and dopamine concentrations in both SCN of scotosensitive hamsters and in the left SCN of scotorefractory hamsters. However, in the right SCN of scotorefractory hamsters there is approximately a 12-hr relation between the daily peaks of the two neurotransmitters. Thus the paired SCN may represent two circadian pacemakers and changes in the phase relations of their activities may produce alternations of seasonal conditions.

65.6 DISPERSED CELL SUSPENSIONS OF FETAL SUPRACHIASMATIC NUCLEUS (SCN) RESTORE CIRCADIAN LOCOMOTOR RHYTHMS TO SCN-LESIONED HAMSTERS. M.N. Lehman, R. Silver, M. Gibson, and E.L. Bittman. Dept. Anat. & Cell Biol., Univ. Cincinnati Coll Med.; Dept Psychol., Barnard Coll of Columbia Univ.; Dept. Medicine, Mt. Sinai Sch. Med.; and Dept. Zool., Univ. Mass. Amherst.

We recently demonstrated that whole tissue grafts of the fetal SCN . restore circadian locomotor rhythms to hamsters previously made arrhythmic by SCN lesions. To determine whether the intrinsic peptidergic organization of the SCN is a prerequisite for functional recovery, we attempted to restore rhythmicity to SCN-lesioned hamsters using dispersed cell suspensions. Adult male hamsters received bilateral electrolytic lesions of the SCN and their locomotor activity was monitored during 4 wks. of constant darkness (DD) and 2 wks. of light:dark (LD) 12:12 to verify the lack of rhythmicity. Twelve arrhythmic animals received bilateral stereotaxic injections, directed toward the medial hypothalamus, of dispersed cells prepared from fetal (E14) anteroventral hypothalamus (80,000 cells/5 ul injection). In order to mark injected cells, mothers received i.p. injections of ^{3}H-thymidine (7.5 uCi/gm body weight) on E11, when peak mitotic activity occurs in the SCN (Crossland & Uchwat, *Dev. Brain Res.* 5:99). Hamsters were housed in LD 12:12 for 1-3 wks. after surgery followed by DD for 10-12 wks. Hamsters with restored rhythms were transferred to LD 12:12 for an additional 10-12 wks. Animals were perfused and vibratome sections (50 um) were immunocytochemically stained for either vasoactive intestinal polypeptide (VIP) or vasopressin (VP), as previously described (Lehman *et al.*, *Neurosci. Abstr.*, 12:210). Alternate sections were processed for autoradiography to visualize the location of radiolabelled donor cells.

In 6 of 12 recipients, dispersed cells of fetal SCN re-established free-running rhythms in DD but not entrainment to LD. The period of these rhythms was 23.56 $\pm$ 0.02 hr (mean $\pm$ S.E.M.). In animals rhythms split into two components, which established a stable phase relationship. Measurement of testes width during 10 wks. of DD consistently revealed large gonads indicating the lack of appropriate reproductive response to photoperiod. In animals with restored rhythms, injected cells labelled with ^{3}H-thymidine were located within the medial hypothalamus, either adjacent to the third ventricle or between the fornix and paraventricular nuclei. Recovered hamsters possessed isolated or small groups of VIP cells in these areas, along with small plexuses of VIP and VP fibers. In animals that did not recover rhythms, radiolabelled cells were not found intracerebrally and were probably injected into the third ventricle. The results suggest that relatively few peptidergic cells and fibers, either isolated or in small clusters, need be present in order for circadian locomotor rhythms to reappear. The period of restored free-running rhythms following cell injections tends to be shorter than that of lesioned hamsters whose circadian rhythms recover after whole tissue grafts. 65.7 SELECTIVE TRANSPLANTATION OF THE FETAL SUPRACHIASMATIC AND PARAVENTRICULAR NUCLEI: STABILITY AND SPECIFICITY IN CYTOLOGICAL AND IMMUNOHISTOCMEMICAL CHARACTERISTICS. S.J. Wiegand, D.J. Earnest and D.M. Gash. Dept. of Neurobiology and Anatomy, Univ. of Rochester Medical Ctr., Rochester, NY 14642.

Vasopressin-containing neurons which develop within transplanted hypothalami are not anatomically homogeneous, but exhibit a number of distinct morphological phenotypes. In addition to occasional large neurons which resemble those of the endogenous magnocellular neurosecretory system, several populations of parvicellular vasopressin-immunoreactive (VPir) neurons have been identified. Two types of parvicellular VPir neuron, in particular, are represented in significant numbers, and both types are often present within a single anterior hypothalamic graft. On the bases of their distinct cytological and connectional characteristics, and their discrete relationships to other chemically identified neuronal populations within the grafts, we have proposed that these two VPir cell types are derived from separate cell lines; one from the anlage of the suprachiasmatic nucleus (SCN) and the other from the developing the paraventricular nucleus (PVN). The present study was designed to test this hypothesis by determining if these two cytologically distinct types of VPir neuron could be harvested, independently, from the developing hypothalamus.

Donor hypothalami were obtained from normal Long Evans rat fetuses at 15-17 days post conception, and the rostral (AHr) and dorsal (AHd) divisions of the developing anterior hypothlamus were dissected free of the remainder of the hypothalamic primordium. The AHr and AHd contain the presumptive anlagen of the SCN and PVN, respectively. The AHv (n=9) or AHd (n=8) obtained from fetal donors were transplanted to the periventricular hypothalamus / third ventricle of adult, VP-deficient Brattleboro rats. Developing neocortex served as a tissue control (n=5). Host animals were sacrificed 6-12 weeks after transplantation, and alternate series of brain sections were processed for the immunohistochemical localization of VP, vasoactive intestinal polypeptide (VIP) and corticotropin-releasing factor (CRF). Viable grafts were recovered from all host animals. All AHv grafts contained VPir cells which resembled those of the endogenous SCN. These VPir neurons were organized into well defined clusters and, invariably, were associated with VIPir neurons of a similar small size (9-13μ). VPir fibers of very fine caliber ramified extensively around the cell bodies of origin and the associated population of VIPir cells, and projected to areas of the host brain that, ordinarily, are innervated by the VP neurons of the endogenous SCN. SCN-like neurons were the predominant VPir cell type in all AHv grafts, and 6 of 9 AHv grafts contained only SCN-like VPir cells. Conversely, SCN-like aggregations of VPir neurons were never identified in AHd transplants. Rather, in 7 of 8 cases, AHd transplants contained VPir neurons which resembled the parvicellular neurosecretory cells of the PVN. These neurons (or a morphologically similar companion population) also contained CRF, but were never associated with VIPir cells. PVN-like VPir neurons were slightly larger (12-18μ), less numerous and less densely packed than the SCN-type identified in AHv grafts, and they projected to vascular as well as neural targets within the graft and host brain.

These results demonstrate that discrete precursor populations of the vasopressinergic neurons of the SCN and PVN are established early in development, that these populations can be independently selected for transplantation using refined microdissection procedures, and that the principal cytological, neurochemical and connectional features of these distinct populations continue to develop in a histotypic fashhion following transplantation.

65.8 TRANSPLANTATION OF SUBTYPES OF VASOPRESSINERGIC NEURONS INTO BRATTLEBORO RATS: SUPRACHIASMATIC GRAFTS GENERATE CIRCADIAN VASOPRESSIN RHYTHMS IN THE CEREBROSPINAL FLUID. D.J. Earnest, C.D. Sladek, D.M. Gash and S.J. Wiegand. Depts. of Neurobiology/Anatomy and Neurology, Univ. of Rochester Sch. of Med., Rochester, NY 14642

The suprachiasmatic nucleus (SCN) of the hypothalamus is an integral neural locus for the generation of circadian rhythms in mammals. Recent studies have utilized neural transplantation technology to underscore this function of the SCN. In view of the significant population of vasopressin (VP) neurons in the SCN and the role of the SCN in the generation of cerebrospinal fluid (CSF) concentrations of this peptide, the present study was conducted to determine whether transplanted SCN neurons release VP in a circadian fashion. Associated anatomical studies demonstrating that the anlagen of the SCN and the paraventricular nuclei (PVN) can be independently selected for transplantation provided a basis for examining the functional specificity of hypothalamic grafts containing these morphologically distinct types of VP neurons.

Developing dorsal and rostral hypothalamic fragments containing the anlage of the PVN or the SCN were obtained from normal Long-Evans (LE) fetuses at E15-17 and transplanted to a periventricular site in adult male VP-deficient Brattleboro hosts. Sham-operated LE rats and Brattleboro rats receiving transplants of developing neocortex were included as controls. Four-ten weeks post-transplantation, cannulae were chronically implanted into the cisternae magna. After a period of recovery, lighting conditions were changed from LD 12:12 to constant light and samples of CSF were collected from individual rats at six hour intervals for 2-5 days. VP concentration in aliquots of each CSF sample was measured by radioimmunoassay. Following CSF sampling, animals were sacrificed and the brains were processed using immunohistochemical procedures to confirm the presence of SCN- or PVN-like aggregations of VP neurons within the grafts.

The temporal profile of VP in CSF was clearly rhythmic in sham-operated LE rats, with peak levels observed during the sampling interval coinciding with the onset of the subjective day (0600h) and low values characterizing the remainder of the circadian cycle. In Brattleboro rats that received cortical grafts (n=4), VP was undetectable in all CSF samples. Measurable levels of VP were observed in all samples collected over a three-day period from a Brattleboro host transplanted with the anlage of the PVN, but no circadian variation was manifested in peptide levels. Similar to LE rats, VP concentrations in the CSF fluctuated on a circadian basis in all Brattleboro rats that received transplants of SCN anlage (n=4). However, the VP rhythms in three of these animals were not phase-coordinated with the rhythms observed in LE rats (i.e., the peaks of the individual rhythms were not coincident with the timing of the VP peak in LE rats), suggesting that the circadian function of these SCN grafts was not influenced by previous exposure to LD 12:12. In the remaining animal with an SCN graft, the peak of the VP rhythm coincided for the first 2 cycles with the onset of the subjective day and the rhythm was heavily damped thereafter.

These results demonstrate that SCN, but not PVN, grafts are capable of generating circadian VP rhythms in the CSF of Brattleboro hosts. In view of this data and the observation that the VP rhythms in 3 of the 4 animals that received SCN transplants were not influenced by lighting conditions before or during CSF sampling, it is unlikely that the host SCN plays a critical role in generating the circadian pattern expressed by grafted VP neurons. Supported by NIH Grant NS19900 (S.J.W.).

65.9 CIRCADIAN PACEMAKER (SCN) TRANSPLANTS INTO LATERAL VENTRICLES FAIL TO RESTORE LOCOMOTOR RHYTHMICITY IN ARRHYTHMIC HAMSTERS. M.E. Harrington, P.J. DeCoursey, D. Bruce, and J. Buggy. Dept. of Psychology, Dalhousie Univ., Halifax, NS, Canada, Dept. of Biology, Univ. of S.C., Columbia, SC 29208, and Dept. of Physiology, Univ. of S.C. Medical School, Columbia, SC 29208.

Ablation of the SCN in hamsters leads to locomotor arrhythmia, and our previous work demonstrated that transplantation of fetal SCN grafts to the 3rd ventricle restored circadian activity rhythms in about 50% of cases. The mechanism by which these grafts containing SCN-like neurons re-established rhythmicity is not known. For this reason, a series of SCN transplants were made in the lateral ventricles of SCN-lesioned hamsters distinctly separating the graft locus from the ablation site.

The protocol involved monitoring of locomotor activity as a behavioral indicator of circadian output. Wheel-running activity of male hamsters was recorded first in DD for 8 days; SCN were then lesioned and activity measured in DD to test for arrhythmia. Host hamsters received transplants into a lateral ventricle of a pair of SCN (1-4 µl) from 13-day old fetuses. Host activity was then recorded in DD for at least 8 weeks to detect recovery of rhythmic activity. Subsequently, animals were sacrificed and the brain prepared for immunocytochemical procedures. Using fifths of 40 µ thickness, frozen sections were stained sequentially for neuropeptide Y (NPY), neurophysin II (NP), vasoactive intestinal polypeptide (VIP), somatostatin (SS), and Nissl substance.

A compact globular graft, densely populated with neuronal cell bodies and processes, was consistently found in a lateral ventricle of each host, firmly attached to the fornix. In several instances, portions of the graft extended to the interventricular foramen as though possibly migrating towards the 3rd ventricle. Vascular connections between host and graft were apparent, but immunocytochemistry for the 4 neuropeptides provided little evidence of communicating nerve fibers between graft and brain. Clusters of cell bodies and processes containing SS, NP, and VIP, were often noted. Each graft contained at least one area of co-localized VIP and NP, indicating an SCN-like structure. In contrast to the dense NPY-staining in most of the graft, NPY fibers were rare within the VIP-NP plexus.

Lateral ventricle grafts containing SCN-like cells did not restore circadian rhythmicity. It appears likely, therefore, that the renewal of circadian rhythmicity by grafts of fetal SCN into the 3rd ventricle does not involve the release of hormone or neuromodulator into the cerebrospinal fluid or vascular circulatory systems.

65.10 A GENETIC MUTATION OF THE CIRCADIAN SYSTEM IN GOLDEN HAMSTERS. M.R. Ralph and M. Menaker, University of Virginia, Charlottesville, Virginia.

We have discovered a genetic mutation in golden hamsters which dramatically shortens the period of their circadian rhythms. The behavior of the mutation suggests that it has occurred at a single, autosomal locus, **tau**, and that the mutant allele, **tau$_s$**, is partially dominant. Animals that are heterozygous for the trait have freerunning periods (in the dark) of 22.3 ± 0.15 hours and homozygous animals have periods close to 20 hours, compared with wild-type siblings which exhibit normal periods of 24.1 ± 0.1 hr.

Entrainment is affected by the mutation. Heterozygous animals either cannot entrain to a 24 hour light/dark cycle (LD 14:10), or exhibit abnormal entrainment. For animals that are able to entrain, the onset of activity in LD 14:10 is 2-4 hours prior to the lights off transition compared with normal animals whose activity onsets normally occur within 1/2 hr. after lights off. The early onsets suggest that a large portion of the delaying region of the animals' phase response curve must be exposed to light to enable entrainment. Animals that cannot entrain to this light cycle show relative coordination. When the rhythm is not coordinated, the observed period is shorter than the freerunning period in constant dark, indicating that the system is being advanced by the light cycle. The latter observations suggest that although the freerunning period is shortened by this mutation, the basic response properties of the circadian system (the ability to delay and advance in response to light) remain intact.

65.11 DROSOPHILA CIRCADIAN CLOCK PROBED WITH ANTIBODIES TO THE period GENE PRODUCT. Kathleen K. Siwicki*, Michael Rosbash*, and Jeffrey C. Hall, Biology Dept., Brandeis University, Waltham, MA 02254

The period (per) gene of Drosophila melanogaster influences behavioral rhythms. The normal 24 hour period of circadian activity rhythms is shortened to 18-20 hours in per^S flies and lengthened to 28-30 hours in per^L flies, whereas per^O flies are arrhythmic (Konopka & Benzer, 1971, PNAS 68:2112). Also, a rhythm in the male's courtship song, with a period of about 1 minute, is similarly disrupted by the per mutations (Kyriacou & Hall, 1980, PNAS 77:6929). This gene encodes a major 4.5 kb transcript, which is expressed in late embryos and adult flies. The sites of embryonic expression have been localized by in situ hybridization, revealing a metameric pattern of expression in the developing central nervous system (James et al., 1986, EMBO J 5:2313).

To investigate the biochemical properties of the per protein and the cellular sites where it acts to regulate behavioral rhythms, we have developed specific antibodies to the protein. From the amino acid sequence predicted by the genomic and cDNA sequences, we synthesized four peptides (12-14 amino acids each). Rabbits were immunized with the peptides crosslinked to thyroglobulin, then anti-peptide antibodies were affinity purified from immune sera.

We define specific binding to the endogenous per protein as immunoreactivity that is present in wild type and absent in per$^-$ flies, that are deleted of this genetic locus. By this criterion, antibodies to two of the peptides react with the per gene product. In sections of adult heads they label bilaterally about 12 neuronal somata between the protocerebral neuropil and the medulla of the optic lobes. These cells are reliably stained, during both the day and the night, in wild type flies entrained by light:dark cycles. Additional staining at the distal ends of the photoreceptors and in a band across the lamina ganglionaris is clear in the middle of the night but is undetectable in the middle of the day. Since the levels of the 4.5 kb transcript are relatively constant (Reddy et al., 1984, Cell 38:701), this difference in the per protein between day and night flies may reflect diurnal fluctuations in post-translational processes (e.g., covalent modifications or subcellular distribution) that affect the accessibility of the peptide epitope or the local concentration of the protein. Whether such changes or even these sites of per expression are involved in its regulation of rhythmic behaviors can now be addressed by using the anti-per antibodies to study the several kinds of genetic variants that lead to abnormal circadian rhythms. (Supported by NS-07873 to K.K.S. and GM-33205 to M.R. and J.C.H.)

65.12 EFFECTS OF DEUTERIUM OXIDE ON ACTIVITY RHYTHMS OF WILD TYPE AND PERIOD MUTANT DROSOPHILA. R.J. Konopka and D.J. Robinson*. Dept. of Biology, Clarkson Univ., Potsdam, NY 13676.

Mutations at the period locus of Drosophila melanogaster alter the period of the circadian locomotor activity rhythm, which is 24 hours in wild type flies. The per^{L1} and per^{L2} mutations increase period length to 29 hours at 24° C., while the per^S mutation shortens the period to 19 hours. The alterations in period induced by deuterium oxide in wild type and period mutant flies were measured at concentrations of 15%, 25%, 35%, and 50%. In all cases, deuterium oxide lengthened the periods of the activity rhythms. This result is in contrast to the effects of temperature on the per mutants; increasing temperature lengthens the period of per^{L1} and per^{L2} rhythms but decreases the period of per^S rhythms. The rhythm of per^{L1} flies was lengthened to a significantly greater extent than the rhythm of per^{L2} flies at concentrations of 15%, 25%, and 35%. The effects of deuterium oxide on the activity rhythms produced by two fragments of cloned wild type DNA from the per locus (8.0 kb and 12.8 kb) were also determined. For each of the two fragments, a lengthening of the period of the activity rhythm by deuterium oxide was observed. However, the characteristics of the lengthening response were different for the two cloned fragments.

66.1 INCREASE OF SUBSTANCE P, MET-ENKEPHALIN AND OTHER NEUROPEPTIDES IN NERVE CELL BODIES AND FIBERS IN A CASE OF DEMENTIA WITH INTENSE ATROPHY OF THE CAUDATO-PUTAMEN OF HUNTINGTON'S TYPE BUT WITHOUT CHOREA. S. Schiffmann* and J.-J. Vanderhaeghen (SPON: M. Meulders). Laboratories of Neuropathology and Neuropeptide Research and of Pathology and Electron Microscopy, Brugmann and Erasme Hospitals, Université Libre de Bruxelles, 808 route de Lennik, B-1070, Brussels, Belgium.

The brain of a 54-yr old man suffering from dementia, with rigidity but without choreoathetosis or familial history of Huntington's disease, was obtained at autopsy and compared to a control brain processed similarly. A severe bilateral atrophy of the caudate and the putamen as in Huntington's disease was present but no lesions characteristic of Pick's or Alzheimer's disease were observed in the sections taken from the cortex including the hippocampal formation, the basal ganglia and the brain stem.

CCK, SP, Met- Leu- and Syn-Enk, NPY, NT and glial fibrillary acidic protein were visualized by immunohistochemistry (PAP Sternberger technique) on thick 40 micrometer cryostat sections from 4% paraformaldehyde fixed tissue. In the caudate and the putamen, a heavy gliosis was present. SP, Met-, Leu-, Syn-Enk nerve cell bodies of large size (25-35 microns) and fibers were more numerous, more intensely stained, showing a dorso ventral gradient of staining, in some places distributed in a patchy pattern (striosomes). No CCK or NT nerve cell bodies, but a diffuse network of thin CCK and NT nerve fibers was easily detectable. A minimal augmentation of the number of the diffusely distributed NPY nerve cell bodies and a moderate augmentation of NPY nerve fibers was observed. There was no change in the pattern of SP wooly fibers in the internal globus pallidum and of Met-, Leu-, Syn-Enk wooly fibers in the external globus pallidus. Using radioimmunoassays with iodinated I125 substance P and CCK-8 (Amersham) an increase of SP but without change in CCK-8 was observed in the caudate and in the putamen. These results are in contrast with the diminution of immunoreactivity for SP and met-enkephalin reported in the striatum and globus pallidus of Huntington's disease both by radioimmunoassay (Emson P.C. et al. Brain Res., 199, 147, 1980) and immunohistochemistry (Ferrante R.J. et al., Neurosci. Lett. 71, 283, 1986). Shrinkage may partially have caused the elevation of neuropeptide levels observed by radioimmunoassay or some of the immunohistochemically observed augmentation of nerve cell bodies and fibers but cannot be responsible for the increase of staining. This increase of staining reveals higher concentration of positive neurons than in the normal brain. This may reflect an increase of synthesis for neuropeptides, especially substance P and Met-enkephalins, in some remaining neurons of the severely atrophied caudate putamen. Such increase may explain the surprising absence of choreoathetosis despite the severe caudate-putamen atrophy.

Supported by Belgian FRSM (3.4523.86-89), Queen Elisabeth Foundation (Neurobiology, 1986-87) and National Lotery (1986).

66.2 CHOLECYSTOKININ AND VASOACTIVE INTESTINAL POLYPEPTIDE IN THE STRIATUM OF PATHOLOGICALLY GRADED CASES OF HUNTINGTON'S DISEASE. M.F. Mazurek, M.F. Beal, S.F. Knowlton*, D.W. Ellison*, E.D. Bird*, J.B. Martin, (SPON: G.M. Brown). McMaster Univ. Med. Ctr., Hamilton, ONT. and Mass. General Hosp., Boston, MA.

In Huntington's disease (HD) the striatum undergoes extensive atrophy. The brunt of this degeneration is borne by spiny projection neurons in the striatal matrix, aspiny neurons and afferent terminals being relatively spared. One might therefore expect transmitters localized to these latter elements to be elevated in concentration in HD, as the surviving neuronal elements increase in prominence in relation to the surrounding tissue matrix. Both cholecystokinin (CCK) and vasoactive intestinal polypeptide (VIP) are found in striatum in subpopulations of aspiny intrinsic neurons and afferent terminals, the latter accounting for most of the immunoreactivity in each case. We studied levels of CCK and VIP in postmortem brain tissue dissected from 12 controls and 24 patients with HD, as defined by the family history, clinical presentation and neuropathological findings. The HD cases were subdivided into those with mild-to-moderate striatal atrophy (Grades I and II by the criteria of Von Sattel et al) and those with severe atrophy of the striatum (Grades III and IV). Concentrations of VIP were increased 3- to 4-fold over controls in both caudate and putamen in HD. These increases were completely unrelated to the degree of tissue atrophy, as values in the Grades I-II cases were no different from those observed in Grades III-IV. Levels of somatostatin and neuropeptide Y (NPY), which are colocalized in aspiny neurons and afferent terminals, were likewise elevated 2- to 4-fold in HD striatum, with no differences between mild-to-moderate and severe cases. CCK levels, by contrast, were normal in HD striatum, except for the caudate nucleus of severe cases, where a significant decrease was found.

These results indicate that the CCK- and VIP-containing neuronal systems are differentially affected in HD striatum. They further show that the increased striatal concentrations of VIP, somatostatin and NPY found in HD brain are not simply a reflection of tissue atrophy, since levels of all 3 peptides were increased as much in Grade I and II cases, many of which have relatively little striatal atrophy, as in the more severely affected Grade III and IV cases.

66.3 LOSS OF DOPAMINE D1 AND PRESERVATION OF D2 RECEPTORS IN HUNTINGTON'S CHOREA STRIATUM, RELATIONSHIP TO THE STRIOSOMAL ORGANIZATION OF THE STRIATUM. J.N. Joyce and A. Winokur. Dept. Pharmacology and Psychiatry, School of Medicine, University of Pennsylvania, Philadelphia, PA 19104

The hyperkinetic motor and cognitive disorders of the subcortical type associated with Huntington's disease (H.D.) has been thought to be caused by an overactivity of the dopamine system innervating the striatum. The difficulty with that hypothesis is that dopamine (DA) receptors are reduced in H.D. (Reisine et al. 1977; Bzowej and Seeman, 1986) suggesting that the effector system for H.D. is actually reduced. Recent studies have indicated that in H.D. the loss of neurons from the striatum is not homogeneous, a preservation of the aspiny interneurons occurs with a corresponding depletion of the spiny output neurons (Kowall et al, 1987). Moreover, the "striosomal" (patch)/matrix organization of the striatum is preserved, as evidenced by the sparing of the AChE and NADPH-diaphorase staining patterns (Kowall et al 1987; Feigenbaum et al, 1986). Since, the organization of the pre- and postsynpatic components of the DA system appears to obey the "striosomal" (patch) and matrix organization of striatum (Joyce et al, PNAS 83:8002, 1986; Joyce et al, Soc. Neurosci. Abstr., 1986), we decided to investigate whether in H.D. selective aspects of this system was changed.

Tissue from two H.D. patients (grade 3/4; 66 yr age, female) were obtained from the Brain Tissue Resource Center of McLean Hospital. Age-matched controls (CO) were obtained at autopsy (P.M.I < 20 hr) from the Hosptial of the University of Pennsylvania. The tissue was sectioned and processed for autoradiography as described previously. The CO striatum showed a correspondence betweeen D2 receptor density ([3H]spiroperidol), AChE patterning and [3H]mazindol binding to DA uptake sites in serial sections. The AChE-rich matrix being rich in D2 receptors and DA terminals The distribution of D1 receptors ([3H]SCH 23390) was also patchy and may be related to AChE-poor zones within the AChE-rich matrix. The H.D. striata showed a profound loss of D1 sites (90%) except in the nucleus accumbens (50% loss), where the patchy organization was still apparent. The D2 sites were reduced only 25 - 30%, although the area of the D2-rich matrix (and AChE-rich matrix) was reduced significantly more than the D2-poor regions. The density of DA terminals appeared to be unaffected in H.D. This suggests that DA input to the D2 receptors is intact in H.D and is unopposed by the D1 receptors because of their more selective loss. It is also consistent with the hypothesis that D2 receptors are located on the aspiny interneurons whereas D1 receptors are located on the spiny output neurons. This may provide a rationale for understanding the hyperkinetic syndrome of H.D.

66.4 CO-LOCALIZATION OF CHOLINE ACETYLTRANSFERASE-AND ACETYLCHOLINESTERASE-CONTAINING NEURONS IN HUNTINGTON'S DISEASE STRIATUM. R.J. Ferrante[1,1], N.W. Kowall[1], L.B. Hersh[2], G. Bruce[2], E.P. Richardson, Jr.[1], Mass. Gen. Hosp., Harvard Med. Sch., Boston, MA[1] and Department of Biochemistry, UTHSC, Dallas TX.[2]

We have previously reported that large aspiny acetylcholinesterase (AChE)-containing striatal neurons are relatively preserved in Huntington's disease (HD)(Ferrante, Brain Res., 1987;411:162-166). There is strong evidence that in experimental animals AChE and choline acetyltransferase (ChAT) co-localize within the same striatal neurons. In HD striatum, biochemical measurements of ChAT are decreased, despite preservation of AChE neurons. In order to resolve the differences between these findings, we examined 50 μm sections of striatal tissue from 10 HD patients and 6 normal controls; the sections were stained immunocytochemically with an antiserum against ChAT, and enzyme-histochemically for AChE, using the Hardy-Heimer method with which AChE is shown as black granular deposits (Hardy, Neurosci. Lett.,1976;3:1-5).

In both controls and HD, ChAT immunoreactivity was present in large multipolar neurons (controls: 37X27 μm, HD: 34X22 μm) uniformly distributed throughout the striatum. In all cases of HD, there was a striking persistence of ChAT neurons in striatal sections; ChAT cell densities were significantly increased in the caudate nucleus (667±32/cm2 vs. 215±13/cm2, $p<0.005$) and putamen (779±34/cm2 vs. 225±22/cm2, $p<0.001$) as compared to controls. In the neuropil, dense ChAT activity was confined to the striatal matrix zone with less activity in the patch compartments. Combined staining for ChAT and AChE within the same sections demonstrated nearly exact co-localization of each reaction product in large striatal neurons. The AChE reaction contrasted black granules with the brown colored end-product of the development of peroxidase with diaminobenzidine, delineating ChAT activity. In both HD and controls, less than 4% of the total population of large neurons in the head of the caudate nucleus contained AChE alone, and less than 2% of the cells were positive for ChAT activity alone.

Our findings confirm the persistence of large cholinergic neurons in HD striatum and extend the co-localization of AChE and ChAT to the human striatum. Reduced striatal ChAT activity in HD is not a consequence of loss of ChAT neurons, but perhaps the result of degeneration of highly collateralized axons and terminals of these cells. This is reflected in the differential reduction of the matrix compartment reported in HD (Ferrante, JNEN,1987,46:12-27).

66.5 THE QUINOLINIC ACID-SYNTHESIZING ENZYME IS INCREASED IN THE BRAINS OF HUNTINGTON'S DISEASE VICTIMS. R. Schwarcz[1], E.D. Bird[2] and W.O. Whetsell, Jr.[3]. [1]Md. Psych. Research Center, Baltimore, MD 21228; [2]McLean Hosp., Belmont, MA 02178 and [3]Dept. Pathology, Vanderbilt Univ., Nashville, TN 37232.

Intrastriatal injection of the endogenous excitotoxin quinolinic acid (QUIN) in the rat results in the degeneration of the majority of local neurons. The neurochemical and neuropathological features of the QUIN-lesioned striatum are virtually indistinguishable from those of the caudate nucleus/putamen complex of Huntington's disease (HD) patients. The enzymes responsible for the immediate biosynthesis (3-hydroxyanthranilic acid oxygenase; 3HAO) and degradation (quinolinic acid phosphoribosyltransferase; QPRT) of QUIN have been identified and partly characterized in human brain. K_m values for the substrates of 3HAO and QPRT are in the low micromolar range, compatible with the brain tissue concentration of QUIN. The V_{max} value for 3HAO, however, is far higher than that for QPRT, indicating stringent in vivo regulation of QUIN's biosynthetic enzyme.

As compared to controls (N=24), which were closely matched for age and post mortem interval (means: 5.5 hours for controls and 7.2 hours for HD patients), 3HAO activity in HD brains (N=25) was found to be elevated in ten of the eleven brain regions studied. No changes in QPRT activity were detected. Increases in 3HAO activity were particularly pronounced in the striatum (+ 370% in the caudate nucleus, $p<0.00001$; + 360% in the putamen, $p<0.0005$), which are known to exhibit the most prominent nerve cell loss in HD. Statistically significant (two tailed student's t-test) increments were also observed in the globus pallidus, substantia nigra, cerebellum, thalamus, hypothalamus, hippocampus and the frontal and parietal cortices but not in the medulla. Kinetic analyses of caudate tissues revealed a large increase in the V_{max} value for 3HAO (from 6.8 nmol/h/mg protein in controls to 31.3 nmol/h/mg protein in HD) and a smaller change in K_m-values (from 1.11 µM in controls to 2.86 µM in HD).

The results indicate that 3HAO in the human brain is predominantly localized in non-neuronal cells and that the increase in its activity in HD may at least in part be a reflection of the astrogliosis known to occur in diseased tissue. However, since significant increments were also noted in brain regions with little documented neuronal loss in HD, for example the hippocampus, yet unrecognized mechanisms of 3HAO regulation might also contribute to the enhanced ability of HD brains to produce QUIN. This finding may be of relevance for clinical, neuropathological and biochemical features associated with HD.

66.6 ISOCORTICAL SUBSTANCE P NEURONS ARE DEPLETED IN ALZHEIMER'S DISEASE. B.J. Quigley Jr.* and N.W. Kowall (SPON:J. Nathanson) Neurology Service, Massachusetts General Hospital, Boston MA 02114.

Substance P-like immunoreactivity(SPLI) measured by radioimmunoassay is reduced in several cortical regions in Alzheimer's disease. (AD). We studied the morphology and distribution of SPLI elements in 6 cortical regions of 3 patients with confirmed AD and 3 normal controls using a monoclonal anti-substance P antibody (Sera Labs.)

In the dentate gyrus, dense terminal staining was seen in the molecular layer, supragranular plexus, and infragranular region. Granule neurons and a band deep in the molecular layer were devoid of staining. Multipolar SPLI neurons were observed throughout the CA fields of hippocampus, and were especially prominent in CA4. Bands of SPLI terminal staining were seen in stratum oriens, radiatum, and lacunosum-moleculare. SPLI fibers were seen in the most superficial and deepest layers of the subiculum that continued into the entorhinal area where SPLI terminals formed clusters in layer II and a continuous band in layer IV. Reactive neurons were not seen in the subiculum but were frequent in the deep layer of entorhinal cortex and infracortical white matter. SPLI perikarya and beaded fibers were found in all isocortical regions examined (Brodmann areas 39,40; 21,22; 10,11; 4,3,1,2; and 17). The greatest density of SPLI perikarya was in areas 3,1,2, and 39,40, while the lowest density was in area 17. In all regions most(78%) SPLI perikarya were located in deep cortical layers and infracortical white matter. Cortical SPLI perikarya were pleomorphic and multipolar with a spherical dendritic field. Infracortical neurons were more often bipolar with tangentially oriented dendritic fields. In all areas except 39,40 SPLI fiber density was greatest in layer I-II. Aggregates of fine, beaded, SPLI fibers were scattered in all cortical layers. The pattern of SPLI was unchanged in the hippocampal formation of AD patients. SPLI fibers were occasionally distorted in association with thioflavine S positive senile plaque cores in CA4. SPLI neurons in the CA fields were normal. Isocortical SPLI neurons, however, were drastically reduced in number in all regions and were often weakly stained, and disfigured with extensive dendritic pruning. SPLI fibers were irregular and formed coarse aggregates distributed in all layers. Intense SPLI globular deposits, at times associated with amyloid plaque cores, were seen in superficial cortical layers. To further assess the biochemical characteristics of SPLI neurons, sections were double stained for NADPH diaphorase and SPLI. All isocortical SPLI neurons contained NADPH diaphorase activity whereas the majority of SPLI hippocampal neurons were diaphorase negative. Previous studies have shown that, unlike SPLI neurons, the density of somatostatin neurons which also contain NADPH diaphorase, is unchanged in AD cortex. SPLI-NADPH diaphorase positive neurons may therefore represent a small subset of diaphorase neurons that degenerate in cerebral isocortex.

66.7 GLUTAMATERGIC NEURONS IN THE HIPPOCAMPUS ARE MORPHOLOGICALLY ABNORMAL AND DEVELOP NEUROFIBRILLARY TANGLES IN ALZHEIMER'S DISEASE. N.W. Kowall K.S. Kosik*and M.F. Beal, Neurology Service Mass. General Hosp , and Center for Neurological Diseases, Brigham and Womens Hosp. , Boston MA 02114.

Although neurofibrillary tangle(NFT) formation is a major pathological feature of Alzheimer's disease(AD), the neurotransmitter content of NFT-bearing neurons has not been well defined. We studied the hippocampal formation of 4 patients with pathologically verified AD and 3 controls with a monoclonal antibody raised against glutamyl-glutamate(INCstar Inc.) and a polyclonal anti-glutaminase(GLN) antiserum. Preabsorption with the target antigen eliminated specific staining of both antisera. GLN specificity was further confirmed by solid phase immunoassay.

In the normal hippocampus, prominent glutamate(GLU) immunoreactive dendritic bundles arising from CA field and subicular pyramidal neurons were prominently stained. Dentate granule cells were moderately immunoreactive. Terminal staining was evident in the molecular layer of the dentate gyrus and stratum lacunosum-moleculare of CA3-1. Mossy fibers were moderately GLU reactive. Pyramidal neurons in the CA fields and subiculum, and dentate granule cells were GLN reactive. Fiber staining was not well seen with this antiserum.

In the AD material, the staining pattern of the dentate granule cells was unchanged. The terminal field of the GLU immunoreactive fibers in the molecular layer of the dentate gyrus was reduced while stratum lacunosum-moleculare staining was unchanged. GLU immunoreactive CA field pyramids were morphologically abnormal with irregular shortened and disorganized dendritic fields. Scattered abnormal GLU reactive neurites in the molecular layer of dentate gyrus and CA fields were associated with thioflavine S fluorescent amyloid cores.

GLU reactive neurons were examined for the presence of tau reactive NFT using double indirect immuno-fluorescence with either monoclonal or polyclonal tau antisera and either anti-GLN or anti-GLU respectively. Fluorescein and rhodamine conjugated second antibodies were used to label mouse monoclonal and rabbit polyclonal antibodies respectively. NFT were often located in GLU or GLN immunoreactive neurons. Occasional NFT were not associated with GLU reactive neurons and similarly many GLU neurons did not contain NFT.

These studies show that glutamatergic pyramidal neurons in allocortex frequently show morphological abnormalities and contain NFT's in AD. Not all glutamatergic neurons, however, are affected. The pyramidal neurons of the CA fields and entorhinal cortex are preferentially involved while dentate granule cells are spared.

66.8 FLUVOXAMINE IN OCD: ANTIOBSESSIONAL OR ANTIDEPRESSANT? W.K. Goodman, D.S. Charney, L.H. Price, P.L. Delgado, S.A. Rasmussen and G.R. Heninger. Clinical Neuroscience Research Unit, Dept. of Psychiatry, Yale University School of Medicine, New Haven, CT 06508, and Brown University School of Medicine, Department of Psychiatry, Providence RI 02906.

The hypothesis that the pathophysiology of Obsessive Compulsive Disorder (OCD) is related to abnormal serotonin (5-HT) function is largely based on treatment response to the potent, but nonselective, 5-HT uptake inhibitor, clomipramine. To examine whether the serotonergic properties of a drug may confer antiobsessional efficacy, the potent and selective 5-HT reuptake inhibitor, fluvoxamine, was studied in depressed and nondepressed OCD patients. METHODS: 42 outpatients with a primary diagnosis of OCD gave informed consent and entered double-blind treatment with either fluvoxamine or placebo for 6 to 8 weeks. Approximately one-half the patients met criteria for major depression. Patients were assessed weekly for symptoms of anxiety, depression, and OCD using standard rating scales. OCD symptom severity was also rated using the Yale-Brown Obsessive Compulsive Scale (Y-BOCS). RESULTS: Fluvoxamine was significantly better than placebo on all measures of OCD and depression. There were 9/21 responders (= "much improved" on CGI) on fluvoxamine compared to 0/21 responders on placebo ($p<.001$, Fisher Exact Test). Y-BOCS scores decreased by 42% in responders but no patient was entirely free of symptoms. OCD response was not related to baseline depression and 6/9 responders were nondepressed. In some cases there was improvement in depression but no change in OCD. During subsequent open treatment with fluvoxamine in patients originally assigned placebo 12/20 were OCD responders. CONCLUSION: Fluvoxamine is effective in the treatment of OCD. The rate and degree of treatment response seems equivalent to published studies of clomipramine in OCD. Its antiobsessional effects do not seem to be dependent on the presence of depression. These data are consistent with the 5-HT hypothesis of OCD, however, since the magnitude of the response is modest, possible involvement of other neurochemical systems (e.g., dopaminergic) needs to be examined.

66.9 PLATELET ADENYLATE CYCLASE ACTIVITY IN PANIC DISORDER D.S. Charney, R.S. Duman, R.B. Innis, S.W. Woods, J.F. Tallman and G.R. Heninger. Dept. of Psychiatry, Yale University School of Medicine, New Haven, CT 06508.

Several lines of evidence suggest that some Panic Disorder patients (PD) exhibit abnormal regulation of noradrenergic activity. These abnormalities include potentiated behavioral, biochemical, and cardiovascular responses to the alpha-2 receptor antagonist yohimbine and alpha-2 receptor agonist clonidine (Charney et al. Arch Gen Psych 1986;43:1042-1054). The molecular mechanism of the noradrenergic dysfunction is not known. It has been hypothesized that abnormalities beyond the alpha-2 receptor recognition site at the level of intracellular effector systems may be involved. In the present study, the platelet was used as a model to investigate the regulation of adenylate cyclase activity in PD patients. METHODS: 39 PD patients and 30 healthy subjects were studied. The effect of epinephrine (300 uM), PGE (30 uM), and NaF (10 mM) on adenylate cyclase activity was evaluated. Platelet adenylate cyclase was determined by method of Jacobs et al. (J Biol Chem 1982;257:2829-2833), and protein by Smith et al. (Anal Biochem 1985;150:76-85). Results are expressed as picomoles of ^{32}P-cyclic AMP formed per mg protein/minute. RESULTS: Basal adenylate cyclase activity was significantly reduced in PD patients (9.9 vs 11.4, $p<.05$). Epinephrine inhibition of adenylate cyclase activity was the same in both groups (68% PD, 69% healthy subjects). In PD, PGE_1 and NaF stimulated adenylate cyclase activity respectively, was decreased compared to healthy subjects (281 vs 314, $p<.02$; 61 vs 78, $p<.001$). IMPLICATION: The similar responses of adenylate cyclase activity to inhibition by epinephrine in PD and healthy subjects indicate that alpha-2 receptor regulation of adenylate cyclase activity may not be abnormal in PD. However, the decreased basal adenylate cyclase activity and blunted responses to PGE_1 and NaF in PD patients suggest possible abnormalities at the level of guanine nucleotide-binding regulatory protein or the catalytic subunit. Any relationship of these platelet findings to noradrenergic neuronal dysfunction in PD or brain intracellular effector function remains to be identified.

66.10 QUANTITATIVE AUTORADIOGRAPHY DEMONSTRATES INCREASED 5-HT_2 RECEPTORS IN THE FRONTAL CORTEX OF SUICIDE VICTIMS. *V. Arango, P. Ernsberger, H. Tierney*, M. Stanley, D.J. Reis and J.J. Mann.* Div. of Neurobiology and Lab. of Psychopharmacology, Cornell Univ. Med. Coll., New York, NY 10021.

In homogenates of the frontal cortex of suicide victims there is a 28% increase in the number of serotonin$_2$ (5-HT_2), but not serotonin$_1$ (5-HT_1), binding sites (Mann et al., *Arch. Gen. Psych. 43*:954-9, 1986). Since there are reduced levels of the 5-HT metabolite 5-HIAA, the results may represent postsynaptic receptor up-regulation secondary to reduced presynaptic serotonergic activity. Using quantitative autoradiography we sought to determine whether the increased receptor number in frontal cortex was localized to specific cortical layers.

Studies were carried out on Brodmann area 9 of the prefrontal cortex (PFC) in brains of suicide victims (N=4) and controls (N=4) matched for postmortem delay and age. Brains were obtained from the NYC ME's office and had a postmortem delay < 18h. Each PFC sample was divided in two: one sample was homogenized to study membrane binding by conventional methods and the other was sectioned for autoradiography. Membranes (P_2 fraction, N=8 subjects) were used to generate ^{125}I-LSD saturation curves (see Mann et al., 1986). For autoradiographic studies (N=8) 15 µm sections were mounted on gelatin-subbed glass slides. The slides were incubated in Tris-maleic acid buffer (pH 7.4) containing 2nM ^{125}I-LSD for 90 min. Nonspecific binding was determined in parallel incubations of adjacent sections in the presence of 5µM ketanserin (to block 5-HT_2 sites) or 10µM 5-HT (to block 5-HT_1 sites). After exposure to Ultrofilm (9-15h) with ^{3}H standards calibrated for ^{125}I, autoradiograms were quantified using computer-assisted image analysis. Specific binding was obtained by subtracting the image of a section displaying non-specific binding from the image of an adjacent section displaying total binding.

In membranes, 5-HT_2 binding sites were increased 39% in the suicide group, while 5-HT_1 sites were unchanged. Integrated measurements of the cortical layers in autoradiograms indicated that mean 5-HT_2, but not 5-HT_1 binding was also increased over controls by 48% (2-way ANOVA by layer and group; $p<0.05$). ^{125}I-LSD binding measured in autoradiograms and in membrane preparations from the same region were highly correlated ($r=0.92$, $p<0.01$). In cortex of both groups 5-HT_1 and 5-HT_2 receptor binding differed between cortical layers: intermediate>outer>inner (2-way ANOVA: $p<0.01$). The increase of 5-HT_2 receptors in the brains of suicides differed between cortical layers (ANOVA, $p<0.01$). The greatest increase was in the outer layers (I & II) which had an increase of 53 ± 19%. The smallest increase was found in the inner layers (V & VI, 25 ± 18%). The intermediate layers, where most of the receptors were found in both groups, showed an increase of 46 ± 25%. There was no difference in the binding to white matter between the suicide (17 ± 6 fmol/mg) and the control (16 ± 6 fmol/mg) groups.

We conclude that a) 5-HT_1 and 5-HT_2 receptors in the PFC are differentially distributed across all cortical layers, b) 5-HT_2 but not 5-HT_1 receptors are increased in gray matter of area 9 of suicide victims, and c) while this increase occurs across the cortex it is greatest in the outer layers.

66.11 IN VIVO MEASUREMENT OF D2 DOPAMINE RECEPTOR ABNORMALITIES IN DRUG NAIVE AND DRUG FREE MANIC-DEPRESSIVE PATIENTS. D.F. Wong*, G. Pearlson, C. Ross, L. Tune*, V. Villemagne*, R.F. Dannals*, J. Links*, H. Ravert*, A. Wilson*, M. Kuhar, H.N. Wagner, Jr.*, A. Gjedde*+ (SPON: W. Jankel). Johns Hopkins Med. Inst., Baltimore, MD 21205; + Montreal Neuro. Inst., Montreal, Canada H3A 2B4.

Increases in caudate D2 dopamine receptor numbers (Bmax) have been found in schizophrenics, but it is unknown if these are specific to schizophrenia or would be seen in any psychotic major mental illness (Wong, D.F., et al. Science, 234:1558-1563, 1986). Furthermore there is evidence that dopamine may be involved in affective illness, since dopamine blocking agents are effective anti-manics, and acute administration of dopamine agonists can cause a hypomanic like state. We therefore measured D2 dopamine receptors in symptomatic patients with major affective disorders (diagnosed according to DSM III) and age matched controls, using ([11C]-N-methyl)spiperone (NMSP), and 2 PET scans, with and without a blocking dose of haloperidol. Six were drug naive and three were drug free for more than one year. We calculated Bmax using a four compartment model (Wong, D.F., et al. J. Cereb. Blood Flow and Metab., 6:137-146 and 6:147-153, 1986). Clinically, the hallucinations, delusions and thought disorder ("psychosis") were quantified using a modified version of the Present State Examination ("mini-PSE"), which yielded an overall psychopathology score.

Bmax values for patients were as follows: (initials, age, sex, diagnosis, mini-PSE score, Bmax in pmoles/g): R.M. 20 yr M, psychotic manic, 37, 45; C.W. 25 yr F, psychotic manic 41, 38; E.W. 40 yr F, psychotic mixed, 47, 28; F.A. 52 yr M non-psychotic hypomanic, 12, 11; L.A 68 yr M, psychotic depressed, 17, 30; J.C. 54 yr M, psychotic manic, --, 12; F.K. 39 yr M, non-psychotic depressed, 9, 11; L.P. 43 yr M, psychotic manic, 13, 27; MD 48 yr F, non psychotic depressed vs. personality disorder, --, 13. Values for controls showed an age related decrease from approximately 20 pmole/g at age 20 yrs to less than 10 pmole/g at age 60 yrs.

Our preliminary conclusions are: 1. Patients with affective disorders overall had higher Bmax values than controls. 2. Patients with psychosis, regardless of whether they were depressed or manic, had higher Bmax values than those who were not psychotic. 3. There was a trend for higher values on the mini-PSE to be associated with higher values of Bmax. These preliminary data suggest that Bmax elevation may not be limited to schizophrenia, but may be present in psychosis of affective disorder as well.

66.12 REDUCED CORTICOTROPIN-RELEASING FACTOR (CRF) RECEPTOR NUMBER IN FRONTAL CORTEX OF SUICIDE VICTIMS. C.B. Nemeroff, M.J. Owens, M. Stanley, A. Andorn* and G. Bissette. Depts. Psychiat. & Pharmacol., Duke Univ. Med. Ctr., Durham, NC 27710; Dept. Psychiat., Columbia Univ., New York, NY 10032 and Clev. Metro. Gen. Hosp., Cleveland, OH 44109.

Corticotropin-releasing factor (CRF), the hypothalamic releasing hormone which regulates the synthesis and secretion of ACTH and other POMC products from the anterior pituitary, also apparently acts as a neurotransmitter in higher CNS centers. There is evidence to show that CRF neuronal activity or integrity is altered in major depression, anorexia nervosa, and Alzheimer's disease. Our two studies (Nemeroff et al., Science 226:1342, 1984 and Banki et al., Amer. J. Psychiat., in press) demonstrating increased CSF CRF concentrations in depressed patients, taken together with a plethora of behavioral data, have led our group to hypothesize that depressed patients hypersecrete CRF. If this is the case, then one would expect to find a decrease (down-regulation) in the density of CRF binding sites in the brains of depressed individuals. In the present study, we measured the number (Bmax) and affinity (Kd) of CRF receptors in the frontal cortex of suicide victims (n=26) and age- and sex-matched controls (n=29).

Approximately 150 mg of tissue was homogenized in cold isotonic sucrose. After low speed and high speed centrifugations, the resulting pellet was resuspended in a Tris-$MgCl_2$-EDTA buffer. Of this suspension, 100 µl was incubated in triplicate with 100 µl of buffer containing 30,000-35,000 cpm of [^{125}I]-Tyr^0-ovine CRF and 100 µl of buffer containing varying amounts of unlabeled r/hCRF in a microcentrifuge tube. After a two hour incubation at 22°C, the tubes were centrifuged. The resulting supernatant was aspirated and the pellet washed with phosphate-buffered saline. The tubes were centrifuged again and aspirated. The remaining pellets were counted for two minutes in an LKB Rackgamma counter. Scatchard analysis revealed no difference between the affinity (Kd) of the radioligand in the two groups. However, a significant decrease (23%, $p=0.020$) in CRF receptor density (Bmax) was found in the suicide group. No significant correlations were found between the Bmax for CRF and sex, age or post-mortem delay.

These findings are concordant with the hypothesis that CRF is hypersecreted in suicide victims as evidenced by a decrease (down-regulation) in the number of CRF binding sites. These findings, taken together with the CSF studies cited above, the studies of Gold and his colleagues demonstrating a blunted ACTH response to CRF, and the preclinical reports of behavioral effects of centrally administered CRF in laboratory animals, are all concordant with the hypothesis that CRF is hypersecreted in endogenous depression. (Supported by NIMH MH-42088, MH-39415, MH-40524, MH-40159, MH-41847 and NIA AG-05128.)

67.1 Behavioural Tolerance Following Continuous Infusions of a Dopamine D-2 Agonist is Reversed by Either Stress or a D-1 Agonist. M.T. Martin-Iverson, S.M. Stahl and S.D. Iversen* Merck Sharp and Dohme Neuroscience Research Centre, Harlow, Essex, UK CM20 2QR

We have previously observed that rats given continuous infusions via Alzet Osmotic Minipumps of a selective dopamine (DA) D-2 agonist, [+]-4-propyl-9-hydroxynaphthoxazine (PHNO) developed complete tolerance to the motor stimulation effects of this drug, but only during the light cycle (Martin-Iverson et al., submitted). Activity induced by PHNO does not develop tolerance during dark periods of a 12 h light-dark cycle. In the present experiments, we investigated possible mechanisms underlying the differential development of tolerance, depending upon the light-dark cycle.

Male Sprague-Dawley rats (300-400g, 6 per group) were implanted subcutaneously with minipumps infusing either PHNO (5µg/h) or vehicle (0.5µl/h) while under ether anaesthesia. Locomotor activity was assessed hourly throughout the duration of the infusions (12-14 days), by recording interruptions of photobeam assemblies in the rats' home cages. Room lights were on each day from 09.00-21.00, and the rats had continuous access to food and water. Additional treatments, consisting of either continuous infusions of the DA D-1 antagonist (20µg/h, sc) or single daytime injections of the D-1 agonist SKF 38393 (6mg/kg i.p.) for 4 successive days beginning on Day 7 of PHNO infusion, were given to some groups. All groups were subjected to a mild stress on some days, which consisted of disturbance associated with changing of food, water and cage litter, lasting about 20 minutes. Activity for the 2h during and after this disturbance was compared to the same time period on days without disturbance.

Vehicle-infused rats exhibited higher levels of activity during the night and after disturbance than during the non-disturbed daytime. Infusions of the D-1 antagonist attenuated nocturnal activity, but had no effect on daytime or daytime stress-induced activity. Daytime injections of the D-1 agonist had no significant effect on activity. Rats receiving infusions of PHNO initially displayed high levels of activity, which exhibited complete tolerance by day 4, but only during the day. Daytime tolerance was reversed for the 2h during and following disturbance. The D-1 antagonist blocked initial daytime activity, stress-induced reversal of tolerance, and attenuated nocturnal motor stimulation by PHNO. The D-1 agonist reversed daytime tolerance to PHNO. These data suggest that tolerance to a selective DA D-2 agonist is mediated by changes in the activation of the D-1 receptor, likely by the endogenous ligand.

67.2 LESIONS OF MEDIAL PREFRONTAL CORTEX DOPAMINE NEURONS: EFFECTS ON AMPHETAMINE SELF-ADMINISTRATION AND DOPAMINE SYNTHESIS IN THE RAT BRAIN. A.P. Leccese and W.H. Lyness. Psychology Dept., Kenyon College, Gambier, OH 43022 and Dept. of Pharmacology, Texas Tech Univ. Health Sci. Ctr., Lubbock, TX 79430.

It has been suggested that dopamine neurons within the medial prefrontal cortex subserved some role in the positive reinforcing effects of the psychomotor stimulants. Microinjections of 6-hydroxydopamine (6-OHDA) into this region, which destroyed a major portion of the dopamine innervation but maintained the integrity of noradrenergic and serotonergic neurons, failed to alter either the acquisition or maintenance of i.v. d-amphetamine self-administration in rats. Compared to vehicle injected controls (sham lesions) the 6-OHDA treated animals acquired the drug abuse behavior and maintained comparable, stable rates of self-injection. The lesions did increase the concentrations of dihydroxyphenylacetic acid and homovanillic acid in nucleus accumbens septi but not the striatum. The increased synthesis of dopamine in the nucleus accumbens septi (demonstrated by increased dihydroxyphenylalanine accumulation) was abolished by the administration of i.v. d-amphetamine in patterns mimicking those of trained self-administration animals.

67.3 REDUCED GABA & GLUTAMATE AND INCREASED SEROTONIN ACTIVITY IN MIDBRAIN-THALAMUS OF RATS FOLLOWING RECOVERY FROM ACUTE THIAMINE DEFICIENCY. P.J. Langlais, R.G. Mair, C.D. Anderson and W.J. McEntee. Research Svc. (151C), VA Medical Center, Brockton, MA 02401.

The anatomic substrates and neurotransmitter substances involved in the cognitive and memory deficits of thiamine deficiency induced Korsakoff's disease remain unknown. In acutely thiamine deficient rats, regional brain monoamine and amino acid neurotransmitter disturbances have been reported but their impact on cognition and memory could not be assessed. In two previous studies we observed significant learning and performance deficits in rats following recovery from a two week bout of PTD-induced thiamine deficiency (pyrithiamine [0.5 mg/kg/day] + thiamine deficient diet) (Mair et al., Brain Res., 360:273-284, 1985; Mair et al., Neurosci. Abstr., 12:745, 1986). Cortical norepinephrine (NE) levels were significantly reduced (by 35%) in the first study, but were reduced by only 6% in the second study (Langlais et al., Brain Res., in press). These differences may have been due to the use of a more severe, prolonged bout of thiamine deficiency in the first study (35% reduction).

In this study, rats were made thiamine deficient and the brains dissected as in the original study and the concentrations of monoamines, metabolites and amino acids measured. Equal size groups of PTD treated and pairfed control rats were sacrificed 2 weeks (N=10) and 9 weeks (N=7) following nutritional restitution. Consistent with our previous results, significant elevations were observed at both recovery periods in NE content of cerebellum and 5-HT & 5-HIAA of midbrain-thalamus and striatum. In cortex, NE was reduced by 23% at 2 weeks and unchanged at 9 weeks, thus failing to demonstrate a persistent diminution of cortical NE. Significant reductions in GABA, glutamate and aspartate levels in midbrain-thalamus but not any other brain areas were observed at 2 and 9 weeks. These findings agree with an earlier report of reduced GAD activity within the thalamus of recovered PTD rats (Thompson & McGeer, Neurochem. Res., 10:1653-1660, 1985) and suggest a permanent loss of thalamic GABAergic activity in this model of Korsakoff's disease. This possibility is supported by our observation of consistent thalamic lesions in recovered PTD rats (Langlais et al., Neurosci. Abstr. 12:751, 1986). The findings of reduced GABA and increased serotonin activity may be related to the purported GABA mediated-inhibition of serotonin activity within midbrain-thalamic nuclei. Supported by Veterans Administration research grant.

67.4 ASYMMETRY IN STRIATAL DOPAMINE RELEASE AND METABOLISM: BILATERAL IN VIVO DIALYSIS IN NORMAL RATS. S.D. Glick, J.N. Carlson, J.L. Baird* and K.L. Drew. Department of Pharmacology and Toxicology, Albany Medical College, Albany, N.Y. 12208.

Asymmetry in the dopaminergic nigrostriatal system of the rat brain has been well documented in this laboratory and others (cf. Glick, Cerebral Lateralization in Nonhuman Species, Academic Press, 1985). Normal hemispheric differences in striatal dopamine levels, metabolites, release, uptake, and receptors have been reported. Studies of such differences have previously been conducted only with postmortem brain tissue (either homogenates, slices or synaptosomes). Using the technique of in vivo brain dialysis, we have monitored release of dopamine and its metabolite DOPAC in both striata of awake, freely moving female rats. Under baseline conditions, an asymmetry in dopamine release was reciprocally related to an asymmetry in DOPAC; that is, DOPAC was higher on the side with lower dopamine and vice-versa. Administration of d-amphetamine sulfate (1.25 mg/kg) enhanced dopamine release and decreased DOPAC-- these changes were frequently much greater in one striatum than the other and appeared to be related to the direction and intensity of d-amphetamine-induced rotation (circling). In accordance with other findings (e.g., Zetterstrom et al., Europ. J. Pharmacol., 132: 1, 1986), the reciprocal relationship between dopamine and DOPAC suggests that when more dopamine is released, there is less intraneuronal substrate for MAO and hence lower DOPAC. Further studies are in progress to determine the relationship of these asymmetric changes to regional variations in dialysis sites within the striata. (Supported by NIDA grant DA03817 to S.D.G.)

67.5 STRIATAL DOPAMINE RELEASE ASSESSED WITH MICRODIALYSIS FOLLOWING UNILATERAL NIGROSTRIATAL DAMAGE. Terry E. Robinson and Ian Q. Whishaw. Departments of Psychology, University of Michigan, Ann Arbor and University of Lethbridge, Lethbridge, Canada.

Most studies on the presynaptic compensatory changes in dopamine (DA) release that are thought to occur following partial damage to nigrostriatal DA neurons have involved indirect measures of DA utilization or in vitro methods for assessing release. The present study was designed to determine the effects of nigrostriatal damage on striatal DA release in vivo, measured with microdialysis in freely moving rats.

Rats received unilateral 6-OHDA lesions of varying severity in the substantia nigra. At least 1 month later concentric (250 µm O.D.) dialysis probes were placed bilaterally in the striatum. The next day extracellular concentrations of DA, DOPAC, HVA and 5-HIAA in dialysate were measured in both the denervated and intact striatum, first during the resting state and then following an injection of 1.5 mg/kg d-amphetamine (AMPH). Striatal tissue was removed and assayed at the end of the experiment.

The most striking finding was that striatal tissue DA concentrations did not predict DA concentrations in dialysate over a wide range of lesion sizes. Massive tissue DA depletion (90-99%; denervated relative to intact side) was accompanied by only relatively small changes in DA levels measured in dialysate during the resting state. In contrast, the depletion of DA metabolites in tissue was accompanied by a comparable depletion in dialysate, and one was highly predictive of the other. In rats with a <95% DA depletion (tissue) AMPH produced a large increase in DA release (dialysate) from both the intact and lesion sides; although the intact side showed greater release than the denervated side. Rats with a >95% DA depletion showed a large increase in DA release from the intact side, but a progressive reduction in DA levels in dialysate obtained from the lesion side (often to non-detectable levels). All rats turned away from the side showing the greatest AMPH-stimulated DA release.

In summary, after even a >90% loss of DA from one striatum the extracellular concentrations of DA are maintained at close to normal levels (in absolute terms), presumably due to compensatory changes in the remaining neurons. If the tissue DA depletion is <95% the denervated side can even release considerable quantities of DA in response to AMPH. However, if the tissue depletion is >95% there appears to be no reserve capacity, and thus no increase in release in response to AMPH. The data may help explain why relatively normal function is maintained after even extensive damage to the nigrostriatal DA system, and why deficits often often appear only when the system is 'challenged'.

67.6 ADRENERGIC RESPONSE TO COGNITIVE ACTIVITY IN A COLD ENVIRONMENT. S.T. Ahlers, J.R. Thomas, J. Schrot, J.F. House, K.F. VanOrden, and R.L. Hesslink. Environmental Stress Department, Naval Medical Research Institute, Bethesda, MD 20814-5055.

Plasma norepinephrine (NE) and epinephrine (E) were sampled in six male subjects before, during, and after a 90 minute exposure in a controlled climate chamber at 4°C and during exposure in the chamber at ambient temperature (22°C). After 45 minutes of exposure subjects performed a cognitive test battery lasting a total of 40 minutes.

NE increased markedly within 2 minutes after exposure to the cold environment and remained asymptotic for 30 minutes during which subjects engaged in no programmed activity. Just prior to, and during the test battery however, NE increased to nearly three times basal levels. A significant but smaller increase in plasma NE was observed when subjects were administered the cognitive test in the ambient environment.

In contrast to NE, E did not increase above baseline in the first 30 minutes of cold exposure but did increase substantially just prior to and during the administration of the cognitive test. A slight increase in E was observed when the test battery was given at normal temperature.

These data indicate that while NE and E responded differentially to cold with NE increasing and E levels unchanged, both catecholamines increased when subjects were engaged in focused mental activity. Moreover, the combined effects of cold stress and mental activity appeared to synergistically modify the release of catecholamines, especially in the case of E, where the release during the cognitive test was augmented during exposure to the cold environment. This work was supported by the Naval Medical Research and Development Command, Research Task No. M0095.04.1054.

67.7 **STRESS- AND COCAINE- LIKE EFFECTS ON AMPHETAMINE- INDUCED ROTATIONAL BEHAVIOR CAUSED BY THE ANXIOGENIC BENZODIAZEPINE INVERSE AGONIST METHYL β-CARBOLINE -3-CARBOXYLATE.** J.N. Carlson and S.D. Glick. Department of Pharmacology and Toxicology, Albany Medical College, Albany, N.Y. 12208

This laboratory has been investigating lateralized changes in dopamine (DA) activation which take place following exposure to mild stress and various stimulant drugs. One technique for assessing these alterations has been to evaluate differences in unlesioned rats' rotational behavior, presumed to result from lateralized nigrostriatal DA activation. We have previously shown that, in the Sprague-Dawley rat, mild footshock stress causes a change in the direction and intensity of d-amphetamine (d-A) induced rotational behavior resembling that induced by cocaine alone (Carlson, J.N., et. al. Pharm. Biochem. Behav. 26:17,1987). We have hypothesized that mild stress and cocaine both selectively activate mesoprefrontocortical DA systems while d-A preferentially activates nigrostriatal and limbic DA; and that stress- induced changes in rotation are subserved by a lateralized cortical modulation of striatal DA function.

It has recently been shown that certain beta-carboline benzodiazepine receptor inverse agonists selectively activate mesoprefrontocortical DA systems (Tam, S.-Y. and Roth, R.H., Biochem. Pharmacol 34:1595,1985; Claustre, Y. et.al., J.P.E.T. 238:693,1986). Previous findings have indicated that cortical DA activating stressors such as uncontrollable footshock and 48 hours of food deprivation (Carlson, J.N. and Glick, S.D., Neurosci. Abstr. 12:1535,1986) cause an increase in the intensity of d-A induced left rotation in the Long-Evans rat while leaving right rotation unaffected. It was thus of interest to compare the effects on d-A rotation of methyl β-carboline-3- carboxylate (β-CCM) to those of mild stress and cocaine in this strain of rat. Rats were tested for d-A rotation (1.56 mg/kg males, 1.25 mg/kg females, i.p.) and were again tested 1 week later 45 min. following a 5.0 mg/kg s.c. dose of β-CCM. In another experiment male and female rats were tested for rotation following 20.0 mg/kg i.p. cocaine HCl. β-CCM caused a selective increase in the intensity of left rotation while lovering or leaving unchanged the intensity of right rotation. Similarly, cocaine caused a strong left rotational bias. These findings indicate that stress, cocaine and β-CCM share a common lateralized action on DA systems. Using these manipulations, neurochemical studies are now in progress to explore lateralized relationships among cortical, limbic and striatal DA systems. **(Supported by NIDA grant DA03817 to S.D.G.)**

67.8 IS THERE A RELATIONSHIP BETWEEN DOPAC RELEASE FROM THE CAUDATE NUCLEUS AND YAWNING BEHAVIOR IN THE FREELY MOVING MALE RAT? N. J. Laping and V. D. Ramirez. Department of Physiology and Biophysics, University of Illinois, Urbana, IL 61801.

It has been shown previously that the nigro-striatal dopamine system is involved in prolactin- and apomorphine- induced yawning. Herein we describe the in vivo dopamine activity of the caudate nucleus via DOPAC measurement from push-pull-perfusates of the caudate nucleus sampled at two minute intervals. This technique allows us to more closely examine any correlation between dopaminergic activity and yawning behavior.

Male Holtzman albino rats were implanted with a 22g stainless steel syringe into the caudate nucleus (2.3mm anterior to the bregma; 2.5mm lateral from the superior sagittal sinus; 4.5mm ventral from the dura mater). Seven to ten days after the surgery the caudate nuclei of these freely moving animals were perfused with a modified KRP medium (16ul/min.), and sampled every two minutes starting between 12:00 and 14:00h. The subjects were monitored simultaneously for motor activity by an animal activity monitor and yawns were noted visually by the investigator.

The two minute sampling rate of DOPAC concentrations of the caudate nucleus revealed an episodic pattern of release with a period of about 8-10 minutes with a mean amplitude of 11.56±2.1pg/min. Interestingly, in an untreated animal that yawned spontaneously, there was a sharp drop in DOPAC and dopamine release just prior to or during the two samples at which yawning occurred (>20pg/min.).

In order to experimentally manipulate the dopaminergic release, subjects received a systemic injection of apomorphine (50ug/kg) at a dose known to induce yawning. Perfused animals in those experiments yawned 15.5±6.0 times in 30 minutes following a systemic APO injection. A pairwise comparison was then performed between DOPAC release over a 10 minute period prior to apomorphine injection and DOPAC release during the sample at which the first yawn occurred. The results show that DOPAC release rates dropped significantly during the first yawn ($p<0.05$) (delta = 22.5±5.9 pg/min., $n=4$). These findings suggest that yawning behavior is displayed with a concomitant drop in dopaminergic activity and support the hypothesis that cholinergic activation of yawning is under dopaminergic inhibitory control.

67.9 CHARACTERIZATION OF HIPPOCAMPAL NOREPINEPHRINE EFFLUX USING IN VIVO DIALYSIS: PHARMACOLOGICAL AND BEHAVIORAL STUDIES. E.D. Abercrombie, R.W. Keller, E.M. Stricker and M.J. Zigmond. Dept. of Behavioral Neuroscience, Center for Neuroscience, University of Pittsburgh, Pittsburgh, PA 15260.

We have examined norepinephrine (NE) efflux in the dentate gyrus of hippocampus of freely moving animals in response to pharmacological and environmental stimuli. A probe was constructed from hollow dialysis fibers (15,000 mw cut-off) so as to provide an active region of dialysis fiber 4.5 mm in length, calibrated with standards, and then stereotaxically implanted under chloral hydrate anesthesia into the dorsal hippocampus. Most of the loop was located in the hilus of the dentate gyrus, the area known to receive the densest NE innervation within the hippocampus. Perfusion (2 ul/min) using artificial CSF was carried out using a Harvard syringe pump via a fluid swivel that permitted relatively unrestricted movement. Animals were allowed to recover from surgery overnight and efflux was monitored for a minimum of two hours prior to each manipulation in order to ensure stable baseline values. Experiments were performed 1-5 days post-operatively. Perfusate was collected every 15 min and 20 ul of each sample was assayed for catecholamines using HPLC with electrochemical detection.

The concentration of extracellular NE in this region was 50-75 nM. After systemic administration of the α_2-adrenergic receptor antagonist, yohimbine (2.0 and 5.0 mg/kg, ip), NE was increased to 125% and 230% of baseline, respectively. Addition to the perfusate of desipramine (0.1 mM), an inhibitor of high affinity NE uptake, increased NE more than 3-fold. Intermittent electric shock to the tail for 30 min provoked a short-lived increase in extracellular NE levels to approximately twice that of baseline. Similarly, a brief 3-fold increase in extracellular NE levels was observed in response to restraint stress of 30 min duration. These stress-induced increases in hippocampal NE efflux were limited to the two 15 min dialysate samples which corresponded to the application of the stressor.

These results demonstrate that changes in hippocampal NE efflux can be measured in response to both pharmacological and behavioral manipulations using in vivo dialysis. In addition, these data lend further support to the hypotheses that the level of activity in central NE systems is partly under the control of α_2-adrenoceptors, that reuptake processes are important in regulating extracellular NE levels, and that the noradrenergic projections of the locus coeruleus are involved in the response of the central nervous system to stress. (Supported in part by USPHS grants MH29670, NS19608, and MH18273.)

67.10 SEQUENTIAL INCREASE IN TYROSINE HYDROXYLASE ACTIVITY IN NORADRENERGIC CELL BODIES AND TERMINAL AREAS AFTER EXPOSURE TO CHRONIC COLD. L.K. Gladstein, E.D. Abercrombie, E.P. Weisberg, B. Kaplan, M.J. Zigmond. Depts. of Behavioral Neuroscience and Psychiatry, Cntr. Neurosci., Univ. of Pittsburgh, Pittsburgh, PA

The norepinephrine (NE)-containing neurons originating in the locus coeruleus (LC) have been implicated in the response of the central nervous system to stress. One mechanism by which this system adapts to conditions of increased demand is via enhanced biosynthetic capacity. This is accomplished by an elevation in the activity of tyrosine hydroxylase (TH), the rate-limiting enzyme in NE biosynthesis. Previous studies have shown that cold stress results in an elevation of TH activity in the LC. We have further examined the stress-induced alterations in TH.

Adult, male rats were shaved and placed in a cold room (5°C) for 3-7 days, while control animals remained in a temperature-controlled environment at 22°C. Animals were killed by decapitation and a region of brain stem containing the LC cell group dissected out. The cerebellum, which contains axon terminals from LC, also was removed. Tissues were immediately placed on dry ice and then stored at -70°C until assayed. TH activity was measured by a coupled decarboxylase assay. TH protein was quantified using immunoblot analysis.

After three days of cold stress, there was a 29% increase in TH activity in LC which was accompanied by an increase in TH protein. After seven days of cold exposure, TH activity was further elevated to 61% of control activity. These results are consistent with our previous finding that TH mRNA is elevated in the LC after chronic cold stress (Stachowiak et al., 1986) and suggest that cold stress increases the synthesis of TH protein. In contrast to our observations in LC, no change in TH activity was found in cerebellum after three days of cold exposure. However, after seven days of cold, a 33% increase in enzyme activity was observed. This delayed rise in TH activity seen in the cerebellum parallels reports of sequential increases in TH activity in the LC, cerebellum, and hippocampus following partial injury to LC neurons with 6-hydroxydopamine (Acheson and Zigmond, 1981) and treatment with reserpine (R. Zigmond, 1979). It suggests that once synthesized, the new TH protein is transported to axon terminals.

These results provide further support that during conditions of increased demand, TH is synthesized in the cell body regions and is transported down the axon to the terminal fields. Additional experiments are currently underway to determine whether the arrival of new TH protein in terminal regions is associated with an increase in the capacity for NE synthesis and release. (Supported in part by USPHS grant NS19608.)

67.11 D-AMPHETAMINE (D-AMPH) DISCRIMINATION BEHAVIOR IS NOT ALTERED BY L-TRYPTOPHAN (L-TRY) OR FLUOXETINE PRETREATMENT. F.L. Smith* and W.H. Lyness. Department of Pharmacology, Texas Tech University Health Sciences Center, Lubbock, TX 79430.

In experiments where rats self-administer i.v. d-AMPH for its reinforcing properties, injections of 100 mg/kg L-TRY or 5 mg/kg fluoxetine significantly reduces drug intake (A. Leccese and W. Lyness, Brain Res., 303: 153, 1984; F. Smith, et al., Pharm. Biochem. Behav. 25: 849, 1986). A concern was that drugs which increase 5-HT receptor activity might alter dopamine mediated reinforcement, causing subsequent reductions in self-injected d-AMPH. In one study where zimelidine reduced conditioned place-preference in rats trained on d-AMPH, it was proposed that increased 5-HT transmission reduced the reinforcing properties of d-AMPH (A. Kruszewska, et al., Eur. J. Pharmac., 125: 283, 1986). To examine this concern, drug discrimination experiments were conducted to determine whether 5-HT agents alter the degree of d-AMPH mediated discrimination behavior. Male Sprague-Dawley rats were trained to discriminate 1.0 mg/kg d-AMPH from saline in a dual-lever food operant paradigm, utilizing a fixed ratio-10 (FR-10) schedule. Using doses between 0.1 and 0.7 mg/kg d-AMPH, a dose-response curve was generated which had an effective dose-50 (ED-50) of 0.34 mg/kg. Serotonergic drugs were then combined with both low and high doses of d-AMPH (0.2 and 0.7 mg/kg) to determine whether increased 5-HT receptor activity alters the degree of d-AMPH mediated discrimination. Activation of 5-HT neurons with 100 mg/kg L-TRY or blockade of 5-HT reuptake with 5 and 10 mg/kg fluoxetine, when combined with d-AMPH, did not significantly enhance or reduce drug-lever responding.

Verifying that dopamine neurons mediate the discriminative properties of d-AMPH was accomplished by combining dopamine receptor agents with d-AMPH. Increasing doses of apomorphine (APO), when combined with 0.2 mg/kg d-AMPH, produced significant increases in drug-lever responding at 1.0 mg/kg. Subsequent combinations of 1.0 mg/kg APO with various doses of d-AMPH produced a significant shift-to-the-left in the d-AMPH dose-response curve. On the other hand, when increasing doses of haloperidol were combined with 0.7 mg/kg d-AMPH, significant reductions in discrimination occurred at 0.2 mg/kg haloperidol.

Thus, d-AMPH discrimination behavior is not enhanced or reduced by manipulations which increase 5-HT receptor activity. This appears to answer two questions: first, d-AMPH reinforcement is not reduced with increased 5-HT transmission as proposed in the place-preference experiments, and second, the reductions seen with self-administered d-AMPH is not the result of 5-HT enhancing dopamine mediated reinforcement. Possibly, by enhancing 5-HT receptor activity, aversive qualities are elicited which produce subsequent reductions in self-injected d-AMPH.

67.12 HALOPERIDOL BLOCKS THE INCENTIVE MOTIVATIONAL PROPERTIES OF FOOD REINFORCEMENT IN RATS. A. Ettenberg and J.C. Horvitz. Department of Psychology, University of California, Santa Barbara, CA 93106

A primary assumption of incentive motivational theories of behavior (e.g. Bindra, 1974) is that the presentation of incentive stimuli can serve to activate a "central motive state" underlying the initiation and maintenance of animal behavior. The "motivating" action of rewarding stimuli has been demonstrated in studies where previously extinguished operant responses are reinstated following a single "prime" with the original reinforcer. If central dopamine substrates play an important role in the neural mediation of food reward, then one might predict that the incentive properties of food (in such a "priming" task) would be prevented by disruption of dopamine (DA) neurotranmission.

In the present study, hungry rats (n=7 per group) were trained to traverse a straight runway for a reward of five 45mg food pellets. Training consisted of a single trial per day over seven consecutive days. On Day 8, the animals were tested with no food reward available in the goal box. Such non-rewarded extinction trials continued until the animals' running times slowed to an arbitrary "extinction criterion" (i.e. 3 times slower than the mean running speed over the final 3 reinforced trials). Once operant running had extinguished, animals were given one final extinction trial (which served as a baseline) and then were tested in one of the following ways: 1) one group (HAL.15/FOOD) was pretreated with 0.15 mg/kg IP haloperidol (a DA antagonist prepared in warm vehicle solution of 0.002M lactic acid and injected in a volume of 1.0 ml/kg) 45 mins prior to a single food rewarded trial; 2) a second group was similarly treated with a higher, 0.3mg/kg, dose of haloperidol (HAL.3/FOOD); 3) group 3 (VEH/0) pretreated with the vehicle solution alone and then experienced a non-rewarded trial; 4) group 4 (VEH/FOOD) was similarly pretreated with the lactic acid vehicle solution but later experienced a food-rewarded trial; and 5) the final group (FOOD/HAL.3) served as a "motor impairment" control group in that these animals were not injected with haloperidol until 1 hr after a rewarded runway trial. The next day the effectiveness of the reward presentation on the previous day's trial was assessed by examining the running speeds of each of these five groups of rats.

The results clearly demonstrated that a) a single food-prime was sufficient to reinstate operant runway responding; b) this "priming" effect was blocked by haloperidol pretreatment; and c) the drug effects could not be accounted for by motor impairment since the FOOD/HAL.3 group behaved indistinguishably from nondrugged food-rewarded animals (i.e. there was no residual motor deficit one day after haloperidol treatments). Together these results suggest that DA systems are involved in mediating the incentive motivational properties of food reward.

67.13 **DIABETES-INDUCED POLYDIPSIA IN RATS: DEPENDENCE ON INTACT DOPAMINE FUNCTION AND MEDIATION BY CENTRAL INSULIN** **M.H. Lewis, M.F. Keresztury*, Q.D. Walker*, L.S. Cook*, B.E. Mileson*, and R.B. Mailman. Departments of Psychiatry and Pharmacology and Biological Sciences Research Center, Univ. of North Carolina School of Medicine, Chapel Hill, NC 27514**

When administered to rats, the pancreatic beta cell toxicant, streptozotocin (55 mg/kg iv) induces a well-characterized model of insulin dependent diabetes mellitus (IDDM). Rats so treated become hypoinsulemic, hyperglycemic, polydipsic and polyuric, hyperphagic (despite weight loss), and, later, develop secondary complications such as retinopathies and peripheral neuropathies. We have selected diabetes-induced polydipsia (DIP) as a behavioral/physiological endpoint with which to examine some of the effects of diabetes on central catecholamine function. Diabetic rats (blood glucose > 400 mg/dL) increased their daily water consumption from ca. 45 mL to ca. 300 mL. In the first study, the effect of selective D_1 and D_2 dopamine antagonists on daily water consumption was assessed. Administration of haloperidol (1 mg/kg ip) significantly suppressed DIP, while not affecting water consumption in control rats. Conversely, SCH23390 treatment did not suppress DIP at any dose tested (0.05 to 0.5 mg/kg ip). Thus, DIP is attenuated by D_2 but not D_1 receptor blockade. In contrast either angiotensin II or lithium-induced polydipsia can be attenuated by both D_1 and D_2 antagonists; effects known to involve the nigrostriatal dopamine system. These data may indicate a differential effect on the sensitivity of dopamine receptor sub-types as a consequence of diabetes.

In a second study, rats were chemically lesioned with the catecholamine neurotoxicant, 6-OHDA, following pretreatment with desipramine (25 mg/kg, i.p.). Water consumption in dopamine depleted animals was found to be markedly reduced relative to controls following induction of diabetes. These data further support the dependence of DIP on intact dopamine pathways. Data from experiments using site-specific injections of 6-OHDA point to the importance of the nigrostriatal dopamine in mediating DIP. We have also examined the role that insulin may play centrally in mediating DIP, independent of its peripheral effects. Preliminary data have demonstrated that icv infusions of insulin suppress DIP. The mechanisms by which insulin may suppress DIP are currently being examined.

67.14 BEHAVIORAL SUPPRESSION IN RATS FOLLOWING BILATERAL MICROINJECTION OF 5-HYDROXYTRYPTOPHAN (5-HTP) IN LATERAL HYPOTHALAMUS SUPPORTS ROLE OF CENTRAL SEROTONERGIC MECHANISMS IN 5-HTP ANIMAL MODEL OF DEPRESSION. J.N. Hingtgen, A. Shekhar*, J.A. DiMicco and M.H. Aprison. Depts. of Psychiatry and Pharmacology and Toxicology and Biochemistry and Program in Medical Neurobiology and Section of Applied and Theoretical Neurobiology, Institute of Psychiatric Research, Indiana Univ. School of Med., Indianapolis, IN 46223.

In a series of studies over a 27 year period 5-HTP has been shown to produce operant response suppression in pigeons and rats working on food reinforcement schedules; these changes in behavior have been correlated with serotonergic increases in specific areas of the brain and have led to the development of the hypersensitive postsynaptic serotonin receptor theory of depression (Aprison et al. In: Neuropharmacol. and Behav., Plenum, p. 23,1978; Aprison and Hingtgen, In: Serotonin, Plenum, p. 267, 1981). Although many studies from our and other laboratories have proposed central mechanisms in explaining this animal model of depression, there remains a possibility that peripheral effects may play a role, since 5-HTP typically has been administered by the systemic route. To demonstrate more clearly that the 5-HTP induced suppression is a centrally mediated phenomenon, we injected rats directly into the hypothalamus, an area previously shown to reflect changes in 5-HT associated with behavioral changes (Loullis et al., Pharm.Biochem. Behav., 959, 1980). Male Wistar rats were trained on a VI schedule for milk reinforcement. After response baselines were established, guide cannulae were stereotaxically placed bilaterally in the lateral hypothalamus. After a recovery period of 4-5 days, 100-500 ng D,L-5-HTP was microinjected bilaterally 15 min after the start of the VI session. Subsequent changes in response rates were monitored over a 2-3 hr session. Significant decreases in responding were observed (50-100% below baseline levels) for as long as 200 min following injection, a behavioral effect comparable to that obtained after a systemic injection of 50 mg/kg D,L-5-HTP. Rats receiving a microinjection of 5-HTP in the posterior hypothalamus did not exhibit a behavioral effect. Rats working on avoidance schedules, when injected systemically with 5-HTP, do not exhibit response suppression (Aprison and Hingtgen, Rec. Adv. Biol. Psychiat. 8, 87, 1966). Similarly rats in the present study working on Sidman shock avoidance schedules failed to exhibit response suppression when microinjected with 5-HTP in the lateral hypothalamus. These data support the important role previously assigned to central mechanisms in the 5-HTP animal model of depression. (Supported in part by training grant PHS MH 17107-03 and USPHS NS 19883).

67.15 EFFECTS OF AMPHETAMINE AND HALOPERIDOL ON CORE TEMPERATURE IN RAT. W. F. Caul, S. D. Comer*, J. D. Nussdorf*, and R. J. Barrett*. Dept. of Psychology, Vanderbilt University, Nashville, TN 37240.

Pharmacodynamic adaptive processes are induced by administration of many centrally and peripherally acting drugs (Lupolover, R., et al., Int. Pharmacopsychiat., 17:194-237, 1982). These adaptive processes are thought to be the basis for biphasic responses to drug (Barrett, R. J., and Rock, R. S., Psychopharm. In press) as well as rebound effects observed following termination of chronic drug treatment (Haefely, W., Pharmacopsychiat. 19:353-361, 1986). One would expect, therefore, that a biphasic temporal pattern of drug response would be present in every homeostatic system affected by the drug. Since the stimulus properties of amphetamine follow a biphasic temporal pattern as revealed using the drug-discrimination procedure (Barrett, R. J., and White, D. K., In prep.), and since amphetamine-induced anorexia is followed by hyperphagia (Caul, W. F., et al., Beh. Neurosci., In press), the purpose of this experiment was to determine the temporal pattern of amphetamine's effect on temperature. The effects of haloperidol were assessed also because it has been reported that while this drug potentiates the effects of dopamine agonists, alone it produces no change in temperature (Lai, H., and Horita, A., 82:335-337, 1984).

Lightly restrained rats received injections (s.c.) of either distilled water, amphetamine (1, 2, or 4 mg/kg), or haloperidol (1, 2, or 4 mg/kg). Oiled number 402 thermistor probes were inserted 8 cm into the rectum and taped to the base of the tail. Air and core temperature were then continuously monitored immediately after drug injection for 8 hours 10 minutes by a Grass Model 7 polygraph. Each rat received the same injection three times with two days intervening between each injection day. Animals were deprived of food and water for 16 hours prior to each injection.

Over the 8-hour recording period, the temperature for control animals increased during the initial 30 minutes and then declined over the next 120 minutes toward an asymptote of 36.7° C. Relative to this control curve, amphetamine elicited an initial hypothermic response that lasted from 30 to 60 minutes. This hypothermia was always followed by hyperthermia. The hyperthermia persisted from 180 to 280 minutes. The data suggest that at higher doses of amphetamine, rebound hyperthermia occurs later in time, is of greater magnitude, and lasts longer. In contrast to these cubic components that describe the effects of amphetamine, the orthogonal polynomial analysis of the effects of Haloperidol reveals that the major component was quadratic. Haloperidol elicited long lasting hypothermia at all doses. No rebound was apparent within the measurement period. Thus, while the explanation for haloperidol's effect is not apparent, amphetamine's pronounced biphasic effect on temperature conforms to expectations derived from knowledge of the biphasic nature of the drug's stimulus properties and it effects on food consumption.

67.16 PANIC DISORDER: TREATMENT, SYMPTOMS, AND PLASMA MHPG. Matthew J. Edlund* and Alan C. Swann. Department of Psychiatry, University of Texas Medical School and Mental Sciences Institute, Houston, TX., 77225, USA.

Norepinephrine may be involved in the physiology of anxiety and the pathophysiology of anxiety disorders. Panic episodes are associated with increased norepinephrine turnover, and drugs or other manipulations that increase norepinephrine release can precipitate panic in susceptible individuals. Yet, there is little information about noradrenergic function in patients with panic disorder under naturalistic conditions, or about relationships between norepinephrine and clinical variables such as symptoms or treatment response. We examined plasma MHPG and clinical measures including Beck Depression Index (BDI), Hamilton Depression Score (HDS), Zung Anxiety Score (ZAS) and frequency of panic attacks in 28 otherwise healthy patients with panic disorder. The patients were compared to 21 healthy controls matched for age, gender, and time of day. The patients had received no psychotropic medicine for at least one month (26 for at least six months). After evaluation, patients were offered outpatient pharmacologic treatment. An average of eight months later, the evaluations were repeated in 24 patients, of whom 12 had remained in treatment. Initial plasma MHPG was lower in patients than in controls (3.31 ± 1.07 (SD) vs 4.41 ± 1.23 ng/ml; $P < 0.002$). Patients were mildly depressed, with mean HDS of 13.4 ± 5.8, BDI 13.4 ± 8.2, and ZAS 42.2 ± 9.3. Plasma MHPG correlated negatively with BDI ($r = -0.49$; $P < 0.01$). Patients who subsequently remained in treatment had significantly lower initial plasma MHPG than those who did not, but did not differ significantly in clinical measures. Clinical measures improved between initial and follow-up evaluations in treated patients. Plasma MHPG increased in the overall group but not in treated or untreated patients alone. Change in plasma MHPG correlated negatively with symptom change in untreated patients but positively in treated patients. Previous reports have found no difference between plasma MHPG between panic patients and controls; in those studies lower plasma MHPG in panic patients could have been obscured by anticipatory anxiety (in double blind studies of manipulations that provoke panic episodes) or rebound effects from recent drug treatment. If low plasma MHPG in panic disorder represents low norepinephrine turnover under resting conditions, this could lead to compensatory hypersensitivity of postsynaptic noradrenergic receptors and subsensitivity of inhibitory autoreceptors, as has been reported (Albus et al., Clin Neuropharmacol 9 (Suppl 4):359). These changes would predispose patients to labile noradrenergic responses, and are compatible with reports that panic patients have increased behavioral sensitivity to norepinephrine (Charney et al., Arch Gen Psychiat 41:751).

67.17 **ALTERATIONS IN DOPAMINE AND SEROTONIN MEDIATED BEHAVIORS PRODUCED BY LESIONS TO THE LATERAL HABENULA.** Paul M. Carvey, LiChiung Kao, Racheal Amdur and Harold L. Klawans. Dept. of Neurological Science, Rush Presbyterian St. Lukes Medical Center. Chicago, IL 60612.

We have previously presented evidence that bilateral lateral habenula (LHb) lesions induced by kainic acid potentiated stereotypic behavior (SB) induced by dopamine (DA) agonists (Soc. Neurosci. Abstr. 12:2 p.920, 1986). We have extended these preliminary findings in relationship to other DA and serotonin (5HT) mediated behaviors.

Rats and/or guinea pigs with verified LHb lesions exhibit the following behavioral profiles relative to sham-operated controls:

1- Increased SB in response to moderate doses (0.2 to 0.75 mg/kg) of apomorphine [both the guinea pig and rat].
2- Decreased cataleptic response to haloperidol (0.3 mg/kg; hanging grid test) [rats].
3- Trials necessary to learn a conditioned avoidance response were the same as sham-operated controls although the escape latency was reduced [rats].
4- Reduced myoclonic jumping response to LSD (300 mmg/kg) [guinea pigs].
5- Prevention of hypersensitive SB response to apomorphine following chronic haloperidol treatment (0.75 mg/kg/3 weeks [rats] 9 weeks [guinea pigs]). Sham-operated, haloperidol treated animals exhibited the usual hypersensitive response in both species.

In addition to these behavioral effects rats exhibited increased striatal DA and DOPAC content in response to 0.75 mg/kg haloperidol administered acutely. Sham-operated, haloperidol treated animals exhibited decreased DA and increased DOPAC levels in their striata relative to saline treated, unoperated controls.

These results suggest that the LHb participates in the expression of both DA and 5HT mediated behaviors. Because of the unique anatomical connections of the LHb it is possible that this structure plays a central role in regulating, and integrating, the activity of the dopaminergic and serotonergic projection nuclei.

67.18 EARLY PREWEANING MATERNAL BEHAVIOR INFLUENCES THE SENSITIZATION OF AMPHETAMINE-INDUCED STEREOTYPY FOLLOWING HALOPERIDOL IN THE ADULT OFFSPRING. H. L. Schreiber, M. Ortiz*, W. Marquez*, M. Garcia*, M. Gonzales, C. Maez, R. Klein, M. Bibb, and L. Calhoon. Dept. Psychology, New Mexico Highlands University, Las Vegas, NM 87701.

In previous studies (see Abst. Soc. Neurosci., 12:1120,1986), we showed that brief relocation of the dam-plus-litter but not mild direct stress of the litter during the early preweaning period diminished the intensity of haloperidol-induced catalepsy but not morphine-induced catatonia in adulthood. The present study investigated the effect of these early manipulations on various drug-induced behaviors, especially the sensitization of amphetamine-induced stereotypy seen after repeated haloperidol or morphine administration.

After litter reduction on the day of birth, dams and litters received the following treatments for the next 10 days: the CONTROL group received ordinary care; the DISTURB group had their nestcages placed in a room adjacent to the vivarium for 30 min/day; the EHANDL group received standard early handling, i.e., the pups were removed from their nestcages for 3 min/day; the EH/DISTURB group received early handling first, then the nestcage relocation manipulation. The offspring were weaned and housed in ordinary fashion until, in adulthood, they were assigned in split-litter fashion to receive water, haloperidol (.33 mg/kg), or morphine (3.33 mg/kg) and testing for activity wheel locomotion and open-field/holeboard exploration in counterbalanced fashion (4 days/week; 2 weeks). Then (week 3), rats received water or progressively higher doses of their assigned drug (haloperidol, 0.5, 1.0, and 1.5 mg/kg; morphine, 5, 10, and 15 mg/kg) and forepaw-on-dowel catalepsy testing for 3 days. Finally (48 hrs later), all rats received d-amphetamine (4 mg/kg), were placed in activity wheels for 30 min and then were moved to a clear plexiglass chamber and videotaped for 4 min. Blind observers rated stereotypy.

A significant interaction of early handling by nestcage disturbance by drug history in stereotypy was found, $F(2,72) = 4.27$, $p < .02$. Further analysis indicated that, while a history of haloperidol treatment increased amphetamine-induced stereotypy in all groups, only the DISTURB group showed significantly less stereotypy than the CONTROL group, indicating that this particular early manipulation had diminished sensitization in adulthood. Other results as well as the rationale for considering nestcage relocation a manipulation of maternal behavior will be presented.

67.19 THE EFFECTS OF LOCUS COERULEUS LESIONS ON MONKEY P300-LIKE POTENTIALS. J. A. Pineda, S. L. Foote, and H. J. Neville. Departments of Neuroscience and Psychiatry, University of California, San Diego, La Jolla, California 92093, The Salk Institute, and Scripps Clinic and Research Foundation, La Jolla, CA. 92037

The hypothesis that the noradrenergic locus coeruleus (LC) system participates in the generation and/or modulation of electrocortical activity associated with specific cognitive processes (i.e., P300) was tested by recording event-related potentials (ERPs) in monkeys before and after bilateral LC lesions. Untrained squirrel monkeys (Saimiri sciureus) were presented with auditory stimuli (2 KHz and 6 KHz tones, 40 ms duration, 60 dB above nHL) occurring once a second in a random Bernoulli sequence. One tone constituted 90% of the trials and the other 10%. ERPs were recorded once a week for four weeks pre- and post-lesion from a montage of chronically implanted epidural electrodes. Pre-lesion ERPs included a long-latency potential recorded in response to the infrequent tones and shown by Pineda et al. to be analogous to the human P300 (Electroenceph. clin. Neurophysiol., in press). Lesions were then made by first localizing the LC with glass micropipettes or metal micro- electrodes to record unit activity. Once localized, cathodal current (0.5 mA, 15 sec) was passed through the metal electrode to make an electrolytic lesion. A knife cut was also made by placing the electrode at the anterior pole of the nucleus and moving it 750 um in the medio-lateral dimension. The extent of LC damage was assessed through reconstructions of the lesions from Nissl-stained sagittal sections through the brainstem. Immunohistochemical verification using dopamine-B-hydroxylase and tyrosine hydroxylase antisera as specific markers of noradrenergic neurons and axons and dopaminergic axons, respectively, was also obtained.

The results indicated that damage to LC cell bodies and to the ascending noradrenergic dorsal bundle (DB) fibers resulted in decreased amplitudes of the monkey P300. In contrast, interruption of DB fibers alone did not significantly affect these potentials. Lesions did not affect the amplitude, latency, or surface distribution of shorter latency potentials such as P52, N106, and P172 or the temporally overlapping N250-900. The specificity of this effect supports the hypothesis that LC activity in response to surprising and attention-eliciting events produces a behavioral state that is a necessary precondition for the generation or modulation of P300-like activity. 67.20 A PARTIAL REVERSAL OF AMPHETAMINE ANOREXIA AFTER INJECTION OF DOPAMINE ANTAGONISTS INTO THE NUCLEUS ACCUMBENS. G. J. Mogenson and M. Wu.* Dept. of Physiology, University of Western Ontario, London, Ontario, Canada N6A 5C1.

Food intake is reduced substantially by amphetamine, a classic anorectic compound. Since amphetamine releases dopamine from axon terminals and blocks the reuptake of this neurotransmitter, it appears that amphetamine anorexia is dopamine-mediated. Consistent with this suggestion is the observation that amphetamine anorexia is reduced or blocked by the systemic administration of dopamine antagonists (Burridge and Blundell, Neuropharmacology, 18:453-457, 1979). The present study was undertaken to investigate whether or not the administration of dopamine antagonists (haloperidol and sulpiride) into the nucleus accumbens, which receives dense dopaminergic projections, also reduced amphetamine anorexia.

Rats were prepared with chronic bilateral cannulae into the accumbens and adapted to a 3 hr feeding schedule which followed 21 hr of food deprivation. Intraperitoneal administration of amphetamine sulphate (2 mg/kg) 10 to 30 min before the feeding period reduced food intake by 70-80% (from 14-18 g to 3-6 g). The effects of bilateral injections of haloperidol (2.5 nmoles in 0.5 ul) into the accumbens on this amphetamine anorexia were compared to bilateral injections of the lactic acid vehicle. Food intake during the first 60 min was 8.58±1.58 g after the administration of haloperidol compared to 3.63±0.66 g after the administration of lactic acid ($t=3.21$, $p<0.02$). However, injections of haloperidol into caudate nucleus did not influence the amphetamine anorexia. The effects of bilateral injections of sulpiride (0.2 ug in 0.5 ul) into the accumbens were also compared to bilateral injections of saline vehicle in a second series of rats. Food intake during the first 60 min was 9.55±1.07 g after the administration of sulpiride compared to 5.45±0.82 g after the administration of saline ($t=3.73$, $p<0.02$).

These observations implicate the dopamine projections to the nucleus accumbens in amphetamine anorexia. Since these dopamine projections have also been shown to contribute to the hoarding of food (Kelley and Stinus, Behav. Neurosci., 99:531-545, 1985) it is of interest to investigate the mechanisms further.

68.1 PROGESTERONE RECEPTOR INDUCTION AND SEXUAL BEHAVIOR BY DIFFERENT ESTROGEN TREATMENT IN MALE AND FEMALE RATS.

H. Coirini* and B. S. McEwen. (SPON:C.Harding). Laboratory of Neuroendocrinology, Rockefeller University, New York, N.Y. 10021.

Sex differences in behavioral response to estrogen (E) and progesterone (P) in rat have been correlated with different levels of estrogen-induced progesterone receptors (CPR) in hypothalamic (HYP) nuclei such as the periventricular preoptic area (PVPOA) and the ventromedial nuclei (VMN) where large sex differences were found. In this study we investigated the possibility that this dimorphism may depend on the E dose used for CPR induction. Repeated daily administration of 10 µg of estradiol benzoate (EB)/day for 3 days produced higher levels of CPR in female than in male hypothalamus-preoptic area (HPOA), while single injections of 2 or 8 µg of EB which are sufficient to facilitate estrous behavior in females do not produce significant sex differences in HPOA. Other authors using a treatment of 3 days of Silastic capsules filled with 10% or 100% estradiol (E2) were able to find significant sex differences in CPR in VMN and arcuate nucleus (ARC) with the lower dose. We measured the levels of CPR in discrete HYP nuclei in adult male and female rats following of 6, 24 and 48h of E2 in Silastic capsules and also measured the feminine sexual behavior caused by these treatments 2h after removal of the implants and 2h following an injection of 0.5 mg P.

CPR levels increased with the time of E2 exposure. Sex differences appear in the same areas at defined times of E2 treatment; e.g. PVPOA showed a significantly higher CPR levels in females (33.5 ± 1.8 fmol/mg prot.) than in males (23.9 ± 3.1 fmol/mg prot.) at 48h E2 ($p < 0.05$) while in VMN these differences appear at 24h E2 (F = 24.2 ± 1.1 ;M = 16.4 ± 1.0 fmol/mg prot.) ($p < 0.05$) and 48h E2 (F = 35.3 ± 2.7 ;M = 21.4 ± 1.1 fmol/mg prot.) ($p < 0.01$). The ARC nucleus showed significantly higher CPR levels in males than in females at 24h E2 (M = 29.8 ± 2.1 ;F = 11.3 ± 0.6 fmol/mg prot.) ($p < 0.01$) and 48h E2 (M = 28.5 ± 1.4 ;F = 25 ± 1.5 fmol/mg prot.) ($p < 0.05$). Lordosis behavior also increased monotonically with the E2 dose. Females showed lower lordosis quotient (LQ) with E2 alone than E2 + P; a similar pattern appears for the lordosis quality score (QS). After 48h of E2 treatment, both LQ and QS were maximal. In males, after 48h E2 treatment and after P administration a few showed poor lordosis.

These results suggest that using large doses of E2 for 48h we are able to consistently show a large sex difference of CPR levels in VMN. On the other hand the induction of CPR in ARC nuclei had a slower response in females than in males with a reduction of differences with longer exposure to E2. Sex differences in display of lordosis behavior, which involves VMN as tirsty, may depend in part on sex differences in VMN CPR levels after E2 priming. Supported by NIH TW03617 (HC) and NSO7080 (BMc).

68.2 LACK OF PROGESTERONE-FACILITATED LORDOSIS IN IMMATURE FEMALE GUINEA PIGS MAY BE REFERABLE TO A DEFICIENCY IN HYPOTHALAMIC NUCLEAR PROGESTIN RECEPTOR (NPR) ACCUMULATION.

D.H. Olster* and J.D. Blaustein (SPON: P. Herron). Dept. of Psychology, Neuroscience and Behavior Program, Univ. Massachusetts, Amherst, MA 01003.

Ovariectomized (OVX) neonatal guinea pigs do not exhibit lordosis in response to estradiol benzoate (EB) or EB plus progesterone (P) treatments which are behaviorally effective in OVX adults. This is thought to be due, in part, to a deficiency in the induction of cytosol progestin receptors (CPR) in the mediobasal hypothalamus (MBH) by EB in young females; paradoxically, however, a corresponding decrease in NPR accumulation after P injection in neonates is not observed (Ryer, H.I. and Feder, H.H., Dev. Brain Res. 13:15, 13:23, 1984). The present study was designed to reevaluate neural NPR accumulation in immature and adult guinea pigs and to determine whether inadequate nuclear estrogen receptor (NER) accumulation may underlie the deficiency in CPR induction by EB in the MBH of immature animals, thus contributing to the inability of these animals to display P-facilitated lordosis.

OVX immature and adult (16 days and 9 wks old, respectively, n=7-8/group) guinea pigs were given EB (10 ug) followed by P (0.5 mg) or oil 40 h later, and tested for lordosis by manual stimulation. Confirming the previous report, 85.7% of EB + P treated adults displayed lordosis, whereas none of the immature females responded. Cytosol estrogen receptor levels in the MBH or POA did not differ in the 2 age groups, but CPR concentrations (fmol specifically bound ^{3}H-R5020/mg protein) in the MBH after EB injection (10 ug 40 h earlier) in adults (22 ± 2, n=8) exceeded those observed in immature animals (18 ± 1, n=8). In contrast to the previous report, a significant difference in NPR accumulation in the MBH 2 h after injection of P (0.5 mg) in EB-primed guinea pigs was also observed: 118 ± 13 fmol/mg DNA in adults vs. 68 ± 10 fmol/mg DNA in immature females (n=12/group). Finally, whereas NER accumulation in adult and immature OVX guinea pigs did not differ in the MBH or POA 2 h after a saturating dose (100 ug) of estradiol was administered, it appears that NER saturation is achieved at a lower absolute dose of estradiol in adults (10 ug) than in immature females (50-100 ug).

These data suggest that the absence of P-facilitated lordosis in immature guinea pigs is due to a deficiency in NPR accumulation in the MBH; this, in turn, may be secondary to a deficient induction of CPR by estradiol. Furthermore, the results suggest that poor NER accumulation may contribute to the smaller induction of CPR by estradiol in immature, as compared to adult, guinea pigs. (Supported by NS 1927, RCDA NS 00970 and BRSG RR07048, all from the NIH.)

68.3 DILUTE ESTRADIOL IMPLANTS, RECEPTIVITY AND PROGESTIN RECEPTOR INDUCTION IN THE VENTROMEDIAL HYPOTHALAMUS OF THE FEMALE RAT.

E. T. Pleim*[1], T. J. Brown[2], A. E. Xagoraris*[1], N. J. MacLusky[2], A. M. Etgen[3] and R. J. Barfield[1]. [1]Dept. of Biol. Sci., Rutgers U., New Brunswick, NJ, [2]Dept. of Obst. and Gyn., Yale Medical School, New Haven, CT, and [3]Dept. of Psychiat. and Neurosci., Albert Einstein College of Medicine, Bronx, NY.

The hypothesis that cell bodies of the ventromedial nucleus of the hypothalamus (VMN) constitute an essential neural substrate for the hormonal induction of female sexual behavior is supported by results from both behavioral and biochemical studies. Dilute estradiol (E_2) implants very near or in the VMN have been reported to prime female sexual behavior in rats. Induction of cytosolic progestin receptors (PRc) in hypothalamic blocks have been correlated with facilitation of receptive behavior. These studies have been hampered by the need to flood the system with supraphysiological levels of E_2 and/or to pool animals to allow measurement of PRc. The Palkovits punch microassay allows measurement of PRc in discrete CNS nuclei; induction in VMN (and other areas) is now detectable with E_2 doses in the physiological range. We combined dilute E_2 implants with the punch assay to examine VMN-PRc and receptive behavior in individual animals.

OVX female Long-Evans rats were given bilateral guide cannulae aimed at the area of the VMN, and primed for 3 days with either: 1) blank implants + oil, 2) blank implants + 0.5 ug estradiol benzoate (s.c.), 3) 0.4% E_2 implants, or 4) 2.0% E_2 implants. On day 4 all rats were injected s.c. with progesterone (P) and tested for receptive behavior. The following week they received the same priming treatments and were sacrificed on day 4 without P injection. Frozen brains were sectioned (300 um), cannulae locations were determined, and the VMN punch-dissected using a 1000 um needle and assayed for PRc.

High average LQs were seen in all groups but group 1. VMN PRc induction was higher in groups 2 and 4 than in group 3. PRc levels in both E_2 implanted groups were higher than in the oil treated controls. LQ scores were higher in the animals implanted with E_2 in the rostral VMN than was the case with more caudally placed implants. With the 0.4% E_2 implants (group 3) LQ was not positively correlated with VMN PRc induction, indicating that PRc levels in the entire VMN are not a good predictor of female sexual behavior in response to local E_2/ systemic P treatment. These results suggest that E_2 exposure of only a subset of neurons in the area of the VMN may be sufficient for activation of lordosis behavior. The positive correlation between rostro-caudal implant placement and LQ suggests that a particularly sensitive site for the activation of this behavior may lie within or near the rostral VMN. (Supported by NIH grants NS 07807 to TJB, MH 36041 to AME, and HD 04484 to RJB).

68.4 AN ULTRASTRUCTURAL AND MORPHOMETRIC STUDY OF THE ARCUATE NUCLEUS IN FEMALE RAT BRAIN FOLLOWING ESTRADIOL TREATMENT.

K.J. Jones, D.W. Pfaff, and B.S. McEwen. The Rockefeller University, New York, NY 10021.

We have demonstrated that a short (2 h) or a discontinuous (2h on/ 7hr off/ 2 hr on) schedule of estradiol (E2) administered to ovariectomized (OVX) rats results in dramatic changes in nuclear ultrastructure in neurons within a brain region critical for controlling reproductive behavior, the ventromedial hypothalamic (VMN) nucleus (Jones et al., J. Comp. Neurol., 1985). These changes are consistent with alterations in RNA synthesis and with the hypothesis that E2 acts in a cascade manner to affect reproductive behavior. More recent molecular data (Jones et al., Molec. Cell Endocrinol., 1986; Molec. Brain Res., 1987) suggest that E2 may act in the VMN and arcuate nucleus (ARC) through mechanisms partly unique to each area. To examine this hypothesis, we ultrastructurally and morphometrically analyzed the early and discontinuous effects of E2 action on neurons within the ARC, a brain region involved in the endocrine components of reproduction. E2 capsules were implanted in OVX rats under the time courses outlined above, with OVX rats serving as controls. The rats were perfused, ARC groups dissected with the aid of a vibratome, and the tissue blocks processed for routine TEM. For EM work, 25 micrographs per rat were collected, for a total of 300 neurons. For morphometry, computerized image analysis was used to collect nucleolar, nuclear, and somal area, and nuclear perimeter and shape from randomly selected 1 um sections through the ARC. The data were analyzed with 2-way ANOVA and the Student-Newman-Keuls test at $p < 0.05$. The results were quite different from the effects of early and discontinuous E2 on VMN neurons. No ultrastructural changes in the nucleolus, nucleus, or RER were noted with either hormone treatment in the ARC. No alterations in nucleolar, nuclear, or somal size, or nuclear shape or envelope length were found. These results suggest that the VMN is more sensitive and exhibits a faster response to E2 than the ARC. The regional differences provide further evidence in support of the hypothesis that estradiol-concentrating brain regions are not homogeneous in their response to steroid hormone administration, and may reflect the functional differences the VMN and ARC subserve in the neural control of reproduction. Supported by grants MH15125 (KJJ), HD05791 (DWP), NSO7080 (BSM).

68.5 REGIONAL SEX DIFFERENCES IN NUCLEAR ESTROGEN BINDING IN THE RAT HYPOTHALAMUS AND PREOPTIC AREA. T.J. Brown and N.J. MacLusky. Dept. of OBS/GYN, Yale University School of Medicine, New Haven, CT 06510.

Numerous studies have demonstrated sex differences in neuroendocrine and behavioral responsiveness to estrogen and progesterone exposure in the adult rat. These sex differences have been correlated with a lower level of estrogen-induced progestin receptors in the periventricular region of the preoptic area (PV-POA) and the ventromedial nucleus of the hypothalamus (VMN) of the male, as compared to the female. To determine if sex differences in estrogen action within these two regions of the brain could be due to a sex difference in nuclear estrogen receptor concentrations, we measured nuclear estrogen binding in discrete microdissected regions of the hypothalamus and preoptic area from gonadectomized/adrenalectomized (GDX/ADX) male and female rats. Rats were treated with a single i.v. injection of 3.6 μg estradiol (E_2)/Kg b. wt. or 36 μg E_2/Kg b. wt. 1 h prior to sacrifice. Animals were perfused with 10% DMSO and their brains were removed and frozen onto cryostat chucks. Serial sections (300 μm thick) were prepared, and the PV-POA, medial preoptic nucleus (mPON), arcuate-median eminence region (ARC-ME) and VMN were removed from the sections using a 500 or 1,000 μm diameter steel punch. Cell nuclei were isolated, extracted with 0.4M KCl and estrogen binding assayed in the nuclear KCl extracts by exchange with 2 nM [^{3}H]E_2. Similar results were obtained with the two dose levels of E_2. Higher levels of estrogen binding were observed in the PV-POA and VMN of the female than the male (PV-POA 3093 ± 154 vs. 1919 ± 95 fmol/mg DNA; VMN 1594 ± 58 vs. 1062 ± 32 fmol/mg DNA, respectively), with a more modest sex difference in estrogen binding in the mPON (1730 ± 113 vs. 1364 ± 80 fmol/mg DNA) (Means ± SEM; N = 9-10). No significant sex difference in nuclear E_2 binding was observed in the ARC-ME. The sex differences in the PV-POA, mPON and VMN do not appear to result from a difference in the retention of estrogen receptors in the cell nuclear fraction: the magnitude of the sex differences in estrogen binding was similar at both 1 and 2 h after E_2 injection. Scatchard analysis of saturation binding data revealed that these sex differences in nuclear estrogen binding reflect a difference in the number of binding sites rather than in binding affinity for [^{3}H]E_2. Parallel studies examined the distribution of estrogen binding sites in the brains of male and female rats using quantitative autoradiography. GDX/ADX rats were administered a saturating dose of 11β-methoxy-16α-[^{125}I]iodoestradiol (sp. act. 40-50 Ci/mmol) and killed 1 h later. Thin cryostat sections (10 μm) were cut through the preoptic region and hypothalamus, exposed against LKB ultrafilm for 3-4 weeks and the resultant autoradiograms quantified densitometrically. Results were consistent with the biochemical studies, indicating a sex difference in estrogen binding in the ventrolateral portion of the VMN and in the medial and periventricular regions of the preoptic area.

These results demonstrate regional sex differences in nuclear estrogen binding which may, at least in part, underly sex differences in responsiveness to estrogen. Supported by NIH grants HD13587 and NS07807.

68.6 UNILATERAL LESIONS OF THE VENTROMEDIAL NUCLEUS OF THE HYPOTHALAMUS DISRUPT LORDOSIS IN FEMALE RATS. Susan B. Greene* and Pauline Yahr. Department of Psychobiology, University of California, Irvine CA 92717.

The ventromedial nucleus (VMN) of the hypothalamus plays a critical role in the hormonal induction of lordosis in female rats. The present study tested the hypothesis that female sexual behavior requires bilateral hypothalamic control.

Ovariectomized Sprague-Dawley and Long-Evans female rats were tested six times for female sexual behavior. At 48 and 24 hr before each test, each female was injected with estradiol benzoate (EB). Six hours before each test, the females were injected with 500 ug progesterone. Progressively decreasing doses of EB were administered until the mean lordosis quotient (LQ) fell below the threshold of 70. For the first test, the first injection was 2 ug EB and the second was 1 ug EB (2/1 ug). By the sixth test, the females received either .5/.5 ug or .2/.2 ug EB. Within each strain, the females were randomly divided into three groups. One group received a left VMN lesion. The second group received a right VMN lesion. The third group was the sham-operated controls. The animals were retested for female sexual behavior 2, 6, 10, and 14 days after the lesions at their assigned threshold dose. On day 18 after the lesions, all females were tested with 2/2 ug EB.

At both the threshold and 2-ug doses, unilateral lesions of the VMN resulted in severe deficits in lordosis compared to the effects of sham operations. At the threshold dose, mean LQ scores after left, right or sham lesions were: 17.9 ± 6.4, 32.1 ± 8.0 and 65.9 ± 8.7, respectively [$F(1, 34) = 18.26$, $p < .001$]. With 2 ug EB, the means were: 56.2 ± 11.9, 60.0 ± 11.9 and 91.4 ± 3.8, respectively [$F(1, 34) = 9.27$, $p < .005$]. The right and left lesions were both effective and there were no differences between strains. At the threshold dose, the deficits produced by the unilateral lesions were as severe as those reported after bilateral VMN lesions. At the 2 ug dose, the unilateral lesion deficits were bimodally distributed with 36% of the females having an LQ ≤ 20 and 54% having an LQ ≥ 80. Only 2 of the 26 lesioned females scored in the midrange. Our data indicate that when the estrogen dose is close to the threshold for eliciting lordosis, the VMN must be intact on both sides of the brain, in most female rats, for the behavior to occur; i.e., bilateral hypothalamic control appears necessary. When the estrogen dose is increased, about half of the females with unilateral VMN lesions respond as well as normal females. Thus under these conditions, unilateral hypothalamic control is often sufficient. Yet a third of the females with unilateral VMN lesions can not respond even to a large dose of estrogen. In these females, hypothalamic control of lordosis may be unilaterally organized.

68.7 SMALL NEOCORTICAL LESIONS IMPAIR THE PERFORMANCE OF LORDOSIS BY GOLDEN HAMSTERS. A. C. Thomas* and J. D. Rose. Department of Psychology, University of Wyoming, Laramie, WY 82071.

Substantial differences have been identified in the subcortical structures controlling lordosis in rats and golden hamsters. These differences in neurobehavioral control appear to extend to the role of the neocortex as well. Cortical ablation or spreading depression facilitates the performance of lordosis in rats, but in hamsters, spreading depression impairs lordosis responding. The present study utilized small, localized neocortical ablations to examine the possiblity that certain cortical regions play a relatively greater role in the control of hamster lordosis than other regions. Ovariectomized golden hamsters in which lordodis responding was induced by sequential injection of estradiol benzoate and progesterone, were tested twice on a test battery evaluating lordosis in response to a sexually active male, and three tests with manually-applied somatosensory stimulation (lordosis maintenance, lordosis elictation latency and lordosis interruption latency). The animals then received, under barbiturate anesthesia, small aspiration lesions of one of the following types: 1) the lumbosacral projection zone, bilaterally; 2) the lumbosacral projection zone, unilaterally; 3) the central face projection zone, bilaterally; 4) the occipital pole, bilaterally; or 5) sham lesions. After a 4-7 day recovery period, the animals were given the battery of lordosis tests three times, at weekly intervals, to assess the effects of the cortical lesions. The results showed that these lesions impaired lordosis responding, but largely without respect to the cortical locus of the lesions. At least 2 hamsters from each of the 4 lesion conditions exhibited complete failure of lordosis in one of the three postlesion tests. Analysis of variance revealed the following lesion effects on the separate response measures: 1) maintenance of lordosis in response to flank stimulation was reduced by all cortical lesions; 2) elicitation of lordosis by stimulation of the lumbar midline region was impaired by all cortical lesions; and 3) interruption of an ongoing lordosis response by face tactile stimulation was impaired by lesions of the face projection region. These lesion effects demonstrated an important degree of neocortical control over a hormone-dependent, species-typical reproductive behavior. The high degree of sensitivity of golden hamster lordosis to localized cortical damage may result from the more sustained nature of the response and broader, more sensitive tactile control of the response than that seen in rats. In addition, these results raise the possiblity that the neocortex may be an important substrate for the action of ovarian hormones in the induction of hamster lordosis. Supported by NIH Grant NS13748.

68.8 **DEFICITS IN FEMALE SEXUAL BEHAVIOR IN THE GOLDEN HAMSTER FOLLOWING KAINIC ACID LESIONS IN THE LATERAL SEPTAL AREA.** G.A. Myatt* AND D.M. Nance. (SPON: D.G. Gwyn). Department of Anatomy, Faculty of Medicine, Dalhousie University, Halifax, N.S., Canada

Patterns of female sexual behavior in the hamster are qualitatively different from those observed in the rat. Female hamsters demonstrate tonic immobility and a sustained lordotic response that can last for several minutes following minimal stimulation from the male while in rats, the lordotic response is highly dependent upon continued stimulation from the male and lasts for only a few seconds following a mount or intromission. Also, the hamster requires both estrogen and progesterone priming in order to display female sexual behavior but the rat can show lordotic behavior following treatment with estrogen alone. Electrolytic lesions in the lateral septal area of female rats produce a facilitation in female sexual behavior and increased behavioral sensitivity to estrogen. However, lesions in the lateral septal area produced by the neurotoxin kainic acid (KA) result in deficits in female sexual behavior following estrogen and progesterone treatment (P.B.&B. 18; 605. 1983). Given these major differences in female sexual behavior between the rat and hamster, we have examined the effects of KA lesions in the lateral septal area of hamsters on patterns of female sexual behavior. Adult female golden hamsters (120-160 g) were ovariectomized and subsequently tested twice for female sexual behavior at two week intervals prior to receiving brain surgery. For all behavior tests, animals were injected sc with 60 μg of estradiol benzoate/kg per day for two days and 0.5 mg of progesterone three hours prior to the behavior test on day three. Behavior tests consisted of placing the test animal in a male's home cage for 10 minutes and recording the latency to the first lordosis (maintaining a lordotic posture for atleast 5 sec), length of the longest single bout of lordosis (300 sec maximum) and total lordosis duration for the entire test. All animals were then randomly assigned to either lesion or sham operated control groups. Animals were deeply anesthesized with Somnotol and either KA (0.375 μg in 0.5 μl) or saline (control) were infused bilaterally into the lateral septal area at the rate of 0.1 μl/minute. The microsyringe was left in place an additional 10 minutes before removal. All animals were subsequently tested again for female sexual behavior as described above at one and three weeks following brain surgery. At the end of the test, the animals were perfused and the brain lesions verified histologically. There were no differences between the lesion and control groups for the two pre-lesion behavior tests. Similarly, performance of the sham operated animals were comparable between the post- vs pre-lesion tests. However, following brain surgery, the KA lesioned animals were significantly different from the sham operated controls on all behavioral measures and for both tests. Relative to the saline group, the KA lesioned animals showed significantly longer latencies to the first lordosis, significantly shorter single bouts of lordosis and significantly shorter total duration of lordosis for both behavior tests. Thus, despite the large species differences in the display of female sexual behavior between rats and hamsters, KA lesions of the lateral septal area produce similar deficits in female lordotic behavior. Therefore, in addition to the known inhibitory role of the septal region, this brain area also exerts facilitory control on female sexual behavior in both rats and hamsters. Supported by MRC of Canada.

68.9 ALPHA-1 AND ALPHA-2 NORADRENERGIC RECEPTORS ARE INVOLVED IN REGULATION OF LORDOSIS BEHAVIOR IN THE GUINEA PIG. P.A. VINCENT AND H. H. FEDER. INSTITUTE OF ANIMAL BEHAVIOR AND DEPT. OF BIOLOGICAL SCIENCES, RUTGERS UNIVERSITY, NEWARK, NJ 07102.

Modulation of lordosis behavior by stimulation of noradrenergic receptor subtypes was examined in ovariectomized, estradiol benzoate (10 ug) primed guinea pigs. In the first experiment, systemic administration of the alpha-2 agonist, UK14304-18 (0.01, 0.5, or 0.1 mg/kg, Pfizer Central Research), produced a significant increase in lordosis behavior when these responses were compared with responses seen in control animals injected with saline. In a second experiment, animals were injected systemically with the alpha-1 agonist methoxamine (0.5 mg/kg), UK14304-18 (0.5 mg/kg), or both drugs given together. Methoxamine or UK14304-18 administered alone facilitated lordosis in only a moderate percentage of animals (17% and 39%, respectively). However, when both drugs were given together, 76% of the animals became sexually receptive. A third experiment showed that lordosis behavior facilitated by UK14304-18 could be attenuated by the administration of the alpha-2 antagonist, idazoxan (2.5 mg/kg). Only 29% of sexually receptive animals continued to show lordosis after they received idazoxan. The results obtained from these and previously reported experiments suggest that both alpha-1 and alpha-2 noradrenergic receptors are involved in regulation of lordosis behavior in the guinea pig.

68.10 NORADRENERGIC FACILITATION OF FEMALE SEXUAL RECEPTIVITY IS INDEPENDENT OF PROGESTIN RECEPTOR STIMULATION. J.E. Thornton, P.A. Vincent and H.H. Feder. Institute of Animal Behavior and Department of Biological Sciences, Rutgers University, Newark, NJ 07102.

The noradrenergic (NE) system plays a role in the modulation of lordosis behavior in the female guinea pig. The alpha NE agonist clonidine facilitates lordosis whereas NE synthesis blockers and alpha NE antagonists decrease lordosis behavior. Alpha NE antagonists also decrease hypothalamic progestin receptor levels. Since progestin receptors play a strong role in the lordosis behavior shown by female guinea pigs, the present study determined whether the alpha NE agonist clonidine facilitates lordosis by stimulating progestin receptors.

Ovariectomized adult Hartley strain female guinea pigs were given a behaviorally subthreshold dose of estradiol benzoate (EB: 10 ug). In Experiment 1, females were then given either the progestin receptor antagonist RU486 (10 mg/kg, Roussel-Uclaf, N=11) or vehicle (N=13) at hr 39 and then all were given the NE agonist clonidine (1mg/kg) at hr 40. In Experiment 2, females were given RU486 (10 mg/kg, N=10) or vehicle (N=10) at hr 39 and then progesterone (P; 0.1 mg) at hr 40. All drugs were injected subcutaneously. Females were checked for lordosis just before clonidine or P and then for 14 hours afterwards.

The progestin receptor antagonist RU486 did not decrease the lordosis induced by EB + the alpha NE agonist clonidine. There was no effect on the number of animals responding, the duration of the response or the mean or maximum response. In contrast, RU486 did significantly decrease all of these measures in animals treated with EB + P. This indicates that although P acts through progestin receptors to facilitate lordosis, the alpha NE agonist clonidine does not.

68.11 REGULATION OF MONOAMINE OXIDASE ACTIVITY (MAO) IN THE HYPOTHALAMUS V.N.Luine and J.C. Rhodes*Dept. Psychology, Hunter College and Rockefeller University, New York, N.Y. 10021.

Monoaminergic endings within preoptic-hypothalamic nuclei participate in gonadal hormone regulation of sexual behavior and gonadotropin secretion. In this study the possible involvement in neuroendocrine regulation of the enzyme responsible for catabolism of serotonin and norepinephrine, MAO, was investigated. MAO activity was measured in gonadectomized (GDX) male or female rats and GDX rats receiving estradiol benzoate (EB) at a dose (5 ug for 42 hr.) which was insufficient to induce lordosis. Activity was also measured in males and females when the same EB dose was followed by 500 ug of progesterone (P). In the EB + P groups, maximal lordosis responding was measured in females, but not males, 3 hrs after P. All rats were sacrificed approximately 15 min following behavioral testing, and MAO activity was measured in micropunched samples of brain. EB increased MAO activity of females in the ventromedial nucleus (VMN) and midbrain central gray (MCG) but not in the arcuate-median eminence (Ar-ME), medial preoptic nucleus (mPOA), or dorsal raphe (DR) cell body region. Responses to EB in males showed a totally different pattern since EB decreased activity in the VMN and Ar-ME and did not affect activity in the other areas. Activity in EB + P treated females was decreased in the VMN and mPOA as compared to EB treatment alone. In males, P administration after EB priming did not affect activity in preoptic - hypothalamic areas, but activity in the DR decreased. These sexually dimorphic responses of MAO to gonadal hormones may be related to serotonergic regulation of lordosis.

The sensitivity of MAO to ovarian hormones suggested that MAO activity, like monoaminergic activities, may show flucuations over the estrous cycle. Thus, activity was measured in females who showed repeated 4-day estrous cycles. Consistent with the pattern of changes found after P administration to EB primed females, activity of MAO in the VMN and POA, but not the Ar-ME, was decreased on estrus. In conclusion, the location of changes in activity of MAO over the estrus cycle and the sexually dimorphic response of MAO to hormones strongly support a role for Type A MAO in monoaminergic regulation of hormone dependent sexual behavior and gonadotropin secretion. (Supported by NIH Grant HD12011).

68.12 ESTRADIOL IMPLANTS IN THE RAT STRIATUM STIMULATE LOCOMOTOR ACTIVITY IN RUNNING WHEELS. Edward J. Roy. Psychology Department, University of Illinois, 603 E. Daniel St., Champaign, IL 61820.

Estradiol (E2) affects several aspects of dopaminergic function in the striatum, including sensorimotor performance (Joyce et al., 1982; Becker et al., 1986). Estradiol also has pronounced effects on the spontaneous activity of rats in running wheels, causing a sharp increase in activity on the night of proestrus. This latter response has been thought to be mediated by the preoptic area (POA), because implants of E2 in the POA of ovariectomized (OVX) animals increase activity, whereas implants in the basal hypothalamus do not (Wade and Zucker, 1970). We report here that implants of estradiol into the striatum also increase activity, apparently without spreading to the POA. Adult Long-Evans female rats were housed in cages with activity wheels attached, beginning at 6 weeks of age. Ten rats that displayed regular 4-day cycles of activity for 5 weeks were ovariectomized and implanted with a 23 g guide cannula (coordinates: AP 0.8 mm from bregma, L + 2.2 mm, DV - 2.5 mm from dura). Five days later hormonal treatments were begun. Intracerebral treatment for 6 rats was a 28 g inner cannula extending 2 mm below the end of the guide cannula, filled with either estradiol (3:7 E2:cholesterol) or cholesterol. Implants were left in place for 5 days and then removed. After 3 days animals were given the opposite treatment. Four animals were given injections of either estradiol benzoate (EB, 2.5 ug s.c.) or sesame oil. Implants of estradiol in the striatum caused increases in running wheel activity with a similar delay and to a similar extent as injections of systemic EB. To determine the spread of estradiol from the site of implantation, animals were treated with the same application of E2. After 3 days, animals were sacrificed, the brains were sectioned coronally, and cuts made along the cannula track and below to the ventral surface. Estradiol was extracted and assayed by RIA. E2 was present at the tip of the cannula and along the track of the cannula dorsally. No estradiol was detectible in the POA (the assay sensitivity was 1-2 nM E2 in tissue). These results raise the possibility that the effect of estradiol on locomotor activity in running wheels is a consequence of actions in the striatum rather than the POA, since implants of E2 into the POA might provide E2 to the striatum via diffusion up the cannula track. If estradiol does affect activity by actions in the striatum, it would be an example of hormonal effects on behavior by non-genomic actions of estradiol, since classical estrogen receptors are not present in the striatum.

68.13 EFFECTS OF PROGESTERONE AND NALTREXONE ON SEROTONIN TURNOVER. D.L. Allen and V.N. Luine.
Rockefeller University, New York, NY 10021.

Gonadal steroids are important regulators of gonadotropin secretion and sexual behavior. Some of the actions of progesterone on LH secretion and sexual behavior are thought to be mediated by serotonin (5-HT). By measuring the increase in levels of 5-hydroxytryptophan (5-HTP) after inhibition of 5-HT synthesis by NSD-1015, King et al. (Neuroendo. 42:344, 1986) reported that progesterone (P) increased the synthesis of 5-HT in preoptic area-anterior hypothalamus, but had no effect in the medial basal hypothalamus. An increase in 5-HT turnover in the medial preoptic area (POA) was also reported after measuring the increase in levels of 5-HT after inhibition of degradation by pargyline. However, in the ventromedial nucleus of the hypothalamus (VMN), P decreased 5-HT turnover. The present study measured 5-HT turnover after P in discrete brain nuclei using the NSD-1015 method in order to localize the effect seen by King et al., and to compare results with studies using the pargyline method to determine turnover. In addition, we studied the effect of naltrexone (NTX), which like P affects gonadotropin secretion and sexual behavior, on 5-HT turnover.

Female rats were ovariectomized and five days later injected with 5 ug estradiol benzoate. After forty-two hours, saline, NTX (3mg/kg) or P (500 ug) was injected, and rats were sacrificed three hours later. NSD-1015 (50 mg/kg) was injected 30 minutes before decapitation. Discrete brain nuclei were removed by the Palkovits "punch" technique and levels of 5-HTP in hypothalamic and preoptic nuclei or the midbrain central gray were analyzed by HPLC. In the medial preoptic area (POA), both NTX and P increased the accumulation of 5-HTP. Neither treatment altered 5-HTP accumulation in the VMN, dorsomedial nucleus, arcuate-median eminence, midbrain central gray, or anterior hypothalamus.

The action of naltrexone on sexual behavior and gonadotropin secretion may be mediated in part by changes in 5-HT turnover in the POA. The effect of progesterone on 5-HTP accumulation in the preoptic area-anterior hypothalamus reported by King et al. can be localized to the POA. Our data agree with King on the lack of an effect in the basal medial hypothalamus, which contrasts with the effect in the VMN seen using the pargyline method. Therefore, progesterone may be altering serotonin turnover in the VMN without affecting its synthesis. (Supported by NIH Grant HD12011 and NIH Training Grant).

68.14 THE EFFECTS ON AGGRESSION AND SEXUAL BEHAVIOR OF BILATERAL ESTROGEN IMPLANTS IN THE FOREBRAIN OF FEMALE SYRIAN HAMSTERS. M.R. Sterner and R.L. Meisel. Purdue University, W. Lafayette, IN 47907.

Earlier studies have implicated several forebrain sites as potential areas for estrogen action on sociosexual behavior in female Syrian hamsters (e.g. Takahashi and Lisk, Physiol & Behav, 34:233). It is not clear whether the decline in aggression reported in these studies is the direct result of hormonal treatment or whether it is a by-product of the testing situation; a receptive female being unlikely to attack a potential mating partner. To avoid this problem, we tested implanted animals with a female stimulus partner (aggression test) as well as an experienced male stimulus partner (sexual receptivity test) to maximize the expression of both aggression and sexual behavior.

In this study, female Syrian hamsters were singly housed for 3 weeks before ovariectomy and guide cannulae implant. Bilateral cannulae were aimed at 1)the ventromedial hypothalamus (VM, n=17), 2) the anterior hypothalamus (AH, n=10), or 3) the medial amygdala (AMY, n=7). After recovering, implanted animals received a baseline behavioral test with no hormone present, followed by a test 3-4 days after intracranial application with 100% powdered estradiol(E_2). Following this test, implant animals received a systemic injection of progesterone (P; 500 ug in 0.1cc oil) followed by the final behavioral test 5-6hrs later.

Animals with VM implants showed a significant decline in the number of attacks on the E_2 + P aggression test as compared to the E_2 alone condition ($p<0.01$). There was no significant difference between the baseline and E_2 only test. The proportion of VM animals displaying lordosis on the receptivity test after E_2 + P was 70.6% (12/17). Animals in the AH group showed a decline in aggression following P which approached significance ($p<.06$). For the AH group, 30% (3/10) of the animals responded with lordosis; however the cannulae of these three receptive animals were located right at the border between the AH and the VM. Finally, animals in the AMY group showed no significant hormone effects on aggression, while 28.6% (2/7) responded with lordosis. These results suggest that the VM is the site most sensitive to E_2 action on sociosexual behavior in the Syrian hamster.

68.15 PRIMING EFFECTS OF MEDIAL PREOPTIC AREA IMPLANTS OF ESTRADIOL ON MATERNAL BEHAVIOR. H.B. Ahdieh, A.D. Mayer* and J.S. Rosenblatt*. Institute of Animal Behavior, Rutgers University, Newark, N.J. 07102.

Previous studies have shown that female rats exposed to low circulating levels of estradiol (E2) during pregnancy, or ovariectomized and treated with estrogen and progesterone for 16 days, exhibit maternal behavior in response to systemic low doses (5 ug/kg) of estradiol benzoate (EB). Nonpregnant ovariectomized-hysterectomized (HO) females require large (100-200 ug/kg) doses of EB to exhibit maternal behavior. The present study investigated whether dilute bilateral implants (1%) of E2 in the medial preoptic area (MPOA) of nonpregnant HO females for 48 hr would enable them to exhibit maternal behavior in response to the low systemic dose of EB. A 1% E2 implant which elevated MPOA nuclear estrogen receptor concentrations to day 16 pregnancy levels resulted in the onset of short-latency maternal behavior 48 hr after systemic treatment with 5 ug/kg EB. The E2 implants in the absence of EB, or cholesterol implants with EB, were ineffective in enhancing maternal behavior. The results support both a priming and triggering role for estrogen in the stimulation of maternal behavior.

68.16 COMPLEX OPERANT BEHAVIOR ACROSS THE MENSTRUAL CYCLE IN THE BABOON: A MODEL FOR PERIMENSTRUAL STRESS. M.G. Paule, M.J. Hulstyn* and E.K. Killam*. Division of Reproductive and Developmental Toxicology, National Center for Toxicological Research, Jefferson, Arkansas 72079 and Department of Pharmacology, UCD School of Medicine, Davis, California 95616.

Performance under Incremental Repeated Acquisition (IRA) schedules was monitored in 3 young adult female baboons (Papio papio) across 3 to 8 regular menstrual cycles (26-35 day mean cycle lengths). Menstrual cycle status was scored by days since the beginning of last observed menses and by visual inspection of perineal tumescence (ischial swelling) and correlated with operant performance. The IRA tasks consisted of the acquisition (learning) of a new sequence of lever presses each test day for food reinforcers. Percent task completed (number of correct lever sequences performed/number correct lever sequences possible in a 30-min session) peaked during the peri-ovulatory periods (individual means = 54, 77 and 89, respectively) and declined to significantly lower values perimenstrually in all 3 animals (individual means = 22, 52 and 54, respectively). Efficiencies (correct responses/total responses) were generally unaffected by menstrual cycle status whereas, response rates (lever presses/min) decreased significantly during perimenstrual periods in most cases. These data suggest that complex operant performance in the nonhuman primate may serve as an indicator of hormonally-related changes in CNS function that may model changes in the human CNS now associated with the pre- and/or perimenstrual period. Supported in part by a grant-in-aid of research from The Society of the Sigma Xi and a UCD President's Undergraduate Fellowship.

68.17 COMPARATIVE BEHAVIORAL EFFECTS OF PROGESTERONE AND ALPHAXALONE.
I.G. Fraile*, B.S. McEwen and D.W. Pfaff.
The Rockefeller University. New York, N.Y. 10021

Studies on social behaviors in syrian hamsters have shown a decrease in aggressiveness following treatment with progesterone. The mechanisms by which progesterone may inhibit aggression in hamsters are not clear, but it has been suggested that this effect could be related to the anesthetic properties of progestins. We have addressed this hypothesis by comparing the effects of progesterone and alphaxalone, one of the most potent anesthetic agents in the progestin family, on aggressive and sexual behaviors and on locomotor activity.

Adult gonadectomized male and female hamsters housed singly were used. One week after arrival the animals were tested for their basal aggressive and sexual behaviors. A week later the individuals assigned to the aggression study were injected s.c. with progesterone or alphaxalone at the same dose (1mg/0.2ml oil) during four consecutive days and they were tested on the last two days, 4-5 hours after injection, in a home-away rotation. Pairs tested were of the same sex, receiving the same treatment.

A week after the preliminary test, the individuals in the sexual behavior study were injected s.c. with 10ug of estradiol benzoate, followed 48 h later by s.c. injection of progesterone or alphaxalone (1mg/0.2ml oil). All animals were tested 4-5 h later for their feminine sexual behavior with a control, group-housed, intact male hamster.

In the locomotor activity study the animals were housed individually in a Wahmann activity wheel. After an habituation period the individuals were injected s.c. 4 days with oil and the following 4 days with progesterone or alphaxalone (1mg/0.2ml oil). The activity was quantified 5 h after the injection.

Alphaxalone treatment did not affect the aggressive display of either sex, whereas progesterone decreased the frequency of aggressive postures and increased the latency to attack, as has been reported previously (Physiol. Behav. 39: 225-229, 1987). Alphaxalone induced precopulatory responses (tail-up) in females but failed to promote receptive behavior, while progesterone induced sexual responses in both sexes. Alphaxalone, but not progesterone, decreased the locomotor activity in both sexes 5 h after the injection, although it was statistically significant only in males on days 1 and 2.

Our results show that a potent anesthetic progestin, alphaxalone, s.c.-injected, may decrease locomotor activity slightly, but it does not affect aggressive performance in hamsters. Therefore, the reduced aggressiveness in the progesterone-treated animals is not likely to be related to the hormone's anesthetic or sedative properties.

68.18 THE EFFECTS OF PROGESTERONE ON PREGNANCY-INDUCED AGGRESSIVE BEHAVIOR IN THREE INBRED STRAINS OF MICE. S. Ogawa, Lab. of Behavior Genetics, Univ. of Connecticut, Storrs, CT 06268

Previously, we reported (Soc. Neurosci. Abs., 12, 841, 1986) the variation in plasma levels of progesterone in three inbred strains of mice which differ in the levels of pregnancy-induced aggressive behavior (PIA). In the present study, the effects of supplemental progesterone on PIA were examined.

Nulliparous females from AKR/J, BALB/cN, and DBA/2J (10-11 wks of age) were mated with a CFW male during the night of estrus and placed in an individual cage on the next morning if a vaginal plug was found (Gestation Day 0). On Day 1, they were treated with subcutaneous silastic implants that contained crystalline progesterone. Females from AKR/J received one (1P) or two (2P) 10mm silastic capsules. Females from BALB/cN and DBA/2J received two (2P) or three (3P) capsules. Control mice from each strain received an empty capsule. They were either tested once on Day 5 or tested repeatedly on Days 5, 9, 13 and 17 (N=6-8/group/hormone treatment/strain). Female aggressive behavior (defined as eight different behavioral acts) toward an unfamiliar, olfactory bulbectomized, group-housed CFW male was recorded during a 10-min observation period. Blood samples were taken immediately after the end of behavioral tests on Day 5 or Day 17 for the determination of plasma levels of progesterone by radioimmunoassay.

On Day 5, 2P-treated and 3P-treated BALB/cN and DBA/2J had similar levels of circulating progesterone as 1P-treated (64-74 ng/ml) and 2P-treated (88-98 ng/ml) AKR/J, respectively. Supplemental progesterone treatment failed to elevate the incidence of PIA further in the highly aggressive strain, AKR/J. Levels of PIA in 1P and 2P-treated AKR/J mice did not significantly differ from those in control mice on either days tested. In the moderately aggressive DBA/2J, progesterone increased the levels of PIA across the gestation period and advanced the onset of PIA. A higher percent of animals showed PIA on Days 5 and 9 in progesterone-treated groups than in the control group. Progesterone-treated DBA/2J mice showed the highest levels of PIA on Gestation Day 9, whereas control mice showed very little aggressive behavior on Day 9 and the maximum levels of PIA on Day 13. Progesterone treatment induced aggressive behavior in the nonaggressive BALB/cN strain on Days 9, 13, and 17 but not on Day 5. PIA levels of progesterone-treated DBA/2J and BALB/cN did not reach the levels of AKR/J.

These results suggest that progesterone might have facilitatory probably modulatory, effects on PIA. Progesterone and estradiol sysnergism in the onset of PIA should be investigated in further studies.

Supported, in part, by a grant from the Conn. Research Fnd. to S.C. Maxson and a fellowship from the Univ. of Conn. (S.O.).

68.19 PRENATAL STRESS AFFECTS STRESS-INDUCED AND MORPHINE ANALGESIA IN RATS. C.H. Kinsley, P.E. Mann and R.S. Bridges, Department of Anatomy and Cellular Biology, Laboratory of Human Reproduction and Reproductive Biology, Harvard Medical School, Boston, MA 02115.

Prenatal stress (PS) affects many of the same behaviors which in adulthood are under the influence of opiates and endogenous opioids. For example, aggressive, maternal, regulatory, and sexual behaviors have all been tied to opioid function in the adult. Recently, Hammer (Brain Res. 360: 65, 1985) reported that opiate receptors develop in a sexually dimorphic pattern, and that androgens normally suppress their formation. Prenatal stress results in severe perturbation of the developmental actions of androgens, and therefore, may disrupt both the formation of opiate receptors and accompanying analgesia. We were interested in determining if two forms of analgesia, morphine-induced (opioid receptor mediated), and stress-induced (cold-water swim, CWS, non-opioid) would altered in prenatally-stressed (P-S) male and female rats. Timed-mated Sprague-Dawley females were exposed to heat and restraint stress (three daily half-hour sessions, 0830, 1230, and 1630 h) from days 14-21 of pregnancy. Control animals remained undisturbed throughout pregnancy. All offspring were cross-fostered to untreated lactating dams at birth. Between 100-120 days of age, baseline tailflick latencies were recorded for all animals. P-S and Control animals were exposed to 3.5 min CWS (2^{o}C) and pain thresholds were determined at 30, 60, 90, and 120 min post-swim. P-S females exhibited significantly lower pain thresholds than Control females, whereas P-S and Control males did not differ. Five to six days later, these same animals were assessed for morphine (5.0 mg/kg) analgesia in a three-hour test, tailflick latencies recorded every 30 min. P-S females exhibited significantly greater analgesia following morphine treatment than Control females, whereas P-S males were significantly less analgesic than Control males. These data suggest that one manner in which prenatal stress may be acting to influence adult behavioral potentials is through alterations of endogenous opioid systems. Supported by NIH 5T32-HD-07130, C.H.K. trainee, NIH 5T32-AM-07337, P.E.M. trainee, and by NIMH (RSDA K02-MH00536) and NIH (HD-19789) R.S.B., awardee.

68.20 FEMINIZATION OF MALE SLEEP CYCLE RHYTHMICITY BY PRENATAL STRESS. W. Fishbein and P.F. Bright*. Psychobiology Lab. CUNY, The City College and Graduate School, New York, 10031.

It is generally recognized that differentiation of sexual behaviors depends on the secretion of testosterone by the fetal testes and prenatal stress alters the perinatal release of circulating testosterone with concomitant changes in adult male sexual behaviors (Ward, I.L., Psychoneuroendocrin., 9:13. 1984). Since sleep-cycle rhythmicity is gender specific (accompanying paper at this meeting), we considered that sleep rhythms might also be altered in males born of stressed mothers.

The procedures are identical to those in our accompanying paper except the pregnant dams received 90 min (0730-0900) per day of heat-restraint stress beginning on day 7 of gestation and lasting 14 days. Within 12 hrs postpartum, 6 male and 6 female CF-1 mice were randomly cross-fostered to a nonstressed lactating dam and reared with five other litter mates until weaning. None of the subjects is a sibling or was reared with any other subject. On day 50 EEG and EMG leads were implanted. The animals were placed in a recording chamber and on day 57 connected to a commutator for 72 hrs adaptation; on day 61 sleep-wakefulness cycles were recorded for the next 48 hours.

The prenatally stressed subjects time asleep (or awake) was indistinguishable in the two sexes. Males averaged 11.07 hrs/24 hrs asleep, females 10.22 hrs, ($F(1,10)=2.04$). Despite this similarity, the stressed males slept significantly more than the control males (9.71 hrs), ($F(1,10)=6.25$ $p<.03$), whereas the stressed females were indistinguishable from the control females (9.63 hrs).

Stressed males and females were indistinguishable on all measures of REMS and SWS, as were stressed and control females.

However, the comparisons of the stressed males with normal males revealed that the stressed males spend significantly more time in REMS than control males ($F(1,10)=9.87$ $p<.01$). Moreover, the difference was totally accounted for by a greater number REMS episodes in the stressed males; 2.33/hr, control males 1.60/hr ($F(1,10)=37.14$ $p<.001$), whereas mean duration of REMS episodes was identical. The stressed males were indistinguishable from the control females.

The results imply that sleep-cycle rhythmicity follows the same general rule as reproductive behaviors: the basic plan is inherently female. In the absence of male hormones the genetic male develops a female brain and female sleep-cycle rhythms. Apparently prenatal stress acts to change the organization of rhythmicity as well as reproductive behavior per se. We think it likely that the critical brain region affected is the sexually dimorphic medial preoptic nucleus of the forebrain by gonadotrophic influences.

68.21 DIETARY TRYPTOPHAN RESTRICTION PRODUCES AN UPREGULATION OF THE NEUROENDOCRINE RESPONSE TO INFUSED TRYPTOPHAN IN HEALTHY HUMAN SUBJECTS. P.L. Delgado*, D.S. Charney, L.H. Price, G. Anderson, H. Landis* and G.R. Heninger, (SPON: J. Cooper) Dept. of Psychiatry, Yale Univ. Sch. of Med., New Haven, CT 06508.

Both increases and decreases in tryptophan (TRP) intake can alter brain serotonin (5-HT) levels in laboratory animals. In humans, dietary TRP restriction has been shown to produce mild impairment of attentive performance and to increase subjective reports of negative moods, although effects on brain 5-HT levels or turnover or neuroendocrine effects have not been demonstrated. There is considerable data indicating that prolactin (PRL) release is mediated, via the 5-HT system, and large doses of intravenously infused TRP have been shown to increase plasma PRL in humans. In order to assess the neuroendocrine effects of dietary TRP restriction, a TRP infusion was administered before and during 2 different magnitudes of TRP restriction diets in healthy human subjects. METHODS: The average USA diet contains 1,200 mg TRP per day. Subjects participated in a 7 day TRP restriction diet composed of normal food designed to be nutritionally balanced which contained either 700 mg TRP per day (11 subjects) or 200 mg per day (6 subjects). Within 7 days prior to beginning the diet and on the morning of the 8th day of the diet each subject received an infusion of TRP (100 mg/kg) at 9 a.m. and plasma was collected at regular intervals for assessment of PRL levels using standard RIA methods. Subjects were fasting the 12 hrs. before the 9 a.m. TRP infusion. Total plasma TRP levels were measured by HPLC prior to each TRP infusion. RESULTS: The peak prolactin response (peak minus base $\pm$ SD) before and on the 8th day of the 700 mg/per day diet was respectively, 11.4 $\pm$ 7.9 and 12.2 $\pm$ 8.1 ng/ml (mean, on diet minus prediet = .9 $\pm$ 4.1 ng/ml, NS). On the 200 mg/per day diet all six subjects demonstrated an increased response and the corresponding values were 16.3 $\pm$ 6.3 and 22.0 $\pm$ 5.5 ng/ml respectively (mean, on diet minus prediet = 5.8 $\pm$ 4.1 ng/ml, $p<.03$). The increase of 5.8 ng/ml in the prolactin response during the 200 mg diet was significantly larger than the increase of .9 ng/ml on the 700 mg diet ($p<.03$). Only the 200 mg diet produced a drop (13%) in the 9 a.m. fasting total TRP levels on the day of the infusion. DISCUSSION: The 200 mg per day TRP diet reduced plasma TRP levels and produced an apparent supersensitivity of the PRL response to the TRP infusion. Since the 700 mg per day TRP diet did not reduce plasma TRP levels or produce a change in the PRL response, this is evidence that the observed effect is specific to dietary TRP levels. The 200 mg TRP diet was well tolerated by the healthy subjects. It may be a useful method for studying the role of dietary TRP and modifying the functional capacity of the 5-HT systems in investigations of human medical and neuropsychiatric disorders.

68.22 LEARNING IMPAIRMENT AFTER REVERSAL OF SLIGHT PTU-INDUCED POSTNATAL HYPOTHYROIDISM IN RATS. M. Akaike*, N. Kato, H. Ohno*, T. Kobayashi* and T. Sakaguchi*. Pharma R&D Division, Hoechst Japan Ltd., Kawagoe, Saitama 350. Dept. of Psychiatry, Shiga Univ. Med. Sci., Otsu, Shiga 520-21, Japan.

Thyroid hormones are essential for the growth and development of the brain, and congenital lack of thyroid secretion induces cretinism marked by mental retardation. The screening of the newborn for such lack has recently started, making it possible to prevent the onset of cretinism. However, hyperactivity and learning deficits have frequently been reported to occur even in children treated within 3 months of age. Rats with severe induced hypothyroidism have been used extensively as a model of cretinism but there has been no good model system for the above hyperactivity and learning impairment. This investigation was undertaken to produce such model in the rat by giving newborn animals via milk the antithyroid drug, n-propylthiouracil (PTU). Methods: Eight females of Sprague-Dawley rats were allowed to litter normally. Four animals were given drinking water containing PTU at 0.02% ad libitum on days 0-19 of lactation and other 4 animals served as controls. Four male and 4 female offspring were selected per litter at delivery and were weighed weekly. The serum level of thyroxine (T_4) was determined at 4 and 10 weeks of age. At 6 weeks, the animals were given 3-min open field trials 3 times at about 15-min intervals and observed for ambulation and rearing. Fifteen males and 15 females were selected per group and given, at and after 13 weeks of age, a trial on the radial eight-arm maze (RAM) per day for 20 days. The 20 trials begun with the first well-performed trial (WT). The brain weight was measured at the end of the maze test. Results: PTU rats showed depressed body weight gains from 2 weeks onward but no change in either serum T_4 level or brain weight. In hypothyroid animals ambulation increased in both sexes during the study while rearing was comparable to that of controls. The RAM test revealed that (a) more trials were required for PTU rats to establish WT, (b) only 3 males and one female reached criterion in the treated group while 13 male and 10 female controls did, and (c) PTU animals made more errors in total and less correct responses in the first 8 choices than controls. Conclusion: In PTU rats, T_4 levels were already normal at 4 weeks of age but ambulation and the number of trials required to establish WT were increased, indicating hyperactivity and lowered adaptability to the environment which are signs of cerebral disturbances. These results suggest that the abnormalities may be related to hippocampal damage known to cause severe impairment for RAM.

68.23 ALTERATION OF THE GABA RECEPTOR-COUPLED Cl^- CHANNEL AND IN VIVO BENZODIAZEPINE RECEPTOR BINDING IN LEARNED HELPLESSNESS. A.L. Morrow, R. Weizman*, A. Weizman*, S.I. Deutsch*, J.N. Crawley, S.M. Paul* and R.C. Drugan, Clinical Neuroscience Branch, NIMH, Bethesda, MD 20892

Recent behavioral evidence suggests that inescapable tail shock may produce alterations in the GABA/benzodiazepine receptor Cl^- channel complex. A putative animal model of depression, learned helplessness involves the failure to learn a shuttle-escape task 24 hours after a session of inescapable tailshock. Thus we have investigated whether the development of learned helplessness alters the function of the GABA-gated Cl^- channel, measuring muscimol-stimulated $^{36}Cl^-$ uptake in vitro. Further, we have labelled central benzodiazepine receptor binding sites in vivo with [^{3}H]Ro15-1788 in rats subjected to this paradigm.

$^{36}Cl^-$ uptake was measured in synaptoneurosomes from cortex (Schwartz et al, 1986) immediately following the shuttlebox learning task. Stimulation of $^{36}Cl^-$ by the GABA agonist, muscimol (50 µM) was reduced approximately 22% in the rats which failed the task ("helpless") compared to naive control rats (ANOVA $p<.05$, Newman Keuls $p<.05$). Rats which learned the task did not show a significant reduction in $^{36}Cl^-$ uptake, compared to naive rats. A similar reduction in $^{36}Cl^-$ uptake in the "helpless" rats (25%) was detected using 5µM muscimol.

In vivo benzodiazepine receptor occupancy was measured by injecting [^{3}H]Ro15-1788 (2.5 µCi) via the lateral tail vein immediately following the final learning trial and sacrificing the rat 20 min. later. Nonspecific binding was assessed by administering clonazepam (5 mg/kg i.p.) immediately prior to the radioligand. Failure to learn ("helpless" condition) was associated with a decrease in specific [^{3}H]Ro15-1788 binding in cerebral cortex (43%), hippocampus (35%), and striatum (33%) compared to naive rats (ANOVA $p<.05$, Newman-Keuls $p<.05$). In hypothalamus and cerebellum, there was a decrease in specific [^{3}H]Ro1501788 binding in both animals that failed and animals that learned compared to naive controls. We are presently investigating whether these alterations in in vivo [^{3}H]Ro15-1788 binding and $^{36}Cl^-$ uptake are due to the stress of inescapable shock or are specific to learned helplessness. These data add support to previous observations that suggest that the GABA/benzodiazepine receptor complex may be functionally altered following exposure to stress.

69.1 SPIDER VENOM BLOCKADE OF DENDRITIC CALCIUM SPIKING IN PURKINJE CELLS STUDIED *IN VITRO*. M. Sugimori and R. Llinás. Dept. Physiol. & Biophys., New York Univ. Med. Ctr., 550 First Ave., New York, NY 10016.

Purkinje cells are known to generate Na and Ca-dependent spikes upon direct stimulation and following activation of the climbing fiber afferents. *In vitro* recordings in guinea pig Purkinje cells have demonstrated that the AG1 toxin from Agelenopsis aperta venom (BioActives, Inc.) is capable of blocking dendritic Ca spikes quite specifically at a concentration of 20 nM, without affecting the rapid Na conductances or the low-threshold non-inactivating Na conductances of the same cells. Thus, direct somatic depolarization of Purkinje cells produced rapid, Na-dependent, repetitive firing as well as oscillatory Ca-dependent spikes. After bath application of AG1 toxin the TTX-sensitive, fast action potentials were modified in the sense that the large afterhyperpolarizations (in part due to activation of a Ca-dependent K conductance) were reduced in amplitude. In addition, the presence of somatic plateau potentials, due to the activation of the low-threshold non-inactivating Na conductance, was unaffected by the toxin. The action of this toxin on dendritic spiking was quite dramatic. Ca-dependent all-or-none responses were clearly blocked as recorded from the somatic level and from direct dendritic impalement. A similar set of experiments were implemented in which the Purkinje cells were activated synaptically via the climbing fiber afferents. Initially, in the presence of AG1 a blockage of dendritic Ca spikes and a simplification of the complex spike in the cells was observed. However, as the blockage continued, the synaptic potential produced by the climbing fiber activation was not blocked. This indicates that the toxin affects Ca-dependent conductance in the dendrites but does not seem to modify greatly the Ca current which generates transmitter release from the climbing fiber. These results suggest that the Ca channels reponsible for mediating dendritic Ca spikes may be different, in some measure, from those responsible for synaptic transmitter release. [Supported by NS-13742 from NINCDS.]

69.2 **BLOCKADE OF HARMALINE-INDUCED TREMORS BY ALCOHOLS MAY BE MEDIATED BY THE LOW THRESHOLD CALCIUM CHANNEL.** C.M.Sinton[1], B.Krosser*, K.D.Walton and R.R.Llinas, Dept. Physiol. Biophys., New York Univ. Med. Ctr., NY 10016 and [1]Pharmaceuticals Divn., Ciba-Geigy Corp., Summit, NJ 07901.

Intracellular recording of inferior olive cells in the guinea-pig brainstem slice (Llinas & Yarom: Neurosci. Abstr. 12, p. 174, 1986) has demonstrated that higher molecular weight alcohols act as blockers of the low threshold calcium channel (LTCC). These blockers thus provide a possible tool for understanding the function of the pacemaking cellular networks of the olivo-cerebellar system, since the LTCC has been implicated in neuronal oscillatory behavior in this system (Llinas & Yarom: J. Physiol. 315, p. 569, 1981). These experiments were designed to address this question by examining the effects in vivo of some alcohols on harmaline-induced tremor. Male rats (Mbf:[SD]) were chronically implanted, under pentobarbital anesthesia, with EMG electrodes inserted between the splenius and acromiotrapezius muscles. After recovery from surgery, the electrodes were connected to a polygraph recorder (Grass Model 78D). Baseline EMG signals were recorded for 15 min, before harmaline was administered (9 mg/kg i.p.), and EMG recordings were then continued for a further 60 min. Harmaline produced marked alterations in the EMG, with behaviorally evident tremors of the head, neck and body corresponding to high amplitude rhythmic EMG oscillations. The animals also tended to crouch to minimize movement, so that the tremors were most evident when the rats were moving. EMG signals were recorded on FM tape for subsequent off-line spectral analysis: the EMG power frequency spectrum after harmaline treatment showed a marked peak between 6 and 9 Hz, the tremor frequency. In subsequent experiments, various doses of 1-octanol, mixed in a Tween-80 vehicle, were administered 15 min after the harmaline treatment, and the EMG power spectrum compared to that obtained with harmaline alone. The vehicle itself had no effect on the tremors. At a dose of 0.25 mg/kg i.p., 1-octanol blocked the harmaline-induced tremor for about 30 min, an effect which was evident both behaviorally and on the EMG power spectrum. Lower doses had little effect, and higher doses caused behavioral sedation that lasted for about 60 min. To examine the specificity of this action of 1-octanol, other isomers of octanol were tested in this protocol, including 2-octanol, 3-octanol and 4-octanol. Results with these isomers were similar although they were not equally effective in blocking the tremors. These data imply that the reported action of higher alcohols on the LTCC may be observable in vivo, and that this model can provide information about the relative potency of different compounds in blocking this channel. Novel therapies for treating tremor may eventually be developed from compounds which selectively block the LTCC.

69.3 USE OF VOLTAGE SENSITIVE DYES TO IMAGE SPATIAL PATTERNS OF CEREBELLAR NEURONAL ACTIVITY. J.H. Kim, M.B. Dunn* and T.J. Ebner. Departments of Neurosurgery and Physiology, Univ. of MN, Mpls., MN 55455.

Voltage sensitive dyes have been shown to be useful for studying the spatial and temporal properties of neuronal ensembles. In this study we used voltage sensitive dyes and image processing technology to evaluate spatial features of the neuronal circuitry of the cerebellar cortex. The cerebellar cortex is an excellent candidate for voltage sensitive dyes with its shallow laminar architecture and known circuitry and physiology. In the anesthetized, ventilated and paralyzed rat, voltage sensitive dyes were used to stain the exposed cerebellar cortex. Although different stryl dyes were tried RH 237 or RH 414 were used in most experiments. The animals were mounted stereotaxically in a modified Zeiss Universal Microscope equipped for epi-fluorescence and electronically shuttered. Parallel fiber stimulation was achieved with a microelectrode inserted just into the molecular layer. Dyes were excited at the appropriate wave lengths from a stabilized DC mercury lamp. After filtering the emitted light the images were recorded using a low light, charge coupled device video camera (384 X 419 pixels) equipped with a second generation microchannel plate intensifier. Removal of DC components, filtering, and windowing of the video signal was performed prior to storage and processing. Image capture and surface stimulation were coupled to the cardiac cycle to reduce movement artifacts. Images of cerebellar activity evoked by surface stimulation were averaged (up to 1200) and appropriate control images subtracted. Image processing was done using the Biomedical Image Processing Laboratory at the University of Minnesota. Electrophysiological field maps evoked by the surface stimulation were also constructed. Resultant images to surface stimulation revealed a "parallel fiber beam" arrangement running longitudinally which was restricted in width but 1-2 mm in length. More complex patterns were also observed. The spatial patterns were graded and modifiable with the intensity of surface stimulation and could be eliminated along with the evoked field potentials by topically applied lidocaine. These preliminary results suggest that voltage sensitive dyes will be an important tool for studying spatial patterns of activity in the cerebellar cortex. Supported in part by NIH grant NS-18338, Minnesota Medical Foundation, EMPI, Inc., and the Graduate School of the University of Minnesota.

69.4 MORPHOLOGICAL AND PHYSIOLOGICAL CHARACTERISTICS OF RAT CEREBELLAR NEURONS IN MATURE AND DEVELOPING CULTURES. D.L. Gruol and C.P. Crimi*, (SPON: M. Howard), Div. Preclin. Neurosci. and Endocrin., Scripps Clinic and Res. Foundation, La Jolla, CA 92037.

We have used immunohistochemical techniques and antibodies to gamma-aminobutyric acid (GABA), parvalbumin (PAV) and cyclic GMP dependent protein kinase (cGPK) to identify populations of cerebellar neurons in culture that exhibit morphological features similar to each of the six neuronal types in the cortical region of the cerebellum in vivo: the Purkinje neuron (PN), granule cell, basket cell, stellate cell, Golgi cell and Lugaro cell. The cultures were prepared from the cortical region of immature cerebella obtained from 20 day rat embryos as previously described (Gruol, Brain Res. 263, 1983). Immunohistochemical procedures were as previously described (Gruol and Franklin, J. Neurosci., 1987). These studies revealed that neurons identified as PNs and cerebellar interneurons (granule, stellate, basket, Golgi, Lugaro) were present at all culture ages. The morphological and physiological properties of these neuronal types were compared at three culture ages: 7-9 DIV, 12-16 DIV and >21 DIV (DIV = days in vitro) reflecting early, intermediate and late periods in cerebellar development. The morphological features of the interneurons were similar at all culture ages, in contrast to the PNs which did not exhibit prominent dendritic structure until 12-16 DIV. Extracellular recordings from the neurons at the different culture ages revealed that all classes of neurons exhibited spontaneous activity but that only a portion of the interneurons were spontaneously active. Spontaneously active interneurons exhibited similar patterns of activity at all culture ages. The patterns were characterized by low firing rates (~2-6 Hz) and irregular spiking. At young culture ages, the PNs exhibited patterns of activity similar to the interneurons; at older culture ages the patterns were significantly different and were characterized by high frequency (>10 Hz) spike activity usually in regular patterns. All cerebellar neurons were excited by the transmitter glutamate (Glu). The response of the interneurons to Glu consisted of a brief burst of spikes at all culture ages. In young PNs, the response to Glu was similar to that observed in the interneurons; at older culture ages the response to Glu was prolonged and multiphasic. These data indicate that the cerebellar interneurons in culture express morphological and physiological properties that are significantly different from the PN. These differences may relate to the different functional roles played by the neuronal types in cerebellar circuitry. (We thank Dr. Paul Greengard for the cGPK antibody and Dr. Marco Celio for the PAV antibody; Supported by NINCDS grant NS271777 and NIAAA grant AA06665).

69.5 MODULATION EFFECT OF CEREBELLAR STIMULATION ON MOTOR SYSTEM EVOKED POTENTIALS IN THE CAT. S.S.Haghighi and W.J. Levy. Dept. of Surgery, Division of Neurosurgery, Sch. of Med. Univ. of Missouri, Columbia, MO 65212.

Excitation of the synaptic membranes in the pyramidal cells of the motor cortex as a result of cerebellar surface stimulation has been reported. Furthermore, similar excitatory postsynaptic potentials (EPSPs) have been documented in the neurons within brainstem and the motor neurons of the spinal cord in decorticated cats.It has been reported that cerebellar stimulation, either directly on the cortex or transcranially through the occipital bone, produces evoked responses in the spinal cord, the peripheral nerves and the muscles. These cerebellar evoked potentials (CEPs) are predominately ipsilateral, are unaffected by pyramidotomy, and may differentially activate extrapyramidal pathways. An interaction between the MEP from motor cortex stimulation and the CEP has also been reported.

To explore this, 7 cats, anesthetized by ketamine, xylozine anesthesia and paralyzed with Pavulon, had MEPs from anodal surface stimulation of the somatomotor cortex. CEPs were elicited through bipolar surface stimulation of the paravermal areas of the cerebellum. The simultaneous stimulation of MEP and CEP produced a 250% increase in the spinal cord response amplitude. Cerebellar stimulation prior to motor cortex stimulation was examined at several interstimulus delays (ISDs). This had a modulation effect with a 450% increased in MEP amplitude. The maximum modulation effect recorded at spinal cord was at 2 msec ISDs (p .02). This modulation effect of the MEP by the CEP may be a useful indicator of motor system status and pyramidal- extrapyramidal interactions

69.6 CEREBELLAR STABILIZATION OF THE VESTIBULOSPINAL REFLEX IN SHARKS - A MODEL SYSTEM. Richard S. Babb. Rockefeller University, York Ave., N.Y., N.Y., 10021.

The classical three-neuron pathway which provides part of a negative feedback loop for stabilizing the retinal image using vestibular information, has its counterpart for stabilizing the body. This latter feedback loop uses the descending branch of the medial longitudinal fascicle (MLF), instead of the ascending branch (Smeets and Timerick, 1981) which is used by the oculomotor system. However, the vestibular organs cannot analyse the angular acceleration into components produced by either passive external torques or torques actively produced by the shark's own trunk musculature. The MLF descending vestibulospinal system would thus have the undesirable characteristic of "correcting" for active movements produced by the shark itself. Such feedback by the vestibulospinal system acting alone could result in instability such as uncontrolled oscillations of the shark's body.

According to the proposed model, active shark movements would be compensated for by activity of the cerebellum and its pathways. A substantial primary vestibular input to the cerebellum is known to be received by the ipsilateral vestibulolateral lobe of the cerebellum (Boord and Roberts, 1980), and some Purkinje cells of the cerebellum are thought to project back to and terminate directly on the vestibular nucleus. Further, the spinocerebellar tracts could carry information about intended movements of the shark's body to the cerebellum. The vestibulocerebellar system is thus a viable candidate for the neural substrate which could act to subtract the active movement component from the vestibular information, leaving the passive component only for the error term used to correct body movement for external perturbations. Such a model entails that the cerebellar cortex would function to compute the amplitude and phase of the active movement compensation. One might speculate that the uniform arrays of Purkinje cells and parallel fibers, common to the cerebella of all extant vertebrates, are necessary for these computations. Such structural commonality suggests that the vestibulocerebellar system might well have originated in our common vertebrate ancestor.

69.7 ZONAL ORGANIZATION OF OLIVO-NODULUS PROJECTIONS IN RABBITS. Raymond T. Henry, John D. Connor and Carey D. Balaban*. Departments of Pharmacology, Anatomy and Surgery. College of Medicine, The Pennsylvania State University, Hershey PA 17033.

Anatomic and physiologic studies indicate that sagittal groups of Purkinje cells form basic functional units of cerebellar cortex. These groups, termed *zones*, are defined by climbing fiber inputs and output projections to distinct pools of cerebellar and vestibular nuclear neurons. The organization of olivo-nodulus projections was assessed with anterograde autoradiographic, anterograde degeneration and retrograde tracing techniques. For anterograde tracing, adult New Zealand white rabbits received injections of either [2,3,4,5-^{3}H]-L-leucine (20 μCi/50 nl) or 3-acetylpyridine (200-250 nl/injection, 27.5 μg/μl) in the dorsal cap (DC), ventrolateral outgrowth (VLO) and beta nucleus (β). After a 1-3 day survival period, rabbits were perfused transcardially under deep pentobarbital anesthesia. Brains were processed histologically with standard autoradiographic or cupric-silver degeneration methods. The retrograde injections were into the nodulus and posterior lobe lobules VII-IX. Four rabbits received iontophoretic injections (2 μA, 1-2 min) of horseradish peroxidase (HRP). Eleven rabbits were given pressure injections (100-150 nl) of both HRP-wheat germ agglutinin complex (10% solution in saline) and rhodamine-labeled latex microspheres (Tracer Technologies, Bardonia, NY) in distinct sites. After a 1-2 day survival, they were perfused transcardially and sections were stained for HRP with a tetramethylbenzidine substrate. Rhodamine microspheres were identified on a Zeiss fluorescence microscope. The data indicate that the caudal aspect of DC projects to a sagittal strip in the medial 0.5-1 mm of the nodulus. The rostral aspect of DC and VLO projects to an adjacent 0.5-1 mm band in the nodulus. The intermedio-caudal DC and adjacent regions of dorsal β project to the lateral margin of the ventral surface of the nodulus. The lateral margin of the dorsal surface of the nodulus and the ventral surface of lobule IXd, though, appears to be innervated by the rostral aspect of the dorsomedial cell column and the rostral medial accessory olive. Finally, regions of the nodulus and IXd on the bank of the postero-lateral fissure represent a transition between DC-VLO and β projection fields to the nodulus and more rostral lobule IX, respectively. These data provide a basis for investigating the significance of nodulus climbing fiber zones for visual-vestibular integration and alterations in cardiovascular tone. 69.8 VESTIBULAR MODULATION OF THE ACTIVITY OF INFERIOR OLIVARY NEURONS IN THE BETA NUCLEUS OF THE RABBIT. N.H. Barmack, E. Mugnaini and B. Nelson*. Neurological Sciences Institute, Good Samaritan Hospital and Medical Center, Portland, OR 97209; and Lab of Neuromorphology, Univ. of Connecticut, Storrs, CT 06268.

Previously we demonstrated that the beta nucleus of the inferior olive contains a dense cluster of GABAergic terminals. Using a double label technique we traced the origin of these GABAergic terminals to the ipsilateral descending vestibular nucleus (DVN). In the present experiment we have recorded the activity of beta nucleus neurons in rabbits during natural vestibular, visual and neck proprioceptive stimulation. Rabbits were anesthetized and positioned in a triaxial servo-controlled rate table with the head fixed at the center of rotation. Horizontal neck proprioceptive stimulation was provided by rotating the body independently of the head. Contrast-rich visual stimuli were rear-projected onto a 70 deg tangent screen. Neurons in the beta nucleus were identified by antidromic stimulation of the nodulus-uvula, the site of termination of the climbing fibers which originate from the caudal beta nucleus. Alternatively, recording sites in the beta nucleus was verified by subsequent histological analysis of marking microlesions. More than 70% of the identified beta nucleus neurons responded to roll vestibular stimulation about the longitudinal axis. Each of these neurons was excited when the rabbit was rolled onto the side which was contralateral to the recording site, and inhibited when the rabbit was rolled ipsilaterally. More than 65% of the cells which were responsive to roll vestibular stimulation evinced a response to static roll positions, indicating an otolithic origin of the vestibular input conveyed from the DVN. These roll-sensitive neurons were not responsive to horizontal vestibular stimulation, horizontal neck proprioceptivestimulation or visual stimulation in either the horizontal or vertical axes. Although most of the roll-sensitive neurons were more sensitive to lower stimulus frequencies (.01-.05 Hz), the range of sensitivity extended to higher frequencies (.1-.5 Hz). Two neurons were sensitive to vestibular stimulation about the vertical axis, but not to vestibular stimulation about the longitudinal axis, nor were they sensitive to visual stimulation in either the horizontal or vertical axes. Only one neuron was sensitive to stimulation of neck proprioceptors.

These data are consistent with our immunocytochemical demonstration of a presumed inhibitory GABAergic DVN projection to the beta nucleus, and further substantiate the general proposition that the characteristic low discharge frequency (1-4 imp/sec) of inferior olivary neurons is entirely adequate to encode sensory events of low temporal frequency. (Supported by EY04778, the Oregon Lions' Sight and Hearing Foundation, and NS09904).

69.9 RELATION OF PRIMARY VESTIBULAR, SECONDARY VESTIBULAR AND CUNEATE MOSSY FIBER AFFERENTS WITH PURKINJE CELL ZONES IN THE POSTERIOR VERMIS OF THE RABBIT CEREBELLUM.

N.M.Gerrits* and I.E.Thunnissen* (SPON: ENA). Dept. of Anatomy, Erasmus University, 3000 DR Rotterdam, The Netherlands.

In a study of the connections of the posterior vermis of the rabbit cerebellum the mossy fiber (mf) input from the vestibular nerve, the vestibular nuclei (VN) and the rostral part of the cuneate nuclei was investigated with anterograde tracing methods using WGA-HRP, Phaseolus vulgaris lectin and tritiated leucine. In a number of cases combinations of these tracers were injected to label different mf afferent systems simultaneously. The results obtained with the different tracers were similar.

It was found that the primary and secondary vestibular mf's share a common termination area. In the lobules IXd and X they are the dominant input. Both types of vestibular mf are present bilaterally, but primary mf are absent from the lateral two-third of the contralateral side. In the lobules IXa-c and VIIIb the number of mf terminals (mft) is very small and present in longitudinal strips: one in the midline flanked bilaterally by two others.

Cuneate mft are restricted to the lobules VIII and XIa-c. At either side of the midline two broad strips of mft are present with a strong ipsilateral dominance. The labeling is separated by narrow strips devoid of mft and also leaves a midline strip free. Rostrally in VIII the lateral strips disappear and the medial one gradually tapers off. Thus the vestibular and cuneate mft occupy complementary areas in the posterior vermis. Overlap is minimal and restricted to the lateral strips in the lobules VIII and IXa-c.

WGA-HRP injected in the VN also labeled Purkinje cells (PC) in the ipsilateral posterior vermis. In the lobules IXd and X the labeled PC's are present over the entire mediolateral extent of the cortex in a more or less continuous layer. From lobule IXc rostralward into VIII they tend to segregate into longitudinal strips. This was most obvious following injections in the medial and descending vestibular nuclei. A narrow midline PC strips matches the vestibular mf strip. Two lateral PC strips coincide closely with the cuneate mf terminal strips.

Thus, the vestibular nuclei receive inhibition from different populations of PC's. One of them driven by primary and secondary vestibular mf, and one driven by a relay in the rostral cuneate nuclei, probably mediating neck input.

69.10 THREE-DIMENSIONAL ORGANIZATION OF EYE MOVEMENTS EVOKED BY ELECTRICAL STIMULATION OF RABBIT FLOCCULUS. J. Van der Steen*, J.I. Simpson and J. Tan*. Depts. Physiol. I and Anatomy, Erasmus Univ., Rotterdam, The Netherlands and Dept. Physiol. & Biophys., New York Univ. Med. Ctr., New York, N.Y. 10016.

The climbing fibers of the rabbit cerebellar flocculus that respond to rotation of the visual world can be divided into three classes on the basis of the orientations of the rotation axes associated with their best modulation (Simpson, Graf & Leonard, 1981). In the present study, the axes of the eye rotations produced by electrical stimulation (1 sec trains of 0.2 msec pulses, 200 Hz, 20 microA) of the alert rabbit's flocculus were determined and compared to the visual climbing fiber best response axes. With two orthogonal coils on each eye, the movements of both eyes were measured simultaneously in three dimensions using the methods of Robinson and Collewijn. Slow (2-5°/sec) movements were evoked most effectively from the deep granular layer and the white matter. A limited number of eye movement patterns were evoked. The most prevalent response component was rotation of the ipsilateral eye about a horizontal axis with an azimuthal orientation of 135-150° posterior to the nose. The sense of the rotation about this axis, which for covenience is called the ipsi 135° axis, was counterclockwise as viewed along the axis toward the rabbit's eye. This rotation occurred either monocularly or with a smaller, but conjugate rotation of the contralateral eye. These rotations about the ipsi 135°-contra 45° axis, and also the evoked vertical axis rotation, are consonant with the coordinate system established by the set of best response axes of the climbing fibers. However, rotations about the ipsi 45°-contra 135° axis were also evoked. For the contralateral eye, the rotation about its 135° axis was counterclockwise; it occurred either alone or as a component of an upward rotation about the roll (nasal-occipital) axis. For the ipsilateral eye, the rotation about its 45° axis was clockwise and occurred in combination with a counterclockwise rotation about the ipsi 135° axis. Given our previous measurements of the climbing fiber best response axes and the finding by Ito, Nisimaru & Yamamoto (1977) that the rabbit flocculus does not act on the ipsilateral posterior canal vestibulo-ocular pathways, rotations about the ipsi 45°-contra 135° axis were unexpected. A tentative explanation of the presence of these rotations is that the climbing fiber coordinate system can be transformed by a Purkinje cell influence on the vestibular nucleus that does eventually include posterior canal pathways. Supported by NS-13742 and FUNGO.

69.11 FASTIGIAL NUCLEUS PROJECTIONS TO BRAINSTEM AUTONOMIC AND OCULOMOTOR NUCLEI IN CATS. Y. Torigoe and R.H.I. Blanks. Department of Anatomy and Neurobiology and Department of Surgery, Division of Otolaryngology-Head and Neck Surgery, University of California, Irvine, California 92717.

Fastigial neurons are related to control of smooth pursuit and saccadic eye movements and to a number of autonomic responses. There have been, however, controversy in the pathways and projections of this nucleus, due primarily to the methodology. Older degeneration techniques invariably interrupt unrelated axons in passage within the cerebellar white matter. For this reason, projections of the fastigial nucleus were investigated using axoplasmic transport of tritiated amino acid. Experiments were conducted in 10 cats. The fastigial nucleus was approached stereotaxically with glass microelectrodes with tip diameters of 5 um, pressure injected with 4-5-^{3}H leucine, and following 2 to 7 day postinjection periods the animals were sacrificed, and brains processed for standard light autoradiography. Our injection sites covered the rostral or caudal on-half of the fastigial nucleus without involvement of the overlying cerebellar cortex or adjacent interpositus nuclei. Projections of this nucleus to the following autonomic areas were determined: contralateral rostral "vomiting center" of Borison and Wang (1949) (parvocellular reticular formation); discrete region of the bilateral, but predominantly contralateral, lateral solitary tract nucleus; moderate contralateral A5 norepinephrine group; strong bilateral inferior and superior salivatory nucleus; moderate to weak bilateral A1 norepinephrine group (in region of the ambiguous nucleus). Fastigial projections to the following oculomotor-related nuclei were found: strong to moderate contralateral nucleus reticularis tegmenti postis; strong contralateral raphe pontis; bilateral lateral and spinal vestibular nuclei and cell groups x and f; contralateral dorsal cap and beta nucleus of the inferior olive; small discrete portions of the contralateral praepositus hypoglossi nucleus; bilateral brainstem reticular formation, some of which are adjacent to the medial longitudinal fasciculus (overlaps the caudal paramediam pontine reticular formation). No labeling was found in the nucleus intercalatus, nucleus of Roller, lateral reticular nucleus (although the region around the nucleus, the A1 group, is labeled) and the medial vestibular nucleus as previously reported in cat studies using degeneration techniques.

In the present study, the fastigial nucleus projections to vestibulo-oculomotor nuclei clarifies previously described pathways. However, some pathways not described in recent studies using axoplasmic transport techniques in other species are found in this study, suggesting a possible species difference as an explanation. In addition, the fastigio-autonomic pathways demonstrated here suggest that the fastigial nucleus has a direct connections with parasympathetic outflow motoneurons (salivatory nuclei), indirect parasympathetic connections via the solitary tract nucleus and "vomiting center"and indirect sympathetic connections via A5 and A1 groups. (Supported by NASA grant #NAG2-288. YT is the recipient of a Research Associate Award from NASA #MAGN-70).

69.12 CEREBELLAR INFLUENCE UPON MEDIAL VESTIBULAR NUCLEUS NEURONS IN WILDTYPE AND WEAVER MUTANT MICE DURING VISUAL AND VESTIBULAR STIMULATION. U.Kindermann* and U.Grüsser-Cornehls* (SPON: R.F. Schmidt). Dept. of Physiol., Freie Universität Berlin, Arnimallee 22, 1 Berlin 33, Germany-West.

In order to examine cerebellar influence upon medial vestibular nucleus neurons during horizontal visual or horizontal vestibular stimulation, experiments were carried out with wildtype (B6CBA) and homozygous weaver mutant mice. The defect in weaver homozygotes (wv/wv) is exclusively cerebellar and results in an almost complete loss of cerebellar granular cells. A disturbance in cerebellar integrity should be reflected in subjacent vestibular nuclei.

Single cell recordings (extracellular) of 17 wildtype and 18 mutant vestibular nucleus neurons were performed during visual (movement of a black and white striped pattern), vestibular (rotation of the animal in the dark) and visual-vestibular (rotation of the animal in light in front of the striped pattern) stimulation. All stimuli movements consisted of horizontal sinusoidal oscillations with an amplitude of ±35°. Frequencies varied from 0.01Hz to 0.6Hz. The recording sites were marked by pontamin sky blue and for normals as well as for mutants the sites were localized in the medial vestibular nucleus. Mutants could be tested under open- and closed-loop conditions, wildtypes only under open-loop.

Unexpectedly the sensitivity (difference between peak or minimum response and spontaneous frequency) of type I and type II medial vestibular neurons in the open-loop condition seemed to be unaffected by the mutation. In wildtypes as well as in mutants a considerable sensitivity increase between 0.05Hz and 0.6Hz took place during vestibular stimulation in the dark. The slope of this increase was about the same for both. In some neurons visual stimulation led to a sensitivity peak at 0.025Hz, while in others it should be assumed that the peak sensitivity occurred at lower frequencies than could be examined. For closed-loop mutant neurons visual excitability is extended to higher frequencies (up to 0.3Hz) and visual sensitivity decreased approximately at 0.4 Hz. In agreement with sensitivity values the gain for normal and mutant mice under open-loop conditions corresponded closely. Closed-loop mutants reached higher visual gain values.

In contrast to sensitivity and gain, the time relationship between peak stimulus velocity and peak response (expressed as phase shift) was considerably altered in mutants. In wildtype type I neurons the visual peak response occurred with phase leads of 17.4 imp/sec ±11 imp/sec (n=5) at 0.01Hz and 10.5 imp/sec ± 24.2 imp/sec (n=9) at 0.05Hz. Mutants showed a tremendous phase lag increase over the same velocity range.

In conclusion, cerebellar granular cell degeneration strongly affects the time relationship between stimulus and response and does not alter the sensitivity and gain under open-loop conditions.

69.13 PURKINJE CELL SPONTANEOUS ACTIVITY AND HARMALINE RESPONSES IN DYSTONIC RATS. S. Stratton, J. F. Lorden & L. E. Mays. Depts. Psychol. and Physiol. Optics, UAB, Birmingham, AL 35294.

Biochemical and pharmacobehavioral studies have emphasized the presence of cerebellar abnormalities in the dystonic (dt) rat, an autosomal recessive mutant with a motor syndrome of CNS origin. The abnormalities observed include increased norepinephrine and decreased cGMP levels in the cerebellum and increased glutamic acid decarboxylase activity in the deep cerebellar nuclei. Behaviorally, dt rats are insensitive to the tremorogenic effect of harmaline. We now report physiological correlates of the dt rat's motor syndrome. This investigation was designed to examine the functional integrity of the two major cerebellar afferent pathways in dt rats, the olivo-cerebellar and mossy fiber pathways.

We recorded extracellular single-unit activity from Purkinje cells of urethane-anesthetized (1.9 g/kg) dt rats and phenotypically normal littermates 20-28 days of age. Spontaneous complex spike (CS) and simple spike (SS) activity of Purkinje cells were discriminated off-line with two amplitude and time window discriminators. Autocorrelograms of CS and SS activity were computed for each cell. An index of spike regularity, the rhythmicity index value, was calculated for each cell's SS and CS activity by dividing the number of counts at the peak of the autocorrelogram by the total number of counts. Following 10-20 min of baseline recordings, we administered harmaline (10 mg/kg, i.v.) to induce rhythmic activation of the olivary neurons and recorded from the same cell for an additional 30-180 min.

In dt rats (n=19), the spontaneous CS firing rate was 46% lower and the SS rate, 66% lower than in controls (n=17). The pattern of SS activity in dt rats was significantly less regular than that in control rats. SS waveforms did not differ between the two phenotypes. However, CSs from dt rats showed fewer secondary wavelets. Harmaline-induced increases in CS frequency and rhythmicity and prolonged suppression of SSs were observed in 47% (8/17) of the cells in normal rats and only 17% (3/17) of the cells in dt rats. Intermittent suppression of SS activity was seen in the remaining 53% of the cells in normal rats, and 41% of the cells in dt rats. Anomalous responses occurred in 29% of the cells in dt rats. The remaining 12% of the cells from dt rats did not respond to harmaline. Thus, in dt rats, spontaneous Purkinje cell activity was slower and less rhythmic, and harmaline responses were more variable than in controls.

Lower spontaneous activity in the Purkinje cells may result from either intrinsic differences in the cells or aberrant inputs. The increased variability in Purkinje cell responses to harmaline suggests that the lack of harmaline tremor is the result of a failure in neurotransmission in the olivo-cerebellar pathway. Future studies will investigate the nature of the cortical abnormalities and their effects on cerebellar output. (Supported in part by NINCDS grant 18062.)

69.14 GABA LEVELS AND AUTORADIOGRAPHIC ANALYSIS OF GABA RECEPTORS IN THE CEREBELLUM OF THE DYSTONIC RAT. J. Lutes, M. Beales*, R. Dawson, Jr., J.F. Lorden, S.F. Hoff and G.A. Oltmans. Dept. of Pharmacology, Chicago Med. School, N. Chicago, IL 60064 and Dept. of Psychology, Univ. of Alabama, Birmingham, AL 35294.

The dystonic rat exhibits symptoms similar to human dystonia musculorum deformans. Light microscopy suggests that the nervous system of this mutant is structurally normal. Neurochemical studies have, however, revealed several cerebellar abnormalities including increased activity of the GABA synthesizing enzyme glutamic acid decarboxylase (GAD) in the deep cerebellar nuclei. The changes in GAD activity suggest increased neurotransmitter activity in the Purkinje cells terminals synapsing on the intrinsic cells of the deep nuclei. The present study examines other components of the GABAergic system in the dystonic rat to determine if additional alterations are present in this mutant.

In vitro autoradiographic studies of 3H-muscimol (MUSC) were conducted according to the method of Pan, et al. (J. Neurochem. 45:1396). Coronal cerebellar sections (10 micron) through the deep nuclei were taken from 25 day old normal and dystonic rats (N=9/group). Quantitative densitometry was used to measure specific binding in granular and molecular layers of cerebellar cortex and in lateral, interposed, and medial divisions of the cerebellar nuclei. A separate group of 20 day old normal and dystonic animals was killed using focused-beam microwave irradiation, and GABA levels in the deep nuclei determined using HPLC with electrochemical detection. It has also been shown that animals with 3-acetylpyridine (3AP)-induced lesions of the climbing fiber system develop increases in GAD activity in the deep nuclei. Therefore, as a comparison, GABA levels were also determined in the deep nuclei of rats treated with 3AP (65 mg/kg) at 20 days of age and killed 4 days post-lesion.

A significant ($p<.02$) 21% decrease in MUSC binding was found in both the lateral and interposed nuclei of dystonic rats. No differences between normals and dystonics were found in GABA levels in the deep nuclei. The normal levels of GABA, in combination with the previously reported increase in GAD activity in the deep nuclei, suggest that the current findings may be an example of receptor down-regulation in the face of increased GABA release. In 3AP-treated rats a significant 35% increase was found in GABA levels in the deep nuclei. This indicates that the lack of change found in the dystonic rats was not due to an inability to detect such a difference. The results indicate changes in multiple components of the GABAergic systems in the cerebellum of dystonic rats. Autoradiographic analysis of the benzodiazepine receptor in dystonic rats is currently being conducted. (Supported by grants from the Dystonia Foundation and NS18062.)

69.15 [^{3}H]GLUTAMATE BINDING IN NORMAL C57BL/6 AND MUTANT MOUSE CEREBELLUM. H. Ni*, A. Frostholm and A. Rotter. Department of Pharmacology, University of California, Irvine, CA 92717.

Glutamate is a major excitatory neurotransmitter in the mammalian cerebellum. Depolarization causes a Ca^{2+}-dependent release of glutamate which binds to, and activates, postsynaptic receptors in a Na^+-independent manner. The action of glutamate is terminated by high affinity Na^+-dependent uptake into astrocytes. Some glutamate may be taken up presynaptically by a Ca^{2+}/Cl^--dependent process. In order to examine the cellular localization of glutamate neurotransmitter systems, the distribution of [^{3}H]glutamate binding sites in cerebella of normal mice (C57BL/6) and Purkinje cell degeneration, staggerer and weaver mutant mice was studied by light-microscopic autoradiography. Slide mounted cryostat sections (20 μm) were preincubated for 15 min at 4°C in PBS (148 mM Na^+; 4.2 mM K^+; 4.9 mM Mg^{2+}; 0.9 mM Ca^{2+}; 148.5 mM Cl^-; 10 mM P_i; pH 7.4), containing 0.05% glutaraldehyde, then washed for 1 min at 4°C in PBS. Sections were incubated for 40 min at 4°C in PBS containing 50 nM [^{3}H]glutamate (52.4 Ci/mmole, NEN). After incubation, slides were washed twice for 1 min at 4°C in PBS and rinsed twice for 10 sec at 0-4°C in double-distilled water to remove residual salts. Slides were apposed to emulsion-coated coverslips (NTB-2, Kodak) and exposed for 10 days, after which time the coverslips were developed in Dektol (1:1). [^{3}H]glutamate binding was inhibited by 1mM glutamate and 1mM quisqualate, but not by 1 mM ibotenic acid, kainic acid, N-methyl-D-aspartic acid (NMDA) and 2-amino-5-phosphonovaleric acid (AP5).

In the cerebellar cortex of normal C57BL/6 mice, a high density of [^{3}H]glutamate binding was observed over the molecular layer, an intermediate density over the granular layer and low density over the deep cerebeller nuclei; the white matter was devoid of labeling. In the 110 day weaver mutant cerebellum, in which the number of granule cells is greatly reduced, the autoradiographic grain density over the molecular and granule cell layers remained similar to that of littermate controls, indicating that the glutamate binding sites are not located on granule cells or their parallel fibers. In the cerebellar cortex of 24-day-old staggerer mice, which is partially depleted of granule, Purkinje and Golgi cells, a reduction in labeling was observed over the molecular layer; this suggests that the remaining Purkinje or Golgi cells contain glutamate binding sites. In the 57-day-old Purkinje cell degeneration mutant cerebellum which was completely devoid of Purkinje cells, the grain density over the molecular layer was reduced to that of the granule cell layer. This finding indicates that a large proportion of the [^{3}H]glutamate binding visualized by our method is associated with Purkinje cell dendrites. These data are compatible with the generally held view that the Purkinje cells of the cerebellum are responsive to glutamate.

69.16 ACUTE AND CHRONIC EFFECTS OF CLIMBING FIBER LESIONS ON CEREBELLAR cGMP LEVELS. L.E. Moss*, G.A. Oltmans, M. Beales* and J.F. Lorden. Dept. of Pharmacology, Chicago Med. School, N. Chicago, IL 60064 and Dept. of Psychology, Univ. of Alabama, Birmingham, AL 35294.

cGMP is distributed throughout the CNS, but is found in particularly high levels in the cerebellum. Within this structure, evidence suggests that cGMP may be concentrated in the Purkinje cells (PC). Initial work on the regulation of cerebellar cGMP levels indicated a direct correlation between cGMP levels and excitatory input to the PC. Activation of the excitatory climbing fiber (CF) input to the PC with the drug harmaline produced large increases in cerebellar cGMP, while loss of CF input (produced by the neurotoxin 3-acetylpyridine (3-AP)) produced decreased cGMP levels. Recent studies, however, suggest a more complex relationship may exist. Although the removal of CF input eliminates complex spike activity in the PC, simple spike (SS) activity more than doubles in the immediate post-lesion period. Then, over a period of several days, the SS activity gradually returns to pre-lesion frequencies. cGMP levels, typically measured at 3-5d post-lesion, are decreased 40-50%. PC activity at this time, however, is still well above control levels. Because of the hypothesized relationship between cGMP levels and PC activity, we measured cGMP levels at 6 post-lesion intervals selected on the basis of published reports indicating increased or normal SS activity at the selected times.

To produce CF lesions 20 day-old Sprague-Dawley rats were treated with 65 mg/kg of 3-AP. Controls were administered saline. Animals were killed by focused-beam microwave irradiation at 6h, 24h, 48h, 7d, 14d, and 20d post-3AP treatment. Cerebellar cGMP levels were determined using a commercially available RIA.

CF lesions produced time-dependent changes in cGMP levels. At both 6h and 24h post-lesion, times when SS activity is greatly increased, there was no significant change in cGMP compared to controls. At 48h and 7d post-treatment cGMP levels were significantly decreased (-28% and -45% respectively) in 3AP-treated rats. Published data indicate that at 48h SS activity is still more than doubled compared to controls. At 7d the firing rate is decreased, but is still above pre-treatment levels. At both 14d and 20d, cGMP levels were not significantly different from controls. At these periods SS activity is reduced and may have returned to pre-lesion rates.

These results do not indicate a direct relationship between cerebellar cGMP levels and SS activity in the cerebellum. The cGMP levels do, however, return to normal at the time the animals show substantial behavioral recovery from the effects of the climbing fiber lesions.
Supported in part by grant NS18062.

69.17 CONCOMITANT INCREASE OF IMMUNOREACTIVE-CHOLECYSTOKININ (IR-CCK8) AND SOMATOSTATIN(IR-SRIF) IN THE CEREBELLUM OF ATAXIC MUTANT MICE: WEAVER, STAGGERER, PURKINJE CELL DEGENERATION(PCD) AND ROLLING MOUSE NAGOYA(RMN).
A.Masui*, K.Matsui*, N.Watanabe*, K.Ando* and N.Kato (S-PON:M.Kabuto) Div. of Neurol., Natl.Ctr.Neurol.Psychiat. Kodaira, Tokyo 187; Dept. of Psychiat., Shiga Univ. Med. Sci., Otsu 520-21; Nishiyama Hosp., Kyoto 617, Japan.

A number of mutations have been described that affect the mouse cerebellum and that are characterized by ataxia. Though a recent study has revealed a favouring effect of TRH on cerebellar ataxia, neuropeptides contents in these mice have been scarcely investigated. This is partly because the cerebellum is thought to be a locus with the least concentration of nearly all peptides. The present study was conducted to study possible changes in IR-CCK8 and SRIF in the cerebellum and cerebrum in 4 types of ataxic mice with different cerebellar pathology. Among these, weavers will be of particular interest since this gene results in a marked loss of mesostriatal dopamine pathway. We have found a concomitant increase of IR-CCK8 and SRIF in the rat brain after chronic interruption of dopaminergic transmission (Soc. Neurosci. Abst.,12:232,1986).

Weaver(wet weight of cerebellum; 37%control), staggerer(21%), PCD(81%) and RMN(96%) mice were killed by microwave irradiation at 8-weeks age (N = 5-10). Unaffected littermates served as controls. The brain was dissected into cerebellum and cerebrum (whole brain except cerebellum) and the tissue was extracted in 0.1N acetic acid. The supernatant was then subjected to the assays. IR-CCK8 and IR-SRIF were measured by enzyme immunoassays developed in the laboratory as reported previously. IR-CCK8 and SRIF both were found to be unequivocally (two to five fold) elevated in the cerebellum of all ataxic mice when expressed as ng/mg wet weight. The cerebrum content of both peptides showed similar elevation yet to a lesser extent. Moreover the peptide contents proved to be increased significantly as well when expressed as total cerebellar content in PCD and RMN. In the weaver, total content of IR-CCK8 in the cerebellum was 175% higher than that in controls despite of marked cerebellar atrophy.

The present results provide another evidence of the close relationship of CCK8 and SRIF, and suggest that the cerebellum in these mice substantially contains both peptides, which may actively participate in the pathogenesis of cerebellar ataxia.

69.18 OLIVO-CEREBELLAR PROJECTION IN LURCHER MUTANT MICE.
J. A. Heckroth and L. M. Eisenman, Dept. of Anatomy, Jefferson Medical College, Philadelphia, PA 19107.

"Lurcher" is a neurological mutation in mice affecting primarily the cerebellum and, consequently, motor behavior. It is known that adult Lurcher mice are entirely lacking in Purkinje cells, and suffer a 90% deficit in cerebellar granule cells, and a 75% deficit in inferior olivary neurons. Analysis of Lurcher/Normal chimeras has demonstrated that the postnatal elimination of Purkinje cells is a direct effect of the Lurcher mutation, while the loss of granule cells and olivary neurons is not. In light of the intimate relationship between climbing fibers and Purkinje cells it is of interest to determine the fate of these afferents in this mutant. In order to demonstrate the distribution of olivo-cerebellar fibers within the cerebellar cortex of Lurcher, we have injected 10-20 nl of 1% WGA-HRP in the inferior olive of six adult Lurchers of 32(2), 67, 72, 85 and 195 days of age, and observed the pattern of terminal labeling in the cerebellar cortex using the TMB method of Mesulam for the visualization of HRP. Labeled axons can be traced from the injection site throughout their course to the cerebellar cortex. Fibers can be seen traversing the cerebellar granular layer, but do not enter the thin molecular layer. Instead they appear to accumulate at the boundary between the granular and molecular layers, forming a plexus at this interface. Interestingly, as in normal animals, the distribution of olivocerebellar fibers is not uniform. Labeled parasagittal bands alternate with unlabeled bands, giving the cortex a longitudinally striped appearance. In cases with large injections involving the reticular formation, there is additional terminal labeling in the granular layer which has the appearance of typical mossy fiber rosettes. We have also made spinal cord injections of WGA-HRP in Lurcher adults, which confirm that mossy fiber afferents terminate in the granular layer of the Lurcher cerebellum in a pattern reminiscent of that seen in normal mice. We have initiated olivo-cerebellar tracing experiments at the ultrastructural level and also studies to determine whether olivo-cerebellar fibers penetrate the molecular layer during development (9-15 days of age) in Lurcher mutants.

This research was supported by NIH grants NS 22093 and NS 16531 to L. M. Eisenman.

69.19 EXPLORATION BEHAVIOR IN PURKINJE CELL DEGENERATION MUTANT MICE.
R. Lalonde and M.I. Botez*. Hôtel-Dieu Hospital, Neurology Service, Montreal, Canada H2W 1T8

Purkinje cell degeneration (pcd) mutant mice lose nearly all Purkinje cells between the third and fourth postnatal weeks. Granule cell loss occurs after the Purkinje cell loss (beginning on the third month). There is also a decrease in retinal photoreceptors in pcd mutant mice, which follows a much slower course than the cerebellar pathology.

Previous experimentation in other cerebellar mutants with Purkinje cell loss (nervous and lurcher) indicated that, in spite of ataxia, these mice are not less active than normal mice. Motor activity was therefore measured in pcd mutants. In addition, spontaneous alternation behavior was tested.

Ten pcd mutant (pcd/pcd) mice and 13 littermate controls (+/-) served as subjects. The mice were at least 4 weeks old at the start of the study. Food and water were available at all times. Exploration behavior was tested in a T-maze.

It was found that, in spite of ataxia, pcd mutant mice were not less active than normal mice in the maze. Contrary to normal mice, the pcd mutants did not alternate spontaneously in either a 2-trial or a 4-trial test. Additional experimentation indicated that whereas normal mice alternated at all three inter-trial intervals tested (15 s, 3 or 6 min), the pcd mutants did not.

These results are in agreement with previous studies of nervous and lurcher mutants in that massive degeneration of Purkinje cells in mice does not cause a reduction in motor activity. On the other hand, the spontaneous alternation rate of pcd mutants is at chance level, indicating that the cerebellum or cerebellar connections has a role in this behavior.

Spontaneous alternation is considered to be an intance of spatially-guided behavior and, in this regard, the results of this study are in agreement with recent clinical findings of impaired visuo-spatial abilities in patients with cerebellar atrophy (Botez et al. Neurology 35: 1152-1157, 1985).

Another possibility is that deficits in spontaneous alternation imply response disinhibition. In that regard, it has been found that animals with cerebellar damage have difficulty in witholding to respond to unreinforced stimuli in discrimination learning tasks. These findings indicate some similarities between animals with cerebellar as compared to limbic system damage in relation to behavior.

69.20 MODIFICATIONS IN THE CHARACTER OF A CONDITIONED RESPONSE PRODUCED BY EXTENSIVE CEREBELLAR LESIONS IN THE DECEREBRATE AMBULATING FERRET.
J.R. Bloedel, C.-C. Zuo*, R. Ferguson*, and J.-S. Lou*. Barrow Neurological Institute, Phoenix, AZ 85013 and Dept. of Physiology, U. of Arizona, Tucson, AZ 85721.

Recent studies in our laboratory have demonstrated that decerebrate locomoting ferrets can acquire a conditioned movement of the forelimb performed to avoid contacting a bar interjected into the forelimb's trajectory during swing phase. We also reported that the relationship between simple and complex spike responses recorded from cells very responsive to the perturbation was not modified during the conditioning process. The purpose of the experiments reported here was to determine if extensive lesions of the vermal and paravermal cerebellar cortex as well as the deep nuclei either modified the conditioned response of the forelimb or eliminated the animal's capacity to acquire this behavior. All animals underwent removal of the above cerebellar regions one to two months prior to the assessment of their conditioned behavior. The lesions spared only the vermal part of lobule I, rostral lobule II and the lateral-most parts of the cerebellar hemispheres; however the nuclei were removed. Following recovery from the cerebellectomy each animal was decerebrated at a supracollicular, supramammillary level, resulting in a preparation that locomoted in response to the moving treadmill. Conditioning trials consisted of interjecting a bar into the trajectory of the limb at the same phase of the locomotor cycle on each successive step. The time course and characteristics of conditioned behavior were noted, and the presence or absence of extinction was also observed. Movements were assessed quantitatively using the combination of a Watscope/Watsmart infrared emitting diode system and a standard video camera. The most striking deficit in these animals was their incapacity to successfully organize a succession of consistently performed conditioned responses over several successive trials. Although they were able to acquire a conditioned response during which they elevated the forelimb over the bar, this behavior was not performed consistently over several successive trials. Alternate strategies were used intermittently to avoid the bar, some of which would interrupt significantly the locomotor cycle. Because conditioned responses were observed clearly with appropriate acquisition and extinction time courses, the lesioned portions of the cerebellum cannot be the site of the plastic changes required for the conditioning. Rather the data suggest that the cerebellum is critical for the organization of movements required to avoid the bar in successive trials while minimizing modifications in the ongoing movement. Supported by NIH grant NS21958.

69.21 SHORT-TERM ENHANCEMENT OF SIMPLE SPIKE RESPONSES BY CLIMBING FIBERS EVOKED BY CORNEAL AIR PUFF STIMULI. C.-C. Zuo* and J.R. Bloedel (SPON: T. Tarby), Barrow Neurological Institute, Phoenix, AZ 85013 and Dept. of Physiology, University of Arizona, Tucson, AZ 85721

Specific regions of the cerebellar cortex and cerebellar nuclei have been implicated as the substrate for the plastic modifications required for conditioning the nictitating membrane reflex in rabbits. Furthermore, the induction by the climbing fiber of a long-term change in Purkinje cell responsiveness to mossy fiber-granule cell-parallel fiber inputs has been proposed as a basis for the acquisition of the conditioned behavior. However, our previous findings indicate that this afferent system produces a short-term enhancement of Purkinje cell responsiveness to parallel fibers, at least when these fibers are activated by natural cutaneous and proprioceptive stimuli. The experiments reported here were designed to determine if this kind of short-term modification occurs for the simple spike responses evoked by air puff stimuli of the cornea, the unconditioned stimulus in the conditioning paradigm alluded to above. Experiments were performed in rabbits decerebrated just rostral to the superior colliculus. Purkinje cells were recorded in the simplex and ansiform lobule. Their simple spike responses to the air puff were compared under two conditions: when the air puff stimuli were applied randomly relative to the occurrence of the cell's spontaneous climbing fiber input, and when the stimuli were applied at short intervals following the occurrence of the climbing fiber input to the Purkinje cell. By alternating the construction of histograms evoked by the randomly applied and climbing fiber triggered air puff stimuli it was possible to determine both the effect of the climbing fiber input on the simple spike response as well as the presence of any persistent changes in the simple spike responses of the neurons. The data confirmed that the simple spike responsiveness of Purkinje cells in the simplex to air puff stimuli is enhanced for short periods (up to 300 msec) following the spontaneous occurrence of their climbing fiber input. Furthermore, no persistence of this effect was observed in any of the cells studied (n=43). Since the action of the climbing fiber input on the dendrite of a Purkinje cell is not believed to be dependent on the modality by which it is evoked, the data suggest that long-term modifications in simple spike responsiveness produced by the climbing fiber system are not likely responsible for the plastic changes underlying the acquisition of the classically conditioned nictitating membrane reflex. Supported by NIH grant NS21958.

TRANSMITTERS IN INVERTEBRATES II

70.1 CLONING OF THE DROSOPHILA GLUTAMATE DECARBOXYLASE (GAD) GENE.[1] F.R. Jackson and K. Elliott.* Worcester Foundation for Experimental Biology, Shrewsbury, MA 01545.

Gamma-aminobutyric acid (GABA) is the major inhibitory neurotransmitter of vertebrates and invertebrates, and has been implicated in the pathogenesis of a number of human neurological and psychiatric disorders. The synthesis of GABA in diverse species is controlled by glutamate decarboxylase (GAD), an enzyme which has been extensively investigated. Recently, Kaufman et al. (Science, 232: 1138, 1986) reported the isolation of feline cDNA clones encoding GAD. We have shown that these feline cDNA sequences hybridize to homologous sequences in restriction-enzyme digests of Drosophila genomic DNA. In order to pursue genetic and molecular studies of GABAergic inhibitory transmitter systems, we have used a feline GAD cDNA as a probe to isolate several homologous genomic DNA and cDNA clones from Drosophila.[2] On the basis of restriction endonuclease mapping, it appears that the Drosophila cDNA clones (3 of them) represent a single gene. Partial DNA sequence information for one cDNA clone indicates that the protein encoded by the fly gene has significant homology with feline glutamate decarboxylase. DNA sequencing, gene dosage studies, and protein expression techniques are currently being employed to verify that we have isolated a Drosophila GAD gene.---The Drosophila GAD-homologous gene has been localized to region 64A of the third chromosome by in situ hybridizations to salivary gland polytene chromosomes. This chromosomal localization will enable us to begin genetic studies to determine the role of inhibitory neurotransmitter systems in the developing nervous system. Ultimately, we wish to study the expression of GABAergic phenotypes during the development and metamorphosis of the Drosophila nervous system.

[1] This research was supported by Worcester Foundation institutional funds. F.R.J. is a recipient of a McKnight Scholars Award.

[2] We thank Allan Tobin (UCLA) for providing a feline cDNA GAD clone and Laurel Newby-Kew for technical assistance.

70.2 GABA-LIKE IMMUNOREACTIVITY IN THE PHOTORECEPTORS AND SUPRAESOPHAGEAL GANGLION OF THE BARNACLE, BALANUS NUBILUS. J.C. Callaway and J.S. Edwards (SPON: S. Hauschka). Dept. of Zoology, University of Washington, Seattle, WA 98195.

As sessile crustaceans, barnacles react to rapid changes in light intensity by withdrawing their feeding appendages into their shell behind two protective opercular plates. The photoreceptors (PRs) of the barnacle, B. nubilus are unusually large non-spiking neurons with axons 1-2 cm long. The diameter of the cell somata and axons can be up to 70um and 40um respectively (Hudspeth and Stuart, J. Physiol. 272:1-23, 1977). The photoreceptors terminate in the supraesophageal ganglion (SEG) which contains several hundred neurons. Whether GABA functions as the PR transmitter has long been debated, but recent physiological studies (Callaway and Stuart, Biol. Bull. 171:491-492, 1986) suggest that GABA may indeed serve this purpose.

An antiserum to a GABA-keyholelimpet hemocyanin conjugate (provided by J. Hildebrand: Hoskins et al., Cell Tiss. Res. 244: 243-252, 1986) was used with the peroxidase anti-peroxidase technique to label 8um paraffin sections of the SEG and ocelli of B. nubilus. About 50 cell bodies were labeled in the SEG. Two pairs of small (ca. 20um) cell somata were located in an area over the PR arbors known to contain second and third order visual interneurons. Other small neurons (<50um) were labeled in specific regions of the ganglion and many were in clusters of 4-6 cells. Some larger neuron somate (>50um, presumed motor or neurosecretory) were labeled above background, but were considerably lighter than the smaller cell bodies.

The antibody densely labeled all three PRs of each of the two lateral ocelli and all four PRs of the median ocellus. Label appeared in the soma, dendrites, axons, and terminals of the PRs. Thus, histochemical findings support physiological approaches to the question of transmitter contents in the barnacle PR.

Supported by NIH grant NB-07778 and the Murdoch Trust.

70.3 A SEROTONERGIC SYSTEM IN *DROSOPHILA MELANOGASTER*. V. Budnik & K. White*. Dept. of Biophysics and Dept. of Biology, Brandeis University, Waltham, MA 02254.

The biogenic amine serotonin (5HT) is implicated in synaptic modulation, behavioral plasticity, and development of connections in a number of animals. The fruit fly *Drosophila melanogaster* is a promising system in which to study the function of this transmitter, since mutations affecting the gene encoding for the enzyme dopa decarboxylase, generate animals deficient in serotonin and dopamine. We here combine anatomical and electrophysiological techniques to describe the pharyngeal system of *Drosophila* larva, and its modulation by serotonin.

The pharyngeal muscles of *Drosophila* are composed of small vertically oriented muscle fibers surrounding the pharynx of the larva. During feeding, these muscles contract in a rhythmic fashion. Several serotonin immunoreactive fibers are observed to project to these muscles. These projections come from the subesophageal ganglion, the brain, and two serotonin-containing cells located in a peripheral ganglion, the frontal ganglion.

Intracellular recordings of the muscle fibers reveal a rhythmic pattern of excitatory junctional potentials, probably representing the feeding motor program of the larva. This rhythmic activity requires a central input, since inputs from the frontal ganglion alone do not elicit rhythmic activity.

Bath applications of glutamate to the pharyngeal muscles suggest that this molecule is likely to be the primary excitatory transmitter at this neuromuscular junction. Serotonin, on the other hand, with a threshold as low as 10^{-8}M produced a reversible, dose-dependent increase in the frequency of EJPs. The significance of this modulation by serotonin is being studied in mutants unable to synthesize serotonin. (Supported by a Brittner predoctoral fellowship to V.B. and a NIH grant GM 31503)

70.4 DIFFERENTIAL EFFECTS OF D(+)-AMPHETAMINE AND RESERPINE ON TARSAL AND LABELLAR TASTE THRESHOLDS OF THE BLACK BLOWFLY. L.C. Sudlow* and L.L. Murdock. Department of Entomology, Purdue University, West Lafayette, IN 47907.

The black blowfly, Phormia regina Meigen, has served as a model system for studying the roles of biogenic amines in the regulation of feeding behavior. For example, injection of the octopaminergic agonist demethylchlordimeform causes a significant lowering of tarsal taste threshold, while injection of D(+)-amphetamine (a biogenic amine depleter in insects) raises tarsal threshold and alters meal size. Recent efforts in this laboratory have indicated that blowfly labellar and tarsal thresholds are regulated in a similar manner after ingestion of food. However, we noticed that flies with high tarsal taste thresholds to sucrose caused by injection of D(+)-amphetamine could still respond to low concentratons of sucrose upon labellar stimulation. To investigate this apparent differential effect of D(+)-amphetamine, groups of 3-day-old flies were injected with 150 mM saline (1 ul) or saline containing 12 ug/fly D(+)-amphetamine (1 ul). Tarsal and labellar taste thresholds were determined 1 hour later. D(+)-Amphetamine caused a significant elevation of tarsal thresholds compared to saline-injected controls. However, labellar thresholds were not significantly elevated 1 hour after injection of D(+)-amphetamine. Levels of the biogenic amines octopamine, dopamine, and serotonin were analyzed by high performance liquid chromatography with electrochemical detection using brains dissected from the D(+)-amphetamine- or saline-injected flies. Brain octopamine, dopamine, and serotonin were all significantly lowered by injection of D(+)-amphetamine. In a second set of experiments, 2 ug/fly of the amine depleter reserpine (solubilized in N,N'-dimethylacetamide then mixed 1:9 with corn oil) was injected into 2-day-old flies. The treated flies were placed in cages and were held for 24 hr. prior to testing. Reserpine caused a significant elevation of tarsal thresholds and only a slight elevation of labellar thresholds. The slight elevation of labellar thresholds may have been due to increased energy reserves resulting from the reduced locomotor activity following with reserpine treatment.

Thus, while the biogenic amines, octopmaine, dopamine, and serotonin, appear to play an important role in the regulation of tarsal taste thresholds, they may not be involved in the regulation of labellar thresholds.

70.5 CHOLINERGIC SYNAPTIC RECEPTORS AND THEIR PHARMACOLOGICAL SPECIFICITIES IN THE ANTENNAL LOBES OF THE MOTH *MANDUCA SEXTA*. B. Waldrop and J.G. Hildebrand. Arizona Research Laboratories, Division of Neurobiology, University of Arizona, Tucson, AZ 85721

The primary olfactory centers of the moth *Manduca sexta* are the paired antennal lobes (ALs) of the deutocerebrum of the brain. Sensory neurons in the antennae project into the glomerular neuropil of the ALs and synapse onto interneurons. Our laboratory has reported previously that acetylcholine (ACh) is synthesized and stored in the antennae and ALs (Sanes & Hildebrand, Dev Biol 52:105-120, 1976; Prescott *et al.*, Comp Bioc Physiol 56C:77-84, 1977), and that the nicotinic receptor antagonist α-bungarotoxin binds in synaptic neuropil in the ALs (Hildebrand *et al.*, PNAS 76:499-503, 1979). Thus the olfactory sensory neurons, like other arthropod chemo- and mechanosensory cells, appear to be cholinergic.

We are studying the actions of cholinergic agonists and antagonists on AL interneurons by using pressure ejection of these agents into the AL neuropil while recording intracellularly from AL interneurons. A 5-barrelled pressure ejection electrode, with each barrel controlled independently by a solenoid-activated valve, allows us to observe the actions of up to five different pharmacological agents on each neuron impaled. The solenoids are controlled from a computer-based, 14-channel stimulation system. The preparation is continuously superfused with saline, and the superfusate can be switched among reservoirs containing different pharmacological agents dissolved in saline.

All interneurons studied thus far respond to the application of ACh, as would be expected if the primary-afferent terminals release ACh. We have observed both excitatory and inhibitory responses to application of ACh. This includes both direct responses by the impaled cells to ACh and indirect responses mediated by other cells. All interneurons also respond to nicotine (applied in solution as the hydrogen tartrate salt). We have not yet found any interneurons to respond to application of the muscarinic agonist oxotremorine sesquifumarate, but these experiments are still in progress. We are also examining the actions of nicotinic and muscarinic antagonists on synaptic responses and on responses to applied agonists. By combining agonist and antagonist studies we are examining the pharmacological nature of the ACh receptors in this preparation.

Supported by NIH fellowship 2 F32 NS07591-03, NIH grant AI-23253 and a grant from the Monsanto company.

70.6 THE DISTRIBUTION AND CHARACTERIZATION OF FMRFAMIDE-LIKE PEPTIDES IN THE BRAIN OF THE MOTH, MANDUCA SEXTA. T.G. Kingan, U. Homberg, J.G. Hildebrand. ARLDN, U. of Arizona, Tucson, AZ. 85721

FMRFamide-like peptides apparently act as chemical messengers in the nervous and neuroendocrine systems of animals from diverse phyla. The distribution of FMRFamide-like immunoreactivity (FLI) was determined by immunocytochemistry (ICC) in the brain and associated neurohemal organs of the moth, Manduca sexta, using antisera provided by D. Price (U. of Florida) and T.L. O'Donohue (NIH). FLI was detected in neurosecretory cells and interneurons in the brain of Manduca. Among the neurosecretory cells of the protocerebrum, about 4 large (probably type Ia) and 10 small (Ib) lateral cells and 3-4 medial (IIa) cells were stained (nomenclature after Copenhaver and Truman, 1986). Immunoreactive (ir) fibers of these neurons were stained, particularily in the dorso-median protocerebrum, the nervus corporis cardiacis I/II, and the corpora cardiaca and allata, and on the surface of the aorta. FLI was detected in all optic neuropils, concentrated in particular strata of the medulla and lobula. FLI-containing cells at the dorsal edge of the medulla send fibers tangentially into the medulla. About 250 darkly and 500 weakly ir-cells lie in the soma rind anterior to the medulla and lobula. Numerous ir-fibers from the medulla and the lobula project into the median protocerebrum. About 100 cells in the lateral cell group of the antennal lobe exhibit FLI. Immunoreactivity appears in all glomeruli, the central neuropil, and fibers of the outer antenno-cerebral tract. Numerous small ir-somata in the pars intercerbralis send fibers into the protocerebral bridge and the central body, of which the upper division is most intensely stained. From the central body, ir-fibers project in the isthmus tracts into the lateral accessory lobes. The mushroom bodies exhibit uniform FLI in subcompartments of the α- and ß-lobes. The tritocerebrum exhibits dense fibrous FLI, and about 20-30 somata per hemisphere have immunoreactivity. The suboesophageal ganglion (SOG) contains about 40 pairs of ir-cells; ir-fibers project from the SOG into the neck connectives. A staining pattern nearly identical to that described for FLI was obtained with antisera against small cardioactive peptide$_b$ and bovine pancreatic polypeptide. We have used the same antisera employed in ICC to develop enzyme-linked immunosorbent assays (ELISAs), which have then been used to monitor the purifications of molecules showing FLI. After a batch-ion-exchange procedure followed by desalting on Sep-Paks, gel filtration chromatography revealed ir-molecules with approximate MWs of 1000 and 4250 Daltons and a minor peak at 7000 Daltons. It appears that at least some Manduca peptides are different than authentic FMRFamide (MW 599 Da.); cation-exchange and reverse-phase HPLC also reveal multiple ir-peptides differing in retention times from authentic FMRFamide. Supported by a grant from Monsanto Co. and NIH grant AI-23253.

70.7 GASTRIN/CCK-LIKE PEPTIDES IN THE BRAIN OF THE TOBACCO HAWKMOTH MANDUCA SEXTA. U. Homberg, T.G. Kingan, and J.G. Hildebrand. Arizona Research Laboratories, Division of Neurobiology, University of Arizona, Tucson, AZ 85721.

Gastrin/CCK-like immunoreactivity has been previously reported in the brain of several insect species, most notably flies [Duve and Thorpe, Gen. Comp. Endocrinol. 48: 381-391 (1981) and Cell Tissue Res. 237: 309-320 (1984)].

To investigate the possible role of gastrin/CCK-like peptides as neurotransmitters in the moth Manduca sexta, we used antisera against gastrin/CCK (provided by J.M. Polak, College University of London) to study the distribution of gastrin/CCK-like immunoreactivity (GLI) in the brain and subesophageal ganglion (SEG). We are currently fractionating extracts of Manduca brains to isolate gastrin/CCK-like peptides.

The most intense GLI was consistently detected in a group of 30-40 pairs of small medial neurosecretory cells (MNCs) in the dorsal protocerebrum [IIb-cells, nomenclature according to Copenhaver and Truman, J. Comp. Neurol. 249: 186-204 (1986)]. Immunoreactive processes of these cells innervate especially the tritocerebrum, the corpora cardiaca, and the wall of the aorta. In addition, four pairs of IIa-MNCs are less intensely immunolabeled. GLI was also detected in most neuropil areas and several cell groups in the brain and SEG. Four groups of immunoreactive cells, totaling about 400 somata, are associated with the optic lobes and give rise to immunoreactive processes in the lamina, several strata in the medulla, and the lobula complex. 30-40 cells are associated with the antennal lobe (AL). GLI-containing fibers project in the AL-commissure and from the AL to the lateral protocerebrum. GLI is found in particular morphological types of neurons in the median protocerebrum, e.g. in neurons of the protocerebro-calycal tract innervating the calyces of the mushroom body, or segmental cells of the central complex. Scattered cells in the tritocerebrum and SEG also exhibit GLI, and fibrous immunoreactive staining is distributed throughout the neuropil.

Colocalization experiments suggest that virtually all gastrin/CCK-immunoreactive neurons are also immunoreactive with antisera against a crustacean pigment dispersing hormone (provided by K.R. Rao, U. of West Florida), a peptide that is structurally not related to gastrin/CCK. Particular groups of gastrin/CCK-immunoreactive cells in various parts of the brain show FMRFamide- or GABA-immunoreactivity.

The gastrin/CCK antisera have been used in the development of a sensitive enzyme-linked immunosorbent assay. We have used this assay to monitor the factionation of tissue extracts for GLI. Immunoreactivity in boiled tissue extracts is retained on anion-exchange resins (DEAE) in 0.1M NaCl and can be recovered during a salt gradient. Supported by a grant from Monsanto Co.

70.8 **ASSOCIATION OF A PROCTOLIN-LIKE PEPTIDE WITH THE OVIPOSITOR MUSCLES OF *LOCUSTA MIGRATORIA*.** Jim H. Belanger and Ian Orchard*. Dept. of Zoology, Univ. of Toronto, Toronto, Ontario, Canada, M5S 1A1.

The innervation and musculature of the ovipositor of *Locusta migratoria* are similar to those previously described for *Schistocerca americana* (K.J. Thompson, *J. Exp. Biol. 122:* 387 - 411). As part of an investigation of pattern generation in this system, we have examined for the possible association of the pentapeptide proctolin (H-Arg-Tyr-Leu-Pro-Thr-OH) with the ovipositor muscles. Proctolin-like bioactivity (PLB) was determined using the oviducal muscles of *L. migratoria* as a bioassay. Authentic proctolin, in amounts from 2 to 200 fmol, produces a dose-dependent tonic contraction in this preparation (A.B. Lange, I. Orchard, and M.E. Adams, *J. Comp. Neurol. 254:* 279 - 286).

Ganglion and muscle extracts were assayed for PLB following Sep-Pak purification and chromatography on RP-HPLC. PLB, co-eluting with ^{3}H-proctolin, was found in the ventral opener, closer, retractor and protractor muscles, in amounts ranging from 0.68 to 1.97 pmol proctolin/mg protein (means of 4 - 5 determinations). Abdominal ganglia VII and VIII, which contain the cell bodies of the motorneurons supplying the ovipositor muscles, contained, respectively, 3.79 ± 0.71 and 9.39 ± 2.63 pmol proctolin/mg protein. When the fractions containing PLB were rechromatographed on a second (isocratic) HPLC system, the majority of the PLB co-eluted with ^{3}H-proctolin.

We conclude that proctolin, or a very similar peptide, is involved in the control of the ovipositor muscles and are currently using immunohistochemistry to further substantiate this.

70.9 PEPTIDE ACTION ON INSECT CARDIAC MUSCLE IS MEDIATED BY INOSITOL TRISPHOSPHATE (IP_3). N.J. Tublitz and P.Q. Trombley*. Institute of Neuroscience, Univ. of Oregon, Eugene, OR 97403.

The CNS of the tobacco hawkmoth, Manduca sexta, contains two bioactive neuropeptides that are released into the blood immediately after adult emerges from its pupal skin. These two peptides, known as the Cardioacceleratory Peptides (CAPs), have been previously shown to facilitate inflation of the adult wings by directly increasing contraction rate of the Manduca heart in vivo. That the CAPs induce a relatively long-term change in cardiac activity prompted a search for the mode of action mediating this physiological response. We report here our evidence suggesting that the CAPs may be acting by stimulating inositol phosphate metabolism.

Initial experiments showed that the response of the heart to pulse applications of either CAP_1 or CAP_2 was markedly reduced in the presence of 10mM Li+. This result implicated the inositol phosphates as a potential second messenger system in this preparation because others have demonstrated that extracellular Li+ blocks the terminal dephosphorylation of inositol 1-phosphate to inositol. This leads to a decrease in the concentration of phosphotidylinositol, the precursor of IP_3. Direct measurements of IP_3 using anion exchange chromatography showed that the CAPs elicit a demonstrable and rapid rise in IP_3 levels. Intracellular IP_3 concentrations rise almost 2-fold within 30 seconds in response to CAP treatment.

To determine whether IP_3 directly affected heart rate, hearts were either permeabilized with 0.5% saponin and pulsed with inositol 1,4,5-trisphosphate (Ins1,4,5P) or intact heart cells were treated with Ins1,4,5P in a solution containing 5% DMSO. Either procedure elicited similar responses, namely that Ins1,4,5P produced a dose-dependent increase in contraction rate of the in vitro heart. Neither IP_2, IP_1, nor inositol were cardioactive under these conditions. Threshold for the IP_3 response was between 0.1 and 1 micromolar. Support for the hypothesis that IP_3 exerts its effect through a rise in cytosolic calcium comes from 2 separate experiments: (1) the IP_3-induced cardioexcitatory response is totally abolished in the presence of EGTA; and (2) A23187, a calcium ionophore, causes an increase in heart rate.

We conclude from these data that the cardioexcitatory effect of the CAPs on the Manduca heart is mediated by intracellular changes in the levels of inositol trisphosphate, which in turn acts to regulate the levels of cytosolic free calcium. Supported by NIH grant #NS-24613.

70.10 NEUROPHARMACOLOGICAL EVIDENCE THAT ACETYLCHOLINE IS A NEUROTRANSMITTER IN THE CRAYFISH VISUAL SYSTEM. C.L. Pfeiffer and R.M. Glantz. Department of Biology, Rice University, Houston, TX 77001

Immunocytochemical studies in this lab have localized Ach in the columnar transmedullary neurons of the second optic ganglion (medulla external, ME) of the crayfish, Procambarus clarkii (Wang-Bennett et al., Neurosci. Abst. 12:243, 1986) with the Ach antibody of Geffard et al. (Science, 229:77, 1985). Other evidence suggests that the transmedullaries convey visual excitation from the lamina columnar projections to the noncolumnar cells of the ME (Wang-Bennett et al., J. Comp. Phys., 1987, in press). Three such noncolumnar cells can be functionally distinguished with intracellular recording in the ME neuropil. These include 14 identified sustaining fibers (SFs), (tonic "on" spiking interneurons) amacrine cells (nonspiking inhibitory interneurons) and tangential cells (hyperpolarizing medulla to lamina neurons).

Each of these cell types was tested for Ach sensitivity in the ME using Ach or carbachol. The SFs respond to light with a sustained compound EPSP, a tonic discharge and a hyperpolarizing "off response." Of 40 SFs tested, 21 exhibited exclusively depolarizing responses to carbachol (10^{-6} to 10^{-8} M) either presssure injected in the ME neuropil or bath applied. 19 SFs exhibited a hyperpolarizing component in the response. Amacrine cells respond to light with a graded depolarization. Carbachol applied to these cells depolarized 9 out of 13 neurons. The remaining 4 cells exhibited a hyperpolarizing component. Tangential cells hyperpolarize in response to light. Of three tested, 2 cells exhibited purely hyperpolarizing carbachol responses. One cell contained a diphasic response.

Cobalt experiments indicate that Ach acts directly on postsynaptic receptors. In 6 preps, cobalt was applied to the ME and synaptic visual responses were blocked by 80 to 100% in SFs and amacrine cells. In each of these cases, the effect of pressure injected carbachol was unchanged. These cobalt experiments also suggest that 2 classes of Ach receptors may coexist on the SFs and amacrine cells. In 5 out of the 6 cells tested, SFs and amacrine cells responded to carbachol with both depolarizing and hyperpolarizing potentials following cobalt treatment. Furthermore, the anticholinesterase, neostigmine (10^{-5} M) acts to potentiate the SF light response by 200% (N = 3).

These results further support the hypothesis that Ach is the neurotransmitter of the columnar transmedullary neurons which provide visual signals to the SFs, amacrine and tangential cells of the ME. Supported by NSF Grant BNS83-12296.

70.11 CHOLINERGIC TRANSMISSION AT SENSORY SYNAPSES OF CRAYFISH LATERAL GIANT ESCAPE REACTION CIRCUIT. F.B. Krasne and M.W. Miller. Department of Psychology and Brain Research Institute, University of California, Los Angeles, CA 90024.

Biochemical analyses of sensory nerves and pharmacological experiments on transmission at selected sensory neuron synapses indicate that ACh is probably a major sensory transmitter in decapod crustaceans such as lobsters and crayfish. We demonstrate here that ACh is the transmitter at junctions between mechanosensitive afferents and first order sensory interneurons in the well studied lateral giant (LG) tailflip escape reaction pathway of the crayfish. Arterially perfused cholinergic agonists depolarize and fire sensory interneurons and depolarize LG dendrites, while cholinergic antagonists depress normally evoked EPSPs in both sensory interneurons and LGs. The pharmacological depolarization of the LGs is due in part to input (via electrical synapses) from interneurons and in part to a direct action of the cholinergic agonists on the LGs themselves (even though they receive no known excitatory chemical synaptic input). The postsynaptic ACh receptors are pharmacologically similar to the nicotinic ACh receptors of sympathetic ganglia; selective skeletal muscle nicotinic agonists and muscarinic agonists are without postsynaptic effects. However, muscarinic agonists depress EPSPs in sensory interneurons and (therefore) also in the LGs. Therefore, it appears that ACh release from the cholinergic terminals of mechanosensory axons is subject to muscarinic down regulation by ACh. We consider it of particular interest that these cholinergic junctions, like the glutamatergic junctions of hippocampus, are subject to cooperativity-dependent long-term potentiation. Supported by USPHS grant NS08108.

70.12 IMMUNOCYTOCHEMICAL LOCALIZATION OF A NEUROTENSIN-LIKE PEPTIDE IN THE LOBSTER, *HOMARUS AMERICANUS*. *S.R. Kirschenbaum, H. Mekeel*, B.S. Beltz and E.A. Kravitz.* Biology Dept., Boston Univ., Boston, MA 02215 and Neurobiology Dept., Harvard Medical School, Boston, MA 02115.

Neurotensin, a tridecapeptide originally isolated from the bovine hypothalamus, serves an important role in gut function in vertebrate species. Recently a neurotensin-like peptide was identified in tissue extracts from the East Coast lobster. By radioimmunoassay, neurotensin-like immunoreactivity (NT-LI) was detected in nervous tissue, hepatopancreas, and cardiac tissue (Soc. Neuro. Abstr. 1984). An 11 residue peptide from lobster hepatopancreas has been purified and sequenced. The peptide has approximately 36% homology to mammalian forms of neurotensin with 4 identical residues at the COOH terminus. Here we report the immunocytochemical localization of NT-LI to the connective tissue sheath surrounding nerves of the stomatogastric system by light and electron microscopic immuncytochemical methods.

Wholemount preparations of the stomatogastric nervous system were processed for immunocytochemistry using a polyclonal antibody that recognizes the COOH terminus of mammalian neurotensin (kindly supplied by Dr. R.E. Carraway). At the light microscopic level, NT-LI is observed in the sheath of the superior oesophageal nerve, the inferior oesophageal nerve, and the proximal portion of the stomatogastric nerve. The label is localized to varicosities 1-2 um in diameter that form a network in the connective tissue sheaths surrounding these nerves. Since the labeled structures look like neurosecretory endings electron microscopy was used to determine if the staining was localized to particular classes of nerve terminals. NT-LI was selectively localized to terminals showing the typical appearance of neurosecretory endings. The terminals, which contain dense-cored granules of approximately 100 nm diameter are adjacent to hemolymph sinuses that may serve to collect released peptide.

Biochemical analyses were performed to determine if the peptide labeled in nervous tissue is similar to the peptide originally purified from the hepatopancreas. A connective tissue sheath extract was compared to synthetic peptide using reverse phase high pressure liquid chromatography. The major peak of NT-LI in the sheath extract elutes with the same retention time as synthetic lobster neurotensin.

The localization of this peptide to neurosecretory endings in nervous tissue of the lobster stomatogastric system raises the possibility that neurotensin like peptides play roles in gut function in species as diverse as primates and decapod crustaceans. In lobsters, peptide released from terminals in the sheath could modulate the activity of axons within the sheath or could, via circulation in the hemolymph, act as a hormone on nearby or distant targets. Physiological studies currently are underway exploring these possibilities. (This work was supported by NIH.)

70.13 THE PRESENCE OF ENKEPHALIN IN THE EYESTALK AND BRAIN OF THE LAND CRAB, GECARCINCUS LATERALIS. M.K. Leung, K. Whitfield,* M. Murray,*E.A. Martinez*and G.B. Stefano. Depts. of Chemistry and Biological Sciences, SUNY/Old Westbury, Old Westbury, NY 11568.

Recent work with opioids point to their involvement with color change regulation in Gecarcinus lateralis. The present study provides additional evidence for the presence of endogenous opioids within the central nervous system of this particular species. Current study revealed binding profile of ^{3}H-etorphine to eyestalk membrane suspensions to be monophasic, stereopspecific and saturable. Scatchard analysis showed a single class of high-affinity binding sites with K_D of 2.3 nM and B_{max} of 15.0 pmole/g protein. The eyestalk neural tissues and cerebral ganglia from 30 crabs were extracted with 1 M acetic acid containing 1% 2-mercaptoethanol and the protease inhibitors; PMSF, pepstatin A, bestatin, phosphoramidon, amastatin and EDTA. The extracts were clarified by centrifugation and purified by Sep-Pak C_{18}. The samples were lyophilized, redissolved in 10% acetonitrile and injected into a HPLC reverse-phase column. The column was eluted with a flowrate of 1 ml/min and a gradient using 0.1% TFA as solvent A and 80% acetonitrile in A as solvent B. One-ml fractions were collected and lyophilized. Fractions 10-17 were dissolved in 1 ml water and 200ul aliquots were used for quantification of Met- and Leu-enkephalin via radioimmunoassay. The results showed that the eyestalk extract contained several fractions with Met-enkephalin activity. Three fractions (10,11,12) in particular exhibited high Met-enkephalin activity with levels beyond the limit of the assay (5000 pg/ml). No Leu-enkephalin was detected in the fraction that corresponded to the retention time of Leu-enkephalin; however, fractions 11 and 12 showed the presence of material with Leu-enkephalin-like activity equivalent to 2000 and 4000 pg/ml, respectively. The cerebral ganglia extract contained both Met- and Leu-enklephalin in the amounts, 550 and 800 pg/15 brains, respectively. In addition, fraction 16 also contained met-enkephalin-like immunoreactive material. This and previous studies demonstrate that these chemical signal molecules have diverse roles in invertebrates. The present study is the first to demonstrate a neural-endocrine role for opioids in invertebrates. Supported by ADAMHA-MARC MH-17138 and NIH-MBRS RR 08180.

70.14 DISTAL RETINAL PIGMENT OF THE FIDDLER CRAB, UCA PUGILATOR: EFFECTS OF HISTAMINE AND GABA ON THE RELEASE OF THE LIGHT ADAPTING AND DARK ADAPTING HORMONES. G. K. Kulkarni* and M. Fingerman. Dept. of Biology, Tulane Univ., New Orleans, LA 70118.

Histamine (HA) and gamma-aminobutyric acid (GABA) inhibit pigment migration in melanophores of Uca pugilator, apparently by inhibiting release of melanophorotropic hormones (Hanumante, M. M. and Fingerman, M., Biol. Bull., 162-256, 1982; Quackenbush, L. S. and Fingerman, M., Comp. Biochem. Physiol., 79C:77, 1984). The current study determined whether HA and GABA also affect release of the light adapting hormone (LAH) and dark adapting hormone (DAH) that regulate migration of the distal retinal pigment, a screening pigment. To analyze the effect of HA, crabs on a white background exposed to 637 lx of light were used. HA (125 nmol/crab) produced dark adaptation of the distal pigment. An H_2 receptor agonist, 4-methyl histamine (4-MeHA)(20 µg/crab), also produced dark adaptation, but an H_1 receptor agonist, 2-methyl histamine, did not. An H_2 receptor blocker, metiamide (20 µg/crab), given 10 minutes prior to injection of 4-MeHA inhibited the action of 4-MeHA. Metiamide alone had no effect. These results suggest HA stimulates DAH release or inhibits LAH release by activating H_2 receptors. Because the study of the melanophores favored the interpretation that HA inhibits release of black pigment dispersing hormone, the hypothesis that HA inhibits LAH release is favored. Presumably, when the distal pigment is in a position intermediate between fully light adapted and fully dark adapted, as herein, both LAH and DAH are released to hold the pigment in that position. Inhibition of LAH release would then cause a shift of the position of the pigment toward dark adaptation. GABA (50-125 nmol/crab) produced light adaptation that was directly related to the dose in crabs in white pans exposed to light, 175 lx. GABA (125 nmol/crab) also produced light adaptation in crabs exposed to 88,532 and 700 lx. Crabs transferred from dim (88 lx) to bright (700 lx) illumination and given 125 nmol/crab of GABA exhibited more rapid proximal migration of their distal pigment, toward the fully light adapted position, than did saline injected controls. But GABA (25-125 nmol/crab) inhibited distal migration of the pigment, toward the fully dark adapted position, in crabs transferred from 700 lx to 88 lx, the amount of inhibition being directly related to the dose. A GABA antagonist, picrotoxin, inhibited the action of GABA when injected 15 minutes prior to the GABA injection. Picrotoxin alone had no effect. A GABA agonist, muscimol, produced a small but significant light adaptation. When muscimol was injected with GABA, the effect was additive. The simplest interpretation of these results with GABA, consistent with its well known role as an inhibitory neurotransmitter, is that GABA inhibited DAH release, resulting in light adaptational responses.

70.15 AN EFFERENT NEUROPEPTIDE IN THE EYE OF *LIMULUS*.
H.K. Lehman and R.B. Barlow, Jr. Institute for Sensory Research, Syracuse University, Syracuse, NY 13244.

A circadian clock in the *Limulus* brain generates efferent optic nerve activity at night. The efferent input to the retina exerts multiple physiological and morphological changes which combine to increase visual sensitivity. Octopamine and a neuropeptide appear to act together to mediate these changes, and we have undertaken this study to identify the neuropeptide and to define its actions in the retina.

Biological activity that increases ERG amplitude in a dose dependent fashion can be extracted with acidified aqueous acetone from the retina, brain and circumesophageal ganglia. Moreover, the activity is destroyed by carboxypeptidase Y, trypsin and pronase and thus appears to be a neuropeptide. All tissues have a similar elution profile from Sephadex G-25, however, several peaks elute from CM-Sephadex. The brain and ganglia extracts contain a predominate peak of bioactivity that is strongly retained by the ion exchange resin, whereas the retinal extract elutes much earlier but is more potent.

HPLC has also been used to fractionate the efferent neuropeptide. The brain/ganglia extracts contain activity that is slightly more hydrophobic than the retinal extracts when eluted from a C-18 reverse phase column with a 10 to 35 % acetonitrile gradient with TFA as a counter ion. Only a single peak of activity elutes from HPLC from either of the ion exchange purified extracts. We are currently isolating and sequencing the retinal peptide.

We have also characterized the actions of the purified neuropeptides on the response of single optic nerves. In brief, the peptide decreases the spontaneous optic nerve discharge and increases the response at high light intensities. The latter effect appears to be correlated with an increase in the ERG amplitude.

This work has been supported by NIH grants EY-05861 (HKL), EY-00667, and NSF grant BNS-8320315 (RBB).

VISUAL SYSTEM: DEVELOPMENT AND PLASTICITY I

71.1 THE ROLE AND REGULATION OF CARBONIC ANHYDRASE-II IN EARLY EYE DEVELOPMENT.
P. J. Linser and J. Plunkett. (SPON: G. Freund). The C. V. Whitney Laboratory and The Dept. of Anatomy and Cell Biology, Univ. of Florida, St. Augustine, FL 32086.

In most vertebrate species, the neural retina is one of the most concentrated sources of the enzyme carbonic anhydrase-II (CA-II). In many species including birds, the primary cellular compartment of CA-II in retina is the Muller glial cells. However, during embryonic development, the enzyme is first expressed in very high levels in all retinoblast cells later becoming restricted to the glia as cell differentiation and maturation occurs. Previous studies showed that high levels of CA-II are measured in the neural ectoderm of the embryonic eye as early as day 3 of development in the chicken. We have examined a potential role of this enzyme in early eye development as well as the timing and inductive influences which control its early expression. In mature eye, CA-II activity is directly involved in the regulation of intraocular pressure. Hence we have tested whether or not CA-II activity influences the spherical expansion of the embryonic eye during early morphogenesis. The inhibitor of CA-II activity, methazolamide, was applied to 3-7 day embryos in shell-free culture by two different methods: topically via microosmotic pumps; and by injection into the extraembryonic cavity around the head. In both cases, significant reduction of eye growth was measured.

Our efforts to understand the regulated timely expression of CA-II have focussed on defining the earliest time and location of CA-II expression and attempting to perturb the expression by blocking normal tissue and cell interactions. Using monoclonal antibody immunohistochemistry we have found that the earliest expression of CA-II occurs in the region of neuroectodermal-skin ectodermal interaction and induction around stage 14 (Hamburger and Hamilton) of development. The antigen appears simultaneaously in a few cells of both the neural retina and lens primordia and thus it seems that CA-II expression is one of the early events following embryonic induction of retina and lens. Even as early as day 3 of development (stage 20-22) the distribution of CA-II distinguishes neural ectoderm destined to become retina or PE from contiguous cells destined to become optic nerve. Perturbation of CA-II expression has only been accomplished thus far by either preventing the interaction of the two ectodermal layers or later in development by dissociating neural cells and plating in sparse tissue culture.

71.2 ADHESIVE MOLECULES IN THE DEVELOPING MAMMALIAN RETINA.
J.A. Robson and S. Carbonetto. Dept. Anat. & Cell Biol., SUNY Health Science Ctr., Syracuse, NY, 13210, and Montreal General Hospital Res. Inst., McGill Univ. Montreal, Quebec, Canada, H3G 1A4.

We are using in vitro methods to study histogenesis in the embryonic rat retina. Of particular interest are adhesive molecules important for cell-substrate attachment (e.g. laminin and its receptors) and cell-cell attachment (e.g. NCAM). We have screened whole eyes and organ cultured retinas from embryonic rats for several of these adhesive molecules using immunocytochemistry.

Embryonic rats between 15 and 21 days post-conception have been used. Eyes were dissected and the retinas were cultured. In some cases, ^{3}H-thymidine (plus or minus cytosine arabinoside as a control) was added to the medium. After 24 hours, these retinas were solubilized and counted with a scintillation counter. Other cultured retinas and non-cultured whole eyes were fixed with paraformaldehyde, embedded in polyethylene glycol and sectioned.

The cultured retinas incorporate as much as 100 times more ^{3}H-thymidine than the controls. In thionine stained sections, the neuroepithelium appears healthy although degenerating cells are present in the region of the future ganglion cell layer. Antibodies to cell-substrate adhesive molecules have not labeled the cultured retinas. However, an antibody to NCAM produces staining throughout them. It is prominent in the inner plexiform layer which appears around embryonic day 19. In the whole eyes, anti-NCAM labeling is like that in the cultured retinas. In addition, antibodies to cell-substrate adhesive molecules label tissue, but not in the neural retina. For example, anti-laminin labels the internal limiting membrane adjacent to the growing axons in the optic fiber layer. It also labels the external limiting membrane, while anti-heparan sulfate proteoglycan labels the choroid. These results are consistent with those from other labs suggesting a role for NCAM in cell migration and retinal differentiation, while laminin may be important for the elongation of ganglion cell axons. (Supported by NIH grants EY03940 and NS19068 and NATO grant 0235/87).

71.3 **CYTOGENESIS OF MONKEY RETINA: COMPARISON OF THE GENERATION OF RETINAL PIGMENT EPITHELIUM AND NEURAL RETINA**. D.H. Rapaport[1], D. Yasumura[2*], M.M. LaVail[2] and P. Rakic[3]. [1]School of Anatomy, University of New South Wales, Kensington, NSW 2033 AUSTRALIA, [2]Department of Anatomy, University of California, San Fransisco, CA. and [3]Section of Neuroanatomy, Yale University, New Haven, CT.

The optic vesicle, an embryonic outgrowth of the diencephalon, generates the neural retina and the retinal pigment epithelium (RPE), two tissues which although quite distinct both structurally and functionally remain closely related throughout life. Both their common embryological origin and spatial proximity suggest that the development of one tissue could be influenced by that of the other. The purpose of this investigation was to compare the timing and pattern of cell birth in the RPE with that of the neural retina which was reported previously (Invest. Ophth. Vis. Sci. 24 (Suppl.): 7, 1983). Pregnant female Rhesus monkeys (Macaca mulatta) were injected with ^{3}H-thymidine on selected post-conception days, and the fetuses allowed to come to term and survive for 2-5 postnatal months. At the time of sacrifice, the animals were deeply anesthetized and perfused. An eye was removed, hemisected along the horizontal meridian, embedded in polyester wax, and processed for autoradiography. Tissue was viewed with incident, polarized light in order to resolve silver grains over the pigmented RPE cells. Three sections from each eye were analyzed by counting all labelled cells in 240μm bins sequentially, from the center of the fovea to the nasal and temporal edges.

No labelled cells were found in either the RPE or the neural retina at E27. At E30, a significant number of labelled cells were found in the RPE (mean=8.3 cells/section) and neural retina (ganglion and horizontal cells only). In both tissues labelled cells were only found in an area from the temporal edge of the fovea extending approximately 2mm into nasal retina, encompassing only ~18% of the retinal length. This region expanded gradually, 1.5 mm into temporal retina and 5.0 mm into nasal retina at E43 (~38% of retinal length), and 3.6mm into temporal and 6.7mm into nasal retina at E56 (~69% of retinal length). Concurrently, labelled cells disappeared from an ever expanding central area. As a result there is an annulus of labelled cells centered on the fovea. This is true for ganglion and horizontal cells; however labelled cells of different classes (amacrine, bipolar etc) are still found in central retina, and as a result the annulus is not apparent unless cell class is taken into account. Other cells in the neural retina are generated in the rough, overlapping sequence: amacrine (E38-E110), cone (E38-E102), bipolar (E38-P17), Müller (E45-E110), and rod (E45-P17) cells. The generation of each cell class follows the same spatial pattern described above. The last labelled cells in the RPE were seen at the edge of the retina, at P17. Thus, the period of RPE cell birth spans the entire sequence of birth of the neural retina, from E30 to P17. These data suggest that whatever mechanism controls the onset, spatial pattern, and cessation of cytogenesis in the retina operates simultaneously on both the neural retina and RPE.

71.4 CULTURED RETINAL NEURONS FORM CLUSTERS IN THE PRESENCE OF NEUROEPITHELIAL CELLS. I. Mody, L. Brandes*, M. Deverill* and J.F. MacDonald. Playfair Neuroscience Unit, Dept. of Physiology, Univ. of Toronto and The Toronto Hosp., Toronto, Ont. M5T 2S8.

Monolayer cultures of CNS neurons (e.g., hippocampus) do not form organized cellular laminations as would be characteristic of these regions. We report here that dissociated cultures of cat, guinea pig and mouse retina differ significantly in this regard. Mammalian retinal cultures demonstrate a period of cellular migration during which "clusters" of neurons are formed (as shown in the chick[1]).

Retinae were dissected from 18 day old mouse (the majority of experiments), 120 day old cat, and 50 day old guinea pig foeti. The eye was removed and the retina micro-dissected. Cells were dissociated and cultured using standard techniques for one to two weeks. In some cases, retinal neurons were grown on feeder plates (that included fibroblasts, etc. instead of neurons) derived from retina, hippocampus, spinal cord or cerebral cortex.

Cultures were photographed under phase contrast microscopy. Neuronal somata were located with respect to each other by assigning each cell to the element of a reference grid. The randomness of the spatial arrangement of neurons was determined by fitting observed data to a Poisson distribution with the same mean. Using an adaptation of Lloyd's Indices of Mean Patchiness[2] it was possible to objectively quantify "clustering" of the neurons.

The following observations were made: 1) Retinal cultures consistently demonstrated significant clustering, whereas mouse hippocampal, cerebral cortical, spinal cord or midbrain cultures did not. 2) When retinal cells were grown on feeder plates derived from other CNS regions, clusters were no longer formed. 3) In contrast, when retinal cells were grown on feeder plates derived from the retina, clustering was again observed. 4) If retinal cells were cultured on half of the same dish with hippocampal neurons (no mixing of retina and hippocampus, but shared media) clustering occurred only on the retinal side. 5) If non-neuronal retinal tissue (including the epithelium) was included with hippocampal neurons, they also could be induced to form clusters. 6) In the guinea pig retina, clustering was related to the inclusion of the pigmented epithelial cell layer. These results suggest that clustering of retinal neurons is dependent upon physical contact with support cells such as the neuroepithelium.

71.5 **NEUROTRANSMITTER-RELATED ACTIVITIES IN DISSOCIATED CULTURES OF MOUSE RETINA NEURONS AND PHOTORECEPTORS** L.E. Politi* and R. Adler. Wynn Center, Wilmer Institute, Johns Hopkins Univ. Sch. of Medicine, Baltimore, MD 21205.

Culture systems recently developed in this laboratory allow growth of purified populations of retinal neurons and photoreceptors from both normal and "rd" (retinal degeneration) mice. The differentiation of these cells in serum-free, chemically defined medium has already been investigated by immunocytochemistry and electron microscopy (Invest. Ophthalmol. Vis. Sci. 28:345, 1987). We report here further characterization of these cultured cells using biochemical and autoradiographic methods for neurotransmitter-related activities. High affinity uptake mechanisms were studied by incubating cultures of normal mouse retinal cells for 15 min at 37° in 10^{-7}-10^{-9} M ^{3}H-γ-aminobutyric acid (GABA), glutamate, aspartate, taurine, or glycine, in the presence or the absence of Na^+. The cultures were lysed to determine intracellular radioactivity by liquid scintillation counting, or fixed in glutaraldehyde and processed for autoradiography.

The cultures exhibited uptake mechanisms for all the putative neurotransmitters mentioned above. Most of these uptakes were almost completely inhibited in Na^+-free medium, although glycine uptake was inhibited only 40-60% under the same conditions. GABA uptake was inhibited 90% by excess unlabeled diaminobutyric acid (DABA), but only 10% by β-alanine. Autoradiographic analysis showed that the uptake mechanisms were differentially distributed among different cell types. For example, GABA was accumulated by more than 95% of the multipolar neurons, but was not taken up by photoreceptors. On the other hand, glutamate and aspartate were taken up by 85-95% of the photoreceptor cells, while labeling was seen in only 40% of the other retinal neurons. This labeling was generally less intense than that associated with photoreceptors. Choline acetyltransferase was also present in these cultures.

These studies demonstrate that differentiating retinal neurons and photoreceptors from normal mice can express characteristic neurotransmitter-related activities in serum free cultures. Work is in progress to compare these normal cells with cultured retinal neurons and photoreceptors from "rd" (retinal degeneration) mice.

71.6 IN SITU HYBRIDIZATION TO LOCALIZE NEUROFILAMENT mRNA IN THE GOLDFISH RETINA. P.S. Jones*, P. Tesser* and N. Schechter (SPON. I. Fand) Depts. of Biochemistry, Pharmacology, and Psychiatry, SUNY at Stony Brook, NY 11794.

In situ hybridization experiments are being performed to determine the sites of synthesis of the goldfish visual pathway neurofilament proteins ON_1 and ON_2. Ex vivo protein synthesis and in vitro translation studies have determined that ON_1 and ON_2 are synthesized in the retina, but not in the optic nerve. We have synthesized and cloned cDNAs for ON_1/ON_2 from mRNA isolated from the retina. We have subcloned a 150 nucleotide Eco R1 fragment encoding a portion of the carboxyl variable region of ON_1/ON_2 into a T_3/T_7 transcription vector and have used this system to synthesize ^{35}S and biotin labeled RNA probes. These transcripts are being used to localize the ON_1/ON_2 message in the retina. Previous experiments using polyclonal antibodies directed against ON_1 and ON_2 revealed high amounts of immunoreactivity in the retinal ganglion cell layer, and lower levels of reactivity elsewhere in the retina. In situ hybridization analysis will determine whether ON_1 and ON_2 are synthesized in various other cell types in the goldfish retina, for example, the amacrine cells. Furthermore, this type of analysis will be able to determine whether the regeneration-induced increase in synthesis of ON_1 and ON_2 occurs in all ganglion cells, or whether it is restricted to a specific subpopulation of cells, for example, the younger, peripherally located retinal ganglion cells. This research is supported by a grant from the NIH (EY-05212 to N.S.).

71.7 RNA SYNTHESIS IN THE GANGLION CELL LAYER OF THE DEVELOPING CAT RETINA. H.E. Pearson, D.L. Smith*, N.K. Rosenblatt*, B.R. Payne and T.J. Cunningham. Depts. of Anatomy, Temple Univ. Sch. of Medicine, Philadelphia, PA 19140, Boston Univ. Sch. of Medicine, Boston, MA 02118 and Medical Coll. of Pennsylvania, Philadelphia, PA 19129.

Ablation of visual cortex in the cat results in primary retrograde degeneration of cells in the dorsal lateral geniculate nucleus (dLGN) of the thalamus. Such degeneration deprives many retinal ganglion cells of their principal target neurons. In cats which survive to adulthood, the long-term effects of the ablation can be seen in the transneuronal retrograde degeneration of retinal ganglion cells, particularly in peripheral retina, and in the reorganization of the axon projections of the surviving cells. We were interested in determining any short-term metabolic changes in retinal ganglion cells which may provide some insight into the mechanisms underlying these morphological effects.

Retinae were obtained from intact kittens and from kittens in which all the contiguous visual cortical areas had been ablated bilaterally on the day of birth (P1). All kittens received bilateral intraocular injections of tritiated uridine 24 hours prior to sacrifice and were perfused with aldehyde fixative on postnatal days 2,4 and 7 (P2, P4 and P7). The area centralis was dissected from each retinal wholemount and the resulting sample embedded in plastic. Sections one micron in thickness were processed for autoradiography and stained through the emulsion with toluidine blue. The density of overlying silver grains was determined for 100 neurons within the ganglion cell layer of each retina.

Within each retina, the grain densities showed a unimodal distribution. There was therefore no evidence of any separation of the different neuronal populations, such as displaced amacrine and ganglion cells, on the basis of differences in uridine uptake. No differences in average grain density were found between intact kittens and those with neonatal visual cortex ablation at any of the ages studied. However, the average grain density in both intact and ablated kittens was significantly higher at P4 than at either P2 or P7, when the densities were not different from each other. These results show that developmental changes occur in the uptake and incorporation of uridine into RNA in neurons of the retinal ganglion cell layer during the first week of postnatal life. The results suggest that this increase in RNA synthesis at P4 relates to developmental events intrinsic to the retina and is independent of interactions with target neurons in the dLGN.

71.8 MATERNAL SUPPLY OF N-3 ESSENTIAL FATTY ACIDS TO THE DEVELOPING MOUSE RETINA. B.L. Scott, J. Moises and N.G. Bazan (Sponsored by H.E.P. Bazan), LSU Eye Center, 2020 Gravier Street, Suite B, New Orleans, LA 70112

The n-3 essential fatty acid family comprises a series of polyunsaturated fatty acids possessing a double bond at the n-3 carbon -- the third carbon from the methyl terminus of the fatty acyl chain. The major n-3 fatty acid found in membranes is docosahexaenoic acid (22:6), which contains twenty-two carbons and six double bonds and is found in high concentrations in synaptic membranes and in the outer segment disk membranes of retinal photoreceptor cells. The function of 22:6 in photoreceptor membranes is not known although the fatty acid may facilitate phototransduction. 22:6 is retained tenaciously by retinal membranes when animals are placed on an n-3 deficient diet. Long-term n-3 deficiency, however, is known to alter the normal electroretinogram (Wheeler et al, Science 188:1312, 1975) and compromise visual acuity (Neuringer et al, J Clin Invest 73:272, 1984). Animals cannot synthesize 22:6 de novo, rather it must be formed by elongation and desaturation of other members of the n-3 family, the most common precursor being linolenic acid (18:3, n-3).

We are interested in the metabolism of n-3 fatty acids and their accumulation in the developing retina. In order to determine in the mouse, the form in which n-3 fatty acids are supplied by the mother to her pups, we have determined the fatty acid composition of the stomach contents and blood plasma of developing mouse pups. Analysis of stomach contents of the pups reflects the composition of the mother's milk. Analysis of plasma obtained from the pups reflects any n-3 metabolism carried out by the developing animals.

Stomach contents and plasma were obtained from 1- to 27-day-old normal C57BL/6J mouse pups. Total lipid extracts were prepared using 2:1 (by vol) chloroform-methanol. Fatty acyl groups were converted to methyl esters and resolved by capillary gas-liquid chromatography, using a 30m x 0.25 mm capillary column containing a 10% SP-2330 stationary phase (Supelco, Inc.).

For the first two weeks of post-natal development, the stomach contents of pups exhibited an 18:3/22:6 molar ratio ranging from 2 to 4, indicating that the maternal supply of n-3 fatty acids was primarily in the 18:3 form. At about 14 days of age, the pups became able to feed on the adult hard-pellet diet, which was found to possess an 18:3/22:6 molar ratio of about 750. Clearly, throughout development, the primary supply of n-3 fatty acids to the developing pups was in the form of 18:3. The plasma samples taken from the pups revealed an 18:3/22:6 molar ratio of less than one at all ages sampled. Thus, the developing mouse pup has the ability to rapidly desaturate and elongate 18:3 supplied by the mother, converting it to 22:6 for subsequent incorporation into retinal lipids. Supported by EY04428.

71.9 THE PRENATAL DEVELOPMENT OF THE A-TYPE HORIZONTAL CELL OF THE CAT'S RETINA: AN ELECTRON MICROSCOPIC AND AUTORADIOGRAPHIC STUDY R.P. Zimmerman, R.L. Fortney & R.H.Polley, Rush Medical College and University of Illinois, Chicago 60612

The development of a specific class of interneuron of the mammalian retina, the A-type horizontal cell (AHC), was studied in the retina of the cat using transmission and scanning electron microscopy and light microscopic tritiated thymidine autoradiography. Where possible, observations were made in central retina; and all times quoted refer to this region.

Previous autoradiographic studies of the retinas of adult cats injected during fetal development have established that AHC undergo their final cell division during the earliest period of neurogenesis, from E22 (embryonic day 22) to E30. Retinas examined electron microscopically during the third through fifth week of development (E20, E24, E28, E35) do not show a distinct morphological population that might represent committed AHC neuroblasts. However, by E40 AHC (labelled by a tritiated thymidine injection at E26) have migrated away from the outer limiting membrane, and their somata are larger than those of either the cones or the ganglion cells produced on the same day.

While the AHC somata form a distinct layer after E40, their processes do not form a continuous outer plexiform layer (OPL) for about another 10 days. The infolded nucleus and electron-lucent cytoplasm characteristic of the adult AHC appear by E49. At this time the AHC dendrites are directed radially as well as horizontally. The dendrites of the AHC become predominantly horizontal and form a continuous OPL at E51 (central retina) or later. By E56 these dendrites are postsynaptic to photoreceptors at flat contacts and dyadic ribbon synapses. The ribbon synapses are complete with arciform densities, presynaptic vesicles and postsynaptic membrane specializations. Thus, morphologically, and perhaps functionally, maturing synapses are found in the OPL more than a week before birth. Supported in part by EY 6163 and EY 4593.

71.10 DEVELOPMENT OF GABA-LIKE IMMUNOREACTIVITY IN HORIZONTAL CELLS AND THE OUTER PLEXIFORM LAYER OF THE RAT RETINA. B-A. Battelle and T. W. Hilton*. C. V. Whitney Laboratory and the Department of Neuroscience, University of Florida, St. Augustine, Florida 32086.

GABA-like immunoreactivity (GABA-LI) has recently been identified in subpopulations of horizontal cells (H-cells) and in the outer plexiform layer (OPL) of a number of mammalian species. We reported the presence of GABA-LI in the rat retina during early postnatal development. Here we describe the development of this GABA-LI during the first two postnatal weeks. GABA-LI was detected in 15 um frozen sections of glutaraldehyde-fixed retinas using antibody purchased from Immunonucler and the PAP technique of Sternberger. Staining was completely blocked when the antiserum was preabsorbed with BSA-conjugated GABA. Sections were cut along the superior-inferior axis and most sections analyzed either passed through or were close to the optic nerve head in the nasal half of the eye.

GABA-LI develops in the H-cells and the OPL with a distinct central to peripheral gradient. On postnatal day 2 (P2) a few cells lightly stained for GABA-LI were observed in the outer 1/3 of the retina near the optic nerve head. At this time strong GABA-LI was already present in the developing ganglion cell, inner plexiform and amacrine cell layers. On P4 a short row of cells and fibers containing GABA-LI was observed near the optic nerve head in the region of the developing OPL. Peripheral to this, other GABA-LI cells were seen scattered in the outer 1/3 of the developing retina extending 3/4 of the distance toward the peripheral edge of the retina. By P-6 a row of cells and fibers containing GABA-LI extended 3/4 of the distance toward the peripheral edge of the retina in the region of the developing OPL. GABA-LI reached the peripheral edge of the retina by P10. The OPL of retinas from P10 rat retinas also stained with antibodies directed against glutamic acid decarboxylase.

GABA-LI also fades from the H-cells and the OPL with a central to peripheral gradient. At P12, it is less intense in the central retina compared to that seen in the periphery, and by P14, it was no longer detected in this layer in the central retina, but faint staining persisted in the periphery. We were unable to detect GABA-LI in this layer in the adult rat retina. Our observation that the GABA-LI appears just as the OPL develops and then declines, suggests that GABA may have a special role to play in OPL development.

Others (Mosinger et al. 1986 and Osborn et al. 1986) using different antibodies directed against GABA have reported GABA-LI in horizontal cells and the OPL of the adult rat retina. It is not clear whether the cells containing GABA-LI described here are the same or different from those found in the adult rat retina.

71.11 A DEVELOPMENTAL STUDY OF GAMMA-AMINOBUTYRIC ACID IMMUNOREACTIVE CELLS AND PROCESSES IN THE EMBRYONIC CHICK OPTIC TRACT. R.H.Granda* and W.J. Crossland, Dept. Anatomy and Cell Biology, Wayne State Univ. Schl. Med., Detroit, MI 48201.

We have previously shown the existence of cells that are immunoreactive to an antibody to gamma-aminobutyric acid (GABA+ cells) in the chick optic tract. These cells have neuronal morphology at the light and electron microscopic level and stain positively with an antibody to neuron-specific enolase. To further understand the origin of these cells, we undertook a study of their morphology and distribution in the chick embryo.

Chick embryos ranging in age from day 10 of incubation (E10) to day 18 (E18) were perfused with a mixed aldehyde solution. Frozen (40-60u.) or polyethylene glycol embedded (10-20u.) sections were incubated in a 1/1000 rabbit anti-GABA antiserum (provided by Dr. R. Pourcho) and visualized with an avidin-biotin system (ABC kit, Vector Labs) using diaminobenzidine as a chromagen.

GABA+ cells were seen in the tract as early as E10. Antibody staining demonstrated neuron-like morphology (bipolar and multipolar) of the GABA+ cells at all stages examined. Many cells near the GLv had one stout process perpendicular to the tract fibers, while other cells lacked the stout process and gave off finer processes parallel to the fibers. At E10, GABA+ cells were seen in the optic tract near the ventral lateral geniculate nucleus (GLv), while at later stages these cells shifted medially toward the chiasm. Thus the cells may originate from the more laterally placed visual centers such as the GLv or optic tectum.

GABA+ growth cone-like enlargements were seen at the ends of GABA+ (presumably axonal) processes between E10 and E14 in the optic tract and could be followed into the optic nerve or into the contralateral optic tract. It is unlikely that the processes originate in the isthmo-optic nucleus because its cells and processes are not GABA+ in the mesencephalon, and therefore the growth cone-like enlargements may originate from the GABA+ tract cells or from "aberrant" projections from other visual centers.

This study was supported in part by grants from the Michigan Eye Bank (W.J.C.) and by an NIH Core Grant (EY-04068). R.H.G. was supported by a fellowship from the Neuroscience Program at Wayne State University.

71.12 MONOCLONAL ANTIBODIES SPECIFIC FOR INTERMEDIATE FILAMENT PROTEINS OF NEURONAL AND NON-NEURONAL ORIGIN IN THE GOLDFISH VISUAL PATHWAY. J. Borchert*, P. Jones*, F. Salles*, and N. Schechter (SPON. W. Quitschke) Depts. of Biochemistry, Pharmacology, and Psychiatry, SUNY at Stony Brook, NY 11794.

We have generated monoclonal antibodies which can distinguish between neuronal and non-neuronal intermediate filament (IF) proteins in the goldfish visual pathway. The IF proteins of this pathway do not match the conventional classification as found in mammalian neural tissue. The predominant IF proteins of the goldfish optic nerve have a molecular weight of 58K, and can be separated into a series of isoelectric variants, designated as ON_1 - ON_4. ON_1 and ON_2 are neurofilament proteins, whereas ON_3 and ON_4 are non-neuronal IF proteins. Peptide mapping analysis indicates that ON_1/ON_2 are similar to each other but differ from ON_3/ON_4 which are also similar to each other.

BALB/c mice were immunized with goldfish optic nerve cytoskeletal proteins. After the fourth immunization, the spleen cells were fused with 8653 mouse myeloma cells. Approximately 500 clones were obtained from the fusion. The clones were screened by reacting the supernatents against cytoskeletal proteins using the ELISA assay which we developed. Forty-five clones produced positive signals. Of these, four clones which were extremely reactive were used to probe the cytoskeletal proteins by Western immunoblot analysis of 2D gels. Three clones reacted specifically with proteins ON_1/ON_2, and one clone reacted with ON_3/ON_4 and a 48K protein which was previously reported to be of non-neuronal origin.

IF proteins consist of a conserved 40K core region which is flanked by two variable domains. These variable domains are responsible for the observed diversity associated with this class of proteins. Therefore, monoclonal antibodies specific for particular IF proteins more than likely recognize epitopes in the variable domains. The monoclonal antibodies against the goldfish IF proteins differentiate a homologous class of proteins from two different cell types, i.e., retinal ganglion cells and glial cells, the former of which displays a remarkable capacity for nerve regeneration. This research is supported by a grant from the NIH (EY-05212) to N.S.

71.13 cDNA CLONING OF THE INTERMEDIATE FILAMENT PROTEINS OF NEURONAL AND NON-NEURONAL ORIGIN IN THE GOLDFISH VISUAL PATHWAY. S. Giordano*, P. Tesser*, and N. Schechter. Departments of Biochemistry and Psychiatry, SUNY at Stony Brook, New York 11794.

We are investigating the structure of the predominant intermediate filament proteins of the goldfish visual pathway. These proteins have a molecular weight of 58K and can be separated into a series of isoelectric variants which have been designated as ON_1-ON_4. ON_1 and ON_2 are similar to each other but differ from ON_3 and ON_4 which are also similar to each other. In vivo and in vitro studies indicate that the levels of synthesis of ON_1 and ON_2 are linked to the regeneration of the optic nerve, whereas the synthesis of ON_3 and ON_4 is rather stable during the process. ON_1 and ON_2 are neurofilament proteins and ON_3 and ON_4 are non-neuronal intermediate filaments. cDNA cloning experiments were initiated in order to compare these proteins at the structural level and also to compare them with other higher vertebrate intermediate filament proteins which may be involved in cell differentiation and neurogenesis.

In addition to a previously reported cDNA library from retina which contained positive clones for ON_1 and ON_2, we have now prepared a cDNA library from optic nerve. The glial cells are the predominant source of RNA from the optic nerve. Although we are only able to obtain approximately 1 microgram of total RNA per optic nerve, we have been successful in translating total optic nerve RNA and have specifically immunoprecipitated ON_3 and ON_4 with anti-ON_3/ON_4 polyclonal antibodies. Furthermore, total optic nerve RNA provided satisfactory templates for cDNA synthesis in the presence of oligo(dT) as a primer. Total RNA was reverse transcribed using RAV reverse transcriptase followed by second strand synthesis using RNase H and DNA polymerase. The cDNA was subsequently methylated, tailed with Eco RI linkers, and cloned into the lambda gt 11 expression vector. A library of over 1.5×10^6 recombinants was generated containing cDNA inserts of approximately 1 KB. We are now employing both polyclonal and monoclonal antibodies to screen this library for positive clones for proteins ON_3 and ON_4.

Intermediate filament proteins contain a 40K core region which is highly conserved with respect to its amino acid composition. The diversity of this class of proteins is generated by variable regions which are adjacent to either side of the core. It has been suggested that these variable regions may be involved in special functions associated with the differentiated state of specific cells. A structural analysis of the goldfish ON proteins will help to determine what the contribution of these variable regions are to the function of intermediate filament proteins in neurogenesis and nerve regeneration. This research is supported by a grant from the NIH (EY-05212) to N.S.

ALTERED RETINAL AMINE NEUROTRANSMITTERS IN FORM-DEPRIVATION MYOPIA. R.A. Stone, T. Lin*, A.M. Laties and P.M. Iuvone. Dept. of Ophthalmology, Scheie Eye Inst., Univ. Pa. Sch. of Med., Philadelphia, PA 19104 and Dept. of Pharmacology, Emory Univ. Sch. of Med., Atlanta, GA 30322.

Deprivation of form vision in the newborn chick causes exaggerated postnatal ocular growth. As a result, distant images focus in front of the plane of the retina, and a myopic refractive error results. The paramount anatomical changes, an increase in axial and equatorial dimensions, resemble common human myopia. We induced form deprivation myopia in day-old male White Leghorn chicks under aseptic conditions and ether anesthesia using one of three procedures, all unilateral:
1) eyelid suture; 2) translucent plastic goggle; or
3) transparent plastic goggle.

At two or four weeks of age, the chicks were killed by decapitation. The visually deprived eyes were significantly larger in both axial and equatorial dimensions than contralateral control eyes. By high performance liquid chromatography with electrochemical detection, the following statistically significant alterations in the concentration of biogenic amines expressed as percent of contralateral control were measured in post-equatorial retinas of the myopic eyes:

	Two Weeks - Percentage Change			Four Weeks - Percentage Change		
	Eyelid Suture	Translucent Goggle	Transparent Goggle	Eyelid Suture	Translucent Goggle	Transparent Goggle
Dopamine	-23%	-20%	-25%	-29%	N.S.*	-23%
DOPAC	-62%	-37%	-42%	---	N.S.	N.S.
Serotonin	+67%	+23%	N.S.	+53%	N.S.	N.S.

*N.S. = Not Significant

Thus, deprivation of form vision in the chick by all three procedures induces a reduction in retinal dopamine concentration at two weeks. This tendency persists at four weeks, at least for two of the experimental conditions. In contrast, serotonin concentrations are elevated after eyelid suture at two and four weeks and after translucent goggles at two weeks. Further work is necessary to seek a role, if any, for biogenic amines in the exaggerated ocular growth that accompanies form deprivation.

71.15 INCREASED POTENTIATION OF POSTSYNAPTIC RESPONSES CORRELATES WITH SENSITIVE PERIOD DURING OPTIC NERVE REGENERATION IN GOLDFISH.
J.T. Schmidt, Dept. Biol. Sci., SUNY Albany, NY 12222.

In this study, I tested for an increased capacity for long term potentiation in the regenerating projection and its possible relationship to the activity driven sharpening of the retinotopic map on tectum. In the normal optic pathway, supramaximal stimulation gives rise to very stable field potentials in tectum (approx. 4 mV maximum negative response in the retinal synaptic layer). After moderate or high frequency trains of stimuli, there are only very small increases (20-30%) in response amplitude (see also Lewis and Teyler, Brain Res. 375:246, 1986). The regenerating projection first yields small field potentials around day 20 postcrush (0.1 mV), and the amplitude becomes larger at longer times postcrush reaching normal by 5 months. At 20 to 30 days postcrush, the small (0.1-1 mV) responses fatigue rapidly during repeated stimulation. However, administering as few as 6 to 20 supramaximal stimuli at 0.1 Hz typically results in a 100 to 200% increase in response amplitude when tested 15 to 30 minutes later. (To test without potentiating, I stimulated only once per 30 min. which resulted in stable potentials.) Subsequent trains of stimuli resulted in smaller percentage gains in response amplitude, but the cumulative gain could be very large, and the increased responses were both stable for many hours and less susceptible to fatigue. At later times during the sensitive period (40-80 days), smaller but significantly enhanced potentiations could still be elicited. I am currently testing whether the NMDA blocker APV can prevent potentiation without decrementing ongoing responses. Doses less than 50 μM cause little reduction in response amplitude, but larger ones in the mM range block transmission. In one fish, the 50 μM dose prevented the potentiation suggesting a possible role for NMDA receptors.

During regeneration the newly formed retinotopic map goes through an activity dependent sharpening process that can be disrupted either by blocking activity with tetrodotoxin or by synchronizing activity with strobe illumination (Schmidt, Cell & Molec. Neurobiol. 5:65, 1985). The lack of sharpening could be seen in electrophysiological maps which indicate uncorrected errors in targeting of regenerated arbors. HRP stained regenerating optic arbors make early widespread branches that are usually eliminated (Schmidt et al., Neurosci. Abstr. 10:667, 1984). In the current model, retinotopically appropriate synapses (and branches) may become more effective (and therefore stabilized) because normally correlated firing of neighboring ganglion cells can cause summation of postsynaptic responses. A requirement for coincident activation of converging inputs bears a formal similarity to associative conditioning, which is thought to involve a change in synaptic circuits, either an increased strength of existing synapses or an increased number of synapses. (Supported by NIH grant EY03736).

CORTEX: MOTOR CORTEX I

72.1 MOTOTOPIC ORGANIZATION OF BABOON PRIMARY MOTOR CORTEX: FACE AND FORELIMB REPRESENTATIONS.
S. McFarlane*, D.D. Samulack, R.S. Waters[1], R.W. Dykes, P.A. McKinley, S.S. Leclerc* and N.J. Kabani* (SPON: D.W. Baxter). Depts. of Physiology, Surgery, Neurology and Neurosurgery, Physical and Occupational Therapy, McGill Univ., Montreal, Quebec H3A 1A1, and [1]Dept. of Anatomy and Neurobiology, Col. of Med., Univ. of Tennessee, Memphis, TN 38163.

Re-representations of muscles, movements, and body parts in primary motor cortex have been described in several primate species, emphasizing the need for a re-examination of the principles of organization for this motor region. Intracortical microstimulation (IMCS) was used to elucidate these principles.

Four female adult baboons (Papio c. anubis) were anesthetized with a mixture of halothane and nitrous oxide. A craniotomy was performed over the primary motor cortex and the dura reflected. A well of dental impression wax was formed and filled with silicon fluid. After surgery the level of gas anesthesia was reduced and spontaneous movements were attenuated with small doses of sodium pentobarbital. Trains of cathodal stimulus pulses (12-13 pulses, 0.2 ms duration, 300Hz) were delivered at 200 μm steps through a tungsten-in-glass microelectrode inserted into the motor cortex. Whenever a motor response was observed, the effective muscle(s) was noted and the threshold for activation was recorded.

The degree of variability observed among the four animals studied was sufficient to preclude pooling the data from individual animals. An overall mototopic progression was apparent in each animal, with muscles of the tongue located most laterally followed in a medial direction by a regular progression of muscles of the face, hand, forearm, and shoulder. The areal extent devoted to any one of these major muscle groups was significantly different among animals. As well, the sequence of individual muscles encountered within any region varied.

Previous reports of a dual forelimb representation were not confirmed in this study. Efforts to subdivide the data into a rostral and caudal map were unsuccessful and it became clear that the same muscle could be represented three or four times at distinctly different sites within the cortex. In all animals, numerous penetrations failed to elicit muscle contractions, suggesting that activation of some portions of motor cortex fail to produce overt contractions. These regions were termed silent zones. The consistent location of silent zones among animals, and the repeated confirmation of their lack of excitatory effect within animals ruled out the possibility of artifact.

Contrary to the situation in other primates and man, most of the effective motor cortex was located on the anterior wall of the central sulcus, with little or none of the cortex located on the gyral crown displaying low threshold motor foci.
(Supported by MRC MA5522 and NSF BNS 83-17662).

72.2 SILENT ZONES AS A CONSISTENT AND INTEGRAL COMPONENT OF THE MOTOTOPIC ORGANIZATION OF BABOON MOTOR CORTEX.
D.D. Samulack, R.S. Waters[1], R.W. Dykes, P.A. McKinley and S. McFarlane*. Depts. of Physiology, Physical and Occupational Therapy, McGill Univ., Montreal, Quebec H3A 1A1, and [1]Dept. of Anatomy and Neurobiology, Col. of Med., Univ. of Tennessee, Memphis, TN 38163.

In an accompanying report we described the organization of the face and forelimb representation of baboon (Papio c. anubis) motor cortex as being composed of a regular progression of body parts, with the tongue region located most laterally, and shoulder regions more medially. However within this pattern of organization, individual muscles were often re-represented as many as four times. While collecting the data for these maps, points in the penetration sequences were often encountered where intracortical microstimulation (ICMS) failed to elicit observable muscle contractions. Initially we assumed that the absence of an observable motor response was the result of electrode failure, level of anesthesia, state of the animal, and/or location of the affected muscle deep within the limb.

Evidence that the silent zones were not an artifact comes from several observations: (i) the silent zones were located consistently at junctions between major muscle groups, (ii) the silent zones were found at comparable locations in each of the four animals studied, (iii) the silent zones were found both earlier and later in the experiment and their locations could be verified on subsequent days by reinsertion of another electrode into a region mapped earlier, (iv) the silent zones were observed at several anesthetic levels. Evidence that the silent zones did not reflect activation of muscle groups that escaped detection, comes from data collected with EMG electrodes. By inserting Teflon coated silver wires into muscles of the hand, forearm, and face, it was possible to check for EMG activity correlated with ICMS that did not elicit overt movements. The results showed that any time an EMG was observed, it was closely related to an observable muscle contraction. Thresholds for EMG and visible muscle contractions seldom differed by more than a few microamperes. Silent zones were characterized by a lack of ICMS-related EMGs as well as a lack of overt contractions.

The role of these silent zones remains an enigma, but their large size and consistent relationship to other parts of the motor cortex suggests that they comprise an important feature of this tissue.

72.3 MOTOR CORTICAL REPRESENTATION PATTERNS SHIFT RAPIDLY FOLLOWING MOTOR NERVE SECTION. J. P. Donoghue, S. Suner*, J. F. Lando* and J. N. Sanes. Center for Neural Science, Brown University, Providence, RI 02912 and Human Motor Control Section, Medical Neurology Branch, NINCDS-NIH, Bethesda, MD 20892

Peripheral nerve injury in neonatal or adult rats alters somatotopic representation patterns in primary motor cortex (MI, Donoghue and Sanes, 1987; Suner et. al., 1986). MI reorganization was observed as early as 8 days following nerve lesions and could be obtained when lesions were restricted to a motor nerve. The present study was designed to determine the shortest interval in which MI representations reorganize following a motor nerve injury.

Intracortical electrical stimulation techniques were used to map MI in 7 rats. Rats were anesthetized with ketamine HCl and PtIr microelectrodes were used for MI stimulation. The electromyogram (EMG) was recorded from the biceps and wrist extensor muscles contralateral to the mapped cortex. Vibrissa and forelimb representations were located by stimulating, with standard pulse trains (60 μA) at 12-16 sites 500 μm apart. A single site within the vibrissa region, about 500 μm medial to the forelimb area, was chosen. The microelectrode was located at this test site prior to transection of the marginal mandibular and buccal branches of the facial nerve and was kept in place for as long as 10 hours in 4 rats. At 15-60 minute intervals forelimb muscles EMG activity was recorded during presentation of 30 stimulation trains. After repeated testing at this site, several of the previously mapped MI sites were stimulated a second time.

At each test site electrical stimulation showed a shift from vibrissa to forelimb movements between 45 and 90 minutes following transection of the facial nerve. Prior to the nerve section, no biceps or wrist extensors EMG was evoked in 2 rats, but in the other 2 rats the averaged EMG revealed a small amount of activity in either biceps or wrist extensors. After nerve section, peak forelimb EMG evoked from the test site was 30-80% of the maximum EMG evoked from stimulation in the normal forelimb area. The maximal muscle activity occurred from 1-7 hours after the facial nerve transection. By 10 hours, muscle activity could still be evoked in 5 of the 8 muscle recordings. When border sites were retested after the nerve transection, different movements (either forelimb or eye) were evoked from some of these sites. In 3 control rats, an electrode was placed in the MI vibrissa region near the forelimb border, the facial nerve was not transected, and muscle activity was recorded every 15 to 30 minutes for the next 6-7 hours. In none of these controls did stimulation within the vibrissa region evoke forelimb EMG.

These experiments demonstrate that one region of MI can assume control over muscle groups that are ordinarily allocated to other MI areas. Within 1-2 hours of a facial nerve transection, electrical stimulation within the MI vibrissa region evoked activity in forelimb muscles. The rapid time course of this shift in MI representation suggests that the basis for reorganization is not anatomical (e. g., collateral sprouting), but is related to mechanisms that regulate the strength of existing synapses. These results further suggest that MI representation patterns are dynamic, and that these changes could be related to allocation of MI cortical tissue according to motor output exigencies.

72.4 FUNCTIONAL GROUPINGS OF MUSCLES IN THE FORELIMB AREA OF PRIMATE MOTOR CORTEX. S.J. Leibovic*, T. S. Buchanan*, J.P. Donoghue, and J.N. Sanes (SPON: V. A. Jennings). Dept. of Brain and Cognitive Sciences, M.I.T. Cambridge, MA 02139, Dept. of Orthopedics, Children's Hospital, Boston, MA 02114, Center for Neural Science, Brown University, Providence, RI 02912, Section of Human Motor Control, NINCDS, NIH Bethesda, MD 20892.

Numerous studies have reported that the primary motor cortex (MI) is organized in terms of movements about a given joint. However, the precise representation of individual and groups of muscles in MI remains unclear. We have combined intracortical electrical stimulation and EMG recording to identify muscle representation patterns in MI. Muscle representations were mapped during ketamine anesthesia (i.v.) in one squirrel monkey and two rhesus monkeys using trains of electrical stimuli (10 pulses, each 200 μsec long, at 333 Hz) delivered through PtIr microelectrodes inserted at 250 to 500 μm intervals in the MI forelimb area. Muscle activity was recorded from 12 arm, forearm, or hand muscles. At each MI stimulation site the EMG evoked in each muscle was simultaneously recorded. Surface maps of integrated EMG were constructed; in the rhesus monkeys this required unfolding of the cortex in the posterior bank of the central sulcus.

Cortical maps showed that most muscles were represented in single contiguous territories, although multiple separate sites where maximal EMG activity could be elicited within this representation were present. For some muscles maximal activity could be evoked from disparate areas separated (>2 mm) by regions of minimal EMG activity. Multiple, completely separate representations were only found for some distal muscles, such as the intrinsic thumb and hypothenar muscles. In all monkeys studies muscles that act synergistically across a single joint have highly overlapping representations in cortex. This includes the elbow flexors, wrist flexors and extensors, and the intrinsic muscles of the thumb. Wrist muscles that can act either as synergists or antagonists occupy largely separate cortical territories. For example, extensor carpi ulnaris and flexor carpi ulnaris which can act as antagonists (to extend or flex the wrist) or as synergists (to produce ulnar deviation), had little overlap in the regions from which maximal EMG was evoked. Pairs of muscles which commonly act together to move the digits have a high degree of overlap in their cortical representation. These include the thumb and finger extensors, as well as the thumb and finger flexors.

These data indicate that regions of motor cortex may be organized to participate in the action of particular muscle groups. The cortical contribution to some movements must therefore require the activation of multiple cortical areas because the muscles are represented in spatially separate zones. Other movements, in particular those involving synergistic muscles, might require cortical activation of only a single site where muscle representations are overlapping. However, our recent findings (Donoghue et al., this meeting) suggest that motor cortex is able to shift representation patterns in short periods of time, at least following nerve lesions so that these relationships may be altered by changing peripheral conditions. Supported by NIH 22517, 25074, 09343, AM26710, and United Cerebral Palsy Foundation.

72.5 SYNAPTIC INTERACTIONS BETWEEN IDENTIFIED PRIMATE MOTOR CORTEX CELLS DURING WRIST ACTIVITY W.S. Smith* and E.E. Fetz, Dept. of Physiology & Biophysics and Regional Primate Research Center, Univ. of Washington, Seattle, WA 98195

We tested the hypothesis that the active response properties of identified motor cortex cell pairs are related to the synaptic interactions between them. Pairs of neighboring neurons were recorded with independently controlled microelectrodes in precentral cortex of Macaque monkeys performing alternating ramp-and-hold isometric wrist torques. Neurons were characterized by their relation to the task, their relative cortical location, and classified as pyramidal tract (PT), non-PT, or corticomotoneuronal (CM) cells. CM cells were identified by post-spike facilitation in spike-triggered averages of rectified forearm EMG activity. *Cross-correlation histograms* were compiled for 233 pairs of identified neurons; 95 of these correlograms exhibited peaks that straddled the origin, indicative of common synaptic input. The peaks had a mean width of 21.8 ± 11.1 (SD) ms, an average mean percent increase of firing above baseline of 21.4 ± 21.2%, and a mean normalized peak area of 0.055 ± 0.041. The widths of the correlogram peaks did not differ significantly for the six possible combinations of cell types; however the mean percent increase and peak areas were larger for pairs that included non-PT cells. The peaks of correlograms between CM cells and non-CM cells were too broad and shallow to artifactually mediate the long-latency, sharply rising post-spike facilitation in spike-triggered averages from non-CM cells.

To determine whether the strength of short-term synchrony between cell pairs was related to the similarity in their firing properties, we also quantified their *covariation*. The degree of covariation was measured as the correlation coefficient (r) of the the smoothed instantaneous firing rates of the two units, using a running 200 ms average. These r values ranged from -0.7 (for inversely varying pairs) to +0.9 (for strongly covarying pairs). The degree of covariation of the cells was not related to their short-term synchrony - measured either by the mean percent increase or the normalized peak area. This result indicates that a significant amount of common input to these cells is not task related; moreover, the covariation of cell pairs appears to be mediated more by covarying parallel inputs than by common synaptic input.

72.6 INPUT-OUTPUT RELATIONS OF NEURONES IN PRECENTRAL AND POSTCENTRAL OROFACIAL CEREBRAL CORTEX OF AWAKE MONKEYS (MACACA FASCICULARIS). C.-S. Huang, H. Hiraba*, G.M. Murray and B.J. Sessle. Faculty of Dentistry, Univ. of Toronto, Toronto, Canada M5G 1G6.

Little information is available of the cortical mechanisms contributing to sensorimotor integration of orofacial movements. This study was designed to delineate the functional organization of the orofacial sensorimotor cortex in terms of (a) afferent inputs, as determined by electrophysiological recording of superficial and deep inputs to single neurones, and (b) efferent outputs, as revealed by intracortical microstimulation (ICMS) delivered to the same recording sites.

In two awake monkeys, a series of microelectrode penetrations was made at 0.5-1.0 mm intervals across the precentral and postcentral cortex; it extended rostrocaudally and mediolaterally 2.0-4.0 mm beyond the boundaries of the orofacial motor cortex (MI), defined as the area within which ICMS (≤20 μA) could induce twitch movements of face, jaw or tongue muscles. At 250 μm intervals within each penetration, light tactile and muscle stretch stimuli were delivered to the orofacial region to test for neuronal responsiveness, and then ICMS was applied to test for orofacial muscle activation. Jaw position and EMGs of temporalis, masseter, genioglossus, and digastric muscles were continuously monitored during the experiment. Electrolytic lesions were placed at selected intracortical sites to aid histological reconstruction.

We confirmed our earlier findings that MI is characterized as a laterally facing horseshoe-shaped facial muscle representation partially enclosing the cortical representations of the jaw and tongue, and that multiple representation of individual orofacial muscles occurs in MI. Sensory inputs were tested for 685 neurones in MI, 609 neurones in primary somatosensory cortex (SI), and 426 neurones in premotor cortex (PM). Deep, and especially light tactile, stimuli were effective in activating 361 neurones in MI, 506 neurones in SI, and 116 neurones in PM. Mechanoreceptive fields were predominantly localized to the perioral region (77% in MI, 73% in SI, 68% in PM) and tongue (19% in MI, 12% in SI, 25% in PM). Sensory input from the same peripheral site was represented multiply in several different areas within MI. While ICMS was ineffective in SI and PM, it evoked orofacial muscle activity at the site of 237 MI neurones receiving sensory input; the majority (86%) of these neurones received their input from the same peripheral region in which the ICMS-induced movement occurred.

The results suggest that multiple representations of orofacial sensory inputs as well as motor outputs are a feature of the functional organization of MI neurones. The close spatial relationship noted between sensory input and motor output may be of fundamental importance in the neural substrate for cortical integration of orofacial movements. (Supported by the Canadian M.R.C.)

72.7 ACTIVITY OF PRIMATE MOTOR CORTEX NEURONES IN RELATION TO TRAINED AND UNTRAINED OROFACIAL MOVEMENTS. G.M. Murray, H. Hiraba*, C.-S. Huang and B.J. Sessle. Faculty of Dentistry, Univ. of Toronto, Toronto, Canada M5G 1G6.

Recent work from this laboratory has defined input-output relations of the orofacial motor cortex in terms of sensory inputs recorded in single neurones, and the motor effects produced by intracortical microstimulation (ICMS, $\leq$ 20 μA) at the site of recording. The aim of this study was to examine the activity patterns of these neurones in relation to functional orofacial movements.

Extracellular single unit recordings were made from the ICMS-defined orofacial motor cortex in a monkey (Macaca fascicularis) while the animal repeatedly performed each of several test movements. These were untrained movements (e.g. mastication, licking, swallowing and tongue protrusion), as well as trained movements in which the animal was operantly conditioned either to protrude its tongue against a force transducer or to bite onto a force transducer. In both trained tasks, the animal was rewarded for maintaining a pre-selected force level for a 1-2 sec period. Masseter, anterior digastric and genioglossus EMGs and the force outputs from the transducers were recorded. Neurones were classified as being task-related if they consistently altered their firing rates, in comparison with control resting levels, during the period of the test movement. The presence of sensory inputs from cutaneous, intraoral or deep receptors was tested for each neurone.

Thirty-three neurones showed increases or decreases in activity in association with untrained and/or trained orofacial movements, and ICMS at the neuronal recording sites evoked twitch movements of the tongue, face or jaw. For 8 of the neurones, a receptive field could be definitively identified in the awake animal: the receptive fields were either cutaneous (n=4) or intraoral (n=4). Seven of these 8 neurones received their input from the same peripheral region in which the ICMS-induced movement occurred. All 8 of them exhibited phasic increases in firing in association with orofacial muscle activities occurring during the untrained movements. Six of these 8 neurones also altered their firing rates during a trained task: 3 showed an increase in firing rate and 3 exhibited a decrease. An additional 2 neurones with identified input-output relations did not alter their firing rates during any of the test movements.

These findings reveal a close relationship in the orofacial motor cortex between orofacial sensory inputs and ICMS-defined motor outputs in neurones which alter their firing rates in association with a variety of trained and untrained movements. Such observations point to an important role for these sensory inputs to the motor cortex in the control of orofacial movements.

72.8 ORIGIN OF CORTICOSPINAL PROJECTIONS TO THE IPSILATERAL SPINAL CORD. K.D. Hutchins* and P.L. Strick. V.A. Med. Ctr. and Depts. of Neurosurg. and Physiol., SUNY-HSC, Syracuse, NY 13210.

The corticospinal tract in macaques contains an **ipsilateral** component which does not cross at the pyramidal decussation. A portion of the ipsilateral pathway travels in the dorsolateral funiculus along with the contralateral component of the tract. Clinical and experimental evidence suggest that the recovery of motor function which follows damage to contralateral motor pathways depends in part on the integrity of this ipsilateral pathway. We have used retrograde transport of horseradish peroxidase (HRP) to define the origin of neurons in the ipsilateral hemisphere which contribute to the ipsilateral corticospinal tract. HRP (Sigma, Type VI) was placed in the dorsolateral funiculus at C2 in 2 monkeys (Macaca nemestrina).

All of the cytoarchitectonic areas of cortex which project via the contralateral corticospinal tract also contribute to the ipsilateral corticospinal tract. This includes five cortical areas in the frontal lobe (e.g., the primary motor cortex, the supplementary motor area, the arcuate premotor area and two areas in the cingulate sulcus) and five regions in the parietal lobe (e.g., the primary somatosensory cortex, the secondary somatosensory cortex, area 7b, granular insular cortex and several portions of area 5). In each cortical area, the size range for cells which contribute to the ipsilateral tract is the same as that for cells which contribute to the contralateral tract. Within the ipsilateral primary motor cortex, substantial numbers of corticospinal neurons were found in regions of forelimb representation located on the crest of the precentral gyrus and in the rostral bank of the central sulcus. Thus, projections to the ipsilateral corticospinal tract include cortical regions involved in the control of distal limb movements. Furthermore, some of these projections originate from the largest cells in the ipsilateral primary motor cortex.

The overall density of corticospinal neurons in the contralateral hemisphere is 20 times that in the ipsilateral hemisphere. However, the peak density of corticospinal neurons in the contralateral frontal lobe is only 7 times greater than the peak density of corticospinal neurons in the ipsilateral frontal lobe. In contrast, the peak density of corticospinal neurons in the contralateral parietal lobe is at least 16 times greater than that in the ipsilateral parietal lobe. These observations illustrate that, compared to the contralateral hemisphere, proportionally more of the ipsilateral projection originates from the frontal lobe than from the parietal lobe.

72.9 DIRECT FACILITATION BY CORTICOSPINAL NEURONS OF SINGLE MOTOR UNITS IN THE HAND MUSCLES OF THE CONSCIOUS MONKEY R.N. Lemon* and G.W.H. Mantel*. (SPON: M. Sofroniew). Anatomy Dept., Cambridge University, Cambridge CB2 3DY, England.

A distinguishing feature of the primate motor system is the presence of direct cortico-motoneuronal (CM) connections, which are particularly well-developed for motoneurones of the intrinsic hand muscles. In the conscious monkey, we have made cross-correlations between discharges of single, identified CM cells and activity recorded from single motor units of the thumb muscle, abductor pollicis brevis (AbPB) (Mantel & Lemon, Neurosci.Lett, in press). For 12/15 selected CM cells, cross-correlation revealed a clear peak. This correlation peak probably reflects the direct, monosynaptic excitation of the motor unit by the CM cell: first, the correlation peaks had brief half-widths (mean 1.9ms $\pm$ 1.1ms); indirect, oligosynaptic effects would be expected to produce broader peaks. We rarely observed any secondary tail-effects in our correlograms. Second, peak latency was consistent with conduction time over the CM pathway: the latency of the correlation peak with a given motor unit was comparable with the latency at which the same motor unit was activated from the pyramidal tract. Third, utilizing the study of Cope, Fetz and Matsumura, (J. Physiol. in press), we predicted that the amplitude of the unitary CM-EPSPs which would underlie the observed correlation peaks would be 50-200uV, consistent with observed values at the CM synapse.

If a correlation was found between a CM cell and one AbPB motor unit, it was found with all concurrently sampled AbPB motor units. Correlations were found with motor units of different sizes: with low-threshold motor units that fired tonically during the gentle (0.5N) precision grip exerted by the monkey and with phasic motor units which were only recruited during the onset of precision grip. These results suggest widespread connections of the CM cell within the motoneuron pool of AbPB. For a given CM cell, the strength of correlation with different motor units was similar, and was directly related to the amplitude of the post-spike facilitation (PSF) seen in spike-triggered averages of surface e.m.g. from AbPB. Our results suggest that strong PSF (peak percentage modulation of 20% or more) reflects stronger, individual CM connections, rather than being due to the recruitment of additional motor units. When PSF was less than 10%, we found no significant correlations between CM cell and motor unit activity.

72.10 CORTICOSTRIATAL NEURONS IN MOTOR CORTEX REFLECT THE PATTERN OF MUSCLE ACTIVITY RATHER THAN THE DIRECTION OF HAND MOVEMENT T.D. Ferguson*, M.P. Heyes* and S.P. Wise (SPON: C. Asanuma), Lab. Neurophysiology, NIMH, Bethesda MD 20892

Putamen neurons discharge at or after the onset of EMG activity and reflect the direction of movement (Crutcher and Delong, Exp. Brain Res. 53: 244, 1984), whereas many neurons in the primary motor cortex (MI) discharge prior to the onset of EMG activity and reflect individual muscle activity independent of the direction of movement. To investigate the type of motor information conveyed to the basal ganglia by MI corticostriatal (CS) neurons, stimulating electrodes were implanted in the putamen of two rhesus monkeys. CS neurons were identified in MI by antidromic activation and studied while monkeys performed operantly conditioned wrist flexion/extension movements over a 50° arc between three equally spaced 8° windows. Neuronal activity was studied when loads were applied that altered tonic muscle activity during maintained wrist position and phasic activity during movement. The EMG activity of selected prime-mover muscles preceded the onset of movement by 70 $\pm$ 24 ms.

Ninety-four CS neurons (antidromic latency = 1.24 $\pm$ 0.47 ms) were antidromically identified. At least 19 of these CS neurons were movement related and verified as antidromically activated by the collision method. Fifteen movement-related non-CS neurons, located near the CS cells were also studied. Eighteen of the 19 CS and 13 of the 15 non-CS neurons increased discharge rate before movement. The others decreased their discharge rate before movement. The time from the pre-movement change in firing rate (unit activity onset) to the onset of movement was 101 $\pm$ 30 ms for CS neurons and 136 $\pm$ 26 ms for non-CS neurons in our sample. Except for one CS cell that was inhibited before both directions of movement, all movement-related CS neurons showed greater activity modulation before one direction of wrist movement (the preferred direction) than the other. Nine of the 19 movement-related CS neurons either showed no change or decreased activity in the nonpreferred direction (directionally specific neurons). During steady holding and movement, tonic and phasic discharge rates, respectively, were increased by loads against the preferred direction of wrist movement in all 9 directionally specific CS neurons. Of the directionally nonspecific CS neurons, 6 were significantly affected by the load.

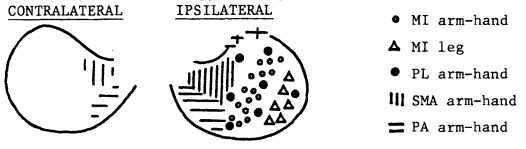
We conclude that: (i) motor information is conveyed via the CS pathway and (ii) because they are affected by loads, CS neurons do not closely resemble putamen cells.

72.11 TERMINAL FIELDS OF CORTICORUBRAL PROJECTIONS FROM SEPARATE ARM-HAND REGIONS IN THE MONKEY'S MOTOR AND PREMOTOR CORTEX.
D. Bulyalert* and D.R. Humphrey, Lab. of Neurophysiology, Emory Univ. Sch. Med., Atlanta, GA 30322

The parvocellular red nucleus (pRN) of the monkey receives substantial projections from the primary motor cortex (MI), the supplementary motor area (SMA), the periarcuate cortex (PA), and area 5 of the posterior parietal lobe (PL) (Humphrey et al, J. Comp. Neurol., 225:75, 1984). Each of the latter three zones projects to the arm-hand area of MI, and also to the cervical spinal cord (Muakassa and Strick, Brain Res., 177:176, 1979; and unpublished observations). The purpose of this study was to determine if the arm-hand regions of these four cortical areas project to separate or to common target areas within the pRN.

Cortical arm-hand (or leg) areas were identified by microstimulation in lightly anesthetized monkeys (cynomolgus, N=6). Two, 0.1 uL injections of 2% WGA-HRP, spaced 1 mm apart, were then made into one of the following arm-hand regions in each animal: MI (N=1), SMA (N=2), PA (N=1), PL (N=2); similar injections were placed in the MI leg area of one animal. After a survival period of 72 hr, the animals were sacrificed, and 50 um (frozen) coronal sections through the red nuclei were processed with TMB (modifed method of Mesulam) for identification of anterogradely labeled cortico-pRN terminals. All sections were examined under both bright- and darkfield microscopy.

Our major findings were as follows. (1) All injected areas sent convergent terminals to a common prerubral zone, just anterior to the rostral pole of the pRN. (2) Regions of the mesencephalic reticular formation dorsal to the pRN also received convergent projections from all injected cortical zones. (3) Within the pRN, however, the various cortical areas tended to project to separate territories, as is summarized in the following drawings of coronal sections through the this division of the RN. Only the projection from PL tended to overlap substantially with those from other (MI) cortical zones. (4) Projections from PL and MI were ipsilateral only, whereas those from the SMA and PA were bilateral, with heaviest termination ipsilaterally. These findings suggest that the pRN contains at least three, perhaps functionally different arm-hand regions, each controlled by a different set of corticorubral inputs. (Supported by NIH Grant NS 10183).



72.12 SYNAPTIC ACTIONS EXERTED BY DIFFERENT ARM-HAND REGIONS OF THE MONKEY'S MOTOR AND PREMOTOR CORTEX ON THE PARVOCELLULAR RED NUCLEUS (pRN).
D.J. Reed, D. Bulyalert* and D.R. Humphrey, Lab. of Neurophysiology, Emory Univ. Sch. Med., Atlanta, GA 30322.

Using anterograde tracing methods, we have shown that the arm-hand regions of the primary (MI) motor cortex, the supplementary motor area (SMA), the periarcuate area (PA), and area 5 of the posterior parietal lobe (PL) project to different subregions of the pRN (Bulyalert & Humphrey, this volume). In the present study, we used recordings of the field potentials evoked in the pRN by stimulation of these different cortical loci to estimate the early postsynaptic responses that are evoked in pRN neurons by each projection system.

Bipolar cortical stimulating electrodes and pRN recording chambers were implanted chronically in two monkeys (one rhesus, one cynomolgus). Under very light ketamine sedation (1.5-2.0 mg/Kg/hr averaged evoked responses (10-20/average) were recorded throughout the pRN (300-320 sequential recording sites) during stimulation of each cortical site; a complete mapping of the nucleus required 4-7 daily recording sessions. The evoked response data were then used to estimate the potential fields that would have existed throughout the pRN at a particular point in time, following stimulation of each cortical site (8-10 and 15-20 msec after stimulation). Average (instantaneous) directions of current flow within the nucleus were then estimated from these voltage contour maps, by drawing vectors orthogonal to computed isopotential lines.

From these data, and from:(1) knowledge of intranuclear projection zones; (2) the fact that pRN neurons are stellate in shape, and thus generate 'open' extracellular potential fields; and (3) observed, extracellular single unit responses, we have estimated the following, initial postsynaptic responses.

CORTICAL SITE	MAJOR DIRECTION OF CURRENT FLOW IN RELATION TO CELL SOMA	PROBABLE PSP
MI hand area	Radially outward	Dendritic EPSP
SMA hand area	Radially outward	Dendritic EPSP
PA arm area	Radially inward-outward	Somatic EPSP
PL arm area	Radially inward-outward	Somatic EPSP

Reversals in the net direction of current flow 5-10 msec after the initial postsynaptic response to stimulation of PA and PL arm-hand zones suggest that the initial somatic EPSP is followed by either a dendritic EPSP, or a somatic IPSP, in the response evoked in pRN neurons by these two corticorubral projections. Thus, cortical 'premotor' zones may have a stronger influence on pRN neurons than do cortical motor areas (MI and SMA). (Supported by NIH Grant NS 10183).

72.13 RELATIONS BETWEEN THE AMPLITUDE OF 2-DIMENSIONAL ARM MOVEMENTS AND SINGLE CELL DISCHARGE IN PRIMATE MOTOR CORTEX.
Andrew B. Schwartz and Apostolos P. Georgopoulos. Bard Laboratories of Neurophysiology, Department of Neuroscience, The Johns Hopkins University, School of Medicine, Baltimore, MD 21205.

We studied the relations between the amplitude of arm movement and the frequency of discharge of 48 arm-related single cells recorded in the motor cortex of two rhesus monkeys. The animals moved an articulated manipulandum over a two-dimensional working surface and captured lighted targets on the plane in reaction time tasks. For every cell, the animals performed a "direction" task, followed by an "amplitude" task. In the "direction" task the animals made movements of equal amplitude but in 20 different directions (from 0 to 360 deg at a 18 deg angular interval); in the "amplitude" task they made movements of four amplitudes (1.5, 3, 6, and 12 cm) in the cell's preferred direction. Fourteen cells were also studied in the "direction" task using movements of different amplitudes. The results were evaluated using an analysis of variance (ANOVA) and a linear regression analysis performed separately on the discharge rates observed during the reaction time and the total time (from the onset of the target until the end of the movement). In the reaction time the discharge rate of 37% of the cells studied showed a statistically significant relation to the amplitude of the movement (ANOVA, F-test, $p<0.05$) whereas 88% of the cells showed a significant relation to the direction of the upcoming movement; all amplitude-related cells were also related to the direction of the movement. In the total time, the percentage of cells that showed a significant amplitude effect increased to 65% (31/48), and in 29/31 cells the linear regression provided a good fit (F-test, $p<0.05$). However, the strength of this effect was rather weak: most (82%) of the statistically significant slopes were below 2 imp/sec/cm, and 43% were below 1 imp/sec/cm. Finally, 82% of the amplitude-related cells were also related to the direction of the movement; moreover, the preferred direction remained very similar in those cells studied in the "direction" task using various movement amplitudes. We conclude, first, that the major input to the arm area of the motor cortex in relation to the initiation of the movement (ie, during the reaction time) concerns the direction of the movement and to a lesser degree its amplitude; second, that the amplitude-related input is weak in magnitude; third, that the amplitude effect on cell discharge is superimposed on the directional effect; and fourth, that the directionality of the cells remains very similar across different movement amplitudes. (Supported by USPHS Grants NS17413 and MH18030.)

72.14 COMPARISON OF MOVEMENT-RELATED NEURONAL ACTIVITY IN PRIMATE MOTOR CORTEX AND PUTAMEN.
M.D. Crutcher and G.E. Alexander. Dept. of Neurology, Johns Hopkins School of Medicine, Baltimore, MD 21205.

It is widely assumed that the motor cortex plays a direct role in the control of limb musculature. However, Crutcher and DeLong (Exp. Brain Res., 53:244, 1984) recently found that neurons in the putamen were preferentially related to the direction of movement rather than the pattern of muscular activity. The aim of the present study was to compare directly the motor cortex and putamen by studying both structures in the same monkeys in order to determine whether movement-related activity patterns in the putamen can be accounted for on the basis of activity in motor cortex.

Rhesus monkeys were trained to perform a visuomotor step-tracking task which required elbow flexion/extension movements with assisting or opposing loads. This paradigm thus dissociated the direction of arm movement from the pattern of muscular activity required to perform the movement. Neurons were categorized as "directional" if they were differentially related to the two directions of movement and had identical patterns of activity for all load conditions. Neurons were categorized as "muscle-like" if they had a static and/or dynamic load effect in the appropriate direction (e.g. enhanced firing when the load opposed movements in the preferred direction). Similar patterns of neural activity were observed in the motor cortex and putamen. Thirty-four percent (36/105) of motor cortex cells and 42% (90/216) of putamen cells were classified as "directional". Thirty-seven percent (39/105) of motor cortex cells and 28% (61/216) of putamen cells were classified as "muscle-like". While there were relatively more "muscle-like" cells in the motor cortex than the putamen, this trend was not significant. The motor cortex and putamen did, however, have different distributions of neural response onset latencies. For the motor cortex, the median time of onset of the neural response was 60 ms before movement onset (range -175 to +125). For putamen, the median onset time occurred at the time of movement (range -240 ms to >300 ms). Although the distribution of putamen neural responses lagged behind that in the motor cortex by 60 ms, there was a small population of neurons in the putamen which became active earlier than neurons in the motor cortex.

The similarity of patterns observed in the motor cortex and putamen, and the fact that the neural onset times in the putamen generally followed those in motor cortex, suggest that much of the movement-related activity in the putamen may be attributable to the dense, somatotopically organized inputs from motor cortex. On the other hand, the earliest movement-related activity in the putamen may result from the overlapping inputs from premotor cortex and/or the supplementary motor area. Neurons in the putamen that manifest such extremely early movement-related activity may contribute to the often suggested role of the basal ganglia in the initiation of movement. (Supported by NIH grant NS - 17678)

72.15 PREPARATORY ACTIVITY IN PRIMATE MOTOR CORTEX AND PUTAMEN CODED IN SPATIAL RATHER THAN LIMB COORDINATES. G.E. Alexander and M.D. Crutcher. Dept. of Neurology, Johns Hopkins University, School of Medicine, Baltimore, MD 21205.

There are a number of reports of neuronal activity in motor cortex related to the preparation for planned limb movements. Recently, we have also found evidence of such activity in the putamen (Alexander, Exp. Brain Res., in press). In both areas, the directionally selective preparatory activity has appeared to be related to the intended direction of forthcoming limb movements, suggesting that this type of activity might represent a neural correlate of "motor set". In all of these studies, however, the directions of the targeted limb movements covaried systematically with the locations of the spatial targets. Thus, to be certain that the directionally selective preparatory activity was actually linked to the intended direction of limb movement, rather than to the spatial location of the target, we devised a motor preparation task that dissociated the direction of the intended limb movement from that of the anticipated target shift.

Three rhesus monkeys were trained to perform a visuo-motor step-tracking task in which elbow movements were made both with and without a preceding preparatory "set" concerning the impending direction of the forthcoming movement. In some blocks of trials, the target shifts and the required elbow movements were in the same direction, while in others the target shifts and the required movements were in opposite directions. While the monkeys performed these two different types of preparatory trials, neuronal activity was recorded from the arm areas of motor cortex and putamen. In the putamen, 22 cells that showed directionally specific preparatory activity were tested with both types of trials. For the majority of these cells (12/22), the preparatory activity was found to depend upon the expected direction of the forthcoming target shift, irrespective of the intended direction of the limb movement required to align the cursor with the target. In motor cortex, 11 neurons that showed directionally selective preparatory activity were tested with both types of trials. In all but one of these cells, the preparatory activity was found to depend upon the expected direction of the forthcoming target shift, rather than the direction of the limb movement.

Thus, both in motor cortex and putamen, much of the preparatory neuronal activity related to targeted limb movements may be coded in terms of spatial rather than limb coordinates. These results suggest that while both of these structures are strongly implicated in the direct control of movement execution they may also play a role in the highest levels of motor preparation.
(Supported by NIH grant NS - 17678).

72.16 COMPARISON OF POSTSPIKE AND POSTSTIMULUS FACILITATION OF FOREARM MUSCLE EMG ACTIVITY FROM RED NUCLEUS SITES IN THE MONKEY. K. Mewes*, G.W. Widener* and P.D. Cheney. Dept. of Physiology, Univ. of Kansas Medical Center, Kansas City, KS 66103.

The sign, distribution and strength of effects on motoneurons of different muscles from single corticomotoneuronal (CM) and rubromotoneuronal (RM) cells can be estimated from spike-triggered averages of rectified emg activity. Whereas spike-triggered averaging reveals the output effects of a single neuron, microstimuli applied to the sites of CM or RM cells activate a collection of neurons near the electrode tip and averages computed from these stimuli reveal the summated output effects of the recorded cell and its neighbors. Using these methods, Cheney and Fetz (J. Neurophysiol. 53:786-804, 1985) showed that the patterns of poststimulus facilitation (PStF) evoked from CM sites closely match the patterns of postspike facilitation (PSpF) produced by individual CM cells at the same sites, suggesting that neighboring CM cells form functional aggregates in which each cell of the aggregate has a similar set of target muscles. The purpose of this study was to: 1) document the distribution of RM-PStF across muscles in comparison to PSpF obtained at the same site, and 2) compare RM-PStF with CM-PStF. Spike and stimulus-triggered averages of emg activity from twelve forearm wrist and digit muscles were computed at 31 RM cell sites in two monkeys during alternating, ramp-and-hold wrist movements. 55% of RM cells facilitated extensors exclusively, 13% facilitated flexors exclusively and 32% cofacilitated flexors and extensors. This clear extensor preference was even more evident in stimulus-triggered averages; at all RM cell sites the strongest PStF was of extensor muscles - even at sites where the PSpF was exclusively of flexors. The mean magnitude of the greatest PSpFs from RM cell sites expressed as PEAK/NOISE RATIO (P/N) was 6.8 compared to 14.6 for 23 CM-PSpFs (normalized to 12K triggers; noise = standard deviation of the baseline points). The corresponding P/N ratios for RM-PStF at 5, 10 and 20 μA stimulus intensity were 26, 56 and 76 respectively; the comparable 10μA CM-PStF was 69. Although CM-PSpF was more than double RM-PSpF, CM-PStF was not significantly larger than RM-PStF. At 3 of 31 RM sites (10%) where 20 μA averages were computed, the muscle with the strongest PSpF was also the muscle with the strongest PStF (35% at 10μA; 42% at 5μA). In comparison, PSpF and PStF (10μA) from motor cortex was strongest in the same muscle at 22 of 23 (96%) sites. At RM cell sites, the muscle field (all muscles with PStF) for 10μA matched the PSpF muscle field at only 5 of 20 (25%) sites, whereas at CM cell sites 86% of muscle fields matched. We conclude that RM cell output preferentially facilitates forearm extensor muscles and that clustering of cells into functional aggregates with common muscle fields is much less clear in red nucleus than in motor cortex. (Supported by NSF grant BNS-8216608)

72.17 DISCHARGE PATTERNS OF PYRAMIDAL TRACT NEURONES IN MOTOR CORTEX DURING A LOCOMOTOR TASK REQUIRING A PRECISE CONTROL OF LIMB TRAJECTORY. T. Drew. Centre de recherche en sciences neurologiques, Univ. de Montréal, Québec, CANADA

To test the hypothesis that the motor cortex plays an important role in locomotion under conditions requiring a precise control of limb trajectory, a task has been devised in which cats have to adjust their gait in order to step over (or between) obstacles of different heights and widths fixed to a treadmill.

Single units were recorded from the forelimb area of the motor cortex of two unrestrained, intact cats using glass-insulated tungsten microelectrodes held in a microdrive attached to the head; cells were identified by stimulation of their axon in the pyramid (AP -7) with chronically implanted microwire electrodes. EMGs were recorded from flexor and extensor muscles acting around the shoulder, elbow, wrist and digits of the contralateral forelimb. Recordings were made initially when the cat walked normally on the treadmill and subsequently as it adjusted its gait to step over the obstacles.

Recordings were made from 46 fast and 11 slow pyramidal tract neurones lying principally around the lateral edge of the cruciate sulcus. Thirty of the 57 neurones changed their discharge patterns when the cat stepped over the obstacles; 16 of these showed a marked increase in their discharge rate. Normally one of the types of obstacles (high or wide) was more effective than the other. Temporal relationships between cell discharge and muscle activity were made on the basis of raster displays. All 16 cells which increased their discharge rate were best related to flexor muscle activity. Although the discharge rate of some cells was linearly related to the amplitude of flexor muscle EMG, others were better correlated with changes in the relative time of the onset of the flexor muscle activity.

In 9 of the loci from which cells were recorded that showed an increase in discharge during the task, an attempt was made to determine the output relations of the cell by using the technique of single pulse microstimulation (Cheney, P.D.and Fetz. E.E., J. Neurophysiol., 53:, 786, 1985). Facilitation of flexor muscle activity was seen from 5 sites; in all 5 cases the results were consistent with the correlations made on the basis of temporal relationships.

The results demonstrate that identified pyramidal tract neurones show marked changes in their discharge patterns during a locomotor task which requires visuo-motor guidance and fine control of limb trajectory. It is suggested that these cells may be implicated in the control both of flexor muscle amplitude and of changes in muscle timing. (Funded by the Fonds de la recherche en santé du Québec (FRSQ) and by the Canadian MRC).

72.18 THE ACTIVITY OF CLOSELY SPACED SINGLE NEURONS RECORDED FROM DIFFERENT REGIONS OF THE CAT MOTOR CORTEX DURING LOCOMOTION. C. I. Palmer. Institute of Physiology, Fribourg University, Switzerland.

This investigation was carried out to examine the motor cortical organization of units modulated with respect to the step cycle. Several neurons were recorded at the same cortical location to ascertain the possibility that units modulated during this movemen-t are organized in a columnar fashion in the motor cortex. These neurons were recorded from chronically implanted microwires on different postoperative days.

Results were obtained from three cats chronically implanted with 7 to 14 electromyographic (EMG) electrodes in muscles activated from intracortical microstimulation (ICMS) at each microwire. They were also implanted with fine wires looped around the distal phalynx of claws in the forepaw and wires set in a sylastic sheet so-wn to skin at the back of the wrist, to electrically activate cortical cells from the periphery. A recording cuff electrode was implanted around the median nerve to record this afferent volley and a bipolar Pyramidal tract (PT) electrode to antidromically identify cortical cells projecting into the PT.

Single units (n94) were recorded from 14 implanted microwires with an average of 7 per electrode site. Units recorded at the same site on different days could be differentiated from each other by their latency and threshold to antidromic or synaptic activation from PT stimulation, size and location of their peripheral receptive field, latency and configuration of their responses to electrical cutaneous stimulation, responses to tapping in their receptive field, also their level of tonic discharge and type of modulation during locomotion. The stability of the position of the electrode in the brain during the weeks of recording was ascertain-ed from the stability of the field potentials from cutaneous and PT stimulation and the ICMS responses in muscles.

The responses of units during locomotion at the different cortical recording sites could be divided into four classes I) the majority of units not modulated, 2) the majority of units modulated during one phase of the step cycle, 3) the majority modulated and their combined activity covering the complete step cycle, 4) the majority activated as would be predicted from the location of their cutaneous receptive field. These regions were found to occur independently of the strength or location of ICMS muscle responses or the number of units projecting into the PT.

Some evidence was found for a columnar organization in unit activity modulated during locomotion but this was not always associated with the activity of a single or synergistic group of muscles.

72.19 **PRIMATE MOTOR CORTEX: LOAD COMPENSATION MECHANISMS AND LIMB STIFFNESS.** John F. Kalaska, Ted E. Milner & Martha L. Hyde. Centre de recherche en sciences neurologiques, Université de Montréal, Montréal, Québec, Canada, H3C 3J7.

We have been investigating the response of shoulder-related motor cortex cells in a 2-dimensional reaching task. The distribution of cell preferred movement directions was uniformly distributed in all directions. The task also requires the monkey to hold its arm in 9 different postures while compensating for loads in 8 different directions. These loads typically caused large continuously-graded changes in the tonic discharge of the cells, centered on one direction called the cell's maximum load axis (MLA). The spatial distribution of MLAs was not uniform, but was strongly bilobed, skewed in the directions perpendicular to the long axis (i.e., hand to shoulder) of the arm. The bilobed distribution tended to be more sharply skewed, the further the arm was held away from the body. Moreover, the MLA of single cells measured at the 9 different postures often varied, so that the spatial orientation of the skewed MLA distributions shifted with the degree of external/internal rotation of the arm in the different postures.

It has been reported that the stiffness of the limb to external perturbations is non-uniform, being greatest along its long axis and least perpendicular to its long axis. This property can be described by an ellipsoidal "stiffness field" whose eccentricity and orientation varies with limb posture (Mussa-Ivaldi et al., J.Neurosci. 5: 2732-2743, 1985). Based on a 3D analysis of limb movement in the task, we estimated the stiffness field of the monkey's arm at the 9 different postures. We likewize found that it tends to be more eccentric when the arm is held further away from the body, and that its orientation shifted with different postures is such a way as to remain approximately perpendicular to the bilobed MLA distributions of our motor cortex sample measured at each posture. We propose that the skewed bilobed MLA distributions in the motor cortex reflect a neural mechanism to compensate for the inherent non-uniform stiffness of the arm. Shoulder-related motor cortex cells play a greater active role in the compensation for static loads pulling the limb perpendicular to its long axis than parallel to its long axis. Changes in skew and orientation of the MLA distribution indicate that the response properties of cortical cells are tuned continually to match changing biomechanical properties of the limb skeletomuscular system in different postures. This also raises the possibility that the movement direction-related discharge of motor cortex cells may be modified with changes in the posture of the limb. This work supported the Medical Research Council of Canada.

72.20 DISCHARGE OF MOTOR CORTEX NEURONS IN CEBUS MONKEYS FOLLOWS KINEMATICS OF IMPOSED AND VOLUNTARY LIMB DISPLACEMENTS. D. Flament and J. Hore, University of Western Ontario, Dept. Physiology, London, Canada.

Recent experiments in cats trained not to resist imposed limb displacements showed that some motor cortex neurons (MCNs) preferentially responded to the acceleration and jerk of the displacements (1). In the present study the question was asked whether neurons responding to the kinematics of arm movement were also present in the primate motor cortex, in response to torque pulse perturbations or when making voluntary, goal-directed movements. The relation of MCN discharge to limb kinematics was analyzed in terms of timing and average firing frequency of neural discharge relative to timing and peak magnitude of the related variable. Only neurons with reciprocal responses to oppositely directed perturbations and movements were analyzed in detail.

Neurons were found that predominantly followed the velocity, acceleration or jerk of elbow movement, in response to perturbations. The majority of neurons followed acceleration (i.e. were acceleration-like). For perturbations of different durations these neurons followed the timing of the acceleratory phases of the displacement. They were sensitive to very small perturbations (< .5 deg) and their discharge was proportional to the acceleration of the displacement, saturating for large accelerations. During voluntary movements their discharge also followed acceleration. Velocity-like neurons were the second most common category. For perturbations eliciting an early burst of neural activity, the duration of this burst was proportional to the duration of velocity. For perturbations of the opposite direction, the latency of the discharge was proportional to the latency of the return velocity. No relationship was found between firing frequency and peak velocity. Velocity-like neurons also followed velocity during voluntary movements.

The results indicate that some MCNs in monkeys are related to, and follow, the derivatives of limb displacement whether it is produced passively or actively. The results support the hypothesis that predictive (derivative) feedback is important in the control of arm movements by motor cortex.

72PO REPRESENTATIONS OF INDIVIDUAL MUSCLES WITHIN THE MOTOTOPIC ORDER OF BABOON FORELIMB MOTOR CORTEX. R.W. Dykes, R.S. Waters[1], P.A. McKinley, D.D. Samulack, S. McFarlane*, N.J. Kabani* and S.S. Leclerc*. Depts. of Physiology, Physical and Occupational Therapy, McGill Univ., Montreal, Quebec H3A 1A1, and [1]Dept. of Anatomy and Neurobiology, Col. of Med., Univ. of Tennessee, Memphis, TN 38163.

Detailed mapping of motor cortex of four baboons (Papio c. anubis), as described elsewhere in this volume, uncovered numerous cases of multiple efferent zones for a single muscle. In some cases the re-representation of an efferent zone was located in a place consistent with the general mototopic order of the representation. A second efferent zone could be interpreted as a contribution to a second map of the body musculature. However, the multiple efferent zones were inconsistent with a second map because either (i) they were clearly contained within the area devoted to the first map, or (ii) they represented a third or fourth efferent zone for the same muscle. The area devoted to any one efferent zone was rarely larger than 3 mm^2 and often less than 1 mm^2.

The hypothesis that there were zones of overlap and co-activation of several muscles within some efferent zones was an adequate explanation for only a limited number of cases. Generally, in situations where more than one muscle could be activated from a single stimulus site, the threshold for activation of one muscle was distinctly greater than for activation of the other. This suggested the possibility that the additional muscles activated at higher stimulus intensities were driven indirectly. These observations suggest that 'lowest threshold' stimulation of a single site in baboon motor cortex activates only one muscle or muscle compartment.

Evidence for low-threshold muscle co-activation was seldom obtained. Co-activation alone, is inadequate to explain the re-representation of muscles. The role that each efferent zone plays in motor control is not apparent from the currently available information.

73.1 INTRINSIC CIRCUITRY OF THE CEREBRAL CORTEX: THE LOCAL AXONAL PROJECTIONS OF CORTICOCORTICAL PROJECTION CELLS. E. L. White and Edith El-Hanany*. Dept. of Morphology, Faculty of Health Sciences, Ben-Gurion University, Beer Sheva, Israel.

Horseradish peroxidase (HRP) was injected into the vibrissal area of the primary motor cortex (MsI) in young adult, male CD/1 mice. The next day, the injected region of cortex was lesioned. Two days later, the mice were perfused with aldehydes, their brains were removed, tissue chopped at 100 μm and reacted with diaminobenzidine to demonstrate the HRP. The result of this procedure was to label with HRP, the cell bodies, dendrites and local axon collaterals of corticocortical (CC) projection cells within the vibrissal region of SmI cortex, and in the same region, by lesion induced degeneration, the axon terminals of cells having somata in MsI cortex. Examination with the light and electron microscopes of single sections through SmI cortex showed HRP-labeled cell bodies to occur in layers II/III and V; HRP-filled terminals of local CC axon collaterals occurred in layers III-VI, but predominated in layer V and to a lesser extent in layer III. Examination of serial thin sections through layer V showed that local CC axon collaterals were presynaptic only at asymmetrical synapses; postsynaptic elements were nearly all spines which are presumed to belong to pyramidal cells, but some were shafts of nonspiny dendrites which are considered to belong to nonspiny nonpyramidal cells. Occasionally, local CC axon collaterals synapsed with spines belonging to HRP-labeled dendrites of CC cells. The preference for local CC axon terminals in layer V to synapse with spines, differs from the situation in layer III where these terminals synapse in roughly equal numbers with spines and nonspiny dendrites, and contrasts sharply with the marked tendency in layers IV-VI of axon collaterals of corticothalamic (CT) cells to synapse onto nonspiny dendrites (White and Keller, J. Comp. Neurol., 1987). These results suggest that in the lower layers of SmI cortex, the local output of CC cells has a direct excitatory effect on pyramidal cells, whereas in the same layers, the local output of CT cells, is directed instead to nonspiny nonpyramidal cells whose activation probably acts to decrease activity within neighboring pyramidal neurons. In the upper layers, the local output of CC cells is evenly split between similar excitatory and excitatory/inhibitory pathways. Supported by N.I.H. grant to ELW # NS 20149-04.

73.2 SYNAPTIC INTERACTIONS INVOLVING THALAMIC AFFERENTS, CORTICOTHALAMIC CELLS, AND GABAERGIC NEURONS IN THE MOUSE BARREL CORTEX. A. Keller and E. L. White Dept. of Morphology, Faculty of Health Sciences, Ben-Gurion University, Beer Sheva, Israel.

Horseradish peroxidase (HRP) was injected into the vibrissal area of the ventrobasal thalamus in young adult, male CD/1 mice. The next day, electrolytic lesions were placed in the injection site. Four days later, the mice were perfused with aldehydes, blocks of barrel cortex were removed, sectioned coronally and processed for HRP histochemistry. Corticothalamic (CT) projection cells, labeled by HRP, were identified and photographed, and then the sections were reacted for GABA immunocytochemistry. The result of this procedure was to label, in the same preparation, the cell bodies, dendrites, and axon collaterals of CT projection cells (by the retrograde transport of HRP), the axon terminals of thalamocortical (TC) relay cells (by lesion induced degeneration), and the cell bodies, dendrites, and axon terminals of GABAergic neurons (by HRP). HRP-filled dendrites, previously determined by light microscopy as belonging to CT cells, were examined in serial thin sections. These dendrites posessed large numbers of spines, whereas GABAergic dendrites were sparsely-spined or nonspinous. HRP labeled GABAergic axon terminals were differentiated from HRP labeled axon terminals of CT collaterals because the GABAegic terminals form only symmetrical synapses, whereas the CT axon terminals form exclusively asymmetrical synapses. Dendrites of GABAergic neurons received TC synapses, and many dendrites also received synapses from CT axon collaterals. All the dendrites belonging to CT cells received both TC synapses and GABAergic synapses. These synaptic interactions provide direct evidence for the existance of a cortical "triad" which has long been hypothesized but not yet supported by anatomical data. This circuitry involves reciprocal synaptic interactions between pyramidal neurons (here, CT cells) and nonspiny, nonpyramidal neurons (here, GABAergic neurons), with both classes of neurons directly receiving TC input. We suggest that this synaptic triad, identified previously in subcortical regions, is a basic feature of the synaptic organization of the cerebral cortex.

73.3 MEMBRANE PROPERTIES AND THALAMOCORTICAL SYNAPTIC RESPONSES IN MOUSE BARREL CORTEX NEURONS: AN INTRACELLULAR STUDY IN VITRO. A. Agmon and B.W. Connors. Dept. of Neurology, Stanford Univ. Sch. of Med., Stanford, CA 94305.

We previously reported the development of an in vitro preparation of the mouse barrel system, in which the neuronal pathway between the ventrobasal nucleus of the thalamus (VB) and the SmI cortex is preserved and functional in a 400 μM slice (Agmon, A. and Connors, B.W., Soc. Neurosci. Abstr. 10:493, 1984 and 11:750, 1985). We now report some of the membrane properties of barrel cortex neurons and their thalamus-evoked synaptic responses.

Thalamocortical slices were prepared as described. Intracellular recordings revealed all three firing-mode classes of cells previously described in the guinea pig neocortex (McCormick et al., J. Neurophysiol. 54:782-806, 1985): slow-spiking accomodating, bursting (restricted to the middle layer of the cortex) and fast-spiking non-accomodating. In most (> 80%) impaled cells a focal stimulus in VB evoked synaptic responses. The extracellular field potential in layer IV, monitored simultaneously, exhibited an early negativity of constant amplitude and latency that was not abolished in a low Ca, high Mn solution, and that followed stimulation frequencies of up to 20 Hz without failure. This negativity was interpreted as arising from the presynaptic volley, and served as point zero for calculating the synaptic latencies of the PSP's. Virtually all cells in layers VI to lower II-III showed a sequence of a monosynaptic EPSP (latency of 1.0-1.1 ms) followed by a disynaptic IPSP (latency of 2.0-2.2 ms). In upper II-III some cells received a disynaptic IPSP alone, while a small fraction showed a disynaptic EPSP followed by a trisynaptic IPSP, or a trisynaptic IPSP alone. The strength of the excitatory inputs varied considerably from one cell to another.

Since all pyramidal cells in layers VI to lower II-III have some part of their dendritic arbor within the thalamic termination zone, our data suggests that, in the thalamocortical system, spatial confluence of dendrites and axons is a sufficient condition for synapse formation. Our electrophysiological results agree with the EM studies of White and co-workers, who found that thalamocortical synapses occur, albeit in different densities, on virtually all the dendritic elements that pass through layer IV of mouse SmI cortex (E.L. White, in Cerebral Cortex, Vol. 5, p. 275, E.G. Jones and A. Peters, eds, Plenum Press, N.Y., 1986).

73.4 **THE FINE GRAINED ORGANIZATION OF THE PROJECTIONS FROM THE BARREL CORTEX OF THE MOUSE; A PHASEOLUS VULGARIS LEUCO-AGGLUTININ (PHA-L) STUDY.**

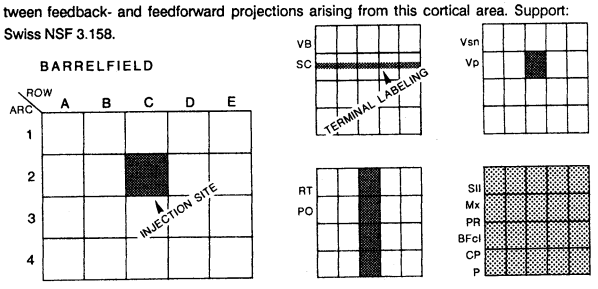
E. Welker*, P.V. Hoogland+* and H. Van der Loos* (SPON: E. Rouiller)

Institute of Anatomy, University of Lausanne, 1005 Lausanne, Switzerland.

+ Department of Anatomy, Vrije Universiteit, 1007-MC Amsterdam, the Netherlands.

The whisker-to-barrel pathway has been used because of its property that in all stations of the pathway the representation of individual vibrissal follicles can be visualized: in the three subnuclei of the descending trigeminal tract (Vsn), the principal trigeminal nucleus (Vp), the nucleus ventro-basalis of the thalamus (VB) and the barrelfield (BF). While it has been demonstrated that signals from single follicles are kept separated from those of neighboring follicles within these regions, it is unknown whether separation persists in projections beyond BF.

To describe the organization of the efferent projections of single barrel columns (BC, i.e. barrel in layer IV plus the cortical tissue above and below), iontophoretic injections of the anterograde tracer PHA-L were made in the BF's of 21 adult mice. On the basis of reconstructions of the sites of terminal labeling, the brain regions receiving BF projections could be divided into four groups, each one characterized by the topography of the distribution of efferents arising from a single BC (*see schema*). The distribution of terminal labeling varies from punctiform in Vsn, Vp, VB and superior colliculus (SC; in the latter two stations one BC projects to an "arc" of units), via an overlap of projections arising from one row of BCs in the reticular (RT) and the posterior thalamic nucleus (PO), towards a completely overlapping projection within restricted zones of SII, motor cortex (Mx), perirhinal cortex (PR), contralateral (CL) BF, caudo-putamen (CP) and pons (P). These differences in organization of the efferents of BF demonstrate a contrast between feedback- and feedforward projections arising from this cortical area. Support: Swiss NSF 3.158.



73.5 PARALLEL PATHWAYS FOR THE FACIAL COMMON FUR AND MYSTACIAL VIBRISSAE OF THE RAT FROM THE BRAINSTEM TO THALAMUS AND CORTEX. F.R. Sharp, M.F. Gonzalez, M.T. Morton*, J.W. Sharp* and C.W. Morgan. Department of Neurology, University of California, San Francisco, and V. A. Medical Center, San Francisco, CA 94121.

The mystacial vibrissae of rows A,B,C were stimulated in awake rats and local cerebral glucose utilization (LCGU) measured quantitatively using the [^{14}C] 2-deoxyglucose method. Ventral portions of ipsilateral Sp5c, Sp5i, Sp5o, and Pr5 were activated. Whereas stimulation of the common fur above the A,B,C vibrissae activated primarily laminae II and III of the most ventral parts of Sp5c, A-C vibrissae stimulation primarily activated laminae III and IV of more dorsal and rostral parts of Sp5c. Sp5i, Sp5o, and Pr5 were minimally activated by stimulation of the common fur above the vibrissae. Common fur stimulation between the vibrissae activated laminae II-V of Sp5c, Sp5i, Sp5o, and Pr5 possibly because of common fur stimulation as well as unavoidable stimulation of the remaining stubs of the mystacial vibrissae.

A-C mystacial vibrissae stimulation increased LCGU in the rostral, dorsal parts of VPM nucleus of thalamus, whereas stimulation of the common fur above the vibrissal pad increased LCGU in caudal, dorsal VPM. A-C vibrissae stimulation increased cortical LCGU in two separate regions, one corresponding to the rat posteromedial barrel field (PSMBF), the other presumed to be in SII. Stimulating the common fur above the vibrissae increased LCGU in a distinct column which was located ventral to the PSMBF and slightly rostral to it in accordance with physiological studies by Welker, Van der Loos, and others. Though all cortical layers were metabolically activated, layer IV had the greatest LCGU increase for both whisker and common fur stimulation.

These results suggest that the mystacial vibrissae and the common fur above them are processed in parallel pathways from the brainstem through thalamus to cortex. They also suggest that the common fur pathways are primarily processed at the brainstem level in the substantia gelatinosa of Sp5c whereas vibrissae inputs are processed primarily in deeper layers of Sp5c as well as all other subdivisions of Sp5 and Pr5.

73.6 LAMINAR AND SYNAPTIC ORGANIZATION OF TERMINALS FROM THE VENTROBASAL AND POSTERIOR THALAMIC NUCLEI IN RAT BARREL CORTEX. C.-S. Lin, S. M. Lu*, and R. M. Yamawaki*. Dept. of Anatomy, Duke Univ. Med. Ctr. Durham, NC 27710.

We have previously reported that, in layer IV of rat barrel cortex, axons from the ventrobasal complex (VB) terminate in the center of individual barrels, while axons from the posterior nucleus (PO) terminate in the surrounding septa. Also, there are differences in the laminar distribution of these two thalamocortical projections. For example, in the infragranular layers, button-like swellings were observed only in upper layer VI for the VB projection and only in layer V for the PO projection. In this report, we describe these two projections at the ultrastructural level. The purpose of the study was to determine (1) whether the button-like swellings observed in different layers at the light microscopic (LM) level actually form synaptic contacts, and (2) whether there are differences in the synaptic organization of axon terminals from VB and PO.

Phaseolus vulgaris leuco-agglutinin (PHA-L) was deposited iontophoretically into either VB or PO. After 4-5 days survival, rats were perfused with a periodate-lysine-paraformaldehyde fixative. Somatosensory cortex and the dorsal thalamus were cut with a vibratome into 50-70 um sections. In order to increase the penetration of the immunoreagents, sections were frozen and thawed in the presence of one of the following cryoprotective agents: dimethyl sulfoxide (DMSO, 5%, 10%, and 20%) or a mixture of sucrose and glycerine (10%+5%, 15%+10%, and 20%+10%) in 0.1 M phosphate buffer. PHA-L was localized by avidin-biotin-complex (ABC) immunoperoxidase methods. After the peroxidase linkage, the sections were treated with diaminobenzidine with heavy metal intensification. Sections with a high density of labeled terminals were processed for ultrastructural studies.

At the ultrastructural level, labeled axon terminals were studied in every layer of the barrel cortex. There are three similarities in the VB and PO projections: (1) Labeled button-like swellings in all layers observed at the LM level are indeed forming synaptic contacts, (2) All the labeled terminals form asymmetrical synapses, and (3) The most common postsynaptic structures observed so far are dentritic spines and small dendrites. So far, the only difference is in layer I, in which we have observed both labeled myelinated and unmyelinated axon segments after PO injections and only labeled unmyelinated axon segments after VB injections.

73.7 INTERNAL ORGANIZATION OF ANATOMICAL AND PHYSIOLOGICAL REPRESENTATIONS OF THE FOREPAW IN RAT SOMATOSENSORY CORTEX. D.R. Dawson, J.T. Wall, H.P. Killackey, and J.H. Kaas. Dept of Psychobiology, U.C. Irvine, CA, and Dept of Psychology, Vanderbilt University, Nashville, TN. (SPON: A. Frostholm)

Rat somatosensory cortex which has been reacted for succinic dehydrogenase (SDH) contains a series of discrete clusters representing the entire body surface. The region corresponding to the forepaw has a particularly well defined, stereotypic pattern of internal organization, consisting of four large SDH bands surrounded by several smaller clusters. The following studies were designed to ascribe functional properties to specific SDH clusters within the forepaw region of cortex.

In the first study, fetal rats resulting from timed matings were exposed in utero on E16 or 17, and specific forelimb digits were removed. Pups were born naturally, on E22 or E23. On PND15, pups were sacrificed, and processed for SDH.

Prenatal removal of specific forelimb digits results in the disappearance of specific SDH clusters in the cortical representation; the loss of ulnar digits is reflected by a loss of the more posterior clusters, whereas loss of radial digits results in disturbances of the anterior clusters.

In a second study, twelve normal adult rats were subjected to standard neurophysiological mapping procedures within the forepaw region of somatosensory cortex, generating comprehensive maps (40-50 penetrations). The forepaw representations of twelve additional rats were mapped in fewer penetrations (10 or less) labelled with either HRP or fast blue fluorescence. Animals with labelled penetrations were sacrificed and the brains processed for SDH. Sections superficial and deep to the SDH pattern were reacted for HRP, using the TMB reaction. The HRP thus served as a marker for a given penetration, which could then be localized within the SDH clusters on the adjacent section. In this manner, penetrations with well defined peripheral receptive fields on the forepaw were related to specific SDH clusters. Fast blue labelled penetrations were visualized directly on SDH sections.

Cells responsive to stimulation of specific structures on the forepaw could be localized to discrete regions of cortex. Radial digits were represented anteriorly and ulnar digits posteriorly. Responses to stimulation of palm pads were evoked medially, and hairy dorsal skin laterally. Animals with labelled penetrations confirmed these findings, permitting a precise association of specific receptive fields with specific SDH clusters.

In summary, the anatomical and physiological maps of the rat forepaw representation in primary somatosensory cortex are in register with each other, such that discrete subdivisions within one can be reliably related to subdivisions within the other.

73.8 **THALAMOCORTICAL RESPONSE TRANSFORMATION IN THE VIBRISSA/BARREL SYSTEM.** **G.E. Carvell* and D.J. Simons. Program in Physical Therapy and Department of Physiology, Univ. of Pittsburgh, Pittsburgh, PA 15261.**

Extracellular recordings were used to examine the response properties of > 150 single cells in the thalamic ventrobasal complex (VB) of adult rats maintained with a slow infusion of fentanyl. Electromechanical stimulators were used to deflect vibrissae in controlled spatial and temporal patterns. Results are compared with data obtained from > 250 cortical barrel neurons. Results show that: 1) the cyclic pattern of stimulus evoked excitation/inhibition that characterizes responses in the barrels is considerably less pronounced in VB; 2) slowly-adapting responses are observed more often in VB than in the cortex; 3) inhibitory interactions between adjacent whiskers are observed less frequently and are less potent in VB; 4) facilitation is observed commonly in VB but rarely in cortex; 5) spontaneous discharge rates are on average 6X greater in VB; 6) VB cells tend to respond more vigorously to whisker deflections at their 'best' angle; 7) in VB, ON responses are more 'tuned' for deflection angle and more cells discharge selectively to either stimulus onset or offset; 8) unexpectedly, many VB cells (~30%) are strongly excited by more than one whisker; in the barrels fast-spike units are more likely than regular-spike units to be strongly multi-whisker.

These functional differences may reflect: a) the known absence of inhibitory interneurons in the VB barreloids and the presence in the cortex of inhibition provided by fast-spike/smooth barrel neurons; b) the ~10:1 ratio of barrel to barreloid neurons whereby, presumably, a single barreloid axon contacts many barrel neurons and a single barrel cell is contacted by axons of many barreloid neurons; and c) the fact that thalamocortical synapses occur more proximally on smooth vs. spiny barrel cells (White, JCN, 181:627-661, 1978). Barrel circuitry transforms the thalamocortical input into a temporal code that underlies operations performed by the rest of the cortical column. **Supported by NIH grant NS 19950.**

73.9 DIFFERENCES IN GAD AND GABA IMMUNOREACTIVITY IN THE SOMATOSENSORY CORTEX OF THE RAT. R.Spreafico, G.Battaglia, C.Frassoni, S.De Biasi* (Spon.ENA) Dept. of Neurophysiology, Neurol Institute C.Besta and Dept. of Physiol and Biochemistry, Section of Hystology and Human Anatomy, 20133 Milano Italy

Aim of the present work is to verify if GAD and GABA antisera label the same neuronal population in different brain areas. Eight deeply anesthetized albino rats were perfused with a 4% paraformaldehyde and 0.1% glutaraldehyde solution in phosphate buffer. Brains were cut in 40 um thick coronal serial sections. Alternate serial sections were than processed for immunohistochemistry according to the pre-embedding paroxidase-antiproxidase (PAP) method (Steinberger 1972) using two different antisera agonist GAD (Oertel et al. 1981) and GABA (Immunonuclear Corp.). Adjecent sections were counterstained with Cresilect Violet to identify the different cortical areas and layers. Two of these animals received colchicine injections in somatosensory cortex or in the ventro basal complex, two days before sacrifice. In two additional animals small blocks of identified somatosensory cortex were dissected out, cut in 10 um thick serial sections by means of a cryostat, and processed with the same procedure described above. Labelled neurons from both anti-GABA and anti-GAD reacted sections, were plotted by means of an x-y plotter interfaced to a Leitz microscope. A total count of 15396 labelled neurons in colchicine treated and untreated animals show that GAD positive neurons in the cortex are approximately the 60% of GABA labelled neurons counted in the adjecent sections. This difference seems to be restricted to the cortex. In fact, in the same animals the ratio between GAD and GABA thalamic labelled neurons in the lateral geniculate nucleus and in the thalamic reticular nucleus was 1:1. Moreover the histogram distribution of areas of immunoreactive neurons in the cortex, calculated on cells with the nucleus evident on the plane of the 10 um thick sections,showed that in the GABA positive neuronal population is present a group of large neurons not present in GAD positive population. These data, although could imply the different specificity of the two antibody used, could suggest the presence in the cortex of a neuronal population in which GABA is synthesized from methabolic way other than glutamate.

73.10 **THE CHOLINERGIC INNERVATION OF SOMATIC SENSORY CORTEX IN THE CAT.** Kristin Barstad* and Mark F. Bear (SPON: C. Elbaum), Center for Neural Science, Brown University, Providence, RI 02912

The cat visual cortex can be readily modified by sensory experience during a critical period of postnatal development. These changes depend critically on the pattern and amount of retinal activity. However, they also appear to require that the animal attends to visual stimuli and uses vision to guide behavior. The neural substrate of these "extra-retinal" influences appears to be the noradrenergic projection from the pons and the cholinergic input from the basal telencephalon. Destruction of these two projections interfere with normal experience-dependent modifications in the visual cortex. We are interested in the possibility that similar mechanisms contribute to the use-dependent shifts in the adult cortical somatotopic map. As a first step in testing this hypothesis, we have begun to characterize the anatomical organization of the cholinergic projection to the somatic sensory cortex in the cat. Previous work has shown that large excitotoxin lesions of the basal telencephalon will deplete acetylcholinesterase-containing axons throughout the neocortex, including the somatic sensory areas. In the present investigation, we sought to identify with greater precision the location of cholinergic neurons that project to S1 cortex. Injections of either HRP or WGA-HRP were made in area 3 and after a 36-48 hour survival period, the brains were processed for routine HRP histochemistry. The distribution of retorgradely labelled neurons was compared with the distribution of cells labelled by choline-acetyltransferase immunocytochemistry. The distribution of labelled neurons in the basal telencephalon after large cortical injections of ~0.75 µl of 30% HRP was surprisingly circumscribed. Most back-filled neurons were found on the border between the globus pallidus and adjacent structures: the internal capsule medially, the putamen laterally, and the substantia innominata ventrally. In addition, labelled neurons were sometimes also found in both limbs of the diagonal band of Broca. As a rule, small electrophoretic injections confined to area 3b yielded very few labelled neurons in the basal telencephalon; however, those that did label usually fell in the zone bordering the globus pallidus. These findings predict that it will be possible to deplete S1 cortex of its cholinergic innervation with relatively small excitotoxin lesions of the basal forebrain. This prediction is currently being tested. (Supported by U.S. ONR contract N000-14-81-K-0041)

73.11 PROCESSING OF INPUTS FROM HAIRY AND GLABROUS SKIN WITHIN THE DIGIT REPRESENTATION OF CAT SI CORTEX. N.E. Fletcher* and P. Zarzecki. Department of Physiology, Queen's University, Kingston, Ontario, Canada, K7L 3N6.

Primary somatosensory cortex forms an orderly representation of the body, but in addition contains neurons with inputs from more than one body location (topographic convergence) or of more than one modality. An issue which we have been pursuing is how these convergent inputs shape cortical neuronal activity. When forelimb nerve trunks are stimulated electrically, there are a variety of interactions among the effects evoked in cortical neurons from separate nerves (Kang et al., Exp. Brain Res., 1985). A problem with using electrical stimulation of nerve trunks is that there is considerable overlap of zones of innervation of paw skin by superficial radial (SR), ulnar (UN), and median (MeN) nerves. However, each nerve also serves autonomous zones of skin on the cat paw where cutaneous stimuli evoke primary afferent activity only in that nerve (Kitchell et al., J. Comp. Neurol., 1982). Therefore, we delivered punctate electrical cutaneous stimuli through loops of stainless steel wire sewn into hairy skin of digits three (D3) and five (D5), and glabrous skin of the metacarpal pad (MCP). These are typical autonomous zones for SR, UN and MeN, respectively. Stimulation of D3, D5 and MCP gave rise to primary afferent volleys only in the expected peripheral nerves and to cortical surface potentials of characteristic latency, waveform and distribution across SI cortex. Intracellular recordings were obtained from neurons within the cortical representation of the digits. Most impalements were made in the focus for D5. As expected, epsps were evoked in most neurons (35 of 39) by D5 stimuli. However, sources of input were not restricted to D5. Epsps were also evoked in many of these same neurons by electrical cutaneous stimulation of D3 and MCP, or both. Convergence of inputs from D3 and D5 were found for 24 of these neurons (62%), and 16 of 32 (50%) also had inputs from MCP. The selectivity of paw stimuli was verified electrophysiologically at the end of recording sessions. Cortical surface potentials evoked from D3, D5 and MCP disappeared one-by-one when the forearm nerves carrying afferent volleys from each skin stimulus site were severed sequentially. Thus, to detect neurons with topographic convergence does not require electrical stimulation of nerve trunks with overlapping peripheral distributions. Furthermore, we predict that neurons in the digit zone of SI cortex will generate psps in response to natural stimulation of hairy as well as glabrous skin of the cat paw. Supported by the MRC of Canada.

73.12 MULTIPLE REPRESENTATIONS WITHIN THE FERRET FIRST SOMATIC SENSORY CORTEX (MUSTELA PUTORIUS FURO). S.S. Leclerc,*[1] F.L. Rice[2] and R.W. Dykes[1]. [1]Depts. of Physiology, Neurology and Neurosurgery and Surgery, McGill University, Montreal, Quebec, Canada, H3A 1A1 and [2]Dept. of Anatomy, Albany medical College, Union University, Albany, NY 12208.

In the present study, anatomical and electrophysiological methods were combined to examine the organization of the somatosensory cortex in the ferret (Mustela putorius furo).

Experiments were performed on 16 animals using sodium pentobarbital anesthesia (35mg/kg). A craniotomy over the left frontal and parietal poles permitted access to the somatosensory region. Multiunit responses were recorded using single barrel carbon fiber electrodes. Cutaneous stimuli were delivered using hand-held glass probes while inputs from deep tissues were activated by tapping or manipulating muscles and joints. The adequate afferent stimulus, receptive field location and threshold were determined for each recording site. A total of 2,904 penetrations were obtained with individual penetrations spaced 50 to 150um apart. Data was recorded from the cortical depth which presented the best multiunit response. In two and four animals respectively, over 500 and over 200 penetrations were made. These results were combined with the data from the remaining animals, to construct the full body and facial representation of the ferret.

The overall features of the somesthetic representation were similar to those observed in other mammalian species. Caudally located body parts were found most medially, adjacent to the longitudinal fissure, while head and face representations were located most laterally. Details of the facial representation were based on a total of 1139 electrode recordings obtained in four experiments. Grouping of recording sites according to receptive field location revealed a dual representation for most facial cutaneous areas. Long rows of recordings across this projection area illustrated that the representations were arranged in a roughly mirror-image pattern. Conclusions concerning body and limb representations were based on data acquired in six cases. Data analysis suggested a dual representation of the forelimb. These conclusions were based upon examination of receptive fields limited to single digits and from comparison between projections arising from both glabrous and hairy surfaces. One of the forelimb representations appeared to receive a larger proportion of small, well-defined receptive fields thereby suggesting a different type of sensory processing. These results support the hypothesis that multiple representations exist within the primary somatosensory cortex of nonprimate mammals.

73.13 ORGANIZATION OF CUTANEOUS INPUT FROM HAND TO PRIMARY SOMATIC SENSORY (SI) HAND AREA IN AN OLD WORLD PRIMATE, ERYTHROCEBUS PATAS. Susan Warren and Mary Carlson. Depts. Psychiatry, Anatomy and Neurobiology and Center for Studies of Higher Brain Function, Washington University School of Medicine, St. Louis, MO 63110.

The organization of cutaneous input from the hand to primary somatic sensory cortex (SI) in Old World prosimian primates is comprised of a single topographic pattern. In forming this pattern, three organizing principles ('P') are followed: P1) input from glabrous and hairy surfaces are separately organized; P2) the distal-proximal axes of both surfaces are oriented serially in the rostral-caudal plane; and P3) the ulnar-radial axis lies in the medial-lateral plane. These principles of organization are violated to varying degrees in Old World anthropoids in which a major expansion of the distal digit tip projection occurs in concert with a reduced projection from the remaining cutaneous surfaces of the hand.

In previous studies of Macaca, Cercopithecus, Miopithecus, we found considerable interdigitation of glabrous and hairy receptive fields (rfs) in violation of P1. Rfs on the palm are compressed to the medial and lateral margins of the digit area, and frequent proximal-distal axis shifts occur within and between cytoarchitectonic areas 3b and 1 in violation of P2. However, in both area 3b and 1, P3 was maintained.

In our recent attempts to characterize the topographic pattern of the hand area in the Old World anthropoid, E. patas, using micro-mapping techniques, we found consistent violations of these principles. Unique to E. patas are the appearance of rfs covering multiple glabrous digit tips (25% of rfs) in area 3b and the presence of mixed glabrous/hairy fields on the dorsal digit (5%)in area 3b and 1. The finding of mixed glabrous/hairy fields violates P1. With more than 60% of the total mapped rfs restricted to the distal tips, and 10% of the remaining rfs located on more proximal portions of the glabrous hand, shifts along the proximal-distal axis are scarce and in violation of P2. Similiar to the Old World anthropoids studied thus far, E. patas preserves a shift from d5 to d1 in the medial-lateral plane of area 1. However, for any given medial-lateral point in area 3b of E. patas, this ulnar-radial axis of orientation appears rotated slightly with ulnar rfs located more superficial and radial rfs located deep in violation of P3.

By expanding these studies to include single unit recordings, we will attempt to determine what part of the organizational differences are reflections of the response properties of the underlying individual neurons, are specific to the species studied, or are attributed to other factors such as development. (Supported by MH 14677 and MH 40157).

73.14 THE FUNCTIONAL TERRITORY OF THE PRIMATE MEDIAN NERVE IN THE HAND SKIN AND CORTICAL MAP OF THE HAND. M. F. Huerta and J. T. Wall. Department of Psychology, Vanderbilt University, Nashville, TN 37240.

The skin on the primate hand contains a dense sheet of low threshold mechanoreceptors. These receptors activate ascending central circuits in an organized fashion and, as a result, somatosensory cortical area 3b contains a somatotopic map of the hand surface. The receptor sheet is connected to central circuits via the median, ulnar, and radial nerves. Two questions were asked in the present experiments. First, what parts of the receptor sheet are innervated by the median nerve? Second, what are the spatial features of the representation of this skin in the area 3b map of the hand?

These questions were addressed in ketamine anesthetized squirrel or owl monkeys in which multiunit recordings were made from the median nerve, or in which the hand cortex was mapped with multiunit recordings following acute transection of the ulnar and radial nerves in the contralateral wrist.

There are two main results. (1) Skin areas that were innervated by low threshold mechanoreceptor inputs in the median nerve were found to be similar when assessed with median nerve fiber recordings, and with cortical neuron recordings in the absence of inputs from the other hand nerves. The median nerve territory consistently included the radial (thumbward) 3/4 of the palm and glabrous skin on digits 1-4. Small areas on glabrous digit 5, the tips or edges of dorsal digits 1-4, and the radial edge of the dorsal hand were also innervated but with more variability. (2) The area 3b hand map normally represents all or most of the hand surface. Following transection of the ulnar and radial nerves, the hand was incompletely represented. The median nerve skin was represented laterally near the face representation and was somatotopically organized to a large extent. This representation was sometimes interrupted by small zones that were unresponsive to cutaneous stimuli. Unresponsive zones were also found between the representation of the median nerve skin and the wrist skin.

These findings indicate that median nerve inputs are sufficient to support a topographically ordered representation of a major fraction of the glabrous surface of the hand. Considered with other findings, these results further indicate that the peripheral innervation fields of the hand nerves overlap. This suggests that the composite topography in the normal hand map emerges from an overlaying of orderly maps of the partially shifted cutaneous field of each nerve. 73.15 DISTRIBUTION OF GAD-LIKE IMMUNOREACTIVE NEURONS IN THE FIRST (SI) AND SECOND (SII) SOMATOSENSORY CORTEX OF THE MONKEY. E.H. Chudler, S. Pretel and D.R. Kenshalo, Jr. Neurobiology and Anesthesiology Branch, NIDR, NIH, Bethesda, MD 20892.

Gamma-aminobutyric acid (GABA) is a major inhibitory neurotransmitter in mammalian neocortex. The distribution of glutamic acid decarboxylase (GAD), the synthesizing enzyme of GABA, has been investigated in SI, but not in SII. The present study used immunocytochemical methods to describe the distribution of GAD-like immunoreactive (GAD-LI IR) somata and axonal varicosities in SII and to compare it with that in SI.

Four monkeys, two of which were pretreated with 5% colchicine intraventricular (25 µl) or intracortical (30 µl), were examined. The survival time ranged from 1-4 days after which the monkeys were perfused with 4% paraformaldehyde and 0.2% glutaraldehyde or 4% paraformaldehyde alone. SI (area 3b) and SII tissue blocks were cut into 30 or 50 µm serial parasagittal or coronal sections. Alternate tissue sections were then incubated in GAD antiserum* for 48 hrs at 4°C and processed for GAD immunoreactivity using the PAP immunocytochemical method. Adjacent sections were stained with cresyl violet. GAD-LI IR somata were counted within vertical traverses of 540 µm and their major and minor diameters were measured.

GAD-LI IR neurons and axonal varicosities were found in all layers of SII and SI. The total number of GAD-LI IR neurons was similar in SII and SI. The mean major and minor diameters, respectively, of GAD-LI IR somata in SII were as follows: layer I, 11.0 x 8.2 µm; layer II, 11.8 x 9.6 µm; layer III, 13.0 x 10.3 µm; layer IV, 12.7 x 10.0 µm; layer V, 17.6 x 13.0 µm; layer VI, 15.3 x 10.8 µm. These values are similar to those obtained from GAD-LI IR somata in SI. Differences existed however, in the density distribution of GAD-LI IR somata and axonal varicosities. The highest density of GAD-LI IR cell bodies was found in layer III of SII and in layer IV of SI. The greatest density of GAD-LI IR axonal varicosities was in layers IV and VI of SI. In SII, the greatest density of GAD-LI IR axonal varicosities was in layer III. Moreover, GAD-LI IR axonal varicosities in SII were less dense in all layers when compared to those of SI.

These observations demonstrate differences in the distribution of GAD-LI IR somata and axonal varicosities in SII and SI. Of particular interest is the smaller amount of GAD-LI IR axonal varicosities in SII compared to SI. Previous studies have shown that receptive field sizes are generally larger in SII than in SI. Since GABA is an inhibitory transmitter that is known to affect receptive field size, it is possible that the difference in GABAergic inhibitory processes may account for the larger receptive fields in SII than in SI. *Anti-GAD kindly provided by Dr. I.J. Kopin, Lab. Clinical Science, NIMH, NIH.

73.16 AN IMMUNOCYTOCHEMICAL STUDY ON GLUTAMATERGIC CORTICO-CORTICAL NEURONS IN THE SOMATIC SENSORY AREAS OF MONKEYS. F. Conti, M. Fabri*, T. Manzoni*. Institute of Human Physiology, University of Ancona, I-60131 Ancona, Italy.

Previous studies on cats showed that cortico-cortical neurons of the somatic sensory areas might use the amino acid glutamate (Glu) as neurotransmitter. The evidence was obtained by using the specific retrograde axonal transport of tritiated D-Aspartate (Barbaresi et al., J. Comp. Neurol., 1987, in press) and by combining the immunocytochemical visualization of Glu with the horseradish peroxidase (HRP) retrograde labelling of cortico-cortical cell bodies (Conti et al.; Manzoni et al.: Abstr. 2nd World Congr. Neurosci., 1987). Since previous immunocytochemical studies (Conti et al., J. Neurosci., 1987, in press) showed that the cerebral cortex of monkeys contains numerous Glu positive neurons, we performed the present experiments to test the hypothesis that also in monkeys cortico-cortical neurons might be glutamatergic. HRP was injected in the somatic sensory areas of adult monkeys (M. Fascicularis). Animals were then perfused transcardially with saline followed by 4% carbodiimide in 0.1M phosphate buffer (pH 7.4) and 4% paraformaldehyde in 0.1M phosphate buffer (pH 7.4). Selected regions of the ipsilateral and contralateral first (SI) and second (SII) somatic sensory areas were cut in blocks and sectioned with a Vibratome (25 µm thick sections). Sections were reacted for HRP histochemistry using a cobalt-enhanced protocol and then for immunocytochemistry using an anti-Glu serum previously characterized (Hepler et al., J. Histochem. Cytochem., 1987, in press). Three types of neurons were observed in both ipsilateral and contralateral hemispheres: i) neurons with only black HRP granules (cortico-cortical neurons); ii) neurons with only pale-brown, diffuse labelling (Glu-positive neurons), and iii) neurons with HRP black granules and pale-brown diffuse labelling (Glu-positive, cortico-cortical neurons). In SI and SII double-labelled neurons were found in both supragranular and infragranular layers. These results show that also in monkeys a large fractions of cortico-cortical neurons may use Glu as neurotransmitter.

73.17 WIDESPREAD THALAMIC PROJECTIONS TO LAYER I OF PRIMATE CORTEX. D.P. Friedman[1,2], J. Bachevalier[1], L.G. Ungerleider[1], and M. Mishkin[1] Lab Neuropsychology[1], NIMH, Bethesda, MD 20892 and Neurosciences Research Branch[2], NIDA, Rockville, MD 20857

A system of "nonspecific" thalamic fibers, which terminate widely in layer I of cerebral cortex and may help to control cortical excitability has long been postulated, but never demonstrated in primates. By contrast, many components of the "specific" system, which projects to layers III and IV of restricted regions of cortex and transmits sensory information, have been extensively described. We now present evidence for a widespread layer I projection system in the macaque that arises from nuclei on or near the thalamic midline.

In two cynomolgus monkeys, isotope injections were made that involved the entire anteroposterior and dorsoventral extent of the thalamic midline, but that did not spread more than 1.5mm from it. Five rhesus monkeys received smaller injections largely restricted to either the magnocellular division of the mediodorsal nucleus (MDmc), nucleus reuniens (Re), or the anterior group. All surgery was performed under deep anesthesia while aseptic procedures were observed. After a survival period of one week, the brains were prepared for autoradiography. Exposure times were 16-69 weeks.

The large injections revealed an extensive projection system that ran in long bands in the outer half of layer I and commonly crossed the borders between cortical fields. This labeling pattern was seen in the ventrolateral, orbital, and subcallosal regions of prefrontal cortex, virtually the entire extent of the temporal lobe ventral to the superior temporal gyrus, the visual fields of the occipital and parietal lobes, the entire extent of the insula, much of the frontoparietal operculum, including gustatory and somatic fields, and in the auditory areas that border the ventral insula. In addition, cortical limbic areas, including the cingulate gyrus, entorhinal and perirhinal areas, the subicular fields, and the hippocampus proper were also labeled.

Injections into MDmc and the adjacent midline nuclei led to dense label in layer IV of orbital cortex and some patches of label in the overlying layer I as well. The injection in Re produced layer I label in subcallosal and orbital cortex. The injection into the anterior group, which involved mainly the dorsal and medial nuclei, and also spread to the adjacent midline nuclei, led to label in both layers I and III of the subcallosal region.

These findings supply evidence for a widespread system of midline thalamic projections to layer I of sensory and limbic cortex. Because the hippocampus and amygdala both project to the midline thalamus, and because damage to this region leads to memory deficits, these layer I projections may form part of a limbic-cortical feedback circuit involved in the formation of memories.

73.18 **POST-ROLANDIC CORTICAL PROJECTIONS OF THE SUPERIOR TEMPORAL SULCUS IN THE RHESUS MONKEY.** Benjamin Seltzer and Deepak N. Pandya. V.A. Hospital, Bedford MA 01730, Boston Univ. Schl. of Medicine.

Previous architectonic and connectional studies identified uni- and polymodal sensory-related regions in the superior temporal sulcus (STS) of the rhesus monkey (Seltzer and Pandya, '78). The present study addresses the efferent projections of these discrete architectonic zones to more distant regions of post-Rolandic cortex, as shown by autoradiographic techniques.

The proisocortex of the rostral STS (area Pro) projects to insular proisocortex, prorhinal cortex, and areas TF and TH of the parahippocampal gyrus (PHG). Polymodal cortex of the upper bank (area TPO) projects to the posterior parietal lobe, insula of Reil, PHG, and cingulate region. The rostral portion of area TPO projects to the inferior parietal lobule (IPL) (areas PFG, PFop, PG, and Opt; Pandya and Seltzer, '82) and lower bank of the intraparietal sulcus (IPS) (area POa; Seltzer and Pandya, '80) while caudal TPO projects to area PG, the depth of the IPS (area IPd; Seltzer and Pandya, '86), and medial parietal lobe (area PGm). Rostral area TPO projects to agranular and dysgranular insula; caudal TPO projects to granular insular cortex. Rostral TPO has the more extensive projections to the PHG whereas caudal TPO projects to the cingulate region (area 23).

Unimodal visual-related sectors of the STS (areas TEa and TEm), located rostral to area "MT" in the lower bank, project only to the PHG and perirhinal cortex. A unimodal somatic sensory area (IPa) in the rostral depth of the sulcus projects to the IPL and lower lip (area PG) and bank (area POa) of the IPS. Auditory-related unimodal cortex in the STS (area TAa) has projections similar to those of the adjacent superior temporal gyrus, viz. PHG, caudal insula, and area 23.

Thus polymodal cortex of the STS has extensive projections, organized differentially according to the rostrocaudal dimension. Rostral polymodal cortex has connections with rostral paralimbic areas (i.e. prorhinal, perirhinal, and rostral insular cortex) while caudal polymodal cortex projects to more caudal paralimbic regions (i.e. area 23, caudal insula). Rostral TPO also projects to previously demonstrated polymodal regions of the PHG (Seltzer and Pandya, '76) and caudal IPL. The ventral temporal and parietal projections of caudal TPO, by contrast, resemble those of the IPL. Finally, unimodal zones of the STS have restricted post-Rolandic projections which are the reciprocal of their afferent cortical connections.

MORPHOGENESIS AND PATTERN FORMATION I

74.1 PATTERN DUPLICATIONS IN THE PNS OF L(1)GIANT GAP MUTANT IN DROSOPHILA MELANOGASTER. J. P. Petschek*and A. P. Mahowald* (Spon; W. D. Lust)Dept. of Developmental Genetics and Anatomy, Case Western Reserve Univ. Sch. of Med., Cleveland, Ohio,44106.

Zygotic lethal mutations at the 1(1)giant locus (1(1)gt; 3A1), a member of the gap class of pattern mutations in Drosophila melanogaster, produce embryos with two regions of segmental defects. Previous work indicates that 1(1)gt+ gene activity is required by the time of segment formation for differentiation of the labial and thoracic T1 and T2 segments in the anterior, and abdominal segments A5, 6, and 7 in the posterior of the embryo. In 1(1)gt mutants, localized cell death within the neural and mesodermal tissue is correlated with the segmental defects observed in the posterior region at 7 hours of development. Later, neuromeres A5-7 fail to form, producing a gap in the ventral nerve cord of the mature embryo. We have examined 1(1)gt embryos to determine the effect of early cell death on development of the central and peripheral nervous systems in the gap region of the mutant. 1(1)gt embryos were immunostained with polyclonal antibody probes directed against Drosophila segmentation gene products fushi tarazu (ftz) and engrailed (en), and neuronal cell surfaces (antibody to HRP). Also, embryos were examined with a set of monoclonal antibodies directed against peripheral nervous system components (Mab 22C10, 5B12, T45; kindly provided by S. Benzer). Our results indicate that despite extensive neuronal cell death, longitudinal connectives are maintained over the gap region, and the pattern duplication of peripheral sensory structures occurs in some mutant embryos.

74.2 NEUROMUSCULAR TRANSFORMATION IN BITHORAX DROSOPHILA MELANOGASTER. A. J. Benson* and D. G. King (SPON: W. Yau). Dept. of Zoology and Dept. of Anatomy, Southern Illinois Univ., Carbondale, IL 62901

Bithorax complex mutations are known to affect nervous tissue. However, most studies of homeotically transformed neural structures have focused on sensory neurons derived from imaginal ectoderm, while relatively few have reported effects on motor systems.

In the present study, extensive homeotic transformation of metathoracic muscles and nerves was observed in flies of the genotype abx pbx bx3/Df(3R)p2. Serial sections revealed that the size, shape and position of transformed metathoracic muscles resembled the normal mesothoracic pattern. Transformed muscles (names adapted from Zalokar 1947, Rev. Suisse Zool. 12:17) were (1) indirect flight muscles including dorso-ventral muscles 1 and 5 and longitudinal dorsal 2 muscles; (2) direct flight muscles including both anterior and posterior pleural muscle groups; and (3) other thoracic muscles including the sternopleural muscle, the longitudinal ventral muscle and leg muscles 1, 2, and 3.

Furthermore, nerves in the transformed segment displayed a pattern of axon diameter and grouping similar to the wildtype mesothoracic nerves. For example, in the normal fly mesothoracic muscle pa4 has no proposed metathoracic homologue, but in the transformed metathorax a corresponding muscle is easily identified. This muscle is innervated by an exceptionally large axon which corresponds in diameter to the motor axon of the normal mesothoracic muscle (King & Tanouye 1984, J. Exp. Biol. 105:231) and which travels in a mixed nerve not seen in the normal metathorax but corresponding in position and composition to the anterior dorsal mesothoracic nerve (ADMN). The pattern of innervation does differ when one observes the pa2 muscle. In the wildtype mesothorax, the pa2 muscle is innervated by the mesothoracic accessory nerve (King & Tanouye 1984), while in the transformed metathorax the pa2 muscle is innervated not by the presumably homologous metathoracic accessory nerve but by the transformed metathoracic homologue of the ADMN. The metathoracic accessory nerve does however show homologous posterior pleural muscle innervations. Therefore, not all axons are identically transformed, and segmental differences may reflect an anterior/posterior transformation gradient.

Finally, preliminary data from pupal bithorax specimens show that a large metathoracic axon, presumably the pa4 motor axon, appears before any muscle differentiation can be noted at the pa4 muscle site. Thus this system, wherein bithorax mutations restructure the metathoracic flight muscles and motor neurons to resemble their mesothoracic homologues, suggests that motor axons may be the architectural precursors which direct muscle transformation. This bithorax system may additionally provide an opportunity for exploring the differentiation of central neurons.

74.3 THE ONTOGENETIC DEVELOPMENT OF SUPRASPINAL AFFERENTS IN GOLDFISH. S.C. SHARMA* AND M. BERTHOUD. Dept. of Ophthalmology, New York Medical College, Valhalla, New York 10595.

The onset and development of descending pathways to the spinal cord was studied following horseradish peroxidase application to the severed thoracic spinal cord of goldifsh embryos ranging from embryonic Stage 23 (onset of heart pulsation) through hatching (Stage 25-100 hrs. after spawning) and posthatched fries (ranging from 2 to 40 days old). Earliest HRP labeled cells were reliably seen in the inferior reticular formation at Stage 23-24 following HRP application at the cervical level. In addition Mauthner cells were also labeled. Within 24 hours a few retrogradely labeled cells were seen in the medial and rostral reticular formation and the nucleus of the medial longitudinal fascicle. At about the same time a few labeled neurons were seen in the future octaval area, however, no clear distinction could be made between octaval nuclear areas until two weeks after hatching. Thus the earliest supraspinal fiber connections appear to be formed simultaneously. Retrogradely labeled cells were seen in the raphae nucleus and in the Ruber nucleus. A corollary ^{3}H-thymidine labeling study confirmed that some cells in these nuclei had ceased DNA synthesis and were postmitotic at Stage 23. HRP labeled cells, however, were not found in the facial lobe and the nucleus preopticus magnocellularis and nucleus ventromedialis. Facial lobe was not differentiated until Stage 25 and a distinct facial lobe was not present till one month after hatching. Since facial lobe neurons and the preoptic area neurons project to the spinal cord in adult, it is speculated that their projection must occur later in development. In addition, transitory projections from hypothalamic area was observed in recently hatched embryos. This projection, however, was missing in adult animals. It appears that during the first few weeks after hatching the number of retrogradely labeled cells increase in number. This observation is supported by continued ^{3}H-Thymidine labeling of cells in these nuclei.

74.4 FROG PREY ORIENTING AND BRAIN DEVELOPMENT: NEURONAL PROLIFERATION IN VENTRAL TEGMENTUM. A. Berkowitz* and P. Grobstein. Dept. of Biology, Bryn Mawr College, Bryn Mawr, PA 19010.

The anuran nervous system must successively serve two different sets of functions. Tadpoles of most species are lateral-eyed grazing herbivores, while frogs are frontal-eyed visual predators who rapidly orient toward and strike at prey. Both sets of functions might in principal be served by a stable, general purpose nervous system laid down early in life. An alternative is that aspects of nervous system organization are highly specific to particular functions. Consistent with the latter possibility are previous findings that an eye-position related change in retinal projections involves metamorphic neuron production. Visual prey orienting in the frog depends on a descending tectofugal pathway, which recent studies suggest involves significant processing in ventral tegmentum. To determine when ventral tegmental neurons are produced, we injected tritiated thymidine into Rana pipiens tadpoles and analyzed autoradiographic labelling in the serially sectioned postmetamorphic brains.

Tadpoles were injected at Taylor and Kollros stages ranging from V to XX, the latter corresponding to forelimb emergence. Labelling was observed in all brains. Injections at the earliest stages resulted in a reasonably compact, roughly sagittal sheet of labelled cells extending through the lateral ventral tegmental gray. Rostrally, the sheet was located at the medial edge of nMLF. Caudally, it extended through the middle of AV and into lateral AD, PV, and PD. Injections at progressively later stages resulted in progressively more medial sheets. Rostrally, the sheet was at the medial edge of the tegmentum for injections at stage XV and became indistinct with later injections. Caudally, medial portions of AD, PV, and PD were distinctly labelled even in the oldest injected animals. For injections after stage XVII, a second labelling pattern appeared. In each of three brains examined, substantial numbers of labelled cells were seen scattered in the white matter lateral to the tegmental gray, an area nearly devoid of labelling following injections at all earlier stages. Scattered labelled cells in nMLF were also relatively more frequent for late than for intermediate injections.

The dominant labelling pattern observed, progressing from lateral to medial across several nuclei in the ventral tegmentum, suggests orderly production, migration, and settling of neurons, such that, irrespective of nuclear boundaries, older neurons lie laterally and younger ones medially. Lateral tegmental structures, which include those so far implicated in frog orienting, thus may have a general purpose organization of use in both tadpole and frog. The late, lateral labelling pattern raises the possibility that there is also some metamorphic alteration in the organization of lateral structures. Many of the scattered lateral cells labelled by late injections appear cytoarchitecturally to be neurons. Our findings also show substantial metamorphic cell addition medially. This may also relate to the metamorphic onset of orienting, and warrants further investigation.

74.5 **OCULOMOTOR NUCLEUS OF XENOPUS LAEVIS : THE NEIGHBOR TO NEIGHBOR RELATIONSHIP OF NEURONS IS ALTERED DURING METAMORPHOSIS.**

G.Escher*, N.Schönenberger* and H. Van der Loos* (SPON: M. Reymond)
Institute of Anatomy, University of Lausanne, 1005 Lausanne, Switzerland.

Each oculomotor (OM) nucleus contains neurons with axons that cross the midline, and neurons that do not. The crossed projection, as shown by HRP labeling, is to the superior rectus muscle, the uncrossed to the medial and inferior recti, and inferior oblique muscles. From premetamorphosis to adulthood, about 30% of the neurons have a crossed projection. In the OM nerve of Xenopus laevis, half of the axons are lost during metamorphosis. Does metamorphosis modify the spatial distribution of these two sets of motoneurons ?

Pre-metamorphic and metamorphic tadpoles, and juvenile frogs, were injected with 2% fast blue in the retro-ocular region of one side; 24 hours later, the opposite side was injected with 2% rhodamine. Two days after the last injection, the animals were anesthetized and their brains processed to be cut horizontally in the cryostat. Sections were examined with the aid of a computer microscope.

No double-labeled cells were identified. Nevertheless, the two populations of neurons are not segregated strictly within the nucleus; rather there is a mosaic pattern. At each horizontal level, a grid superimposed on computer-generated drawings divided each left and right nucleus into squares whose sides measured 90 μm. In premetamorphic tadpoles (n=8), 21% of the squares contained both fast blue labeled and rhodamine labeled cells; for metamorphic animals (n=4), this value was 27%, and for juvenile frogs (n=4), 42%.

The number of labeled cells per occcupied square ranged from 1 to 14; with metamorphosis, the percentage of those that contained more than 5 cells had increased from 14% to 31%. A cell-by-cell analysis showed that at premetamorphosis, 21% of all cells have a nearest neighbor with a different label, at metamorphosis 25%, and 31% in the juvenile.

In summary, after metamorphosis, neurons are clustered more tightly, and more clusters contain neurons with crossed and with uncrossed axons.

Without discarding other mechanisms, we hypothesize that this intermingling of neurons is enhanced by a continuing migration, beyond metamorphosis, of motoneurons whose axons have already reached their target. Support : SwissNSF 3.158.

74.6 DEVELOPMENT OF THE OPTIC TECTUM IN LATE PREMETAMORPHIC STAGE OF THE BULLFROG. L.C. Towns and N.J. Uray. Department of Anatomy, Kirksville College of Osteopathic Medicine, Kirksville, MO 63501.

In a previous report (Towns, et al., Soc. Neurosci. Abstr., Vol. 12 Part 1, 1986, p. 319) the development of the optic tectum during the first 26 weeks of larval growth was described. During the initial period of larval development (2-3 weeks), cells proliferate in the rostrolateral quadrant of the optic tectum then migrate caudally. At later ages (8-14 weeks), an arc of proliferating cells lies rostromedial to caudolateral across the tectum and by 26 weeks the principal zone of proliferation is caudomedial. The present experiment describes tectal development during weeks 26-52 as the larva approaches the prometamorphic period when the hindlimbs begin to grow. Larvae were injected with [^{3}H]-thymidine at 26 weeks, 7, 8, 9, 10, 11, or 12 months and were then killed at 53 weeks of age; the entire brain and spinal cord were processed for standard autoradiography. The current results demonstrate that from week 26 to 52, a time period that corresponds to late premetamorphic stages, the principal zone of cell proliferation remains in the caudomedial sector of the optic tectum where the developing, laminated tectum meets the membranous posterior wall. The posterior wall of the optic ventricle diminishes in size but remains membraneous. However, the region of the optic tectum which lies between the membraneous posterior wall and the already formed anterior region continues to differentiate by at least two mechanisms: ependymally derived cells migrate outward and cells which proliferate in the adjacent thickened area push medially between pia and ependyma.

Scattered cell proliferation is seen in other areas of the tectum, also. The ependyma and subependyma are labeled throughout the tectum at all ages injected. When tadpoles are injected at 26 weeks, the ependymal layers are diffusely and uniformly labeled at 53 weeks. The label becomes increasingly heavy and punctate with later injections until injections made at 52 weeks (one week prior to sacrifice) reveal only discrete, heavily-labeled cells scattered throughout the ependyma. In addition to ependymal labeling, scattered medium-to-heavy labeled cells are seen throughout the previously developed optic tectum, principally in cell layers, at all injected times.

74.7 THYROXINE-INDUCED CEREBELLAR DEVELOPMENT IN THE PREMETAMORPHIC BULLFROG TADPOLE. N.J. Uray, S.L. Pyatt*, and M.D. Stuart.* Department of Anatomy, Kirksville College of Osteopathic Medicine, Kirksville, MO 63501.

Numerous studies have shown that thyroxine treatment of large premetamorphic tadpoles induces premature cerebellar differentiation. This study examines the effect of thyroxine treatment on cerebellar development during the entire premetamorphic period which ranges from early stages of cerebellar differentiation to advanced stages of development. Bullfrog (Rana catesbeiana) tadpoles were raised from eggs and their ages were noted beginning with the time they swam free of their jelly-coat. At various time periods ranging from 3 weeks to 12 months of age, groups of tadpoles were treated with thyroxine (sigma, L-thyroxine sodium pentahydrate) by immersion at the concentration of 1:100M. After 2-4 weeks of thyroxine exposure the tadpoles were fixed, their brains dissected out, made into slides, stained with H and E, and were examined.

Our findings show that thyroxine induces premature development of the cerebellum at all the stages examined, however, the degree of development is not uniform. The overall effect of thyroxine is the promotion of corticogenesis, and evidence of this is apparent even in larvae treated at 3 weeks of age. In successively older age groups, the area of the cerebellar plate which demonstrates a cortical pattern in response to thyroxine treatment increases, however, the ventral part of the cerebellar plate continues to be occupied by amorphous cell masses. Thus, in young tadpoles only part of the cerebellum is competent to respond to thyroxine by forming a cortical pattern prematurely. In older premetamorphic tadpoles starting at 6 months of age, most of the cerebellum is able to form a cortical pattern, and in 12 month old tadpoles, the entire cerebellum is competent to complete cortical formation.

The increase in tissue in young larvae which are capable to form an adult-like cortical pattern in response to thyroxine indicate that cerebellar formation in the frog tadpole may proceed in a modular fashion by the activation of discrete zones of cerebellar tissue capable of undergoing differentiation and maturation. A zone of competent cerebellar tissue which can form a cortical pattern appears to pass through the cerebellar plate as a wave starting at the dorsal free edge and proceeding ventrally. The passage of this zone of competent cerebellar tissue through the cerebellar plate appears to be an age-dependent phenomenon. Supported by KCOM Warner Fund (to N.J.U.).

74.8 MATERNAL AND ZYGOTIC EFFECTS OF THE RECESSIVE MUTANT JERKY (jk) IN XENOPUS LAEVIS ON BRAIN AND ANTERIOR SPINAL CORD DEVELOPMENT AND FUNCTION. R. Tompkins, T. Bui*, B. Levet*, O. Shafey*, Q. Le*, D. Reinschmidt*. Biology Dept., Tulane Univ., New Orleans, LA 70118.

Homozygous jerky (jk/jk) tadpoles of the South African clawed frog, Xenopus laevis, derived from heterozygous crosses develop normally until stage 49. From then until metamorphosis they exhibit episodic behavioral abnormalities. Tail tip movements cease and swimming depends on trunk muscles only, or, in some cases all motility ceases and the animals rest on the bottoms of their containers. Heavy feeding and darkness exacerbate these symptoms whereas starvation and strong light alleviate them. Rearing tadpoles in lithium carbonate solutions suppresses the mutant phenotype. Mutant animals are normal after metamorphosis.

Offspring of jk/jk females mated with any genotype male are normal until stage 32. Subsequently, morphogenetic stasis affecting only the anterior spinal cord and brain occurs until death at stage 41-43. Grafting analysis showed that the posterior portions of maternally affected embryos are viable in combination with normal anterior parts, but that the reciprocal chimerae die of the maternal effect. Normal genotype anterior half/ jk/jk posterior half chimeric tadpoles develop normally. Hence both the maternal effect and the zygotic effect are similarly localized.

Two-dimensional electrophoresis revealed that a peptide component, measuring about 47 kd, of normal eggs and normal tadpole brain is absent from the eggs and tadpole brains of jk/jk animals. The mutant allele is associated with a similar size peptide with an altered isoelectric focusing position. Although injection of whole cytoplasm of normal eggs into fertilized eggs of jk/jk females partially corrects the maternal effect, injections of poly A^+ RNA from normal eggs has no effect on the expression of the maternal effect. These results suggest that the maternal effect on anterior spinal cord and brain development, and the zygotic effect on the function of these same structures, is due to the absence of the peptide associated with the normal allele.

74.9 FORMATION OF INDIVIDUAL MUSCLES IN THE CHICK THIGH. S. Schroeter and K.W. Tosney. Department of Biology, University of Michigan, Ann Arbor, MI 48109.

Although individual muscle targets appear to provide specific guidance for the corresponding motoneuron populations, we know little about the processes underlying the development of individual muscles from the large pre-muscle masses in the chick thigh. At the light microscopic level, any two incipient muscles are separated by "cleavage planes," regions of lower cell density that progress in a characteristic proximo-distal or disto-proximal direction. Different phases of cleavage can be seen in serial, 15 µm plastic sections through stage 26-32 thighs. We selected sections showing distinct phases of cleavage and reembedded them for ultrastructural analysis as in Tosney and Landmesser (1986, *J. Histo. Cytot.* 34: 953).

One possible explanation of muscle separation is that myotubes do not differentiate in the incipient cleavage planes. However, we frequently found cells containing myofibrils within the developing cleavage planes. This rules out the possibility that spatially patterned differentiation of muscle cells is responsible for the development of separate muscles.

Our results suggest that differentiating muscle cells are actively removed from the forming cleavage plane. We found macrophages and other cells that appeared to be engulfing isolated myotubes within forming cleavage planes and at the edges of muscles. These were never seen within the body of the muscle. The phagocytosis appeared to be specific: all engulfed cells had myofilaments. In addition, we occasionally saw cells with pycnotic nuclei that may have been dying. Active removal of cells would explain the gradual decrease in the number of differentiated myotubes between muscles that were separating.

We do not know if the phagocytosis is mainly responsible for the decrease in cell density that separates muscles or if it is a secondary mechanism for removing cells that have become isolated as the muscles are separated by other cellular mechanisms. In either case, cell death and phagocytosis of myotubes appears to play an important role in the patterned individualization of these muscles.

74.10 **CELL LINEAGE DETERMINES THE INCREASE IN THE TOP GRADIENT DURING RETINAL DEVELOPMENT.** M. Schneider and D. Trisler, Sect. Cardiology, Baylor Coll. Med., Houston, Tx 77030 and Lab Biochem. Genet., NHLBI, NIH, Bethesda, Md 20892.

TOP is a cell surface molecule that is distributed topographically in a 35-fold gradient from the dorsal margin to the ventral margin of avian retina (Trisler,et al., PNAS, 78, 2145, 1981). The gradient is present at all developmental ages tested from day 3 postfertilization to adult. However, the magnitude of the gradient increases 20 times during embryonic growth of the retina from a 1.8-fold gradient in d.3 embryos to a 35-fold gradient in d.12 embryos. The retina grows by accretion of rings of cells at the peripheral margin. The TOP gradient increases during development by progeny cells at the dorsal pole of the gradient expressing more TOP than parental cells and those at the ventral pole expressing less than parental cells. Cells dividing along the axis of the gradient showed the greatest magnitude of change in TOP expression during retinal growth. Little or no change in TOP expression occured in cells with growth along the perpendicular axis. Intermediate rates of change were found during cell division at a 45° angle to the gradient axis.

Ablation of cells at the poles of the gradient in 60 hr. embryos altered TOP expression during subsequent retinal development. Cells at the dorsal pole of d.13 embryo retinas 11.5 days after dorsal ablation expressed 50% less TOP than normal and those at the ventral pole after ventral ablation expressed 300% more TOP than normal. Cells in other regions of these retinas expressed normal levels of TOP.

Cells from dorsal, middle, and ventral retina grown separately as monolayer cultures in vitro expressed a level of TOP equivalent to that expected for cells from those positions in vivo. Retinal cells from d.8 embryos grown in vitro 6 days showed the same rate of change of TOP expression as cells in vivo during this period of development. Dorsal cell cultures increased TOP per mg of cell protein; those from middle retina were unchanged; and those from ventral retina decreased TOP expresson. TOP synthesis was blocked by 1 µg/ml Actinomycin D and by 2 µg/ml Cycloheximide. TOP was lost from retina cells grown in the presence of these drugs (TOP turnover $T_{1/2}$ in Cycloheximide was 5 hrs and in Actinomycin D was 6 hrs).

Thus, TOP expression is tightly regulated. The TOP gradient is present early in retinal development. Retina cells are determined by 60 hrs postfertilization for their level of TOP expresson and that of their progeny. The pattern of TOP expression in retina during subsequent development depends on cell lineage.

74.11 A MONOCLONAL ANTIBODY DIRECTED AGAINST THE NERVE GROWTH FACTOR RECEPTOR DELINEATES THE BARREL SUBFIELD IN DEVELOPING RAT SOMATOSENSORY CORTEX. Nigel G. F. Cooper, John B. Schweitzer and Dennis A. Steindler. Dept. of Anatomy and Neurobiology, Dept. of Pathology, Univ. of Tennessee, Memphis, TN 38163.

It has previously been shown that the peroxidase conjugates of various lectins recognize glycosylated molecules in the prospective sides and/or septae (in preference to the hollows) of the barrel subfield of mouse somatosensory cortex during a restricted period of time in early postnatal development (Cooper, N.G.F. and Steindler, D.A., J. Comp. Neurol., 249:157, 1986). It has also been shown that the GFAP-positive immature glia are located predominantly within the presumptive septae of the barrel field during the same postnatal period (Cooper, N.G.F. and Steindler, D.A., Brain Res., 380:341, 1986). Both of these patterns of binding are lost in mature somatosensory cortices. We now report that monoclonal antibody 192 (Mab 192), a well-characterized monoclonal antibody that recognizes only the rat nerve growth factor (NGF) receptor, binds to the sides/septae in preference to the hollows of the developing barrel subfield of the rat during a similar developmental period. Postnatal rats, aged P3 to P21 (day of birth = P1), were anesthetized and perfused with standard fixatives. Following removal of the brains, the hemispheres were flattened, 50 um tangential sections were cut and the sections incubated in 5 to 10 ug/ml solutions of Mab 192. They were then developed using standard avidin-biotin horseradish peroxidase methods. Well-delineated barrel subfields showing both large and small barrels were demonstrated by Mab 192 immunohistochemistry on days P5 thru P7, but barrel fields did not appear to be present after the second postnatal week. The barrels detected with Mab 192 occur before the adult neuronal barrel patterns are established. Since the pattern obtained is the same as that obtained with lectins and monoclonal antibody against GFAP, and since the lectin binding pattern has been localized to glial processes ultrastructurally, it appears that radial glia/immature astrocytes express the NGF receptor during development. Our hypothesis is that a population of central glial cells may express the NGF receptor as a mechanism involved in axonal guidance during development. These observations may also be relevant to previous observations on the distribution of nerve growth factor-inducible glycoproteins which reveal patterns related to fiber tract formation during development. This work was supported by USPHS grants EY-02708, NS-20856 and NSF grant BNS-8603593.

74.12 WGA- AND CON A-BINDING GLYCOPROTEINS AND THE PROCESS OF NEURULATION. L.I. Nelson*, Y. Ersahin*, R.G. Higbee, D.G. McLone, and P.A. Knepper. Div. of Neurosurgery, Children's Memorial Hospital and Northwestern University Medical School, Chicago, IL 60614.

The coordination of cellular interactions, e.g., recognition and adhesion, in the process of neurulation requires a combination of intercellular and extracellular events that are under the direction of the genome. Although a variety of glycosylated adhesive molecules have been implicated in neurulation, neither the precise time of expression nor concomitant changes in other classes of glycoproteins are known.

In the present study, chick embryos were studied at 39, 45, 51, and 68 hours of incubation at 37°C (stages 10, 11, 13, and 16, respectively). In order to determine the overall biochemical changes, embryos were fixed in 100% ethanol for 24 hours at 4°C to stabilize the tissues for microdissection of the neuroepithelium. The neuroepithelium was solubilized in lysis buffer for one- and two-dimensional polyacrylamide gel electrophoresis and Western blots using peroxidase-coupled Concanavalin A (recognizes mannose and glucose) and wheat germ agglutinin (recognizes N-acetyl-glucosamine and sialic acid). Proteins were detected by silver staining. Two-dimensional maps indicated that several proteins varied, i.e., appeared, disappeared, or changed in their coordinates during the time frame of 39 to 68 hours: tail, 5 variances, and head, 9 variances, which represented approximately 7% of all observed proteins.

Western blots revealed numerous differences in glycosylation patterns in the four stages of neurulation. WGA-binding protein profiles were: (1) 22 minor and four major glycoproteins with apparent molecular weights of 8, 20, 66, and 185 Kd; and (2) four WGA-binding proteins changed in the developmental process, i.e., a progressive increase in the glycosylation of 8-, 14-, and 170-Kd proteins and a progressive decrease in the glycosylation of a 66-Kd protein. Con A-binding profiles were: (1) 18 minor and 12 major glycoproteins; and (2) three Con A-binding proteins changed, i.e., a progressive decrease in the glycosylation of 24-, 30-, and 97-Kd proteins.

These results indicate that there are demonstrable changes in WGA- and Con A-glycosylation patterns of proteins during the process of neurulation in the developing chick embryo; and (2) these differences in the type or amount of glycoproteins may be involved in the process of normal or abnormal neurulation.

Supported in part by Greater St. Louis Spina Bifida Association and Osco, Inc.

74.13 SITES OF SEROTONIN UPTAKE AND BINDING PROTEIN IMMUNOREACTIVITY IN THE CULTURED MOUSE EMBRYO: ROLES IN MORPHOGENESIS? J.M. Lauder, H. Tamir** and T. Sadler* Dept. of Anat., Univ. N.C. Sch. Med., Chapel Hill, NC 27514 and Div. Neurosci., N.Y. State Psychiat. Inst., NY, NY 10032 **.

Serotonin (5-HT) and related compounds have been proposed to influence morphogenesis of early embryos, and 5-HT has been localized in the notochord, neural tube, somites and endoderm of the neurulating chick embryo (Wallace, J.A., Am. J. Anat., 165:261, 1982). To investigate this question in a mammalian animal model, sites of 5-HT uptake and synthesis have been examined in mouse embryos cultured in the presence of 5-HT or precursors. Additionally, serotonin binding protein (SBP) has been localized adjacent to these 5-HT sites and the teratogenicity of 5-HT and related compounds has been established. Mouse embryos 9 or 12 days in gestation (E9 or E12) were grown in whole embryo culture. For immunocytochemistry, embryos were cultured for 3-4 hrs in the presence of: 5-HT (10^{-4}, 10^{-5} or 10^{-7}M) + nialamide (N, 10^{-5}M) and L-cysteine (C, 10^{-3}M), 5-HTP (10^{-5}M) + NC, NC alone, C alone or were left untreated. These treatments were repeated in the presence of the specific 5-HT uptake inhibitor fluoxetine (fluox, 10^{-5}M). Embryos were fixed, embedded in paraffin, sectioned and stained with specific antisera to 5-HT or SBP using the ABC peroxidase method. For studies of malformations, E9 embryos were cultured for 24 or 48 hrs in the presence of these same substances, followed by fixation and preparation for SEM or plastic sections. Sites of 5-HT immunoreactivity (IR) were found in the heart and hindgut of E9 embryos. At E12, such sites were found in the epithelia of the head, face, neck (visceral arches) and oral cavity. Sites were also seen in parts of the otocyst and brain. In all cases except the oral cavity, mesenchyme adjacent to these sites exhibited heavy SBP-IR. Moreover, when embryos were cultured in the presence of 5-HT, NC or fluox, malformations of the visceral arches and forbrain were seen which increased in frequency and severity in a dose-dependent manner. Fluox was the most teratogenic in this regard and also caused heart defects. These results suggest that 5-HT may play a role in morphogenesis in the mouse embryo, a process which may be vulnerable to the influence of psychoactive drugs acting through serotonergic mechanisms during critical periods of development.

74.14 **BIOMETRICAL GENETIC ANALYSIS OF A CEREBELLAR FOLIATION PATTERN.** **P. Cooper*, M. Hahn*, J. Hewitt*+, and R. Benno. Dept. of Biol. Wm. Paterson College of N.J. 07470, and +Dept. of Human Genetics, Med. Coll. of Virginia 23298.**

In this study we sought to describe genetic influences on cerebellar foliation patterns in inbred strains of mice. We used a 4 x 4 diallel cross breeding design with the inbred strains DBA/2J, C57BL/10J, Balb/cJ, and SJL/J. This cross generated 16 genetic groups and we used approximately 5 liters per genetic group. Mice were sacrificed on day 42 ± 2 by CO_2 inhalation and weighed. Their brains were removed and weighed to 0.1 mg accuracy. Whole brains were placed in 4% buffered formalin overnight and then cut along the mid-sagittal plane. The right half of the brain was stained with cresyl violet and viewed under a dissecting scope for cerebellar foliation pattern. Two distinct foliation patterns were noted: Type I (Mouth) in which the 3rd primary branch of the arbor vitae was split into two distinct foliate branches by a sulcus and Type II (No Mouth) in which the 3rd primary branch ended in a single cerebellar folia.

Contrary to earlier studies, we found a lack of consistency existed for the phenotypic expression of cerebellar foliation pattern in the homozygotes (i.e. inbred strains) of the diallel cross. Only one strain (DBA) showed a consistent phenotypic foliation pattern (Type I). The other three inbred strains exhibited both Type I and Type II patterns.

Next we investigated the relationship between foliation pattern and brain weight. We suspected that a relationship would exist since we had previously shown that mice selected for low brain weight [the L-line of the Fuller Brain Weight Selection (BWS)] exhibited the Type I pattern. We compared the brain weights of animals that had Type I or Type II foliation patterns and found a significant difference: Type I animals had smaller brains. A point biserial correlation, however, showed that foliation pattern accounted for only 13% of the variance in brain weight.

We next developed a genetic analysis for discrete data (Mouth/No Mouth) based on Hayman's Analysis of Variance procedure for a diallel cross. The results of that analysis indicate: significant additive genetic effects, a significant directional dominance effect, and a maternal effect. The interpretation of these results within the theory of biometrical genetics indicates an evolutionary history of directional selection pressure for the presence of a cerebellar foliation phenotype which includes a mouth pattern at the third branch of the arbor vitae.

In summary, we have shown that cerebellar foliation pattern in mice is highly dependent upon genotype. Further, the Type I pattern has undergone positive selection pressure. We are currently assessing the degree to which genes and the environment interact to influence cerebellar foliation patterns in mice.

74.15 PRE- AND POST-NATAL ONTOGENY OF 5-HT INNERVATION IN THE RAT SPINAL CORD. N. Rajaofetra*, F. Sandillon*, M. Geffard* and A. Privat* (Spon ENA), Neurobiologie du Développemment, INSERM U.249-CNRS L.P.8402, Institut de Biologie, 34060 Montpellier, France, and IBCN, CNRS, Bordeaux, France.

The development of 5-HT innervation in the spinal cord was studied from embryonic day 14 (E14) to adulthood. Sprague-Dawley rats were fixed by perfusion with 5 % glutaraldehyde in phosphate buffer, and vibratome sections were processed for immuncytochemistry with a 5-HT antiserum. For electron microscopy, the section were flat-embedded in araldite, and thin section were performed. 5-HT neurons growing backwards from raphe nuclei invade the spinal cord at E14, and reach the caudalmost levels by E16-E17. In longitudinal sections, axons are seen by E15, at cervical and upper thoracic levels, to invade the presumptive grey matter from the anterior and lateral funiculi. This occured either by sharp angulation of the axon, or by branching of a collateral. By E16, the anterior horn and the intermediolateral columns are profusely innervated by very thin and varicose fibers, and synapses are seen with EM in these two locations, at E17 and E18, involving 5-HT immunoreactive boutons. After birth, 5-HT innervation of these two areas evolves progressively from a diffuse netwotk to a more restricted pattern, especially at the thoracic level for the intermediolateral column, and at cervical and lumbar levels for the anterior horn. The adult pattern is reached by postnatal day 20 (P20). The growth of axons towards the dorsal horn becomes noticeable by E19, when fibers invade the neck of the horn from the lateral funiculus, and innervation proceeds diffusely until P5. At P7, thin fibers course dorsally and laterally along the border of the grey matter, and ramify profusely in layers I and II. The adult pattern is also reached by P20. This progressive organization, contrasting with early innervation, will be discussed in comparison with the maturation of motor and sensory circuitries of the spinal cord. Supported by INSERM, CNRS, and an IRME fellowship to N.R.

74P0 **THE ZEBRAFISH HINDBRAIN IS SEGMENTALLY ORGANIZED.** Bill Trevarrow, Walter K. Metcalfe, Charles B. Kimmel, and Dan Marks Institute of Neuroscience, University of Oregon, Eugene, OR 97403

The evolutionary origin of the vertebrate head, including the brain, is unknown. According to one theory it arose by specialization of rostral body segments; thus the brain represents a rostral extension of the spinal cord. In the zebrafish the myotomes are overtly segmented, and in the spinal cord identified neurons are serially reiterated at intervals corresponding to the length of a myotome. In accord with the above theory we have shown previously that in the hindbrain there are clusters of interneurons, some of which are individually identified, that are also serially repeated. Early in development the repeat length is the same as a trunk segment.

We have now extended the evidence for head segmentation in the zebrafish. We have identified segmental swellings (neuromeres) of the hindbrain at 17 hours post-fertilization (h) using Nomarski optics with living embryos and by SEM with fixed material. At this stage a single cluster of interneurons within each neuromere is labeled with a monoclonal antibody. By 24 h, more neurons are labeled within these clusters, and smaller segmentally repeated clusters of neurons have formed at the boundaries between the neuromeres. At 48 h, staining with other monoclonal antibodies shows a segmental pattern of a variety of other structures in the hindbrain, including fiber tracts, radial glia, neuropil areas, and other neurons. We propose that the organization of these structures is the result of a segmental plan of hindbrain development.

Does segmentation extend to other structures of the head? In more rostral areas of the brain (the midbrain and forebrain) neurons develop as clusters of cells, but not in an obviously segmental manner. We have not yet identified head somitomeres beside the brain, but the seven branchial arches that underlie it are in register with the rostral seven hindbrain segments. Thus, in both the head and body the segmental pattern includes peripheral structures as well as the CNS. Supported by NS17963.

PROCESS OUTGROWTH II

75.1 PUTATIVE GLIA DURING *DROSOPHILA* NEUROGENESIS. J.R. Fredieu*and A.P. Mahowald*. (SPON: H. Gluck) Dept. of Developmental Genetics and Anatomy, Case Western Reserve Univ.Sch. of Med., Cleveland, Ohio 44106.

The role of glia during neural development in lending structural and metabolic support, as well as providing guidance cues for advancing growth cones is well documented in the vertebrate literature. Recently, non-neuronal cells have been implicated in serving as guideposts and substrate pathways for pioneer growth cones in the embryonic grasshopper and *Drosophila* nervous systems. During a screen of monoclonal antibodies (kindly provided by Dr. Seymour Benzer) raised against adult *Drosophila* heads, Mab 5B12 was found to recognize two subsets of cells which do not label with antibodies to horse radish peroxidase: one set is located in the ventral midline just dorsal to the central neuropil; the second set is located lateral to the CNS in each hemi-segment and project laterally in a pattern coincident with the peripheral nervous systems.

Whole embryos (2-21hrs) were dechorionated in 50% chlorox, permeabilized in heptane, and fixed in 10% formalin or 4% paraformaldehyde. Prepared embryos were then incubated in antibody overnight at 4°C, washed in PBS, and incubated in secondary antibody conjugated to FITC, RITC, or HRP.

Cells, positive for Mab 5B12, are detectable in the embryo beginning at about 10-11hrs of development within the ventral midline of each segment dorsal to the neuropil. Later, beginning anteriorly, clusters of cells lateral to the CNS in each hemi-segment stain positive for Mab 5B12. As development proceeds, these lateral cells extend processes into the periphery and elaborate a pattern coincident with the developing PNS. Simultaneous incubations of late embryos in Mab 5B12 and rabbit anti-HRP reveal a close association of the peripheral nervous system with these "glial" processes, in particular, the anterior and posterior fascicles of each segmental nerve.

Dissociated cells from gastrula stage embryos plated on glass coverslips in appropriate media will differentiate into a variety of cell types including neurons. A sub-population of cells in culture is visualized with Mab 5B12. Presently, experiments are underway to investigate lineage relationships, as well as, selective affinities of neuronal cell-types for Mab 5B12 positive cells both of which may reveal a cooperation between neuronal and non-neuronal cells during development.

75.2 THE BRANCHING PATTERN OF A LEECH MOTONEURON DEPENDS UPON ITS INNERVATION OF THE NORMAL OR AN ECTOPICALLY-LOCATED TARGET ORGAN. C.A. Baptista* and E.R. Macagno. Dept. of Biological Sciences, Columbia University, New York, NY 10027.

The bilateral pair of rostral penile evertor (RPE) motoneurons are found in the sixth segmental ganglion (SG6) in the leech *Hirudo medicinalis* (B. Zipser, *J. Neurophysiol.* 42:455, 1979). In the adult, each cell projects its principal process to the contralateral side of SG6 where it bifurcates, one branch exiting the ganglion along the anterior nerve root and the other exiting along the anterior interganglionic connective. The latter branch travels to SG5 and exits along its anterior nerve root. Both root branches then innervate the male genitalia, which are located between SG5 and SG6. Dye-filling of the RPE neurons at early developmental stages reveals, however, the existence of additional extraganglionic projections (e.g., posteriorly towards SG7, beyond SG5 towards SG4, and in the posterior nerve root of SG6). Most of these have almost entirely disappeared by 50d (embryogenesis is completed by 30d), when the adult morphology of the RPE neurons is evident. Thus, several projections disappear over the course of differentiation of these motoneurons, as is the case for several other leech neurons, and those projections that remain are those that do innervate the target organ.

To test for the possible involvement of the target organ in the determination of the adult pattern of axonal projections of the RPE neurons, we first ablated the male genitalia at 10d of development, when branches of the RPE neurons are just beginning to innervate the organ. When examined at 50d, the RPE cells in the experimental animals showed not only the usual projections and those normally lost, but also a profusion of additional ones. These novel projections extended many segments anteriorly or posteriorly and erratically to the body wall and back into the nervous system, and even, in a few cases, appeared to innervate the female genitalia between SG6 and SG7. Ablation of the female genitalia, or prevention of the normal innervation of the male organ via one of the two normal routes, for example, did not elicit the extensive changes in morphology that followed ablation of the normal target.

As a second test, male genitalia were transplanted at 10d of development to ectopic, more posterior locations in hosts that had also had their normal male genitalia ablated. More than half of the RPE cells examined at 50d in these experiments had been able to exit from more posterior ganglia (SG7 or SG8) and innervate the ectopic organ. In these cases, only the unusual projections innervating the target were of large caliber, while the few remaining projections in other directions, including those that would normally innervate the target, were much thinner and appeared to be atrophying or retracting.

These observations suggest to us that the RPE neurons are initially programmed to extend multiple branches and to grow out and explore many pathways in order to find their target. Once some branches encounter the target, an interaction with the target triggers a signal that causes the inhibition of growth and atrophy of other processes of the neuron which have failed to find the target and the maintained growth and increase in diameter of the successful ones. Lacking a target, growth continues in an unchecked manner, but encountering an ectopically located target leads to the retention of novel projections and the loss of the normal ones. (Supported in part by NIH Grant NS-20336.)

75.3 SELECTIVE NEURITE RETRACTION BY SOME LEECH NEURONS CAN BE PREVENTED BY CUTTING GANGLIONIC NERVE ROOTS EARLY IN DEVELOPMENT. W.-Q. Gao* and E.R. Macagno (SPON: D. Hood). Dept. of Biological Sciences, Columbia University, New York, NY 10027.

Our previous studies (*J. Neurobiol.* 18:295, 1987) showed that, from 10 to 18 d of embryogenesis, AP and AE neurons in the leech CNS have lateral projections to the periphery through two contralateral nerve roots as well as longitudinal projections toward adjacent ganglia along the interganglionic connective nerves. While the lateral peripheral projections are maintained throughout the life of the animal, the longitudinal projections gradually atrophy and disappear before the end of embryogenesis (30 days). Ablation of AP or AE neurons in individual segmental ganglia at about 10d of development resulted in the retention of the longitudinal projections of adjacent homologues, suggesting that homologues play a role in the normal loss of longitudinal projections.

To begin to assess whether competition for peripheral targets or a direct inhibitory interaction among homologous neurons might be responsible for the loss of early projections, we cut the nerve roots in midbody ganglia at various times in development, thus severing the direct early projections of neurons to peripheral targets in the same segment. The pattern of projections of these neurons was then observed by injecting them with dye in 30d or older animals.

In those cases in which nerve roots were cut before AP or AE longitudinal projections begin to atrophy (i.e., before 18 days), the affected neurons retained and expanded their longitudinal projections to and sometimes even beyond adjacent ganglia, irrespective of whether they succeeded or failed to re-establish the severed projections along the regenerated nerve roots, while all neighboring homologues displayed normal axonal projection patterns. The rescued longitudinal processes were generally found to branch and project to the periphery in adjacent ganglia, following closely in the nerve roots the projections of the local homologous neuron. Preliminary physiological and dye-fill studies of AE neurons in adult experimental animals show that these abnormal peripheral projections make funcional connections to peripheral targets. In those cases in which nerve roots were cut after the longitudinal processes had atrophied (i.e., after 30d), however, no longitudinal processes were found. The severed nerve root projections were re-established in most of these cases. These observations suggest that atrophied projections do not have the capacity to regenerate, even when the neuron is completely disconnected from its peripheral targets. In control experiments, neither severing longitudinal projections before atrophy nor non-specific damage to the nervous system appeared to affect the final axonal branching patterns of AP or AE neurons.

These results show that neuronal processes which are normally fated to atrophy can be rescued by early disconnection to peripheral targets and suggest that a direct interaction among homologues is not sufficient to explain the loss of initial projections by these leech neurons.

(Supported in part by NIH Grant NS-20336.)

75.4 AGE-DEPENDENT CHANGES IN THE DENDRITIC MORPHOLOGY OF RAT SYMPATHETIC NEURONS IN VITRO. [1]D.A. Bruckenstein*, [2]M.I. Johnson, and [1]D. Higgins. [1]Dept. of Pharm &Ther., State Univ. of N.Y., Buffalo, NY 14214 and [2]Dept. of Anat., Washington Univ., St. Louis, MO 63110

Previous studies have shown that neurons from the embryonic rat superior cervical ganglion fail to form dendrites when they are cultured in serum-free medium in the absence of nonneuronal cells (Trans. Amer. Soc. Neurochem. 17:209). To determine whether there might be developmental changes in the morphological capacities of sympathetic neurons, we compared the ability of embryonic (20-21 day) and postnatal (1-2 months) sympathetic neurons to form dendrites under the same culture conditions. Dendrites were distinguished from axons by light microscopic criteria after the intracellular injection of Lucifer Yellow, by differential immunostaining with an antibody to the nonphosphorylated forms of the M and H neurofilament subunits, and by the autoradiographic localization of RNA within dendrites.

When maintained in the absence of nonneuronal cells, most neurons (>75%) derived from postnatal ganglia were multipolar and extended both axons and dendrites. Most often the dendritic morphology of postnatal neurons was relatively simple with cells commonly having from 2 to 6 short (50-200 micron), relatively unbranched dendrites. In contrast, most (>80%) embryonic neurons were unipolar and had only a single axon. These data indicate that postnatal sympathetic neurons that had well-established arbors in situ have the capacity to regenerate dendrites when grown in dissociated cell culture in the absence of nonneuronal cells; in contrast, embryonic neurons which had only primitive arbors at the time of dissociation are unable to extend dendrites under these conditions.

To determine whether similar changes in regenerative capacity might occur with aging in vitro, ganglia were removed from embryonic rats and grown as explants for 3 weeks in the presence of nonneuronal cells; under these conditions, embryonic neurons within the explant became multipolar. Moreover, most neurons obtained from such aged explants extended dendrites when they were subsequently maintained in dissociated cell culture. Thus, the acquisition of the capacity to form dendrites in dissociated cell culture is not dependent upon normal afferent input or upon contact with the target tissue. (Supported by NS 22126 and GM 07145)

75.5 LONG TERM SURVIVAL OF RAT HIPPOCAMPAL NEURONS AT LOW DENSITY: ADVANTAGES OF LOW OXYGEN. G. J. Brewer*, C. Peterson and C. W. Cotman. Dept. Psychobiology, Univ. California, Irvine, CA 92717.

The study of the development and plasticity of hippocampal circuitry would greatly benefit from methods which allow the long term culture of neurons at low density under precisely defined culture conditions. Defined media supports culture of neurons at high density but not low density; serum-containing medium is inconsistent and associated with massive glial proliferation. We report that isolated hippocampal neurons from embryonic day 18 rats can be cultured for several weeks at densities low enough to allow identification of individual connections when maintained in an environment of reduced oxygen. Neurons develop in vivo at subatmospheric concentrations of oxygen with physiological anti-oxidants in a close-pack environment that reduces diffusion of small molecules. To simulate these conditions, a serum-free medium with added anti-oxidants was studied. Improved survival and neuritogenesis relative to that seen in serum-based cultures suggested a toxic role of oxygen. This chemically defined medium, derived from the formulation of Romijn, omits ascorbate, but includes vitamin E, glutathione, pyruvate, catalase and superoxide dismutase as antioxidants. To directly test the effect of reduced oxygen, cultures incubated in 9% oxygen were compared to those in the normal 19.7% oxygen (95% air). Cultures in low oxygen were superior to those in normal oxygen. Further improvement in neuronal survival was produced by covering the cells with a glass cover slip an hour after plating. Neuronal survival relative to uncovered cultures increased from 40% to 90% at 5 days, with processes on nearly 80% of the cells. Covered cells exhibited a ring of neuronal growth which did not extend to the center or the edge of the cover slip. In 9% oxygen the outer ring of growth was closer to the edge of the cover slip than in normal oxygen. The cover slip did not provide an additional substrate for attachment since removal of the slip left the neurons attached to the original substrate. However, this removal resulted in cell death within 24-48 hours suggesting exposure to a toxic factor. Although variations in glial cell content (<10%), pH, and pCO_2 were unlikely explanations of the high survival, a role for autocrine factors is still suggested by the density dependence of survival below 10,000 cells/cm^2. These results suggest that growth in a diffusion-limited space, reduction of the oxygen concentration to physiological levels and control of toxic oxidation with physiological antioxidants can improve the survival and neuritogenesis of isolated hippocampal neurons in primary culture making these cultures potentially useful for studies in neuronal connectivity.

75.6 REGENERATING AXONS REESTABLISH NORMAL SECTORAL ORDER IN THE OPTIC BRACHIA OF GOLDFISH. R. Bernhardt and S.S.Easter, Jr. The University of Michigan, Ann Arbor, MI 48109.

The positions of retinal axons in the cross section of the normal optic pathway of goldfish reflect their retinal origins, defined as r, the radial distance of the parent somata from the center of the retina, and θ, the sectoral (or clock face) position (Bernhardt and Easter, J. Comp. Neurol. 254: 493, 1986). We have now examined sectoral order in experimental pathways regenerated after optic nerve crush.

In fish that had survived for 2-4 months after nerve crush HRP was applied to a stab wound in the retina, on either the nasal, temporal, dorsal, or ventral radius. This application labels a narrow sector of ganglion cells, extending from the lesion site to the retinal periphery, and their axons. The axons were traced in serial cross sections of the pathway.

On the retinal side of the crush axons of common θ (a "θ-group") were clustered. On the tectal side of the crush, in the regenerated portion of the nerve, they were scattered, occupying 75-88% of the total cross sectional area. Comparable θ-groups in control nerves remained clustered and occupied approximately 50% of the cross sectional area. Regenerated axons tended to reaggregate at the nerve/tract junction. More downstream in the tract they were often arranged in a criss-cross pattern, indicative of changes in their neighbor-neighbor relationships. In the normal pathway such changes lead to the segregation of axons of dorsal and ventral hemiretinal origins into the ventral and dorsal brachia of the tract, respectively (Scholes, Nature 278: 620, 1979; Springer and Mednick, J. Comp. Neurol. 247: 233, 1986). In agreement with previous studies (Attardi and Sperry, Exp. Neurol. 7: 46, 1963; Stuermer and Easter, J. Comp. Neurol. 223: 57, 1984) we find that the brachial choice is reestablished by regenerating axons. Moreover, we find that within the brachia regenerated axons of nasal and temporal retinal origins occupy different subregions, as in the normal. The visual impression of reordering was confirmed by counting individual labeled axons and calculating their densities as a function of position within the cross sectioned dorsal brachium. While the regenerated order was less precise than normal, the distribution peaks of nasal and temporal axons did not overlap. Regenerated axons exited the brachia and stratum opticum in a normal sequence; temporal ones rostrally, nasal ones more caudally. Regenerating axons have no predecessors to rely on for guidance. Our results suggest that they might have access to θ-specific cues in the non-axonal environment of the tract and its brachia. (Supported by EY-00168 to SSE.)

75.7 **DETECTION OF AREAS OF NEURITE EXCLUSION IN CULTURES OF RAT FETAL CORTEX.** R. D. Todd (SPONSOR: S. Guze) Department of Psychiatry, Washington University School of Medicine, St. Louis, MO 63110.

The mechanisms by which cortical neurons migrate to their final brain locations and extend neurites to their targets are complex and incompletely understood. Differential cell adhesion has been suggested as one mechanism for cell and neurite guidance. This theory proposes that the direction of cell migration or growth cone elongation can be altered by substrate adhesiveness. Chemotactic factors, both attractive and repellant, have also been proposed as mechanisms for cell and neurite guidance. In this case, cells or growth cones travel along gradients of diffusing molecules. We have detected transiently present structures in primary cell cultures which seem to exclude or inhibit growing neurites and may represent the presence of a differentially adhesive substrate for cell and growth cone motility or the presence of a repellant chemotactic factor.

Frontal cortices from E15 to E23 fetal rats were dissected, triturated, and plated onto poly-lysine coated dishes as single cell suspensions. Within one or two days of plating, rare structures were observed which consisted of a central cell (or cells) surrounded by an area free of neurites and enclosed by a border or corral of neurites. The structures were from 20 to 60 microns in diameter. The central cell or cells excluded trypan blue. From day E15 to about E17.5 there was an exponential increase in the number of these structures from about 5 to about 200 per million viable plated cells. After about day E17.5 there was a dramatic decrease in these structures to less than 5 per million viable cells on day E19. Similar structures were observed on collagen coated dishes and in cultures of hippocampal cells. Preliminary electrophysiological and antibody staining studies suggest these structures contain viable non-neuronal cells. The properties and time course of the presence of these structures are consistent with their involvement during development as negative regulators of cell and growth cone movement.

75.8 GROWTH OF CORTICOSPINAL AXONS THROUGH A GLIAL DEFICIENT ENVIRONMENT. M. A. Pippenger*, T. J. Sims, and S. A. Gilmore. Dept. of Anatomy, University of Arkansas for Medical Sciences, Little Rock, AR 72205.

The major corticospinal tract in the rat, located at the base of the dorsal funiculus, does not grow into the lumbosacral region of the spinal cord until the latter part of the first postnatal week. The growth of these axons into and through the lumbosacral region was studied in normal rats and in rats in which a 5 mm length of the lumbosacral spinal cord was exposed to x-rays on the third postnatal day. The irradiated rat model was used since the exposure to x-rays markedly decreases the number of glia and, thus, alters the milieu through which the developing corticospinal axons must grow.

The developing corticospinal axons were studied by horseradish peroxidase (HRP) tracing techniques. HRP chips, dried from a saline solution containing 50% HRP and 4% Nonidet P-40, were placed on the pial surface overlying the cerebral cortex of two groups of rats on postnatal day 1, 2, 3, 4, 5 and 8. One group consisted of normal rats and the other of rats irradiated (4000 R) over the lumbosacral spinal cord on postnatal day 3. Two days following HRP application the rats were killed by perfusion and the spinal cords were removed, sectioned, and processed by the tetramethyl benzidine (TMB) procedure.

Anterograde filling of growing tips (growth cones) was readily observed on all days studied. That the HRP-filled structures were in fact growth cones was supported by observations made in spinal cords stained by the Golgi method during the first postnatal week. By 3 days postnatally (time of irradiation) growth cones were present in the high thoracic levels but not in the lumbosacral region. Growth cones were not observed in the latter region until day 5, and by day 7 corticospinal growth cones were present at all levels. These observations were consistent for both normal and irradiated spinal cord. Thus, despite the marked, radiation-induced loss of glia (especially astrocytes) from the region to be occupied by the ingrowing corticospinal axons, the development of the tract appeared to be normal with respect to location and to time of arrival of the axons in the lumbosacral region. Supported by NIH grant NS-04761.

75.9 CULTURED SQUID NEURONS EXTEND NEURITIC PROCESSES. T.D. Parsons and R.H. Chow*. Dept. of Physiol., Univ. of Penn., Phila, PA 19104 and Marine Biological Laboratory, Woods Hole, MA 02543.

The squid giant axon arises from the fusion of hundreds of smaller axons. These smaller axons originate from cell bodies located in the giant fiber lobe (GFL) of the stellate ganglion. Using an isolated GFL neuron preparation (Loligo pealei) developed by Llano and Bookman (1986), we have begun to study the extension of processes from these cells. GFL neurons obtained from healthy squid reliably produced neuritic processes in culture. The processes were of two types -- a sheet-like veil or thin branching neurites. The latter type was often associated with bulbous expansions at the termini, at branch points, or at sites of contact among branches from two different cells. On poly-L-lysine substrate, veiling usually occurred by the fourth or fifth day in culture, while the branching processes appeared by one week to ten days. The elaboration of the outgrowths by the GFL neurons was influenced by the culture substrate and incubation temperature. This culture system in which isolated somata develop neurites over several weeks may permit the study of spatial and temporal expression of ionic conductances.

75.10 SOME GROWTH CHARACTERISTICS OF AXONS IN A RE-GROWING OPTIC TRACT IN NEONATAL HAMSTERS. L.S. Carman*, S. Jhaveri* and G.E. Schneider. Dept. of Brain & Cognitive Sciences, M.I.T., Cambridge, MA 02139.

In Syrian hamsters, retinotectal axons transected on or before postnatal day 3 (P3; P0 = day of birth) will grow across the lesion site and reinnervate their normal tectal target (So et al., '81). However, if their normal tectal target is ablated, they grow across the necrotic tissue, cross the midline, and terminate in the opposite tectum (Schneider, '73). If the eye ipsilateral to the ablated tectum is enucleated, this recrossing projection expands across the entire surface of the undamaged tectum. This study examines growth characteristics of recrossing axons during the period immediately following the lesions.

Combined lesions--ablation of right superior colliculus (rSC) and enucleation of the right eye (rEE)--were made in 22 Syrian hamsters on P1. The left eye was injected with horseradish peroxidase (HRP) either 4 hr or 1-2 days after rSCrEE lesions. In some cases, the left optic tract was transected at the time of HRP injection to ensure that we were observing only recrossing axons in the left SC. Hamsters were perfused 20 hr after eye injections, and brain sections were processed for visualization of the HRP. Age of the animal refers to the time of perfusion.

By P2 (24 hr after rSCrEE), regrowing axons have crossed the necrotic right SC and have reached or crossed the midline. The longest pioneers at this age extend 260 μm (mean for 3 cases) from the midline, and 1260 μm from the center of the rostral edge of the lesion. By P3, pioneers extend 620 μm (mean for 7 cases) into the intact tectum, and by P4 pioneers extend 850 μm (mean for 12 cases). These data indicate that recrossing axons are not growing at a uniform rate. In the initial 24 hr after surgery, they grow at a minimum estimated rate of 25 μm/hr, but may advance at an estimated 60 μm/hr (depending on exact route of single axons). These rates are conservative estimates, since their calculation assumes that axons begin regrowing immediately after injury, and that the rate is uniform from lesion edge to the midline. After P2, growth rate slows to approximately 10 μm/hr. This shift in growth rate occurs by the time the axons cross the tectal midline.

Regrowing axons typically cross the damaged rSC in two fasciculated bundles: a ventral bundle grows below or through the dead tissue, and a dorsal bundle follows a tissue bridge above a fluid-filled cavity. After crossing the midline, axons appear to defasciculate, forming a 'spray' of extending axons. These recrossing axons are oriented mediolaterally and grow within the superficial gray layer; they are not restricted to the optic fiber layer as in normal animals.

Normal retinotectal axons in embryonic hamsters grow at 80 μm/hr and form dense fascicles, extending to the caudal tectal margin (Jhaveri et al., '83). By P0, they initiate a slower, non-fasciculated growth of collateral and terminal branches. Thus, left tectal tissue in the early lesion cases, which normally supports arborizing axons by P2, may provide some signal to alter growth characteristics. 75.11 DRG NEURITE EXTENSION IN THE ABSENCE OF EXOGENOUS GROWTH FACTORS. E.D. Pollack and V. Liebig*. Inst. Study Develop. Disabil. and Dept. Biol. Sci., Univ. Ill. at Chicago, Chicago, IL 60608

In contrast to the generally held assumption that neurons of dorsal root ganglia do not extend substantial neurites in vitro in the absence of exogenous NGF or appropriate target tissue products, we find that the DRG of frog tadpoles do not have these requirements when grown in defined medium on a polylysine surface. Whole lumbosacral DRG of larval Rana pipiens at stages V, IX, XI and XV were explanted individually onto poly-DL-lysine coated coverglasses in Sykes-Moore chambers with defined medium lacking NGF. Although nearly 100% of the explants exhibited outgrowth, stage V DRGs had relatively short neurites, while those from stage IX were of greater average length. Quite clearly, DRGs from stage XI tadpoles exhibited maximal outgrowth with extraordinarily elaborate neuritic arrays often by 48 hours. Extensive neuritic outgrowth was a characteristic of 100% of the stage XI explants by 4 days in vitro. Even at two weeks in vitro, the growth cones remained highly active, although they tended to be confined within the dense meshwork of neurites in the outgrowth zone. Individual neurites often exhibited regularly spaced collaterals, or anchors, to either the surface or adjacent neurites giving a "step-ladder" appearance. For each stage, there seems to be a limit to the outgrowth zone, beyond which neurites do not extend, but instead turn back toward the explant or wander tortuously within this zone. Slightly older stage XV DRGs had neuritic growth that was decremental to that of stage XI. In contrast to this NGF-independent growth on polylysine, DRGs placed on collagen (type I) fail to extend neurites unless exogenous NGF is provided or the explant is co-cultured with a developmentally appropriate target tissue. As the stage-responsive DRGs on polylysine are long-lived in the absence of NGF, we suggest that an appropriate substratum can subserve the function of NGF in vitro. It is possible that the extended neurites in these cultures are from an NGF-independent neuron population, while NGF-dependent neurites are not observed. However, we then would have expected to see neurites extended on collagen as well. Similarly, if the explant itself were the source of NGF then outgrowth should occur on collagen also. This finding points to the need for increased attention to the relative roles for growth factors and attachment surfaces in understanding nerve fiber growth phenomena in vitro.

75.12 **DOPAMINE AND NICOTINE INHIBIT GROWTH CONE ACTIVITY AND NEURITE OUTGROWTH IN TWO DIFFERENT MORPHOLOGICAL CLASSES OF CHICK RETINA NEURONS.** **K.L. Lankford, M.I. Fonseca* & W.L. Klein Dept. Neurobiology & Physiology, Northwestern University, Evanston, IL 60201**

Increasing evidence suggests that, in addition to their role in synaptic communication, neurotransmitters may also play a role in the morphological differentiation of neurons (Barnes 1986, Science 234: 1324-1326). In a previous report, we described a dopamine stimulated inhibition of growth cone activity and neurite outgrowth in approximately 25% of cultured embryonic chick retina neurons (Lankford et al 1987 Neurosci. Lett. 75: 169-174). In this report we further characterize the morphological response to dopamine and describe a population of neurons in the retina that responds in a similar manner to cholinergic agonists. Neurons were cultured on glass coverslips, inserted into a Dvorak-Stotler chamber and monitored before, during and after exposure to dopamine (1uM), carbachol (1mM), or nicotine (100 uM) with continuous VEC-DIC microscopy. Morphological characteristics of the neurons and changes in neurite length, filopodial length, and filopodial movement were assessed from photographs of recorded images. Dopamine sensitive neurons were characteristically monopolar or bipolar, with narrow growth cones and short, thin filopodia. A great variability was observed in the magnitudes of the dopamine responses in different cells. Neurite lengths were reduced 7-85%, and total filopodial lengths were reduced 14-70% within 10 minutes after dopamine addition. Nicotine and carbachol sensitive neurons were multipolar and had larger cell bodies, longer neurites, more well defined growth cones, and more robust filopodia than dopamine sensitive neurons. Sensitive neurons responded to nicotine or carbachol with a strong inhibition of filopodial activity, and in some cases, a retraction of filopodia or neurites. Cell morphologies and the detection of a cholinergic response in neurites extending from explants suggest that cholinergic agonist sensitive neurons may be ganglion cells. Preliminary results indicate that nicotine responsive cells are not inhibited by dopamine, and dopamine responsive cells are not inhibited by nicotine. The data presented here suggest that both dopamine and nicotine inhibit neurite outgrowth in different populations of embryonic chick retina neurons.

75.13 AN ULTRASTRUCTURAL STUDY OF AXONAL DIFFERENTIATION IN HIPPOCAMPAL NEURONS IN CULTURE. J.S. Deitch and G.A. Banker (SPON: F.A. Haun). Department of Anatomy, Albany Medical College, Albany, NY 12208

Hippocampal neurons elaborate two morphologically and molecularly distinct classes of processes, axons and dendrites, which arise by a stereotypical sequence of developmental events (Dotti and Banker, Soc. Neuro., this volume). Initially the neurons extend several short processes that are morphologically indistinguishable from each other. Several hours later one of these processes undergoes a rapid increase in growth rate. This process becomes the axon; the remaining short processes subsequently become dendrites. We have examined the ultrastructural changes that occur during the course of these events.

Hippocampal neurons, dissociated from 18-day-old fetal rat brains, were plated onto polylysine-treated Aclar coverslips. After 1-2 days in vitro, shortly after axons first appear, the cultures were fixed in a glutaraldehyde-osmium tetroxide solution and embedded in Maraglas. Individual neurons were selected and photographed by phase-contrast microscopy to identify the axon and presumptive dendrites. The cells were then sectioned parallel to the substrate, so that all of their processes could be examined in a few sections.

In mature hippocampal neurons in culture, ribosomes are restricted to the soma and dendrites. After 1-2 days in vitro polyribosomes were present throughout the somatic cytoplasm and in the short presumptive dendrites, their density decreasing with distance from the soma. Polyribosomes were found along the axon as well, but were present at a much lower density, and found mostly in small clusters near the axonal periphery. The growth cones of the two types of processes also differed in two important respects. For one, the body of axonal growth cones contained an extensive reticulum of elongated membranous elements; this was a minor component of the dendritic growth cones. Furthermore, a number of axonal growth cones contained large, organized bundles of microtubules; often these looped back toward the cell body. Single scattered microtubules were more common in the growth cones of presumptive dendrites.

The greater amount of membrane and distinctive microtubule organization in the axonal growth cone may well be associated with the more rapid growth rate of the axon. The presence of small clusters of polyribosomes in the axon may represent a dilution of ribosome content, without replenishment, during the conversion of one of the short, ribosome-rich processes to the axon.

(This research was supported by NIH grant NS17112.)

75.14 THE DEVELOPMENT OF POLARITY BY HIPPOCAMPAL NEURONS IN CULTURE. C. G. Dotti* and G. A. Banker. Department of Anatomy, Albany Medical College, Albany, NY 12208

During the first week in culture hippocampal neurons establish distinct axonal and dendritic processes that differ in shape, in molecular constituents, and in synaptic polarity. By sequential photography and time-lapse video recording of individual cells, we traced the sequence of morphological changes by which this polarization is established.

Hippocampal cells were obtained from the brains of 18 d fetal rats and plated onto polylysine coated coverslips. The cells first established several short processes, about 15um in length, which were tipped with growth cones. These processes were initially indistinguishable from one another in appearance or behavior, but after several hours one of them began to grow much more rapidly than the others. It became the axon. Significant elongation of the remaining processes began a few days later; they became the cell's dendrites. In a few instances two processes exhibited the rapid growth characteristic of axons, but only one maintained this growth; the other retracted and subsequently became a dendrite.

These results suggest that, when neuronal processes first arise, each may be equally capable of forming either an axon or a dendrite. To test this possibility, we cut the axons of young hippocampal neurons during the first day after the axon developed (n=122). Over 80% of the cells survived for at least a day following surgery. In about 30% of these cases, the original axon regenerated. In the remainder, one of the other processes, which if undisturbed would have become a dendrite, instead became the axon. Frequently the stub of the original axon persisted following the transection; if so, it subsequently became one of the cell's dendrites. In some cases cells were maintained for an additional 5 days and the respecification of the cell's processes was confirmed by differential distribution of Microtubule-Associated Protein 2.

These results show that the processes of hippocampal neurons are not rigidly determined when they first develop, but have the capacity to form either axons or dendrites. The acquisition of axonal characteristics by one neuronal process apparently prevents the others from becoming axons; they subsequently become dendrites.

(Supported by NIH Grant NS17112; C.D. was supported by a Fogarty International Fellowship.)

75.15 **THREE-DIMENSIONAL GROWTH AND DIFFERENTIATION OF SINGLE HIPPOCAMPAL NEURONS IN HYDRATED COLLAGEN LATTICES.** P.W. Coates. Dept. Cell Biol. & Anat., Texas Tech Univ. Sch. Med. Lubbock, TX 79430.

When neurons from cerebral hemispheres, hypothalamus or spinal cord are cultured on three-dimensional substrates that simulate extracellular matrix and consist of hydrated native collagen lattices (3-D HCL), they quickly express - as single cells - features that characterize neurons including morphologically identifiable axons and dendrites that grow into the matrix (Coates, Dev.Br.Res.25:11,1986; SN Abs.12:1504,1986; SN Abs.11:762,1985). To determine whether individual neurons from the hippocampus could also regenerate distinct neuronal features when cultured in such systems, dissociated cells from late gestation fetal rat hippocampi were cultured at low cell density using three different 3-D HCL preparative methods: 1) a "sandwich" in which neurons were plated on a polymerized matrix and covered with another layer of matrix; 2) incorporation of neurons into the matrix before polymerization and 3) plating neurons on a polymerized matrix alone. Within hours, single hippocampal neurons grew axons and dendrites that coursed three-dimensionally within all matrices. However, it was technically difficult to satisfactorily observe, photograph and measure axons and dendrites in the first two methods. Therefore, quantitative and qualitative analysis was performed on single hippocampal neurons grown using the third method. Microscopy revealed many well-differentiated long and short axon neurons. Axons typically grew straight and originated from the soma or a basal dendrite; some were branched and/or displayed varicosities. Growth cones were prominent. Apical and basal dendrites exhibited first order branching. An image analysis system coupled to an inverted phase contrast microscope and microcomputer was used to measure indices of growth and differentiation of single hippocampal neurons. Within 3 days after plating, mean axon length was over 500 um/neuron, mean length of dendrites/neuron was about 200 um and the average total length of all processes combined was 700 um/neuron. Other indices also increased during the test period. These data show that when cultured in 3-D HCL systems, single hippocampal neurons grow rapidly and are capable of expressing an inherent plan for characteristic neuronal morphology that does not require physical contact with other neurons, glia or other non-neuronal cells. (Support from The Salk Institute-Texas Research Foundation and NIH NS20802.)

75.16 CLUSTERS OF DENSE-CORE VESICLES BEHAVE AS AUTONOMOUS BODIES WITHIN THE GROWTH CONES OF APLYSIA NEURONS IN VITRO. M. Chen, D.W. Burmeister, C.H. Bailey and D.J. Goldberg. Ctr. for Neurobiology and Behavior and Depts. of Pharmacology, Anatomy & Cell Biology, and Psychiatry, Columbia U. Coll. of P. & S. and N.Y.S. Psychiat. Inst., N.Y., NY 10032.

Growth cones of the Aplysia neurons B1 and B2, grown in culture and viewed with video enhanced contrast - differential interference contrast microscopy, display a previously undescribed structure. This large, irregular, refractile body (LIRB) is an insular structure that seemingly floats in the cytoplasm of the central, vesicle rich region of the growth cone and is distinct from both lysosomes and lipid droplets. Video observations revealed that LIRBs were present within minutes of the first formation of growth cones from freshly plated neurons and were seen in growth cones of neurons in culture for as long as 6 days. The formation of most LIRBs occured through the agglomeration of smaller refractile structures at the periphery of the growth cone into larger LIRBs, with both vesicles and mitochondria apparently fusing with them. The LIRBs in turn tended to coalesce with both other LIRBs and with a broader band of similar appearing material frequently seen at the proximal end of the growth cone. As the proximal region of the growth cone matured, there was a tendency for the newly forming neurite to "squeeze" the LIRBs and associated materials forward so that individual LIRBs advanced with the growth cone.

Complete electron microscopic reconstructions from serial thin sections of individual identified growth cones demonstrated a one-to-one correspondence of the LIRBs with dense accumulations of membranous organelles. The LIRBs contained predominately dense-core vesicles similar to synaptic vesicles previously identified in these cells, interspersed with mitochondria and occasional profiles of smooth ER. There was no delimiting membrane to the structure, but it was characterized by the absence of the mesh-work of cytoplasmic ground substance seen in the other regions of the growth cone. The same LIRB characteristics were seen within small LIRBs on the periphery of the growth cone and the large mass of LIRB-like material in the central proximal regions of the growth cone. The appearence of this material changed, however, in the region where the growth cone becomes neurite. Here aligned cytoskeletal elements appeared to break up the material, and the intravesiclar distance in the remaining clumps was reduced.

Although the function and significance of the LIRB is as yet unclear, its persistence over time argues that it is not simply a reaction to axotomy, and its ability to segregate many membranous organelles could be important in the overall membrane economy of the growing axon tip.

75.17 **Patterning the Location of Dissociated Cerebellar Cells on Artificial Substrates** D. Kleinfeld* & P.E. Hockberger (SPON: B. Friedman) Dept. of Molec. Biophys., AT&T Bell Laboratories, Murray Hill, NJ 07974.

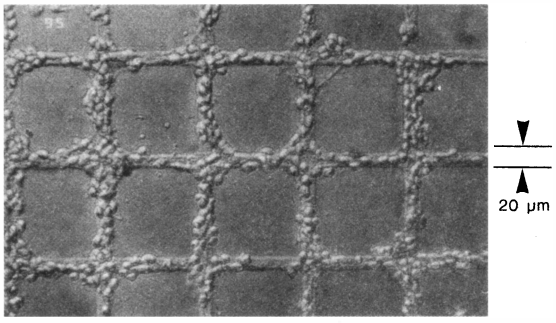
We present a method for patterning the location of cells cultured on two-dimensional substrates. The method uses a combination of surface chemistry and photolithographic techniques. The adhesive properties of either silicon or silicon dioxide (quartz) surfaces were controlled by covalently linking small organic molecules to the surface with silane coupling agents. Patterns of selected adhesivity were formed using standard photochemical resist materials and lithographic masking techniques.

Dissociated cerebellar cells from perinatal rats were cultured on chemically patterned substrates. Surfaces linked with ethylenediamine, via a propyl spacer group, were used to form regions that promoted cell adhesion. The attachment of cells was inhibited by linking alkane chains, such as tetradecane, to the surface and plating the cells in media containing 5 % to 10 % (v/v) serum.

The gross morphology, immunoreactivity (GFAP and NSE) and electrical activity of cells cultured on patterned substrates was similar to that of cells cultured on conventional substrates, *i.e.*, poly-*D*-lysine coated glass. Neurons and their processes could be confined to grow on lines with a width smaller than 10 μm. This width is comparable with the diameter of the smallest cells in the cerebellum, *i.e.*, granule neurons. The patterned growth of the neurons was maintained up to 10 days *in vitro*. This time is consistent with the development of electrical excitability of the neurons in these cultures.

The results of this work suggest that surface modification techniques may be useful for controlling and studying the guidance of neural processes. These techniques may also be useful for studying the formation of synapses in ordered neural structures.

P. E. H. was supported in part by AFOSR grant no. F49620-85-C-0009.



75.18 MODULATION OF NEURITIC EXTENSION OF IDENTIFIED LEECH NEURONS. J.W. MCRORIE III*, B. ZIPSER, DEPT. PHYSIOLOGY, MICHIGAN STATE UNIVERSITY, EAST LANSING, MI 48824

We are studying molecular events underlying the regeneration of individual, identified leech (Hirudo) neurons in dissociated culture. Our probes are monoclonal antibodies to surface and intracellular antigens of leech neurons. Characterizing the neuritic growth patterns of identified neurons in isolated culture, we have made the following observations.

The distance over which neurites extend on the substrate Con A is a characteristic feature for a given class of neurons. A modulatory neuron, the Retzius cell, and a presumptive modulatory neuron, the AP cell, project neurites over a mean distance of 190 microns. In contrast, sensory neurons, the N and P cells, project neurites over a mean distance of 60 microns. Thus, in tissue culture, modulatory neurons project over a 3 fold greater distance than sensory neurons. The short neurites of sensory neurons in culture are an unexpected finding since, in vivo, sensory neurons regenerate vigorously. Comparing the axoneuritic projections of modulatory and sensory neurons in the CNS and periphery suggests that sensory neurons and modulatory neurons are differentially affected by substrate clues. The Retzius and AP cells project neurites three dimensionally throughout the neuropile while N and P cells project predominently into a 2 dimensional plane. Neuritic extension in our culture system may be affected by interactions between the plant lectin Con A and surface glycoconjugates. Specific surface glycoconjugates are increasingly being identified in vertebrate and invertebrate sensory neurons. Thus, individual types of neurons appear to have their own distinct regeneration patterns utilizing substrate clues for neuritic extension.

We observed dramatic differences between AP neurons that were explanted with axonal stumps versus those explanted just as cell bodies in terms of a) primary origin of neuritic projections, b) varicosites resembling typical synaptic endings and c) molecular characteristics as probed with monoclonal antibodies. Thus, the anatomical and molecular characteristics of a neuron can change depending on whether it regenerates from a residual axonal stump or an isolated cell body.

76.1 MATURATIONAL CHANGES IN FETAL LAMB EEG. Y. Zhu*, S. Clare* G. Dwyer* and H.H. Szeto*. (SPON: M. Okamoto). Dept. of Pharmacology, Cornell University Medical College, New York, NY 10021

We have followed the maturation of the EEG of 10 fetal lambs thoughout the third trimester. A minimum of 3 hours recording was obtained from each fetus 1-2 times/week. Continuous EEG analysis was accomplished using a microcomputer-based system that permitted a sampling rate of 1/30 seconds. Power spectral analysis revealed two fundamental waveform patterns in all fetuses. They differed primarily in percent power distribution (% Dist.) and amplitude of selected Hz bands. Major maturational changes in the two patterns are summarized below:

Pattern I

Gastational	% Dist.			Amplitude		
age(days)	1-4Hz	8-13Hz	15-30Hz	1-4Hz	8-13Hz	15-30Hz
120	45	20	20	376	161	165
120-130	50	17	18	887	284	319
130	53	15	17	1286	350	408

Pattern II

Gastational	% Dist.			Amplitude		
age(days)	1-4Hz	8-13Hz	15-30Hz	1-4Hz	8-13Hz	15-30Hz
120	31	24	29	214	159	197
120-130	32	21	29	394	254	346
130	29	19	36	410	271	506

In addition, the frequency and the duration of the fundamental harmonic cycling of these 2 EEG patterns changed with maturation.

76.2 EEG SLEEP CHANGES IN AN ANIMAL MODEL OF DEPRESSION. D. M. Gartrell* and J. M. Weiss (SPON: P.G. Simson). Duke Univ. Sch. of Med., and Dept. of Psychiatry, Duke Univ. Med. Ctr., Durham, NC 27710.

Rats exposed to uncontrollable shock (UCS) have been shown to exhibit both behavioral depression and behavior consistent with anxiety. Studies using behavioral observation have found that these rats have an increase in waking during the light cycle without a compensatory increase in sleep during the dark cycle (Weiss, Simson, Ambrose, Webster, and Hoffman, in: Advances in Behavioral Medicine, vol 1 [Katkin and Manuck, eds.], 1985, 233-275). The study reported used EEG recordings to examine sleep changes produced in rats by UCS.

Seven pairs of Sprague Dawley rats were implanted with skull electrodes for recording hippocampal and cortical EEG, and cervical muscle electrodes for recording EMG. Beginning two days after surgery, one animal of each pair (the experimental rat) was exposed to 3 hours of UCS on two consecutive days. The second animal in each pair was placed in the shock apparatus but no shock was given. Shock sessions occurred just prior to the onset of the 12 hour light cycle. Recordings during the light cycle were made for 6 days. The first recording day corresponded to the first day of UCS. Recordings were visually scored in 30 second epochs as either waking, REM sleep, non-REM sleep, or non-REM sleep interrupted by waking.

Following UCS, experimental rats showed more waking, more interrupted non-REM sleep, longer REM sleep latencies, less REM sleep, and a lower REM sleep percent than control animals. In general, effects were largest immediately following the UCS, and then dissipated across the 6 days of recording. Statistically significant differences were as follows: experimental rats showed more waking on the first ($p<.05$) and third ($p<.001$) days, showed more interrupted non-REM sleep on the third day ($p<.05$), showed longer REM sleep latencies on the first ($p<.005$) and second ($p<.005$) days, showed less REM sleep on the first through fourth days ($p<.005$ on each day), and showed a lower REM sleep percent on the first through fourth days ($p<.01$ on each day). There were no statistically significant differences between the experimental and control animals on the fifth and sixth recording days.

Evidence indicates that locus coeruleus (LC) neurons are hyperactive in rats exposed to UCS. In that REM sleep is not seen when the LC is active, the decrease in REM sleep seen in this study may be a result of this alteration in LC activity. Stimulation of the LC in a human subject was found to produce sleep changes similar to those seen in this study (Kaitin, Bliwise, Gleason, Nino-Murcia, Dement, & Libet, Biol. Psychiat., 21, 1986, 710).

The sleep changes in this study resemble those in humans with anxiety disorders. Thus, there may be an anxious component to the depressive condition produced by uncontrollable shock.

76.3 MACROPHAGE PROCESSING OF BACTERIA; CNS-ACTIVE SUBSTANCES ARE PRODUCED. L. Johannsen*, J. Wecke*[1], J. M. Krueger, Dept. Physiology and Biophysics, University of Tennessee, Memphis, TN 38163 U.S.A., and [1]Robert Koch-Institut of the Federal Health Office, Berlin (West), F.R.G.

Several muramyl peptides (MPs), including a slow wave sleep (SWS)-promoting substance extracted from brain, increase SWS in mammals. MPs are well known constituents of bacterial cell wall peptidoglycan. However, there are no synthetic pathways known in mammals for MPs. This led to the proposal that MPs might be vitamin-like. We report here that macrophages, when fed bacteria, process the bacterial cell walls, release MPs, and the resulting macrophage supernatants have biological activity.

Bone marrow-derived murine macrophages were fed viable *Staphylococcus aureus* that were ^{14}C-marked in their cell wall (*Arch. Microbiol.* 121: 103, 1979). Supernatants of the macrophages were collected after 3, 12, 48, and 96 h of digestion, pooled, and freeze-dried. The supernatant was processed by gel filtration. Fractions containing ^{14}C in the molecular weight ranges between 5,000 D and the salt volume were pooled and dried. After suspension in artificial CSF, the samples were heated to 60°C for 30 min to eliminate biological activity of lymphokines. Fifty ul were injected into a lateral ventricle of male rabbits, and EEG, brain temperature, and movement were recorded for 6 h during daytime. Rectal temperatures were taken immediately before and after the experiment.

The infusion of the macrophage supernatant resulted in enhanced SWS and body temperature and decreased REM sleep (Table). The time course of these effects (not shown) was similar to those observed after MP administration, *i.e.*, an hour delay before long-lasting (6-10 h) effects are observed. This time course is different from that elicited by prostaglandins or lymphokines.

Table	Control	Experiment
% SWS	51 ± 2	72 ± 5
% REMS	4.5 ± 0.6	0.9 ± 0.2
% AWAKE	45 ± 2	28 ± 5
Temp. Diff. (6h-0h)	0.0 ± 0.1	1.8 ± 0.1

(all means ± std. err., n = 8)

Present results provide a possible mechanism for our recent findings that infection of rabbits with *S. aureus* also enhances SWS. The processing of bacterial cells walls into low molecular weight products by macrophages is a daily occurrence, as well as an early event in the initiation and amplification of the immune response. That the resulting products enhance SWS suggests a role for MPs in sleep regulation and an early involvement of the CNS in the immune response. Supported by ONR N00014-85-K-0773 and DFG JO 149/1-1.

76.4 GROWTH HORMONE-RELEASING FACTOR INCREASES BOTH NON-REM SLEEP AND REM SLEEP IN RABBITS. F. Obal, Jr.*, L. Johannsen*, A. B. Cady*, and J. M. Krueger (SPON: L. Share), Department of Physiology and Biophysics, University of Tennessee, Memphis TN 38163.

The well known association between non-REM sleep (NREMS) following sleep onset and growth hormone (GH) release may indicate that (i) NREMS promotes GH secretion or (ii) the regulation of GH release and sleep onset involve common mechanisms. In support of the latter assumption, recent findings suggest that intracerebroventricular (icv) administration of the GH-releasing factor, GRF, may induce sedation and increase EEG slow wave activity and both NREMS and REMS in the rat (*Neuroendocrinology* 42: 467, 1986; *Clin. Neuropharmacol.* 9(S4): 459, 1986; *Neuropharmacology* 26: 75, 1987). The aim of the present experiments was to study the sleep effects of GRF. Rabbits were implanted with EEG electrodes, brain thermistors, and a guide cannula for icv injections. Sleep-wake activity was recorded for 6 h following icv infusions of either GRF (Human GRF1-40) or artificial CSF (20 ul) as control during the light cycle.

DOSE		POSTINJECTION HOUR 1			TOTAL RECORDING TIME		
nmol/kg	N	Wakefulness	NREMS	REMS	Wakefulness	NREMS	REMS
0.01	7	-13.7 ± 4.4*	+15.5 ± 3.7*	-1.8 ± 0.9	-5.3 ± 2.5*	+4.6 ± 2.4	+0.6 ± 0.5
0.1	8	-21.4 ± 4.7*	+19.9 ± 1.6*	+1.5 ± 1.0	-9.3 ± 2.1*	+5.5 ± 1.6*	+3.8 ± 1.1*
1.0	6	-29.5 ± 6.2*	+24.2 ± 6.0*	+5.3 ± 2.7	-17.8 ± 3.6*	+12.0 ± 3.5*	+5.8 ± 0.8*

*Wilcoxon test, two-tailed

Icv infusions of GRF elicited a dose-dependent suppression of wakefulness and increases in both NREMS and REMS. The effect on NREMS was most pronounced in postinjection hour 1. The 6-h recording time showed significant increases in REMS in response to both 0.1 and 1.0 nmol/kg GRF. Brain temperature was not affected by GRF.

The results clearly show that exogenous GRF has a definite NREMS-inducing effect. The increases in REMS might be secondary, possibly due to GH secretion (*Neuroendocrinology* 18: 1, 1975; *Horm. Behav.* 6: 189, 1975; *Biol. Psychiat.* 15: 613, 1980). We conclude that GRF is a putative endogenous sleep-promoting substance. (Supported by NIH NS-25378.)

76.5 EFFECTS OF STAPHYLOCOCCUS AUREUS INFECTION ON SLOW WAVE SLEEP IN RABBITS. L. Toth* and J. M. Krueger (SPON: T.W. Gardiner), Animal Resource Division and Department of Physiology and Biophysics, University of Tennessee, Memphis, TN 38163.

Increased body temperature and altered immune system activity are well known features of infectious disease. Several compounds associated with infectious processes, including muramyl peptides and interleukin 1, are pyrogens and immunomodulators. Another action of these agents is the potentiation of slow wave sleep (SWS) (Fed. Proc. 45:2552, 1986). Subjective reports of increased "sleepiness" often accompany states of illness; however, the effects of infectious disease on sleep have not been evaluated systematically. To examine the effects of an infectious disease on sleep, EEG was monitored in 14 adult male New Zealand white rabbits during a 24-hr control period and for 48 hr following intravenous inoculation with 10^7 to 10^8 colony-forming units of Staph. aureus. Despite variability in the time course and the magnitude of responses, every animal tested showed enhanced SWS following inoculation. The time spent in SWS increased by about 50% during a 6-16 hr period post-inoculation (PI) and then returned to control levels. The enhancement of SWS was associated with increases in both the amplitude of EEG slow waves (from 6-8 hrs PI) and the duration of individual bouts of sleep (6-16 hrs PI). After 18 hrs PI, both the amplitude of EEG slow waves and SWS bout duration dropped below control levels, eventually returning to baseline by 48 hrs PI. The inoculation also produced several changes that typically are associated with infectious disease. Rectal temperatures increased by 1-2°C within 6 hrs PI and remained elevated for 48 hrs. The febrile effects of the inoculation could thus be dissociated temporally from the somnogenic effects. Hematologic analysis revealed a severe lymphopenia in all animals and a marked neutrophilia in most animals tested. The lymphopenia generally persisted for 48 hrs PI. The neutrophil response was more variable in terms of both magnitude and duration. Those animals that failed to develop a strong neutrophil response tended to show a shorter duration of enhanced SWS and a more severe clinical progression than did animals with marked neutrophilia. Postmortem blood cultures were positive in 10 of the 14 animals tested.

These data thus demonstrate that inoculation of rabbits with Staph. aureus results not only in the febrile and hematologic manifestations of infectious disease, but also in a pronounced increase in SWS. The time courses of these effects differed substantially, suggesting that they result from separate mechanisms. We speculate that changes in SWS represent an adaptive response to infectious disease. Supported by ONR-N00014-85-K-0773 and NIH-NS25378.

76.6 **PROTEIN SYNTHESIS IN THE RAT BRAIN IS LINKED TO SLOW WAVE SLEEP BUT NOT TO REM.** P. Ramm & C. T. Smith*. Dept. of Psychology, Brock University, St. Catharines, Ont. and Dept. of Psychology, Trent University, Peterborough, Ont. Canada.

The restorative hypothesis of sleep function proposes that SWS and/or REM sleep are linked to restoration of cerebral proteins. We have used [14C]leucine autoradiography (Smith, C. et al., J. Neurosci. 4:2489-2496, 1984) to test the restorative hypothesis.

Twenty-seven rats received recording electrodes, and cannulae in the femoral artery and vein. Four days after surgery, the freely-moving animals were REM-deprived for 24-72 hr. They were then returned to their home cages, where they received intravenous injections of L-[1-14C]leucine. During the next 45 min, EEG and EMG recordings were made and arterial blood samples were taken for the measurement of plasma levels of [14C]leucine and of free leucine. The animals slept quite normally during the leucine incubation period, and many showed elevated levels of REM.

Following the incubation period, the brains were extracted, cut, and autoradiographs were prepared. Rates of regional cerebral protein synthesis were calculated by computer densitometry.

Correlations were obtained between regional rates of protein synthesis, and the proportion of injected L-[1-14C]leucine cleared from plasma during wakefulness, SWS and REM. Effectively, the correlations show the relation between the rate of protein synthesis, and the amount of time spent in wakefulness, SWS or REM.

Correlations Between Cerebral Protein Synthesis and State

Wake	SWS	REM	Total Sleep
-.14	.54*	-.31	.15

* ($p < 0.01$, two-tailed)

Higher rates of (global) cerebral protein synthesis are associated with higher SWS times. We did not observe a link between REM and cerebral protein synthesis. This global pattern was replicated regionally. Most brain regions exhibited moderate positive correlations (up to .68 in the iterpeduncular nucleus) with SWS, and non-significant negative correlations with REM. These data suggest a restorative function linked specifically to SWS. They also converge with previous metabolic findings (Ramm, P. & Frost, B.J., Brain Res 365:112-124, 1986) to suggest that fundamental life processes in cerebral tissues are differentially linked to SWS and REM. (Supported by the Natural Sciences and Engineering Research Council of Canada).

76.7 **UNIT ACTIVITY DURING CATAPLEXY: FIRST RECORDINGS OF SINGLE NEURON ACTIVITY IN THE NARCOLEPTIC ANIMAL.** J. M. Siegel, R. Nienhuis, R. Paul, H. Fahringer, T. Kilduff, and W. C. Dement. Neurobiol. Res., VAMC Sepulveda, CA 91343, Dept. of Psychiatry, UCLA School of Medicine, Los Angeles CA 90024, Stanford University School of Medicine, Stanford, CA.

The narcoleptic dog provides an opportunity to investigate, at the neuronal level, the pathology producing cataplexy, a sudden loss of muscle tone occurring in both canine and human narcoleptics. Cataplexy has been thought to be an manifestation of a hyper-excitable REM sleep atonia mechanism activated during waking states. Studies in the cat indicate that the medial medulla forms the final common pathway for generating the atonia of REM sleep. Receptor binding studies have demonstrated abnormalities in the medial reticular formation of the narcoleptic dog. Accordingly, we have begun to record unit activity in the medial medulla of these animals in both normal REM sleep and cataplexy.

Five narcoleptic doberman/labrador dogs between 3 months and 6 years of age served as subjects. Cataplectic attacks were elicited by play, by providing novel food or by injecting physostigmine. The unit recording technique was similar to that used in previous studies of medullary unit activity in the unrestrained cat (Brain Res. 179:49-60, 1979).

Units were recorded in the rostral nucleus gigantocellularis and magnocellularis of the medulla. As in the normal cat, most medullary units in the narcoleptic dog had high discharge rates in REM sleep. However, despite their high discharge rates during REM sleep with its associated muscle atonia, most cells decreased discharge rate during cataplectic attacks. 94% of the cells encountered (n=61) decreased or ceased discharge during cataplexy. REM sleep discharge in these cells tended to be phasic, with burst discharge especially during periods of rapid eye movement, and short pauses at other times. A second cell type comprising less than 6% of the cells encountered (n=4), had increased or maximal discharge during cataplexy and discharged at high rates during REM sleep. In contrast to the first group, discharge in the second group tended to be continuous in REM sleep.

We hypothesize that most medial medullary cells are not contributing to the atonia of REM sleep and cataplexy. REM sleep discharge in these cells is related to the motor activation of this state. We further hypothesize that the cells in our second group, which are active in relation to cataplexy, form the final common brainstem pathway generating atonia in REM sleep. Increased excitability of these cells in narcoleptics, leading to waking discharge, is responsible for cataplexy.

76.8 **LOCALIZATION OF NEURONS AND TRANSMITTERS INVOLVED IN THE PONTO-MEDULLARY INHIBITORY SYSTEM.** Y. Y. Lai and J. M. Siegel, Sepulveda VAMC, Sepulveda CA 91343 and Dept of Psychiatry, UCLA School of Medicine, Los Angeles CA, 90024.

Injection of cholinergic agonists into the dorsolateral pontine tegmentum produces a loss of muscle tone, often in conjunction with other signs of REM sleep. A number of studies have indicated that the medial medullary region, which receives projections from the dorsolateral pontine area, forms the final common brainstem pathway for triggering atonia. However, since atonia has been elicited only by electrical stimulation of the medial medulla, it remains possible that this effect is due to activation of fibers of passage and not cell bodies. Moreover, the localization of the neurons involved and the neurotransmitters responsible for activating them is unknown. Chemical stimulation of the medial medulla has not been reported to produce atonia.

To answer these questions we have performed a series of studies in 18 adult decerebrate cats. Tracheostomy, cannulation of both femoral artery and vein, and decerebration were performed under halothane-oxygen anesthesia. Electromyograph activity was recorded from neck and forelimb muscles. The inhibitory areas in pontine and medullary reticular formation (PRF and MMRF) were identified by electrical stimulation. Once the inhibitory area was located, the stimulating electrode was removed and 0.5 µl of each pharmacological agent was injected through a 26-gauge Hamilton 1µl microsyringe. Chemicals were dissolved in Ringer solution in the concentration of 0.2M of L-glutamate (Glut), 0.2M of L-glutamic acid diethyl ester (GDEE), 2 µg/µl of r-D-glutamylglycine (DGG), 200 µg/µl of acetylcholine (Ach), 8 µg/µl of carbachol (Carb), and 2 µg/µl of atropine.

Microinjection of Glut into PRF (5/5) and rMMRF (14/17) but not the caudal MMRF (cMMRF; 1/11) inhibitory areas produced bilateral inhibition of the muscle tone. This muscle atonia induced by Glut injection could be blocked or attenuated by GDEE in PRF and GDEE and DGG in rMMRF. However, Ach injection in PRF (4/4) and cMMRF (11/13) but not the rMMRF (1/11) was found to produce bilateral muscle atonia. Atropine blocked this Ach effect. Carb injection in all three areas produces a long period of muscle atonia with a short latency (≤3 min) in PRF and cMMRF and a long latency (≥20 min) in rMMRF, suggesting that the effect of rMMRF injection resulted from Carb diffusion to either PRF or cMMRF. We conclude that at least three neurochemically distinct regions in the brainstem can trigger muscle atonia: 1) A dorsolateral pontine region sensitive to Ach and glutamate. 2) A rostral medullary region sensitive to glutamate but insensitive to Ach. 3) A caudal medullary region sensitive to Ach, but insensitive to glutamate.

76.9 CARBACHOL EXCITATION OF MPRF NEURONS IN VITRO: A POSSIBLE MODEL FOR MECHANISMS OF DESYNCHRONIZED SLEEP GENERATION. R.W. Greene and R.W. McCarley. Neuroscience Lab., Dept. of Psychiatry, Harvard Med. Sch./Brockton VAMC, Brockton, MA 02401

A behavioral state characterized by all of the phenomena of desynchronized sleep is elicited by localized injections of ugm amounts of cholinergic agonists in the medial pontine reticular formation (mPRF). However, the mechanisms by which ACh agonists produce these effects have remained unclear since the in vivo iontophoretic applications of ACh and extracellular recordings previously used have intrinsic limitations. They can not: (1) determine if effects are pre- or post-synaptic; (2) assure the application of physiological concentrations; (3) determine effects on resistance; or (4) determine the duration of effects. We thus turned to intracellular recordings in the in vitro mPRF slice preparation.

Coronal slices, 500uM thick, from young rats (7-11 days old) were cut with an ultrasonically vibrating blade and then totally submerged in a modified Haas chamber. Standard intracellular recording techniques were used with glass pipettes containing 2M KCl; neurons had stable membrane potentials more negative than -58mV and > 5mV action potential overshoot. Bath-applied carbachol (0.25-1.0um) produced a depolarization of 16 ± 6mV S.D. amplitude in 6 of the 7 mPRF neurons tested with an increase of input resistance observed in 5 neurons (mean increase 21 ± 18% S.D.). One neuron had a transient hyperpolarization preceeding the depolarization.

Of particular interest as a mechanism for desynchronized sleep effects was the long time course of the carbachol action. The time from onset of carbachol-induced depolarization to peak effect was 2-4 minutes, and recovery time following removal of carbachol ranged from 7 to 26 minutes, despite our set-up's having a complete exchange of perfusion media every 30 seconds. That this long-duration depolarization was not dependent on synaptic activity was demonstrated by its presence with tetrodotoxin added to the perfusion medium. In 4 of 4 neurons tested atropine (0.25 - 1uM) blocked these carbachol effects, suggesting the involvement of muscarinic receptors. The cholinergic excitatory effects, depolarization and increased membrane resistance, and their time course are consistant with a neurotransmitter role for ACh in generation of naturally-occuring desynchronized sleep episodes.

76.10 BRAINSTEM MECHANISMS OF ALERTING. W.A. Ball*, A.R. Morrison, R.J. Ross, D.R. Levitt, P.J. Gresch*, and G.L. Mann*. Sleep Res. Lab., Vet. Sch., Univ. of Pa., Phila., Pa. 19104-6045.

Ponto-geniculo-occipital waves (PGO) are spontaneous, macropotential waves typical of lateral geniculate (LGN) recordings in paradoxical sleep (PS) of cats. We earlier showed that PGO can also be elicited by repeated tones in both slow wave sleep (SWS) and PS. PS was characterized by a lack of habituation to the tones; SWS was not (Morrison,A.R. and Bowker,R.M., Acta Neurobiol. Exp.,35: 821-840,1975). This indicated that PS is a state of "hyperalertness" defined in part by an absence of habituation of the elicited waves. We report here a more rigorous, quantitative analysis of this phenomenon that has suggested a degree of habituation of elicited PGO in PS but at a rate slower than in SWS.

Four cats had standard electroencephalogram (EEG), LGN, electrooculogram (EOG), and electromyogram (EMG) electrodes implanted. After 12 days, they were presented tones (1000 Hz, 90 msec, square wave at 90 db) in SWS and PS. A session consisted of up to 32 tones (interstimulus interval= 5 sec) in a sleep state with polygraph and FM tape recording of PGO. Cats were tested twice a day on 2 consecutive days in one sleep state, then 2 additional days in the other. Sham trials consisted of stimulus time marks without tones.

Within 200 msec after the stimulus, tones were more likely than sham stimuli to elicit PGO in both sleep states ($p<.01$). Overall, tones in PS elicited PGO more readily than tones in SWS ($p<.01$). A rapid decrease in the probability of eliciting a PGO wave in SWS accounted for the difference: by trial 8 the proportion of trials with waves at least 40% as large as the first elicited wave had fallen from .68 to .22. The pattern in PS differed markedly: the probability remained constant at about .5 across 16 trials, then showed a decline to .29 by the end. On all but the first 4 trials, the probability of eliciting a PGO was greater in PS.

The data replicate our earlier results that overall, PGO are elicited more frequently in PS than SWS. Close analysis of the pattern across trials reveals that the probability of eliciting PGO in PS did decline, albeit much more slowly than in SWS. The frequency of spontaneous PGO did not decline, however, across the experimental session during either tone or sham trials. This suggests the possibility of true,if slow, habituation in PS rather than a decrease in the underlying responsiveness of the PGO system (e.g., during a change of state to SWS or PS).

This work was supported by grants NS 13110 and MH 14654.

76.11 ACTION SITES FOR SLEEP AND EEG EFFECTS OF MORPHINE IN CATS. J. de Andrés and I. Corpas*. Depto. Morfología. F. Medicina. UAM. Madrid 28029. Spain.

Sleep deprivation and some types of EEG/behavioral dissociation are basic phenomena observed across species after morphine and other opiates administration. These features are easily noticeable in the cat, since under low single doses of morphine sulfate (MS), this animal presents a dose dependent suppression of both Non-Rem and Rem sleep, and during the insomnia period it exhibits a peculiar wakefulness associated with a high voltage-slow frequency burst pattern in the concomitant EEG (De Andres et al. Pharmacol. Biochem. and Behav. 21:923-928. 1984). To learn about the CNS sites (prosencephalon vs. brain stem) involved in the above mentioned MS actions, we have used cats with a mesencephalic transection to study: a) the MS effects on the EEG of the isolated forebrain, and b) the MS effects on Rem sleep of the decerebrate cat .

Under general anaesthesia (Nembutal 35 mg/Kg.) intercollicular transections were performed in 11 adult cats. Electrodes were implanted in motorsensory and visual cortices to record EEG of the isolated forebrains. Also, to characterize Rem sleep of the decerebrate cats, two electrodes were stereotaxically placed in the pons (PGO activity), as well as, the standard ones to record EOG and EMG. Experiments elapsed one week from surgery . Single doses of MS (.5, 2.0 and 3.0 mg/kg, via i.p.) were administered 7 days apart. EEG of the isolated forebrains and polygraphic records of the decerebrate cats were taken during the next 24-72 hrs after MS. Pearson's correlation coeficient was used to compare MS dose with the onset latency of Rem sleep in the decerebrate cats. Two-way ANOVAs were used to compare the amount of synchronized and desynchronized activity in the forebrains as well as the amount of Rem in the decerebrate cats.

In the cases that a complete transection was achieved with little damage of the mesencephalon (transections at prepontine level in 7 cats), all MS doses were followed by a long lasting continous desynchronized EEG, full mydriasis was associated with the EEG desynchronization. These effects were independent of the behavior exhibited by the descerebrate cats . Naloxone blocked the EEG and pupil effects of MS, since at least for one hour after the antagonist, the isolated forebrain EEG was fully synchronized with myotic pupils. Decerebrate cats presented a dose dependent decrease in the amount of Rem during the first 24 hrs, reaching to an initial suppression that -depending on the MS dose- could last a few hours. However, these effects were moderate in comparison with the Rem suppressión seen previously with the same doses in intacts cats. Likewise, decerebrate cats did not manifest a strong behavioral activation which resembled the behavioral wakefulness exhibited by intacts cats under MS. Moreover, present results showed that Rem suppression in decerebrate cats had always a shorter duration that the MS effects seen in the isolated forebrains.

In summary, our results indicate that: 1) Prosencephalic mechanisms are seemingly not involved in the generation of the electroencephalographic slow burst activity produced by morphine . 2) Rem sleep suppression is only partially originated in the lower brain stem, suggesting that the prosencephalon and/or mesencephalon generate/s a strong Rem sleep inhibition under morphine, and 3) Behavioral wakefulness under the drug might essentially depend on prosencephalic and/or mesencephalic structures.

76.12 EFFECT OF INSULIN INJECTION ON ELECTROENCEPHALOGRAPHIC (EEG) SLEEP IN THE RAT. M.J. Bakalian* and J.D. Fernstrom (SPON: M.H. Fernstrom). Departments of Psychiatry and Behavioral Neuroscience and the Center for Neuroscience, University of Pittsburgh, Pittsburgh PA 15213.

Brain serotonin (5HT) neurons are involved in sleep regulation. In particular, recent studies suggest that stimulating 5HT receptors suppresses rapid-eye-movement (REM) sleep, while producing minimal effects on non-REM sleep. Insulin injection reportedly suppresses REM sleep (Sangiah et al. Life Sci 31:763,1982). Since insulin injection stimulates brain tryptophan uptake and 5HT synthesis (see Fernstrom J.D., Physiol Rev 63:484,1983), it may suppress REM sleep by indirectly stimulating brain 5HT synthesis and release. However, the insulin dose employed by Sangiah et al. (1 IU/kg) reduced blood sugar levels substantially. Thus, one cannot conclude if insulin suppressed REM sleep via an increase in 5HT release or via a non-specific effect of hypoglycemia. We have begun to examine this issue, to ascertain which mechanism accounts for the reduction in REM sleep.

Male Sprague-Dawley rats (300 g) underwent stereotactic placement of cortical, dorsal hippocampal and nuchal electrodes (Vivaldi et al. EEG clin Neurophysiol 58:253, 1984). Following recovery, they were placed in special recording chambers with an internal, 12:12 light:dark cycle. EEG electrodes were connected to a Grass Model 78 polygraph, which was output both to pen chart recorders and to an Apple II+ microcomputer. The Apple detects and stores waveband data used in the scoring of sleep-waking states. For these studies, rats (n=8-11 at each dose) were fasted 12-hr before insulin (Iletin U-100, Lilly; 0.25, 0.5, or 1.0 IU/kg) or vehicle injection at light onset. EEG recordings were made for 6-hr thereafter.

First, fasting did not alter the normal occurrence of REM and NREM sleep (comparing fasted and non-fasted rats receiving vehicle). And second, insulin injection into fasted rats caused a statistically-significant (ANOVA), dose-related increase in latency to REM sleep (a doubling [low dose] to quadrupling [high dose]) and significant reductions in total REM sleep time (16-75%) and the number of REM episodes (40-60%). A small, statistically-significant reduction in NREM sleep time also occurred at the 1 IU/kg dose, but no effect on any NREM sleep measure was observed at the lower doses. Our results therefore affirm the finding that insulin injection suppresses REM sleep, but contrasts with the earlier data in showing a small NREM sleep suppression, rather than the reported increase. Studies now in progress will ascertain if these effects are altered when glucose is administered with insulin, to prevent insulin-induced hypoglycemia. If they are not, the results will suggest that the effects of insulin on REM sleep may be mediated specifically by an enhancement of 5HT synthesis and release by brain neurons.

Supported by a grant from the NIMH (MH38178).

76.13 FEVER ALTERS CHARACTERISTICS OF SLEEP IN RATS. M.Price*, S.Kent* & E. Satinoff. Dept. of Psychology and Program in Neural and Behavioral Biology, Univ. of Illinois, Champaign, IL 61820

Fever alters both the amount and organization of sleep. We recorded stages of sleep and waking and body temperature (Tb) in 6 male Long-Evans rats (b.w. 350-450 g). Rats were kept on a 12:12 light/dark cycle with an ambient temperature (Ta) of 23 $\pm$ 1^{o}C with food and water always available. The rats were placed in the sleep-recording chamber (Ta 23^{o}C) and left there overnight. At the start of the next day's light cycle, chamber Ta was set to either 20 or 30^{o}C, and 1 hr later the rats were injected subcutaneously with 5 ml saline. Sleep and Tb were then computer-recorded for 24 hr at the given Ta. 24 hr after the saline injection, the rats were injected with 30% brewer's yeast in saline, after which recording was continued for another 30 hr.

At both Ta's, peak febrile responses of 1.5-2.2^{o}C occurred within 8 hr post-injection, after which there was a 0.5-1.0^{o}C decline over 4-5 hr to a level that was maintained for at least a day and a half. Normal circadian Tb rhythmicity was thus temporarily abolished: Tb in the dark after the daytime injection was close to normal nighttime Tb, whereas Tb's in the next light period were elevated relative to normal daytime Tb's and, in fact, were within 0.5^{o}C of normal nighttime high Tb's. The difference between the fever and saline conditions at the time of the circadian trough Tb at Ta 30^{o}C was 0.6^{o}C higher than that at 20^{o}C.

At both Ta's fever increased slow-wave-sleep (SWS) and decreased waking. The largest changes occurred at night: SWS increased from 15-35% compared to daytime increases of 3-5%. The percentage of REM sleep to total sleep time changed in the opposite direction: the ratio decreased 20-50% during the day and increased 50-200% during the night.

These results indicate that febrile Tb is not simply the same as the normal Tb rhythm, only elevated, but rather that it is primarily an elevated Tb during the day. The results further show that SWS and REM sleep are both affected by fever, but the circadian changes in each are different.

76.14 EVIDENCE AGAINST SEROTONIN-MEDIATED SLEEP INDUCTION FOLLOWING ADMINISTRATION OF L-TRYPTOPHAN. D.W. Preussler and M.E. Trulson. Dept. Anat., Coll. Med., Texas A&M Univ., College Station, TX77843.

Self-administration of large doses of the essential amino acid L-tryptophan has become widespread for the induction of sleep. Numerous clinical studies in human as well as animal research support the hypothesis that large doses of L-tryptophan decrease sleep latency. Since a major metabolic route of L-tryptophan in the brain is its conversion to the monoamine neurotransmitter, serotonin (5HT), it has been assumed that L-tryptophan-induced sleep is attributable to 5HT produced by administration of tryptophan. This hypothesis is supported by numerous studies that have implicated the serotonin in the sleep/waking cycle. We directly tested the hypothesis that L-tryptophan induces sleep by producing excess 5HT. Cats received bilateral injections of 5,7-dihydroxytryptamine (5,7-DHT) or saline into the lateral ventricles and were implanted with macroelectrodes for recording the electroencephalogram (EEG), neck electromyogram (EMG), and eye movement potentials (EOG). After recovery from surgery and adaptation to the recording chamber, the animals were given L-tryptophan at a dose of 50 mg/kg by oral administration. The latency to sleep onset was monitored. The results showed that L-tryptophan produced a significant decrease in sleep latency in both 5,7-DHT and control groups. Furthermore, there was no significant difference in the latency to sleep onset between control and experimental groups of animals. At the completion of the study the brains were removed and assayed for 5HT and its major metabolite, 5-hydroxyindolacetic acid (5HIAA) using high pressure liquid chromatography and electrochemical detection. Animals that had received 5,7-DHT exhibited a depletion of 5HT and 5HIAA between 82 and 97%. An additional group of animals received L-tryptophan (50 mg/kg) and were sacrificed for assay 1 hour later. The animals that had received 5,7-DHT showed no significant increase in 5HT or 5HIAA above the levels found in 5,7-DHT animals that received no treatment. On the other hand, the normal animals that had received L-tryptophan showed large increases in brain 5HT and 5HIAA. These data demonstrate that L-tryptophan is effective in reducing sleep latency, but that the effect does not appear to be mediated by 5HT, since L-tryptophan was just as effective in inducing sleep in animals that had destruction of brain 5HT neurons by 5,7-DHT as in control animals. Furthermore, neurochemical data showed that these chemically-treated animals had no increase in brain 5HT or 5HIAA even though sleep latency was decreased by the same magnitude as in the control group. Thus, L-tryptophan appears to induce sleep through some mechanism other than producing an increase in brain 5HT.

76.15 GAMMA-HYDROXYBUTYRATE IN MONKEYS - SEDATIVE OR CONVULSANT? R.K. Nakamura, M. Myslobodsky, R. Coppola, J. Johannesen-Conway*, Y. Salu*, and A.F. Mirsky. National Institute of Mental Health, Bethesda, MD 20892.

The evaluation of drug activity can be more informative if physiological measures are combined with well controlled behavioral observations. Here we report on such a combination used to evaluate gamma-hydroxybutyrate (GHB).

GHB has been reported to produce a state in monkeys resembling petit mal status. This implies that an animal would produce erroneous responses immediately prior to, and discontinue any cognitive effort concurrently with, an episode of GHB-induced generalized 3 cps wave-spike bursts in the EEG. This prediction was not confirmed in the present study. Rhesus macaques (Macaca mulatta) were trained to perform in a go/no-go visual discrimination task. Thereafter bipolar transcortical electrodes were implanted in the hemisphere contralateral to the preferred hand so that the short electrode of the pair penetrated the dura by 0.5 mm; the longer one was located in the depth of the cortex or in the white matter 2 mm away from the cortical surface.

All monkeys were unable to complete the task involving lever-pressing for water-reward when administered GHB (125 or 250 mg/kg, esophageal intubation) and exhibited signs of reduced postural control and somnolence punctuated by episodes of arousal under stimulation. EEG showed local and generalized hypersynchronous activity. While occasional wave-spike bursts did occur, they were poorly regulated often 'focal' (ie. developed only in isolated areas), and had a frequency of 1.5-2.0 cps. At the same time, there were pronounced changes in event-related potentials to visual stimuli with a large increase in the amplitude of the slow components during continued accurate performance. In this state, animals could easily be roused by sensory stimuli. All of them reacted with a characteristic aversive-aggressive display when confronted by a direct gaze.

Overall, these effects are interpreted to be more consistent with GHB as a potent hyponotic rather than convulsant agent.

76.16 INCREASED REM SLEEP IN RATS SELECTIVELY BRED FOR CHOLINERGIC HYPERACTIVITY. J.C.Gillin, P.J. Shiromani, D.Levy,* C.A.Goodrich,* A. Norman & D.Overstreet. Psychiatry, SDVAMC & UCSD, La Jolla, CA 92093, Univ Cincinnati College Med (AN), & School Biol Sci, Flinders Univ South Australia, Bedford Park, South Australia (DO)

Overstreet and colleagues (1) have developed a strain of rats which show a central cholinergic hyperactivity. The Flinders Sensitive Line (FSL) of rats show a greater sensitivity to cholinergic agonists and have increased number of muscarinic receptors in the striatum and hippocampus compared to controls. Given the strong link between cholinergic mechanisms and REM sleep (REMS) (2,3), we hypothesize that the FSL rats should have increased REMS.

14 male rats were used. Eight rats were of the FSL strain while six rats were Flinders Resistant Line (FRL). The latter group was derived by breeding successive generations of rats least sensitive to DFP and it has been established that this group is not different from a randomly bred stock. Two weeks after recovery from surgery (Nembutal), a two day adaptation period was used and then a continuous 48 hr sleep recording was obtained. The sleep records were scored for awake, drowsy, slow wave sleep and REM sleep. The 48 hr sleep records were averaged to yield a 24 hr sleep record. The identity of the rats (i.e FSL or FRL) was revealed after the EEG records were scored and data entered into the computer. 3H-QNB was used as the ligand in the receptor assay.

There were no significant differences between the two groups in total sleep time, waking, drowsy or slow wave sleep. Both groups demonstrated a similar circadian rhythm in REMS. However, the FSL rats had significantly more REMS during the 1500 and 1800 hr time periods ($P<.05$). The increased REMS seen in the FSL rats occurred because they entered into REMS significantly more often from drowsy than from slow wave sleep. This suggests that in the FSL rats the latency to REMS onset is considerably faster compared to the control rats. Preliminary data suggest that the FSL rats have increased number of muscarinic receptors in the brainstem (FSL B max=28.9 picomole/gm, Kd=246.7, n=3; FRL=24.3, 220, n=5).

The alterations in REM sleep are consistent with the amassed evidence that increased central cholinergic activity produces a corresponding selective increase in REM sleep. We suggest that these rats may provide a means to study depression and narcolepsy where a central cholinergic hyperactivity is hypothesized to contribute to the mood, sleep, and REM sleep disturbance.

76.17 Regional Cerebral Metabolic Rates After Sleep Deprivation: Hoang-Ly, J.C. Wu, M.S. Buchsbaum, J.C. Gillin, Psychiatry Dept., Univ. Calif. Irvine, Irvine, CA 92717 (Sponsor: R. Jevning)

Introduction: Sleep deprivation (SD) has been used as an experimental probe to infer what role sleep plays in behavioral and neurochemical activities and functions. Positron emission tomography (PET) scans were done to assess changes in local cerebral glucose utilization after SD.

Methods: Four normal controls (4 males, x = 25.3 + 6 yr) were studied. The subjects were scanned twice. The subjects were in a normal waking state on the first occasion and had slept the night before. The subjects were sleep-deprived for the entire night on the second occasion.

The subjects performed the Continuous Performance Test during the thirty-minute uptake after injection of 4 to 5 mCi of 18-fluorodeoxyglucose for both scans. Nine slice images were obtained on the CTI NeuroEcat IV scanner with an in-plane resolution of 7.6 mm. Glucose metabolic rates for the scan were derived according to the model of Sokoloff.

Results: Metabolic rates for the caudate are presented relative to the whole slice metabolism. Normal controls showed a significant decrease (21%) in relative caudate metabolic rates after sleep deprivation on the left side only using paired t-tests ($p < .05$, 1 tailed).

Patients also showed a decrease in frontal/occipital ratio after sleep deprivation (before SD = 1.10, after SD = 1.04, T = 1.78, DF = 3, $p < .05$, 1 tailed).

(This study was supported in part by NIMH, MH 30914, and by Upjohn Pharmaceutical)

76.18 ROLE OF α-1-ADRENOCEPTORS IN REM SLEEP AND CATAPLEXY. E.J.M. Mignot*, C. Guilleminault, S.S. Bowersox and W.C. Dement. Sleep Disorders Center, Stanford Univ. Sch. of Med., Stanford, CA 94305.

The purpose of this study was to investigate the possible involvement of central alpha-1 adrenergic receptors in the cataplexy manifested by genetically narcoleptic Doberman pinschers. Treatment of narcoleptic dogs with prazosin, a selective alpha-1 adrenergic receptor blocker, was found to exacerbate cataplexy, while treatment with the alpha-1 agonist methoxamine ameliorated the cataplexy. Subsequent studies demonstrated that the beneficial effects of amphetamine in narcolepsy are mediated indirectly through alpha-1 stimulation. The possibility that the observed effects were due to peripheral alpha-1 cardiovascular involvement was excluded. The effects of prazosin in combination with atropine and with methylatropine were also examined. Results described suggest that the cholinergic neurons implicated in cataplexy and REM sleep are directly or indirectly controlled by alpha-1 adrenergic receptors. Binding studies using ^{3}H-prazosin reveal an increase in alpha-1 receptor binding apparently limited to the amygdala. Little is known about the physiological role of central alpha-1 adrenergic receptors; the results reported strongly implicate these receptors in canine narcolepsy, an autosomal recessive disorder of REM sleep.

76.19 GENDER DIFFERENCES IN THE ULTRADIAN CYCYLICITY OF SLEEP. P. F. Bright* and W. Fishbein. (Spon: P. Sajovic) Psychobiology Lab, CUNY, The City College and Graduate School, New York 10031.

Many sex-related variations in nonreproductive behaviors have been described in humans and animals (Beatty, W.W., Horm. Behav., 12, 112, 1979; Halpern, D., Sex Diff. Cog. Abil., Erlbaum, NJ,1986) yet to our knowledge no quantified sex differences in sleep cycle rhythmicity have been reported.

As part of a large multivariate experiment in CF-1 mice designed to study the effects of prenatal stress on various parameters including sleep-wake cycles, we observed highly significant gender differences in the amounts of SWS and REMS displayed. This report centers on the sleep cycle rhythmicity of 6 male and 6 female control subjects. Each subject was born from a mother that had a normal pregnancy, free of the stress treatment imposed on the experimental dams. Within 12 hours postnatally, each subject was randomly cross-fostered to a normal lactating mother and reared with five other litter mates until weaning at 22 days of age. None of the twelve subjects is a sibling or was reared with any other subject. From day 22 to 50 the animals were housed (5-7 per cage), separated by sex, with other control mice which were employed in other aspects of the larger experiment.

On day 61, after surgical implantation of chronic indwelling EEG and EMG electrodes, adaptation to the commutator cables and recording environment, sleep-wakefulness cycles were recorded continuously over a 48 hr. period; throughout the recording session food and water was available ad libitum and as a result the animals were completely undisturbed.

The time spent asleep (or awake) over 24 hrs. was indistinguishable in the two sexes. Males average 9.71 hrs/24 hrs. asleep, females 9.63 hrs. Despite this invariance the distribution of time spent in REMS and SWS was quite different.

Over all 24 hours females spend significantly more time in REMS than males ($F(1,10)=5.90$ $p < .035$) and this differencce was most distinguishable during the day cycle ($F(1,10)=5.36$ $p < .043$). Furthermore the difference is totally accounted for by a greater number of REMS episodes in the females; 2.19/hr, males 1.60/hr ($F(1,10)=14.59$ $p < .003$), whereas the average duration of the REM episodes was precisely the same, 2.35 min vs 2.35 min.

The significantly greater amount of REMS in females measured over 24 hours was not reflected in a reciprocally greater amount of SWS in males ($F(1,10)=1.38$).

Our findings are the first to indicate that the regulation of sleep cycles is sexually dimorphic. The data point to the Y chromosome as a mediator of sleep-cycle control through the sexually dimorphic preoptic and suprachiasmatic nuclei of the basal forebrain by gonadotrophic influences.

76.20 APOMORPHINE-STIMULATED GROWTH HORMONE RELEASE IN HUMAN NARCOLEPSY. T. Baker, R. Hitzemann, J. Hirschowitz*, K. Gujavarty*. Dept. Psychiatry and Behav. Sci., SUNY Stony Brook, NY 11794

Narcolepsy is a lifelong neurological disorder that occurs in humans, dogs, and horses. It is characterized by excessive daytime sleepiness and abnormal tendency for REM sleep or dissociated REM sleep phenomena (cataplexy, hallucinations, sleep paralysis). Neurochemical studies of narcoleptic dogs, including measurement of monoamines and their metabolites in CSF and brain tissue, have indicated abnormal turnover of dopamine (Mefford, I. et al., Science, 220:629, 1983; Faull, K. et al., Brain Res., 242:137,1982).

The apomorphine-stimulated growth hormone test (AGHT) can be used to assess the functional sensitivity of dopamine receptors in vivo. Administration of low doses of the dopamine agonist apomorphine elicits the release of neuroendocrine hormones within 1-2 hours. Growth hormone (GH) is released via stimulation of the hypothalamic postsynaptic D2 receptors. In the present study, we studied D2 receptor sensitivity in narcoleptic humans to test the hypothesis of impaired dopamine turnover in this disorder.

Narcoleptic volunteers (N=25) and normal controls (N=12) were given 10μg/kg apomorphine by i.m. injection at 10 a.m. after an overnight fast. Blood samples were collected via indwelling i.v. catheter at 10 min. intervals during baseline and from 40-90 min. post-injection. GH concentration was determined by radioimmunoassay.

Narcoleptic subjects were divided into two groups; those not using therapeutic medications, and those who were long-term CNS stimulant users, either pemoline (a dopamine agonist) or methylphenidate (more general monoamine agonist properties). Chronic use of CNS stimulant compounds was associated with blunted GH response, as measured by peak GH release or integrated total GH release. Males showed greater peak GH release than females in both medicated (M) and non-medicated (NM) groups: peak GH (ng/ml) NM males (N=6), 32.8 $\pm$ 6.2 vs. M males (N=6), 22.6 $\pm$ 5.9; NM females (N=7), 17.2 $\pm$ 10.2 vs. M females (N=6), 6.8 $\pm$ 4.3. Age was a significant factor influencing apomorphine-stimulated GH release in all groups, with older subjects showing blunted peak and total release. Finally, non-medicated narcoleptic subjects showed a non-significant trend toward elevated GH release, as compared with normal controls (22.6 $\pm$ 11.9 vs. 18.8 $\pm$ 4.5).

These data demonstrate that long-term use of the CNS stimulants pemoline and methylphenidate may cause a blunted GH release on the AGHT. One interpretation of these results is that chronic use of monoamine agonists by narcoleptic subjects leads to down-regulation of hypothalamic D2 receptors. The data suggesting a trend for narcoleptic subjects to have elevated GH release, compared to normal controls, suggests that D_2 receptors may be up-regulated. This finding is consistent with the hypothesis of chronically impaired dopamine release in human narcolepsy syndrome.

76.21 SLEEP STATES IN NEONATES MONITORED AT HOME. E.B. Thoman and M. K. Pugsley*. Biobehavioral Sciences, U. of CT, Storrs, CT 06268.

Using an automated procedure for sleep recording, the sleep of 10 male and 10 female fullterm infants was monitored for 24-hour periods in the home once a week during the first to fifth weeks of life. A pressure sensitive mattress, placed in the infant's crib, was used for recording analog signals from respiration and body movements. The motility signals were recorded on a single channel of a small Oxford 24-hour recorder which was placed under the infant's crib. The system was put in the home one day, then retrieved the following day.

In the laboratory, the recorded signals on the data tapes were demodualted and digitized. They were then computer scored for states using a pattern recognition program which employs a template matching process. For each 30-second epoch, the state was scored as either: Active Sleep (AS), Quiet Sleep (QS), Active-Quiet Transitional Sleep (AQ), Sleep-Wake Transition (TR), or Wakefulness (WA). The states were measured as percent of time spent in the crib during the 24-hour period. Other measures included: the amount of time spent in each of the states, the number of state changes per hour of sleep, the length of Active Sleep bouts, and the length of Quiet Sleep bouts.

Reliability of each state was established by assessing the measures of each state for individual differences over the five weeks. This was accomplished by using a two factor repeated measures analysis of variance for each variable. Individual differences were tested by dividing the Mean Square for Subjects by the Mean Square for Subjects by Weeks.

Significant individual differences were found for AS, QS and AQ. Significant developmental trends over these early weeks were found for the mean length of AS, and QS bouts. The amount of time spent in AQ, TR, and WA, and the number of state changes per hour were found to be remarkably constant over the five weeks. These results were found despite the variations which typically occur in the home week to week.

Validity of state measures obtained by this automated recording procedure was assessed by comparing the data from this study with other studies of infants of the same age, using different observational techniques. First, the mean state distribution over weeks was compared with that from a study in which direct behavioral observations were used (Thoman & Davis, Dev. Psychobiol., in press). A 7-hour daytime period from each study was compared. The time spent in AS, QS, and AQ did not differ. The amounts of time in Wa and TR did differ significantly. Secondly, the 24-hour data were compared with 8-hour nighttime recordings using a time lapse video procedure (Anders & Keener, Sleep, 8:173, 1985). The state distributions were very similar for the two studies. These comparisons establish the validity of the state monitoring and computer scoring procedure.

76.22 PROPORTIONAL JERK: A NEW PARAMETER OF MOTION APPLIED TO OCULAR ACTIVITY IN INFANTS DURING 'SLEEP'. E. Aserinsky. Department of Physiology, Marshall University Schl. of Med., Huntington, WV 25704

The third derivative (jerk) of motion has essentially never been studied in regard to biomedical function. Enthusiasm for its use would be dampened by anticipation that it might simply parallel velocity changes. As a remedy, the concept of jerk has been modified (Aserinsky, E. Psychophysiol., 23:340, 1986) and termed 'proportional jerk' (PJ). PJ is a ratio without units, and is proportional to the change in the rate of acceleration relative to av velocity. The usefulness of PJ is that it can be measured without knowledge of the absolute amplitude or velocity of a mvt, values which in the case of the EOG fluctuate with the corneoretinal potential. Also, PJ can be an index of the 'smoothness' of a mvt, and thus may provide insight into the mechanism of neural control. In the aforementioned paper, the REMs of sleeping adults had an av PJ of 0.101 which was signif. ($p<.05$) higher than the 0.082 found for spontaneous waking saccades under closed lids. This suggested that neural control was not the same for waking and sleeping (dreaming) mvts.

A PJ analysis similar to the one above is presently reported for eight infants, age 12 wks, in order to ascertain whether, as in adults, oculomotor characteristics of so-called REMs are distinguishable from waking saccades. This is of interest because the crucial consideration for designation of a 'REM state' in these young infants is that the lids are shut rather than open while fast eye mvts are present. The typical adult pattern in which the REM state follows non-REM sleep is not seen in these infants. Is it possible that instead of being a REM state the infants are awake with the eyes shut? The EOG potentials from 8 infants were obtained from records of a previous study (Lynch, J.A. & Aserinsky, E., Behav. Brain Research, 20:175 1986) and dichotomized into saccades occurring in the conventionally defined REM state and into saccades appearing with the lids open.The eye mvts were limited to conjugate mvts which showed no vertical vector. All such mvts in one 'REM pd' for each subject were submitted to PJ analysis on an Apple computer, and were compared with all pure horizontal mvts occurring in eyes-open (waking) pds comparable in length to the 'REM pds'. The results revealed that the mean (+S.E.) PJ for all the subjects in the 'REM state' was $0.073 \pm .005$ (101 eye mvts) which was not signif. different from the value of $0.078 \pm .003$ (166 eye mvts) for eye mvts in the waking state. Since small mvts tend to have higher PJ values than large mvts, the data were reanalyzed for mvts restricted to the 9^{o}-12^{o} range; these PJ values were $0.068 \pm .004$ for REMs, and $0.071 \pm .003$ for waking saccades----again an insignificant difference.

PJ appears to be sensitive to differences in motion which are not revealed by velocity or simple third derivative measures. While the latter parameters tend to be higher for mvts with the eyes open versus eyes closed, this is not true for PJ.

76.23 **NEUROPSYCHOLOGICAL AND EVOKED POTENTIAL MEASURES OF COGNITIVE FUNCTION IN SLEEP APNEA.** **V.L. Rothenberger*, J.A. Walsleben*, and N.K. Squires* (SPON: M.A.Nathan). Dept. Psy., State Univ. New York, Stony Brook, 11794.**

Sleep apnea is a syndrome characterized by repeated episodes of cessation of respiration during the night, which may result in severe hypoxia and disrupted sleep. Daytime symptoms of sleepiness and cognitive deficits are common. Treatment with continuous positive nasal air pressure (nCPAP) produces rapid and dramatic relief of the daytime symptoms. This study was undertaken to document the subjective complaints and to determine whether the daytime symptoms are the result of brain dysfunction as a consequence of the repeated hypoxic episodes, or whether they reflect sleepiness produced by repeated disruptions of sleep. Eight subjects with sleep apnea were given a battery of neuropsychological and evoked potential tests. Testing was performed on the evening prior to treatment with nCPAP, on the night following the initiation of treatment, and four months after continued nightly treatment.

Clinical evaluation of sleep parameters performed before the initiation of treatment indicated that sleep was profoundly disturbed prior to treatment. Neuropsychological testing indicated deficits in measures of attention and memory. Recordings of the auditory brainstem evoked responses (ABRs) showed slowed conduction in the auditory pathway, and prolonged latencies of the long-latency components of the auditory evoked response (N2, P3) indicated delays in the speed of cognitive decision processes.

Tests performed after the initiation of nCPAP treatment indicated that the subjects' sleep patterns had returned almost to normal values. Also, the latency of the P3 component normalized. There was no change in neuropsychological performance or in the ABRs. At the four-month follow-up test essentially the same pattern was observed; the ABRs still indicated slowed conduction in the auditory pathway while the long-latency evoked potentials remained in the normal range.

Overall the data confirm that sleep apnea produces pervasive psychological deficits. The ABR results indicate that there may be permanent changes in brain function, perhaps as a result of the repeated hypoxic episodes. Other abnormalities, particularly the excessive sleepiness and the reduced speed of cognitive processes are more transient and may involve disruption of brain metabolism that resolves rapidly after treatment with nCPAP. Also, the data indicate that cognitive evoked potentials are sensitive to brain dysfunction that does not involve structural damage and that these potentials may provide a sensitive index of treatment efficacy.

77.1 COMPARISON OF TETRAHYDROAMINOACRIDINE AND PHYSOSTIGMINE AFTER ACUTE AND CHRONIC ADMINISTRATION IN RATS. K.A. Sherman and E. Messamore*, Dept. of Pharmacology, Southern Illinois University School of Medicine, Springfield, IL 62708.

Tetrahydro-9-aminoacridine (tacrine, THA) reportedly results in marked improvement in patients with Alzheimer-type dementia (Summers et al., NEJM 315:1241, 1986). This contrasts with the relatively circumscribed and variable response to physostigmine (PHYSO) (Sherman et al., In: CNS Disorders of Aging, 1987, in press). THA is a reversible inhibitor of brain and red blood cell acetylcholinesterase (IC_{50}: 1 μM) with only slightly less potency than PHYSO in vitro (IC_{50}: 0.3-0.5 μM). To characterize the pharmacological properties of THA after in vivo administration, we examined the effects on behavior (maintenance of splay posture and inhibition of forward locomotion in an open field) and brain cholinergic mechanisms following acute and chronic s.c. injection of THA. These results were compared with previous findings after PHYSO. Inhibition of forward walk occurred by 1 hr and hindlimb splay posture was affected by 2 hr after acute THA treatment; both effects lasted for more than 4 hr after 15 mg/kg THA·HCl s.c. By contrast, effects of a maximal dose of PHYSO sulphate (0.88 mg/kg, s.c.) occurred within 15 min, but lasted less than 2 hr. During the first two weeks of repeated administration of THA (10 mg/kg, s.c., b.i.d.), tolerance developed to the effects on splay posture and forward locomotion. Increasing the dose of THA to 15 mg/kg partially reinstated the locomotor deficit, but not the effect on splay. Tolerance to the locomotor deficit occurred within 3 d of continued treatment with the higher dose. Acute administration of THA (10 mg/kg, s.c.) resulted in inhibition of in vitro high affinity choline uptake (HACU) in P_2 fractions from hippocampus (-31 ± 4% of control) and cortex (-20 ± 4%), but did not affect striatal HACU. After 48-54 d of THA administration, the effects on HACU were less in hippocampus (-19 ± 3%) and cortex (-12 ± 3%); striatal HACU was unaffected. The inhibition of hippocampal HACU after acute PHYSO (0.88 mg/kg) was greater (-44 ± 5%) and this effect was not altered with repeated administration (-45 ± 5%). Although the inhibition of acetylcholinesterase (52-58%) was comparable in the various brain regions, acute PHYSO resulted in elevation of HACU in cortex (+20 ± 11%), whereas repeated administration resulted in reduced cortical HACU (-20 ± 11%) (acute vs. chronic PHYSO: $p<.05$). Neither acute nor chronic PHYSO affected striatal HACU. Thus, THA has a longer duration of action and produces less presynaptic compensatory inhibition after acute treatment; tolerance to THA is more profound behaviorally and neurochemically. These differences in pharmacological characteristics may contribute to a different spectrum of clinical activity. (Supported in part by SIU-CRC.)

77.2 DIFFERENTIAL EFFECTS OF THREE CHOLINESTERASE INHIBITORS ON BRAIN ACETYLCHOLINE. M. Hallak* and E. Giacobini (SPON: M. Downen). Department of Pharmacology, Southern Illinois University School of Medicine, P.O. Box 3926, Springfield, IL 62708 USA

The effect of three drugs producing inhibition of cholinesterase (ChE), physostigmine (PHY), metrifonate (MTF) and tetrahydroaminoacridine (THA) on the activity of ChE and on levels of acetylcholine (ACh) and choline (Ch) on the brain of the rat were compared. Both single-dose and multiple-dose regimens were studied. Following a first i.m. dose of the inhibitor (PHY, .3 mg/kg; MTF, 80 mg/kg and THA, 20 mg/kg) ACh levels increased 70%, 45% and 70%, respectively. A second and subsequent administration of PHY and MTF produced the same increase in ACh. On the contrary, THA failed to raise ACh levels inspite of persisting 40% ChE inhibition. Toxic symptoms were more severe with THA. In addition, THA (1 mM) inhibited K^+-stimulated ACh release from striatal slices. ^{3}H-Ch pools were also lower following THA treatment. Cholineacetyltransferase activity was not inhibited by any of the three inhibitors at a wide range of concentrations. The results of this study reveal some major differences among the effects of these substances in brain and between the effect of single and repeated administrations of the drugs on CNS levels of ACh. These findings have potential clinical implications for the symptomatic therapy of Alzheimer patients, suggesting new strategies and modes of administration of ChE inhibitors in order to achieve optimal effects at minimal-toxic levels. (Supported by National Institute of Aging #AG05416-01A1)

77.3 ACETYLCHOLINESTERASE INHIBITION: A FUTURE THERAPY FOR ALZHEIMER DISEASE? E. Giacobini, M. Hallak* and R. Becker. Departments of Pharmacology and Psychiatry, Southern Illinois University School of Medicine, P.O. Box 3926, Springfield, IL 62708 USA

A decline in memory and cognitive function during physiological aging and in senile dementia of Alzheimer type have been related to a decline in cholinergic function. One approach to improve cholinergic activity in brain is to increase acetylcholine (ACh) levels by inhibiting the enzyme acetylcholinesterase (AChE). We compared the effects of various types of cholinesterase (ChE) inhibitors [physostigmine (Phy), metrifonate (MTF) and tetrahydroaminoacridine (THA)] on experimental animals and humans (Hallak, M. and Giacobini, E., Neuropharmacology, 26:5, 1987). The effect of various routes of administration of ChE inhibitors on plasma and brain ChE activity, as well as on ACh levels in brain was studied (Hallak, M. and Giacobini, E., Neurochem. Res., 11:1037-1048, 1986; Mattio, T. et al., Neuropharmacology, 25:1167-1177, 1986). We studied the relationship between ChE inhibition in plasma, red blood cells (RBC) and brain. A linear correlation was found between the percent of ChE activity in brain and the percent of ChE activity in plasma or RBC following i.m. administration of Phy. With MTF i.m. after 60 min, brain, plasma and RBC ChE are also inhibited in the same proportion with a linear relation between ChE activity in plasma vs. ChE in brain. Thus, in the rat, the general pattern of ChE inhibition in plasma is similar to that in brain. If this relation is true for humans as well, plasma ChE activity could be utilized as an index of Phy and MTF effects in the CNS. In addition, based on our results in the rat, it seems possible to correlate directly Phy concentration in plasma with the ChE inhibition in brain. These conclusions have clinical implications suggesting new strategies and modes of administration of ChE inhibitors in order to achieve maximal therapeutical effects at nontoxic levels (Giacobini, E. and Hallak, M., In: Senile Dementias: Early Detection, pp. 337-341, 1986). (Supported by National Institute of Aging #AG05416-01A1)

77.4 PROGRESS IN THE SEARCH FOR PROTECTANTS AGAINST SOMAN TOXICITY G.H. Sterling, P.H. Doukas*, K.J. O'Neill* and J.J. O'Neill
Depts. of Pharmacology, Hahnemann University and Temple University Schools of Medicine, Philadelphia, PA 19102

Soman is an organophosphonate cholinesterase inhibitor. It is, therefore, generally assumed that the acute toxicity following exposure is the result of excessive accumulation of acetylcholine (ACh). Standard therapy with atropine, artificial respiration and oxime is ineffective due to the rapid "aging" of soman-inactivated cholinesterase rendering the enzyme insensitive to reactivation. In this study, compounds known to affect presynaptic disposition of ACh were evaluated as potential enhancers of the standard treatment regimen. Studies in our lab with rats demonstrated in vivo protection afforded by compounds exhibiting in vitro activity as inhibitors of high affinity choline uptake (HAChU) and choline acetyltransferase, (ChAT). N-allyl-3-quinuclidinol (NAQ), a potent inhibitor of HAChU developed in this lab and N-hydroxyethyl-naphthylvinylpyridine (NHENVP), a quaternary ChAT inhibitor, significantly reduced the mortality following an LD-90 dose of soman in the presence of atropine and 2-PAM. We have recently begun to evaluate in vitro inhibitors of ACh synthesis and release for protective efficacy in a guinea pig model. Animals were given Soman (S.C.) followed one minute later by atropine (16 mg/kg, I.M.). Compounds to be evaluated were administered I.M. at 2 min to 2 hrs prior to the soman. Atropine alone, significantly increased the LD-50 of soman from 28 ug/kg to 46 ug/kg. NAQ enhanced the protective effect of atropine; when given at 100 umol/kg, I.M., the compound reduced the overall percent mortality of soman (50 ug/kg) from an LD-80 (in the presence of atropine alone) to an LD-10. NAQ was most effective when administered 30-60 min prior to soman. NHENVP (3-10 umol/kg, I.M.) also enhanced the protective effect of atropine, reducing overall mortality to an LD-20. In contrast to NAQ, NHENVP was most effective when administered 2-30 min prior to soman. At doses of soman producing an LD-80 at 1 hr post-soman, in the presence of atropine, both NAQ and NHENVP prevented deaths at that time point.

The results confirm our previous findings in rats. It is suggested that compounds that disrupt presynaptic ACh synthesis in vitro may prove effective in treating organophosphate poisoning. The data provide insight for the design of protectants against soman toxicity. Further studies are underway to determine if the protective effects of these compounds correlate with their ability to reduce ACh levels in vivo. (This work was funded by USAMRDC - DAMD17-86-C-6243).

77.5 RELEASE OF CHOLINESTERASE FROM RAT CAUDATE NUCLEUS. P. DeSarno*, E. Giacobini and M. Downen (SPON: J. Couch). Department of Pharmacology, Southern Illinois University School of Medicine, P.O. Box 3926, Springfield, IL 62708 USA

It has been suggested that cholinesterase (ChE) may be released from neuronal tissue following high K^+ (Greenfield, S. et al., Nature, 284:355-357, 1980; Greenfield, S. et al., J. Comp. Neurol., 214:87-92, 1983) or drug stimulation (Bareggi, S.R. and Giacobini, E., Neurosci. Res., 3:335-339, 1978; Scarsella, G. et al., J. Neurosci. Res., 4:19-24, 1979; Greenfield, S. and Shaw, S.G., Neurosci., 7:2883-2893, 1982). We have studied the release of ChE from CNS using rat caudate slices following: a) electrical stimulation (5, 10, 100 Hz, 10 min); or b) high K^+ (50 mM, 10 min; 105 mM, 60 min) by means of continuous superfusion or tissue incubation. ChE release was monitored, following equilibration (15-75 min) in oxygenated Krebs solution, for a period of up to 120 min. ChE molecular forms were also analyzed in the perfusate and in the caudate. Acetylcholine release was also measured under these conditions. In non-stimulated controls, spontaneous release of ChE was measured starting 15 min after dissection. This release showed a continuous decrease in time up to 3 hrs. Cholinesterase activity increased significantly following 5 Hz electrical stimulation and 105 mM K^+ stimulation. K^+ (105 mM) evoked ChE release was more long-lasting than electrically evoked release (5 Hz). Our results demonstrate that electrical stimulation (5 Hz) but not 50 mM K^+ stimulation increase the spontaneous release of ChE from caudate slices. In addition, prolonged depolarization with 105 mM potassium which produces a complete but reversible depletion of acetylcholine from synaptic vesicles (Gennaro, J.F. et al., J. Physiol., 280:237-247, 1978) also increased the spontaneous release of ChE. In conclusion, these results suggest that ChE can be released from the CNS following neuronal depolarization and that this release is different from acetylcholine release. The demonstration of a normal release of ChE might help us to interpret changes in CSF ChE activity under normal and pathological conditions in humans (Giacobini, E., Neurobiol. of Aging, 7:392-396, 1986). (Supported by National Institute of Aging #AG05416-01A1).

77.6 INCREASED CHOLINE ACETYLTRANSFERASE ACTIVITY IN A HUMAN CHOLINERGIC NEUROBLASTOMA CELL LINE IS CONTROLLED BY POST-TRANSLATIONAL MECHANISMS. D. Casper and P. Davies*. Departments of Neuroscience and Pathology, Albert Einstein College of Medicine, The Bronx, New York, 10461.

Human neuroblastoma clone MC-IXC, originally isolated by Dr. J. Biedler at the Memorial Sloan-Kettering Cancer Center, Rye, New York, was used to investigate the mechanism of regulation of the enzyme choline acetyltransferase (ChAT). We have previously shown that retinoic acid, sodium butyrate, and high cell density all increase the specific activity of ChAT several fold from its basal levels in these cells. This increase can be expressed with respect to either protein content or cell number, as they are directly related under inducing or control conditions.

We now report that inhibitors of either messenger RNA or protein synthesis, namely α-amanitin, emetine and cycloheximide do not block the induction of ChAT activity by either retinoic acid or sodium butyrate. Cycloheximide concentrations of 1 μg/ml for 24 or 48 hours effectively block both protein synthesis and cell division, as demonstrated by rate of uptake of labelled precursors and incorporation into the appropriate macromolecules. The agent also appears to increase the half-life of the enzyme, as specific activity increases upon incubation with cycloheximide in the absence of other inducing agents. Using cycloheximide, no decrease in specific activity is measurable over 48 hours, suggesting a low rate of turnover of this enzyme, consistent with its low abundance in all cell types which contain it. Cycloheximide also potentiates the activation of ChAT by 0.5mM sodium butyrate, suggesting decreased synthesis of an inhibitor, perhaps with protease activity. Similarly, naphthylvinyl pyridinium derivatives, which specifically inhibit ChAT activity, have been used in a similar fashion in culture to demonstrate the lack of measureable new ChAT synthesis for up to 48 hours.

Kinetics experiments provide further evidence for a binary process of activation or stabilization of ChAT molecules. Lineweaver Burke analysis for retinoic acid-activated ChAT demonstrates an increase in the Vmax of ChAT of approximately 2.2 fold with respect to both acetyl CoA and choline that can account for the concommitant increase of the same magnitude in ChAT activity without changes in the Km for either substrate.

Combined with the data obtained using mRNA and protein synthesis inhibitors, it appears that ChAT activity in this system is regulated by either the activation of existing ChAT molecules or by the stabilization of those previously active.

77.7 N-TERMINAL SEQUENCE OF CHICK BRAIN CHOLINE ACETYLTRANSFERASE. J.L. Dahl, D.B. Bloom*, M.L. Epstein†, and C.D. Johnson‡. Depts. of Pharmacology, Anatomy†, and Zoology‡, University of Wisconsin, Madison, WI 53706.

Choline acetyltransferase was purified to apparent homogeneity from chick brain and optic lobes and the amino terminal amino acid sequence determined for 13 cycles by automated amino acid sequencing procedures. The purification procedure involved polyethylene glycol precipitation, followed by chromatography on CM-Sephadex and a monoclonal antibody affinity column. Purification could also be accomplished by these chromatographic steps after the enzyme was partially purified by acid and $(NH_4)_2SO_4$ precipitation. When subjected to SDS-polyacrylamide gel electrophoresis, the purified enzyme ran as a single band with an apparent molecular weight of 68,000 daltons. In preparation for amino acid sequence determination, immunoaffinity-purified ChAT was concentrated in a Centricon microconcentrator whose membrane had been washed with 25% acetic acid and then with water. After an initial concentration step, the protein was washed with three successive 500 µl portions of 0.1 M NH_4HCO_3, after which the NH_4HCO_3 was removed by lyophilization. The amino-terminal sequence of the protein was determined with an average repetitive yield of 91%. Sequence analysis was performed on an Applied Biosystems 470A Protein Sequencer using no vacuum programs and methanolic HCl conversion. Resulting phenylthiohydantoin derivatives of amino acids were identified and quantitated by high performance liquid chromatography on an IBM Instruments LC/9533 using an IBM C-18 column. The first 13 residues are: pro-asp-leu-glu-lys-asp-met-gln-lys-lys-glu-lys-asp.

77.8 EXPRESSION OF THE DROSOPHILA CHOLINE ACETYLTRANSFERASE GENE IN ESCHERICHIA COLI. H. Sugihara*, V. Andrisani* and P.M. Salvaterra (SPON: J.K. Ono). Division of Neurosciences, Beckman Research Institute/City of Hope, Duarte, CA 91010.

The character of a neuron can be defined by the specific neurotransmitter which it uses to stimulate its target cells. Choline acetyltransferase is the specific enzyme for synthesis of the neurotransmitter acetylcholine. To investigate gene regulation of the cholinergic neurotransmitter phenotype, we have isolated a cDNA clone for this enzyme (Itoh, et al., Proc. Natl. Acad. Sci. USA 83:4081-4085).

RNA analysis of Drosophila head poly $(A)^+$ RNA using the cDNA insert as a probe showed the choline acetyltransferase mRNA to be $\approx$4.7K nucleotides long. The isolated cDNA consists of a coding region that is 2190 nucleotides long, followed by a 3'-noncoding region 284 nucleotides in length. This cDNA clone is thus not full length. To isolate longer Drosophila choline acetyltransferase clones, we have screened several Drosophila head cDNA libraries using this cDNA insert as a probe. We have identified several positive clones with inserts up to 3.3 Kbases and are currently characterizing them in detail.

The coding region of our original cDNA clone spans 728 amino acids which is longer than that required for synthesis of the Mr 67K protein that is estimated for purified Drosophila choline acetyltransferase. Using this insert we constructed plasmids which express choline acetyltransferase activity in E. Coli host JM105 by subcloning into the expression vector pkk223-2 (Pharmacia). This plasmid contains a trp-lac promoter, and one construct we have isolated expresses choline acetyltransferase activity after addition of isopropyl-β-D-thiogalactoside (IPTG). The coding region of our cDNA clone thus has enough information to produce active enzyme.

77.9 EFFECT OF DIISOPROPYL PHOSPHOROFLUORIDATE (DFP) ON CA3 AND CA1 RESPONSES IN RAT HIPPOCAMPUS. D. Lapadula*, L.S. Jones, M. Abou-Donia, and D.V. Lewis. Depts. of Pharmacology and Pediatrics, Duke Univ. Med. Ctr., Durham, NC 27710.

Previous work by others has shown that DFP does not have a marked effect on hippocampal CA1 neurons (Williamson and Sarvey, Neurosci. Abs. 10:167.12). As an extension of our own studies on the role of [Ca2+]i in mediating the neurotoxic effects of DFP, we have examined the effects of DFP on the CA3 and CA1 subfields of rat hippocampus and found that it is a potent epileptogenic agent for CA3 neurons.

625 μ slices from adult, male Sprague-Dawley rats were prepared in the normal fashion. A monopolar stimulating electrode was placed in s. radiatum between the two recording electrodes, which were placed in s. pyramidale of CA1 and CA3 so that the effects of DFP could be monitored in both regions simultaneously. The slices were continuously perfused with artificial cerebrospinal fluid (ACSF); DFP was tested at various concentrations (1-500 μM) by adding it hyperosmotically to the ACSF bathing the slice.

Results showed that while 1 μM DFP had little or no effect on the responses from either region, 10 μM DFP produced spontaneous bursting in CA3 and CA1 within 10 minutes of being washed onto the slice. The bursts were frequent, complex, and apparently irreversible with washing. 5 μM atropine delayed, but did not reliably block the appearance of these bursts, and neither 5 nor 10 μM atropine could reverse the bursting, although the frequency did decrease with time. The effects on CA1 were less marked, in that the bursts were smaller than those in CA3 and appeared to be slightly delayed. The latter observation may indicate that the epileptic activity in CA1 is a downstream reflection of the activity in CA3, rather than of intrinsic hyperexcitability in CA1. At high concentrations of DFP (above 25 μM), the DFP suppressed triggered responses in both regions, though spontaneous bursting of CA3 continued.

The greater epileptogenic effect of DFP on CA3 than CA1 is in agreement with studies using convulsant drugs such as penicillin or bicuculline, and further emphasizes the dissimilarities between CA3 and CA1. Additional studies on the effects of DFP on CA3 neurons may provide information on the mechanisms of epileptogenesis generally, and the convulsant properties of organophosphates specifically.

77.10 **ACTIONS OF PYRIDOSTIGMINE AND CARBACHOL ON DORSOLATERAL SEPTAL NEURONS STUDIED INTRACELLULARLY FROM RAT SEPTUM *IN VITRO*.** Linda A. Wong*, Hiroshi Hasuo* and Joel P. Gallagher (SPON: O.S.Steinsland). Department of Pharmacology and Toxicology, University of Texas Medical Branch, Galveston, Texas 77550.

Previous anatomical and *in vivo* studies have suggested that dorsolateral septal neurons are cholinoceptive. However, little is known about the direct membrane actions of cholinergic agents on these neurons. Our current findings with pyridostigmine, a reversible cholinesterase inhibitor, and carbachol, a mixed cholinergic agonist, indicate that both pyridostigmine and carbachol activate nicotinic receptors, directly, to alter membrane properties and synaptic responses of dorsolateral septal neurons. Conventional intracellular techniques were used when recording from dorsolateral septal neurons in a rat septal slice preparation. Drugs were applied by superfusion. Carbachol (1 to 100 μM) caused a concentration dependent membrane hyperpolarization of dorsolateral septal neurons which was associated with a decrease in membrane input resistance and suppression of spontaneous firing activity. Atropine (2 μM) decreased but did not block the response to carbachol. Mecamylamine (20 μM), however, completely blocked the effect of carbachol, indicating that nicotinic receptors might be involved. Superfusion of pyridostigmine (1 μM) also produced effects similar to carbachol, i.e., membrane hyperpolarization accompanied by a decrease in membrane input resistance and suppression of spontaneous firing. In both cases, spontaneous activity returned with enhanced firing and bursts of action potentials after the wash out of drugs. When the superfusion solution was altered by changing to a low calcium/high magnesium composition, the hyperpolarizing effect of pyridostigmine persisted. Mecamylamine (10 μM), but not atropine (10 μM), was able to block the hyperpolarizing action of the drug. These results suggest that pyridostigmine was acting directly on a postsynaptic nicotinic receptor. In addition, pyridostigmine affected the synaptic response evoked by focal stimulation of the dorsolateral septum. In particular, the late hyperpolarizing potential was depressed.

Our findings indicate that: (1) cholinoceptive neurons are present in the dorsolateral septal nucleus; (2) cholinergic effects of carbachol and pyridostigmine are mediated through nicotinic receptors; and (3) synaptic transmission at dorsolateral septal neurons is affected by cholinergic agents. (Supported by DAMD-17-86-C-6032).

77.11 EFFECTS OF CARBACHOL ON PYRAMIDAL NEURONS IN THE IN VITRO HIPPOCAMPAL SLICE. L.S. Leung and C.Y. Yim. Depts. of Clinical Neurological Sciences and Physiology, Univ. of Western Ontario, London, Canada. N6A 5A5

Effects of perfusion of carbachol (CCH) at 10^{-3} to 10^{-5} M on pyramidal neurons in the in vitro rat hippocampal slices were examined in a series of 40 experiments. Stable intracellular recordings (characterized by resting membrane potential of > 60 mV with overshooting action potentials) were made from more than 30 pyramidal neurons in the CA1 and CA3 layers. In all neurons recorded, CCH perfusion produced 5-10 mV membrane depolarization which was in 80% of the neurons accompanied by a clear increase in membrane resistance. Excitatory postsynaptic potentials (EPSPs) following stimulation of the stratum oriens or stratum radiatum were attenuated by CCH. The attenuation was not entirely due to membrane depolarization since restoring the membrane potential to the control value by passing hyperpolarizing currents failed to fully restore the attenuated EPSP. Inhibitory postsynaptic potentials (IPSPs) following stratum radiatum or stratum oriens stimulation were were similarly attenuated by CCH. It was observed, however, that restoration of the somatic membrane potential to the normal resting potential by current injection consistently resulted in a partial reversal of the IPSP compared to the control. Modeling of the pyramidal cells as contiguous cable compartments indicates that IPSP reversal does not result from conductance changes only at the soma when the somatic membrane potential is restored. Other possibilities, including a shift in the IPSP equilibrium potential by CCH, are being considered. Extracellular field potential recordings indicated that both the population EPSP and population spike were attenuated while the threshold and latency of the evoked population spike were increased by CCH. These results suggest that CCH may produce selective depolarization of the soma, and that presynaptic inhibition of both excitatory and inhibitory afferents seems probable.

77.12 ELECTROGRAPHIC CHANGES FOLLOWING LESIONS OF RODENT NUCLEUS BASALIS. P.G. RAY* and W.J. Jackson. Department of Physiology and Endocrinology, Medical College of Georgia, Augusta, GA 30912.

Changes in central cholinergic activity have been closely related to changes in the EEG. We are currently investigating EEG frequency changes which follow damage to the major source of cortical cholinergic innervation in the rat, the nucleus basalis magnocellularis.

Male Sprague-Dawley rats were infused bilaterally with 4ug ibotenic acid in .8ul phosphate-buffered saline. Screw electrodes were implanted in the skull over frontal, parietal and visual cortices. Sham-operated animals served as controls. Following a 14-day recovery period, each animal was familiarized with the recording chamber during five daily sessions. During the final recording session, the animal was allowed to sleep and was aroused by the presentation of an auditory stimulus lasting 8 seconds. All EEG data during the session were recorded by polygraph and stored on magnetic tape. The animals were sacrificed and choline acetyltransferase (ChAT) activity was determined in each cortical region.

The EEG data were analyzed by determining the spectral power from 1-31 Hz at 1 Hz increments using a Fast Fourier Transform routine. Three 4s epochs of EEG representing the sleep period immediately prior to arousal and two 4s epochs during stimulus presentation were analyzed. 1-12 Hz activity was expressed as a percent of the total power (1-31 Hz) in each epoch and averaged to determine a final value of percent slow wave activity (%SWA) present during sleep or arousal.

In the frontal region of lesioned animals, the level of ChAT activity ranged from 0-45% below that of controls. A significant negative relationship was shown to exist between the level of ChAT activity and the %SWA present during sleep ($r = -.5489$, $p < .005$) and during the aroused state ($r = -.5074$, $p < .05$). This finding is in accord with the suggested role of acetylcholine in influencing EEG background rhythms. However, this ChAT activity-EEG frequency relationship was apparent only in the frontal cortex. In the parietal area, where comparable ChAT declines were seen, no similar correlations were found. Also with regard to frontal EEG activity, the lesioned animals, as a group, showed a greater response to the stimulus, as indicated by a larger decline in SWA on arousal than that shown by controls (Mann-Whitney U Test, $p < .05$). There was a similar tendency seen in the parietal EEG but the difference there did not reach statistical significance. This enhanced response to the stimulus may be related to attentional disturbances, as a result of changes in the cortical signal-to-noise ratio (Warburton, D.M. From: Inhibition and Learning, Boakes, R.A. and Halliday, M.S. (eds.), 431-460, 1972). ChAT activity levels declined no more than 25% in the visual cortex; no correlative relationships were seen.

77.13 CHARACTERIZATION OF LATERAL DORSAL TEGMENTAL NEURONS, IN VIVO, BY ANTIDROMIC AND ORTHODROMIC ACTIVATION. S.J. Grant, Dept. Psychology, Univ. of Delaware, Newark, DE 19716, G.R. Christoph, Neuroscience Section, E.I. Dupont de Nemours and Co., Inc., Wilmington, DE 19898, A.Y. Deutch, Depts. of Pharmacology and Psychiatry, Yale University School of Medicine, New Haven, CT 06510.

The lateral dorsal tegmental nucleus (LDT) lies rostral and medial to the locus coeruleus (LC) in the pontine tegmentum. Anatomical studies have shown that the LDT consists of cholinergic and peptidergic neurons which project primarily to limbic structures. Although the anatomy of the LDT is now well characterized, the present studies provide the first description of LDT neuronal activity.

Extracellular single unit activity was recorded from chloral hydrate anesthetized rats. After localizing the LC in vivo, recordings were made in a region extending up to 0.6 mm medial and 1.5 mm rostral to the LC. This region represents the boundaries of the Ch6 cholinergic cell group in the LDT. Recording sites were histologically verified by depositing a small amount of dye from the tip of the recording pipette at the end of each successful penetration.

To date, 74 neurons have been recorded from the LDT in 12 rats, and 37% responded to single pulse electrical stimulation of known projection areas. Nearly all LDT neurons had large, initially positive action potentials, and most LDT neurons responsive to stimulation (70%) were not exhibit spontaneously active. LDT neurons were antidromically activated from the antero-ventral thalamus (AV), dorsal bundle (DB), and ventral tegmental area (VTA). These neurons had slow conduction velocities (0.23-0.63 m/s) indicative of fine, non-myelinated axons. LDT neurons were also orthodromically activated from the medial pre-frontal cortex (MPFC), AV, VTA, and lateral habenula (HAB). Stimulation of all of these sites evoked a marked excitation of LDT neurons except for HAB which was inhibitory. In addition, some LC neurons located in the rostral A6 region also were orthodromically activated by MPFC stimulation. Afferent projections to the LDT and LC from the MPFC and VTA were confirmed using anterograde tracing techniques (PhAL).

It is likely that some of these recordings correspond to Ch6 cholinergic neurons since dye spots were located within clusters of NADPH diaphorase positive cells (a histochemical marker for brainstem cholinergic neurons).

REGULATION OF AUTONOMIC FUNCTION I

78.1 NEUROPEPTIDE ACTIONS AND INTERACTIONS WITH NON-CHOLINERGIC POTENTIALS EVOKED BY URETERIC NERVE STIMULATION IN THE GUINEA PIG INFERIOR MESENTERIC GANGLION (IMG) IN VITRO. A. Dray, R. Amann and M. Hankins. Sandoz Institute for Medical Research, London, England.

The ureter is densely innervated with sensory nerve fibers (Sikri et al 1982, J. Anat. 133, 425) some of which project via the i.m.g. Ureteric fibers contain and release a number of neuropeptides including calcitonin-gene related peptide (CGRP), substance P(SP), neurokinin A (NKA) and neuropeptide K (NPK), a 36 amino acid peptide containing the NKA sequence at its C-terminal end. These peptides are possible neurotransmitters mediating non-cholinergic depolarization in the i.m.g. evoked by ureter distension or ureteric nerve stimulation (Amann et al 1987, J. Physiol. press). To examine this we have compared the effects of these peptides on i.m.g. neurones and their interactions with the ureteric nerve evoked slow-e.p.s.p. Adult guinea pigs were killed by cervical dislocation. The i.m.g. with attached nerve trunks and both ureters, was removed to a recording chamber and superfused with oxygenated Tyrode solution (37°C, flow 5ml/min) containing atropine and hexamethonium. One ureteric nerve branch (UN) was stimulated with a bipolar platinum electrode and intracellular recordings were made from principal ganglion cells using a 3 M KCl-filled micropipette. Drugs were administered in the superfusate. Repetitive stimulation of UN evoked a s-e.p.s.p. in 45% of randomly sampled cells. Membrane conductance was usually unchanged though in some cells a small increase occured. The amplitude and duration of the s-e.p.s.p. was related to the stimulus intensity and the membrane potential. The s-e.p.s.p. was abolished by TTX (1μM), by low calcium (0.2mM) high magnesium (12mM) perfusion or following desensitization of C-fibers with capsaicin (2μM). Most neurons (80%) were depolarized by SP (1μM) with either an increase or decrease in membrane conductance. NKA (1μM) and NPK (1μM) depolarized a similar proportion of cells (50 and 54% respectively). Membrane conductance was increased or decreased by NKA but consistently decreased by NPK. However NPK also hyperpolarized some cells (9%) and occasionally a sequence of hyperpolarization followed by depolarisation was observed. The similar actions of NKA and NPK suggest that in the majority of cases the activity of NPK was mediated by its C-terminal sequence. CGRP (1-10μM) was generally ineffective though some cells were depolarized (13%)or hyperpolarized (6%). The UN evoked s-e.p.s.p. was attenuated or abolished in the presence of supramaximal concentrations (2μM) of SP, NKA or NKP but unaffected by CGRP. These observations suggest that the UN evoked s-e.p.s.p. is produced by primary afferent C-fiber activation and that SP, NKA or NPK but not CGRP may be mediators of this potential in the i.m.g.

78.2 EFFECTS OF THE INTRATHECAL ADMINISTRATION OF VIP, SUBSTANCE P AND CGRP ON THE MICTURITION REFLEX OF THE CAT. M. Kawatani, C. Takeshige*, and W.C. de Groat. Dept. Physiology, Medical School, Showa Univ., Tokyo, Japan and Dept. Pharmacology, Medical School, and Center for Neuroscience, Univ. Pittsburgh, Pittsburgh, PA 15261.

Previous studies revealed that a number of neuropeptides including vasoactive intestinal polypeptide (VIP), substance P and calcitonin gene related peptide (CGRP) are present in afferent neurons innervating the urinary bladder of the cat and rat. The present experiments were undertaken to determine whether the intrathecal administration (IT) of these peptides alters the central reflex pathways controlling bladder function in the cat.

In 25 chloralose anesthetized cats bladder activity was monitored by recording intravesical pressure via a urethral cannula. Pelvic and hypogastric nerves (HGN) and postganglionic nerves on the surface of the bladder were isolated for electrical stimulation or recording. Drugs were injected IT via a polyethylene tube inserted through the dura at the level of the sacral or middle lumbar spinal segments. In some cats an outflow cannula was also inserted IT to allow for superfusion of the cord with artificial CSF. Some animals were spinalized at the T_{12} segment 1-3 months prior to the experiment.

The administration of low doses of VIP (0.1-1 ug) elicited small increases (10-20%) in the frequency and/or amplitude of spontaneous bladder contractions in 50% of the cats. Larger doses of VIP (2-50 ug) markedly or completely depressed bladder activity and reflex firing on bladder postganglionic nerves. The threshold inhibitory dose of VIP ranged from 2-10 ug. The magnitude and duration of the depression were dose dependent, large doses producing inhibition lasting 1-1.5 hrs. VIP did not inhibit the micturition reflex when applied to middle lumbar segments. VIP did not affect reflex firing on the hypogastric nerves. The inhibitory effect of VIP was more prominent in chronic spinal cats in comparison to normal cats. VIP-inhibition was antagonized by the prior IT administration of VIP antiserum (1:500 dilution, 1 ul/min for 30 min).

CGRP (0.5-20 ug) also elicited a prolonged (20-30 min), dose dependent decrease in the amplitude and frequency of bladder contractions, whereas substance P (0.1-10 ug, IT) increased the frequency of bladder contractions for 10-20 min.

These data raise the possibility that neuropeptides which are contained in bladder afferent pathways may have a modulatory influence on the sacral reflex mechanisms controlling micturition.

78.3 EFFECT OF INTRATHECAL SUBSTANCE P ON MICTURITION CONTRACTIONS IN URETHANE ANESTHETIZED RATS. B. Mallory and W.C. de Groat. Dept. of Pharmacology, and Center for Neuroscience, Univ. of Pittsburgh, Pittsburgh, PA 15261.

Evidence from previous studies suggests that substance P (SP) may be involved as a neurotransmitter in the reflex pathways controlling the urinary bladder. The present studies were undertaken to further explore the role of SP in the control of micturition.

Isometric micturition contractions were recorded in female Wistar rats anesthetized with urethane (1.2g/kg). The urinary bladder was cannulated transurethrally with PE 60 tubing and infused with saline to produce rhythmic bladder contractions. An L-2 laminectomy was performed and injections of SP or a substance P analog (pGlu5,MePhe8,Sar9)-SP 5-11 (SPA) dissolved in sterile water (1-5 ul) were made under the dura using a microsyringe and 30g needle.

Control injections of water had no effect on bladder contractions or baseline bladder pressure whereas SP (10-100ug) or SPA (25ug) elicited facilitatory or inhibitory effects. The onset of these effects was always within 5 min of the injection. The facilitatory effect of SP or SPA was noted in 8/11 rats. In the presence of ongoing bladder contractions, facilitation was characterized by a 50% or greater increase in the frequency of bladder contractions. The duration of facilitation was 2-60 min and was dose dependent. If the bladder volume was maintained below the micturition threshold so that the bladder was quiescent, the peptides initiated bladder contractions or increased baseline bladder pressure.

In two rats, a trimodal response was seen with an initial early excitation consisting of one or several bladder contractions within 3 min of injection followed by a period of complete inhibition of bladder contractions for 1.5-20 min which in turn was followed by a prolonged (20-90 min) facilitation of contractions.

In four rats the predominate effect of SP or SPA was a complete inhibition of bladder contractions however the first effect noted immediately after injection of SP (10-60ug) was an increase in baseline bladder pressure of 5-20 cm H_2O lasting 0.5-5 min followed by a prolonged inhibition (10-60 min) of bladder contractions and subsequent recovery. In one rat a short lasting (2-5 min) inhibitory response to SP or SPA was seen.

These data raise the possibility that SP may be involved in inhibitory as well as facilitatory mechanisms in the lumbosacral reflex pathways to the urinary bladder. The facilitatory effect of SP is most prominent which is consistent with the view that SP may be a transmitter in the afferent limb of the micturition reflex.

78.4 THE EFFECTS OF CAPSAICIN ON MICTURITION AND ASSOCIATED REFLEXES IN THE RAT. C.L. Cheng* and W.C. de Groat (Spon: A.M. Booth). National Defense Medical Center, Taipei, Taiwan, Rep. of China, Dept. of Pharmacology, and Center for Neuroscience, Univ. of Pittsburgh, Pittsburgh, PA 15261

Recent studies have revealed that the urinary bladder (UB) receives an innervation from two types of afferent fibers (myelinated and unmyelinated) which may subserve different functions. The role of these two types of afferents in the initiation of micturition and pseudo-pain responses (ie., arterial pressor reflexes) was examined in the present experiments by studying the effects of capsaicin (CAPS), a neurotoxin, which acts selectively on small diameter afferents.

Experiments were conducted on urethane anesthetized female Wistar rats, in which blood pressure (BP) and bladder pressure (BLDP) were recorded through carotid artery and urethral catheters. Spontaneous bladder contractions (ranging from 40-60 cm H_2O intravesical pressure) and associated increases in BP (11-28 mm Hg) were elicited by distension of the UB under constant volume conditions. Inhibitory reflexes to the bladder elicited by mechanical stimulation of the uterine cervix were also tested for their sensitivity to CAPS.

Small doses of CAPS (5-10 mg/kg, s.c.) produced a rapid onset (20-30 min) suppression of the arterial pressor responses accompanying each contraction of the UB but did not change bladder activity or inhibitory bladder reflexes to cervical stimulation. Large doses of CAPS (30-70 mg/kg, s.c.) abolished bladder activity for 18-24 hrs.

Chronic CAPS treatment (125 mg/kg, s.c. in divided doses on 2 consecutive days) 4 days prior to the experiment also markedly suppressed the arterial pressor responses associated with bladder contractions (4.6 $\pm$ 1.2 mm Hg in CAPS-pretreated rats versus 23.4 $\pm$ 9.2 mm Hg, vehicle controls) but did not significantly depress the amplitude of rhythmic contractions of the UB. However, these doses of CAPS shifted the volume threshold for inducing micturition (0.47$\pm$ 0.1 ml, in controls versus 0.62 $\pm$ 0.1 ml in CAPS-pretreated). CAPS also suppressed the eye wipe test and the bladder inhibition elicited by cervical stimulation.

These data indicate that afferent pathways from the UB which trigger arterial pressor responses and those from the uterine cervix which mediate bladder inhibition are very sensitive to CAPS and therefore are likely to be unmyelinated, whereas those from the UB which trigger micturition appear to be CAPS insensitive larger diameter myelinated axons. It is concluded that the nociceptive information from the UB is carried by a population of afferents distinct from those which initiate the micturition reflex.

78.5 CARDIOVASCULAR EFFECTS OF CHRONIC CERVICAL SPINAL TRANSECTION (ST) IN THE RAT: A MODEL OF AUTONOMIC HYPERREFLEXIA. J. W. Osborn, Jr., R. F. Taylor, and L. P. Schramm. Dept. of Biomed. Eng., The Johns Hopkins Sch. Med., Baltimore, MD. 21205

We have developed a chronic spinal rat model with a complete spinal transection at C8. We describe results of preliminary investigations of the determinants of mean arterial pressure (MAP) and of cardiovascular responses to distension of the urinary bladder after ST.

Male Sprague-Dawley rats were instrumented with chronic arterial and venous catheters for MAP measurement and intravenous drug administration respectively. A gastric cannula was also implanted for long-term administration of water and nutrients as described below. The rats were placed in a temperature controlled caging unit and allowed two days for recovery. On the second recovery day, food and water were removed and a continuous intragastric infusion of a liquid diet was started and maintained at a constant rate for the duration of the protocol. The study began the next day. Daily measurements of MAP were obtained two days before and 8 days after ST. A bladder cannula was implanted at the time of ST to facilitate bladder emptying. Body temperature was maintained at pre-ST levels by ventilating the cage with warmed humidified air.

For the two control days, MAP averaged 99 $\pm$ 4 (mean $\pm$ SE) and 100 $\pm$ 4 mmHg. MAP fell to 74 $\pm$ 3 mmHg the first day after ST and ranged between 79 $\pm$ 3 and 87 $\pm$ 4 mmHg (mean = 83 $\pm$2) for the duration of the study. One week after ST, pharmacological blockade of sympathetic or vasopressin (AVP) vasoconstrictor actions had no significant effect on MAP. In contrast, angiotensin II (AII) blockade resulted in a 27 $\pm$ 4 mmHg fall of MAP.

Small stepwise increases of bladder pressure from zero to 20 mmHg increased MAP 15 $\pm$ 3 mmHg and did not significantly alter heart rate (HR). The same stimulus following atropine administration resulted in a small increase of HR (+12 $\pm$ 8 bpm) and an enhanced pressor response (+22 $\pm$ 3 mmHg). Alpha adrenergic blockade, in the presence of atropine, significantly attenuated the pressor response (+5 $\pm$ 4 mmHg) whereas the HR response was not changed (+12 $\pm$ 6 bpm).

These data suggest that 1 week after ST, there was minimal sympathetic vasoconstrictor activity, and chronic hypotension was only partially corrected by other mechanisms. MAP was supported by circulating AII whereas AVP vasoconstrictor activity was minimal. Sympathetic activity was reflexly increased at spinal levels in ST rats by modest elevations of urinary bladder pressure. Although supraspinal control of sympathetic activity was absent after ST, pressor responses to bladder inflation were buffered by baroreflex control of cardiac vagal activity.

78.6 PROJECTIONS FROM CERVICAL SPINAL CORD TO LOWER THORACIC CORD IN THE RAT. J.A. Eberhart and L.P. Schramm. Department of Biomedical Engineering, Johns Hopkins University School of Medicine, Baltimore, MD 21205.

Previous reports from this laboratory suggest that neurons in cervical spinal cord play a role in the regulation of sympathetic activity. Although propriospinal connections between the cervical and lumbosacral enlargements have been thoroughly studied, cervical projections to thoracic spinal cord have attracted less attention. The purpose of the present study was to identify long, descending, propriospinal projections from cervical spinal cord that might mediate the observed sympathomodulatory effects.

Each of 25 rats received a unilateral pressure injection (10-50 nl) of 4% Fluoro-Gold (Fluorochrome, Inc.) at T9. Injections were made with a glass micro-pipette (15-25 μ tip) in either the dorsal horn or the intermediate gray matter. Survival time was either 5 or 20 days. Frozen horizontal sections of spinal cord were cut at 40 μ, and alternate sections were counterstained with thionin. Retrogradely labeled cells in unstained sections were plotted on projection drawings of adjacent, counterstained sections.

Larger (30-50 nl) injections (which labeled both dorsal horns, much of the intermediate gray matter, and part of the ventral horns in several segments of thoracic cord) resulted in many retrogradely labeled cervical neurons. In all cervical segments, labeled cells were located in the more lateral portions of the dorsal horns, and they were very numerous near the central canal. Labeled neurons were also found in the dorsolateral funiculi, particularly in the region of the lateral cervical and lateral spinal nuclei. There were also a few cells in the ventral horns. Smaller (10-20 nl) injections (labeling only one dorsal horn) produced many fewer retrogradely labeled cervical neurons scattered in the dorsolateral funiculi, dorsal horns, and near the central canal.

These results demonstrate that neurons in the dorsal horn, intermediate zone, and dorsolateral funiculus of the cervical spinal cord project directly to the lower thoracic cord. Some of the dorsolateral cervical neurons, in particular, may represent descending systems regulating sympathetic preganglionic neurons.

This work was supported by NIH grant HL16315 (LPS) and by the Hopkins/Dana Sabbatical Program (JAE).

78.7 CERVICAL SPINAL CORD NEURONAL RESPONSES TO GREATER SPLANCHNIC NERVE STIMULATION. E.W. Akeyson*, R. Sarrafizadeh* and L.P. Schramm. Depts. of Neuroscience and Biomedical Engineering, The Johns Hopkins University School of Medicine, Baltimore, MD 21205.

Visceral afferents are known to influence the firing of thoracic spinal neurons, and the response properties of such thoracic viscero-receptive neurons have been well studied. This afferent information can also influence spinal circuits at other spinal levels. Therefore, we have recorded responses of neurons in spinal segments C2-C4 to electrical stimulation of the left greater splanchnic nerve (GSN) in chloralose-anesthetized, artificially-ventilated rats.

A small fraction of cervical spinal neurons at C2-C4 responded to ipsilateral GSN stimulation. They were located in the marginal zones of laminae II through VII and in laminae IX. Most (91%) exhibited spontaneous activity with high average rates (mean= 21.9 ± 4.0 Hz). The majority of responsive neurons were inhibited by GSN stimulation (59%), but excitations (35%) or excitation/inhibition combinations (6%) were also observed. Inhibitions elicited by GSN stimulation were tightly locked to the stimulus, and they often lasted in excess of 100ms (range = 23-335ms). Excitations were characterized by one or two short duration bursts (mean= 48.6 ± 16.7 ms) of typically 2-8 spikes/ burst.

The majority of neurons received a convergent cutaneous mechanoreceptor input. Typical cutaneous receptive fields included the posterior aspect of the head, the neck, the shoulder, and the upper forelimb, but they rarely extended caudally to the thorax. A very small number of responsive neurons exhibited receptive fields which encompassed the entire side of the body from neck to lower limb.

Several neurons were tested extensively with electrical stimulation of the skin. In all cases, neurons inhibited by GSN stimulation were also inhibited by cutaneous stimulation, and vice versa. Neurons with cutaneous receptive fields restricted to the head, neck and shoulder were not affected by high intensity electrical stimulation (10mA) to the skin of the abdomen and lower limb.

These results indicate that there exists a small population of neurons in the gray matter of upper cervical spinal segments whose activity is modified by abdominal visceral afferents. Their responses to GSN stimulation are varied, and, therefore, they may constitute multiple visceral processing populations. Many neurons receive a cutaneous input from cervical dermatomes combined with a visceral input from abdominal "viscerotomes" while failing to exhibit cutaneous input from thoracic dermatomes. Supported by NIH grants HL16315 and 5-T32-GM07309-12.

78.8 MUSCARINIC AGONISTS POTENTIATE NICOTINE-STIMULATED CATECHOLAMINE SECRETION FROM ISOLATED-PERFUSED GUINEA PIG ADRENAL GLANDS. M.A. Oleshansky, Y. Nakazato*, R.M. Smejkal* and P.K. Chiang, Divisions of Neuropsychiatry and Biochemistry, Walter Reed Army Institute of Research, Washington, D.C. 20307-5100.

Several lines of evidence suggest that muscarinic and nicotinic receptors are involved in acetylcholine (ACh)-stimulated catecholamine secretion from adrenal medulla. It was originally noted that pilocarpine stimulated catecholamine secretion from perfused cat adrenal glands. Additionally, atropine was noted by several groups to decrease the ACh-stimulated release of catecholamines from the adrenals of various species. Subsequently, both muscarinic and nicotinic receptors have been identified in bovine chromaffin cells. Recent studies have demonstrated that muscarinic agonists potentiate nicotine-stimulated catecholamine release from isolated-perfused bovine adrenals and dispersed chromaffin cells. To further characterize the role of muscarinic receptor stimulation in ACh-stimulated catecholamine secretion, we examined the responses of selective cholinergic receptor agonists and antagonists on the isolated-perfused guinea pig adrenal preparation.

Both adrenal glands were perfused with Locke solution through a polyethylene cannula inserted into the lower aorta and the perfusates were collected from a cannula in the caudal vena cava. Drugs dissolved in Locke solution were perfused for one or two minutes. Norepinephrine (NE) and epinephrine (EPI) were assayed by a conventional HPLC method.

ACh stimulated NE and EPI secretion in a dose-dependent manner over the range of 10^{-6} to 10^{-3} M. Atropine (10^{-5} M) shifted the dose response curve to ACh to the right while hexamethonium (5 x 10^{-4} M) tended to decrease the response to higher concentrations of ACh with little effect on catecholamine secretion at the lower concentrations of ACh. ACh-stimulated catecholamine release was completely blocked by a combination of the two drugs. Nicotine or the muscarinic agonists, oxotremorine or pilocarpine, stimulated catecholamine release. One min pretreatment with oxotremorine (10^{-5} M), which only weakly stimulated catecholamine secretion, increased nicotine (5 x 10^{-5} M)-stimulated release of NE and EPI two fold. Application of nicotine (5 x 10^{-5} M) for one min every fifteen min produced progressively smaller increases of catecholamines secretion upon repeated exposure. Muscarinic agonists were able to reverse the tachyphylaxis seen upon repeated exposure to nicotine.

These experiments demonstrate that ACh-stimulated catecholamine secretion from isolated-perfused guinea pig adrenal glands involves both nicotinic and muscarinic receptor activation. Our findings support the recent work with dispersed bovine chromaffin cells which demonstrates that muscarinic agonists potentiate nicotine-stimulated catecholamine release. The dual regulation of ACh-stimulated catecholamine secretion through muscarinic and nicotinic receptors may be involved in both the potentiation and prolongation of the actions of ACh on the adrenal medulla under conditions of stress.

78.9 CATECHOLAMINE SECRETION FROM THE FELINE ADRENAL MEDULLA AS A FUNCTION OF TIME FOLLOWING HIGH SPINAL TRANSECTION. S.L. Stoddard, D.M. Gaumann*, G.M. Tyce and T.L. Yaksh*. Dept. of Anat., Indiana Univ. Sch. of Med., Fort Wayne, IN 46805 and Dept. of Neurosurg. Res., Mayo Clinic, Rochester, MN 55905.

Paraplegic patients with cord transections above the sympathetic outflow frequently exhibit the syndrome of autonomic hyperreflexia in response to a range of visceral and somatic stimuli. Although the manifestations of this syndrome are generally attributed to the release of norepinephrine (NE) from the sympathetic nerve terminals, the role of the adrenal medulla in this situation has not been investigated. Therefore, the purpose of this study was to determine the output of catecholamines from the adrenal medulla in response to both visceral and somatic stimuli following acute (1-4 days) and chronic (14-35 days) transection of the spinal cord at T2-T3. For the experiments, cats were anesthetized with halothane and rendered decerebrate. After decerebration, the halothane was removed. Blood pressure was continuously monitored through a femoral cannula and blood samples were withdrawn directly from the left adrenolumbar vein. Catecholamine levels were determined by HPLC. Bladder distention (60 mm Hg) and ipsilateral sciatic stimulation (50 Hz; 40V; 0.5 sec pulse width; 1 sec on, 1 sec off) were used as visceral and somatic stimuli, respectively. Neither stimulus increased mean arterial blood pressure (MAP) in acutely-transected cats, while both stimuli elicited increases in MAP > 30 mm Hg in chronically-transected cats. Furthermore, the mean increases in NE, epinephrine (EPI) and dopamine (DA) were notably greater in the chronically-transected animals (Table 1). These data suggest that, 1)there is a reorganization of adrenal medullary spinal control mechanisms that occurs by 2 weeks following high cord transection, and 2)autonomic hyperreflexia may involve significant adrenal medullary activation, which has not previously been described. [Supported by NS-15641 and AM-34988(TLY)].

TABLE 1: Mean changes in Catecholamine Levels (ng/ml)

	Bladder Distention		Sciatic Stimulation	
	Acute	Chronic	Acute	Chronic
NE	1.01	22.89	0.25	27.45*
EPI	2.79	16.74*	0.40	19.83*
DA	0.16	-0.73	-0.14	8.62

(*p ≤ 0.1 as compared to acute transection; n = 4, each group)

78.10 FREQUENCY DEPENDENT ADRENAL RELEASE OF CATECHOLAMINES AND NEUROPEPTIDES DURING SPLANCHNIC NERVE STIMULATION IN CATS. D. Gaumann[1]*, T. Yaksh[2]*, G. Tyce[3], D. Lucas[4]* and D. Roddy[4]* (SPON: R. Weinshilboum). Departments of [1]Anesthesiology, [2]Neurosurgery Research, [3]Physiology and [4]Gastroenterology, Mayo Clinic, Rochester, MN 55905.

Stimulation of the left major splanchnic nerve (SN) was performed in 6 cats to evaluate the frequency-dependent release of norepinephrine (NE), epinephrine (EPI), dopamine (DA), met-enkephalin (ME), neuropeptide Y (NPY) and neurotensin (NT) from the left adrenal. Experiments were performed under 1 MAC of halothane anesthesia and baseline samples S1 were taken 1 hr after the termination of the surgical procedure from the adrenal vein (AD) and the femoral artery (FA). Samples S2 were taken during SN stimulation at 5 Hz (1 msec stimulus, 30 volts, train rate 0.5 sec), and samples S3 under SN stimulation of 50 Hz. Plasma levels of catecholamines (CA) and neuropeptides (NP) under baseline conditions with a MABP of 111±14 mm Hg (mean ± SE) are shown in Table 1. EPI, NE and NPY levels in the AD were consistently higher than in the FA, which points to their selective adrenal release under baseline conditions. SN stimulation at 5 Hz evoked a pronounced increase in MABP (+ 33±11 mm Hg from baseline) and a selective release of NE, EPI and ME from the adrenal. SN stimulation at 50 Hz evoked a further increase in MABP (+ 54±12 mm Hg from baseline) and AD CA and NP levels. The increase in NE, EPI and DA was most pronounced with approximately the same ratio of release as under 5 Hz stimulation. Only at high frequencies was there a selective release of NT and NPY from the adrenal. The proportional release of ME from the adrenal, compared to NE and EPI, was less pronounced under 50 Hz than under 5 Hz SN stimulation. Though CA and NP are co-stored in adrenal chromaffin cells, their extracellular movement following low and high frequency SN stimulation, appears differentially evoked. (Supported by NIH grant NS-16541 (TY), 1986 Burroughs Wellcome Research Fellowship (DG).)

Table 1: Plasma Levels at Baseline (mean ± SE)

Source	NE (ng/ml)	EPI (ng/ml)	DA (ng/ml)	NPY (ng/ml)	ME (pg/ml)	NT (pg/ml)
AD (n=6)	6.8 ± 3.8	39 ± 25	0.2 ± 0.3	1.5 ± 0.5	49 ± 15	39 ± 5
FA (n=4)	0.3 ± 0.1	0.3 ± 0.2	0.3 ± 0.3	0.9 ± 0.1	46 ± 12	42 ± 8

Table 2: Increase in Plasma Levels During Splanchnic Nerve Stimulation (Ratio of Baseline, mean ± SE)

Source	NE (ng/ml)	EPI (ng/ml)	DA (ng/ml)	NPY (ng/ml)	ME (pg/ml)	NT (pg/ml)
AD (5 Hz)	6.5 ± 2.8	4.0 ± 1.3	0.8 ± 0.2	1.3 ± 0.4	3.1 ± 1.0	1.8 ± 0.3
FA (5 Hz)	2.0 ± 0.6	2.5 ± 1.6	1.0 ± 0.4	1.0 ± 0.1	1.0 ± 0.3	1.0 ± 0.1

78.11 SPINAL AND PERIPHERAL PHARMACOLOGY OF THE URINARY BLADDER IN UNANESTHETIZED RATS. P.A. Durant* and T.L. Yaksh* (SPON: P.R. Wilson). Neurosurgical Research Unit, Mayo Clinic, Rochester, MN 55905.

Using a chronic unanesthetized rat model (Am. J. Physiol. 251: 1177, 1986) we studied the spinal and peripheral pharmacology of the cholinergic, adrenergic, serotonergic and ganglionic systems by examining the dose dependent effects of receptor selective agonists after intrathecal (IT) and intraperitoneal (IP) injections. A polyethylene-100 tubing was chronically implanted through the vertex of the bladder. A polyethylene-10 tubing was inserted in the IT space through the cisternal membrane down to the lumbar level. Both catheters were tunneled subcutaneously to exit at the level of the neck and the scalp, respectively. To examine the volume-evoked micturition reflex (VEMR), the unanesthetized rat was placed in a restraining cage over a strain gauge mounted collecting device for measurement of urine volume. The bladder catheter was connected to a pump for continuous saline infusion (250 µl/min) and to a transducer for monitoring bladder pressures. The following parameters of the VEMR were routinely measured: baseline pressure, bladder opening pressure, peak pressure (PP) and volume of urine expressed per bladder contraction (V/C). The importance of using unanesthetized animals was demonstrated by the inhibition of the VEMR in rats anesthetized with pentobarbital, ketamine, chloralose and halothane. Carbachol (IP), serotonin (IP), apomorphine (IP and IT), dopamine (IP and IT), norepinephrine (IP and IT), methoxamine (IP) and ST-91, an α_2-agonist (IP and IT) evoked an increase in contraction rate (e.g. a reduction in V/C). In all cases, the VEMR during these periods of increased frequency was such that the volume expressed was equal to the volume infused (e.g. there was no residual volume). Atropine (IP), hexamethonium (IP), norepinephrine (IP), isoproterenol (IP and IT) and phentolamine (IP) induced significant drops in PP, suggesting relaxation of the bladder outlet and/or bladder body. Carbachol (IT), atropine (IT), serotonin (IT), methysergide (IP and IT), hexamethonium (IT), cis-flupentixol (IP and IT), methoxamine (IT), terbutaline (IP), phentolamine (IT), yohimbine (IP and IT) and propranolol (IP and IT) produced virtually no effects on micturition at the highest doses examined. The lack of effect of IT injected antagonists suggests that spinal cholinergic, serotonergic, dopaminergic and adrenergic systems are not routinely active during the VEMR. Those systems might be activated in special circumstances, such as the voluntary act of retaining urine. The present study represents the initial efforts to characterize the pharmacology of spinal and peripheral receptor populations regulating the VEMR in the unanesthetized, intact rat. (NIH grant NS-19650 and Mayo Foundation.)

78.12 ELECTROPHYSIOLOGICAL INVESTIGATION OF SEXUAL REFLEXES EVOKED BY STIMULATION OF THE DORSAL NERVE OF THE PENIS IN THE RAT AND CAT. W.D. Steers*, B. Mallory, and W.C. de Groat. Dept. of Pharmacology, Univ. of Pittsburgh, Pittsburgh, PA 15261.

The dorsal nerve of the penis (DNP) serves as the somatic afferent limb for multiple sexual reflexes mediated by autonomic efferents. These reflex pathways provide a model for studying somatovisceral integration and the parasympathetic and sympathetic events associated with sexual function.

Male Wistar rats and cats were anesthetised with urethane and chloralose, respectively, prior to exposure of the DNP, pelvic (PV), hypogastric (HG) and penile (PN) nerves for stimulation and recording. Animals were paralyzed with pancuronium and artificially ventilated.

Electrical stimulation of the DNP evoked responses on PN, PV and HG. PN responses in the rat consisted of an early response (ER) with a latency of 47±14 ms and a late response (LR) at 100±18 ms. The ER was eliminated by PV crushing and stimulation frequencies $\geq$3 Hz, while the LR was reduced but not eliminated by these two maneuvers. The LR and not the ER was consistently abolished after ganglionic blocking agents. Only the ER was present after chronic spinal cord transection at T8. These data suggest that the ER was a central reflex originating in the lumbosacral cord. The LR has not been completely defined but may be a supraspinal reflex.

PV stimulation elicited axonal volleys (0.3-5 ms) and occasional ganglionic responses on PN. HG stimulation also elicited responses (11±2 ms) which were abolished by ganglionic blockade. DNP stimulation produced 13±4 ms and 44±16 ms responses on HG; the latter were eliminated by crushing HG centrally.

Preliminary studies in the cat have shown the nerves from the pelvic plexus caudad to the prostate (PN) could be activated by DNP, PV and HG stimulation. DNP stimulation produced long latency discharges (200-300 ms) on these nerves. Spontaneous neural activity on some PN was either facilitated or inhibited by electrical stimulation of the DNP or tactile stimulation of the penis. Stimulation of PV and some PN produced an increase in intracavernous pressure and penile erection suggesting that the DNP reflex may be involved in penile vasodilatation. PV and HG stimulation evoked responses sensitive to ganglionic blockade.

These results combined with previous axonal tracing studies reveal that nerves projecting to the penis from the pelvic plexus contain both parasympathetic and sympathetic pathways whose distal ganglia are distributed randomly. The central reflex mechanisms involve both spinal and supraspinal centers. Studies are underway to determine the sexual functions corresponding to these reflexes.

78.13 AUTONOMIC INNERVATION OF REPRODUCTIVE ORGANS IN THE RAT: ANALYSIS OF THE COMPOSITION OF THE CAVERNOUS NERVE. W. G. Dail, D. Trujillo* , G. Walton* and D. de la Rosa*. Department of Anatomy, University of New Mexico, School of Medicine, Albuquerque, NM 87131.

Previous studies have shown that the cavernous nerve, a presumed postganglionic nerve pathway from the pelvic plexus to penile erectile tissue, also contains a large number of ganglion cells as well as afferent nerve fibers. The present study uses retrograde tracers to analyze the target organs of the neuronal perikarya in the trunk of the cavernous nerve and to localize other neurons whose fibers traverse this nerve. The dyes fluorogold or true blue were placed in the penile crura, penile bulb, bulbourethral gland or on the cut end of the cavernous nerve. Neurons to the penile crura were found in the major pelvic ganglion (195±8.1) and in the more proximal end of the cavernous nerve (106±11.9). In contrast, neurons which innervate the bulbourethral gland are distributed evenly along the length of the cavernous nerve (217±20.5) with a smaller number in the major pelvic ganglion (66±11.8). Dye in the penile bulb filled neurons in the major pelvic ganglion (201±17.3) and in neuronal clusters of the cavernous nerve (531±22.3). There was no evidence of double labeled neurons when multiple target organs were injected with different dyes. Dye placed on the cut end of the cavernous nerve filled neurons in dorsal root ganglia L_6-S_1, sympathetic chain ganglia and preganglionic autonomic neurons at spinal cord levels L_1-L_2 and L_6-S_1. Preganglionic neurons in the L_1-L_2 spinal cord segments were located in the dorsal commissural nucleus while those at the L_6-S_1 segments were found mainly in the intermediolateral gray matter. The presence of adrenergic fibers was confirmed by catecholamine histofluorescence of chronically-ligated cavernous nerves.

Separate populations of neuronal perikarya along the cavernous nerve innervate the penile crura, penile bulb and the bulbourethral glands. Neurons in the cavernous nerve are innervated mainly from preganglionic neurons of the sacral parasympathetic nucleus but also receive preganglionic innervation from the sympathetic hypogastric nerve. There is a topography of the cavernous nerve in that neurons to the bulbourethral gland are located more distally along the nerve than neurons which innervate the penile crura. The relatively large number of neurons labeled after injection of the penile bulb may represent innervation to penile smooth muscle and to glands associated with the urethra. The field of innervation of sensory fibers and sympathetic fibers in the cavernous nerve is not known. Supported by NIH RO1NS1983-04 and NIH RR08139-10.

78.14 THE AUTONOMIC INNERVATION OF THE PENIS AND CLITORIS OF THE RAT. Sookja K. Chung and Kevin E. McKenna, Dept. of Physiology, Northwestern Univ. School of Medicine, Chicago, IL 60611

The present study was motivated by 3 questions. First, what are the sex differences between the autonomic innervation of the penis and clitoris (P/C)? Second, is there a viscerotopic organization in the distinction of preganglionic neurons innervating a given organ? Third, what are the relative contributions of sympathetic (SYMP) and parasympathetic (PSYMP) innervation of the P/C ? The P/C in the rat is innervated by the pelvic ganglion, a mixed sympathetic - parasympathetic ganglion, via the cavernous nerve as demonstrated by gross dissections. Electrical stimulation of this nerve in the male induces vasodilation of the penis, indicating that it may play a role in erection.

Injection of tracer material into the P/C labelled ganglion cells in the pelvic ganglion proper but also cells distributed throughout the length of the cavernous nerve. This finding suggested that it may be possible to label some of the preganglionic neurons (PGNs) innervating these ganglion cells by applying tracer to the cavernous nerve close to the ganglion. Mature male and female rats were anesthetized with halothane and the pelvic ganglion was exposed. The cavernous nerve was identified and cut close to the ganglion. The central cut end was incubated for 1 hour in HRP, fluorogold, or fast blue. Following survival times of 2 to 6 days, the rats were reanesthetized and perfused with buffer and fixative. The pelvic ganglion, spinal cord, and dorsal root ganglia (DRG) were removed and sectioned with cryostat. HRP material was processed with theTMB technique. Examination of the pelvic ganglia revealed that tracer application was confined to cavernous nerve and did not diffuse into the ganglion.

In both sexes, labelled neurons were found in the lateral horn in segments L6-S2, the dorsal commissure of T13-L2, and the DRG of L6 and S1. The L6-S2 neurons were distributed in a tight column at the gray-white matter border. Location and morphology indicated that these were clearly PSYMP PGNs. Comparison of the distribution of these neurons and PSYMP PGNs labelled from pelvic nerve indicate that P/C PGNs are cospatial with non-P/C PGNs in this nucleus.

The labelled neurons in the T13-L2 segments were distributed in a more diffuse column in the dorsal commissure. Only a few cells were seen in the lateral horn. The distribution and morphology of these cells indicate clearly that they are SYMP PGNs. These neurons were also cospatial with non-P/C PGNs labelled from the hypogastric nerve.

Labelled DRG neurons and terminal fibers in the spinal cord were seen in L6-S1 segments, indicating that the cavernous nerve afferents travel in the pelvic nerve.

The distribution and morphology of labelled neurons were similar in male and female rats. However, there were clearly fewer SYMP and PSYMP PGNs in the female, demonstrating a strong sexual dimorphism in the innervation of the P/C.

This study suggests that both SYMP and PSYMP PGNs may be involved in erection of the P/C. Further, there appears to be little viscerotopy of PGNs innervating the P/C and that male and female innervation shows a strong quantitative difference.

78.15 SEXUAL REFLEXES EVOKED IN ACUTELY SPINALIZED, ANESTHETIZED RATS. Kevin E. McKenna and Sookja K. Chung, Dept. of Physiology, Northwestern Univ. School of Medicine, Chicago, Il 60611

The spinal mechanisms involved in control of sexual function remain largely unknown because of the lack of a suitable model in which invasive procedures can be used while reliably eliciting sexual reflexes. The present study demonstrates the utility of the acutely spinalized, urethane anesthetized male rat as a suitable model for studying spinal sexual reflexes. These reflexes appear comparable in many respects to activity seen in rats in copula.

Mature male rats (300-400g) were anesthetized with urethane (1.0g/kg S.C.) and spinalized at spinal segment T5-T9. EMG electrodes were placed in the ischiocavernosus muscle (IC), bulbospongiosus muscle (BC) while the dorsal nerve of the penis (DNP), motor branch of the pudendal nerve (MPN), and cavernous nerve (CN) were prepared for stimulating and recording. Intracavernous pressure (ICP) was recorded with a needle placed in the penis and connected to a pressure transducer. Similar to previous reports using unanesthetized, chronically spinalized rats (Hart, 1967; Sachs, 1983), penile reflexes (erections, cups, flips) could be elicited in this preparation by pulling back the preputial sheath and maintaining pressure on the base of the penis. However, in our hands, this technique was inconsistent in producing penile reflexes and often required long periods of time between trials. We determined that the most consistent, reliable and repeatable stimulus for penile reflexes is mechanical or chemical stimulation of the mucosa of the urethral bulb. Inserting a fine (0.6mm O.D.) catheter into the urethral bulb and manipulating it a few mm. invariably produced penile reflexes. These reflexes consisted of bursts of activity in MPN motoneuron axons and CN vasodilator fibers. These bursts produced either spikes of pressure or staircase increases in ICP.

The penile reflexes consisted of strong bursts of activity of BC muscles and often simultaneous activation of the IC. These bursts lasted from 500-900 msec. They were associated with increases of ICP of 50 to over 400 mmHg which led to full erection, with cups forming in strong reflexes. The bursts occurred with intervals of 1 to 2 seconds. The number of bursts in a sequence was related to the strength and duration of urethral stimulation, but always persisted long after manipulation had ceased. For example, a 5sec manipulation led to a series of bursts lasting approximately 20sec and a 45sec manipulation evoked a sequence of bursts lasting almost 2.5 min. Strong responses resembled ejaculatory events and would often expell the urethral catheter and secretory (bulbourethral?) fluid.

The bursts of BC and IC activity were preceded by 100-200msec by bursts of activity in the CN, which provides vasodilator input to the penis. Short latency (16-20 msec) reflexes could be elicited in this nerve by stimulation of the glans or DNP.

Injection of normal saline into the urethral bulb caused very little response, although hypertonic saline elicited sustained contraction of the BC muscle and sustained erections. The effects of various components of seminal fluid are being examined to test the hypothesis that ejaculation may be induced by chemical stimulation of the urethral mucosa by seminal secretions.

78.16 VAGINOCERVICAL PROBING ELEVATES BLOOD PRESSURE AND INDUCES ANALGESIA BY SEPARATE MECHANISMS. J.M. Catelli, A.F. Sved and B.R. Komisaruk. Inst. Animal Beh., Rutgers Univ., Newark, NJ 07102.

Previous studies have shown that vaginocervical stimulation (VS) produces profound analgesia. Since increases in blood pressure (BP) have been shown to increase pain thresholds, the present studies examined if the analgesic response to VS was secondary to cardiovascular effects of VS. VS, applied as a calibrated mechanical probe force against the cervix, increased BP >50 mmHg and increased heart rate (HR) >80 bpm in conscious, restrained rats. This response began immediately with the onset of stimulation and reached its maximal level within 10 seconds. The magnitude of the response was proportional to the force of the VS applied over a range of 50-600 grams (g). Administration of propranolol (1 mg/kg iv) attenuated the HR response to VS, whereas administration of chlorisondamine (5 mg/kg iv) abolished both the increase in BP and HR in response to VS. These results indicate that VS stimulates the sympathetic nervous system and that the tachycardia resulted from vagal withdrawal as well as sympathetic activation. The analgesic effect of VS, as measured by tail flick latency, was unaffected by any of the drug treatments that abolished the BP and HR elevating effects of VS. Furthermore, elevation of BP by administration of phenylephrine (5 ug/kg iv), to a level comparable to that produced by VS, did not produce analgesia. These results demonstrate that VS produces elevations in BP and HR which are due primarily to an increase in sympathetic activity. In addition, the increase in HR in response to VS appears to be partly due to a decrease in parasympathetic activity. The analgesia produced by VS is independent of the elevation in BP produced by VS.

78.17 AFFERENT FIBERS SUPPLYING INTERNAL REPRODUCTIVE ORGANS IN THE FEMALE RAT. K.J. Berkley[1], A. Robbins*[,1,2] and Y. Sato*[,2]. [1]Dept. of Psychology, Florida State Univ., Tallahassee, FL 32306; [2]Dept. of Physiology, Tokyo Metropolitan Inst. of Gerontology, Tokyo 173 Japan.

The purpose of this three-part study was to survey the sensory supply of female reproductive organs in the rat. In the first part, injections of horseradish peroxidase into large areas of the uterus produced labeled ganglion cells in the L1 through S1 dorsal root ganglia, with most located in L2 and L6. This result indicates that uterine afferent fibers in the rat travel to the central nervous system through both the hypogastric and pelvic nerves. In the second part, responses of single units to mechanical stimulation of the uterus and vagina were studied in the distal ends of the cut hypogastric and pelvic nerves. In the hypogastric n., receptive fields were most often located on the uterine body particularly over the cervix. Effective stimuli included steady pressure, stretching, squeezing and probing, often at intensities which produced transient ischemia around the probe. In the pelvic n., receptive fields were most often located in the vaginal canal adjacent to the cervix. Effective stimuli were much less intense, rarely producing ischemia. In the third part, responses of multiple units in both nerves to algesic and hypoxic chemical stimulation were studied in an in vitro preparation of the isolated uterus. Fibers in both nerves responded in a dose-dependent manner to the algesic chemicals bradykinin, 5 hydroxytyptamine (5HT) and potassium chloride, with differences in the configuration of the responses primarily to 5HT. Fibers in the pelvic n. were more sensitive than those in the hypogastric n. to hypoxic chemicals (sodium cyanide; CO_2 dissolved in buffer). Only high doses of these hypoxic chemicals activated hypogastric n. fibers, whereas pelvic n. fibers responded to lower doses in a dose-dependent manner.

These results indicate that the hypogastric and pelvic nerves contain afferent fibers supplying female reproductive organs in the rat and that there are significant functional differences between them in the information they each convey.

Supported by NIH grant R01 NS 11892 and the Japanese Society for the Promotion for Science.

78.18 ENHANCEMENT OF TRANSMISSION AND BLOCKADE OF LTP IN BULBOSPINAL PATHWAYS TO SYMPATHETIC PREGANGLIONIC NEURONS (SPGNs) BY PHORBOL ESTERS. Scott C. Steffensen*and Donald N. Franz, Department of Pharmacology and Toxicology, Univ. of Utah School of Medicine, Salt Lake City, Utah 84132.

A recently developed intraspinal microinjection technic (Soc. Neurosci. Abstr. 12:537, 1986) was used to examine the effects of phorbol esters on intraspinal transmission to SPGNs to test the possibility that the excitability of SPGNs is regulated in part by the phosphatidyl inositol system and, more specifically, protein kinase C. The effects of phorbol esters on LTP of intraspinal transmission, which typically reaches 200% of control and subsides within 30-40 min, was also determined.

Sympathetic discharges, recorded from T2 and T3 preganglionic rami and analyzed by signal averaging, were evoked at 0.1 Hz by microelectrode stimulation of descending excitatory pathways in the cervical dorsolateral funiculus of unanesthetized spinal cats. Phorbol 12,13-diacetate or phorbol 12,13-dibutyrate, dissolved in artificial CSF (1 ug/ul), were pressure injected through micropipettes into the SPGN neuropil near the middle of the T2 or T3 segment. Dye injections in 1-2 ul of vehicle were confined to a 10-15 ul volume along the longitudinal axis of the SPGN neuropil of the injected segment. Microinjections of 1 ug of either phorbol ester into one segment markedly enhanced intraspinal transmission through that segment to 200-240% of control levels within 10 min. Transmission returned to control levels by 1.5-2 hr, but subsequent injections were ineffective for more than 3 hr. During this time, the ability of the intraspinal pathway to generate LTP following a brief tetanus (50 Hz, 10 sec) was completely lost in the pre-injected segment. However, neither transmission nor generation of LTP through the adjacent, uninjected segment were affected.

The marked enhancement of transmission to SPGNs by phorbol esters is likely mediated by activation of protein kinase C which may increase SPGN excitability by phosphorylation of membrane proteins. The results also imply regulation by the phosphatidyl inositol second messenger system. The ability of phorbol esters to prevent both subsequent responsiveness and generation of LTP also suggests a role for protein kinase C in the generation of LTP as has been proposed for LTP in the hippocampus (Akers et al., Science 231:587, 1986; Malenka et al., Nature 321:175, 1986).

78.19 INTRASPINAL MICROINJECTION OF PHORBOL ESTERS BLOCKS GENERATION OF CYCLIC AMP IN SYMPATHETIC PREGANGLIONIC NEURONS (SPGNs). Donald N. Franz and Scott C. Steffensen*, (SPON: S.A. Turkanis), Dept. of Pharmacology and Toxicology, Univ. of Utah School of Medicine, Salt Lake City, Utah 84132.

Previous studies showed that i.v. phosphodiesterase (PDE) inhibitors or microinjection of two cyclic AMP analogs, forskolin (Soc. Neurosci. Abstr. 12:537, 1986), or phorbol esters into the SPGN neuropil markedly enhanced intraspinal transmission to SPGNs. It thus appears that both cyclic AMP and phosphatidyl inositol second messenger systems are involved in regulating SPGN excitability. The present study tested the possibility that activation of protein kinase C by phorbol esters might influence the cyclic AMP system in SPGNs as has been shown in several other, non-neuronal cell types.

Sympathetic discharges, recorded from T2 or T3 preganglionic rami and analyzed by signal averaging, were evoked at 0.1 Hz by microelectrode stimulation of descending excitatory pathways in the dorsolateral funiculus of unanesthetized spinal cats. Drugs, dissolved in artificial CSF, were pressure injected through micropipettes into the SPGN neuropil of either the T2 or T3 segment while recording evoked sympathetic discharges from both segments. Microinjection of 1 ug of phorbol 12,13-dibutyrate into one segment, which produced a typical phase of enhancement to about 200% of control, completely prevented the typical enhancement produced by subsequent microinjection of the PDE inhibitor, RO 20-1724 (2 ug) or the adenylate cyclase activator, forskolin (1 ug), into that segment. Enhancement of transmission by i.v. IBMX (1 mg/kg) was also prevented through the phorbol-injected segment but not through the adjacent, uninjected segment. However, microinjection of 1 ug of dibutyryl cyclic AMP into a phorbol-pretreated segment produced the typical prolonged enhancement seen in the absence of phorbol ester.

These results demonstrate that transient activation of protein kinase C by phorbol esters can block receptor-coupled generation of cyclic AMP in SPGNs. Since the phorbol esters block the effects of both PDE inhibitors and forskolin but not that of dibutyryl cyclic AMP, the inhibitory effect of phorbol esters appears to be mediated directly upon adenylate cyclase, perhaps through protein kinase C-induced phosphorylation of the enzyme.

78.20 PARAVENTRICULAR NUCLEUS STIMULATION: EFFECT ON RENAL NERVE ACTIVITY. C.L. Riphagen and Q.J. Pittman. Neuroscience Research Group. Univ. of Calgary, Calgary, Alberta, Canada T2N 4N1

The paraventricular nucleus (PVN) has projections, some of which are vasopressinergic, which descend to the lower thoracic intermediolateral cell column region from which the efferent renal innervation arises. Previously we have reported that intrathecal administration of arginine vasopressin (AVP) to this spinal region can alter kidney function (Riphagen, C.L. & Pittman, Q.J., Brain Res. 336: 346, 1985) and increase renal nerve activity (Riphagen, C.L. & Pittman, Q.J., Proc. West. Pharm. Soc., (in press). In this study we tested the hypothesis that electrical stimulation of the PVN could alter renal nerve activity and examined the role of AVP in the response using an intrathecally administered AVP antagonist.

Seven male Sprague-Dawley rats were anaesthetized with Inactin (0.12g/kg, i.p.). A monopolar stimulating electrode was implanted stereotaxically with the tip directed towards the left PVN. Intrathecal administration of vehicle or the AVP antagonist was made via a cannula threaded caudally in the subarachnoid space from the atlanto-occipital region to T10-12. The left kidney was exposed via a paravertebral incision and a renal nerve was sectioned as it entered the hilus. Multifibre renal nerve activity (RNA) in each animal was recorded conventionally in response to electrical stimulation of the PVN after perfusion of the intrathecal space with vehicle and later with the AVP antagonist $d(CH_2)5Tyr(Me)AVP$. The position of each electrode tip was examined histologically.

In 4 of the animals, the electrode tip was found to be positioned within the PVN. In these animals, electrical stimulation of the PVN (2-9V) resulted in a biphasic excitation of RNA (with the peaks of excitation occurring at between 100-150 msec and 150-250 msec after stimulation) followed by a period of inhibition (at 250-450 msec) prior to recovery. In 3 of these animals that were treated with AVP antagonist, the second excitatory peak was abolished. In 3 different animals in which the electrode tip lay just outside the PVN, a monophasic excitatory response to PVN stimulation, with a latency of 100-150 msec, was observed. Treatment with the AVP antagonist attenuated the excitatory peak in two of the animals but increased the magnitude of the response in the third.

The results of this study suggest that electrical stimulation of the PVN can alter RNA, producing a biphasic excitatory response. A descending AVP pathway may be involved in the second excitatory peak.

78.21 ELECTRICAL AND GLUTAMATE STIMULATION OF THE PARAVENTRICULAR NUCLEUS ELICITS BRADYCARDIA IN PENTOBARBITAL-ANESTHETIZED RATS. D.N.Darlington, J.Shinsako* and M.F.Dallman*. Dept. of Physiology, University of California, San Francisco, CA 94143 USA.

We examined the role of the hypothalamic paraventricular nucleus (PVN) for regulation of heart rate, arterial blood pressure and adrenocorticotropin (ACTH) secretion before and after microinjection (glass pipet, 50-80um OD) of glutamate or electrical stimulation of the PVN. Experiments were performed one hour after placement of femoral artery and vein cannulas. 50nl of 0.5M sodium-glutamate (pH7.4) injected over 2 minutes into the PVN elicited a decrease in heart rate (-80±6 bpm, n=7) while injection of sodium-acetate (50nl, 0.5M, pH7.4) had no effect (0±8 bpm, n=6). Bradycardia was elicited when glutamate was injected into the posterior part of the nucleus, but not when injected into the anterior part, above, or lateral to the PVN. The decrease in heart rate usually began 60 to 90 seconds after the onset of the 2 minute injection. Arterial pressure also decreased in response to every injection that elicited a bradycardia. Plasma ACTH did not change 5, 10 or 20 minutes after injection of glutamate or acetate (50 or 100nl) into the posterior PVN. To confirm the findings that chemical stimulation of the PVN elicits a bradycardia, bipolar concentric electrodes were placed in the PVN. Heart rate decreased as a function of current strength (range tested-50 to 500uA, 50Hz, 0.5msec for 10 sec) plateauing at 100uA. 20uA did not elicit significant changes in heart rate. Arterial blood pressure demonstated a biphasic response with increasing stimulus strength, decreasing at strengths less than 100uA and becoming variable with greater current intensity. The greatest decrease in heart rate also occured at 50 Hertz (range tested-5 to 300, 50uA, 0.5msec for 10 sec). A mapping study (50Hz, 50uA) demonstrated that the greatest decrease in heart rate was elicited from areas in and around the PVN.

We conclude that excitation of cell bodies in the PVN leads to a decrease in heart rate and blood pressure, however glutamate excitation of PVN neurons does not elicit ACTH release. Supported in part by KD2872 and HL29714.

78.22 CARDIOVASCULAR RESPONSES TO TIBIAL NERVE STIMULATION ARE NOT ABOLISHED BY FOCAL COOLING OR BY ANESTHETIC BLOCKADE OF THE VENTROLATERAL MEDULLA IN ANESTHETIZED CATS. T.G. Waldrop* and D.E. Millhorn (SPON: D.C. German). Dept. of Physiology, Univ. of Illinois, Urbana, IL 61801 and Dept. of Physiology, Univ. of North Carolina, Chapel Hill, N.C. 27514.

Neurons located superficially in the ventrolateral medulla (VLM) are well known to be involved in the maintenance of resting arterial pressure. Superficial cooling, electrolytic lesions or chemical blockade of the VLM causes hypotension in anesthetized cats and rats. In addition, several cardiovascular responses including those elicited by baroreceptor stimulation, cerebral ischemia and stimulation of the fastigial nucleus are modulated by neuronal structures in the VLM. These findings have led to the suggestion that all sympathetic outflow from the medulla originates from the VLM. The purpose of this study was to test this hypothesis by determing the effects of blockade of the ventrolateral medulla upon cardiovascular responses to a known somatoautonomic reflex. Adult cats anesthetized with chloralose and urethane were studied. Arterial pressure and neural correlates for sympathetic outflow (cervical nerve activity) and respiratory output (phrenic nerve activity) were recorded in response to tibial nerve stimulation before and during neuronal blockade of the ventrolateral medulla. The tibial nerve was stimulated at an intensity that activates all categories of afferent fibers. Blockade of the VLM was performed by focal cooling in one group of cats and by flooding the VLM surface with lidocaine in a second group of animals. Both types of blockade produced immediate decreases in arterial pressure, phrenic nerve and cervical nerve activities. However, neither cold block nor anesthetic blockade prevented the increases in arterial pressure, phrenic nerve activity and cervical nerve activity elicited by stimulation of the tibial nerve. In contrast, the responses to tibial nerve stimulation were abolished by transection of the cervical spinal cord. The arterial pressure and cervical nerve responses to activation of baroreceptor afferents (stimulation of a carotid sinus nerve) were attenuated by focal cooling of the VLM. These findings show that not all somatoautonomic reflexes are dependent upon activity of neurons located superficially in the ventrolateral medulla. Therefore, sympathetic outflow from the brainstem is not limited solely to neural networks located superficially beneath the surface of the ventrolateral medulla. Thus, other brain sites must also contribute to sympathetic outflow to the spinal cord.

Supported by NIH grants #HL38433 and #HL33831 and the American Heart Association.

78.23 EFFECTS OF CHEMICAL STIMULATION OF POSTERIOR HYPOTHALAMIC NEURONS UPON THE BARORECEPTOR REFLEX. R.M. Bauer* and T.G. Waldrop* (Spon: G.A. Iwamoto). Department of Physiology and College of Medicine, Univ. of Illinois, Urbana, IL 61801.

Several laboratories have shown that electrical stimulation in the posterior hypothalamus inhibits the baroreflex. However, these studies are difficult to interpret since it is not known if the attenuation of the baroreflex results from activation of fibers of passage or from stimulation of cell bodies located in the posterior hypothalamus. In addition, electrical stimulation of the hypothalamus often does not provide a stable baseline upon which the baroreflex can be tested. Therefore, the purpose of the present study was to determine the effects of chemical stimulation of posterior hypothalamic neurons upon the arterial pressure and heart rate response to baroreceptor stimulation. Experiments were performed in adult cats anesthetized with chloralose and urethane. Most of the cats were paralyzed with gallamine triethiodide and ventilated during the experiments. Arterial pressure and heart rate were recorded during activation of arterial baroreceptors before and after microinjection of the GABA antagonist picrotoxin (5 ng/nl) into the posterior hypothalamus. The baroreceptors were stimulated by increasing the pressure in a vascularly isolated carotid sinus and by intravenous injections of phenylephrine (20-50 micrograms). Picrotoxin was pressure injected through micropipettes (20-40 micron tips) positioned stereotaxically in the posterior hypothalamus (A9, L1.5, V-3). Injection sites were marked with fast green dye for subsequent histological verification of injection sites. The fall in heart rate produced by activation of the baroreceptors was attenuated by microinjections of picrotoxin into the posterior hypothalamus. The fall in arterial pressure evoked by increasing carotid sinus pressure (CSP) was slightly reduced by the picrotoxin injections. All of the effects of picrotoxin were reversed by microinjections of the GABA agonist muscimol (5 ng/nl) into the same site in the hypothalamus. Mean results ± SEM (n=10) are as follows:

	Control	Picrotoxin	Muscimol
Phenylephrine (Δbpm/ΔmmHg)	-0.642±0.2	-0.346±0.1	-0.637±0.2
Increased CSP (Δbpm)	-19.4±5.3	-8.1±2.0	-26.6±7.0

These results show that the depression of the baroreflex elicited by hypothalamic stimulation results from activation of cell bodies in the posterior hypothalamus. In addition, a GABAergic mechanism appears to be involved in the hypothalamic modulation of the baroreceptor reflex.

Supported by NIH grant #HL38433 and the American Heart Association.

CARDIOVASCULAR REGULATION: CNS PATHWAYS I

79.1 FUNCTIONAL RELATIONSHIP BETWEEN CARDIOVASCULAR AREAS IN THE MEDULLA.
R. Urbanski and H.N. Sapru, Dept. of Pharmacology and Section of Neurosurgery, Univ. of Med. & Dent. of NJ-New Jersey Med. School, Newark, NJ 07103.

In the medulla three areas with cardiovascular function have been identified. These are: the nucleus tractus solitarius (NTS), the ventrolateral medullary pressor (VLPA) and the ventrolateral medullary depressor area (VLDA). Anatomic interconnections between the NTS and the VLDA and VLPA have been demonstrated. Interconnections between the intermediolateral cell column of the thoraco-lumbar cord (IML) and the VLPA and the NTS have also been identified. However, the role of these projections has not been clearly established. In this investigation, a pharmacological approach was used to study the importance of these anatomic pathways in cardiovascular regulation. Urethane anesthetized male Wistar rats (n=30) were used. The NTS, VLPA and VLDA were identified bilaterally with microinjections of L-glutamate (L-glu; 1.77 nmole/site). Unilateral microinjections of L-glu into the NTS evoked a fall in BP (32.5 ±2.8 mmHg) and HR (42±6 bpm). Unilateral microinjections of muscimol (90 pmole) or lidocaine (8.5 nmole) into the VLPA or VLDA blocked the L-glu response from the ipsilateral (but not contralateral) NTS. A higher dose of L-glu (5 nmole) into the NTS evoked a rise (instead of a fall) in BP when the ipsilateral VLDA was inhibited with muscimol. Depressor responses to this dose of L-glu persisted in the contralateral NTS. These results suggest that the pathways: (i) from the NTS to the VLDA mediate hypotensive responses, (ii) from the NTS to the VLPA mediate hypertensive responses, (iii) from the NTS to the IML may not be involved in cardiovascular regulation.

Support: NIH (HL24347) and AHA (NJ).

79.2 CARDIOVASCULAR ACTIONS OF CHOLINERGIC AGENTS IN THE DEPRESSOR AREA OF THE VENTROLATERAL MEDULLA: ROLE OF M_2 MUSCARINIC RECEPTORS. H.N. Sapru, A.J. Krieger* and K. Sundaram*. Neurosurgery & Pharmacology, UMDNJ - New Jersey Medical School, Newark, NJ 07103.

The depressor area in the ventrolateral medulla (VLDA) plays an important role in cardiovascular regulation. The role of cholinergic agents in this area has not been studied. This investigation was designed to study the cardiovascular actions of the following muscarinic agonists and antagonists in this area. Agonists used: cis-methyldioxolane (a specific agonist of M_2 receptors), McN A343 (a specific agonist of M_1 receptors), carbachol (non-specific agonist) and physostigmine (elevates the levels of endogenous acetylcholine). Antagonists used: AFDX 116 (a specific M_2 muscarinic receptor antagonist), pirenzipine (a specific antagonist of M_1 receptors), atropine (non-specific antagonist). The doses of agonists and antagonists varied between 0.004-4 nmole/site. Male Wistar rats (n=40) were anesthetized with pentobarbital or decerebrated at mid-collicular level. Blood pressure (BP), splanchnic nerve activity (SNA) and heart rate (HR) were recorded. The rats were artificially ventilated. Ventral medulla was exposed and VLDA identified bilaterally by microinjections of L-glutamate (1.77 nmole/site). Microinjections of cis-methyldioxolane into the VLDA evoked a decrease in BP, SNA and HR which lasted for 20-30 min. Intravenous injections of the same doses of this agent failed to evoke a response. Preliminary experiments indicate that microinjections of AFDX 116 into the VLDA do not evoke any response. However, these injections of AFDX 116 blocked as well as prevented the depressor responses evoked by cis-methyldioxolane. Microinjections of McN A343 or pirenzipine into the VLDA failed to evoke any response. These results indicate that the depressor and bradycardic responses evoked by cholinergic agonists in the VLDA are mediated via the M_2 receptors.

Support: N.I.H (HL 24347) and American Heart Assoc. (NJ).

79.3 M_2 MUSCARINIC RECEPTORS MEDIATE PRESSOR RESPONSES TO CHOLINERGIC AGONISTS IN THE VENTROLATERAL MEDULLARY PRESSOR AREA. K. Sundaram* and H.N. Sapru (SPON: R. Howland). Neurosurgery & Pharmacology, UMDNJ - New Jersey Medical School, Newark, NJ 07103.

Microinjections of cholinergic agonists into the ventrolateral medullary pressor area (VLPA) evoke increase in blood pressure (BP) and heart rate (HR). Recently two major subtypes of muscarinic receptors have been identified. This investigation was designed to study the role of these muscarinic receptor subtypes in pressor responses of cholinergic agonists in the VLPA. Male Wistar rats (n=30) were anesthetized with pentobarbital or decerebrated at mid-collicular level. BP, splanchnic nerve activity (SNA) and HR were recorded. The rats were artificially ventilated. Ventral medulla was exposed and VLPA identified bilaterally by microinjections of L-glutamate (1.77 nmole/site). Microinjections of cis-methyldioxolane (a specific agonist of M_2 receptors) in the doses of 0.004-4 nmole/site into the VLPA evoked increase in BP, SNA and HR which lasted for 20-30 min. Intravenous injections of the same doses of this agent failed to evoke a response. Microinjections of AFDX 116 (a specific M_2 muscarinic receptor antagonist) into the VLPA in the doses of 0.2-4 nmole/site evoked depressor responses. The depressor responses lasted for 15-20 min. These injections of AFDX 116 blocked as well as prevented the pressor responses of cis-methyldioxolane. Microinjections of AFDX 116 into the VLPA blocked the pressor responses to intravenously administered physostigmine. Microinjections of McN A343 (a specific agonist of M_1 receptors) or pirenzipine (a specific antagonist of M_1 receptors) in the doses Of 0.4-4 nmole/site into the VLPA failed to evoke any response. Microinjections of pirenzipine into the VLPA did not alter the pressor responses to intravenously administered physostigmine. These results indicate that the pressor and tachycardic responses evoked by cholinergic agonists in the VLPA are mediated via the M_2 receptors which may be under tonic excitatory cholinergic control because AFDX 116 caused a fall in BP and HR when microinjected at this site.

Support: N.I.H (HL 24347) and American Heart Assoc. (NJ).

79.4 ORTHOSTATIC AND HYPOXIC CHALLENGE DEFICITS FOLLOWING ROSTROVENTROLATERAL MEDULLARY LESIONS IN DOGS. K.J. Dormer, M.F. Wilson*, S.R. Ashlock* and D.J. Brackett*. Dept. Physiology and Biophysics and V.A. Medical Ctr., Okla. City, OK 73190.

In a continuing effort to evaluate the physiological role in conscious dogs of the subretrofacial region of epinephrine-containing cells in the rostroventrolateral medulla (C_1 area or nucleus reticularis rostroventrolateralis or RVL) we have presented various challenges to the conscious dog that elicit sympathoexcitatory responses (Fed. Proc. 46(3):676, 1987). If this putative vasomotor center, RVL, is universally important in cardiovascular control then any challenge should be affected following cytotoxic lesions. Thus, conscious dogs were instrumented to measure cardiac output (CO) and volumetric aortic blood flow (Transonic Systems, Inc.), aortic pressure (AP) and heart rate (HR, Konigsberg Inst.) and various peripheral blood flows using 20 MHz pulsed-Doppler. Orthostatic challenge was given using a supported tilt table from supine to 75° head-up tilt. Hypoxia (10% O_2 in N_2) was also administered through a mask assembly alternating with room air. Plasma catecholamines were also measured during quiet laboratory conditions. Experiments were conducted before and after small partial, unilateral 100 nl kainic acid lesions were made in the RVL. Histological verification of lesion sites showed that the analogous RVL area in the dog was injected. No changes in motor performance or behavior was noticed. The reduction in plasma catecholamines (n=4 dogs) as shown below in pg/ml of plasma

was consistant with the lowered resting AP during rest (108 ± 12 vs 94 ± 9 pre/post) and in response to 75° tilt (increasing 16 ± 2 vs 14 ± 13 over resting values). Heart rate and CO both increased at rest post lesion but in response to 75° tilt the HR response was reduced (68 ± 23 vs 45 ± 3) while the CO increased (0.3 ± .6 vs 0.8 ± 0.9). This apparent decrease in peripheral resistance and afterload can attribute to the increased CO that is seen during tilting and exercise as shown in earlier studies. The CNS ischemic response to 10% O_2 elevated HR, AP and CO in 3/3 dogs but these responses were all reduced 10-50% following unilateral lesions. These data suggest that the RVL is involved in vasomotor control and that small, incomplete, cytotoxic lesions can produce small changes in responses to cardiovascular stressors in conscious dogs. Thus, we support anatomical and neurophysiological data of others which suggest RVL is a brainstem vasomotor center. Supported by Presbyterian Health Foundation and V.A. Research Service.

79.5 CHARACTERIZATION OF CARDIOVASCULAR AND RESPIRATORY ACTIVITY IN THE CAUDAL VENTROLATERAL MEDULLA A.C.Bonham, J.Jeske, and D.O.Nelson, Dept. of Physiology, Northwestern Univ. Medical School, Chicago, IL 60611

The caudal ventrolateral medulla (CVLM) contains the ventral respiratory group (VRG); vagal preganglionic motor neurons; and neurons, including the A_1 cell group thought to be part of the central baroreflex circuitry and/or to provide tonic inhibitory input to the rostral VLM. Previous studies have shown that electrical or chemical stimulation in CVLM decreases arterial pressure (AP) and heart rate (HR); however, with the exception of one study in cats (McCrimmon et al., 1986), the region has not been systematically mapped for respiratory and cardiovascular effects. Accordingly, the first objective was to determine whether nanoliter injections of the excitatory amino acid agonist, DL-homocysteine (DLH, 20mM, pH7.4) produce selective effects on AP, HR or respiration. AP, HR, and diaphragm EMG were recorded in urethane-anesthetized rats. The mapped region extended 1mm rostral to 2mm caudal to calamus scriptorius, 1.5-2mm lateral to midline, and 1.5mm ventral to the dorsal surface of the brainstem to the base. Injections (3-20nl) were made via glass pipettes (10-20µm O.D) connected to a pressure injection system. Just medial to nucleus ambiguus, 1.8-2.4mm ventral to the dorsal surface and 1.5-1.8mm lateral to midline, DLH (20nl) decreased the amplitude and frequency of diaphragm EMG discharge with no effect on HR or AP. Lateral (0.2mm) to this site, from 1.5-2.2mm ventral to the dorsal surface, DLH produced a bradycardia (60±20bpm) that was blocked by iv atropine. When the pipette was displaced 0.2mm ventrally, DLH (3-15nl) decreased AP (10-40mmHg). In some cases, the depressor response was accompanied by a bradycardia (30-60bpm); however, the decrease in AP was not changed following prevention of the bradycardia with iv atropine.

To characterize neurons potentially involved in baroreflex function, the DLH-identifed depressor regions were explored using extracellular recording for units which were sensitive to changes in AP. AP was slowly raised or lowered, respectively, by graded infusions of phenylephrine or nitroprusside. In the ambiguual region in which DLH depressed diaphragm EMG, neurons were recorded which discharged with respiratory periodicity and were presumably part of the VRG. Approximately 0.5mm ventrolateral to the respiratory activity, in the region in which DLH decreased AP, neurons with various arterial pressure-activity profiles were identified: (1) spontaneously discharging neurons characterized by decreases in activity as AP increased and silence at AP 130-150mmHg. In some, but not all cases, unit activity was increased when AP was reduced to 50-60mmHg, (2) spontaneously firing units with discharges than increased when AP increased to 110-130mmHg and decreased when AP was lowered to 60mmHg, and (3) units which were silent at resting AP (85-110mmHg), but discharged when AP was lowered to 50-60mmHg. These results suggest that while excitation of cell bodies in CVLM decreases AP, indicating activation or facilitation of baroreflex inhibition of sympathetic outflow, the region contains neurons which are inhibited and excited by increases in AP. (HL 29033, NS 23423, and HS 07243).

79.6 NORMOTENSION IN CONSCIOUS RATS AFTER LESION OF ROSTRAL VENTROLATERAL MEDULLA (RVLM). K.L. Cochrane*, R.A. Buchholz and M.A. Nathan (SPON: L.P. Felpel). Dept. of Pharmacology, The University of Texas Health Science Center, San Antonio, TX 78284-7764

Bilateral electrolytic lesions of the RVLM causes hypotension in rats anesthetized with urethane but not in rats anesthetized with chloralose or pentobarbital (Fed. Proc. 45:293, 1986). This study extends those observations to conscious rats tested at 1 and 5 days after lesion of the RVLM. Captopril (5 mg/kg, iv) and chlorisondamine (1 mg/kg, iv) were used to assess the contribution of angiotension II and the sympathetic nervous system to the maintenance of mean arterial pressure (MAP) and heart rate (HR). Baroreflex sensitivity (BRS), defined as the slope of the inter-beat interval as a function of the change in systolic arterial pressure after phenylephrine (PE, 3 µg/kg, iv) or acetylcholine (ACh, 1 µg/kg, iv) was also assessed.

Cardiovascular Values - One Day Post Lesion

Group		Baseline MAP	Baseline HR	Captopril MAP	Captopril HR	Chlorisondamine MAP	Chlorisondamine HR
Lesion,	n=7	111±2	393±17	93±2*‡	400±26	54±2*	360±10*
Control,	n=18	117±3	405±11	107±4*	434±10*	56±2*	367±6*

Cardiovascular Values - Five Days Post Lesion

Group		Baseline MAP	Baseline HR	Captopril MAP	Captopril HR	Chlorisondamine MAP	Chlorisondamine HR
Lesion,	n=8	105±3	362±10	96±3*	378±14*	58±3*	290±7*

Control,	n=13	.37±.04	1.26±.23	.51±.05#	1.07±.15

*p≤.05 from previous value; ‡p≤.05 versus control; #p≤.05 versus one day value; MAP=mmHg±SE; HR=bpm±SE; BRS=msec/mmHg

No differences were found between the groups during the baseline period or after chlorisondamine on postlesion days 1 and 5 and after captopril on postlesion day 5. However, MAP after captopril fell to a lower value in the lesion group as compared to the control group on postlesion day 1. The reduction in MAP after captopril 1 day postlesion was associated with an increased HR in the control group but not in the lesion group. The BRS to PE was similar in the lesion and control groups at 1 and 5 days postlesion. In contrast, BRS after ACh was abolished at 1 day and depressed at 5 days postlesion in the lesion group. These observations suggest that vasomotor and cardiomotor tone is unaffected by lesions of the RVLM and that, in the absence of the RVLM, other areas of the brain can maintain MAP and HR at normal values. (Supported by HL35635).

79.7 CATECHOLAMINERGIC METABOLISM RECORDED IN THE ROSTRAL VENTROLATERAL MEDULLA OBLONGATA DURING HEMODYNAMIC VARIATIONS IN ANESTHETIZED RATS. J.Y.Gillon*, L.Quintin, I.Colin*, B.Renaud and J.F.Pujol*. Lab.de Neuropharmacologie,UA CNRS 1196, Faculté de Pharmacie and Lab.de Neuropharmacologie Moléculaire, Faculté de Médecine Alexis Carrel, Université Claude Bernard,Lyon, France.

In vivo voltammetry using carbon fibre electrodes allows to record catecholaminergic (CA) metabolism in several dopaminergic and noradrenergic areas in the brain.By using this technique, we sought to determine if it was possible to detect an electrochemical signal in the C1 group of adrenergic cell bodies, a group wich lies in the rostral ventrolateral part of the medulla oblongata.In this region, a small electrochemical peak was recorded at +55 mV,a value which corresponds to the oxidation potential of 3,4 dihydroxyphenylacetic acid (DOPAC) in vitro.The site of electrochemical recording was always in the area where the adrenergic cell bodies are located, as evidenced after the end of experiments on sections of medulla incubated with antibodies against phenylethano-lamine-N-methyltransferase and revealed with peroxydase-antiperoxydase complex.Moreover, pharmacological characterizations showed that i)the tyrosine-hydroxylase inhibitor α-methylparatyrosine (αMPT,250 mg.kg^{-1} ip) suppressed totally this peak ii) the dopamine-ß-hydroxylase inhibitor FLA-63 (30 mg.kg^{-1} ip) produced a marked increase of the peak height and iii) the monoamine-oxydase inhibitor pargyline (75 mg.kg^{-1}) had an effect similar to αMPT.These results indicate that the most important contributor to the electrochemical signal should be DOPAC.Finally, the modifications of the oxidation peak were studied during hemodynamic variations induced in the circulatory system of anesthetized, ventilated and paralyzed rats. Major hemorrhage, maintained 30 min, induced a fall in arterial pressure below 50 mmHg and a marked increase in CA peak height. The same pattern of results was observed when the vasodilator sodium nitroprusside was infused. These results suggest that in vivo voltammetry combined with carbon fibre electrode could be a usefull technique to monitor the CA metabolic activity of the cardiovascular neurons of the C1 group.

79.8 **CATECHOLAMINERGIC NEURONS IN THE HUMAN ROSTRAL VENTROLATERAL MEDULLA.** *J.L. Callaway*, V. Arango, D.A. Ruggiero, M. Anwar*, J.J. Mann and D.J. Reis.* Div. of Neurobiology and Lab. of Psychopharmacology, Cornell Univ. Med. Coll., New York, N.Y. 10021.

Adrenergic neurons in the C1 area of the rostral ventrolateral medulla (RVL),are of importance due to their presumed role in the tonic regulation of arterial pressure, baroreceptor reflex and the chemosensitivity associated with the ventral medullary surface. The connections of these neurons have been studied primarily in the rat, cat and non-human primate, whereas little is known about them in the human brain. As a first step in analyzing the functional biochemical anatomy of catecholamine (CA)-neurons in the human, we used antisera against tyrosine hydroxylase (TH) and phenylethanolamine N-methyltransferase (PNMT) to localize medullary CA-containing neurons and processes, focusing on the C1 area of RVL. Samples from 3 neuropathologically normal human brains (< 9 hr postmortem) were collected at autopsy, fixed, sectioned frozen (-18°C) at 35 µm and incubated with antisera to TH and PNMT using a modification of the peroxidase-antiperoxidase method.

Cells staining for TH were located throughout the ventrolateral medulla (VLM). The majority of cells staining for TH and PNMT, and therefore adrenergic, occured in the RVL. Axons of TH-immunoreactive neurons in the RVL projected: 1) dorsally in a series of parallel trajectories towards the dorsomedial reticular formation and the nucleus of the solitary tract (NTS) and vagal complex, 2) longitudinally as fascicles running parallel to the neuraxis 3) ventrolaterally towards the ventral surface (VS) of the RVL where they terminated, and 4) medially into the raphe, where they arborized. Similar systems of fibers were labeled for PNMT; the longitudinal bundles were limited to the principal tegmental bundle and concentrated dorsally. Fibers containing PNMT were also identified in the medullary raphe and on the medullary VS. TH- and PNMT-labeled processes were observed making close contacts with blood vessels. In the dorsomedial medulla, neurons exhibited immunoreactivity to both TH and PNMT. In the NTS three principal subgroups of TH immunoreactive neurons were seen: a ventromedial, intermediate and dorsal group. Perikarya containing PNMT were restricted to the dorsolateral aspect of the NTS. TH- and PNMT-immunoreactive processes were identified in the medial and dorsolateral NTS; others appeared to project from NTS toward VLM. Immunoreactive fibers were observed within the solitary tract suggesting that axons of CA neurons in brain project peripherally, or that primary visceral afferents employ CAs as their neurotransmitters in the human.

We established several homologies between human and other species: a) we confirmed that the C1 area of RVL and a dorsolateral C2 segment of NTS harbor perikarya containing both TH and PNMT which are probably adrenergic. TH neurons in the caudal VLM (A1 area) and the other NTS subgroups of the A2 area do not contain PNMT and are probably noradrenergic. b) Processes containing both enzymes formed a pathway in the dorsal tegmentum equivalent to the C1-spinal tract seen in other species. c) The above pathway, and the presence of fibers of RVL interconnecting with NTS, raphe, intraparenchymal microvessels and the ventral surface suggest that the autonomic and chemoreceptor functions attributed to the C1 area also may apply to the human.

79.9 **ANTIBODIES TO A *p*-AMINOCLONIDINE CONJUGATE AS PROBES FOR IMIDAZOLE AND α_2-ADRENERGIC RECEPTOR BINDING SITES: IMPLICATIONS FOR THE STRUCTURE OF CLONIDINE-DISPLACING SUBSTANCE.** *M.P. Meeley, P. Ernsberger, P.M. McCauley*, A.C. Towle and D.J. Reis* Div. of Neurobiology, Cornell Univ. Med. Coll., New York, NY 10021.

Clonidine interacts potently with both imidazole binding sites and α_2-adrenergic receptors in brain (Ernsberger et al., *Eur. J. Pharmacol. 134*: 1, 1987). An endogenous clonidine-displacing substance (CDS) also binds to both receptor types, with a 30-fold greater selectivity for imidazole sites (Ernsberger et al., *J. Hypertension 4 (Suppl.5)*: S109, 1986). Anti-drug antibodies have been used successfully as probes for specific recognition sites of receptor proteins. Recently, we have raised polyclonal antibodies to a conjugate of the clonidine analog *p*-aminoclonidine (PAC) (Meeley et al., *Soc. Neurosci. Abstr. 12*: 963, 1986). We sought to (a) determine the specificity of the binding of clonidine-related ligands to anti-PAC antibodies, relative to the specificities of imidazole and α_2-adrenergic receptors; and (b) examine the specific recognition by anti-PACs of endogenous CDS, the structure of which is unknown.

Polyclonal antibodies were raised in rats (anti-PAC_1) and in rabbits (anti-PAC_2) immunized with PAC coupled to hemocyanin as described previously (Meeley et al., *op. cit.*). The ligand specificity of binding to anti-PACs was examined using a competitive radioimmunoassay with ^{3}H-PAC (1nM) as the radioligand. Binding to both anti-PAC_1 and $_2$ was specific. Compounds shown to bind with high affinity to either (a) imidazole sites, such as the imidazoles cimetidine, histamine, and imidazole-4-acetic acid; (b) α_2-adrenergic receptors, such as the phenylethylamines norepinephrine and epinephrine; or (c) both receptor sites, such as idazoxan and phentolamine, tyramine, 1-benzylimidazole, and yohimbine, did not cross-react with anti-PAC antibodies. Only those agents which bind to both receptor sites, and which contain phenyl, as well as imidazol(in)e, ring moieties in their structures, competed for binding to specific antibody recognition sites, as indicated by their anti-PAC_1 IC_{50} values (nM): PAC (3.7 ± 0.5), clonidine (4.8 ± 1.0), oxymetazoline (3,400 ± 1,200), naphazoline (28,000 ± 14,000), tolazoline (110,000 ± 20,000) (n=4–24).

CDS, partially-purified from bovine brain (Meeley et al., *Life Sci. 38*: 1119, 1986), also inhibited specific ^{3}H-PAC binding to anti-PAC antibodies. The inhibition was dose-dependent (IC_{50}, 4.2 ± 0.2 Units, n=4); complete inhibition was obtained with 10 Units of CDS. Scatchard analysis of saturation binding data for ^{3}H-PAC in the presence of 3 Units of CDS showed that it had no effect on the apparent affinity of anti-PAC_2 for the radioligand (control: K_D, 0.45 ± .03 nM; with CDS: K_D, 0.44 ± .04 nM). However, a significant number of anti-PAC binding sites was blocked by CDS (control: B_{max}, 187 ± 10 nmol/mg IgG; with CDS: B_{max}, 130 ± 9 nmol/mg IgG). Immunoprecipitation experiments carried out by incubating increasing dilutions (1:100–1:100,000) of anti-PAC_2 with 2 Units of CDS showed that authentic CDS, i.e., that which displaces ^{3}H-PAC binding in a radioreceptor assay, is the same substance which is recognized by anti-PAC antibodies.

We conclude that (a) chemical determinants, critical for binding to anti-PAC antibodies, constitute a unique sub-set of structural requirements for interaction with both imidazole and α_2-adrenergic receptor sites; and (b) CDS may share structural elements with clonidine and related compounds since anti-PAC antibodies also recognize the endogenous substance.

79.10 ELECTRON MICROSCOPIC EVIDENCE THAT CELLS IN THE NUCLEUS TRACTUS SOLITARIUS PROJECT TO THE C1 EPINEPHRINE CELL GROUP. J. R. Carithers and D. P. Baker. Dept. of Veterinary Anatomy, Iowa State University, Ames, IA 50011

Abundant evidence indicates that epinephrine producing cells in the rostral ventrolateral medulla (the C1 cell group) project to the intermediolateral cell column of the spinal cord and are involved in maintenance of cardiovascular sympathetic tone. The cardiovascular region of the nucleus tractus solitarius (NTS), the primary center for termination of baroreceptor afferent fibers, has been shown by light microscopic studies to project to the region of the C1 cells. It has been suggested that this projection from NTS to the rostral ventrolateral medulla is responsible for baroreflex inhibition of vasomotor tone.

This investigation was undertaken to determine if fibers from the NTS synapse directly on C1 cells. A craniotomy was performed on ten rats under ketamine anesthesia, and 20 nl of 2% horseradish peroxidase (HRP) was injected slowly into the cardiovascular portion of the left NTS. The animals were killed after 24 hours. HRP reaction product was developed using DAB as the chromogen, and the tissues were processed for electron microscopy. C1 cells were positively identified by the presence of phenylethanolamine-N-methyltransferase immunoreactivity at the electron microscopic level using colloidal gold.

Colloidal gold was localized in the cytoplasm of C1 cells in the rostral ventrolateral medulla. Terminals containing HRP reaction product synapsed upon neuronal somas and dendritic processes containing colloidal gold. These results demonstrate at the electron microscopic level that cells in the area of the NTS project directly to C1 cells. This projection may be a connection by which stimulation of the baroreceptors causes inhibition of the medullary vasomotor center.

Supported in part by USDA PL95-1113 Section 1433 and NIH HL-14388.

79.11 PROJECTIONS FROM THE NUCLEUS OF THE SOLITARY TRACT (NTS) ONTO PNMT-IMMUNOREACTIVE CELLS IN THE VENTRAL MEDULLA OF THE RAT. M.B. Hancock* (SPON: J. Kitay). Department of Anatomy and Neurosciences, The University of Texas Medical Branch, Galveston, Texas 77550.

Phaseolus vulgaris-leucoagglutinin (PHA-L) was iontophoretically deposited (Gerfen, C.R. and P.E. Sawchenko, Brain Res., 290:219, 1984), into the nucleus of the solitary tract (NTS) of Sprague-Dawley rats anesthetized with Nembutal and urethane. Following survival times of 4-12 days, the rats were deeply anesthetized and perfused transcardially with 4% paraformaldehyde, the brains were removed, and sectioned (30 μm) on a Vibratome. The sections were stained first for PHA-L-immunoreactive (PHA-LI) elements with the PAP technique and nickel-intensified diaminobenzidine (Ni/DAB). Black-stained, PHA-LI cells and processes were present in NTS, and PHA-LI fibers could be traced into the ventrolateral medulla. The medullary sections were then immunostained for phenylethanolamine N-methyl transferase (PNMTI) with the PAP method and DAB alone. PNMT-immunoreactive (PNMTI) cells were stained amber. Black-stained PHA-LI terminal fields were present amongst amber-stained, PNMTI cells in the ventrolateral medulla. Varicose, PHA-LI fibers were observed coursing along the surface of PNMTI dendrites, and PHA-LI processes were seen on the somata of PNMTI cells.

These observations indicate that neurons in the solitary nucleus may have direct effects on adrenaline cells in the ventrolateral medulla. Adrenaline cells in the ventrolateral medulla have been linked to tonic vasomotor activity (Ross, C.A., et al., J. Neurosci. 4:474, 1984), and the close anatomical association between fibers originating in NTS and PNMTI cells in the ventral medulla suggests a direct functional relationship between these elements that may have a role in cardiovascular regulation.

79.12 AN IN VITRO SLICE PREPARATION OF THE CANINE DORSOMEDIAL MEDULLA FOR ELECTROPHYSIOLOGICAL INVESTIGATION OF AUTONOMIC NUCLEI. W.D. Knowles, K.L. Barnes and C.M. Ferrario. Departments of Brain and Vascular Research and Neurology, The Research Institute of The Cleveland Clinic Foundation, Cleveland OH 44106.

We have developed an in vitro slice preparation of the canine dorsomedial medulla which is appropriate for extracellular and intracellular electrophysiological investigations of the autonomic nuclei in this region. The preparation allows stable intracellular penetrations of the larger neurons and stable extracellular recordings with excellent signal to noise ratio. The stability of the preparation allows applications of exogenous substances while maintaining the recordings. It is thus possible to make direct measurements of the effects of neuromodulators and receptor blockers on neural activity.

Dogs (8-12 kg mongrels) are anesthetized with halothane, loose ligatures are placed around the vertebral and carotid arteries, and the dorsal medulla is exposed. Anesthesia is tapered as tolerated during the later portion of the surgery. The medulla is cooled with ice-cold oxygenated physiological saline, and the neck arteries are tightly ligated. The brainstem is transected through the caudal pons and about 5 mm posterior to the obex and removed. After the pia and arachnoid are stripped, the dorsomedial medulla is blocked and then cut with a vibrating slicer into 400 μm thick horizontal sections while submerged in cold (3°-4°C) physiological saline. The sections are then placed in an interface type slice chamber at 36°C. The elapsed time from ligation of the arteries to placing the slices in the chamber is approximately 7 to 8 minutes. The slices are allowed to recover for one hour before recording.

Standard in vitro electrophysiological techniques are used to record neural activity for as long as 6 hours after slice preparation. Intracellular penetrations of good quality and long duration (30-60 minutes) are obtained from large neurons. Extracellular recordings with excellent signal to noise ratio (> 10:1) and long duration (> 45 minutes) are routinely obtained from the smaller neurons of the nucleus tractus solitarii and surrounding regions. Extracellular micropipettes are filled with 0.9% NaCl saturated with Fast Green dye, which is iontophoretically ejected to mark recording sites. We routinely apply exogenous substances in microdroplets on the surface of the slice while maintaining recordings. Our accompanying presentation (Barnes et al, this volume) shows the results of angiotensin peptides applied to nucleus tractus solitarii neurons. (Supported in part by NIHLBI grant HL-6385 and the Reinberger Foundation).

79.13 EFFECTS OF ANGIOTENSIN PEPTIDES ON SINGLE NEURONS RECORDED FROM AN IN VITRO PREPARATION OF THE CANINE DORSOMEDIAL MEDULLA. K.L. Barnes, W.D. Knowles, and C.M. Ferrario. Departments of Brain and Vascular Research and Neurology, The Research Institute of The Cleveland Clinic Foundation, Cleveland, OH, 44106.

We have previously obtained substantial physiological evidence that the area postrema (ap) and nucleus tractus solitarii (nTS) in the dorsomedial medulla (DMM) of the dog normally function as reciprocally counterbalanced influences on sympathetic vasomotor outflow. Chronic studies in conscious animals have also confirmed our hypothesis that removal or excessive activation of either structure may lead to dysregulation of arterial blood pressure. Recently, Averill et al. [Brain Res., 1987 (In press)] showed that microinjection of pmol doses of angiotensin II (Ang II) into the medial nTS of the dog causes pressor effects and tachycardia. In addition, we have localized within the canine ap, nTS, and dorsal motor nucleus of the vagus (dmnX) a discrete pattern of high affinity Ang II binding sites which is dependent on intact vagal innervation of the DMM (Diz et al., Brain Res Bull 17: 497-505, 1986). These findings have now led us to investigate directly the effects of Ang II on single neurons in an in vitro slice preparation of the canine medulla which we have developed.

Stable extracellular recordings were obtained from neurons in 400 μm thick horizontal slices of the DMM (for details, see W.D. Knowles et al., this volume). In 15 neurons located in or adjacent to the medial nTS (identified by Fast Green dye marks), the effects of microdrop application of either Ang II (8 pmol/μl) or artificial cerebrospinal fluid (aCSF) onto the surface of the slice surrounding the recording electrode were examined. The neurons were generally unresponsive to aCSF applied to the brain slice. Application of Ang II substantially increased the firing rate of 8 of the 15 neurons studied. The other 7 neurons were not responsive to Ang II. In most cases, the firing rate increased steadily to a peak at 1-2 min following Ang II application to the slice, then returned slowly to base line over the next 5-10 min. In 4 of the 15 neurons, the effects of both Ang II and its analogue [Sar^1,Thr^8] Ang II were tested. [Sar^1,Thr^8] Ang II produced a rapid onset, brief excitation in 3 of the 4 neurons. These 3 neurons were also excited by Ang II. Administration of [Sar^1,Thr^8] Ang II blocked the excitatory response to subsequent administration of Ang II in these 3 responsive cells. The remaining cell did not respond to application of either Ang peptide.

These experiments have begun to map the Ang II-responsive neural substrate for the cardiovascular actions of this peptide in the canine DMM. (Supported in part by NIHLBI grant HL-6835 and the Reinberger Foundation).

79.14 ORIGIN OF ATRIAL NATRIURETIC PEPTIDE-IMMUNOREACTIVE INNERVATION OF THE NUCLEUS OF THE SOLITARY TRACT IN THE RAT. K.M. Hurley, D.G. Standaert and C.B. Saper, Depts. of Pharm. & Physiol. and Neurol., University of Chicago, Chicago, IL 60637 and Dept. of Pharm., Washington Univ. Sch. Med., St. Louis, MO 63110.

Atriopeptin (AP), the atrial natriuretic peptide, is a 28 amino acid circulating hormone that is secreted by the atria of the heart, resulting in natriuresis, diuresis and vasodilatation. We recently described the distribution of AP-immunoreactive (APir) cell bodies and fibers in the rat brain, including the heavy APir innervation of the medial and commissural parts of the nucleus of the solitary tract (NTS) and the dorsal motor vagal nucleus (DMX). These areas have been associated with cardiovascular regulation, suggesting that AP may serve as a central neurotransmitter in this system. However, the origin of this APir innervation has not been established.

We therefore injected the dorsal vagal complex (DVC) in a series of rats with Fast Blue (2%) dye, 50-80 nl, and one week later treated them with 150 μg of colchicine, i.c.v. Thirty-six to forty hours later, the animals were pefused with 4% paraformaldehyde and sections through the brain and vagal ganglia were stained by an immunofluorescence method for AP. The injection sites were large, and included portions of the adjacent dorsal column nuclei, reticular formation and hypoglossal nucleus.

A relatively small number of double-labeled neurons was observed in the brain, mostly in the parvocellular part of the paraventricular nucleus of the hypothalamus and in the retrochiasmatic area. Other double-labeled cells were found in the laterodorsal and pedunculopontine tegmental nuclei; these cell groups project to the areas adjacent to, but not including, the DVC. No APir cell bodies were found in the vagal ganglia, and removing these ganglia did not effect the APir innervation of the DVC. Our technique did not allow us to determine whether intrinsic neurons within NTS contribute to the APir fiber innervation of the nucleus. However, the only extrinsic source of this innervation that we could identify consists of a small number of APir neurons in the hypothalamus.

Our results suggest that AP may serve as a neurotransmitter that subserves hypothalamic modulation of cardiovascular afferent transmission in the NTS.

79.15 CARDIOVASCULAR RESPONSES MEDIATED BY THE RELEASE OF GLYCINE INTO THE NUCLEUS TRACTUS SOLITARIUS OF RAT. S.C. Robertson* and W.T. Talman. (SPON: H. Damasio). Department of Neurology, VA Medical Center and University of Iowa, Iowa City, Iowa 52242.

The inhibitory amino acid glycine, found in high concentrations in the nucleus tractus solitarius (NTS) is released from the neurotransmitter pool into the NTS and is inactivated by high affinity uptake mechanisms. We sought to determine the role of glycine in the regulation of arterial pressure and heart rate by the medial subnucleus of the NTS. Thirty-eight adult male Sprague Dawley rats were anesthetized and instrumented for recording intra-arterial pressure, the administration of intravenous drugs, and the stereotaxic placement of microinjections into the brain stem. Glass micropipettes filled with artificial CSF as a control vehicle or with glycine, strychnine, or glutamate were positioned in the medial subnucleus of NTS and 25 nl injections were made into that nucleus. The site of all injections, marked by a vital stain, was confirmed postmortem. Glycine, like glutamate, an excitatory amino acid, elicited immediate dose-related hypotension and bradycardia. The threshold dose was 2 nmols and the maximally effective dose was 10 nmols. The maximal effect was a fall of mean arterial pressure of 35.5 ± 8.0 mmHg (mean ± SEM) from a baseline of 83.7 ± 12.5 mmHg and a fall of heart rate of 32.9 ± 16.0 bpm from a baseline of 324.7 ± 37.6 bpm. Strychnine, 67 pmols, completely blocked the cardiovascular responses of the maximally effective dose of glycine but when injected bilaterally into the NTS did not alter baroreflex mediated reflex bradycardia elicited by pressor doses of phenylephrine given intravenously. The hypotensive and bradycardic responses to glycine were highly localized to the dorsal medial subnucleus of the NTS and did not occur with injections outside the NTS. As previously reported, injections ventral to the NTS caused hypertension and tachycardia. When low doses of glycine (4 nmols) were injected prior to the injection of glutamate (250 pmols)into the same site, the excitatory response of glutamate was significantly attenuated or abolished. These data suggest that glycinergic mechanisms in the NTS may play an important role in central cardiovascular regulation. The responses to glycine are distinctly different from GABA, another inhibitory amino acid, and may be mediated through different reflex pathways. 79.16 INTRAPARENCHYMAL DISTRIBUTION OF OPIOIDS INJECTED INTO RAT DORSAL VAGAL COMPLEX J.W. Nemitz and A.H. Hassen, Depts. Anat. and Physiol., WVSOM, Lewisburg, W.Va. 24901.

The microinjection of a mu opioid receptor agonist into the rat hindbrain has been shown to elicit different cardiovascular responses depending upon the site of injection. In the present experiments we have used autoradiographic techniques to examine the distribution of a labelled (H^3) mu-agonist, D-Ala^2, $MePhe^4$, Gly-ol^5 enkephalin (DAGO, Amersham) after microinjection into the dorsal vagal complex (DVC) of anesthetized rats.

Experiments were conducted on male Sprague-Dawley rats anesthetized with urethane (1.6 g/kg, i.p., plus supplemental doses as needed), intubated, placed in a Kopf stereotaxic frame and ventilated with a mixture of air and O_2. A partial craniotomy was performed to allow a glass micropipette (OD = 28um), containing the H^3-DAGO (.3 nmol in 10 nl), to be inserted into the DVC. The H^3-DAGO was microinjected using a General Valve Corp. Picospritzer II. Continuous recording of systolic and diastolic blood pressure, mean arterial pressure, and heart rate was made throughout the experiment. The animals were sacrificed with an overdose of pentobarbital, the brain stems removed and frozen on dry ice. Serial frozen sections (20 um thick) were cut on a cryostat, mounted on subbed glass slides, dipped in photographic emulsion (Kodak NB-2), stored in lightproof boxes and developed after an exposure period of 2 - 6 weeks. Developed slides were analyzed for distribution of injected label.

Dense labelling in the DVC was observed after microinjection of H^3-DAGO into the nucleus of the tractus solitarius (nTS). Silver grains were observed to be arranged in circular patches over neuronal cell bodies of the nTS, ipsilateral to the injection site. Label distributed in a rostro-caudal orientation over an average distance of 1000 um. Labelling was also observed to occur in the dorsal motor nucleus of the vagus (DMnV) and the hypoglossal nucleus. Following microinjection into the DMnV, label again remained ipsilateral, was observed as circular patches over neuronal cell bodies and had a rostro-caudal orientation. Label was also observed in the nTS and the hypoglossal nucleus. No label was observed in the area postrema, regardless of the injection site. Although the labelled DAGO was never limited to the primary injection site, but was observed to distribute in an extensive rostro-caudal plane and to nuclei adjacent to the microinjection, the cardiovascular responses elicited from these sites are dissimilar. Thus the relative contributions of nTS and DMnV to specific cardiovascular responses elicited with the microinjection of DAGO remains to be determined.

79.17 **EFFECTS OF VAGAL RICIN INJECTION ON A2 CATECHOLAMINERGIC NEURONS OF THE RAT MEDULLA.** **T.N. Oeltmann* & R.G. Wiley**(SPON: W.Dettbarn) **Medicine & Neurology Dept, Vanderbilt U. and VAMC, Nashville, TN 37232.**

Concern exists as to whether or not suicide transport of ricin remains restricted to motor neurons originally transporting the toxin. Although double labelling studies have given conflicting results at levels rostral to the obex, A2 noradrenergic neurons caudal to the obex are not thought to project axons through the vagus nerve even though they reside among and adjacent to motor neurons of the the dorsal motor nucleus of the vagus. In the present study, we sought to determine if unilateral destruction of vagal motor neurons by suicide transport of the toxic lectin, ricin, injected into the cervical vagus nerve would also destroy A2 neurons. Either 50 or 270 ng of ricin was unilaterally pressure microinjected into the left cervical vagus nerve of 11 anesthetized, adult male Sprague-Dawley rats. After 3-14 days, rats were reanesthetized and transcardially perfused with aldehyde fixative (FAGLU for catecholamine histofluorescence, N=7, or formaldehyde for anti-tyrosine hydroxylase immunohistochemistry, N=4). Alternate transverse sections of the medulla were stained with cresyl violet to confirm complete destruction of the dorsal motor nucleus of the vagus. 4 control rats (2 for histofluorescence and 2 for anti-TH immunoperoxidase) were processed identically except that toxin injection was omitted. All fluorescent or immunoperoxidase labelled neurons in the dorsomedial medulla between the decussation of the medial lemniscus and the obex were counted without knowledge of which side was injected. There were no significant differences between right and left sides with respect to numbers of catecholaminergic neurons in the A2 of control and ricin-injected animals. Using FAGLU histofluorescence, A2 cell counts on the injected side were 101.3% +/- 3.7 (SEM) of the contralateral control side, and by anti-TH the injected side was 96.5% +/- 13.4 of control. We conclude: 1 - A2 neurons caudal to the obex do not project axons through the vagus, and 2 - using the doses in this study, the neuronal lesion subsequent to vagal ricin injection remains restricted to vagal motor neurons. 79.18 PROJECTIONS OF THE VAGAL MOTOR COMPLEX: A DOUBLE LABELING STUDY. D. P. Baker and J. R. Carithers. Dept. of Veterinary Anatomy, Iowa State University, Ames, IA 50011

Labeled cells have been observed in the region of the medullary vagal complex after injection of horseradish peroxidase (HRP) into the spinal cord as far distally as the lumbar region. Our investigations have focused on identifying projections from the medulla that could be involved in the baroreflex. Therefore, we were interested in confirming these reports, and in determining whether cells projecting to the spinal cord were, indeed, parasympathetic preganglionic neurons that also project via the vagus nerve.

A dorsal laminectomy was performed on ten rats, and 200 nl of 4% HRP were injected into the second thoracic segment of the spinal cord. Although the needle was directed toward the left intermediolateral cell column, the injection solution diffused significantly, and in some rats most of the left half of the cord was labeled. Immediately thereafter, the cervical vagus was dissected free at the thoracic inlet and 1 ul of 2% Fluoro-Gold solution was injected into the perineurium. The rats were killed 24 to 48 hours later, and the tissues were processed for light microscopy, using TMB as the chromogen.

Cells double labeled with dark HRP reaction product and brilliantly fluorescent Fluoro-Gold were present in the nucleus ambiguus. Double labeled cells were also present in the dorsal motor nucleus of the vagus. Approximately 25% of the cells containing Fluoro-Gold also contained HRP reaction product in both nuclei. There were no cells in this nuclear group which were singly labeled with HRP.

The spinal projection from vagal preganglionic cells, which we have identified, could provide an anatomical substrate for parasympathetic modulation of the activity of preganglionic sympathetic neurons. Such modulation could contribute to inhibition of sympathetic vascular tone during activation of the baroreflex. Projections from the nucleus tractus solitarii, the primary projection target of baroreceptor afferent fibers, have been identified in association with cells in this group. Together, these connections may constitute one of the simplest pathways in the baroreflex complex.

79.19 RESPIRATORY MODULATION OF SYMPATHETIC-RELATED RAPHE NEURONS. C.A. Connelly, D.C. Bolser*, and J.E. Remmers. Dept. of Medicine, University of Calgary, Health Sciences Centre, Calgary, Alberta CANADA, T2N 4N1

Raphe pallidus and obscurus neurons correlated with sympathetic activity were investigated in thirteen decerebrate, paralyzed, artificially ventilated cats. Phrenic and inferior cardiac sympathetic activities were recorded as indices of respiratory and sympathetic activities, respectively. Computer averaging techniques were used to assess sympathetic, cardiac, and respiratory-related activity patterns in the raphe neurons, recorded using intracellular methods. Raphe unit spike triggered averaging of sympathetic activity was used to detect the sympathetic-related activity patterns found in twenty-one of the thirty-six neurons recorded. The number of sympathetic-related cells primarily discharging at frequencies of 1-10 Hz, 11-30 Hz, and 31-70 Hz, respectively, was 7:9:5. Spike triggered averages from slowly discharging (2-3 Hz) neurons were indistinguishable from those of rapidly discharging (e.g. 20 Hz) neurons. We also recorded irregularly firing cells that discharged slowly with intermittent high frequency (greater than 20 Hz) bursts of activity correlated with decreased sympathetic activity. None of the sympathetic-related raphe neurons were antidromically activated by spinal cord stimulation. Respiratory cycle triggered averages of raphe neuron activities indicated that eleven of the sympathetic-related neurons exhibited respiratory characteristics; the usual pattern of respiratory modulation was relative hyperpolarization during late expiration and early inspiration. Respiratory cycle triggered histograms of the raphe unit spikes revealed that cell discharge was associated with the membrane depolarization during late inspiration/early expiration. ECG (R wave) triggered histograms of raphe unit spikes indicated cardiac-related activity patterns in nine neurons. Seven of the cardiac-related cells were also sympathetic-related. Five of the raphe neurons exhibited combined cardiac, respiratory and sympathetic-related activity patterns. Moment to moment variability of cardiorespiratory discharge patterns and the lack of bulbospinal projections suggest an integrative function for these neurons. CARDIOVASCULAR REGULATION: CNS PATHWAYS II

80.1 MICROINJECTIONS OF CALCITONIN-GENE-RELATED PEPTIDE IN THE CENTRAL NUCLEUS OF THE AMYDGALA BLOCKS NORADRENERGIC CARDIOVASCULAR EFFECTS. R. J. Leonzio*, J. P. Card, A. Zaspal*, W. Price*, P. Timmermans*, and J. S. Schwaber, (Spon: W. F. Herblin) E. I. du Pont de Nemours and Co., Medical Products Department, Wilmington, DE 19898.

The central nucleus of the amygdala (CeA) exerts a major influence on cardiovascular function through its interconnections with brainstem. Several chemically-distinct afferents terminate differentialy within subfields of the central nucleus. Understanding the interactions among these peptides and neurotransmitters is required to clarify the mechanisms by which the CeA regulates cardiovascular performance. The peptide calcitonin-gene-related peptide (CGRP) has been described by others to have both central and peripheral actions on the cardiovascular system. CGRP is also of particular interest due its very dense innervation of projection neurons in the CeA relevant to amydgaloid regulation of cardiovascular performance. CGRP-containing fibers that originate in the parabrachial nucleus form dense pericellular aborizations around neurons in the CeA that are particularly dense in the lateral central and lateral capsular subdivisions. The present study examined the interaction in the CeA of CGRP and NE in the control of blood pressure. Chronically implanted cannulae were stereotaxically positioned for bilateral injection of compounds into the CeA. The effects of CGRP (0, 0.16, 0.33, 0.66, or 1.32 pmole/0.5 µl) and/or NE (0 or 25 nmole/0.5 µl) on heart rate and blood pressure were measured with a chronic arterial cannula while the rats were awake and unrestrained. The administration of NE alone significantly increases mean arterial pressure by 30.6% with a peak effect 3 to 4 min after injection. CGRP blocked the NE-induced increase in blood pressure in a dose-related manner with an ED_{50} of 0.4 pmole/0.5 µl. CGRP alone had no effect in the range of doses used. Control placements of cannula outside the CeA also were without NE or CGRP effects. Our evidence suggests that CGRP-containing afferents from the parabrachial nucleus function to attenuate the hypertensive effects of endogenous NE in the CeA.

80.2 CALCITONIN-GENE-RELATED PEPTIDE CONTAINING NEURONS IN THE PARABRACHIAL NUCLEUS PROJECT TO THE CENTRAL NUCLEUS OF THE AMYGDALA. J.S. Schwaber, C. Sternini, N.C. Brecha, W. T. Rogers*, J.R. Dubin* and J.P. Card. E. I. du Pont de Nemours and Co. (JSS, JRD, JPC & WTR), Wilmington, DE 19898 and UCLA Sch. of Med. (NCB, CS), LA, CA 90034

The source, distribution and morphology of axons displaying calcitonin-gene-related peptide (CGRP) immunoreactivity in the central amygdaloid nucleus of the adult rat was investigated with immunohistochemical and combined immunohistochemical-axonal transport techniques. Immunoperoxidase methodology demonstrated an extremely dense plexus of CGRP immunoreactive axons that is differentially concentrated within the lateral capsular and lateral central subdivisions of the central nucleus. No immunoreactive neurons were observed in the central nucleus in any of the experimental animals. A characteristic feature of this fiber plexus is the prominent pericellular arborization of immunoreactive axons surrounding the somata of unlabeled neurons. The number of cells receiving this dense pericellular terminal arborization increases at caudal levels of the central nucleus. Retrograde transport of rhodamine-labeled microspheres or Fluorogold combined with immunohistochemical localization of CGRP immunoreactivity demonstrated that the major source of this fiber plexus arises bilaterally from multipolar CGRP-containing neurons in the ventrolateral aspect of the parabrachial nucleus. Combined retrograde dye transport and CGRP immunohistochemistry established that many of the neurons in the central nucleus which receive dense pericellular innervation from CGRP immunoreactive axons are projecting caudally to either the parabrachial nucleus or the nucleus tractus solitarius. These results strongly suggest the relevance of CGRP input to the central nucleus in cardiovascular and other autonomic function. Ascending CGRP-ergic influences may act directly or in concert with catecholaminergic or other peptidergic inputs to influence chemical-specific pathways mediating the effects of environmental stressors on cardiovascular function.

80.3 AMYGDALA MEDIATION OF CARDIOVASCULAR RESPONSES: EFFECTS OF ELECTRICAL STIMULATION AND INJECTIONS OF NEUROPEPTIDES. T.S. Gray and M.R. Brown. Dept. Anat., Loyola Univ. Sch. Med., Maywood, IL 60153 and Depts. Med. & Surg. UCSD Med Ctr., San Diego, CA

The central nucleus of the amygdala (Ce) mediates cardiovascular changes in response to defense- or fear-provoking stimuli through its connections with autonomic regions of the hypothalamus and brainstem. The Ce also contains at least sixteen different types of neuropeptide-containing terminals. The purpose of the present study is to: 1) To determine if the Ce is the only site within the amygdala that when stimulated will cause increases in heart rate (HR) and mean arterial pressure (MAP); 2) To determine which neuropeptides when injected into the Ce will affect HR and MAP.

The subjects of the study were male adult Sprague-Dawley rats. Prior to all surgical procedures animals were anesthetized with ether or sodium pentobarbital (40 mg/kg). Four days prior to experiments either a bipolar platinum electrode (Plastic Products) or a silastic-tipped polyethylene-50 cannula (Plastic Products) was implanted unilaterally within the amygdala of each animal. Femoral artery catheters were placed in all animals 3-4 h prior to experiments for measurement of HR and MAP. Electrical stimulation was conducted using a Grass S44 stimulator and a Grass SIU5 stimulus isolation unit. Stimulation was delivered over a 30-s period and consisted of monophasic pulses each 0.5 ms in duration at 50 hz and at currents of 15-75 uA. All experiments were performed in unanesthetized, unrestrained animals.

Electrical stimulation of the Ce consistently elicited both increases in HR and MAP. Increases in HR and MAP could be obtained using current levels as low as 15 uA with maximal responses typically obtained at current levels of 50 uA. Increases in HR and MAP were obtained from stimulation of other regions of the amygdala, but were not as consistent as those elicited from Ce stimulation. There were no sites where decreases in HR and MAP were consistently observed.

Results of neuropeptide injections into the Ce demonstrated that only 5 of the 16 neuropeptides caused changes in HR and/or MAP. Thyrotropin releasing factor (TRF) and calcitonin gene-related peptide (CGRP) induced increases in both MAP and HR. Angiotensin II and somatostatin-28 injections caused increases in MAP and decreases in HR. Bombesin injections in Ce induced increases in MAP, but did not alter HR. Thus, TRF and CGRP injections into the Ce produced increases in MAP and HR that most resemble those seen in learned responses to aversive stimuli. The results of these experiments lend further credence to the hypothesis that the Ce is responsible for amygdaloid-related changes in MAP and HR associated with defensive behaviors or emotional responses to environmental stressors. 80.4 BRADYCARDIC RESPONSE TO STIMULATION OF THE AMYGDALOID CENTRAL NUCLEUS IS PROPORTIONAL TO ARTERIAL BLOOD PRESSURE. J.P. Pascoe, D.J. Bradley* & K.M. Spyer*. Department of Physiology, Royal Free Hospital School of Medicine, Rowland Hill St., London NW3 2PF (UK)

Many findings suggest that the amygdaloid central nucleus (ACE) may contribute to cardiovascular regulation, particularly during emotional states (Kapp et al., 1984). Consistent with this notion are the existence of direct projections from the ACE to cardiovascular regulatory nuclei in the brainstem, including the nucleus of the solitary tract and the dorsal motor nucleus of the vagus (NTS/DMN, Hopkins & Holstege, 1978), and the finding that stimulation of the ACE activates many neurons in these areas including a portion of those that receive an excitatory input from baroreceptor afferents (Cox et al., 1986). These and other observations (Pascoe & Kapp, 1985) have led us to hypothesize that increased activity in ACE projections to the NTS/DMN complex might serve to facilitate the baroreceptor-vagal reflex. Based upon this hypothesis we have tested the prediction that bradycardic responses to stimulation of the ACE should be proportional to arterial blood pressure (BP).

New Zealand white rabbits were anesthetized with α-chloralose, the trachea was intubated, a femoral vein was cannulated, and a Swan-Ganz catheter was inserted through a femoral artery until its tip was positioned in the descending aorta at the level of the diaphragm. A monopolar stimulating electrode was implanted in the ACE. Cardiovascular responses to stimulation of the ACE (150-500 μA, 0.5 ms, 100 Hz) then were assessed during periods in which BP was decreased using sodium nitroprusside (2-10 μg/kg) or increased in the rostral arterial compartment by inflating the tip of the Swan-Ganz catheter. Mean BPs ranging from 65-140 mmHg were obtained in this manner.

Resting heart rate was correlated inversely with BP (r's -.70 to -.88, $p<.01$) and ranged from 252-360 bpm. Stimulation of the ACE always evoked bradycardia and hypotension. In each experiment (N=7) bradycardic response magnitudes were correlated with the arterial BP at the onset of ACE stimulation, such that higher BPs were associated with larger bradycardic responses (r's from .67 to .86, $p<.01$, slopes from 0.5 to 1.1, intercepts from 43 to 91 mmHg). The durations of bradycardic responses to ACE stimulation when BP was increased were longer than those seen during periods of resting or low BP ($\bar{X}$'s= 12.0 vs. 7.2 and 7.0 s). Depressor responses to ACE stimulation were smaller when BP was increased or decreased, as compared to control responses ($\bar{X}$'s= 5.6 and 9.1 vs. 16.2 mmHg).

These data demonstrate that bradycardia to stimulation of the ACE is proportional to arterial BP and thus at least partially dependent upon baroreceptor afferent activity, and are consistent with the hypothesis that activity in the ACE projection to the NTS/DMN may facilitate the baroreceptor-vagal reflex in the rabbit. Supported by the British Heart Foundation. J.P.P. is a Fellow of the American Heart Association and the British Heart Foundation.

80.5 DIENCEPHALIC REGIONS CONTRIBUTING TO SYMPATHETIC NERVE DISCHARGE IN THE ANESTHETIZED CAT. K.J. Varner, Z-S. Huang*, S.M. Barman and G.L. Gebber. Depts. of Pharmacol. and Physiol., Michigan State Univ., East Lansing, MI 48824.

We (Huang et al., Am. J. Physiol., in press) have reported that midbrain transection in the chloralose anesthetized cat is accompanied by transient (lasting ≈30 min) decreases in blood pressure (33±4 mmHg) and inferior cardiac postganglionic sympathetic nerve discharge (SND; 38±7%). Two observations led us to conclude that the transient effects of midbrain transection reflected the loss of a forebrain-dependent component of SND rather than a nonspecific phenomenon such as generalized trauma. First, SND was correlated to frontal cortical activity prior to midbrain transection. Second, following recovery from the effect of midbrain transection, a second transection placed more caudally in the midbrain failed to affect blood pressure and SND.

The current study was initiated to determine whether the forebrain contribution to basal SND in baroreceptor-denervated cats anesthetized with chloralose is dependent upon the integrity of medial diencephalic structures. For this purpose, the effects of midbrain transection at stereotaxic plane A3 on blood pressure and SND (cumulatively integrated) in control cats were compared with those observed in cats in which radio frequency current was used to lesion bilaterally discrete regions of the hypothalamus or medial thalamus.

Lesions of the medial hypothalamus at a level including the paraventricular nucleus failed to alter the reduction of blood pressure and SND produced by midbrain transection. Extension of medial lesions caudally into the posterior hypothalamic region, however, significantly attenuated the effects of midbrain transection on blood pressure and SND. The effects of midbrain transection were similarly attenuated by lesions of the medial forebrain bundle and portions of the lateral hypothalamic region. Unexpectedly, lesions of the medial thalamus (0—3.5 mm lateral to midline) between stereotaxic planes A7 and A11 also significantly attenuated the effects of midbrain transection on blood pressure and SND. These lesions included portions of the following medial thalamic nuclei: centralis lateralis, centralis medialis and medialis dorsalis. These results have led us to conclude that the medial thalamus as well as the posterior and lateral hypothalamic regions are involved in mediating the forebrain-dependent component of basal SND in anesthetized cats. The relationships between medial thalamic and hypothalamic structures involved in sympathetic control remain to be elucidated. (Supported by HL33266 and HI13187.)

80.6 PREFRONTAL STIMULUS-PRODUCED HYPOTENSION. S.G.P. Hardy and D.E. Holmes*. Dept. of Anatomy, Univ. of Miss. Med. Ctr., Jackson, MS 39216.

It has recently been demonstrated, in anesthetized rats, that stimulus-produced hypotension (SPH) can be elicited from the medial prefrontal cortex (PFC). The present study was conducted in order to better understand the involvement of the PFC in cardiovascular control.

In urethane anesthetized (2g/Kg) rats, bipolar electrical stimulation (a 12 sec train of 1 ms square waves, delivered at 20 Hz with current intensity of 50-1500 uA) was administered to various sites within the frontal cortex, including medial PFC, lateral PFC, infralimbic cortex and frontal convexity cortex. The effects of stimulation upon blood pressure and heart rate were monitored. Stimulation of both the lateral PFC and ventral portion of the medial PFC (i.e. prelimbic cortex) consistently resulted in SPH. However, stimulation of the lateral PFC usually produced greater decreases in blood pressure (often decreases of 50% from baseline) and with lower stimulus thresholds (as small as 90uA). Within the lateral PFC, the most effective sites for supporting SPH were located caudally. Stimulus sites within the infralimbic cortex also consistently supported SPH (similar in magnitude as that elicited from the lateral PFC). Stimulation administered to the lateral PFC or infralimbic cortex also resulted in bradycardia, occurring in synchrony with SPH. Stimulation at sites in the frontal convexity cortex had no effect on blood pressure or heart rate.

SPH had a rapid onset (suggesting a neural substrate) with maximum hypotension observed at approximately 8 sec following the stimulus onset. Furthermore, SPH was a short-lived effect. Returns to baseline measurements usually were initiated before the electrical stimulus ceased. Hypertensive responses to frontal cortex stimulation were not observed.

To determine whether SPH is mediated via the vagus nerves, injections (1-3mg/Kg; i.v.) of either atropine methyl nitrate or gallamine triethiodide were administered to block vagal influences. Bilateral vagotomies were occasionally also performed. In none of these cases was SPH blocked; therefore, demonstrating that SPH is not mediated via the vagus nerves.

To determine whether SPH may be mediated via sympathetic inhibition, norepinephrine (NE) was administered (0.03 mg/Kg; i.p.). This produced a hypertensive state that remained steady over a 20 min. period. During this period, SPH was blocked. After the effects of NE had dissipated, SPH could again be elicited. This finding suggests that SPH may be mediated via sympathetic inhibition.

80.7 ELECTROLYTIC LESIONS OF THE REGION OF THE PARAVENTRICULAR NUCLEUS TRANSIENTLY REDUCE CHRONIC RENAL HYPERTENSION. T.C. Herzig, R.A. Buchholz, J.R. Haywood. Department of Pharmacology, The University of Texas Health Science Center, San Antonio, Texas 78284-7764.

Hypertension has been attenuated by lesions of the paraventricular nucleus (PVN) region in both the Dahl salt-sensitive and SHR models of hypertension. Anatomical tracing studies have shown pathways between the anteroventral third ventricle (AV3V) region and the paraventricular nuclei, suggesting the importance of these brain regions in sodium-induced rises in arterial pressure. Since one-kidney, figure-8 renal hypertension is a sodium-dependent model of increased arterial pressure, the goal of the present study was to determine the contribution of the PVN to one-kidney, figure-8 renal wrap hypertension.

One-kidney, figure-8 renal wrap or sham operation (unilateral nephrectomy) was performed in male Sprague-Dawley rats. Rats were instrumented 26 days later with femoral artery and vein catheters for daily measurement of mean arterial pressure (MAP) and heart rate (HR) and administration of drugs. On day 28 post wrap or sham a bilateral electrolytic lesion of the PVN was performed. On day 7 post lesion, the contribution of the sympathetic nervous system, renin-angiotensin system, and arginine vasopressin to increased MAP was assessed sequentially by blockade of each system.

MAP was significantly elevated in the wrapped group prior to lesion; ablation of the PVN significantly reduced MAP from 150.0 ± 9.4 mmHg to 110.0 ± 2.9 mmHg. In the sham group, the lesion reduced MAP from 117.7 ± 1.8 mmHg to 98.9 ± 4.4 mmHg. However, in both groups MAP returned to pre-lesion values by day 7 post lesion. HR increased significantly in both groups on day 1 post lesion, but subsequently decreased to control levels. Histological examination indicated two types of lesions: complete ablation of the PVN or encroachment upon the rostral portion of the PVN. However, MAP and HR responses were similar with both types of lesions. Effects of ganglionic blockade on MAP were greater in wrapped animals (-43.6 ± 5.2 mmHg) than in sham animals (-26.2 ± 3.1 mmHg). Likewise, the response to combined blockade of the sympathetic nervous system, renin-angiotensin system and vasopressin was greater in wrapped animals (-77.8 ± 6.3 mmHg) than in sham animals (-43.0 ± 3.1 mmHg).

These studies suggest that the PVN contributes to renal hypertension. However, with ablation of the PVN region it appears that neurohumoral mechanisms compensate to return MAP to pre-lesion levels. (This work was supported by HL36080 and HL32977).

80.8 THE EFFECTS OF ISOFLURANE, HALOTHANE, MIDAZOLAM, AND ETOMIDATE ON PRESSOR RESPONSES INDUCED BY CNS STIMULATION IN CHRONICALLY IMPLANTED CATS. W. T. Schmeling, D.C. Warltier and J.P. Kampine. Departments of Anesthesiology and Pharmacology. Medical College of Wisconsin. Milwaukee, WI 53226

The systemic hemodynamic actions of the volatile anesthetics isoflurane and halothane and the intravenous agents etomidate and midazolam have been well documented. However, few studies have investigated the actions of these agents on central cardiovascular control sites. The purpose of the present investigation was to examine the actions of these agents on central nervous system (CNS) pressor (P) areas in chronically implanted cats. Chronic implantation allowed comparison of anesthetic effects to the conscious state. Cats (2.0-3.5 kg) were chronically implanted with bipolar stimulating electrodes in the regions of the ventrolateral hypothalamus (Hyp) (A=10.0, L=2.5, D= -4.0) and mesencephalic reticular formation (RF) (A=2.0, L=2.0, D= -1.0). The right carotid artery and external jugular vein were catheterized for measurement of arterial pressure and drug administration, respectively. In selected animals, a Statham electromagnetic flow probe was positioned around the abdominal aorta for measurement of aortic blood flow. All animals were allowed to recover for 7-10 days. Control experiments consisted of stimulation (S) sequences at 1,2, and 4 times "threshold" current levels to elicit pressor responses. Isoflurane (1.5, 2.5, and 3.0%), halothane (0.5, 1.0, and 2.0%), etomidate (3 mg/kg), or midazolam (7.5 mg/kg) were then administered in separate experimental groups. After establishing a steady hemodynamic state with each agent, S sequences were repeated. Despite minimal alterations in blood pressure, heart rate, or aortic flow, both etomidate and midazolam produced significant ($P < 0.05$) attenuation of P responses to S in RF. The Hyp P responses appeared more resistant, decreasing but not significantly. Both halothane and isoflurane markedly attenuated the evoked P responses, nearly abolishing responses at the highest concentrations. The action of isoflurane was more pronounced than halothane, particularly at RF sites. Significant changes in associated flow patterns were also observed with these agents, reflecting alterations in induced vasomotor tone to S. The results support the concept that disruption of CNS cardiovascular centers may contribute to the alterations in hemodynamic stability produced by these anesthetic agents. (Supported by grants from NIH HL 36144, the Veterans Administration, and the American Society of Anesthesiology.)

80.9 THE EFFECT OF PREOPTIC HYPOTHALAMIC LESIONS ON CEREBRAL BLOOD FLOW AND REDISTRIBUTION OF CARDIAC OUTPUT FOLLOWING HEMORRHAGE. S. L. Bealer and D. W. Busija*, Dept. Physiology and Biophysics, University of Tennessee, Memphis, TN 38163.

The periventricular tissue surrounding the anteroventral portion of the third cerebral ventricle (the AV3V region) is critical for cardiovascular regulation. Electrolytic ablation of this brain area reduces blood volume and decreases survival following severe hemorrhage. The present experiments were designed to determine if ablation of the AV3V region alters cardiac output and/or distribution of regional blood flow before and after hemorrhage in the conscious animal.

Rats underwent electrolytic ablation of the AV3V region or control surgical procedures and were allowed 2-3 wks to recover from the acute effects of these surgeries. Cardiac output and regional blood flow were then measured using 15 um radiolabelled microspheres before, and 2 and 15 min following hemorrhage. The hemorrhage procedure consisted of withdrawing blood from a femoral artery catheter until mean arterial blood pressure was approximately 65 mm Hg.

Under resting conditions, cerebral blood flow was significantly greater (216 ± 30 mm Hg/ml/min/100 g) and cerebral vascular resistance was lower (0.6 ± 0.09 mm Hg/ml/min/100 g) in rats with AV3V lesions than in control-operated animals (132 ± 16 mm Hg/ml/min/100 g; 0.92 ± 0.1 mm Hg/ml/min/100 g, respectively), while mean arterial pressure, cardiac output, and regional blood flow to other organs was similar between experimental groups. Hemorrhage that reduced blood pressure to 65 mm Hg in both groups decreased cerebrovascular resistance in control-operated rats (0.52 ± 0.1 mm Hg/ml/min/100 g), but not in rats with AV3V lesions (0.48 ± 0.1 mm Hg/ml/min/100 g). Cardiac output and redistribution of regional blood flow to other organs were similar between rats with AV3V lesions and control-operated animals following hemorrhage. These data demonstrate that electrolytic ablation of the AV3V region results in a selective increase in cerebral blood flow and decreased cerebral vascular resistance, but does not alter the reflex changes in regional blood flow evoked by hemorrhage. (Supported by USPHS grants HL-25877 and HL-30260 and a grant from the American Heart Association, Tennessee Affiliate.)

80.10 DEPRESSOR RESPONSES ELICITED FROM LATERAL HYPOTHALAMIC AREA AFTER L-GLUTAMATE MICROINJECTIONS. S.E. Spencer, W.B. Sawyer, and A.D. Loewy, Depts. of Neurology and Anatomy & Neurobiology, Washington University School of Medicine, St. Louis, Missouri 63110

The role of the lateral hypothalamic area (LHA) in cardiovascular control was studied in Sprague-Dawley rats which were anesthetized with sodium pentobarbital (35 mg/kg). Microinjections of L-glutamate were made at different rostral-caudal levels of the LHA. In each experiment, 15 nl of a 500 mM solution containing 1.25 μCi of ^{3}H-glutamate was injected. The animals were maintained on a respirator and changes in arterial blood pressure and heart rate were monitored. At the end of the experiment, the brains were processed for autoradiography and the injection sites reconstructed.

The tuberal region of the LHA (LHA_t) which lies lateral to the ventromedial nucleus of the hypothalamus (VMH) was stimulated. This produced a decrease in arterial blood pressure of 20.4 ± 1.3 mmHg and a bradycardia of 34.8 ± 3.9 bpm ($\bar{x}$±SEM; n=49) Preliminary analysis of these experiments suggest that the ventrolateral portion of the LHA_t is concerned with blood pressure regulation, while injections in the vicinity of the perifornical region and dorsomedial part of the LHA_t appear to regulate heart rate. Stimulation of the posterior region of the LHA (LHA_p) which lies caudal to the region of the VMH and lateral to the mammillary nuclei produced smaller depressor changes: arterial blood pressure = -15.9 ± 2.8 mm/Hg and heart rate = -23.8 ± 5.8 bpm (n=17). Stimulation of the subthalamic nucleus (n=6) caused minimal changes: blood pressure = -7.5 ± 2.1 mmHg and heart rate = -8.3 ± 2.8 bpm.

In order to determine whether the bradycardic changes were mediated via the sympathetic and/or vagal fibers, pharmacological blockade experiments with either the β-blocker - timolol (0.5 mg/kg; n=5), or the muscarinic blocker - atropine methyl nitrate (2.0 mg/kg; n=7) were performed. Stimulation of the LHA_t region after either blocker caused approximately a 25% attenuation of the bradycardic response, suggesting the response is mediated by both limbs of the autonomic nervous system. When both drugs were administered, the heart rate response was attenuated by ~90% (n=4). The blood pressure response was attenuated by ~25% with atropine but not with timolol.

Our results demonstrate that when the LHA_t and LHA_p are activated by L-glutamate, it produces a depressor response -- not pressor responses as has been suggested by earlier electrical stimulaton studies. The latter findings are likely to be due to fibers-of-passage, not the cells of the LHA.
(Supported by USPHS grant 25449; ADL is an Established Investigator of the American Heart Association.)

80.11 CONNECTIONS BETWEEN CARDIOVASCULAR AREAS OF THE HYPOTHALAMUS AND THE PERIAQUEDUCTAL GREY REGION OF THE RABBIT D.R. Liskowsky, R.W. Winters, P.L. Vera, P.M. McCabe, & N. Schneiderman. Dept. of Psychology, Univ. of Miami, Coral Gables, FL 33124

The midbrain periaqueductal grey region (PAG) has been implicated in a constellation of behavioral and cardiovascular responses labelled the 'defense' response. The cardiovascular component of the defense response is in part characterized by an increase in blood pressure and heart rate. In the present study we examined the areas of PAG which elicited a cardiovascular response when electrically stimulated. The connections between cardiovascular related areas of the hypothalamus and PAG were also studied.

The PAG was examined using train electrical stimulation (100-300 uA, 100 pulses/sec, 10 sec.) in urethane anesthetized rabbits. Stimulation of the dorsal-lateral portion of the rostral PAG, at the level of the posterior commissure, resulted in a pressor response accompanied by either a sustained tachycardia or a tachycardia which converted to a bradycardia as blood pressure increased. Stimulation of the ventro-lateral PAG, at a level just posterior to the above area, resulted in a pressor response accompanied by a reflexive bradycardia. Injection of either glutamate (1 uM) or DL-homocysteic acid (1uM) elicited the same cardiovascular responses from this area. No other sites were identified in the PAG that produced cardiovascular changes when electrically stimulated.

We also examined the extent to which stimulation of cardiovascular related areas of the hypothalamus could activate single cells in the PAG. Single unit activity was recorded using glass micropipettes filled with 0.05 M sodium acetate and having an outside tip diameter of $\leq$ 2um. Electrical stimulation or application of glutamate to the perifornical nucleus and the region between the columns of the fornix and the paraventricular nucleus, resulted in a pressor response and tachycardia. Electrical stimulation (200-300 uA, 100 pulses/sec, 3 sec) of this region was found to alter the discharge rate of many single units in the PAG. The response of the units to hypothalamic stimulation was variable. Some units increased their firing rate only during stimulation while others maintained a higher than baseline rate of firing after stimulus offset. Other units were inhibited by hypothalamic stimulation. All of the units that responded to hypothalamic stimulation were localized to the rostral half of the PAG.

It is possible that cardiovascular responses elicited from PAG, which may be involved in the defense response, are modulated by these descending hypothalamic projections.

80.12 **CENTRAL NERVOUS SYSTEM ACTIONS AND INTERACTIONS OF CORTICOTROPIN-RELEASING FACTOR AND OPIOIDS ON CARDIOVASCULAR FUNCTION.** L. A. Fisher, Dept. of Pharmacology, College of Medicine, University of Arizona Health Sciences Center, Tucson, AZ 85724.

The neurochemical mechanisms by which the central nervous system (CNS) mediates stress-induced alterations of cardiovascular function are not fully understood. The rationale to investigate the role of corticotropin-releasing factor (CRF) and opioid peptides in generating CNS-initiated cardiovascular responses to stress is based on experimental evidence regarding: 1) the distribution of CRF, opioid peptides and their receptors in brain areas known to be critical loci for autonomic, endocrine and cardiovascular control; 2) the release of CRF and opioid peptides within the brain in response to physical and psychological stressors; 3) the potent CNS effects of CRF and opioid peptides on autonomic, endocrine and cardiovascular parameters; and 4) the co-localization of CRF and opioid peptides within individual neurons thus suggesting their potential simultaneous release upon neuronal firing. To examine the CNS interactions of CRF and opioid peptides on cardiovascular function, studies were performed in which CRF and receptor subtype selective opioid peptides were administered into the CNS, alone and in combination, while monitoring cardiovascular parameters. All experiments utilized conscious, unrestrained rats previously instrumented with lateral cerebroventricular (icv) cannulae for peptide administration and femoral arterial catheters for direct measurement of pulsatile arterial pressure (AP) and heart rate (HR). The following receptor subtype selective opioid compounds were tested: mu or universal/B-endorphin (B-Endo) and [D-Ala^2, NMePhe^4, Gly-ol^5]-enkephalin (DAGO); delta/leucine-enkephalin (Leu-Enk) and [D-Pen^2, D-Pen^5]-enkephalin (DPDPE); kappa/dynorphin-A(1-17) (DYN) and the nonpeptide agonist, U50,488H. CRF (0.015-1.5 nmol, icv) elicited enduring elevations of AP and HR. B-Endo (0.025-2.5 nmol, icv) produced negligible and inconsistent effects on AP and HR whereas DAGO (0.05-0.5 nmol, icv) increased both AP and HR. Leu-Enk (30-300 nmol, icv) and DPDPE (1.5-15 nmol, icv) evoked transient elevations of AP and HR. The nonpeptide kappa agonist, U50,488H (21.5-215 nmol, icv) had no effects on AP and HR except at the highest dose where it increased AP and decreased HR. DYN (0.1-3.0 nmol, icv) caused delayed and transient elevations of AP and HR. A dose of DYN (0.1 nmol, icv) that did not alter AP or HR when given alone, delayed and suppressed CRF-induced elevations of AP and HR. These results suggest: 1) agonists presumed selective for a particular opioid receptor subtype, e.g., mu or kappa, do not necessarily produce identical CNS cardiovascular actions; and 2) co-localized peptides, i.e., CRF and DYN, may modulate/modify the CNS actions of each other.

80.13 CARDIOVASCULAR RESPONSES IN CAT FROM ELECTRICAL STIMULATION IN THE DIAGONAL BAND OF BROCA. C.W. Dempesy and D.E. Richardson. Department of Neurosurgery, Tulane University School of Medicine, New Orleans, Louisiana 70112.

In attempting to learn how rostral limbic areas which subserve emotional behavior states might elicit concomitant cardiovascular expression, the rostral limbic forebrain of anesthetized cat was surveyed with stimulating electrodes. Modest cardiovascular changes could be generated in several regions, but stimulation within the diagonal band of Broca (DBB) invariably produced a spectrum of striking cardiovascular phenomena, including large blood pressure and heart rate changes and temporary suppression of the baroreflex. In cats in which the baroreflex was permanently suppressed, stimulation confined to the rostromedial horizontal limb of the DBB yielded a basic pattern of depressor (bradycardia) responses at low currents, shifting to pressor (tachycardia) responses (70 - 100 mmHg, 30 - 50 bpm) at high currents. Although electrical stimulation of forebrain areas immediately rostral and dorsal to the DBB generated cardiovascular changes, the responses were usually small in comparison. However, pressor-active sites in the DBB only yielded depressor responses when stimulated with glutamate, while some pressor-active sites in this rostrodorsal region responsed with pressors when chemically stimulated. Lesion of the DBB reduced the responses from these rostrodorsal pressor sites. Electrical stimulation of strong pressor (tachycardia) sites in the DBB generated large releases of circulating epinephrine (EPI). Pressor responses, tachycardia, and circulating EPI releases induced by DBB stimulation were significantly reduced by lesions either of the medial forebrain bundle (MFB) area in the ventrolateral hypothalamus, or of the C1-area in the medulla. Finally, DBB stimulation-induced pressor responses were significantly reduced by mechanical or chemical sympathectomies. These results suggest that the DBB pressor responses arise from stimulation of axons of passage, which originate from neurons located rostrodorsal to the DBB and which continue projecting caudally (directly or multisynaptically) via the MFB to the medullary C1-area, where the effects are expressed peripherally by ordinary sympathetic mechanisms. This model extends the cardiovascular control network in the basal brain proposed by S.M. Hilton (Brain Research, 87:213-219, 1975) to the rostral septal region, and suggests a possible mechanism by which the emotional substrate of the brain may recruit the cardiovascular system to meet emergency needs.

80.14 EFFECT OF STIMULATION OF FASTIGIAL NUCLEUS ON CEREBRAL BLOOD FLOW IN CATS. J.L. Williams, D.D. Heistad, J. Siems, and W.T. Talman. University of Iowa and V.A. Medical Center, Iowa City, IA 52242.

Electrical stimulation in the region of the rostral fastigial nucleus (FN) produces a pronounced pressor response. In rats, stimulation of the rostral or caudal FN has been reported to produce almost 2-fold increases in cerebral blood flow (CBF), even in sites which do not elicit a pressor response. In this study, we have used a new approach to directly measure blood flow through a cortical artery during stimulation of the FN in cats.

In 9 chloralose-anesthetized, paralyzed cats, a pulsed-Doppler crystal was placed under a pial artery (312±35 μm diameter, mean±SE). Thus, blood velocity was measured continuously in an artery to the parietal cortex. Vessel diameter was measured simultaneously. Changes in CBF were calculated as the product of velocity and cross-sectional area of the vessel.

In the rostral FN, electrical stimulation of 7 sites from which pressor responses could be elicited also increased CBF. Stimulation of 3 other rostral sites with a similar threshold for pressor responses produced no change in CBF. Threshold pressor responses (10 mmHg) were usually achieved at stimulus amplitudes $\geq$ 25 μA (50 Hz, 0.5 ms). With mean arterial blood pressure maintained at control levels by rapid withdrawal of arterial blood, stimulation at 100-250 μA increased CBF 19±5%. High amplitude stimulation (400-500 μA) of 2 sites increased CBF 41%. The changes in CBF were manifested by increased velocity, but vessel diameter did not change. CBF increased gradually after the onset of stimulation and reached a peak level in approximately 1 minute. This maximal level of flow was sustained until termination of the stimulus. Arterial blood gases and pH were maintained at baseline levels throughout the stimulation of the FN. Stimulation of areas outside the rostral FN, including caudal regions, elicited no changes in arterial blood pressure or CBF.

Autoregulation was examined periodically by measuring flow during modest hypertension produced by aortic occlusion. After an initial rise, CBF declined rapidly and approached control levels within 20-60 seconds. Intravenous administration of Evans blue indicated that the blood-brain barrier was intact at the end of the experiments. Sites of stimulation were confirmed histologically.

The results indicate that electrical stimulation of the pressor region of the rostral FN in the cat can produce a modest increase in CBF. Stimulation of caudal regions of the FN elicits neither a pressor response nor any change in CBF.

80.15 CHEMICAL ACTIVATION OF PARABRACHIAL NEURONS ELICITS A PRESSOR RESPONSE IN THE CAT. J.S. Hade*, T.S. Donta*, S.W. Mifflin* and R.B. Felder (SPON: A.K. Affifi). Cardiovascular Center, Dept. of Internal Medicine, University of Iowa, Iowa City, Iowa 52242.

Electrical stimulation of parabrachial nucleus (PBN) results in a pressor response characterized by an increase in arterial pressure and tachycardia (in cat) or bradycardia (in rabbit). Although these responses are presumed to be mediated by PBN neurons, the cardiovascular effects of chemical stimulation of neurons in this region have not previously been determined.

In pentobarbital anesthetized, paralyzed and mechanically ventilated cats, we recorded mean arterial pressure (MAP), heart rate (HR), and phrenic nerve activity (PNA) during low intensity (25-50 μA), electrical stimulation (ES) or microinjection (MI) of l-glutamate (l-glu, pH=7.4, 100 mM), kainic acid (KA, pH=7.4, 2 mM), or saline (isosmotic, pH=7.4) at the same site. Microinjections were made through two pipettes glued to a tungsten monopolar stimulating electrode (100 Kohm resistance), so that the tips of the stimulating electrode and the ejecting pipettes converged on approximately the same point. The responses to MI of either 40-100 (Group I: n=7) or 300-400 (Group II: n=11) nanoliters l-glu were compared with the responses to ES at PBN locations in 16 animals. In Group I, MAP (control 95.3±2.6, $\bar{x}$±SE) increased 12.7% and 20.7% with ES at 25 μA and 50 μA, respectively. In response to MI of l-glu, MAP increased 12.2% from 95.7±3.2 mmHg. In Group II, MAP (control = 96.2±2.9) increased 17.2% with 25 μA and 28.8% with 50 μA ES and 13.8% (from 100.7±3.2 mmHg) in response to l-glu MI. We observed no changes in HR and no consistent changes in PNA in response to ES or either volume of MI. Saline injected in comparable volumes (n=5) had no effect.

In four experiments, KA (300-400 nanoliters) transiently blocked the pressor response to ES of PBN. Prior to KA, MAP was 88.3±1.3 mmHg, and increased 22.9%, 39.3% and 62.7% on ES at 25 μA, 50 μA and 100 μA, respectively. MI of KA resulted in a transient increase (4.5%) in MAP. Following KA, MAP increased only 1.0%, 8.2% and 19.9% with ES at 25 μA, 50 μA and 100 μA respectively. Following a mean recovery time of 31.5±6.4 minutes, these responses were 12.4%, 28.7% and 41.8%, indicating a return toward control.

Microinjection in PBN of l-glu, used in these studies as a general neuronal excitant, elicited an increase in MAP comparable to low threshold electrical stimulation. KA blocked the pressor responses to low threshold electrical stimulation in PBN. These data provide evidence that the pressor response to electrical stimulation of PBN is mediated by neuronal elements within PBN and not by fibers of passage originating from neurons elsewhere.

80.16 PRESSOR AND DEPRESSOR FUNCTIONS OF THE A5 CELL GROUP. R. G. Drye*, D. L. Whittington*, R. H. Baisden and M. L. Woodruff. Department of Anatomy, Laboratory of Neurobehavioral Science, Quillen-Dishner College of Medicine, East Tennessee .State University, Johnson City, TN 37614.

The A5 region, located in the lateral brainstem tegmentum at the ponto-medullary junction, is a discrete area of norepinephrine-containing neurons having apparent influence on blood pressure (BP). Electrical stimulation studies (Loewy et al., Brain Res., 178, 196-200, 1979; Woodruff et al., Brain Res., 379, 10-23, 1986) suggest that A5 produces a BP pressor effect. Conversely, studies using excitatory amino acids to stimulate A5 (e.g. Neil and Loewy, Brain Res. 241, 271-278, 1982) report a depressor effect on BP. The present study examined the differential response of BP to electrical or L-glutamate stimulation of A5 in anesthetized New Zealand rabbits exposed to various experimental conditions. Aspiration lesions of the nucleus tractus solitarius (NTS) resulted in substantial reduction of the depressor response to microinjections of the neuroexcitant L-glutamate into A5. Administration of the catecholaminergic neurotoxin, 6-hydroxydopamine, resulted in a preservation of the L-glutamate-induced depressor response, but eliminated the pressor effect of electrical stimulation. Electrical stimulation, when presented after L-glutamate injections, produced a markedly decreased magnitude, or even a reversal, of the expected pressor response. Local injection of a L-glutamate antagonist resulted in a blocked depressive response to L-glutamate but had no effect on the increased BP of electrical stimulation. We conclude that the A5 region contains two neuronal systems. One is L-glutamate sensitive, interacts with the NTS and exerts a depressor effect on BP. The second is less sensitive to L-glutamate, highly sensitive to electrical stimulation, exerts its effect via the intermediolateral column of the spinal cord and produces a BP pressor response. (Supported by a Grant-in-Aid to MLW from the American Heart Association with funds contributed in part by the AHA Tennessee Affiliate.)

80.17 NEUROPEPTIDE Y, CENTRAL NERVOUS SYSTEM EFFECTS OF CARDIOVASCULAR FUNCTION. N. Scott*, V. Webb* and M.R. Brown (SPON: C. Cheung). Autonomic Physiology Lab., UCSD Medical Center, San Diego, CA 92103.

Neuropeptide Y (NPY) has been reported to exert variable effects on mean arterial pressure (MAP) and heart rate (HR), depending on the site of administration of this peptide into the central nervous system (CNS). This study has assessed the mechanism by which NPY given into the lateral ventricle (icv) decreases HR. Experiments have been carried out in awake, male Sprague-Dawley rats equipped with chronic icv, jugular venous and femoral artery catheters. NPY given intravenously (iv) produced a dose-dependent increase of MAP and decrease of HR. NPY (20-200 pmoles) and peptide YY, but not $[Phe^{27,36}]$-NPY^{21-36}, given icv produced a prolonged slowing of HR without changing MAP. Iv passive immunization against NPY prevented the changes of HR and MAP following NPY given iv, but did not prevent the decrease of HR when NPY was given icv. These observations support the conclusion that NPY-induced slowing of HR is secondary to a CNS rather than a peripheral action of the peptide secondary to its leaking out of the brain.

To evaluate the efferent mechanism by which NPY produced slowing of HR, experiments were performed using atropine methyl nitrate. Atropine given iv either before or after icv administration of NPY caused HR to return to those of control animals; results consistent with NPY producing sympathetic withdrawal rather than parasympathetic stimulation. Consistent with this conclusion, NPY given icv did not change plasma concentrations of epinephrine or norepinephrine despite dramatic reductions of HR. Thus, there was no compensatory increase of sympathoadrenomedullary activity following NPY-induced bradycardia.

Effects of NPY on baroreflex function were studied by constructing a MAP-pulse interval response curve using nitroprusside and phenylephrine infusions. NPY given icv resulted in a MAP-pulse interval curve that was upwardly displaced and parallel to the control curve. The changes in the MAP-pulse interval response curve induced by NPY are most consistent with a modulation of baroreflex set-point, without a change in baroreflex gain. Whether the effects of NPY on HR observed in these studies represent the summated actions of NPY exerted at different brain sites has not been determined. However, the relevance of summated versus single site actions of NPY or other peptides depends on the patterns of release and/or biodistribution of endogenous peptide under physiologic conditions. In conclusion, NPY acts within the CNS to slow HR. This effect is associated with decreased sympathetic influence on HR and a resetting of the baroreflex.

80.18 AN ADRENAL-MEDIATED, NALOXONE-REVERSIBLE ANTAGONISM OF THE INCREASE IN HEART RATE FOLLOWING INTRATHECAL ADMINISTRATION OF SUBSTANCE P AT THE LOWER THORACIC SPINAL LEVEL IN THE RAT. K. Yashpal* and J.L. Henry (SPON: R.B. Malmo). Departments of Physiology and Psychiatry, McGill University, Montreal, Quebec, H3G 1Y6

Intrathecal administration of substance P (SP) at the ninth thoracic spinal level increases the adrenal output of catecholamines (Neurosci. 15:529-536,1985) and increases heart rate and arterial pressure (J. Autonom. Nerv. Syst. 18:93-107,1987). As both humoral and neural mechanisms may mediate these cardiovascular responses a study was done to determine the effects on heart rate and arterial pressure in adrenalectomized (ADX) vs intact rats. Male Sprague Dawley rats (approx. 350 g) were anaesthetized with urethane (2.5 g/kg i.p.) and implanted acutely with an intrathecal PE-10 catheter passed via the atlanto-occipital junction to the T9 level. PE-60 catheters were implanted in the carotid artery to measure arterial presure and heart rate and in the femoral vein for injection of drugs. ADX was bilateral using a surgical method; control rats were sham operated. After 30 min, baseline readings were taken over 5 min and SP was delivered intrathecally in a dose of 6.5nmoles in 10ul of artificial CSF; the catheter was flushed with 10ul of CSF. In control experiments CSF replaced the SP solution. Readings were then taken over the next 30 min. SP increased heart rate and arterial pressure in both groups of rats: ADX (n=15), +394±16.6 (SEM) bpm and +21±4.0 mmHg; intact (n=10), +379±20.4 bpm and +20±4.8 mmHg, respectively. CSF administration failed to induce any changes in either parameter. While the magnitude of these responses was the same in the two groups, the increase in heart rate was significantly more abrupt in the ADX rats ($p<0.05$). This suggested that the adrenals are not necessary for the expression of the cardiovascular responses and that they might be secreting a factor which slows the neurally mediated cardioacceleration induced by administration of SP. To examine this possibility, as opioids are co-released with catecholamines from the adrenals, naloxone (10 mg/kg) was given i.v. 5 min before administration of SP (n=7); the SP-induced cardiovascular changes were similar in magnitude to those seen earlier. The time course of the cardioacceleration resembled that in the adrenalecotmized rats, suggesting that the factor secreted by the adrenals was opioid in nature. In addition, 8 rats were pretreated with nalorphine methochloride (10 mg/kg, s.c.), an opiate antagonist which does not cross the blood-brain barrier; the cardioacceleratory response to SP resembled that in ADX rats, sugesting that the site of action of the opioid factor is peripheral. These results suggest that intrathecal administration of SP induces the release from the adrenals of a factor which is opioid in nature and which slows a neurally-mediated cardioacceleration by an action in the periphery. (Supported by Quebec Heart Foundation)

80.19 ADRENAL AND NON-ADRENAL SYMPATHETIC PREGANGLIONIC NEURONES IN THE CAT: PHYSIOLOGICAL PROPERTIES AND RESPONSES TO SEROTONIN.
S.B. Backman, H. Sequeira-Martinho* & J.L. Henry, Depts. of Psychiatry & Physiol., McGill Univ., Montreal (Quebec) H3G 1Y6

Sympathetic preganglionic neurones (SPNs) projecting to the adrenal medullae receive a unique set of chemically identifiable synaptic terminals distinct from neighbouring, non-adrenal SPNs (Neuroscience 7: 1155, 1982). Adrenal SPNs vs non-adrenal SPNs lend themselves well to electrophysiological studies because adrenal SPNs, but not non-adrenal SPNs, can be activated antidromically from their target organ. Thus, in the present study, the two types of SPN were compared for their physiological properties and their response to serotonin. Cats were anaesthetized (chloralose), paralyzed (pancuronium bromide) and ventilated artificially (end-tidal CO_2 3-6%; phrenic nerve discharge regular and stable). Spinal segments T8-T10 were exposed. Extracellular single unit spike activity was recorded from the central barrel (containing 2.7M NaCl) of multi-barrelled micropipettes; barrels for iontophoresis contained serotonin creatinine sulphate (50mM in 0.16M NaCl, pH 3.3 or 4.5), methysergide maleate (10mM in 0.16M NaCl, pH 4.0) and control solution (0.16M NaCl, pH 3.3 or 4.5). Positive sites of recording were identified by Pontamine Blue deposits; all were in the intermediolateral nucleus. A unit was classified as SPN if it responded antidromically to electrical stimulation of the greater splanchnic nerve or adrenal medulla, with non-adrenal SPNs responding only to stimulation of the greater splanchnic nerve and adrenal SPNs to adrenal stimulation. Of the 19 adrenal SPNs, 17 discharged spontaneously (mean rate of discharge ±S.D., 1.3±0.5 spikes/s); the pattern of activity was irregular and none discharged with a phasic pattern. Of the 83 non-adrenal SPNs 70 discharged spontaneously (mean rate 2.0±1.5); 10 of these units demonstrated a phasic pattern of activity clearly related to phrenic nerve discharge, lung inflation or oscillations in arterial pressure. Mean latencies of antidromic responses were 19.5±6.2ms (adrenal SPNs) and 15.9±4.8 (non-adrenal SPNs). Serotonin (10-100nA) increased the firing rate of 7/9 adrenal SPNs and 32/35 non-adrenal SPNs; depression was never observed. Excitation was similar for both types of SPN, being typically slow in onset (mean latency 58.6±46.6s) and prolonged in after-discharge (mean duration 131±75s). Responses were similar whether using serotonin at a pH of 3.3 or 4.5, suggesting that the absence of a depressant effect cannot be accounted for by pH, as observed with cortical neurones (Brain Res.40:552,1972). The excitatory response to serotonin was antagonized by methysergide (60-100nA) with 2/3 non-adrenal SPNs and with the one adrenal SPN tested. These data suggest that the two types of SPN share some physiological properties and show similar responses to serotonin. (Support: Canadian and Quebec Heart Foundations. Stairs Foundation of McGill Univ. & NATO)

80.20 TRANSNEURONAL AND AFFERENT TERMINAL LABELING OF SYMPATHETIC PREGANGLIONIC NEURONS WITH THE C-FRAGMENT OF TETANUS TOXIN.
J.B. Cabot, A. Mennone* and N. Bogan*. Department of Neurobiology, SUNY at Stony Brook, Stony Brook, NY 11794.

Sympathetic preganglionic neurons(SPN's) exhibit several somatic shapes and dendritic alignments. It is unknown if morphological diversity presages peripheral functional specificity. This issue is approachable anatomically, but requires the identification of a "marker" molecule that is transported retrogradely, transsynaptically and transneuronally. Recent evidence suggests that the C-fragment of tetanus toxin (CTTx) is such a "marker" and that it can be immunohistochemically recognized using a monoclonal antibody (Evinger C. and Erichsen, J., Brain Res.,**380**:383, 1986). Our preliminary light and electron microscopic data confirm that CTTx is transported retrogradely, transsynaptically and transneuronally following injections in the peripheral autonomic nervous system.

Experiments were performed in anesthetized pigeons. Injections of 1-2ul of 15% CTTx were made in paravertebral ganglion 14. Pigeons were sacrificed (pentobarbital, 1mg/kg) at 5-15 hrs; 1,3, 5 days; and 1-5 wks. CTTx was localized immunohistochemically (monoclonal antibody provided by Drs. Erichsen and Evinger). Light microscopically, the following observations have been made: (1) SPN's are transsynaptically, transneuronally labeled in T4 and T5 and retrogradely labeled in caudal C14, T1-3; (2) The aggregate transsynaptic, transneuronal transport rate is > 4mm/hr; (3) Retrograde CTTx labeling of SPN's is most apparent at 5hrs and gradually appears to diminish by 3 days; (4) Terminal labeling within the SPN neuropil (C14-T5) is evident at 5 hrs and persists for at least 4 wks before becoming immunohistochemically undetectable at 5wks postinjection.

Ultrastructural localization of CTTx (survival intervals of 5,10 and 15hrs) revealed that retrogradely labeled SPN's exhibited somatic, dendritic and axonal accumulations of CTTx. Reaction product was localized: (1) as granular appearing, diffusely distributed cytoplasmic inclusions; (2) within individual membrane bound vesicles; and (3) in multivesicular bodies. Afferent terminal labeling of synaptic input onto CTTx-labeled SPN somas as well as on large and small dendrites was present at 5hrs; the density of such terminal labeling increases with survival time (10 and 15hrs) and persists for at least 21 days. At all time points examined (5,10,15 hrs and 21 days) it has been repeatedly observed that unlabeled synaptic boutons are interposed between CTTx containing terminals. These data suggest transsynaptic specificity of CTTx transport may exist. (JBC is an Established Investigator of AHA; supported in part by HL24103).

TRANSPLANTATION II

81.1 ADHESIVE PROPERTIES OF NEURAL CELL AGGREGATES FORMED 'IN VITRO'.
J.A. Colombo+, *G. Charton++, +Department of Anatomy, College of Medicine, University of South Florida, Tampa, Florida, U.S.A. ++INSERM U-29, Hop. Port Royal, Paris, France.

Aging of neural cell populations constitute a limiting factor in the probability of such cells to grow outside their natural environment. In addition to severe mechanical trauma inflicted by procedures during cell dissociation of adult brains, changes in cell adaptability and viability as they may relate to time have also been suggested. Somewhat similar conditions may ensue when dissociating monolayer cultures for transplantation purposes. The possibility of using floating cell aggregates cultured 'in vitro' previous to transplantation provides a relatively safe procedure to avoid additional trauma (Colombo and Molina, 1986). The work reported here deals with further testing such procedures. Transfer of floating aggregates from rotating to stationary conditions was utilized to assess their ability to attach and grow, after various times in rotating culture.

Mechanically dissociated septal, and mes-metencephalic fetal tissue (E15-E17) was plated in 35mm uncoated dishes at $1X10^6$ cells per dish, in several culture media. Dishes were placed in rotating conditions (approximately 80 rpm), in a 5% CO_2/air atmosphere at 37°C. Three-day tests were run to evaluate attachment of aggregates after three or seven days in rotating cultures. Dishes on stationary cultures were coated with polylysine or Matrigel. Percent of aggregates attached to the substrate was significantly reduced when media was not supplemented with 10% fetal calf and horse defined sera, or when cytosine arabinoside was added to the culture media during rotating conditions.

Culturing cells for seven days also resulted in a decrease of the number of attaching aggregates, although DMEM with sera was used. Septal cells, under present conditions, appeared to be more affected by time than mes-metencephalic cells in rotating culture.

While eight day old, first generation aggregates failed to attach, second generation aggregates formed after trypsination of the former resulted in aggregates that regained their attachment capacity, followed by neuritic growth. The association of preculturing and cytosine arabinoside treatment with reduced glial population, supports the contention that glial cells subserve a critical role for the attachment of these cell aggregates, under present culture conditions. The observed 'inhibition' with time followed by 'disinhibition' after trypsin treatment, suggests a change in molecules bound to cell membranes. In conclusion, present results confirm the potential viability of early cell cultures in aggregate form, suggest that under standard culture conditions changes take place with time that reduce their ability to adhere 'in vitro' to certain substrates, and show that trypsin can restore such capacity.

81.2 **SYNAPTIC CONNECTIVITY OF DOPAMINE AFFERENTS IN THE DORSAL STRIATUM OF WEAVER MUTANT MICE**
B. Ghetti and L.C. Triarhou. Dept. of Pathology, Div. of Neuropathology, Indiana Univ. Sch. of Med., Indianapolis, IN 46223.

Striatal dopamine (DA) deficiency in weaver mutant mice is associated with a substantial loss of mesencephalic DA neurons. The concentration of striatal DA in weaver mutants reaches its maximal value on postnatal day 20 and eventually declines to 25% of the control value. Accordingly, the number of DA neurons in the substantia nigra represents 60% of the normal number on day 20 and becomes 30% of the normal value by day 90. Aim of the present study was to examine the form of synaptic connectivity established by DA afferents in the weaver striatum at the time when striatal DA concentration is at its peak level. To this end, 20-day-old weaver homozygotes, along with age-matched weaver heterozygotes and wild-type mice were studied by electron microscopy after immunocytochemical labeling for tyrosine hydroxylase. Quantitative analyses of the relations of tyrosine hydroxylase immunoreactive nerve terminals were carried out in the dorsolateral striatum, which receives DA innervation from the substantia nigra proper. In wild-type mice, 73% of the contacts were non-junctional, 1% was junctional asymmetrical, and 26% were junctional symmetrical. The majority of contacts (92%) were with dendrites and spines. In weaver heterozygotes, 71% of the contacts were non-junctional, 4% were junctional asymmetrical, and 25% were junctional symmetrical. Again, 91% of the contacts were with dendrites and spines. In homozygous weaver mutants, 83% of the contacts were non-junctional, 1% was junctional asymmetrical, and only 16% were junctional symmetrical. The majority of contacts (88%) were with dendrites and spines. The proportion of axosomatic contacts in the striatum of weaver homozygotes was double of that found in normal animals.

The reduced incidence of junctional synapses in weaver homozygotes is in all likelihood suggestive of inadequate synaptogenesis. Further, the increased incidence of axosomatic contacts is indicative of synaptic immaturity, as such contacts are commonly seen in early developmental stages. Our results support the developmental nature of the nigrostriatal deficit in weaver mutants, since the synaptic investment of striatal neuronal elements by DA afferents appears to be immature at the time when nigrostriatal synaptogenesis is normally complete.

81.3 **SYNAPTOLOGY OF DOPAMINE AFFERENTS IN THE DORSAL STRIATUM OF WEAVER MUTANT MICE FOLLOWING GRAFTING OF VENTRAL MESENCEPHALIC TRANSPLANTS**
L.C. Triarhou, W.C. Low and B. Ghetti. Dept. of Pathology, Div. of Neuropathology, and Dept. of Physiology and Biophysics, Indiana Univ. Sch. of Med., Indianapolis, IN 46223.

We have previously reported that ventral mesencephalic anlagen survive following grafting to the striatum of weaver mutant mice and reinnervate the dopamine (DA) depleted basal ganglia of the recipients (Proc. Natl. Acad. Sci. USA 83: 8789-8793, 1986). Aim of the present study was to examine the form of connectivity established by graft deriving DA afferents in the host striatum. Grafts were obtained from normal embryos at E15 and implanted into a surgical cavity overlying the dorsal striatum of adult weaver recipients. Tissues were processed for electron microscopic immunocytochemistry using a primary antiserum against tyrosine hydroxylase. At the time of examination, recipient weaver mutants were 8.5 months old and the grafts had survived for 4.5 months. Grafts were found to contain an estimated 100-1,000 tyrosine hydroxylase immunoreactive neurons. Tyrosine hydroxylase immunoreactive fibers, displaying the characteristic varicosities, innervated the dorsal striatum to a depth of 1,000 μm. In the non-grafted striatum, 91% of the contacts of tyrosine hydroxylase immunoreactive nerve terminals were non-junctional, 1% was junctional asymmetrical, and only 8% were junctional symmetrical. These proportions contrasted with the corresponding percentages found in normal animals, which are respectively 73%, 1%, and 26%. In the grafted striatum, 70% of the contacts were non-junctional, 2% were junctional asymmetrical, and 28% were junctional symmetrical. These percentages approximated the corresponding values in normal animals. The majority of contacts in the reinnervated striatum were with dendrites and spines. However, the proportion of axosomatic synapses in the reinnervated striatum was three times higher than that found in the striatum of normal animals. We conclude that: (1) In spite of a naturally occurring degenerative process, the basal ganglia of weaver mutant mice are receptive to synaptic investment by DA afferents originating in normal donor tissue. (2) In repopulating the previously denervated weaver striatum, graft deriving DA afferents display a connectional selectivity, i.e., they establish synaptic relations preferentially with those cellular domains that are normally innervated by DA nerve terminals. In this context, it is possible that DA fibers originating in the grafts invest postsynaptic sites that had either been vacated from their presynaptic DA input or had never received one. (3) A certain degree of anatomical immaturity may be suggested by the increased incidence of axosomatic contacts, which is a feature of the developmental morphology of the neostriatal anlage.

(Supported by USPHS grant RO1-NS14426).

81.4 **FUNCTIONAL INNERVATION OF THE NEOSTRIATUM IN WEAVER MUTANT MICE BY GRAFTED MESENCEPHALIC DOPAMINE NEURONS**
W.C. Low, L.C. Triarhou, Y. Kaseda, J. Norton, and B. Ghetti, Depts. of Physiology and Biophysics, Pathology (Neuropathology), Psychiatry, and Program in Medical Neurobiology, Indiana University School of Medicine, Indianapolis, IN 46223.

Transplants of dopamine neurons have been extensively studied using various experimental models of parkinsonism. These animal models have used neurotoxins such as 6-hydroxydopamine (6-OHDA) and N-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP) to destroy dopamine (DA) nerve fibers and neurons in order to replicate the degeneration of the nigrostriatal DA pathway seen in patients with Parkinson's disease.

The inherited loss of dopamine neurons in the substantia nigra pars compacta has been documented as part of the phenotypic expression in weaver mutant mice. A previous study has reported that DA-containing ventral mesencephalic grafts were capable of surviving and innervating the striatum of host weaver mutants (Proc. Natl. Acad. Sci., 83:8789-8793, 1986). In the present study, we provide evidence for the functional reinnervation of the striatum of weaver mutants by grafts of fetal ventral mesencephalic tissue.

Adult weaver mutants received ventral mesencephalic tissue from normal fetuses, placed on the surface of the dorsal striatum on the right side of the brain. Animals were tested for methamphetamine-induced circling behavior 113 - 141 days after transplantation. They were given methamphetamine (2.5 mg/kg body weight, i.p.) and placed in a stainless steel cylinder (17 cm in diameter and 18 cm high). Turning behavior was monitored by three observers during 1 minute intervals at 4-5, 9-10, 14-15, 19-20, and 24-25 minutes after the injection of methamphetamine. For each animal, the total number of rotations was determined for both left and right turns in increments of half body turns. Mean values for rotations to the left and right were calculated for each animal.

As a group, unoperated weaver mutants circled to the left 10.0 ± 1.6 (mean ± SEM) times, and to the right 8.7 ± 1.6 times during the 5 minutes of observation. In comparison, mutants with lesions and without grafts circled slightly more frequently to the left and slightly less frequently to the right (13.4 ± 3.3 and 5.0 ± 1.2 respectively). Weavers mutants with non-surviving nigral grafts circled 12.6 ± 2.6 times to the left and 8.71 ± 2.58 times to the right. No significant differences in rotational behavior were determined among these three groups. Weaver mutants with surviving tyrosine hydroxylase-immunoreactive neurons, on the other hand, displayed a marked increase in the number of rotations to the left (35.8 ± 8.5) in comparison to the three other groups along with a slight decrease in the number of rotations to the right (3.6 ± 1.9). The rotations to the left in animals with surviving implants represented a 358% increase above that of unoperated weaver mutants, a 266% increase above that of weavers mutants with lesions, and a 283% increase above that of weavers mutants with non-surviving grafts.

These results demonstrate that grafted dopamine-containing neurons establish a functional innervation of the weaver striatum and suggest that grafting of neural tissue is a viable approach in restoring motor function in genetic degenerative disorders of the nigrostriatal system.

81.5 FETAL CORTEX TRANSPLANTS DO NOT ENHANCE RECOVERY OF LOCOMOTION FOLLOWING SENSORIMOTOR CORTEX LESIONS IN RATS.
J.M. Held, D.G. Stein, A.M. Gentile, S. Quesnel*, D.M. Basso. Dept. of Physical Therapy, Univ. of VT., Burlington, VT. 05405.

Two studies were carried out to evaluate whether fetal brain tissue transplants could enhance recovery of locomotion following sensorimotor (S-M) cortex damage in rats. In the first study, 23 mature male Charles River Rats were pre- and postoperatively trained and tested on a narrow elevated runway. Seven rats were sham-operated (SHAM), and 16 sustained bilateral sensorimotor cortex lesions. Seven days later, one group of 8 animals received fetal transplants from sensorimotor cortex of 19 day old fetuses (S-M 19) while the other 8 lesioned (LES) plus the SHAM rats sustained a sham operation. Postoperatively, both the LES and S-M 19 rats were impaired on two levels when compared to SHAMS, but LES and S-M 19 did not differ from each other. The two levels of analysis were: behavioral (Mean Run Time, No. of Errors, Days to Pre- operative Criterion) and movement (Quantitative Measures of Movement Patterns of the hindlimb). Histiology revealed that most of the transplants did not survive.

Since sensorimotor cortex differentiates early, we hypothesized that S-M transplants taken earlier, or frontal (F) cortex transplants, would survive better. Therefore, we trained and lesioned three more groups of rats, and seven days later performed transplants from S-M cortex (fetal age 15 days, 7 rats; fetal age 17 days, 8 rats) or frontal cortex (fetal age 19 days, 6 rats). All three groups were clearly impaired postoperatively, but did not differ from each other on either the behavioral or the movement level of analysis.

When comparing across the two experiments, there is a suggestion that fetal tissue transplants may in fact have been detrimental. First, 70-80% of rats in all transplanted groups have longer Mean Run Times than lesioned animals. In addition, a more aberrant movement pattern consisting of a very low initial flexion phase of the swing cycle of the hindlimb was observed in at least one transplant group after the rats had achieved preoperative performance levels. Preliminary evidence suggests that some of the transplants in the three groups of the second experiment did not survive. Further histological analysis is being carried out. Apparent differences may be more evident after adjusting for presence/absence of transplants.

Thus, fetal brain tissue transplants from different sites (S-M or F cortex) or of different fetal ages (15,17, or 19 days) failed to produce a demonstrable enhancement in recovery. In fact, the transplants may have been disruptive to the normal recovery process.

81.6 ABNORMAL POPULATIONS OF MUSCARINIC CHOLINERGIC RECEPTORS IN FETAL STRIATAL TRANSPLANTS CORRELATE WITH TRANSPLANT-INDUCED LOCOMOTOR RECOVERY.
A. W. Deckel, R. G. Robinson, and T. H. Moran, Dept Psychiatry, N.J. Med Sch, U.M.D.N.J., Newark, NJ., 07103 and Dept Psychiatry and Neuroscience, Johns Hopkins Univ Sch Med, Baltimore, MD 21205.

Past work in various laboratories has demonstrated that fetal striatal transplants, when placed into the kainic acid or ibotenic acid lesioned striatum, partially remediate the locomotor and "cognitive" deficits caused by the lesion, but do not remediate locomotor deficits under conditions of DA or muscarinic cholinergic drug stimulation. The current experiment examined to what extent muscarinic cholinergic receptor systems develop in the transplant, and the relationship between these transplants and transplant-induced locomotor recovery.

Thirty six adult female rats were divided into four groups, including control (sham lesion/sham tran), lesion only (kainic acid lesion/sham tran), lesion and transplant (ka lesion and E18 fetal striatum (str)), and tran only (sham lesion/str tran). Kainiate lesions (0.8 ug delivered in 0.4 ul PBS, ph=7.4) were made bilaterally in the anterior-medial str (coordinates A1.5, L2.2., H 4.5). One week later, 2.0 ul of E18 fetal str was mechanically aspirated into a capillary tube and implanted back into the lesioned adult str.

Six months following surgery, animals were run in an activity monitor that assessed a wide range of locomotor activities. Each animal received, on an every other week basis, one of 6 drugs, including saline (1ml/kg), amphetamine (1 mg/kg), apomorphine (0.2 mg/kg), haldol (1 mg/kg), scopolamine (0.8 mg/kg) and pilocarpine (1 mg/kg). Following completion of the locomotor assessments, muscarinic cholinergic receptor binding was determined. Twenty five um slices were incubated either directly in 1nM tritiated N-methyl scopolamine to give a measure of total binding, or scopolamine plus 100 uM carbechol or 1uM atropine, respectively. Binding values for M1 and M2 receptors were calculated via densitometry.

The kainic acid lesions caused a pronounced hyperactivity under the saline, amphetamine, apomorphine, and scopolamine drug conditions. The fetal strital transplants reversed the hyperactivity in the saline condition, but had little effect on locomotor behavior under the various drug conditions. M1 receptor density was found to be significantly higher in the transplanted tissue compared to control str, while M2 receptors were significantly reduced in density in the transplants. M1 receptor density was not correlated with locomotor behavior, however M2 receptors significantly correlated with locomotor activity in each of the drug groups except for the saline condition.

81.7 DEVELOPMENT AND FUNCTION OF FETAL HUMAN BRAIN TISSUE IN IMMUNOCOMPROMISED RODENT CARRIERS: THE USE OF ATHYMIC NUDE RATS. A. Seiger, L. Olson[1]*, I. Stromberg[1]*, M. Bygdeman[2]*, P. Bickford-Wimer[3], A.-C. Granholm[3]*, J. Stevens[3]*, B. Hoffer[3]. Dept. of Neurological Surgery, Univ. of Miami Sch. of Med., Miami, FL; [1]Dept. of Histology, Karolinska Institute, Stockholm, Sweden; [2]Dept. of OB-GYN, Karolinska Hospital, Stockholm, Sweden; [3]Dept. of Pharmacology, Univ. Colorado Health Sciences Ctr., Denver, CO.

Human fetal tissue fragments were collected following elective abortions in the seventh to eleventh week of gestation using procedures which were approved by the Ethical Committee of the Karolinska Hospital and conformed to guidelines of the USPHS. Under a stereomicroscope, it was possible to identify most areas of the developing human brain and prepare tissues suitable for xenografts to the anterior chamber of the eye or the brain of immunocompromised rodent hosts. We have previously shown structural and functional maturation of cortical and subcortical areas in the anterior chamber of the eye and of dopamine neurons grafted to the dopamine-denervated striatum in rats receiving daily cyclosporin injections. Recently, similar transplantations have been carried out in athymic nude rats. Intraocularly, human brain tissue survives and develops significantly better in nude rats than in Sprague-Dawley rats treated with cyclosporin (10 mg/kg/day). Cortex cerebri, cortex cerebelli, the hippocampal formation and the spinal cord develop characteristic structural and functional properties in oculo as evidenced by immunohistochemistry using antibodies against GFA, neurofilament, laminin, tyrosine hydroxylase, NPY, other neuropeptides, and by extracellular recording techniques. Data from cyclosporin-treated as well as nude rats suggest that development occurs according to a human rather than a rodent timetable. Electrophysiological evidence suggests development of an intrinsic circuitry in cerebellar grafts and of sensitivity to noradrenaline. In cortex cerebri grafts, penicillin superfusion increased discharge rates of pyramidal neurons. We conclude that xenografting from tissue fragments of human fetuses to nude athymic rats provides a unqiue model in which to perform invasive studies of defined areas of the developing human nervous system.

81.8 CROSS-SPECIES SEPTO-HIPPOCAMPAL TRANSPLANTS OF THY-1.2 IMMUNOREACTIVE CELLS. R.J. McKeon, J. Wells, B.P. Vietje,* and D.G. Wells.* Department of Anatomy and Neurobiology, University of Vermont, Burlington, VT 05405.

A variety of experiments have suggested that cross-species transplants of embryonic neurons survive, differentiate, and may innervate an adult host. One limitation of these studies has been the difficulty in differentiating between host and donor cells in long term transplants. In the present experiments, embryonic cells (E 15-17) from the septal-basal forebrain region of Thy-1.2 positive C57Bl/6 mice were transplanted to the dentate gyrus of Thy-1.2 negative adult Sprague-Dawley rat hosts. In situ, the Thy-1.2 antigen is not fully expressed until 20 days postnatally. Consequently, host animals were sacrificed between 3 and 8 weeks following transplantation in order to allow the Thy-1.2 antigen to reach adult levels. Hippocampal sections were processed immunocytochemically for the presence of Thy-1.2 reactive cells. Staining was seen as early as 4 weeks, corresponding to the delayed expression of Thy-1.2 in situ. The greatest intensity of staining was noted at 8 weeks. The transplant site consisted of a large mass of reactive tissue in the dorsal leaf of the dentate gyrus. Reactive fibers were seen extending from the transplant into the host neuropil. In some animals, these fibers appeared to begin organizing in a laminar fashion. However, this organization differs from the pattern of AChE histochemical staining, leaving the relative contributions of host and donor cells in the cholinergic relamination of the hippocampus in question. Frequently, Thy-1.2 reactive cells were found away from the body of the transplant, primarily in the hilus and in the molecular layer of the dentate gyrus. These cells were large, in a variety of shapes, with long processes which ramified extensively within the molecular layer. Experiments are in progress to determine the feasibility of using Thy-1.2 immunoreacitvity to identify donor cells at later time points, measure the survivability of transplanted cells, and study the potential for xenogenic transplants to form functional synapses with the host.

TRANSPLANTATION II

81.9 FLUORESCENT MICROSPHERES IMPLANTED IN THE HIPPOCAMPUS SHOW "MIGRATION." B.P. Vietje,* J. Wells, D.G. Wells,* and M.E. Dunn* (SPON: M. Ariano). Department of Anatomy and Neurobiology, University of Vermont, Burlington, VT 05405

In our previous studies of xenogenic transplants, injected cells appeared to have migrated along the cleavage planes of the hippocampus. In order to differentiate between active migration and passive displacement, we injected fluorescent polystyrene microspheres (6.49 ± 0.4 um) into the hippocampal formation. The fluorescent microspheres were found at substantial distances from the injection site in a pattern which might be interpreted as migration. However, because the beads can reasonably be assumed to have no capacity for active migration, the observed distribution could be due to passive displacement. The fluorescent beads outside of the injection site were distributed characteristically in three ways. 1) The beads were found along the cleavage planes of the hippocampal formation. The cleavage planes are found above the stratum oriens, along the obliterated hippocampal fissure and on the hilar side of the dentate granule cell layer. The beads spread along these planes singly or in small groups with no apparent connection to the main injection site. This appeared as "migration." From the cleavage planes, microspheres frequently gained access to the ventricles. 2) Beads also were seen at considerable distances from the main injection site; e.g., the diencephalon and cortex. Most of these beads were associated with blood vessels, and we assume the apparent "migration" occurred by paravascular circulation. 3) A few beads were found neither in the cleavage planes nor associated with blood vessels. The beads that were found in the hilus were frequently in this category. To control for artifactual displacement of beads, pairs of brains were sectioned in opposite directions and we did not consider in our analysis any beads that appeared on either surface of the sections. We conclude that transplanted neurons, which appear outside of the injection site, may not necessarily have arrived there by active migration but by other means as demonstrated by fluorescent microspheres.

81.10 REPAIR OF THE BLOOD-BRAIN BARRIER DURING THE FIRST WEEK AFTER SEPTO-HIPPOCAMPAL TRANSPLANTS. J. Wells, B.P. Vietje,* D.G. Wells* and M. Fiala.* Department of Anatomy & Neurobiology, University of Vermont, Burlington, VT 05405.

The act of transplanting neurons into a host brain breaks the blood-brain barrier (BBB) allowing the host to begin its immunological response to the injected antigens. Since it takes a few days to build up a pool of activated killer lymphocytes, the rapid repair of the BBB would seem to be critical for the survival of the transplanted cells--particularly for xenogenic transplants. In the present experiment, we determine the characteristics of the repair of the BBB during the first week after transplantation. Embryonic mouse or rat cells from the septal-basal forebrain region were transplanted into the dentate gyrus of rat hosts. Using the procedure of Rosenstein and Brightman (Science 221:879, 1983), HRP was injected into the femoral vein before the animal was perfused. Brain sections were then processed to demonstrate TMB reaction product. Within a few hours of the transplantation, the HRP was found in the host to be uniformly distributed around the perimeter of the injection site and extended out into the surrounding tissue in a gradually decreasing concentration. Similar reactions were seen at the surface of the cortex where the injection needle first penetrated and along the needle tract. One day after transplantation, there was a partial repair of the BBB at the injection site and along the needle tract, but not at the cortical surface. The distribution of the HRP became discontinuous around the perimeter of the injection site in the hippocampal formation. The thinner, more peripheral, parts of the injection site and the needle tract appeared to be repaired first. In the bulbous portion of the injection site, HRP continued to infiltrate the host hippocampus but was usually less dense and less extensive than at the earlier time points. There was little change in the distribution of HRP during the remainder of the first week after transplantation. The changes in the BBB were the same in both xenogenic and homogenic transplants. In summary, the BBB was partially repaired within the first day. The repair of the BBB was never complete around the transplant site during the first week, but the areas that were repaired--the thinner perimeters of the injection sites-- were the areas where the survival of labelled xenogenic neurons were also observed.
Supported by NS 23266.

81.11 INVOLVEMENT OF MHC ANTIGENS IN NEURAL ALLOGRAFT REJECTION. K. Rao,* H. W. Kunz,*° T. J. Gill,*° and R. D. Lund (SPON: J. Hermanson), Dept. of Neurobiology, Anatomy and Cell Science, and the °Dept. of Pathology, Uni. of Pittsburgh, Sch. of Med., Pittsburgh, PA 15261

We have shown previously that xenografts of embryonic (E13-14) CD-1 mouse retinae that had integrated and survived for prolonged periods in a host rat brain, are rejected when a CD-1 mouse skin graft was placed on the flank of the recipient animal.

We have extended these studies using highly inbred congeneic strains of rats. Embryonic (E14-15) dark agouti (DA) rat retinae were transplanted into the brains of neonatal brown Norway (BN) rats. The host immune system was subsequently challenged with skin grafts of animals which differed from the recipients at (i) the MHC loci only, (ii) the non-MHC loci only, and (iii) both the MHC and the non-MHC loci. Serum samples drawn before and after skin grafting were analysed for antibodies directed against cells expressing MHC or non-MHC antigens alone, or in combination. This was done in order to determine the significance of these antigens in the host immune response to the neural graft, as well as the subsequent skin graft. Appropriate controls were incorporated into the experimental design.

Animals were sacrificed within two weeks following skin grafting, and frozen sections were examined after using the following stains: cresyl violet for cell bodies, a neurofibrillar stain for fiber projections from the transplanted retina, and the Fink Heimer stain to show degenerating fibers.

Serum antibody data indicated that in 7 of 17 cases studied, the host immune system had been sensitized by the neural graft. Rejection of the neural grafts was served after skin grafting when the skin differed in either MHC or non-MHC antigens with respect to the host.

These results emphasize an instability of neural allografts even when placed in the brains of neonatal rats prior to the development of full immunocompetence.

Supported by grants CA18659, EY05283 from NIH and a grant from the Samuel and Emma Winters Foundation.

81.12 COURSE OF TRANSPLANT REJECTION WITHIN THE CNS. M. B. Houston, H. W. Kunz,*° T. J. Gill,*° and R. D. Lund. Dept. of Neurobiology, Anatomy and Cell Science, and °Dept. of Pathology, Uni. of Pittsburgh, Sch. of Med., Pittsburgh, PA 15261.

Recently it has been shown both in vitro and in the CNS, in vivo, that neurons and astrocytes are capable of expressing the major histocompatibility complex (MHC) antigens which, in peripheral tissues, are required for recognition by the immune system (L. Lampson, TINS, 10:211, 1987). Our experiment was designed to elucidate the sequence of events leading to immuno-rejection of a neural graft placed into the brain.

Retinae or cerebral cortices were removed from CD-1 mice at embryonic day 13 and transplanted into either the midbrain or cerebral cortex of neonatal Sprague-Dawley rats. At 30 days of age, one group of rats received a graft of CD-1 skin approximately 1 cm^2. Animals were perfused 1 to 8 days following skin grafting, and adjacent 25μm frozen sections reacted immunocytochemically for murine MHC, rat-specific Common Lymphocyte Antigen (T and B cells), GFAP (astrocytes), and a mouse-specific neuronal cell-surface antigen designated M6 (viable transplanted neurons). The same protocol was followed for control animals, which received a neural transplant but no skin graft.

MHC labeling in control animals was restricted to areas along the vasculature within the transplant but no lymphocytes were observed. Numerous astrocytes were present within the transplant. Two days after skin grafting, MHC labeling was evident in parenchyma of the graft and surrounding host brain, but lymphocytes were still not observed. GFAP positive astrocytes became prominent in the graft, areas containing transplant innervation, and surrounding host tissue. At 8 days post-skin grafting, there was heavy lymphocytic infiltration into the transplant, as well as into surrounding host tissues. Vascular cuffing was prominent, and the transplant shows signs of degeneration.

This study provides insite into how immunological privilege becomes compromised in the brain and indicates that a complex interaction involving MHC antigens, the immune system (lymphocytes) and CNS glia (fibrillary astrocytes) occurs during transplant rejection. Supported by NIH grants EY05283, CA18659, and a grant from the Winters Foundation.

81.13 EVIDENCE FOR THE SURVIVAL OF RETINAL GANGLION CELLS IN NEONATAL RETINAL GRAFTS BY THY-1.1 IMMUNOCYTOCHEMISTRY. J.R.Blair and J.E.Turner. Dept. of Anatomy, Bowman Gray School of Medicine, Wake Forest Univ., Winston-Salem, NC 27103

Thy-1 is a 17,500 Kd cell surface glycoprotein found on the surface of a number of different cell types in mammalian tissues. In the retina only the retinal ganglion cells express this particular cell surface protein. The rat exhibits the Thy-1.1 form of the protein in contrast to the Thy-1.2 form produced by certain strains of mice. Utilizing the OX-7 monoclonal antibody to Thy-1.1, we have examined neonatal retinal grafts made to the lesioned retinas of adult hosts using a previously described paradigm (Turner, J.E. and J.R. Blair, Dev. Brain Res., 1986), in order to establish the presence of surviving ganglion cells in the grafts. The OX-7 antibody was employed in conjunction with the avidin-biotin technique for antigen identification using HRP/DAB as the enzymatic marker for localization in tissue sections. Initial work with adult retinal control tissues showed the OX-7 antibody to be very specific in localizing the Thy-1.1 antigen to the optic fiber layer (OFL), ganglion cell layer (GCL) and inner plexiform layer (IPL) of the retina. No labeling was seen when either the 1° or 2° antibody was omitted. Nor was there any labeling when a monoclonal antibody for Thy-1.2 was substituted for OX-7. Neonatal grafts were processed for Thy-1.1 immunocytochemistry 1 and 12 weeks after grafting. In both instances specific positive labeling was observed in the graft tissues. Utilizing the host retina as a positive internal control, the labeling was shown to be localized to the same regions of the graft tissue as in the host. While not all cells in the ganglion cell layer were positively labeled, many of the larger cells were, corresponding to those with the characteristics of GCs seen in counterstained sections. The staining in 1 week grafts was more diffuse than that of the older grafts suggesting that the ganglion cells may still have been undergoing maturation or remodeling connections with other cells in the graft. The importance of these findings lies in the survival of the retinal ganglion cell as the only output cell of the retinal graft. Thus the presence of ganglion cells is critical if retinal grafts are to play any role in the repair of damage due to disease or trauma with concomitant with regain of function.

81.14 DONOR AGE INFLUENCES THE SUCCESS OF RETINAL TRANSPLANTS TO ADULT RAT RETINA. R. Aramant, M. Seiler and J. E. Turner. Dept. of Anatomy, Bowman Gray School of Med., Wake Forest Univ., Winston-Salem, NC 27103.

We have recently developed a technique for grafting embryonic rat retina into an adult rat retinal lesion site (Turner, J.E. and J.R. Blair, Dev. Brain Res., 26: 91-104, 1986). A penetrating lesion through retina on the dorsal surface of the eye creates an area devoid of retina into which the graft is placed. Retinal donor tissue is inserted by a 26 gauge needle attached to a 10 μl syringe through the lateral edge of the sutured lesion into the vitreous side. We report in this study that the rat retina can be successfully grafted within a long time period which extends into the first two weeks of postnatal life. At 4-7 weeks after transplantation E15 and PN1-2 (postnatal) grafts were organized in layered folded sheets and rosettes. Donor tissue from PN1-2 rats demonstrate no significant differences in their ability to form successful transplants. However, grafting success begins to diminish gradually starting between PN2-4 and reaches a low point in organization and survival by PN14. PN21 grafts illicit an immunological rejection-like response. Although early postnatal retinal tissue can be successfully grafted, E15 embryonic retinas make better transplants for their ability to form consistent laminae and to integrate with host tissue in a fresh lesion site when observed 7 weeks after transplantation. E15 grafts exhibited an increase in the number of laminae (i.e., 6-7 of the 9 retinal layers, excluding the retinal pigment epithelium) compared to only 3-5 for PN1 grafts. Light microscopic observations indicated in E15 grafts the presence of ganglion cell (GCL), inner plexiform (IPL), inner nuclear (INL), outer plexiform (OPL), outer nuclear (ONL), and outer limiting membrane (OLM) layers. Occasionally evidence of developing inner photoreceptor cell segments was found in E15 graft rosettes. In contrast, PN1 grafts possessed only a GCL, IPL, INL and ONL. Characteristically absent from both E15 and PN1 grafts was a continuous optic fiber layer and inner limiting membrane. In this study it was also confirmed by the use of a Fast Blue labeling technique that retinal tissue which was found in the lesion site indeed belonged to the graft and not to the host.

81.15 DEVELOPMENT OF GLIAL MARKERS IN HOST AND GRAFT RAT RETINA AFTER TRANSPLANTATION. M. Seiler and J. E. Turner, Department of Anatomy, Bowman Gray School of Medicine, Wake Forest University, Winston-Salem, NC 27103

E15 retinae were transplanted into fresh retinal lesion sites of adult hosts (see Turner and Blair, Dev. Brain Res., 26:91-104, 1986). Animals were sacrificed 3-5 hrs, 1-15 days, 5 and 7 wks after surgery. After vascular perfusion with saline and fixation with 4% Paraformaldehyde, the eyes were processed for immunocytochemistry on frozen sections with a monoclonal mouse GFAP antibody (Debus et al., EMBO J., 1: 41-45, 1982) and with a polyclonal rabbit antiserum against S-100 protein (ICN, former Miles Inc.). In normal retina, only Astrocytes (AS) in the optic fiber layer and few Mueller cell (MC) fibers in the inner plexiform layer stained for GFAP. 3-5 hrs after transplantation, GFAP-filled reactive MC appeared in the peripheral part of the lesioned dorsal retina where ganglion cells (GC) axons had been axotomized. After 1 day, GFAP immunoreactivity of MC was also found in the central part of the ventral retina. After 2 days, MC stained for GFAP throughout the entire (dorso-ventral) extent of the host retina; but up to seven weeks after transplantation, there remained a dorso-ventral gradient of MC GFAP immunoreactivity in response to the lesion (denser and more intense staining of MC in dorsal retina). Thus, MC injury response seemed to be initiated by axotomized GC and to spread in a declining "wave" through the entire retina. S-100 staining in host retina did not change after injury; the antiserum stained AS and MC cell bodies, fibers and the internal and external limiting membrane (ILM + ELM). At the host-graft interface, occasionally a dissolution of the ILM could be seen. Within the graft, S-100 stained cells were found first 4 days and GFAP+ fibers 8 days after transplantation. 15 days after transplantation, the ELM within graft rosettes stained faintly for GFAP and S100, indicating MC maturation and reactivity. By 5 and 7 wks after transplantation, the graft was filled with intensely staining GFAP+ and S-100+ multipolar AS and bipolar MC, thus exhibiting a reactive appearance. Within graft rosettes MC were distributed radially, indicating their importance for the formation of retinal layers. AS were found everywhere in the graft (not restricted to the vitreal surface), concentrated along blood vessels, but less frequent in graft rosettes. This abnormal AS distribution might explain the lack of a continuous ILM within the graft. In the graft, the two retinal glial cell types develop from undifferentiated precursors into injury-reactive glia. This work was supported by grant No. EY04377 (National Eye Institute) awarded to JET.

81.16 NEOCORTICAL TRANSPLANTS GRAFTED INTO THE NEWBORN RAT BRAIN DEMONSTRATE A BLOOD-BRAIN BARRIER TO MACROMOLECULES. R.S. Swenson, J.C. Sørensen*, J. Zimmer* and A.J. Castro (Spon: G. Celesia), Univ. of Illinois Sch. of Med., Chicago, IL 60612; Instit. of Anat. B, Aarhus Univ., Denmark and Dept. of Anat., Loyola Univ. Stritch Sch. of Med., Maywood, IL 60153.

Systemically injected HRP and endogenous serum albumin was recently found to penetrate the blood brain barrier (BBB) and permeate fetal neocortical tissue grafted into adult host rats (Science 235:772-774, 1987). In the present study we examined BBB permeability in adult rats that received fetal neocortical grafts at birth. Accordingly, fetal (E14-17) cortical tissue dissected from fetuses removed from sodium pentobarbital anesthetized (50 mg/kg) dams was transplanted into hypothermic-anesthetized newborn (0-2 day old) rats. Using a glass pipette, transplants were placed just posterior to a cortical lesion made by aspiration rostral to bregma immediately before grafting. Transplant BBB permeability to systemically injected HRP and endogenous immunoglobulin (Ig) was examined 3-5 months later. HRP was administered via a jugular venous canula in a dosage of 1mg/5g body weight and animals were sacrificed 30 minutes post-injection by overdose of pentobarbital followed by cardiac perfusion with 1% paraformaldehyde, 1.25% glutaraldehyde. HRP histochemistry on frozen sections through the host brain and transplant was done according to routine methods using TMB as the chromogen. Another group of animals was perfused with 4% paraformaldehyde, and sections through the host brain and transplant were examined immunocytochemically using HRP conjugated goat anti-rat immunoglobulin (Sigma).

In HRP injected animals, TMB reaction product was observed within the ventromedial hypothalamus, subfornical organ and area postrema. These areas which normally lack a BBB to macromolecules were also found to be immunoreactive to Ig. However, neither HRP nor endogenous Ig were found within the transplants.

These findings demonstrate the establishment of an effective barrier to the penetration of macromolecules into transplants of fetal neocortical tissues placed within the cerebral hemisphere of newborn recipients. These findings are in contrast with the results of previous studies involving the grafting of neocortical tissue into adult recipients and imply that host age affects the vascular development within transplanted neuronal tissue. (Supported by NIH Grant NS 13230 and by funds from the Danish MRC.)

81.17 VASCULARIZATION OF THE NEONUCLEUS CONSTRUCTED BY EMBRYONIC NEURONS GRAFTED IN THE ADULT CNS AS A CELL SUSPENSION. I. Dusart, F. Nothias, F. Roudier and M. Peschanski INSERM U 161, 2 rue d'Alésia 75014 Paris, France

This study is part of a general project considering the nervous tissue reconstructed by fetal cells grafted homotopically as a cell suspension into an area of the central nervous system previously neuron-depleted. Results presented here concern the morphology of capillaries and the function of the blood-brain-barrier (BBB).

Rats have been studied after neuron-depletion due to the injection of kainic acid into the dorsal thalamus (n=7) or after neuron-depletion followed by grafting of E 15-16 cells (labeled with ^{3}H-thymidine) taken from the thalamic primordium (n=10). Two additional rats (1 lesion and 1 lesion-grafted) have been used for regular electron microscopy analysis. Two types of techniques have been used : perfusion with Indian ink followed by freeze-cutting on a cryostat (n=9) and circulation of horseradish peroxidase followed by aldehyde fixation and regular peroxidase histochemistry using 3 3' 5 5' tetramethylbenzidine (n=8)

In the intact thalamus, there is a regular vascular network of relatively narrow capillaries (average diameter 5 µm). HRP does not cross the BBB. Ultrastructurally, the capillaries are bordered by a thin epithelial cell, a basal membrane and small astrocytic expansions successively. In the lesioned zone, the vascularization is quite different : (i) numerous capillaries have enlarged diameter (up to 30 µm) and irregular caliber ; (ii) HRP is present in extravascular spaces and, in particular, in pericytes ; (iii) ultrastructurally, capillaries are surrounded by a thick mantle formed by loosely arranged astrocytic processes. The neonucleus formed by grafted neurons exhibits a normal vascular network both in terms of morphology of the capillaries and in the function of the BBB.

Whatever the origin of the epithelial cells which form the capillaries of the neonucleus (fetal thalamic primordium or adult neuron-depleted thalamus), they have probably their genetic program in common. This permits to suggest that the neuronal environment these cells encounter in the neonucleus is the major incitation for them to reorganize a vascularization comparable to that of the intact tissue. Development of capillaries in the neo-nucleus is presently under study.

81.18 INTACT BLOOD-BRAIN BARRIER IN LARGE NEOCORTICAL TRANSPLANTS IN THE RAT BRAIN. M.H. Lee, A.S. Lossinsky, A. Rabe and H.M. Wisniewski*. New York State Institute for Basic Research in Developmental Disabilities, Staten Island, NY 10314

The mammalian brain is protected by a blood-brain barrier (BBB) which isolates it from plasma and provides the brain with a tightly controlled homeostatic environment. Introduction of a transplant with a dysfunctioning BBB could not only affect the development and neurophysiological function of the transplant, but also allow serum proteins and neurotoxins to gain a direct access to the host brain. A recent study (Rosenstein, Science, 235:721, 1987) found that small transplants of fetal neocortical tissue in juvenile rats lacked a BBB to macromolecules. It is important to know whether the BBB is absent under other transplantation conditions. To determine whether a large fetal neocortical transplant introduced into a host brain during the early period of postnatal development would also fail to retain the BBB, we examined the brains of rats with prenatally induced micrencephaly bearing large fetal (E17-18) neocortical transplants given at 7-12 days of age. A slow infusion (0.5cc/min) of 50 mg of horseradish peroxidase (HRP) (Sigma VI) in 0.5ml of Ringer's solution was administered into the femoral vein of 1 year old male rats weighing 480g on average, and allowed to circulate for 1 hour before sacrifice by transcardiac perfusion with aldehydes. The brains were sectioned either 50-80µ on a Vibratome or frozen at 25µ, and incubated for HRP detection with diaminobenzidine. All animals in the transplant group had a large (over 200mm^3) tranplant occupying the intracranial space formed as a result of cerebral hypoplasia. In each animal, the transplant had established parenchymal interface at numerous sites with the host brain. No obvious sign of protein exudation was seen in any part of the transplant or in the host brain. Many disorganized blood vessels were identified in each transplant, but all were free of HRP; isolated areas of focal leakage of HRP from small segments of individual vessels were observed both in the transplants as well as in the host brains of a few animals. In one animal whose brain contained a huge abscess, involving over half of the basal ganglia and cerebral cortex of one side of the hemisphere with which the transplant interfaced, HRP filled the entire surface of the parenchyma surrounding the abscess to a depth of 1mm, while the transplant, 2-3mm away from the exudate, remained unaffected. It was concluded from these observations that the BBB in large fetal neocortical transplants retains its normal function, at least with regard to macromolecules.

81.19 RETINAL TRANSPLANTS MEDIATE A PUPILLARY REFLEX IN HOST RATS. H. Klassen,* R. D. Lund. Dept. of Neurobiology, Anatomy and Cell Science, Univ. of Pittsburgh, Sch. of Med., Pittsburgh, PA 15261.

To examine the functional efficacy of retinal transplants, retinae from E14 rat embryos were dissected free of investing membranes and placed over the midbrain of neonatal rats from which the right eye had been removed prior to transplantation. Five months later the left optic nerve was cut intracranially to eliminate afferent visual input while sparing the efferent pupilloconstrictor pathway running in the oculomotor nerve. Three days later the skull was opened and the transplant was exposed lying either rostral to the superior colliculus or displaced to a position over the cerebellum. When the transplant was illuminated, pupilloconstriction of the host eye resulted, with the degree of constriction dependent upon the level of illumination. Dilation followed cessation of illumination. These pupillary responses were abolished by damaging the transplant and by lesions localized to the pretectal region. No pupillary responses could be elicited in control animals that had undergone similar surgery to the experimental group, but had not received transplants.

The results indicate that retinal transplants are not only able to respond to changes in light intensity but also to relay this information to the pretectal region to effect an appropriate pupillary response in the host eye. Therefore, besides modulating complex behavior patterns as has been shown for nigral and basal forebrain grafts, neural transplants can also drive simple reflex pathways in response to natural stimuli. REGENERATION I

82.1 3-DIMENSIONAL CULTURE OF NEONATAL AND ADULT ASTROGLIAL CELLS IN NITROCELLULOSE IMPLANTS : A NEW MODEL FOR EXAMINING GLIAL-NEURONAL INTERACTIONS.
J. Rudge, G. Smith and J.Silver. Neuroscience Program, Dept. of Developmental Genetics and Anatomy, Cleveland, Ohio 44106

The mammalian central nervous system loses the capacity for axonal outgrowth as it ages such that regenerating axons in damaged CNS will only grow short distances into adult brain tissue. We are studying the mechanisms which allow axons to regenerate in young but not in adult CNS. To examine this question we have used the astrocyte coated nitrocellulose prosthesis model developed by Silver (Smith et al. 1986 JCN 251:23). A 0.45μ nitrocellulose filter implanted into the region of the corpus callosum in acallosal neonates is invaded by glial cells and other non-neuronal elements. Prior to 8 days of age these cells present a conducive surface to regenerating axons (Critical Period) but after 8 days (Post-critical Period), implantation results in the formation of a glial-fibroblastic scar around the nitrocellulose. We are interested in the changing properties and interactions of the young and old cell populations on the implant with respect to their capacity to promote axon outgrowth. To study these cell changes in a defined system we have increased the pore size of the nitrocellulose to 8μ, removed the implants from critical period and post-critical period brain and placed them into serum-free culture. The cells migrate on and into the nitrocellulose which protects them upon removal from the brain as well as dispensing with the need for an enzymatic dissociation step. The result is a stable population of cells derived from neonatal and adult rat brain which are viable for several weeks in culture and present in the same state as they were in situ. Immunocytochemical characterization of cells associated with the implants shows that at the critical period, cells are predominantly astrocytes with a minority of fibroblasts, oligodendrocytes and macrophages. The astrocyte cell bodies are found primarily at the surface of the implant inserting processes into the pores of the filter but also in arrays along the surface. In contrast, the post-critical period implants exhibit a greater percentage of fibroblasts, oligodendrocytes and macrophages. The fibroblasts are found at the surface of the filter while the macrophages migrate deep into the pores. The astrocytes which are still in the majority, have increased in size and have thick entangled processes. We intend to use this model to examine the ability of cells in and on the critical and post-critical period implants to promote neurite outgrowth in coculture with purified populations of neurons.

82.2 CAN IMMATURE GLIA IN THE RAT OPTIC NERVE PROMOTE AXONAL REGENERATION? N. Giftochristos* and S. David. Neurosciences Unit, The Montreal General Hospital Research Institute and McGill University, 1650 Cedar Avenue, Montreal, Canada, H3G 1A4.

There is increasing evidence that the CNS glia might play a crucial role in the failure of axonal regeneration in the adult mammalian CNS. Recent studies suggest that in contrast to glia in the adult rodent corpus callosum (CC), glia from the developing CC may be capable of promoting axonal regeneration.

We have carried out experiments to determine whether CNS glia in the developing rat optic nerve are also capable of promoting the growth of injured axons. The rat optic nerve was also chosen because much is known about the development of the various glial cell types in the nerve. Segments of optic nerve 3-4 mm in length, from E_{20}, P1, 5, 10 and adult Lewis rats were grafted into the peroneal nerve of adult female Lewis rats. After 8-12 months, longitudinal cryostat sections through the graft and adjacent peripheral nerve (PN) were double labeled with a rabbit anti-GFAP and a monoclonal antineurofilament (RT97) antibodies and visualized with appropriate fluorescein and rhodamine conjugated secondary antibodies, respectively. The majority of the PN axons bypassed the CNS grafts to re-enter the distal PN segment. This was true of grafts of all ages. However, a very small number of axons penetrated the optic grafts (up to 20/graft) and of these, 40% extended through the entire length of the grafts. There were no differences in the number of axons growing through the embryonic, neonatal and adult optic nerve segments.

There are at least 4 possible explanations for these results: (1) Injury-induced changes in immature and mature optic nerve glia may not favour axonal growth. (2) Glia from optic nerves of E_{20} and older rats may be incapable of supporting axonal growth but glia from younger rats may do so. (3) An increased number of axons may have grown through the embryonic and neonatal optic grafts, but may have degenerated at long survival times. (4) Greater affinity of the growing axons for Schwann cells rather than immature CNS glia. We are currently doing experiments to exclude the last 3 possibilities.

82.3 PC12 NEURITE PROMOTING FACTOR FROM ADULT TRANSECTED NERVE IS DISTINCT FROM NERVE GROWTH FACTOR.

Deborah Anne Lee*, Anthony J. Windebank, Marceil D. Blexrud*, Joseph F. Poduslo
Peripheral Nerve Center, Departments of Neurology and Biochemistry, Mayo Clinic and Mayo Foundation, Rochester, MN 55905

Endoneurial explants from permanently transected, adult rat sciatic nerve secrete a factor which induces dorsal root ganglion neurons to extend neurites in the absence of exogenous nerve growth factor (NGF). This factor (SN) is found in low amounts in explants removed 0-2 weeks after transection but reaches high levels in explants cultured after 3 and up to 5 weeks post-injury (Windebank and Poduslo, 1986, Brain Res. 385:197-200). We have compared SN with NGF in its ability to induce neurite outgrowth from a pheochromocytoma cell line (PC12). The explant-derived factor appears to be distinct from NGF in several important characteristics. Neurite outgrowth obtained from saturating levels of SN (81±51μ) was significantly less than with saturating concentrations of NGF (50 ng/ml (176±256μ), compared to untreated PC12 cells (59±25μ) (Means ± SD). Unlike NGF, this SN induced outgrowth could not be blocked with anti-NGF antibody (86±78μ). When saturating amounts of NGF and SN were used in combination, they demonstrated an additive effect of longer neurite outgrowth (209±206μ), which suggests two different growth factors using separate receptors. This was confirmed by the finding that SN does not compete with ^{125}I-NGF in a receptor-binding assay on PC12 cells or dorsal root ganglion neurons. PC12 cells in the presence of 50 ng/ml NGF showed only 57±0.08% of the ^{125}I-NGF binding found in the absence of unlabeled NGF; however, with saturating levels of SN, binding was 99.0±0.1% of control. With dissociated dorsal root ganglion neurons, the respective values were 64±0.1% (50 ng/ml NGF) and 107±0.2% (SN). We conclude that SN is a neurite-promoting factor distinct from NGF whose timing of expression after transection may indicate a role in regeneration. Additionally, PC12 cells provide a convenient system in which to study the biochemical action of SN. (Supported by NINCDS Grants NS-14304 and-NS 20551).

82.4 AXOTOMISED TROCHLEAR MOTONEURONS:THEIR MORPHOLOGY AND SYNAPTIC ORGANIZATION.

E.H.Murphy (1)and R.Baker(2). (1) Dept of Anat., Med Coll. PA., Phila., PA 19129; (2). Dept. Physiol. & Biophysics, NYU Med. Ctr., New York, NY 10016.

In earlier studies of axotomized cat trochlear motoneurons (TMn), we reported that the physiological profiles of these neurons were not distinguishable from normal 2-3 weeks after axotomy (Murphy et al, Neurosc.Abst.1985). However, after a longer survival (2-4 months), at least 50% of the axotomised TMns die. Of those neurons that survive, many regenerate to their original target and their mean soma size of is significantly larger than normal (Murphy et al Neurosci. Abst. 1986). The consequences of such changes might also be evident in the dendritic arborizations and the physiological profiles of these long term surviving TMns. Our aims in the present study, therefore, were to characterise the dendritic arborizations and establish their physiological profiles.Intracellular recordings were made in axotomised TMns in each nucleus 2 - 4 months following unilateral trochlear nerve section. Stimulating electrodes were placed on the ipsi and contra IVth and vestibular nerves. Following penetration and physiological recording of individual neurons, one or two TMns were filled intracellularly with 10% HRP to permit reconstruction and measurement of the dendritic arborizations. In axotomised, HRP filled neurons, the number of proximal dendrites was not changed, but the mean size of the proximal dendrites was decreased compared with normal, even in TMns in which the soma size was much larger than normal. In 2 neurons in which the entire dendritic arborization was reconstructed, its extent and the number of secondary and tertiary dendrites was not noticeably different from normal.Of all HRP filled neurons, only one was not antidromically activated. This TMn was also the only neuron in which an axon collateral was observed, and it exhibited the smallest mean dendrite diameter of all neurons studied. Antidromic field potentials in axotomised nuclei were localised and of small amplitude.By contrast, intracellular records from axotomised TMns showed in all cases normal antidromic SD invasion. However, the antidromic potential amplitude and the resting membrane potential were noticeably less than in the contralateral control TMns. Vestibular inhibitory and excitatory field potentials were nearly normal in amplitude and duration. The intracellular amplitude and duration of EPSPs and IPSPs in all axotomised TMns were not distinguishable from normal. Since the soma constitutes a small part of the total cell surface area, the results indicate that, despite an increased mean soma size, the total cell membrane area of axotomised TMns is decreased because the dendrites are narrower (see Gustaffson & Pinter, J. Physiol.'84). Thus, although the ratio of soma size to dendrite is altered, the presence of normal synaptic excitation and inhibition suggests there may be little alteration in distal dendritic membrane properties. NIH EY02007 and NS24707.

82.5 MORPHOLOGICAL AND METABOLIC INDICES OF THE RESPONSE TO AXOTOMY OF ABDUCENS MOTONEURONS.

Dara Tashayyod* and E.Hazel Murphy. (SPON: M.C. Kennedy). Department of Anatomy, Medical College of PA., Phila., PA 19129.

The distribution of cytochrome oxidase (CO), a mitochondrial enzyme involved in the electron transfer chain, has previously been shown to correspond well with areas of high metabolic activity, as revealed by 2-deoxyglucose uptake. We hypothesised that the response to axotomy might be associated with an increase in metabolic activity. In the present study, therefore, we have studied the relationship between changes in density and distribution of CO staining and changes in morphological characteristics observable in Nissl stained material in abducens motoneurons at various time periods after axotomy.

In anesthetised Sprague Dawley rats, the abducens nerve was transected unilaterally below the sinus cavernosus. Animals were allowed to recover for survival periods from 1 to 5 weeks and then sacrificed and their brainstem processed for CO (Wong-Riley,Brain Res. 79) and Nissl. In the Nissl material, the number of neurons in the abducens nucleus was counted and their cross sectional area measured on the axotomised and control side. In CO material the density of CO staining in the control and axotomised side was compared, using quantitative densitometry.

Chromatolytic changes in the axotomised motoneurons were not observed. However, other changes detectable in Nissl material, as listed below, were first observed 2 weeks after axotomy. Axotomised cells tended to fall into 2 extreme groups in the distribution of Nissl substance. Some were very faintly stained and appeared to be undergoing cell death. Others were more densely stained than normal. Cells in the control nucleus appeared normal in the range of Nissl staining observed. By 4 weeks after the axotomy, the axotomised nucleus evidenced significant cell death. On average the number of neurons in the axotomised nucleus was reduced by approximately 50% compared with normal. At 5 weeks postoperative the soma size of surviving axotomised cells was significantly larger than normal. Changes in CO staining were evident earlier than changes in Nissl material but were not in the predicted direction. Within one week of axotomy, a significant decrease in CO staining was observed in the neuropil of the axotomised nucleus, and this difference increased progressively during the the first 4 postoperative weeks. At 4 and 5 weeks post-axotomy, the axotomised nucleus appeared greatly decreased in the intensity and area of CO staining.

The changes in CO suggest that there are indeed changes in energy metabolism following axotomy. The observation that, within the nucleus, there are at least 2 subpopulations, only one of which survives axotomy, suggests that these metabolic changes may not be uniform among the entire population.

82.6 A CONDITIONING LESION DOES NOT FURTHER STIMULATE TUBULIN AND ACTIN SYNTHESIS BUT FURTHER DECREASES NEUROFILAMENT SYNTHESIS IN THE FACIAL NUCLEUS OF THE RAT.

W. Tetzlaff*, M.A. Bisby, C.A. Krekoski* and I.M. Parhad (SPON: R.C. McGarry). University of Calgary, Calgary, Canada, T2N 4N1.

We have demonstrated previously that in the axotomized rat facial nucleus the synthesis of actin and tubulin is increased while synthesis of the neurofilament proteins (NfP) is decreased. Here, we analyzed whether a conditioning lesion (CL) of the facial nerve, which speeds up the velocity of axonal elongation by 40%, further stimulates actin or tubulin synthesis or decreases NfP synthesis in the facial motoneurons.

These cytoskeletal proteins were separated by 2-dimensional gel electrophoresis of the isolated facial nuclei 2 h after administration of [35S]-Methionine into the brainstem. Synthesis was measured by quantitative densitometry of the fluorographs taken from these gels. In a complementary approach, we used cDNA probes β-α1-tubulin (α-tubulin) and neurofilament-68 (NF68) to evaluate mRNA expression of these components using in situ hybridization. For the CL the left facial nerve was crushed; 7 days later, the right and left nerves were crushed (test lesion). This allowed a comparison of the single lesioned (SL) and CL facial nucleus in the same animal.

There was no difference in actin or tubulin [35S]-methionine incorporation when comparing the SL to the CL facial nucleus, 7 days after test lesion. In situ hybridization with the tubulin cDNA followed by film autoradiography did not show an overall difference of the SL facial nucleus versus CL. In contrast, neurofilament [35S]-methionine incorporation (NF68, NF150) was further decreased on the CL side. This was also evident by in situ hybridization. Immunocytochemistry with a monoclonal antibody to NF68 and NF150 (Boehringer) revealed significantly less immunostaining in the facial axons at the inner genu of the CL side 7 days after axotomy.

Thus, the CL resulted in an additional decrease of neurofilament synthesis, which was already decreased by a SL; in contrast, elevated tubulin synthesis did not further increase with a preceding CL. Neurofilaments are believed to interact with microtubules during axonal transport. Our findings support the hypothesis that less neurofilament-tubulin interactions might occur in conditioned axons, which could allow a greater proportion of the tubulin to travel in the faster SCb component rather than with the neurofilaments in the SCa component of axonal transport.

82.7 **SLOW AXONAL TRANSPORT AND SYNAPTIC PLASTICITY**

L.Di Giamberardino, G.Filliatreau* and P Macioce*
Département de Biologie, C.E.N. de Saclay, 91191 Gif-sur-Yvette,France.

We have been studying the modification of the axonal transport of the axonal cytoskeleton, labelled after intraspinal or intraganglionic injection of ^{35}S-methionine, during post-crush regeneration and in streptozocin (STZ) diabetic rats. The cytoskeletal proteins, first separated into a polymer-enriched and a soluble-enriched fraction, were analyzed by autoradiography of polyacrylamide gel electrophoresis. Our results indicate that the cytoskeletal components carried with SCa (whose polymeric fraction were composed mostly of neurofilaments and microtubules) undergoes very litle modification when they cross the crushed region of the nerve inside the new neurites stemming from the severed axons. As if, for SCa, entering a newly made axonal sprout was just the same as advancing into the intact axon. On the other hand, our results on early STZ-diabetic rats indicate that the speed of the axonal transport of neurofilaments in sensory axons is reduced by 70%. Which could be correlated with the sensitivity loss often observed in diabetic neuropathy.
These results could indicate that slow axonal transport is more implicated in maintaining synaptic integrity than is currently thought. Synaptic integrity and function is generally associated to rapid axonal transport, which carries membrane proteins and enzymes necessary to synaptic maintenance and transmission. Yet, if synaptic integrity were to depend on synaptic plasticity, then slow axonal transport would become a crucial mechanism and its impairment would result in synaptic "rigidity" and eventually degeneration. Quantitatively, slow axonal transport could afford to renew a nerve ending from several times a day to once every few days for large endings.

82.8 MORPHOMETRIC ANALYSIS OF EARLY CELL BODY CHANGES EXHIBITED BY AXOTOMIZED MOTOR NEURONS. L.L.Hall, K.R.Latham* and R.C.Borke. Depts. of Physiology, Medicine and Anatomy, USUHS, Bethesda, MD 20814-4799.

The retrograde response of different neuronal populations following axotomy is extremely variable. Regenerative and degenerative phenomena contribute to the cell body response, but the significance of specific somatic changes is unclear. Quantification of the nuclear and perikaryal post-injury events has been limited. A morphometric approach may highlight aspects of the retrograde reaction important for successful regeneration. In the present study, we have applied morphometric techniques to the analysis of hypoglossal motor neurons 7 days post-axotomy (dpa).

The left hypoglossal nerve was transected in adult, male, Sprague-Dawley rats. Sham-operated and normal control rats were also used. At 7 dpa the animals were transcardially perfused with dilute and concentrated aldehydes. Sections were cut through the extent of the hypoglossal nucleus, post-fixed in osmium tetroxide, incubated in tannic acid and processed routinely for plastic embedding. Ultrathin sections were collected on copper grids and stained with lead citrate. Eight neurons were analyzed per hypoglossal nucleus. A micrograph of each cell (2500X) was used to estimate the nuclear fractional volume (Vv) and surface density (Sv) per cell and nucleolar Vv per nucleus. Four micrographs of the perikaryon (11,700X) per cell were used to estimate mitochondrial and lysosomal Vv and rough endoplasmic reticulum (RER), Golgi apparatus (GA) and smooth membrane Sv of the cytoplasm.

Neurons from control and sham-operated rats were typical multipolar neurons with spherical, centrally located nuclei and parallel cisterns of RER in the cytoplasm. Injured neurons displayed classical features of the retrograde reaction. Chromatolysis was ubiquitous while nuclear eccentricity and nuclear membrane invaginations were seen in some cells. The nuclear Vv and Sv were not altered by axotomy. The average nuclear Vv was 27% and 24% in control and injured neurons. The average nuclear Sv ranged from 1313.0/cm to 1136.3/cm in the control and injured groups. The nucleolar Vv was increased significantly from 4.3% among controls to 7.4% in the injured cells. A significant reduction of the average RER Sv from 42,453.3/cm to 29,119.3/cm occurred. Smooth membrane Sv significantly increased from 2,114.3/cm in normal to 4,966.8/cm in axotomized cells. The GA Sv and mitochondrial and lysosomal Vv did not change 7 dpa.

The morphometric techniques used in this study have provided specific information about the ultrastructural changes induced by axotomy. Notably, chromatolysis, or the dissolution of the long parallel cisterns of RER, corresponded to a 25% loss of RER surface area. Also, an increased nucleolar Vv and smooth membrane Sv were measured. Other organelles were not significantly altered 7 dpa.

82.9 ROLE OF MONOAMINERGIC INNERVATION IN CEREBELLAR ECTOPIA AFTER POSTNATAL X-IRRADIATION OF POSTNATAL RATS. W.J. Anderson, P.E. Kunkler*, and D. Cooper*. Indiana University School of Medicine and Indiana State University, Terre Haute, IN 47809.

The finding of heterotopic cell nests in the cerebellum of the human and animals has received a vast amount of attention in the literature. Heterotopic cell nests in normal cerebella are quite common, and often transient. They have all the appearances of an arrested migration of granule cells from the external granular layer (EGL) to their ultimate destination in the internal granular layer. Studies by Ebels et al. and Altman have found there is a consistent heterotopia (ectopia) of migrating granule cells in the molecular layer of x-rayed rat pup cerebella, and concluded that the normal timing of migration of these cells from the EGL was disrupted so that normal mossy fiber projections were not inhibited, resulting in their projection into the molecular layer where they contacted the delayed migrating granule cells to form normal synaptic relationships with them. This study was performed to see whether monoaminergic innervation of the cerebellum was altered in x-ray produced regeneration of the EGL, where granule cell ectopia is consistently found in adult animals. Long-Evans hooded rats were bred and at birth were assigned to eleven conditions: x-rayed at birth with 1 to 5 200r daily doses; x-rayed at day 4 with 1 ti 5 200r daily doses; and controls. All animals were sacrificed at 30 days of age and prepared for routine histology or histofluorescence histochemistry using the glyoxylic condensation method of de la Torre. The newborn group receiving 2 to 5 daily doses of x-ray displayed the maximal ectopia. These cerebella displayed most granule cells arrested in the molecular layer. Noradrenergic innervation was intense in all ectopia of all experimental conditions. Noradrenergic fibers increased as a function of increased ectopia and did not appear to be related to vasculature. Increased monoaminergic innervation of Pukinje cell somata, indicated by pericellular terminal endings were common in most regenerated cerebella. Whether the pericellular terminations was due to a direct effect upon growth cones, or is a restoration of neurotransmitter homeostasis is presently unknown. This study suggests that although mossy fibers are present in ectopia, noradrenergic innervation may play a major role in the altered migration of granule cells.

82.10 NORADRENERGIC INNERVATION OF THE REGENERATING EXTERNAL GRANULAR LAYER OF THE RAT AFTER POSTNATAL X-IRRADIATION. P.E. Kunkler*, W.J. Anderson and D. Cooper*. (Spon. N.A. O'Connell) Indiana University School of Medicine and Indiana State University, Terre Haute, IN 47809

In previous studies, our laboratory indicated that fractionated x-irradiation in rat pups begun at: birth, 4 days, 8 days, and 12 days and continued until the external granular layer of the cerebellum was destroyed and not reconstituted resulted in an alteration in the number of noradrenergic fibers in the cerebellum of the 4-day and 8-day treatment group when observed at 30 days of age. This indicated that x-irradiation may induce axon sprouting of noradrenergic fibers from the locus coeruleus at ages older than the first appearance of climbing fibers and might be a compensatory mechanism for the altered neurochemistry of the cerebellum due to the loss of various postnatal neurons due to the x-irradiation. This compensation in recircuitry was considered in conjunction with previous findings by Crepel et al. for Purkinje cell axon collaterals, and Anderson and Stromberg for basket cell axons. This study was performed to see whether monoaminergic innervation of the cerebellum was altered after varying x-irradiation doses that allowed regeneration of the EGL to occur. Long-Evans hooded rats were bred, and at birth were assigned to eleven conditions; x-irradiated at birth with 1 to 5 200r daily doses; x-irradiated at 4 days of age with 1 to 5 200r daily doses; and control animals for each age group. Rat pups were sacrificed at 24, 48, 72 hours after their last dose and at 10 days of age. All animals were prepared for routine histology or the histofluorescence histochemistry using the glyoxylic acid condensation method of de la Torre. Control animals never revealed any noradrenergic fibers reaching the EGL. During regeneration at both birth and 4-day conditions, increased noradrenergic innervation of the EGL could be seen 24 to 48 hours after the last treatment. These results indicate that in the regenerating EGL, cell migration is inhibited and cell multiplication is increased due to the radiation effect and the noradrenergic fibers may play a major role in this development phenomenon.

82.11 **A Chronic Chamber for Direct Observation Of Nervous System Function in vivo** W. J. Levy, R. Rumpf, M. Humphries, Neurosurgery, Univ. of Mo. School of Med. Columbia, MO 65212

Nervous system function can be studied by direct observation in tissue culture, or by in vivo studies which usually do not allow the study of individual neural elements. Tissue culture does not allow the study of cells in their normal enviornment or with the effect of a blood supply. We are reporting the use of a chamber which allows individual cell and axons to be observed in vivo. It consists of two glass coverslips 5mm square spaced 20-70 microns apart. sealed on their edges with silicone elastomer, except for two ports 2mm long at opposite ends of the chamber. The peroneal nerve in the hindlimb of a 250 gm Sprague-Dawley rat is sectioned and run into the two ports on each side. The chamber is then left implanted in the hindlimb of the rat, and repeatedly inspected by reanesthetizing the animal and opening the wound under sterile conditions. The system can be studied on a Nikon Optiphot Nomarski microscope with image enhancement.

Chambers in 13 rats had an average growth rate of 0.6 mm/day. A fan of material could be observed growing from the proximal to the distal port, and neovascularization occurred from both ports. The system under microscopic observation allowed visualization of individual axons and cells in an environment which resembled tissue culture in appearance, with the addition of blood flow. The nerve regenerated across the chamber and innervated the distal muscles, with an observable twitch, nerve signal and EMG signal distal to the chamber from stimulation proximal to the chamber. Section or selective xylocaine block of the chamber at the proximal port resulted in a loss of these responses. EM of the chamber contents revealed axons and Schwann cells. This system may allow useful studies of neuronal function, as well as effects of blood flow.

82.12 EFFECTS OF CUTANEOUS SENSORY NERVE CRUSH AND REGENERATION ON NEURONS IN CORONAL CORTEX (AREA 3b) OF CATS. G.A. Brandenberg and M.D. Mann. Department of Physiology and Biophysics, University of Nebraska Medical Center, Omaha, NE 68105.

Previous investigations of nerve crush and repair have emphasized the transient nature of changes in cortical activity and the completeness of restoration to preinjury conditions. These changes include encroachment of activity from skin areas neighboring the denervated field into the cortex which normally contains the representation of that field and enlargement of receptive fields of individual neurons. In no case, has the enlargement of receptive fields included ipsilateral skin fields, nor has an ipsilateral representation been described for SI cortex. We present evidence for unexpected changes in receptive fields of SI cortical neurons which persist after functional recovery is completed.

Extracellular recordings were made of the activity, evoked by electrical stimulation of each paw, in neurons in the forepaw focus of somatosensory cerebral cortex of control cats and cats in which the sensory nerves to the contralateral forepaw had been crushed 31 to 63 days previously. Neurons that responded only to stimulation of the contralateral forepaw were classified as sa neurons; those that responded to stimulation of both forepaws were classified as sb neurons; those that responded to stimulation of both contralateral paws were classified as sc neurons; and those that responded to stimulation of at least three paws were classified as m neurons. The ratio of sa : sb : sc : m neurons in control cats was 46 : 3 : 0 : 0, and in cats that had undergone nerve crush it was 104 : 15 : 3 : 26. The distribution of sa neurons across the thickness of the cortex was similar in both control and experimental animals, with a mode at 0.5 mm. Sa neurons from experimental cats responded with more spikes per discharge, longer latency, and higher threshold than sa neurons in control cats. Frequency-following ability was similar for both groups of neurons. M neurons from experimental cats were distributed deeper in the cortex than sa neurons. When compared with experimental sa neurons, the m neurons responded with longer latencies and poorer frequency-following ability, however, the number of spikes per discharge and threshold were not significantly different. The appearance of wide-field (i.e., sc or m) neurons after temporary loss of sensory input was not expected because 1) there normally is no detectable excitatory input to this tissue from the hind paws, 2) no previous investigation of damage and regeneration had found any such neurons in this tissue, and 3) previous investigators had claimed that the cortex returns to control conditions after crush and regeneration. Of several possible explanations for the appearance of wide-field neurons in the tissue, the most likely appears to be that deafferentation strengthens previously subthreshold inputs to neurons somewhere along the somatosensory system.

82.13 CENTRAL ARBORS OF NEONATALLY AXOTOMIZED TRIGEMINAL PRIMARY AFFERENTS THAT FAIL TO REFORM NORMAL PERIPHERAL CONNECTIONS. N.L. Chiaia and R.W. Rhoades. Dept. of Anatomy, University of Medicine and Dentistry of New Jersey-School of Osteopathic Medicine and Robert Wood Johnson Medical School, Piscataway, NJ 08854.

We have employed intra-axonal recording and horseradish peroxidase (HRP) injection techniques to ask whether a failure to reform normal peripheral receptor associations after axotomy results in abnormal central arbors for sensory ganglion cells. We have transected the infraorbital (IO) nerve in hamsters on the day of birth, allowed the animals to survive to adulthood, and then recorded and filled with HRP the central axons of fibers that were determined, by electrical stimulation, to have regenerated axons into the IO nerve. All injections were made in the trigeminal spinal tract near the border between subnucleus interpolaris and subnucleus caudalis.

We recovered 13 IO primary afferents that had no identifiable peripheral fields and obtained physiological data from an additional 19 such fibers. These axons had an average peripheral conduction velocity (determined by two-point stimulation) of 29.8 ± 10.0 m/s. This was slower than that for normal IO axons (40.3 ± 8.5 m/s), but not significantly different from that of regenerate IO fibers that did have peripheral fields (27.4 ± 10.3 m/s).

The central morphology of "no-field" primary afferents was quite variable, but there were a number of differences between them and IO axons in interpolaris and caudalis of normal hamsters (Chiaia, N.L. et al., J. Comp. Neurol., in press). The average number of collaterals for primary afferents with no peripheral fields was 4.0 ± 1.7 in interpolaris and 3.3 ± 2.3 in caudalis. The value for caudalis was lower than that for any functional class (vibrissa-related, skin, or guard hair) of primary afferent we have analyzed in normal, adult animals, but that in interpolaris was nearly the same as that for normal, slowly adapting vibrissa afferents and guard hair related fibers. The average cross-sectional areas for the largest interpolaris and caudalis arbors of each no field axon were 0.022 ± 0.008 mm^2, and 0.037 ± .023 mm^2, respectively. The value for the interpolaris arbors was about one-half of that for normal V primary afferents while that for the caudalis arbors was nearly normal.

These data thus demonstrate that failure to reform normal receptor associations after neonatal axotomy does result in abnormalities in central arbor morphology for trigeminal primary afferents.

82.14 EFFECTS OF TEMPERATURE ON THE LONG TERM SURVIVAL OF ENUCLEATED AXONS. R.A. Sheller, J.W. Moehlenbruck*, J.A. Blundon*, S.A. Halls, G.I. Garcia*, G.D. Bittner. Department of Zoology and Institute for Neurological Sciences, The University of Texas at Austin, Austin, TX 78712

When mammalian axons are severed from their cell bodies, the severed distal stump degenerates within a couple of days, a process termed Wallerian degeneration. When many lower vertebrate or invertebrate axons are severed, the distal stump often survives for months or years, a phenomenon known as long term survival (LTS) (see Bittner, Amer. Zool., 1987, in press). Cancalon (Progress in Neurobiology, 25: 27-92, 1985) has reported that axonal degeneration during LTS is a temperature dependent process which occurs in a proximal to distal direction at a rate equivalent to slow axonal transport in garfish olfactory axons. We are examining various characteristics of LTS as a function of temperature in crayfish medial giant axons (MGA's), crayfish segmental lateral giant axons (SLGA's), and goldfish Mauthner axons.

Crayfish (4-9cm in body length) are acclimated at temperatures which they experience in their environmental range (5°C, 10°C, 15°C, 20°C, and 25°C) for at least two weeks before the entire ventral nerve cord is severed between the first and second abdominal ganglion. The animals are sacrificed weeks to months later and the ventral nerve cord is removed in order to sample resting potentials, action potentials, and conduction velocities at several different points in MGA's and SLGA's. The ventral nerve cord is then fixed and processed for light and electron microscopy observations of axonal morphology. Preliminary results from these studies indicate that there are no physiological differences in the LTS of MGA's or SLGA's at the different temperatures. We find no evidence of a proximal to distal temperature-dependent degeneration.

Concurrently, we are examining the temperature dependence of LTS in severed Mauthner axons of goldfish kept at 10°C, 20°C, and 30°C. Goldfish are equilibrated for 1-2 weeks at each temperature before the spinal cord is severed, effectively enucleating the Mauthner axons. Mauthner axons are sampled at post-operative intervals of 10 days for 70-80 days and LTS determined using electrophysiological and morphological criteria. Mauthner axons survive for at least 35 days at 20°C. Degeneration of severed Mauthner axons does not continuously proceed in a proximal to distal direction at any temperature.

82.15 A CONDITIONING LESION ACCELERATES RECOVERY OF ONLY SOME OF THE ELECTRICAL PROPERTIES OF BULLFROG B-CELLS WHICH ARE ALTERED BY AXOTOMY. M.E.M. Kelly, M.A. Bisby and K. Lukowiak. Dept. Med. Physiology, Univ of Calgary, Calgary, Alta. T2N 4N1, Canada.

Axons which have been subjected to a previous conditioning lesion (CL) regenerate more rapidly following a subsequent test lesion (TL) than axons which have only received a single TL. The CL effect may be due to both metabolic changes in the cell body and environmental influences derived from non-neuronal elements at the site of injury (1). We have investigated the effect of a prior CL on axotomy-induced alterations in the membrane properties of bullfrog B-type sympathetic neurones. In response to a TL alone, these include a decrease in the duration of the afterhyperpolarization (AHP) following an action potential (AP), a decreased AHP amplitude and a slowing of AP repolarization (2).

To determine whether conditioning influences (i) the magnitude of the axotomy-induced changes observed in somal membrane properties and (ii) the time course of their recovery, we compared the effects of a single TL with those of a CL followed by a TL. At intervals following either a TL alone, or a CL followed 7 days later by a TL made at the same site, the IXth and Xth ganglia were removed for electrophysiological investigation. Growth of axons was confirmed by retrograde axonal transport of rhodamine-tagged beads injected into the nerve distal to the TL.

AHP duration recovered much earlier in conditioned cells (14 days after TL) than in unconditioned cells (42 days). A decrease in AHP amplitude did not occur until 21 days after the TL in conditioned cells, 28 days in unconditioned cells, so the time interval from the first lesion was the same. Increases in AP duration began somewhat earlier in conditioned cells (14 days) than in unconditioned cells (28 days). Neither AHP amplitude nor AP duration recovered to normal by 63 days. In no instance was the response to a single lesion further increased by the second lesion.

The distinction between the behavior of AHP duration and that of AHP amplitude and AP duration following conditioning suggests that the underlying membrane conductances are distinct, and differentially regulated during regeneration. The accelerated recovery of AHP duration in conditioned axons which regenerate faster suggests that the underlying conductance is regulated by retrograde trophic factors derived from cells of the distal nerve. 82.16 REGROWTH OF NEUROSECRETORY AXONS TO FENESTRATED VESSELS OF TRANSPLANTED TISSUES Y. Kadota and M. Brightman (Spon. J. Bressler) Laboratory of Neurobiology, National Institute of Neurological and Communicative Disorders and Stroke, National Institutes of Health, Bethesda, MD 20892

A major target of neurosecretory axons (NSA) is perivascular basal laminae around fenestrated capillaries (FC) in the posterior lobe of the pituitary gland. Do mature, regenerating NSA terminate selectively on the FC of the posterior lobe compared with the FC of other tissues that, normally, are not innervated by NSA? Fragments about $1mm^3$, of pineal gland, adrenal medulla and posterior lobe, taken from 2 - 5 week old, inbred, Fisher rats were grafted bilaterally to the hypothalamic, retro- chiasmatic area of adult Fisher rats. This area includes axons from both neurosecretory nuclei but no FC. Two to four weeks later, the grafts were processed for immunohistochemical localization of NSA and for electronmicroscopy. Vascular approximation with NSA was defined as direct apposition to the FC or 4 μm from them, associations characteristic of neurosecretory terminals and FC in normal posterior lobes. At 2 weeks, a few regenerating NSA entered all three types of grafts. Most of the NSA were encapsulated by non-neuronal cells, some of them being Schwann cells. Partially encapsulated or free NSA were closely associated with the FC of the 3 grafts : 72 ± 27/mm^2 in pineal, 20 ± 7/mm^2 in medulla, and 261 ± 200/um^2 in posterior lobe. According to the Kruskal - Wallis test for statistical significance, there was a significantly greater number of NSA - FC associations in the pineal and posterior lobe grafts than in the adrenal medulla transplants ($p < 0.05$). However, 5 out of 8 adrenal grafts had NSA - FC approximations ranging from 10 to 25/mm^2 in frequency. Thus, even in adrenal tissue, which normally is not innervated by NSA, close neurovascular associations can be formed. At 4 weeks, the number of FC, NSA and vascular associations in pineal and adrenal tissues did not change significantly. However, in posterior lobe grafts, there was a greater number of NSA - FC associations (2095 ± 891/mm^2) than in 2 week old grafts (261 ± 200/mm^2; $p < 0.05$). We conclude that regenerating NSA can form close associations with FC from different sources to the same degree, but that posterior lobe tissue is more conducive to the ingrowth of many NSA so that there are more of these axons available to establish perivascular associations.

82.17 EXPRESSION OF APOLIPOPROTEIN B,E(LDL) RECEPTORS AND UPTAKE OF APOLIPOPROTEIN E-CONTAINING LIPOPROTEINS BY THE REGENERATING RAT SCIATIC NERVE. J.K. Boyles*, D.Y. Hui*, K.H. Weisgraber*, R.E. Pitas*, and R.W. Mahley*. (SPON: T.W. Kraft). Gladstone Foundation Laboratories, Univ. of California, San Francisco, CA 94140-0608.

Regeneration of peripheral nerves, including axon sprouting, elongation, and remyelinization, requires the biosynthesis of large quantities of cholesterol-rich membranes. Therefore, a key component of regeneration may be an efficient lipid transport mechanism. Apolipoprotein (apo-) E, a lipid transport protein synthesized by macrophages entering the injured nerve, has previously been shown to accumulate in high concentration in the distal segment. Apolipoprotein E has the capacity to bind to apo-B,E(LDL) receptors, resulting in the delivery of cholesterol to the cells for use in membrane biosynthesis. Immunocytochemistry was used in the present study to elucidate the role of the apo-B,E(LDL) receptor and apo-E in regeneration of the crushed sciatic nerve of adult rats. Anti-bovine apo-B,E(LDL) receptor and anti-rat apo-E-specific antisera were used to evaluate the distribution of these antigens in crushed nerves taken 1 day to 15 weeks after injury.

In the normal sciatic nerve, low levels of reactivity specific for apo-B,E(LDL) receptors are found along the cell membranes of Schwann cells, whereas the cells of the neurolemma and nerve axons show little reactivity. Just 1 day after a crush injury, a high level of reactivity for the apo-B,E(LDL) receptor is detected immediately proximal to the injury in the axonal stumps. As axonal sprouts grow, they show intense reactivity for apo-B,E(LDL) receptors. Reactivity within the regenerating nerve axons dissapears from the wound site by about 1 week after injury, but it can still be identified in the growing tips farther distal in the nerve. As myelinization of regenerated axons begins, Schwann cells express apo-B,E(LDL) receptors along their membranes.

Apolipoprotein E production within the wound is seen within 24 hours of injury. Tissue macrophages that migrate into the wound secrete apo-E, as shown by the intense reactivity for apo-E within their Golgi apparatus. By day 3 monocyte-derived macrophages begin apo-E production as well. Nerve sprouts take up apo-E, as shown by the presence of apo-E within their cytoplasm. This apo-E is contained in a granular compartment, perhaps a lysozome or prelysozome. Fluorescently labeled apo-E-containing lipoproteins infused at the site of a cut nerve are also taken up by regenerating axons. At the time of active myelinization of regenerated axons, apo-E accumulates within the nerve.

These results suggest that the environment of the peripheral nerve supports nerve regeneration by supplying cholesterol and phospholipids through a specific receptor-mediated process.

82.18 **GALVANOTROPIC REGENERATION FOLLOWING DELAYED TREATMENT OF THE DAMAGED MAMMALIAN PERIPHERAL NERVE.** **P.A. Fornano, M.F. Zanakis, and B.J. Albala (SPON: M.A. Palmatier) American Biointerface Corp., New York, NY**

The use of *galvanotropic neural guides*, specifically galvanotropic nerve cuffs to facilitate peripheral nerve regeneration is efficacious when applied immediately after injury. Clinically, however, most nerve injuries are not treated immediately, and significant amounts of delay (from days to months) may occur before surgical intervention. The present study outlines experiments designed to assess the efficacy of the TRAXON™ model galvanotropic nerve cuff compared to a standard (passive) nerve cuff following delayed treatment. The sciatic nerves of rats were crushed at mid-thigh using smooth tipped needle holders. This method results in a significant lesion in continuity of the nerve. A piece of 9-0 suture was placed through the epineurium at the injury site for marking purposes. The wound was closed and the animals returned to their cages. After 10 days, the wounded area was re-opened to expose the damaged nerve. At this time, a 13mm long active galvanotropic nerve cuff (TRAXON™) was placed over the nerve, with the anode oriented just proximal to the lesion site, while the cathode was oriented 12mm distal to the lesion. The cuff is designed to deliver 1μ ampere to the tissue. Control animals received an inactive device (ie., a standard silicone nerve cuff). All animals were allowed to survive for 12 days post-implantation (22 days post lesion). The portion of the sciatic nerve at the cathodal electrode (12mm from the lesion) was removed, cut in cross sections and treated with fluorescent antibodies to neurofilament protein. Counts of neurofilament-positive profiles were made and compared between groups in a blinded fashion. The results indicate clear evidence of axons in both groups of animals. However, in nerves treated with an active device, the mean number of axons was 767 (±203), while the mean number of axons in controls was 250 (±218). The difference was statistically significant with $p<0.05$. These results indicate that galvanotropic nerve cuff treatment is efficacious in facilitating the regeneration of damaged axons of the mammalian peripheral nervous system even after a delay of many days between injury and treatment. Thus, the clinical use of such a device to aid in the repair of damaged human peripheral nerves is supported by this study.

82.19 **GALVANOTROPIC REGENERATION OF THE MAMMALIAN PERIPHERAL NERVE.** **B. J. Albala, M. J. Politis and M. F. Zenakis (SPON: R. Meibach) American Biointerface Corp., New York, NY and Dept. of Anatomy, Univ. of Saskatchewan, Canada**

The application of static electric fields (EF's) to damaged peripheral nerves will result in axonal regeneration at an accelerated rate toward the cathodal electrode. However, detailed characterization of this response has been lacking. The following study utilizes the lesioned rat sciatic nerve model in order to demonstrate histologically that the mammalian PNS is capable of a more rapid rate of regeneration following the application of EF's. The sciatic nerves of rats were transected at mid-thigh, and 1cm of the distal stump was lifted and frozen on a piece of dry ice. The cut ends were then sutured together, and a *galvanotropic neural guide* device (TRAXON™) was placed over the lesion with the anode just proximal to the coaptation site, and the cathode 13mm distal to it (delivering 1μA to the nerve). At the appropriate time points, the nerves were removed and analyzed for the presence of axons using fluorescent antibodies to neurofilament protein. Neurofilament-positive (NFP) profiles 1mm distal to the cathode were determined at 6, 12 and 18 days after lesion/implantation. Control animals received either an inactive electrode implant or a reverse current (anode distal to the lesion) device. Histological analysis indicated that the NFP counts of the "cathode distal" treated groups were consistently greater than both controls at each time point. The NFP counts between the "cathode distal" group and "inactive electrode" controls were statistically significantly different at 6 days (X±SEM: 45±6 vs 10±9; $p < .05$) and at 12 days (311±29 vs 77±29; $p < .01$), respectively. The "cathode distal" treated rats also had more NFP counts in the distal nerve at 18 days (439±65) than did the matched "inactive electrode" controls (196±68), but this difference was not statistically signficant. The "anode distal" control animals were not significantly different than the "inactive electrode" controls at any time point studied. Thus, the efficacy of *galvanotropic neural guide* devices in facilitating regeneration of damaged peripheral nerves following immediate application is supported by these studies.

PEPTIDES: ANATOMICAL LOCALIZATION I

83.1 LIGHT AND ELECTRON MICROSCOPIC ANALYSIS OF IMMUNOREACTIVE DYNORPHIN IN THE SPINAL DORSAL HORN OF THE RAT H.J. Cho* and A.I. Basbaum. Departments of Anatomy and Physiology, UCSF, San Francisco 94143.

Light microscopic studies have established that immunoreactive dynorphin cells and terminals are concentrated in laminae I, outer II and V of the spinal dorsal horn. This pattern is more restricted than that seen for enkephalin and suggests that dynorphin cells may have a more selective association with the transmission and/or control of nociceptive messages than the enkephalin neurons. In this study we addressed the relationship of primary afferent fibers to the dynorphin synaptic organization in the superficial dorsal horn of the rat.

To identify degenerating primary afferent terminals, several rats underwent a multiple dorsal rhizotomy (L5-S1). Some of those rats were also treated with an intrathecal injection of colchicine (20ug/ul; 10ul). Twenty four hours later all rats were perfused with a mixed paraformaldehyde/glutaraldehyde fixative. Coronal and transverse sections of the lumbar cord were immunoreacted with an antiserum directed against dynorphin B (courtesy of Dr. Ekhard Weber).

Dynorphin immunoreactive cell bodies were common in lamina I and outer IIo. Surprisingly, both the number and density of labelled cells were significantly greater on the deafferented side of the cord. At the EM level, labelled cell bodies were found postsynaptic to both normal and degenerating axon terminals. Symmetrical synaptic contacts predominated on labelled cells. Immunoreactive dendrites also received synaptic inputs from normal and degenerating primary afferents. In this case, however, asymmetric synaptic contacts predominated. Dynorphin immunoreactive axons were associated with a variety of unlabelled profiles. Seventy-six percent were found presynaptic to unlabelled dendrites. Asymmetric axodendritic contacts slightly outnumbered those with symmetrical contacts. Ten percent of the labelled axon terminals were presynaptic to unlabelled spines; eight percent were presynaptic to unlabelled cell bodies. All of the latter contacts were symmetrical. Finally, a small number of associations between immunoreactive dynorphin terminals and unlabelled terminals, including degenerating primary afferent terminals, were seen. Some labelled dynorphin terminals were unequivocally postsynaptic to degenerating primary afferent fibers. A few examples in which dynorphin terminals appeared presynaptic to primary afferents were found, but synaptic specializations were not clear.

The large increase in dynorphin cell staining in deafferented, colchicine treated rats, indicates that dynorphin synthesis is increased under these conditions. This observation parallels studies which showed increases in dynorphin message in arthritic rats. Although a quantitative estimate is not available, it appears that dynorphin neurons are more closely associated with primary afferent fibers than are enkephalin neurons. It is unlikely, however, that spinal dynorphin neurons provide a significant input to primary afferent fibers.

Supported by PHS NS 14627 and 21445.

83.2 DISTRIBUTION OF SEVEN DIFFERENT PEPTIDES IN HUMAN SPINAL CORD. K. Chung, R.P. Briner*, S.M. Carlton and K.N. Westlund-High. (SPON: R.L. Weiner). Marine Biomedical Institute and Departments of Anatomy & Neurosciences and Division of Neurosurgery, University of Texas Medical Branch, Galveston, TX 77550.

Immunohistochemical methods permit the precise anatomical study of neurotransmitter specific pathways in the peripheral and central nervous systems of many vertebrates. The present study describes the comparative distribution of seven different peptides in four levels (cervical, thoracic, lumbar and sacral) of human spinal cord using the peroxidase-antiperoxidase technique (PAP) at the light microscopic level. The peptides examined were substance P (SP), vasoactive intestinal polypeptide (VIP), methionine-enkephalin (M-ENK), bombesin (Bomb), somatostatin (SOM), cholecystokinin (CCK) and thyrotropin releasing hormone (TRH). Each of the above peptides has been previously identified in the spinal cord of other vertebrate species including rat, cat and monkey. Tissue was obtained from six human cadavers with a short post-mortem interval (4-10 hr.) and no spinal cord pathology. The spinal cord was removed, sliced transversely into 0.5 cm in lengths and fixed in 4% paraformaldehyde in 0.1 M phosphate buffer (PB), pH 7.4, for 2-5 days. The fixative was then replaced with a 20% sucrose solution in 0.1 M PB. Frozen sections (50 μm) were cut in the transverse plane and collected in PB. The sections were treated with 1% sodium borohydride for 30 minutes and immunostained according to the protocol of Sternberger ('79). An absence of immunoreactivity was observed when each antibody was preabsorbed with its antigen. The distribution of Bomb-, SP-, CCK-, and M-ENK-like immunoreactivity was localized in three regions: the superficial dorsal horn (laminae I, II and outer III), the intermediate gray matter (especially lateral laminae V to VII) and the gray matter adjacent to the central canal in all four levels of the spinal cord. The distribution of immunoreactivity for SOM in the spinal cord was very similar to that of SP and CCK, with the exception that only the inner portions of lamina II and the outer parts of lamina III were stained. The VIP-like immunoreactivity was visualized in Lissauer's tract, marginal layer of dorsal horn, in the intermediate gray and the central gray but only in the sacral spinal cord. The TRH-immunoreactivity is observed in teminals and neurons in the ventral horn of spinal cord. This study extends our knowledge of chemical anatomy of spinal cord to human system.

Supported by NIH grant NS11255 and the Muscular Dystrophy Association.

83.3 ULTRASTRUCTURAL CHARACTERIZATION OF CALCITONIN GENE-RELATED PEPTIDE IMMUNOREACTIVE FIBERS INNERVATING THE RAT PANCREAS. C. Sternini, N. Brecha and J. P. Card. Depts. of Medicine and Anatomy, UCLA School of Medicine, Los Angeles, CA 90024 and Medical Products Department E. I. Dupont de Nemours and Company, Willmington, DE 19898.

In a previous investigation (Sternini and Brecha, Gastroenterology, 90:1155, 1986) we have demonstrated that the rat pancreas is innervated by capsaicin-sensitive sensory afferents containing calcitonin gene-related peptide immunoreactivity (CGRP-I). In the present study we have utilized electron microscopic immunocytochemical techniques to characterize the fine structure of this afferent innervation. Rat pancreata were fixed with aldehyde solutions, cut in small pieces, processed for immunohistochemistry using a CGRP antiserum raised in rabbit against [Tyr] rat CGRP23-37 and the avidin-biotin method, embedded in plastic and cut on an ultramicrotome. Immunoperoxidase reaction product was confined to axons and terminals located within the stromal compartment and the perivascular space of arterioles of the exocrine pancreas. Immunoreactive fibers in the stromal compartment were a prominent component of nerve bundles that coursed among the pancreatic acini and were surrounded by collagen and fibroblast processes. Within these bundles, CGRP-I was confined to thin, unmyelinated axons which coursed among other unlabeled axons and dendrites. The dendrites, which apparently arise from neurons in the intrapancreatic ganglia, were often in close proximity to immunoreactive axons and terminals. However, we were not able to identify any synaptic specialization between these profiles. Abundant immunoreactive axons and terminals were also evident within bundles of nerve fibers in the perivascular space surrounding small arterioles. These fiber bundles consisted of numerous thin, unmyelinated axons which were separated from the smooth muscle of the arterioles by a distinct basal lamina. Once again, no synaptic specialization was apparent between the nerve fibers comprising individual bundles. In both the stromal compartment and the perivascular space immunoreactive afferents characteristically contained lucent, spherical vesicles which were approximately 40 nm in diameter. CGRP is a biologically active peptide which has been shown to affect exocrine pancreatic secretion and to be a potent vasodilator. The present findings, demonstrating the presence of CGRP terminals and axons in close vicinity to the exocrine pancreatic structures and vasculature provides a morphological basis for a CGRP-mediated control of pancreatic functions, perhaps acting directly on the acini or indirectly via control of blood flow.

83.4 CALCITONIN-GENE RELATED PEPTIDE-LIKE IMMUNOREACTIVITY (CGRP-LI) IS FOUND IN PRIMARY AFFERENT NEURONES WITH A- AS WELL AS THOSE WITH C-FIBRES, IN THE RAT. P.W.McCarthy* and S.N.Lawson*. (SPON: M.R. Duchen). Dept. of Physiology, Medical School, Bristol BS8 1TD

Intracellular recordings were made in vitro at 37 ± 1°C, from neurones of L4, L5 and L6 DRGs of 6-8 week female wistar rats. Conduction velocities (CVs) were calculated from the conduction time from stimulating electrodes on the peripheral nerve or dorsal root to the cell body. After electrophysiological recordings were complete, an intracellular injection of fluorescent dye (either ethidium bromide or Lucifer yellow) was made. The ganglia were fixed with Zamboni's fixative and 7 µm frozen serial sections were cut. The indirect immunofluorescent technique was used to examine the CGRP-LI of the dye labelled neuronal somata, with a polyclonal anti-CGRP antibody, (see Gibson et al. J. Neurosci. 4, 3101-3111, 1984).

Sixty labelled neurones were tested for CGRP-LI. Of those with C fibre CVs (<1.3 m/s), 4/11 showed CGRP-LI and these had a mean CV of 0.91 m/s, range 0.61-1.3 m/s. These fibres conducted rather faster than those of CGRP-LI negative C fibre neurones, which had a mean CV of 0.64 m/s, range 0.43-0.87 m/s. Of the neurones tested which had Aδ fibres (CV 2-12 m/s), 7/19 showed CGRP-LI and had a mean CV of 7.1 m/s, range 2.4-12 m/s. The neurones negative for CGRP-LI in this CV range had a mean CV of 9.32 m/s, with a range of 2-12 m/s. Of the neurones with Aα/β CVs (>12 m/s), 5/29 showed CGRP-LI. These had a mean CV of 18.35 m/s, range 13-26 m/s, very similar to the mean and range of those with Aα/β fibres which did not show CGRP-LI.

In conclusion, we have direct evidence that CGRP-LI can be shown not only in primary afferent neurones with C fibres, but also in a substantial proportion of primary afferents with A fibres, both in the Aδ and Aα/β CV ranges.

83.5 A LIGHT AND ELECTRON MICROSCOPIC LEVEL ANALYSIS OF CGRP IN THE SPINAL CORD OF THE PRIMATE. S.M. Carlton, D.L. McNeill*, K. Chung and R.E. Coggeshall. Dept. of Anatomy & Neurosciences and Marine Biomedical Institute, Univ. of Texas Medical Branch, Galveston, TX 77550.

Calcitonin gene-related peptide (CGRP), a substance predicted from a nucleotide sequence derived from a gene for calcitonin, is located immunocytochemically in dorsal root ganglion (DRG) cells and fibers in laminae I and II of the dorsal horn (DH) of the spinal cord. The above findings suggest a possible role of CGRP in primary afferent systems. The present study describes the light and electron microscopic localization of this peptide in the DH of the monkey.

Three adult monkeys (M. fascicularis) were perfused with 3% paraformaldehyde, 3% glutaraldehyde and 0.1% picric acid in 0.1M cacodylate buffer. Spinal cord segments from the lumbar enlargement were removed and post-fixed overnight. Vibratomed sections (25 µm) were rinsed in 1% sodium borohydride. Tissue for EM analysis was exposed to low concentrations of alcohol to increase antibody penetration prior to immunostaining. Tissue for LM analysis was immunostained with solutions containing Triton-X. Antiserum was raised in rabbits against synthetic human CGRP and used at a dilution of 1:2000 with the PAP method.

LM analysis demonstrated immunostained fibers and varicosities throughout lamina I, II outer, lateral V and X. No cell bodies stained positive for CGRP in the DH. Analysis at the EM level demonstrated that CGRP positive terminals contained an abundance of dense core vesicles (DCV) as well as round clear vesicles. Two major terminal types were observed: a round to ovoid shaped terminal participating in only one synaptic interaction and a glomerular type terminal arrangement with one CGRP terminal indented by several postsynaptic profiles. Post-synaptic profiles consisted of small to medium sized dendrites. However, two CGRP-positive profiles were observed synapsing directly onto somae in lamina I. Two labeled terminals were often seen abutting each other however, a functional interaction could not be determined. These findings are steps towards unravelling the synaptic architecture of the CGRP system in the primate DH. (Supported by NS 11255, NS 17039 and the Florence and Marie Hall Endowment.)

83.6 DISTRIBUTION AND COLOCALIZATION OF NEUROPEPTIDE Y AND TYROSINE HYDROXYLASE IMMUNOREACTIVITY IN THE GUINEA PIG LIVER. L. Goehler, C. Sternini and N. Brecha, Depts. of Psychology, Anatomy, and Medicine, UCLA and Center for Ulcer Research and Education, VA-Wadsworth, Los Angeles, California 90024.

Neuropeptide Y (NPY), the neuronal component of the pancreatic polypeptide family, has been localized in the central nervous system and in the periphery, including the cardiovascular and digestive systems. Colocalization studies have demonstrated that NPY immunoreactivity is expressed in catecholamine fibers innervating the heart and the splanchnic vasculature. Catecholamine nerve fibers have been found to innervate the liver of several species. In this study we have investigated the distribution of NPY immunoreactivity in the liver of the guinea pig and its possible colocalization with tyrosine hydroxylase (TH), a marker for catecholamine neurons. Guinea pig livers were fixed in a paraformaldehye-picric acid solution and sectioned at 15-30 µm on a cryostat. The cryostat sections were processed for immunohistochemistry by standard immunofluorescence techniques using rabbit antisera to NPY (kindly provided by J. K. McDonald) and to TH (kindly provided by A. W. Tank and N. Weiner). For colocalization studies, tissue was stained for NPY immunoreactivity, photographed, and the antigen-antibody complex eluted in a sulphuric acid-potassium permanganate solution. Tissue was then restained using TH antisera. NPY immunoreactivity was observed in single, varicose fibers and bundles innervating the hepatic vasculature. Single varicose fibers were also observed in the liver parenchyma, running through the spaces of Disse and the central acini. Thin, single fibers were often observed to surround the hepatocytes. The distribution of TH immunoreactivity was very similar to that of NPY immunoreactivity. Colocalization studies demonstrated that most of NPY immunoreactive fibers also contained TH immunoreactivity, which, taken together with the observation of NPY immunoreactivity in sympathetic ganglion cells, suggest that the hepatic NPY immunoreactive fibers are sympathetic. Sympathetic fibers innervating the liver have been implicated in the control of hepatic blood flow and glucose metabolism. The results of this study, showing the presence of NPY immunoreactivity in nerve fibers in the liver parenchyma and vasculature and its colocalization with TH, suggest that NPY may have a role in these hepatic functions, perhaps acting in concert with noradrenaline.

83.7 CALCITONIN GENE-RELATED PEPTIDE-LIKE IMMUNOREACTIVITY APPEARS TO BE PRESENT IN PREGANGLIONIC SYMPATHETIC B-TYPE, BUT NOT C-TYPE, NEURONS IN THE BULLFROG. J.P. Horn and W.D. Stofer. Dept. of Physiology, University of Pittsburgh School of Medicine, Pittsburgh, PA 15261.

When paravertebral sympathetic ganglia in the bullfrog were stained using an antiserum to rat calcitonin gene-related peptide (CGRP), many axons, but not cell bodies, were found to contain CGRP-like immunoreactivity. Although many of the stained axons had the appearance of sensory through-fibers, closer examination revealed immunoreactive synaptic boutons making contacts with most of the larger profiles of ganglion cell bodies. To examine the possible origins of the immunoreactive axons and boutons, sections of dorsal root ganglia (DRGs) and the spinal cord were stained. As expected from earlier work by others (eg. Gibson et al., J.Neurosci. 12,3101(1984)), the DRGs were found to contain a subpopulation of neurons with CGRP-like immunoreactivity and, in the spinal cord, CGRP-like immunoreactivity was present in ventral motoneurons and in fibers in the dorsal horn. In addition, however, we found immunoreactive cell bodies in the intermediolateral nucleus. Moreover, stained cells in the intermediolateral cell column were present only in sections cut rostral to the level of spinal nerve 6. All staining in ganglia and the cord was blocked by pre-absorbing the antiserum with 10^{-7}M rat CGRP and was unaltered by pre-absorption with 10^{-7}M to 10^{-5}M substance P, LHRH, bombesin or neurotensin.

To interpret further these findings, additional experiments were focused upon paravertebral sympathetic ganglia 9 and 10. In previous work, it has been shown that sympathetic neurons in these ganglia can be classified as B- or C-type based on the conduction velocities of their axons. In addition, B cell bodies are larger, as a group, than C cell bodies, and ganglionic B cells are selectively innervated by preganglionic neurons in the intermediolateral nucleus between spinal nerves 4 and 6 while ganglionic C cells are selectively innervated by preganglionic neurons in the intermediolateral nucleus between spinal nerves 6 and 8 (Stofer and Horn, Soc.Neurosci.Abstr. 12,542(1986)). To determine the origin of CGRP-like immunoreactivity in ganglia 9 and 10, spinal nerves were cut between DRGs and rami communicantes and allowed to degenerate for 2 weeks. After nerves 3 and 4 were cut, the staining of boutons on large cell bodies was eliminated, but not that of through-fibers. By contrast, cutting nerves 7 and 8 had no effect on staining in ganglia 9 and 10. When the sympathetic ganglia at the level of the nerve cuts were examined, the numbers of immunoreactive through-fibers were reduced. Together, these results support the hypothesis that CGRP-like immunoreactivity in ganglia 9 and 10 is present in sensory axons and in preganglionic sympathetic B-type, but not C-type, fibers.

83.8 IMMUNOHISTOCHEMICAL CORRELATION OF CALCITONIN-GENE-RELATED PEPTIDE AND OTHER REGULATORY PEPTIDES IN SYMPATHETIC GANGLIA. Ch. Heym*, W. Kummer*. Dept. of Anatomy, Univ. of Heidelberg, D-6900 Heidelberg (SPON: R.W. Rieck)

The occurrence of calcitonin-gene-related peptide (CGRP) immunoreactive (IR) nerve fibres and ganglion cells in paravertebral sympathetic ganglia of various species (rat, guinea pig, cat, dog) was investigated applying the biotin-streptavidin-technique. In 7µm section series the distribution of CGRP-IR structures was correlated with those being IR to antibodies against vasoactive intestinal peptide (VIP), enkephalins (ENK), neuropeptide y (NPY), somatostatin (SOM) and dopamin-ß-hydroxilase (DBH).

In rat and guinea pig, CGRP-IR fibres were present in all investigated ganglia. CGRP-IR cell bodies were visible only in the guinea pig superior cervical ganglion (SCG) after preganglionic denervation. CGRP-IR in these neurons exhibited co-occurrence with VIP-IR but did not show co-existence with IR to NPY or the catecholamine-synthetizing enzyme DBH.

In the untreated cat, CGRP-IR perikarya were scattered throughout the SCG and stellate ganglion. These neurons were also VIP-IR and a subpopulation of them was supplied by DBH-IR and ENK-IR fibre baskets. Other CGRP-IR/VIP-IR perikarya received either SOM-IR- or both, DBH-IR and NT-IR fibre supply. In addition to singly scattered CGRP-IR/VIP-IR neurons, clustered VIP-IR perikarya,being nonreactive to CGRP were observed in the stellate ganglia. These cell bodies received a dense SOM-IR innervation. The upper thoracic ganglia contained clustered VIP-IR nerve cell bodies, similar to those seen in the stellate ganglion, whereas CGRP-IR/VIP-IR neurons were very infrequent. CGRP-IR structures in the dog SCG resembled those in cat.

The findings indicate the existence of a population of CGRP-IR postganglionic sympathetic neurons which, in part, represent a subpopulation of VIP-IR neurons.

83.9 DISTRIBUTION OF SUBSTANCE P (SP), CALCITONIN GENE-RELATED PEPTIDE (CGRP), GALANIN (GAL), SOMATOSTATIN (SOM), ENKEPHALIN (ENK), C-FLANKING NEUROPEPTIDE Y (CPON), VASOACTIVE INTESTINAL POLYPEPTIDE (VIP) AND THYROTROPIN-RELEASING HORMONE (TRH) IN HUMAN SPINAL CORD. PRESERVATION OF IMMUNOREACTIVITY IN DORSAL HORN, AUTONOMIC NUCLEI AND ONUF'S NUCLEUS IN MOTOR NEURONE DISEASE (MND). S.J. Gibson*, J.M. Polak, H-C. Su*, T. Katagiri*, [1]J. Ball*, [1]S.R. Bloom*, [2]S. Holland*, [2]J.T. Hughes*, [3]D.B. Brownell*, and [4]R.O. Weller*. Depts. of Histochemistry and [1]Medicine, RPMS., London W12 OHS, U.K, [2]Dept. of Neuropathology, Radcliffe Infirmary, Oxford, U.K., [3]Dept. of Neuropathology, Frenchay Hosp., Bristol, U.K., [4]Dept. of Neuropathology, Southampton Gen.Hosp., Southampton, U.K.

A major feature of motor neurone disease (MND) is loss of motoneurones from the ventral horn, although certain groups, eg. Onuf's nucleus which innervates external anal and urethral spincters, are spared. In the spinal cord the majority of peptides are localised to sensory and autonomic areas but are present in significant concentrations in the ventral horn where some (SP, TRH) modulate motoneurone excitability. To determine which peptides are possibly implicated in the aetiology of MND, sections from 36 MND and 26 control spinal cords were immunostained with antisera to SP, CGRP, GAL, SOM, CPON, ENK, VIP and TRH using the PAP method.

Peptide distribution was apparently unaltered in the dorsal horn and autonomic nuclei. In the dorsal horn, immunoreactive (IR) fibres were concentrated in laminae I-III with relative densities CGRP> SP>GAL>SOM>ENK>CPON>VIP. Cell bodies IR for SOM and ENK were observed in laminae I-III. All peptides studied were localised to fibres in autonomic nuclei with TRH, SOM, ENK and CPON being the most abundant. In the ventral horn of controls some CGRP-IR motoneurones were present. SP-, GAL-, SOM-, ENK-, TRH- and CPON-IR fibres were scattered throughout the grey matter but were most apparent apposing motoneurones. Onuf's nucleus was densely innervated with SOM-, ENK-, CPON- and VIP-IR fibres. In the ventral cord of MND cases, no CGRP-IR soma were seen and there was a reduction in number of IR fibres compared to controls (due to loss of motoneurones). In contrast, Onuf's nucleus was unaffected. Since vesicorectal function is maintained in MND we may speculate that not only is Onuf's nucleus but also the peptides found associated with it involved in regulation of bladder and rectal function. Further studies are required to establish the possible trophic relationships between motoneurones and peptides.

83.10 CRANIAL MOTOR NEURONS CONTAIN GALANIN-LIKE IMMUNOREACTIVITY IN RAT BRAIN. Robert Y. Moore. Depts. of Neurology and Neurobiology, SUNY-Stony Brook, Stony Brook, NY 11794

Galanin is a 29 amino acid peptide isolated from porcine intestine and sequenced by Tatemoto et al (1983). It has been demonstrated in the peripheral and central nervous sytem (Rokaeus et al, 1984) and very detailed accounts of the distribution of galanin-like immunoreactivity (GAL-LI) in the rat central nervous system have been published recently (Skofitsch and Jacobowitz, 1985; Melander et al, 1986). These studies demonstrated numerous GAL-LI cell bodies in cerebral cortex, hypothalamus, locus coeruleus and in brainstem raphe nuclei but not in primary motor neurons. In reviewing normal rat material prepared with a GAL antibody (Peninsula Labs) we found apparent GAL-LI in the neurons of all cranial motor nuclei innervating striated muscle in colchicine pretreated brains. This was not evident without colchicine pretreatment.

To investigate this further, adult rats were anesthetized and subjected to unilateral section of either the 7th or 12th cranial nerve or the sciatic nerve. The animals were sacrificed after a three to four day survival under deep anesthesia and sections were prepared for immunohistochemistry using the ABC method (Hsu et al, 1981) with antisera to GAL or the calcitonin gene related peptide (CGRP). CGRP has been demonstrated previously in both spinal and cranial motor neurons (Gibson et al, 1984; Skofitsch and Jacobowitz, 1985; Kawai et al, 1985). In the control material from this study, CGRP-LI is present in spinal and cranial motor neurons without either colchicine pretreatment or nerve section. No GAL-LI is evident in control sections. After 7th or 12th nerve section, CGRP-LI is greatly increased in motor neurons of the appropriate nucleus extending from individual neuronal perikarya to demonstrate extensive dendritic arborizations. Similarly, after 7th nerve section, a large number of facial motor neurons show GAL-LI and, after 12th nerve section, a large number of hypoglossal nucleus neurons show GAL-LI. No increase in GAL-LI is observed in lumbosacral spinal motor neurons after sciatic nerve section.

These observations indicate that motor neurons of cranial nerve nuclei contain both galanin and CGRP whereas spinal motor neurons contain only CGRP. The significance of this differential co-localization of peptides in cholinergic motor neurons remains to be elucidated. Supported by NIH grant NS-16304.

83.11 COEXISTENCE OF NEUROPEPTIDES IN LUMBAR DORSAL ROOT GANGLIA OF THE CAT. M.G. Johnson, K.E. Miller, and V.S. Seybold, Dept. of Cell Biology and Neuroanatomy, University of Minnesota, Minneapolis, MN 55455.

Substance P (SP), vasoactive intestinal peptide (VIP), somatostatin 15-28 (SS), and cholecystokinin octapeptide (CCK-8) have been reported to coexist in perikarya of dorsal root ganglia (DRG) in the cat. In addition, SP and calcitonin gene-related peptide (cGRP) have been reported to coexist in varicosities in the spinal cord of cat where they are presumed to be of primary afferent origin. The purpose of this study was to quantify the extent of coexistence of SP with cGRP, SS, or CCK-8 in dorsal root ganglion cells of the cat. Four male cats (1.5-2.5kg) were cannulated intrathecally and colchicine was administered (500μg in 200μl) at spinal segments ranging from L5-S3. After 48 h., animals were anesthetized and transcardially perfused with fresh Zamboni's fixative. DRG L5 or L6 were removed, and cryostat sections (5-10μm) of these tissues were stained using a technique for the simultaneous visualization of 2 antigens by immunofluorescence. Immunoreactive perikarya were counted in each tissue section using the presence of a nucleus as the criterion for including a cell in each population of immunoreactive cells. Population totals were determined for the number of immunoreactive cells from the same ganglion level of each cat. The percent of coexistence was then calculated for combinations of 2 peptides using the following equation:

$$\frac{\text{number of cells stained for peptides B + A}}{\text{number of cells stained for peptide A}} \times 100 = \text{\% of cells containing peptide A that also contain peptide B}$$

Finally, a mean±SEM of each percentage was determined. We report that 79.8±0.3% of SP cells contained cGRP, while 35.6±8.1% of cGRP cells contained SP (n=910). For combinations of SP and CCK-8, 42.5±8.7% of SP cells contained CCK-8, while 53.0±2.3% of CCK-8 cells contained SP (n=494). For combinations of SP and SS, 25.6±2.7% of SP cells contained SS, while 76.8±7.3% of SS cells contained SP (n=296). A few leu-enkephalin immunoreactive cells were found in some ganglia, and they were always also immunoreactive for SP. No perikarya were immunoreactive for VIP, oxytocin, vasopressin, or dynorphin A (1-8) at the levels examined. These data confirm that neuropeptides coexist in the lumbar DRG of the cat, but indicate that in no case, is the extent of coexistence of SP with cGRP, CCK-8, or SS complete. These data are useful in classifying populations of primary afferent perikarya, and such classification of neurons may ultimately lead to predictions regarding their functional properties. Furthermore, localization of peptides in DRG perikarya will be the groundwork for studies aimed at the role of peptides as neuromodulators in spinal cord circuitry. This work supported by NS 17702.

83.12 LOCUS COERULEUS (LC) NEURONS PRODUCE, BUT DO NOT TRANSPORT, NEUROPEPTIDE TYROSINE (NPY). E.L.Gustafson and R.Y. Moore, Depts. of Neurology, Neurobiology and Psychology, SUNY at Stony Brook, Stony Brook, NY 11794

The LC is comprised of noradrenaline (NA)- producing neurons that project widely over the neuraxis with major terminal fields in the cerebral cortex, thalamus, cerebellum and spinal cord (Moore and Card, 1984). The projections of LC neurons are somewhat topographically organized (Loughlin et al, 1986) and, since only a portion of the neurons contain both NA and NPY (Everitt et al, 1984), the topography of LC projections could be determined by transmitter content. To investigate this problem further, the following studies were carried out. First, the exact number and location of NPY-immunoreactive (NPY+) neurons in the rat LC was determined in colchicine-pretreated brains. NPY+ neurons are present throughout the LC, with a slight preferential location in rostial and dorsal parts of the nucleus, and are 48% of the total neuronal population. Second, the number and distribution of neurons in LC and the distribution of axonal plexus demonstrated by NPY antisera was compared to that shown by antisera raised to the C-flanking peptide of the NPY precursor (CPON; Allen et al, 1985). CPON-like immunoreactive neuronal perikarya in LC and axonal plexuses in areas innervated by LC are identical to those shown by NPY antisera indicating that LC neurons express NPY messages. Third, the number of retrogradely-labeled, NPY+ neurons in LC was analyzed after large injections of fluorogold into neocortex, thalamus or cerebellum. The results are expressed as the percent of total LC neurons that are retrogradely-labeled and NPY+ for each injected area: neocortex, 60%-42%; thalamus, 46%-18%; cerebellum 23%-10%. The latter are of particular interest as thalamus contains little NPY and cerebellum none. Fourth, intraventricular 6-hydroxydopamine treatment markedly reduced DBH immunoreactivity in areas that receive an LC innervation. However, in areas that also have a dense NPY+ plexus, particularly the neocortex, the NPY+ innervation is unaffected. Further, 6-hydroxydopamine abolishes retrograde transport of tracer from cortex to LC.

These data indicate that NPY content is not determinant of the projection patterns of LC neurons. They can be interpreted three ways. First, NPY and NA could be differentially distributed in LC neuron axons such that collaterals to brainstem contain NPY whereas those to forebrain contain only NA. Second, NPY may be present in such low amounts in LC neuron axons that it is not demonstrable with the antisera used. Third, and this seems most likely, NPY is produced in some LC neuron perikarya but is not transported to the axon or its terminals. This would indicate a local neuronal function. Supported by NIH grant NS-16304.

83.13 LOCALIZATION OF DESCENDING METHIONINE-ENKEPHALIN- AND SUBSTANCE P-IMMUNOREACTIVE NEURONS FROM THE MEDULLA IN THE CAT. V. Krishna Reddy*, Simon J. Fung, Robert M. Bowker, and Charles D. Barnes, Dept. of VCAPP, Washington State Univ., Pullman, WA 99164-6520.

Within recent years, immunocytochemical studies have revealed the presence of many different peptide-containing neurons located in the medullary raphe and gigantocellular nuclei. Two of these peptides -- methionine-enkephalin and substance P -- are known to colocalize with many of the serotonergic cells in the raphe nuclei (Glazer et al., 1981; Leger et al., 1986; Lovik et al., 1983). In the present study, the locations of the spinally projecting neurons containing either SP- or M-ENK-like immunoreactivity are shown by employing a combination of axonal transport methods and peptide immunocytochemistry. In anesthetized cats, the enzyme horseradish peroxidase (HRP) was injected bilaterally into the lumbar or cervical enlargements, followed by colchicine administration into the lateral ventricle 48 hours later. The animals were then routinely perfused after a 24-36 hour survival period and the brains were prepared for frozen sectioning (25-30 μm). The brainstem sections were first reacted for HRP using diaminobenzidene and heavy metal intensification and then incubated in antisera raised to either SP or M-ENK (dilutions 1:6000). The sections were processed by peroxidase immunocytochemistry. The resulting sequence revealed brown-stained neurons containing black HRP granules in double-labeled cells.

Following the tissue processing, many spinally projecting SP-like neurons were evident in each of the three medullary raphe nuclei -- the raphe magnus, raphe obscurus, and raphe pallidus. The double-labeled cells were distributed among both immunoreactive and HRP-filled cells. In a similar manner, M-ENK-like neurons were seen to project to the spinal cord from these same nuclei. Quantitative analyses are currently in progress to ascertain the extent of these descending peptidergic pathways and how they are related to the population of 5HT neurons located in these same nuclei. The results of this study demonstrate directly that the SP-like and M-ENK-like cells originating from the medulla have extensive projections to the spinal cord in the cat. In addition, these findings will be discussed in relation to the descending 5HT populations and to the colocalization of these peptidergic neurons with 5HT cells. (Supported by NIH grants NS22321, NS20979 and NS24388.)

83.14 EDINGER-WESTPHAL NEURONS WHICH PROJECT TO SPINAL CORD CONTAIN CORTICOTROPIN RELEASING FACTOR IN THE CAT. R.Y. Chung*, P. Mason, A. Strassman, R. Maciewicz, Neurology Service, Massachusetts General Hosp., and the Neuroscience Program, Harvard Medical School, Boston MA 02114.

The Edinger-Westphal nucleus (EW) is a well-defined collection of medium sized neurons lying dorsal and anterior to the somatic divisions of the oculomotor nucleus. Although classically regarded as the source of parasympathetic preganglionic neurons that innervate the orbit, in the cat, rat, and monkey, EW neurons project to the cerebellum and to the superficial layers of the caudal trigeminal nucleus and spinal dorsal horn. Many EW neurons that project to spinal cord exhibit immunoreactivity for choline acetyltransferase as well as the peptides substance P and cholecystokinin (CCK).

Since corticotropin releasing factor (CRF) has been localized to cells in posterior hypothalamus and medial midbrain (including EW) in the rat, the present study was conducted to determine whether CRF-like immunoreactivity (CRF-LI) is also present in cat EW neurons that project to spinal levels.

In colchicine pretreated animals, a high density of cells in the ventral, medial midbrain exhibit CRF-LI; these cells are primarily concentrated within the boundaries of EW. Within EW, CRF-immunoreactive cells extend in a continuous distribution from the caudal pole of EW rostrally into the anteromedian nucleus (AM). Although most EW cells are immunoreactive for CRF-LI, no staining is observed in the oculomotor nucleus or adjacent nuclei. To determine whether EW cells with CRF-LI project to spinal cord, immunohistochemistry for CRF was combined with retrograde transport of horseradish peroxidase (HRP) injected into the cervical cord. In these cases, numerous EW and AM neurons labeled with HRP also exhibit CRF-LI. EW may therefore be one source of previously described CRF fiber and terminal staining at spinal levels.

The distribution of neurons exhibiting CRF-LI within EW and AM is similar to the population of EW cells which contain substance P and CCK. Since a large proportion of EW cells exhibit CRF-LI, it is likely that many EW neurons contain both CRF and another peptide. Since the descending pathway from EW to spinal cord terminates in superficial dorsal horn, the descending peptidergic system containing CRF in the present study may be important in the modulation of somatosensory inputs. This suggestion is supported by recent reports of analgesic effects following systemic CRF administration.

84.1 NUCLEUS RAPHE-MAGNUS (NRM) CONTRIBUTION TO STIMULATION-PRODUCED ANALGESIA (SPA) I. MEASUREMENT OF THRESHOLD VARIABILITY.
I.D. Hentall[1], N.M. Barbaro*, H.L. Fields, [1]Dept. of Physiol., Univ. Puerto Rico Med. Sci. Campus, San Juan, PR 00936 and Depts. Neurosurg. and Neurol., UCSF, San Francisco, CA 94143.

Electrical stimulation in or near the nucleus raphe magnus (NRM) suppresses spinal nociceptive reflexes such as the tail flick reflex (TF). If a fixed stimulation current is used to determine the liminal current (I_t) required to suppress the TF, the results are erratic. Thus, a method which rapidly and more reliably determines I_t is needed to enable further study of NRM modulation of spinal reflexes. In an attempt to provide such a method, we used trains of pulses of steadily decreasing intensity.

Rats were maintained in a lightly anesthetized state using i.v. infusion of methohexital which provides stable TF latencies (3.5-5.0 s) while eliminating signs of discomfort. A computer controlled the stimulation parameters and provided a 10 s period of constant intensity stimulation (50 Hz monopolar) followed by pulses of steadily decreasing intensity. Tail movement was detected by a strain-gauge, and the stimulus current at which the tail flicked was taken as the I_t. The starting current and rate of amplitude decline were varied to determine what effect these parameters had on I_t. I_t measurements were made in 50μM vertical steps through the NRM or repeatedly at single sites.

In the region of lowest I_t the mean was 4.4μA (S.D.-3.7 N=315). At each of these low I_t sites in NRM, variation was large. Individual values (inμA) for a typical series were (0(no flick), >15 (above starting current), 3.8, 5, 5.4, 12.8, >15μA). Slower ramps or higher starting currents did not raise mean I_t. Possible explanations for the wide variation in I_t among individual trials include the precise region of heated skin, the state of spinal neurons or external influences on NRM neurons.

This method enables rapid determination of SPA threshold. An estimate of the number of neurons involved in TF suppression can be obtained from our previous determination (Hentall et. al, J. Neurophysiol. 51:978-985, 1984) of NRM average neuronal density ($\approx$4000/mm^3) and threshold distance relations ($\approx$600/mm^2). Using these values, the number of NRM cell bodies activated by this minimum I_t (4.4μA) is approximately 11.5 Because approximately 20% of NRM neurons are off-cells (suspected TF inhibitors) the number of off-cells held active by stimulation at 4.4μA would be 2.5. Thus, electrical activation of a small number of NRM neurons appears to be responsible for TF suppression.

84.2 PUTATIVE PAIN MODULATING NEURONS IN THE LATERAL MESENCEPHALIC AND PONTINE RETICULAR FORMATION OF THE RAT.
C.M.Haws, A.M.Williamson and H.L.Fields. Departments of Physiology and Neurology, University of California, San Francisco, CA 94143.

Neurons whose firing rate increases (on-), decreases (off-) or remains unchanged (neutral) just prior to a tail withdrawal from noxious heat have been identified in the rostral ventral medulla (RVM) and, more recently, in the periaqueductal grey (PAG), both areas of the brainstem which, when stimulated produce a profound behavioural analgesia. Electrical stimulation of the reticular formation lateral to the PAG also produces a behavioural analgesia, the lowest threshold sites being the nucleus cuneiformis and pontine nucleus parabrachialis dorsalis. The following study was carried out to confirm that these regions of the lateral mesencephalic and pontine reticular formation are sensitive sites for stimulation-produced analgesia (SPA) and to investigate the possibility that on- and off-cells may also be present within these areas.

Single unit recording and testing for SPA (10 μA, 400 μs pulses at 50 Hz) were carried out in the caudal mesencephalic and rostral pontine reticular formation of the lightly barbiturate-anesthetized rat. SPA could be obtained at 10 μA or less from the nucleus cuneiformis, the nucleus parabrachialis and the ventral pontine reticular formation. On-(46 of 168 characterized cells) and off-cells (n=6) were found only in regions showing low-threshold SPA. As in the RVM, on- and off-cells in these more rostral areas had large receptive fields and their changes in activity preceded the tail flick response by several hundred milliseconds. However, these cells differed from those found in the RVM in that only a small minority (approximately 32%) of the cells encountered showed tail-flick related activity, and tail-flick related cells showed levels of spontaneous activity lower than in RVM. Furthermore, in contrast to RVM, spontaneous activity in these areas appeared to be independent of the depth of anaesthesia. These cells also did not have obvious periodic cycles of activity.

Thus, on- and off-cells have been characterised in another area of the brainstem sensitive for SPA, providing support for the involvement of these areas in pain modulation.

84.3 NUCLEUS RAPHE MAGNUS (NRM) CONTRIBUTION TO STIMULATION-PRODUCED ANALGESIA II. CORRELATION OF CELL TYPE WITH SPA THRESHOLD
N.M. Barbaro*, I.D. Hentall[1], H.L. Fields, (SPON: D. McDonald), Depts. Neurosurg. and Neurol., UCSF, San Francisco, CA 94143 and [1]Dept. of Physiol., Univ. Puerto Rico Med. Sci. Campus, San Juan, PR 00936.

The nucleus raphe magnus (NRM) has a well documented role in the modulation of spinal nociceptive reflexes such as the tail flick reflex (TF). Recently, neurons in this region have been classified as on-, off- and neutral cells, according to their response during the TF. On-cells are excited and off-cells are inhibited just before and during the TF. Manipulations which excite the off-cell such as electrical stimulation of periaqueductal grey or NRM and morphine administration, suppress nociceptive reflexes. Conversely, increased on-cell activity is associated with shorter TF latencies. Since electrical stimulation of the NRM inhibits the TF at low currents (presumably by holding a very small number of off-cells active), the proximity of the stimulating electrode to an off-cell might be expected to affect the precise electrical threshold (I_t) for reflex suppression.

As in our adjacent study, I_t was found by delivering computer generated pulse trains of decreasing intensity to the NRM of lightly anesthetized rats and measuring the current at which the TF occurred. The NRM stimulating electrode was also used to determine cell types during vertical penetrations. A mean I_t was determined for each cell from an average of 7 measurements. Only sites with one identifiable cell type were used. Trials with I_t above the initial (maximum) current were excluded. The mean I_t was 4.6μA (S.E.=0.68) near off-cells (n=11), 6.5μA(±1.00) near on-cells (n=16) and 6.0μA(±0.89) near neutral cells (n=17).

On- and off-cells were found to have a slightly different, although overlapping, spatial distribution, thus analysis of covariation was unable to show that cell type, rather than location was correlated with I_t. However, studies of individual neurons were suggestive of this. Maps were made of mean spike height and mean I_t around 12 individual cells. Despite great variability on individual trials, 5 of 6 off-cells showed clearly decreased I_t with increased spike height, and one cell showed the reverse. No correlation between spike height and I_t was seen for 6 on-cells.

These data suggest that each activated neuron has a significant effect on the TF. Off-cells appear to suppress these reflexes and on-cells seem to facilitate them. The fact that electrical stimulation in this region nearly always inhibits the tail flick suggests a more powerful role for the off-cell than for the on-cell in spinal nociceptive modulation.

84.4 Iontophoresis of the GABA antagonist bicuculline blocks off-cell pause: Evidence for GABA-mediated control of putative pain modulating neurons in the rostral ventromedial medulla.
M.M. Heinricher, C.M. Haws*, and H.L. Fields. Dept. of Neurology, Univ. of Calif., San Francisco, CA 94143

Off-cells are putative pain modulating neurons in the rostral ventromedial medulla (RVM) of the rat; it has been proposed that they are the RVM output neuron that inhibits nociceptive transmission (Fields & Heinricher, Phil. Trans. R. Soc. Lond. B, 308:388, 1985). Off-cells pause just prior to the tail flick response (TF) elicited by noxious heat, and they are activated by morphine in doses sufficient to produce antinociception. Off-cell activation by morphine is probably indirect, via inhibition of an inhibitory interneuron, since all known direct cellular effects of opiates are inhibitory. One likely candidate for the substance released by the hypothesized interneuron is GABA. GABA is found in the RVM, and microinjection studies indicate that GABA plays a significant role in the nociceptive modulating functions of the region. In the present study we have used single unit recording and iontophoresis of the GABA antagonist bicuculline to investigate the role of GABA in control of off-cell activity.

Male Sprague-Dawley rats were maintained in a lightly anesthetized state by a continuous infusion of methohexital at a rate which prevented signs of discomfort and allowed a stable TF latency of 4-5 s. Single unit activity in RVM was recorded using the center barrel of a 5-barrel glass pipette. Drug barrels contained bicuculline methiodide (BIC), GABA, strychnine (STR) or glycine. One barrel, filled with 3M NaCl, was used for automatic current compensation. Both spontaneous firing and TF-related changes in activity were monitored.

BIC (10 nA, 5 min), but not STR (10-20 nA, 5-15 min) blocked the TF-related pause of all off-cells tested. In most cases, BIC also increased the spontaneous firing rate. Within 1-2 min of initiating BIC ejection, most off-cells became continuously active, with a significant increase in peak firing rate.

A second class of TF-related neurons has been identified in the RVM. These cells, on-cells, show a sudden burst of activity which begins just prior to the TF, and their activity is suppressed by morphine. Unlike off-cells, on-cells did not show consistent changes in activity related to iontophoresis of BIC.

These results demonstrate the importance of GABA in control of the activity of the off-cells. They provide support for the hypothesis that a GABA-containing interneuron mediates the off-cell pause, and are consistent with the notion that opiates act in the RVM by disinhibiting off-cells.

84.5 ALTERATIONS OF RESPONSE PROPERTIES OF SPINOCERVICAL AND SPINOTHALAMIC TRACT CELLS BY BRAIN STEM STIMULATION. C.M. Owens*, P.J. Foreman* and W.D. Willis. Dept. of Anat. & Neurosci. and Marine Biomed. Inst., Univ. of Texas Med. Br., Galveston, TX 77550.

Spinocervical (SCT) and spinothalamic (STT) tract cells transmit nociceptive information from the periphery to the thalamus and their activity can be modulated by descending pathways originating in medial brain stem nuclei. These cells can be classified based on their responsiveness to innocuous and noxious mechanical stimuli applied to their cutaneous receptive fields. We investigated the possibility that stimulation in the medial brain stem can alter the classification of a given tract cell by changing its responses to mechanical stimulation of the skin.

To date, 10 SCT cells have been examined in 7 cats and 2 STT cells in 2 macaque monkeys (Macaca fascicularis). The animals were anesthetized with alpha-chloralose and sodium pentobarbital and paralyzed with gallamine triethiodide. End-tidal CO_2 and body temperature were monitored and kept within normal limits. Tract cells were recorded extracellularly in the lumbosacral enlargement using carbon filament microelectrodes (impedances of 2-5 megohms). STT cells were identified by antidromic activation from the contralateral ventral posterior lateral thalamic nucleus. SCT cells were identified by antidromic activation from the of ipsilateral dorsolateral funiculus at the level of caudal C3 but not from C1 (or from C1 but with a 50% or more reduction in conduction velocity between C1 and C3). Activity was recorded in the form of peristimulus time histograms. Responses were determined to brushing and to three gradations of compressive stimuli ranging from marginally painful to frankly painful. The control responses were compared with those evoked during repetitive stimulation in the medial medulla or midbrain (333 Hz, 0.1 to 1 ms pulses, up to several hundred μA). Classification was done by discriminant analysis based on a large reference population of primate STT cells classified using k means cluster analysis. Data were either normalized across the responses of a cell ("within neuron" analysis) or for each response across the population of cells ("between neuron" analysis). There were 4 response classes for each analysis.

Repeated stimulation trials in the absence of brain stem stimulation resulted in classification of the cell into the same group in either analysis. Brain stem stimulation could result in a shift of the cell into a different class when the "within neuron" analysis was used. Preliminary observations suggest that SCT cells in the cat are much less responsive than STT cells observed in the monkey. Therefore, the "between neuron" analysis should be done based on a larger sample of SCT cells rather than by comparison with the reference set of STT cells.

84.6 RECOVERY WITH MICRODIALYSIS OF SEROTONIN (5HT) RELEASED IN DORSAL HORN OF CAT SPINAL CORD. L.S. Sorkin, M.G. Hughes*, W.D. Willis and D.J. McAdoo. Depts. of Anatomy & Neurosciences and Human Biological Chemistry & Genetics, and Marine Biomedical Institute, Univ. of Texas Medical Branch, Galveston, TX 77550.

5HT, a putative neurotransmitter implicated in descending analgesia systems, is found in synaptic endings throughout the spinal cord gray matter. To examine its release in specific areas, we developed a dialysis technique that allowed us to introduce some substances into and to retrieve others from extracellular fluid in a discrete region of the dorsal horn. Cats were anesthetized with alpha-chloralose and pentobarbital, paralyzed and artifically respired. After a lumbar laminectomy, a hollow dialysis fiber (150μm ID, 9μm wall, 9kD cutoff) was inserted transversely through the spinal cord. The fiber was coated except for a 1 mm segment that was positioned in the dorsal horn. Ringers' solution was pumped through the fiber at approximately 5μl/min. Samples were collected every 10 min. The collected fluid was assayed for 5HT and its metabolite, 5-hydroxyindole acetic acid, using HPLC with electrochemical detection. At the end of each experiment, ferric chloride followed by potassium ferrocyanide was pumped through the fiber so that a Prussian blue mark could be used to define the dialysis site. In some trials, the Ringers' solution was replaced by fluid containing 100 mM K^+ (substituted for Na^+), 100 mM K^+ and 2 mM Co^{++} (substituted for Ca^{++}), or 0.35 mg/ml parachloroamphetamine (PCA). Serotonin was sometimes, but not always, present in detectable quantities in control samples. PCA or 100 mM K^+ in the perfusate solution caused release of 5HT. However, 100 mM K^+, in the presence of zero Ca^{++} and 2 mM Co^{++} was ineffective in causing 5HT release. Additionally, the ipsilateral dorsolateral funiculus (DLF) was electrically stimulated (0.5 msec long pulses at 5 Hz) rostral to the dialysis site concurrent with sample collection during some trials. This also caused 5HT release. Often the elevated levels of 5HT outlasted the stimulation for up to 40 min.

Thus, with our dialysis system we have demonstrated calcium dependent potassium evoked release of 5HT. This coupled with DLF stimulation evoked release indicates that the 5HT we are measuring is of neural origin.

84.7 QUANTITATIVE CHARACTERIZATION OF INHIBITION OF SPINAL NOCICEPTIVE TRANSMISSION FROM THE LATERAL RETICULAR NUCLEUS (LRN). A.J. Janss and G.F. Gebhart. Dept. of Pharmacology, Univ. of Iowa, Iowa City, IA 52240.

Involvement of the LRN in the caudal ventrolateral medulla in centrifugal modulation of nociceptive transmission has been demonstrated in the rat using the analgesiometric tail-flick and hot plate tests; behavioral tests are an indirect measure of nociception and cannot discriminate between inhibition of motor and sensory activity. In this study, inhibition of nociceptive spinal neurons from the LRN in rats was characterized.

Rats were anesthetized with pentobarbital (45 mg/kg) for cannulation of the femoral artery and vein and tracheotomy. They were paralyzed with pancuronium (0.4 mg/kg iv) and ventilated with a gaseous mixture of N_2O:O_2 (2:1). Anesthesia was maintained throughout the experiment by infusion of pentobarbital (5-7 mg/kg/hr iv). The spinal cord was exposed between segments C2-C3 and T12-L2 by laminectomy. Stimulation electrodes were lowered into the contralateral ventrolateral quadrant of the cervical spinal cord (VLQ), ventroposteriolateral nucleus of the thalamus (VPL), and LRN; a recording electrode was placed in the lumbar spinal dorsal horn.

All 47 units studied responded to mechanical stimuli and to noxious heating (50°C) of the skin of the footpad; rostral projections were identified by antidromic invasion with stimulation (0.5 μs, 0.5 Hz) in the VPL and VLQ. Stimulation-produced inhibition (constant cathodal current; 100 μs, 100 Hz) of neuronal responses to heat in the caudal medulla was maximal in the area of the LRN. The mean threshold intensity of LRN stimulation for inhibition of unit responses to heat was 13.0 ± 1.8 μA and the mean intensity attenuating neuronal responses to heat to 50% of control was 34.4 ± 3.3 μA. Inhibition of spontaneous activity of nociceptive neurons by LRN stimulation did not differ in magnitude from inhibition of responses to heating of the skin. Unit response to graded heating of the skin (42-50°C) was a linear, monotonic function. Stimulation in the LRN decreased the slope (42 ± 4% of control) of the stimulus response function and increased the neuronal response threshold (2.0 ± 0.7°C). Monosoduim glutamate (50 nmoles) microinjected into stimulation sites attenuated neuronal responses to heat only when microinjected into the LRN (mean = 35 ± 6% of control). Microinjections of lidocaine made into the ventrolateral medulla blocked LRN stimulation-produced inhibition without affecting neuronal spontaneous activity or responses to heating of the skin. These results clearly establish a role for the LRN in the modulation of spinal nociceptive transmission, but the LRN does not appear to be the supraspinal source of tonic modulation in the rat. Supported by NS 19912 and T32 GM07069.

84.8 CHEMICAL VS. ELECTRICAL INHIBITION OF DORSAL HORN NEURONS FROM THE BRAINSTEM IN THE RAT. S.L. Jones and G.F. Gebhart. Dept. of Pharmacology, University of Iowa, Iowa City, Iowa 52242.

Opioid receptors and peptides have been identified in brainstem sites which also have been demonstrated to be involved in stimulation-produced descending inhibition of spinal nociceptive transmission [e.g., locus coeruleus/subcoeruleus (LC/SC), nucleus raphe magnus (NRM), periaqueductal gray (PAG)]. Morphine, which has been demonstrated to act supraspinally (as well as at the spinal level), is hypothesized to modulate spinal nociceptive transmission via activation of endogenous descending inhibitory systems.

The objectives of this study were: 1) to quantitatively examine the effects of morphine microinjections in the PAG, the LC/SC and the NRM on responses of dorsal horn units to noxious heat (50°C), and 2) to quantitatively compare morphine's effects with glutamate- and stimulation-produced inhibition of unit responses to heat in the deeply pentobarbital-anesthetized, paralyzed rat.

Morphine sulfate (MS; 10-20 μg, 0.5 μl) was microinjected into 12 sites in the midbrain PAG. Dorsal horn unit responses to noxious heat were inhibited to 64.3 ± 7.6% of control at 8/12 sites; MS had no effect on unit responses to heat at 4/12 sites in the PAG. At 8/13 sites in the pontine LC/SC, MS microinjections inhibited unit responses to noxious heat to 63.8 ± 9.9% of control; at 3/13 sites unit activity was increased to 137.9 ± 8.2% of control and at 2/13 sites MS produced no change in unit activity. The microinjection of MS into the medullary NRM produced inhibition of unit responses to noxious heat at 8/12 sites to 59.8 ± 5.9% of control and had no effect at 4/12 sites in the NRM.

Summarized below are the mean effects (± SEM) of MS and glutamate microinjections and electrical stimulation on unit responses to noxious heat for sites in the PAG, the LC/SC and the NRM where both glutamate and MS microinjections were made at the same sites (n=5). Inhibition is expressed as % of control.

	μA	Stim	MS	Glutamate
PAG	95.0 ± 5.0	16.3 ± 8.1%	62.2 ± 11.3%	60.7 ± 1.5%
LC/SC	100.0 ± 0.0	23.7 ± 7.8%	60.5 ± 12.7%	55.8 ± 11.6%
NRM	85.0 ± 10.0	45.4 ± 12.0%	53.9 ± 7.5%	55.7 ± 13.6%

These results suggest that MS can modulate spinal nociceptive transmission by activating the PAG-NRM bulbospinal relay at either the midbrain or medullary level or the pontine coeruleospinal pathway.

Supported by NS 19912, DA 02879 and GM 07069.

84.9 PERIAQUEDUCTAL GRAY STIMULATION INDUCES GASTROINTESTINAL UPSET WHILE PRODUCING CUTANEOUS ANALGESIA. K.F. Green and D.S. Sacks. Psychology Dept., California State University at Long Beach, 90840 and Psychology Dept., Bowling Green State University, Bowling Green, Ohio, 43402.

Abundant evidence indicates that electrical stimulation of the periaqueductal gray (PAG) can block cutaneous pain. In contrast very little work has been done on the effect of PAG stimulation on pain of visceral origin, such as gastrointestinal (GI) upset induced by injected lithium chloride. The present work addressed this problem.

The subjects were 28 male Wistar rats with unilateral PAG electrodes. When stimulated, all showed consistent, profound cutaneous analgesia in the tail flick test. Four groups were defined as follows. Group LS, the experimental group, drank water sweetened with saccharin, and was then injected with lithium chloride and stimulated in the PAG for the 2-hr duration of the GI upset. On a later day this group (as were all other groups) was tested with sweet water for a conditioned flavor aversion (CFA). Group L24S, the CFA control, drank sweet water and was injected with lithium chloride; 24 hr later the PAG was stimulated for 2 hr. Group S24L, the PAG stimulation control, drank sweet water and was stimulated for 2 hr; 24 hr later lithium chloride was injected. Group N, the no-lithium no-stimulation control, simply drank sweet water.

PAG stimulation did not attenuate GI pain, as indicated by CFAs in Group LS that were as strong as CFAs in Group L24S. Indeed, PAG stimulation alone produced CFAs to sweet water in Group S24L. No CFAs were shown in Group N.

Later tests, where PAG stimulation was paired with one side of a shuttle box, indicated no aversion to an environment. Therefore the aversive consequences of PAG stimulation were due to internally referred visceral stimuli.

Similar findings of GI upset accompanying morphine or rotation stress-induced somatic analgesia have been reported. These data reinforce accounts of behavior that point to separate mechanisms for processing information in somatic and visceral milieus. It may be that manipulations that induce somatic analgesia also induce GI upset.

84.10 THE PAG: AN EXAMINATION OF THE DISTRIBUTION OF OPIOID AND NON-OPIOID SITES, THEIR INTERACTION, AND THE ROLE OF SEROTONIN. D.S. Nichols*, B. Thorn, and G.G. Berntson, Psychobiology Program, Dept. of Psychology, The Ohio State University, Columbus, Ohio 43210.

The midbrain periaqueductal gray (PAG) has been reported to support stimulation-produced analgesia (SPA) in both humans and animals. Some sites within the PAG have qualities that suggest an endogenous opiate system, characterized by naloxone-reversibility, a diminuation of the analgesic affect following repeated stimulation, and the development of cross- tolerence between two PAG sites. Stimulation of other sites within the PAG results in analgesia that is not naloxone reversible. Naloxone-reversible sites have been reported primarily in the ventral PAG , and non-naloxone-reversible sites primarily in the dorsal PAG. Stimulation of both systems appears to activate intraspinal systems, which may or may not utilize serotonin.

The present study examines the distribution of opioid and non-opioid sites within the PAG, the interaction of these sites through the production of cross-tolerence, and the ability of the serotonin antagonist, methysergide to reverse the SPA from each. Albino rats were stereotaxically implanted with two monopolar stimulating electrodes, aimed at sites varying along ventral-dorsal, medial-lateral, and anterior-posterior axes. Analgesia was produced by a 10 sec. stimulation utilizing biphasic rectangular-wave pulse pairs of 1-msec. duration at a 50 Hz frequency, with intensity ranging from 10-300 microamps. The effect of stimulation was examined with the tail-flick test. Each animal underwent a series of tests to determine SPA characteristics. If a site supported SPA, it was then tested for naloxone-reversibility (10 mg/kg naloxone), and 48 hours later for methysergide-reversibility (3 mg/kg methysergide) to assess the opioid and serotonin contributions to the SPA. If two sites within an animal supported SPA, one site was stimulated to tolerence and then stimulation was transferred to the second site to determine if cross-tolerence occurred.

240 sites were sampled, of which 80 supported SPA. Preliminary histologies support the ventral-dorsal distribution of opioid and non-opioid sites, with predominantly a midline focus. This distribution is present throughout the anterior-posterior extent of the PAG. Cross-tolerence was obtained between dorsal and ventral sites and this was bi-directional. Methysergide was found to reverse SPA from both naloxone-reversible and non-reversible sites. The findings suggest that although these systems are anatomically distinct, they do not operate independent of each other and that serotonin is a common element.

84.11 INFLUENCE OF INJECTIONS OF MORPHINE INTO THE PAG AND AMINE ANTAGONISTS INTO THE SPINAL CORD ON NOCICEPTIVE RESPONSES ORGANIZED AT DIFFERENT LEVELS OF THE CNS IN THE RAT. G. S. Borszcz, A.H. Lichtman*, & H.C. Hughes. Dept. of Psychology, Dartmouth Coll., Hanover, NH.

We have recently shown that by applying the psychophysical method of constant stimuli to a wheel turn / tail flick paradigm, thresholds of nociceptive responses organized at different levels of the CNS can be assessed simultaneously (Borszcz & Lichtman, 1986). This paradigm requires rats to turn a wheel in order to terminate shock applied to the tail. The probability of wheel turn (cephalic) and tail flick (spinal) responses at each of several current intensities was assessed, and the resulting psychometric functions were evaluated to determine nociceptive thresholds.

Using these procedures the influence of morphine sulfate microinjected into the ventrolateral periaqueductal gray (vPAG) on wheel turn and tail flick thresholds was examined. Since the antinociceptive effects of morphine microinjected into the vPAG are partially the result of activating noradrenergic and serotonergic receptors within the spinal cord, the influence of intrathecally administered amine antagonists on morphine induced antinociception was also studied. Each rat was chronically implanted with a cannula directed towards the vPAG and an intrathecal catheter whose tip rested near the lumbar enlargement of the spinal cord. After recovery, nociceptive baseline thresholds were obtained for both tail flick and wheel turn responses. Nociceptive thresholds were again assessed after: 1) microinjection of morphine sulfate into the vPAG (3*ug*/.5*ul*), 2) intrathecal injection of the amine antagonists (methysergide and phentolamine, 15*ug*/15*ul* each), and 3) combined microinjection of morphine sulfate into the vPAG and intrathecal injection of amine antagonists.

Preliminary results indicate that microinjection of morphine into the vPAG elevates wheel turn thresholds to a greater degree than tail flick thresholds. The intrathecal administration of amine antagonists had little influence on baseline threshold values for either response. When morphine microinjection was accompanied by intrathecal administration of amine antagonists, tail flick thresholds were reinstated to baseline levels while wheel turn thresholds remained significantly elevated. These results are comparable to those reported by Yaksh (1979) using the radiant heat / tail flick and hot plate / paw lick tests, and indicate that the neural mechanisms subserving cephalically versus spinally organized nociceptive responses are differentially influenced by morphine administration.

84.12 SYNAPTIC ORGANIZATION OF THE NUCLEUS RAPHE DORSALIS OF THE CAT. G. Chazal[1] and P.T. Ohara. Anatomy Department, University of California, San Francisco, San Francisco, CA 94143, USA. [1]I.N.S.E.R.M., U-6, 280 Bd. Ste Marguerite, 13009 Marseille, FRANCE.

The nucleus raphe dorsalis (NRD) is a major source of 5-HT projections to other regions of the CNS and is involved in a number of CNS functions including pain modulation. This study describes the synaptic organization of NRD and provides anatomical evidence for dendro-dendritic interactions.

Adult cats were perfused under deep barbiturate anaesthesia with 2% Paraformaldehyde/ 2% Glutaraldehyde in 0.1M phosphate buffer, pH 7.6. 50um vibratome sections of the brain stem were osmicated, dehydrated in alcohols, stained with uranyl acetate and embedded in Epon. Areas containing Nucleus Raphe Dorsalis (NRD) were trimmed from the vibratome sections and serially sectioned for electron microscopy. For all terminal types the nature of the synaptic contact was confirmed using serial section analysis.

Five different classes of terminals are identified based on the shape and packing density of the synaptic vesicles and type of contact they establish. The most common class (RDI-type) contains densely packed, round, agranular synaptic vesicles and establish asymmetrical synaptic contacts. A second class (RDII-type) also contains spherical synaptic vesicles but establishes symmetrical synaptic contacts with dendrites of all sizes. Most of the terminals in these two classes contain a few dense-cored synaptic vesicles but a small sub-group contains many dense-cored vesicles. A third, less frequent, class (RSI-type) have sparsely packed spherical synaptic vesicles and the majority of these terminals have asymmetrical contacts. A fourth terminal class contains pleomorphic synaptic vesicles (P-type) and contact dendrites of all sizes and usually establish symmetrical synaptic contacts. Finally, boutons thought to be the vesicle-filled excresences of dendrites (PSD) are found. Such boutons contain pleomorphic vesicles, are presynaptic to other PSDs as well as conventional dendrites and are presynaptic to other PSDs as well as conventional dendrites and are postsynaptic to the other terminal types described.

Somata within the nucleus exhibited somatic spines but receive few synaptic contacts. Most axo-somatic terminals contain either round or pleomorphic vesicles and have postsynaptic thickenings intermediate between the symmetric and asymmetric type. (Supported by NS 23347 and INSERM-France to GC).

84.13 ORGANIZATION AND CYTOCHEMISTRY OF BRAINSTEM NEURONS WITH DIVERGENT COLLATERALS TO THE MIDBRAIN PERIAQUEDUCTAL GREY (PAG) AND THE SPINAL CORD. Kwiat, G.* and Basbaum, A.I. (SPON: N.M. Lee). Dept. of Anatomy, University of California, San Francisco 94143.

The analgesic action of electrical stimulation of the midbrain periaqueductal grey (PAG) is thought to result, in part, from activation of medullary serotonergic and noradrenergic neurons, which, in turn, project to and inhibit spinal nociceptive neurons. The analgesia may also involve activation of neurons which have divergent projections to the PAG and the spinal cord. This study used a multiple labelling approach to address the latter possibility.

First, 2 to 3 ul of a 5% solution of the retrograde tracer, True Blue, was injected bilaterally into the cervical enlargement. Three days later, a second retrograde tracer, WGA-apoHRP-Au (Basbaum and Menetrey, 1985) was microinjected into the PAG. Four days later the rats were perfused with a 4% paraformaldehyde fixative. Twenty micron cryostat sections were silver intensified (to visualize the gold) and an immunofluorescence procedure was used with antisera directed either against 5HT, or, to identify catecholamine neurons, tryosine hydroxylase (TH).

Both the nucleus raphe magnus (NRM) and adjacent reticular formation contained a large number of gold-labelled cells. Of these, about 20% also contained True Blue, ie, they project to both the PAG and spinal cord. Despite the large number of spinally projecting 5HT neurons in this region, none of the True Blue-gold double labelled cells were 5HT immunoreactive. Some 5HT immunoreactive neurons in the nucleus reticularis paragigantocellularis lateralis projected to the PAG, but these did not also project to the cord. Other cells in this region had divergent collaterals to the PAG and spinal cord but were not 5HT immunoreactive.

Triple labelled cells containing TH immunoreactivity and retrograde labels from PAG and spinal cord were found in the locus coeruleus and A5 cell group. Other TH cells in the ventrolateral medulla, nucleus of the solitary tract, and locus coeruleus projected to the PAG but were not retrogradely labelled from the spinal cord. Spinally projecting TH positive cells in the Kolliker Fuse nucleus did not project to the PAG.

These data indicate that there is a widespread pontomedullary catecholaminergic projection to the PAG. A component of this projection derives from cells with divergent collateral projections to the spinal cord. In contrast, the spinally-projecting 5HT neurons of the NRM do not collateralize to the PAG. Further studies of the cytochemistry of the raphe neurons which do collateralize to PAG and cord, and which may contribute to the analgesic action of PAG electrical stimulation, are in progress.

Supported by NS14627 and 21445.

84.14 THE RELATIONSHIP OF ENKEPHALIN AND NEUROTENSIN IMMUNOREACTIVE TERMINALS WITH PERIAQUEDUCTAL GRAY-RAPHE MAGNUS PROJECTION NEURONS. F.G. Williams* and A.J. Beitz. Dept. of Veterinary Biology, Univ. of Minnesota, St. Paul, MN 55108.

The midbrain periaqueductal gray (PAG) is a key component of the brain's endogenous analgesia system. Several lines of evidence suggest that the neuropeptides enkephalin (ENK) and neurotensin (NT) play a role in PAG-induced analgesia. The present study was undertaken to determine if ENK and/or NT-containing synaptic terminals interact with PAG-raphe magnus projection neurons.

Wheat germ agglutinin-horseradish peroxidase (WGA-HRP, 1ug) was injected into the raphe magnus of 10 Sprague-Dawley rats (275-300 grams) under chloral hydrate anesthesia. Twenty-four to thirty-six hours later the animals were perfused with calcium-free Tyrode's solution, followed by 4% paraformaldehyde/0.4% glutaraldehyde. Brains were post-fixed for 12 hours before sectioning at 50 microns on a vibratome. WGA-HRP was visualized on the sections using tetramethylbenzidine (TMB) as described by Rye, et al. (1984). After the TMB reaction, sections were immunohistochemically stained either for NT, using rabbit antibody kindly supplied by Dr. L. Jennes, or for ENK using a rabbit antibody kindly supplied by Dr. R. Elde. Primary antibodies were visualized using Vectastain ABC kits and diaminobenzidine. Sections were processed both for light and electron microscopy.

PAG neurons retrogradely-labeled from raphe magnus were most concentrated in the caudal region of the PAG, where they are found immediately ventral to the aqueduct. Some retrogradely-labeled neurons were observed in the dorsal raphe nucleus. By light microscopy, numerous puncta immunohistochemically stained for NT and ENK were also concentrated in this region. Electron microscopy was then employed to clarify possible relationships between these immunoreactive structures and retrogradely-labeled PAG projection neurons. For both antisera, greater than 90% of the immunostained structures were terminal boutons containing both dense-core and round agranular vesicles. Immunopositive dendrites were rare and no positive perikarya were observed. Most NT and ENK-positive terminals were immediately adjacent to unlabeled dendrites characterized by a light cytoplasm. Two or more positive terminals were often observed forming symmetrical synapses with a single unlabeled dendritic profile. Both NT and ENK-positive terminals were also observed in contact with dendrites containing retrograde TMB label from raphe magnus. NT and ENK immunoreactive terminals were rarely observed on the perikarya of neurons containing retrograde label. These results suggest that both ENK and NT immunoreactive terminals interact with PAG neurons that project to raphe magnus.

84.15 THE INFLUENCE OF PAIN AND MORPHINE ON LOCAL CEREBRAL GLUCOSE UTILIZATION IN THE RAT. S.R. Cohen and E.D. London. Neuropharm. Lab., NIDA Addiction Research Center, Baltimore, MD 21224.

To identify brain areas which might play a role in different types of pain and morphine-induced analgesia, rates of local cerebral glucose utilization (LCGU) were assessed in rats with and without pain which received morphine or saline. Particular attention was paid to forebrain and limbic areas to focus on the affective component of pain and morphine's effect.

The 2-deoxy-D-[1-^{14}C]glucose (DG) technique of Sokoloff et al., (J. Neurochem., 28:897, 1977) was used to measure LCGU. Rats were assigned to one of three pain groups: no pain, formalin pain, or tail-immersion pain. Rats in the formalin pain group received an injection of 0.05 ml 2.5% formalin into the plantar surface of a hindpaw 30 min before DG (100 uCi/kg, i.v.). Animals in the tail-immersion pain group had their tails dipped in a 55°C water bath at the following times after the DG injection: 2, 4, 8, 10, 14, 16, 20, 25, 30, 35 and 40 min. In addition, each rat received either morphine (8 mg/kg, s.c.) or saline 30 min before DG.

No effect of either type of pain could be discerned in any of the 48 brain regions studied. These included the brainstem nuclei implicated in pain and analgesia (e.g., dorsal raphe, raphe magnus, gigantocellular nucleus (n.), paragigantocellular n., periaqueductal gray) and somatosensory areas (ventroposterolateral thalamic n. (VPL), gracile n., somatosensory cortex), as well as limbic areas (e.g., accumbens n., septal n., habenula, amygdala).

Morphine decreased LCGU in 17 regions, including many forebrain and limbic sites. Significant decrements were observed in the lateral septal n., paratenial, centromedian, VPL, gelatinosus, mediodorsal, and paraventricular thalamic nuclei, medial prefrontal cortex, lateral hypothalamus, ventral tegmental area, stria medullaris, lateral habenula, median raphe n., interpeduncular n., mammillary bodies, and entorhinal cortex. In contrast, morphine increased LCGU in the external cuneate n.

In most areas, LCGU was the same ipsilateral and contralateral to the catheterized leg. However, LCGU was decreased in the contralateral VPL as compared to the ipsilateral VPL in all groups, possibly due to the intraoperative use of a local anesthetic (bupivacaine HCl, 1 mg).

Anatomical sites involved in interactions between morphine and pain could not be determined as the pain stimuli did not affect LCGU. Nevertheless, the decrements in LCGU produced by morphine in limbic and forebrain structures in this study are consistent with the clinical observation that much of morphine's analgesic effect is due to a reduction of the affective component of pain.

84.16 **PHARMACOLOGIC CHARACTERIZATION OF SPINAL CORD 5-HT$_1$ RECEPTOR SUBTYPES.** **F.P. Zemlan and R.M. Murphy. Lab. of Geriatric Research, and Dept. of Physiol. and Biophysics, Univ. of Cincinnati College of Medicine, Cinti, OH 45267-0555.**

Recent biochemical and behavioral studies indicate that serotonin (5-HT) may differentially affect pain transmission at the spinal level. With the recent discovery of multiple 5-HT$_1$ binding sites in the spinal cord, it is possible that the variable effects of 5-HT at the spinal level may be mediated by particular 5-HT$_1$ receptor subtypes. The present studies report our initial findings characterizing these multiple 5-HT$_1$ binding sites in spinal cord.

Saturation experiments using [^{3}H]5-HT and the selective 5-HT$_{1A}$ ligand [^{3}H]8-OHDPAT (0.10 - 45 nM) indicate the presence of both high (K_D = 0.10 nM) and low (K_D = 3-6 nM) 5-HT binding sites in spinal cord. Increasing concentrations of Mg^{2+} or Ca^{2+} (10^{-6} - 10^{-1} M) significantly increased specific high affinity [^{3}H]5-HT binding. No significant increase in binding occurred at higher ligand concentrations (>5 nM).

At lower ligand concentrations (0.3 nM), which predominantly labeled higher affinity [^{3}H]5-HT binding sites, addition of GTP decreased specific binding by 80%, while at ligand concentrations (10 nM) which predominantly labeled lower affinity sites, GTP decreased [^{3}H]5-HT by only 40%. In the presence of divalent cations GTP concentrations above 10 uM eliminated all higher affinity [^{3}H]5-HT binding sites.

Competition of 5-HT agonists and antagonists (10^{-15} - 10^{-4} M) against [^{3}H]5-HT (0.3 nM - 5 nM, 0.1 mM GTP) yielded steep inhibition curves (n = 0.98 - 1.07) for 5-HT, 5-MT metergoline and cyproheptadine. Competition curves for 8-OH-DPAT, buspirone, 5-MeODMT, mCPP, quipazine and TFMPP were shallow with Hill coefficients between 0.77 and 0.51 suggesting the presence of two binding sites for these competitors.

Selectivity of competing agonists (500 nM) for 1A and 1B receptors ([^{3}H]5-HT = 0.5 nM) was determined in the presence of 100 nM mCPP and 100 nM 8-OH-DPAT respectively. Kinetic parameter estimates indicated that 40% of spinal cord [^{3}H]5-HT binding sites were labeled in the nanomolar range by 1A selective agonists (8-OH-DPAT, buspirone and 5-MeODMT) while the remaining 60% were labeled by 1B selective agonists (mCPP, quipazine and TFMPP).

The present studies characterized two distinct 5-HT$_1$ binding sites in spinal cord. Reference to our behavioral data reported at this meeting indicate that the two 5-HT$_1$ receptor subtypes may have opposite effects on spinal pain transmission. (NS18326 and NS07840)

84.17 SELECTIVE 5-HT1A AND 5-HT1B AGONISTS DIFFERENTIALLY AFFECT SPINAL PAIN REFLEXES. E.J. Purpus*, R.M. Murphy and F.P. Zemlan (SPON: N. Sperelakis). Lab. of Geriatric Research, and Dept. of Physiol. and Biophysics, Univ. of Cincinnati Col. of Med., Cinti, OH 45267.

The present study reports the effects of selective 5-HT_{1A} and 5-HT_{1B} agonists on the sensitivity of three spinal nociceptive reflexes.

Two days after spinal transection, animals were injected i.p. at 20 minute intervals with increasing doses (0, 0.1, 0.4, 2.0, 13 mg/kg) of either a 5-HT_{1A} selective agonist (8-OHDPAT, buspirone) or a 5-HT_{1B} selective agonist (mCPP, TFMPP). The nociceptive sensitivity of the ventroflexion, dorsiflexion and lateral flexion reflexes was quantified as size of the RF area of the reflex in cm^2 (1 cm^2 = 8.1 mg).

Both the 1A agonists produced significant dose-response related increases in the sensitivity of all three spinal reflexes. The following ED_{50}'s were obtained: ventroflexion - buspirone ED_{50} = 0.15 mg/kg, 8-OHDPAT ED_{50} = 0.30 mg/kg; dorsiflexion - buspirone ED_{50} = 0.03 mg/kg, 8-OHDPAT ED_{50} = 0.019 mg/kg; and lateral flexion - buspirone ED_{50} = 0.015 mg/kg, 8-OHDPAT ED_{50} = 0.017 mg/kg.

An opposite effect of 1B agonists administration on the ventroflexion reflex was observed with a significant dose-response related decrease in sensitivity to noxious stimulation seen at all doses (mCPP ED_{50} = 1.6 mg/kg; TFMPP ED_{50} = 1.06 mg/kg).

The effects of 1B agonists administration on the dorsiflexion and lateral flexion reflexes was variable with the lowest dose (0.1 mg/kg) producing a significant increase in sensitivity followed by a significant dose-response related decrease in nociceptive sensitivity seen at the higher doses.

Selectivity of the above sensory hypersensitivity to spinal 1A receptors was assessed employing the 1A selective blocker spiperone (0.001, 0.01, 0.1 and 1.0 mg/kg). An increase in sensitivity to noxious stimulation was seen following buspirone treatment (2 mg/kg). However, subsequent administration of increasing doses of spiperone resulted in the total blockade of the buspirone effect.

The present study indicates that two days after spinal transection, the ventroflexion reflex is most sensitive at differentiating between 5-HT_{1A} and 5-HT_{1B} agonists. The results also indicate that the two 5-HT_1 receptor subtypes characterized in our receptor binding study reported at this meeting may have opposite effects on spinal pain transmission. (NS07840 and NS18326)

84.18 FUNCTIONAL LOSS OF THE 5-HT_{1B} PRESYNAPTIC RECEPTOR IN SPINAL CORD OF AGED RATS. R.M. Murphy and F.P. Zemlan. Lab. of Geriatric Research, and Dept. of Physiol. and Biophysics, Univ. of Cincinnati College of Medicine, Cinti, OH 45267-0555.

Although certain biochemical changes in the 5-HT system have been identified with the normal aging process, no known functional changes have yet to be examined. The present study reports our initial findings assessing the effects of aging on the functional integrity of the presynaptic 5-HT_{1B} receptor in spinal cord.

Lumbar spinal cord slices (0.4 mm thick) from adult (3 mos.) and aged (18 mos.) rats were incubated for 15 min at 37°C in 5 ml Krebs-Ringer buffer containing 100 nM [^{3}H]5-HT. Two spinal cord slices were transferred to each chamber and superfused with oxygenated medium containing 100 nM fluoxetine, at a rate of 0.5 ml/min. Samples were collected at 3 min intervals. After 60 min, the tissue was exposed to elevated potassium (25 mM K^+) for 6 minutes. Drugs (concentrations: 1 nM - 100 nM) were present throughout the last 20 min of basal efflux and during the 6 min exposure to the elevated K^+. The fractional efflux rate was determined as previously described (Eur. J. Pharm. 63: 179,1982).

The 5-HT_{1B} selective agonist mCPP, and 5-HT produced a significant 25-70% reduction in the K^+-evoked release of [^{3}H]5-HT in adult rats. The 5-HT_{1A} selective agonists 8-OHDPAT and 5-MeODMT produced a dose-dependent increase (5-29%) in K^+-evoked [^{3}H]5-HT release. Only at 100 nM was the increase significant for 8-OHDPAT ($p<.05$).

In aged rats, mCPP and 5-HT, in contrast to the adult rats, resulted in increased (10-50%) K^+-evoked [^{3}H]5-HT release similar to the effect produced by the 5-HT_{1A} agonists in the adult rat.

Additionally, 5-HT (100 nM) resulted in a substantial 50% increase in spontaneous release in aged rats. This is in contrast to no effect of 5-HT or the other drugs on the normal slow decline in basal [^{3}H]5-HT release in adult rats. Possible alterations in the transmembrane sodium gradient in the aged rat may account for these results.

The present study indicates the functional loss of the 5-HT_{1B} presynaptic receptor in the spinal cord of aged rats. Although more extensive studies are required before firm conclusions can be reached, the present study indicates that the serotonin system mediating spinal pain transmission may be compromised in aged rats. (NS07840)

84.19 STIMULATION-PRODUCED ANALGESIA FROM SITES IN THE VENTROLATERAL PONS IS MEDIATED BY A SPINAL ALPHA 2-ADRENERGIC SYSTEM. J.F. Miller & H.K. Proudfit, Dept. of Pharmacology, Univ. of Illinois College of Medicine, Chicago. IL 60680.

Stimulation of the rat ventrolateral tegmentum (VLPT) produces a potent analgesia, as measured by the tailflick test (Miller & Proudfit, Soc.Neurosci.Abstr., 10: 201, 1984). The present experiments demonstrate that the stimulation-produced analgesia (SPA) obtained from VLPT sites is mediated by a spinal alpha 2-noradrenergic system.

Adult female Sprague-Dawley rats were implanted with both a unilateral bipolar stimulating electrode in the VLPT (AP:+0.4 mm; L:1.6 mm; V:+1.4 mm) and an intrathecal catheter ending in the lumbar subarachnoid space. Following a 4-5 day recovery period, baseline tailflick latencies (TFLs) were determined and the rats were screened for analgesic VLPT sites. Stimulation parameters were: 60 Hz, 0.1 msec square wave pulses, 50-300 uA. In the first experiment, rats in which VLPT stimulation markedly elevated TFLs then received an intrathecal microinjection of either the alpha-adrenergic antagonist phentolamine HCL (30 or 60 ug) or the beta antagonist ±-propranolol HCl (111.6 ug). Control animals received an equal volume microinjection of saline vehicle. In the second experiment, rats with analgesic VLPT placements received intrathecal microinjections of either the alpha 1-selective antagonist WR-4101 (37 ug), the alpha 2-selective antagonist yohimbine (37 ug), or saline. For all animals, the effectiveness of VLPT stimulation in elevating TFLs was again assessed 15, 30, and 60 min after drug injection.

Intrathecal administration of phentolamine was found to antagonize SPA elicited from VLPT sites in a dose-dependent fashion, with the higher dose completely abolishing the analgesic effect of VLPT stimulation. Propranolol, on the other hand, was ineffective in blocking SPA from VLPT sites. An alpha 2 receptor system is indicated, in that yohimbine, but not WR-4101, also attenuated SPA obtained with electrical stimulation of VLPT sites.

Immunohistochemical staining of a small number of brains from the first experiment for dopamine-beta-hydroxylase (DBH) showed the electrode placements to lie medial to DBH-immunoreactive neurons in the rostral pons located along the border of the lateral lemniscus.

This work was supported by USPHS Grant DA03980.

84.20 ALTERATIONS IN THE ACTIVITY OF DORSAL HORN NEURONS PRODUCED BY ELECTRICAL STIMULATION OF NEURONS IN THE VENTROLATERAL PONTINE TEGMENTUM. F.M. Clark, L.F. Fitzgerald* and H.K. Proudfit Dept. of Pharmacol., Univ. of Ill. at Chicago, Chicago, IL 60680.

Electrical stimulation of the nucleus raphe magnus (NRM) inhibits the firing of spinal cord dorsal horn neurons. Such inhibition is mediated by a direct raphespinal serotonergic projection from the NRM and by a bulbospinal noradrenergic projection from unidentified catecholamine-containing neurons. We have recently demonstrated that electrical stimulation of the ventrolateral pontine tegmentum (VLPT) produces antinociception which is mediated by noradrenergic neurons. These data indicate that the catecholamine bulbospinal neurons in the VLPT may be those neurons activated by electrical stimulation of the NRM. The present study was designed to characterize the effects produced by electrical stimulation of VLPT neurons on the activity of nociceptive dorsal horn neurons.

Female Sprague Dawley rats (250-350 g) were anesthetized with urethane (1.2 g/kg) and body temperature was maintained at 37°C. The right internal carotid artery was cannulated to monitor blood pressure and a laminectomy exposed the lumbar spinal cord. A bipolar stimulating electrode was stereotaxically lowered into the VLPT and recordings were made from dorsal horn neurons with glass microelectrodes. Stimulus parameters were 0.1msec square wave pulses varying in frequency from 100 to 300 Hz. and in intensity from 25 to 400 microamps.

A total of 74 units responsive to mechanical stimulation were isolated. All recorded units were located in the spinal cord dorsal horn in laminae I-VI and their cutaneous receptive fields were ipsilateral and confined to the right lower limb. All units were responsive to either brush and/or pinch with toothed forceps. Once a unit was characterized, the effect of electrical stimulation within the VLPT on the unit's firing characteristics was examined. Systematic electrode penetrations were made through the VLPT just medial to the rubrospinal tract. Of the 44 cells tested, the response to noxious stimulation was increased in 18 cells, inhibited in 17 cells and 9 cells were not affected. All units affected were either responsive to noxious stimulation alone or were responsive to both innocuous and noxious stimuli. Excitation and inhibition were elicited from similar locations in the VLPT.

The results of these studies indicate that stimulation in the VLPT produces both excitation and inhibition of dorsal horn neurons. These findings are consistent with behavioral studies which indicate that both antinociceptive and aversive effects can be elicited by electrical stimulation of various sites in the VLPT. (This work was supported by USPHS Grant DA03980).

84.21 EFFECTS OF NUCLEUS RAPHE MAGNUS STIMULATION ON NOCICEPTION AFTER INTRATHECAL INJECTION OF 5'-N-ETHYLCARBOXAMIDE ADENOSINE. Aran, S. and Proudfit, H.K. Dept. of Pharmacology, Univ. of Illinois at Chicago, Chicago, IL 60680.

Recently, we have demonstrated that intrathecal injection of norepinephrine (NE) and 5'-N- ethylcarboxamide adenosine (NECA), an adenosine analog, interact synergistically to produce antinociception. The present studies were undertaken to determine whether the release of endogenous NE produced by electrical stimulation of neurons in the nucleus raphe magnus (NRM) also interacts synergistically with intrathecally-injected NECA.

Male Sprague Dawley derived rats (350-400 gm) were implanted with an intrathecal catheter and a bipolar stimulating electrode. The tip of the stimulating electrode was located near the dorsal margin of the NRM. One week after surgery baseline nociception was determined using the tail flick test. After determination of baseline tail flick latencies (TFLs), a stimulus-response curve was generated for electrical stimulation of the NRM (square wave pulses: 100 usec, 50, 100, and 150 uA, 60 Hz) applied for 60 sec. NRM stimulation produced statistically significant increases in TFLs using current intensities of 100 and 150 uA. Animals were then given an intrathecal injection of a subeffective dose of NECA (0.3ug/15ul). TFLs were determined again 30 and 60 min after drug injection and stimulus-response curves were constructed at both time points. This dose of NECA, in the absence of prior NRM stimulation, did not produce any significant changes in TFLs (separate control group). However, TFLs were increased significantly by NECA when it was injected after NRM stimulation. Although NRM stimulation produced significant antinociception before the injection of NECA, such stimulation failed to further increase TFLs above the elevated TFL values observed after the injection of NECA.

To determine whether NE was involved in producing the antinociception observed following NECA and NRM stimulation the alpha-noradrenergic antagonist phentolamine (PHE) was injected intrathecally. The elevated baseline TFL produced by NECA, which was observed following NRM stimulation, was reversed by PHE.

These data suggest that endogenous NE, released in the spinal cord by electrical stimulation of NRM neurons, potentiates the antinociceptive effects of the adenosine agonist NECA. (This work was supported by USPHS Grant DA 03980).

84.22 EVIDENCE FOR THE CHOLINERGIC MEDIATION OF THE ANTINOCICEPTION INDUCED BY ELECTRICAL STIMULATION OF THE PEDUNCULOPONTINE TEGMENTAL NUCLEUS IN RATS. M.A. McCartney and H.K. Proudfit. Dept of Pharmacology, University of Illinois at Chicago, Chicago, IL 60612.

The nucleus raphe magnus (NRM) and adjacent magnocellular reticular formation have been shown to mediate antinociception. Raphe spinal neurons in the NRM appear to be activated by cholinergic neurons since injection of the cholinergic agonist carbachol into the NRM produces antinociception which can be reversed by the cholinergic muscarinic antagonist atropine. There is also anatomical and electrophysiological evidence for a cholinergic projection to the NRM region from the pedunculopontine tegmental nucleus (PPTg)/ nucleus cuneiformis area. The purpose of our studies was to provide behavioral evidence that the cholinergic projection from the PPTg to the NRM mediates antinociception.

Bipolar stimulating electrodes were implanted into the PPTg area of male Sprague Dawley-derived rats. Guide cannulas for subsequent microinjections were placed in the area of the NRM in a separate group of animals. Upon recovery, baseline nociception was measured using the tail flick test. The PPTg area was stimulated (60 Hz, 25-250 uA, 100 uS square wave pulses) and tail flick response latencies were obtained, both during and 60 sec after the 60 sec period of stimulation. Atropine sulfate was injected, either subcutaneously (1 mg/kg) or directly into the NRM (5 ug in 0.5 ul saline) to determine whether the stimulation-induced antinociception was mediated by cholinergic receptors. Electrical stimulation and testing were repeated after the injection of atropine.

A significant increase in tail flick latency (309%) was observed during the 60 sec stimulation and return to baseline values occurred within 60 sec after the cessation of stimulation. This hypoalgesia was reversed by systemic atropine administration. Atropine administration alone had no effect on baseline tail flick latencies. In addition, preliminary studies indicate that microinjection of atropine into the NRM also reversed the stimulation-induced antinociception.

These studies provide evidence for a cholinergic projection from the PPTg to the NRM that mediates antinociception in rats. This work was supported by USPHS Grant DA 03980.

COMPARATIVE NEUROANATOMY: AMPHIBIANS, REPTILES AND BIRDS

85.1 IMMUNOREACTIVITY OF SOMATOSTATIN, SEROTONIN, SUBSTANCE P, AND ENKEPHALIN IN THE MESENCEPHALON OF RANA PIPIENS. DS Adli, WLR Cruce, and RH Ho. Neurobiology Program, Northeastern Ohio Universities College of Medicine, Rootstown, OH 44272 and Department of Anatomy, Ohio State University, Columbus, OH 43210.

Contrasting results regarding the localization of somatostatin (SOM), serotonin (5HT), substance P (SP), and enkephalin (ENK) in the frog CNS have been reported. To investigate this matter, we used the PAP method of Sternberger to localize these neurochemicals in adjacent sections obtained from the mesencephalon of a Ranid frog. Its mesencephalon is made up of (i) the optic tectum, dorsally, (ii) the tegmentum, ventrally, and (iii) the torus semicircularis, in between the two former structures.

Adult northern leopard frogs were fixed by perfusion with Zamboni's solution. Coronal and horizontal sections were cut at a thickness of 30-50 um on a vibratome. The sections were then processed for the localization of somatostatin like (SLI), substance P like (SPLI), serotonin like (5HTLI), and enkephalin like (ELI) immunoreactivities. As controls, adjacent sections were incubated in specific preabsorbed primary antibody serum.

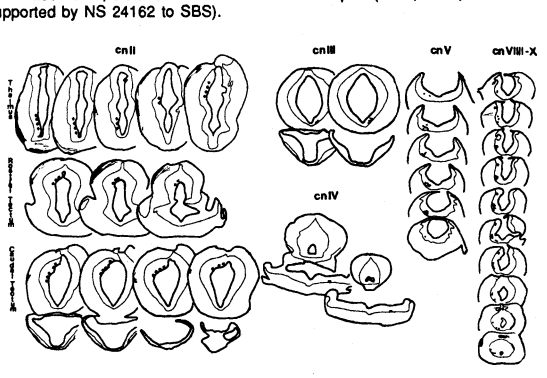
Each neurochemical has a laminar distribution pattern in the optic tectum. Immunoreactivities for all four can be found not only in the region dorsal to layer 6, but also in layers 5 and 3. An intense ELI is seen as a layer close to the dorsal surface. Positively stained cell bodies in layer 6 (ENK, 5HT, and SOM cells) and in layer 4 (SOM cells) have processes projecting towards the dorsal surface of the tectum. In the torus semicircularis where SPLI, 5HTLI, and ELI are present, we only detect SP stained cells.

In the tegmentum, the entire gray (encompassing all four of Potter's fields) is rich with immunoreactivities to ENK, SP, 5HT, and SOM. The densest SPLI in the gray area is in the periventricular region. Cells in the anterodorsal field (AD) and nucleus profundus mesencephali are heavily labelled with ENK containing terminals. ENK cells are found in the anteroventral field (AV) and the ventral posteroventral field (PVV). Within this tegemental region, the ventromedial AV and the dorsolateral part of PV contained SOM cells, as did the dorsal part of nucleus interpeduncularis (NIP). NIP, itself, is rich with 5HTLI, SPLI, and SLI. 5HTLI and SPLI are also present in nucleus isthmi (NI), with the cell plate of NI being heavily labelled for 5HT. Other heavily labelled 5HT cells are located in the dorsal raphe and laterally in the stratum album. Some lightly labelled 5HT cells are also observed medial to red nucleus.

Supported in part by grants from the Stark County United Way, the Ohio Board of Regents, and the National Institutes of Health.
We thank Dr. Elde for the 5HT and ENK antibodies.

85.2 CRANIAL NERVE NUCLEI OF THE SALAMANDER *NOTOPTHALMUS (TRITURUS) VIRIDESCENS*. M.C. Anderson*, B.M. Davis and S.B. Simpson, Jr. (SPON: W. L. Muhlach).Biological Sciences, Univ. of Illinois at Chicago, Chicago, Il,60680

Regeneration of the salamander spinal cord has been studied for over a hundred years because of all adult (i.e. post-developmental) vertebrates, salamander shows the most robust recovery following major spinal lesions. Despite its long history as a model for regeneration we still do not know the source of regenerated spinal axons and neurons. Recently our laboratory has begun examining these issues to provide a foundation for future experiments at the cellular and molecular level. Our first experiments examined the regenerated bulbospinal projection to the lumbar spinal cord following a complete thoracic transection. While significant regeneration of bulbospinal axons was seen (in some case > 50%), it was difficult to identify the various regions of the salamander brain which were participating in the regeneration process. Unlike other vertebrates the salamander brain contains no discrete nuclei or identifiable landmarks. All somata lie in layers next to the brain ventricles with no apparent organization. The cells are surrounded by white matter which varies in thickness. Since no brain atlases exist, HRP was used to backfill cranial nerves. In this way cranial nerve motor nuclei and sensory terminations were identified as a first step in providing an atlas for the salamander brain. These results show that despite the lack of apparent organization the cranial motor nuclei are present in discrete groups. The overall pattern of cranial sensory and motor input suggests that *triturus* contains nuclei homologous to other vertebrates brain nuclei. CN=cranial nerve, __ = HRP filled somata, __ = putative sensory terminals, fine lines = HRP filled fibers, distance between sections =100µm. (MCA, BMD, SBS supported by NS 24162 to SBS).



85.3 MUSCULOTOPIC ORGANIZATION OF THE HYPOGLOSSAL NUCLEUS IN THE GRASS FROG (Rana pipiens). A. Sokoloff, Biological Anthropology, Harvard University, Cambridge, MA 02138.

Recent tracer studies in the rat and cat have demonstrated that specific tongue muscles are innervated by discrete groups of neurons in the hypoglossal nucleus (HGN). Neurons innervating the styloglossus and hyoglossus muscles are located in dorsal or dorsolateral HGN regions, neurons innervating the genioglossus muscle are located in ventral HGN regions, and neurons innervating the geniohyoid muscle are located in a cell column lying ventral to the main body of the HGN. The tongue of the grass frog differs structurally and functionally from the tongue of mammals. To determine the extent of musculotopy in the ranid HGN and to provide a comparative basis for understanding evolutionary changes in HGN organization, the innervation of tongue musculature in the grass frog was investigated.

Discrete injections of the retrograde tracer WGA-HRP were made into tongue and geniohyoid muscles of twenty six frogs. Tongue, brainstem and cervical spinal cord were removed, sectioned and processed for peroxidase with tetramethyl benzidine. Injections into the hyoglossus muscle label neurons in dorsal HGN regions. Labeled neurons are present from caudal HGN levels to the rostral pole of the HGN but are not observed in the caudal pole of the HGN. Injections into the genioglossus basalis muscle label neurons in ventral and lateral nucleus regions at caudal and middle HGN levels. Injections into the genioglossus medialis muscle label neurons in dorsal regions at caudal levels, throughout the nucleus at middle HGN levels, and in ventral regions at rostral HGN levels but do not label neurons in the rostral pole of the HGN. Injections into the geniohyoid muscle label neurons in a column lying ventral to the main body of the HGN. Neurons labeled with geniohyoid injections are present from middle to rostral nucleus levels.

These results demonstrate that the musculotopic organization of the HGN of Rana pipiens is similar to the general pattern of HGN organization described for mammals. Such similarity suggests the possibility that the spatial organization of HGN motoneurons has been conserved in evolution. In light of the structural and functional differences in the tongues of ranids and mammals, conservation of HGN organization suggests that evolutionary divergence of tongue function might be due more to alterations in the muscular architecture of the tongue than to changes in the pattern of HGN organization.

85.4 FMRFamide-IMMUNOREACTIVE NEURONS IN THE TERMINAL NERVE AND BRAIN OF AMPHIBIANS EXHIBIT SEASONAL DIFFERENCES. L.E. Muske and F.L. Morre. Zoology Department, Oregon State Univ., Corvallis, OR 97331

The terminal nerve (TN), a ganglionated nerve associated with the olfactory system, is present in most vertebrate classes. Neurons immunoreactive (ir) to gonadotropin-releasing hormone (LHRH) have been identified in the TN of teleosts, elasmobranchs, mammals and amphibians. Immunoreactivity to the molluscan tetrapeptide FMRFamide and to other neuroactive substances has been found in the TN of fishes, but except for LHRH-ir, there is no immunocytochemical information on the TN in other taxa. We used immunocytochemical techniques and a variety of antibodies to examine the brains and olfactory systems of three representative amphibians. Immunoreactivity was visualized using avidin/biotin immunoperoxidase (Vector Labs) or immunofluorescent techniques.

In the tree frog Hyla regilla, antisera to FMRFamide (Dockray LI35, Bishop/O'Donohue 231) labeled TN fibers throughout distal olfactory and vomeronasal nerves, and TN fibers and perikarya extending from the proximal olfactory nerves to the anterior commissure. The distribution of FMRFamide-ir closely resembles that of LHRH. Double labeling studies indicate, however, that FMRFamide- and LHRH-ir TN neurons comprise separate populations. In Rana pipiens, a few FMRFamide-ir fibers, possibly belonging to the TN, were found in the olfactory nerve. FMRFamide-ir was never found in the olfactory system or TN of the urodele Taricha granulosa.

Immunoreactivity to Substance P (SP), pancreatic polypeptides and tyrosine hydroxylase (TH) has been identified in the TN of fishes. Antisera to these substances (SP: Immunonuclear Corp.; NPY: Polak 1101, Terenius 102B; TH: Tank/Weiner 16) produced labeling in the brain, but not in the TN of amphibians.

In all three species, anti-FMRFamide also labeled periventricular cell bodies in the caudal preoptic area (POA) and dense fiber network throughout the brain. In Hyla and Taricha, FMRFamide-ir neurons exhibited differential staining associated with the seasonal cycle: Staining in the POA was more intense, and more TN neurons were visualized in breeding, compared with non-breeding individuals. The presence of FMRFamide-ir in the TN, a structure that has been implicated in reproductive behaivor, and the seasonally-related differences in FMRFamide-ir label in amphibians, suggest a possible role for this substance in reproduction or related behaviors.

85.5 ASCENDING PROJECTIONS OF THE TORUS SEMICIRCULARIS IN RANID FROGS. T. J. Neary. Anatomy Dept., Creighton University, Omaha, NE 68178.

Wheat germ agglutinin-horseradish peroxidase conjugate (WGA-HRP) was applied into the midbrain auditory center (torus semicircularis) of bullfrogs (Rana catesbeiana) under tricaine anesthesia. The frogs survived 4 days and WGA-HRP was visualized using tetramethyl benzidine. After WGA-HRP applications in the medial or auditory torus, labelled ascending fibers were followed ipsilaterally in two bundles, one passing through the hilus of the torus ("hilar pathway") and the other coursing just medial to the ventral optic tract ("ventrolateral (VL) pathway"). Fibers continuously left the hilar pathway laterally to course through and apparently terminate in tectal laminae 3 and 5. Several of these fibers passed through the tectum to enter and terminate in the pretoral grey. The hilar pathway ended in a periventricular system of fibers running in the cell-free zone between the dorsal and ventral thalamus. The VL pathway ascended through the mesencephalon and eventually joined the lateral forebrain bundle (LFB). Fibers from the VL pathway contributed to light terminal fields in the following thalamic nuclei: posterior, ventromedial (VM), ventrolateral (ventral part, VLv) and anterior. They also formed a light terminal field laterally adjacent to the posterior nucleus and possibly another in the posteroventral part of the lateral nucleus. VL pathway fibers terminated heavily in the ventromedial third to one-half of the central thalamic nucleus and moderately in the rest of the central nucleus and anterior division of the lateral nucleus (La). A few toral fibers continued with the LFB to enter the striatum, while a few others left the LFB to join the medial forebrain bundle and enter the caudal septum. Contralateral toral projections were observed to the anterior and central nuclei, and La in the thalamus, and to the pretoral grey, optic tectum, and opposite torus in the midbrain.

All applications in the lateral, somatosensory torus have, so far, spread into the optic tectum. The pattern of projections seen in these cases was similar to that described for medial toral applications with the following major differences: 1) projections to the neuropil adjacent to La, the nucleus of Bellonci, the corpus geniculatum, and the lateral pretectum were present and these can be attributed to tectal involvement (Scalia, 1976); 2) projections to the medial part of the central nucleus were reduced; 3) projections to VM and VLv were increased. This last difference is notable in view of the presumed somatosensory projection to VM and VLv from the obex region (Neary and Wilczynski, 1977) for it suggests a possible convergence of somatosensory information from the obex and midbrain upon these two ventral thalamic nuclei.

85.6 MORPHOLOGICAL AND IMMUNOCYTOCHEMICAL EVIDENCE FOR A RETINOPETAL PROJECTION IN ANURAN AMPHIBIANS (RANA CATESBIANA AND XENOPUS LAEVIS). H. Uchiyama*, T.A. Reh° and W.K. Stell, Dept. Anat. and Lions' Sight Centre, and °Dept. Med. Physiol., Univ. Calgary, Calgary, Alberta, Canada T2N 4N1

Retinopetal neurons (neurons efferent from the brain to retina) have been shown in most vertebrates by means of modern neuroanatomical tract tracing methods. However, in anuran amphibians, their existence is controversial. Although some researchers have suggested their presence by physiological data, Scalia and Teitelbaum (1978) denied it in frogs and toads judging from failure of brain neurons to label retrogradely after intraocular HRP injection. In this study, we describe centrifugal fibers from the brain to the retina and tentatively identify the cells of origin by means of immunocytochemical and HRP tracing methods.

Both tadpoles and adults of Rana catesbiana and Xenopus laevis were used. For immunocytochemistry, we used three antisera; anti-FMRFamide (Fa) (O'Donohue 231), anti-LHRH (Sherwood GF4) and anti-substance P (SP)(INC lot 8352022). This SP antiserum has been shown to recognize N-terminal sequence around amino acid (3-7) of SP after preabsorption with SP fragment (7-11) (Stell et al., 1987). The pattern of immunoreactivity with this preabsobed antiserum was almost identical with that of Fa in this study.

We observed identical patterns of Fa-immunoreactive (ir) fibers in the optic nerve and retina in both Rana and Xenopus adults and tadpoles. In the retina, these fibers run in the optic nerve fiber layer, pass through the ganglion cell layer and inner plexiform layer (IPL), run in the junctional layer between the IPL and inner nuclear layer (INL), and terminate at the innermost sublayer of the INL. We found inconsistently a few weakly Fa-ir amacrine cells, which were not stained with the anti-SP serum, in contrast to the Fa-ir fibers. We observed no LHRH-ir fibers in the retina or optic nerve of either tadpoles or adults. Near the entrance to the brain the Fa-ir fibers in the optic nerve make a tight bundle which can be traced rostrally in the ipsilateral preoptic area to the septo-preoptic junctional area. Seven days after optic nerve crush, the Fa-ir fibers disappeared, distal but not proximal to the crush. Fa-ir perikarya were distributed similarly in both Rana and Xenopus brain. They were seen in (a) diagonal band of Brocha, (b) median septal nucleus (MSN), (c) bed nucleus of anterior commissure (bnAC) of Hoffman, (d) anterior preoptic area, and (e) caudal portion of periventricular preoptic nucleus (cPPN). In adults, the distribution pattern of LHRH-ir perikarya overlapped with that of Fa-ir perikarya in most nuclei. However, large bipolar or multipolar neurons in bnAC and granular neurons in cPPN, like the fibers in the retina and optic nerve, were immunoreactive for Fa and SP(3-7), but not LHRH.

These immunocytochemical data may suggest that neurons in bnAC are the origin of Fa-ir centrifugal fibers to the retina. We were not able to label these neurons (or any others) retrogradely by injecting markers intraocularly. But by HRP injection into the septum and anterior preoptic area of adult Rana, we labeled fibers that run caudally in the preoptic area and enter the ipsilateral optic nerve. This may confirm the Fa-ir retinopetal pathway suggested by the immunocytochemical data.

85.7 COEXISTENCE OF SUBSTANCE P WITH LEU-ENKEPHALIN OR CALCITONIN GENE - RELATED PEPTIDE IMMUNOREACTIVITIES IN THE AMPHIBIAN CNS.

A. Fasolo, D. Taverna, B. Mulatero, § L. Gribaudo (SPON: European Neuroscience Association)
Dipartimento di Biologia Animale. Lab. Anatomia Comparata. Via Giolitti, 34 - 10123 Torino (Italy).
§ C.S.I.-Piemonte. C.so Unione Sovietica, 216 - 10136 Torino (Italy)

Co-localization studies for neuroactive substances were undertaken as a new tool for comparative analysis of the vertebrate CNS.

Employing symultaneous double immunofluorescence staining (for primary antibodies raised in different species), the distribution of Substance P (SP) immunoreactivity (IR) was compared with other reaction patterns for neuropeptides (in particular for Leu-Enkephalin - Leu-Enk - and Calcitonin Gene-Related Peptide - CGRP -) in the untreated CNS of two representatives of Amphibia (Triturus cristatus, Urodela; Rana esculenta, Anura).

Leu-Enk-IR appeared co-distributed with SP-IR in several areas of the amphibian brain and in particular in the dorsal and tuberal hypothalamus, preoptic area, striatum, rhomboencephalon. Moreover, the coexistence of the two immunoreactivities was observed in some fibres and neurons in the preoptic area, tuberal and dorsal hypothalamus. CGRP-IR was co-localized with SP-IR in the primary sensory afferent fibres of the spinal cord and of some cranial nerves. In the outer zone of the neurohypophysial median eminence and in the posterior hypothalamus (frog), CGRP-IR and SP-IR appeared co-distributed, but not coexisting.

Computer graphic representation and semiquantitative evaluation of coexistence were performed by interactive image analysis.

85.8 THE ACCESSORY OPTIC SYSTEM IN A LIZARD.

Neil M. Montgomery, Robin Mergendalh and Rebecca Minard*
Psychology Department, Univ. of Mass., Amherst, Mass. 01003.

The accessory optic system of Anolis carolinensis was investigated using both HRP histochemistry and the Golgi technique. The afferents to accessory optic nucleus of the basal optic root (nBOR) were determined by the retrograde transport of HRP from the nucleus. The retinal afferents to nBOR consisted of large diameter axons up to 3um in diameter. Other afferents included the ventrolateral portion of the corpus striatum, the anterior portions of the corpus geniculatum lateralis ventralis and in the pretectal region the nucleus lentiformis mesencephali and the nucleus geniculatum pretectalis. The efferent projections of nBOR were to the contralateral nBOR, the nucleus lentiformis mesencephali as well as bilateral projections to the oculomotor nuclei, the nucleus interstitialis, the cerebellar cortex and the inferior olivary nucleus.

The cells in nBOR were extremely variable in size and shape. Cell counts through the nucleus indicate an average of 2400 cells in nBOR. Of these cells 35% were confirmed as neurons by HRP histochemistry. The remaining population appear to be glia or interneurons. Retrograde labelling indicated that the largest neurons 10-20um in diameter and the medium elongated neurons 10 by 5um contributed the the projections to the cerebellum, inferior olivary nucleus and commissural connections. The cells projecting to the oculomotor and interstitial nuclei were all of the elongate type. The dendritic fields of nBOR neurons were small and restricted to the nucleus. The large neurons often had dendrites no more then 20um in length.

Comparing the present results with our earlier analysis of the nucleus of the basal optic root in Rana pipiens we find an increase in the number of cells and the diversity of cell types. The nBOR of lizard also shows smaller dendritic fields then that frogs. The connectivity of the two systems is remarkably similar. The major differences appear to be the connections with the striatum and cerebellum in Anolis. Finally, in Rana pipiens the oculomotor neurons send dendrites directly into nBOR. In Anolis, the oculomotor neurons dendritic field is smaller (like that of nBOR neurons) and does not enter nBOR.

85.9 MIDBRAIN AND SPINAL PROJECTING NEURONS OF REPTILIAN DORSAL COLUMN NUCLEUS.

M.B. Pritz and M.E. Stritzel*. Div. Neurol. Surg., Univ. of California Irvine Medical Center, Orange, CA 92668.

Reptiles, like mammals, possess a prominent dorsal column nucleus (DCN). In mammals, the DCN is a heterogenous area in terms of its input, output, and intrinsic organization. In Caiman crocodilus, the only non-mammalian amniote in whom the neural circuitry of the dorsal column system has been investigated from periphery to the telencephalon, the DCN projects to three main targets: the spinal cord, the cerebellum, and the midbrain somatosensory recipient area. We investigated the relay cell populations in the DCN of Caiman that project to two of these regions: the spinal cord and the midbrain somatosensory recipient area.

The origin of spinal cord projecting DCN neurons was determined by application of horseradish peroxidase (HRP) crystals to cut fibers after myelotomy in 7 animals undergoing a 1 to 3 level cervical laminectomy. The source of midbrain projecting DCN cells was investigated by HRP injections into the midbrain somatosensory recipient area by a transtectal approach in 11 animals. In each experiment, tissue was processed by standard neurohistochemical techniques using tetramethylbenzidine as the chromogen.

Retrogradely labeled DCN neurons observed after spinal injections were located ipsilaterally in the posterior one-half of the DCN, immediately ventral to the main body of the DCN, as determined by the latter's input from the dorsal funiculus. In favorable preparations apical dendrites were visualized extending into the main DCN in close relationship with incoming dorsal funicular axons. On the other hand, retrogradely labeled DCN cells observed after HRP injections of the midbrain somatosensory recipient area were located contralaterally in the posterior one-half of the main body of the DCN. Favorable retrograde DCN labeling demonstrated a variety of cell shapes and dendritic morphology. No DCN cells in the rostral half of the nucleus were observed after either spinal or midbrain injections.

The results of these 2 experiments suggest that DCN relay cells that project to the spinal cord and midbrain somatosensory recipient area originate from separate neuronal populations. Furthermore, the locus of these 2 separate DCN relay cell populations in Caiman are similar in location to spinal and mesencephalic projecting DCN cells in cat. These latter findings coupled with previous studies on the neural circuitry of ascending somatosensory systems in Caiman suggest that not only are these somatosensory neuronal circuits and nuclear groups phylogenetically ancient, but that individual relay cell populations within the DCN have arisen early in evolution.

85.10 QUANTITATIVE REGIONAL VARIATIONS OF NEUROTRANSMITTER MARKERS IN AMNIOTE TELENCEPHALON.

A. Contestabile* and R. Bissoli*(SPON: European Neuroscience Association). Biol. Dept.,Bologna Univ.,Italy.

Neurotransmitter histochemistry has been used in comparative neurology to establish identity or diversity among presumedly homologous brain areas. Following the concept of chemical neuroanatomy,we have undertaken a study on the levels of neurotransmitter markers in telencephalic regions of turtle,pigeon and rat. Brain samples were microdissected from fresh telencephalic slices and the levels of cholinergic,GABAergic and excitatory amino acidic markers were assayed. Independently from the expected variability in absolute levels of neurotransmitter markers in the different species,some common patterns could be noticed. In basal telencephalon,highest GABAergic levels were measured in the paleostriatum followed by the nucleus accumbens and neostriatum;cholinergic activity was highest in the neostriatum,the difference with the paleostriatum being small in turtle and pigeon and large in rat;the medial septum-diagonal band complex consistently showed higher cholinergic and GABAergic levels than the lateral septum;high affinity D-3H aspartate uptake was higher in the neostriatum than in the paleostriatum,the difference increasing enormously in rat. Among cortical and cortical-equivalent areas,D-3H aspartate uptake was higher than in basal telencephalon with the exception of the rat neostriatum;the dorsal ventricular ridge (DVR) of turtle and pigeon showed uptake levels close to those of cortical structures;GABAergic activity was 20-40% of the level in the paleostriatum. Cholinergic activity in cortical and cortical-equivalent areas showed a large variability:it was 11-17% of the neostriatal value in turtle cortices,19% in the rat neocortex,26% in the rat archicortex and 47% in the paleocortex,30% in the avian Wulst,51-55% in the turtle DVR and from 3 to 30% in different areas of the pigeon DVR. The variability in the relative levels of neurotransmitter markers may reflect modifications of neuronal connectivity and/or intrinsic neuronal populations. For instance,the dramatic increase of uptake in the mammalian neostriatum is likely due to the massive glutamatergic input from the neocortex; on the other hand the increased difference between cholinergic levels in the neo and paleostriatum may be related to the increase of cholinergic interneurons in mammalian neostriatum,possibly associated with loss of cholinergic neurons (either intrinsic or extrinsic in the paleostriatum. Ultimately,these evolutionary patterns may result from plastic brain responses to different selective pressure.

85.11 COMPARATIVE ASPECTS OF THE TELENCEPHALIC CORTEX IN LIZARDS: PUTATIVE HOMOLOGIES WITH THE MAMMALIAN HIPPOCAMPUS.
W.K. Schwerdtfeger, M.J. Lorente* and F. Martinez-Garcia*.Citologia e Histologia, Facultad de Ciencias Biologicas, E-46100 Burjasot/ Valencia (Spain).

The cerebral cortex of lizards consists of medial, dorsomedial, dorsal and lateral areas, comprising layers 1 (molecular layer), 2 (principal cell layer), and 3 (polymorphous cell layer).Main cortical afferents are from the septum, thalamus, mamillary bodies and raphe nuclei; the lateral cortex is reached by a projection from the olfactory bulb. The raphe projection is serotonergic and terminates mainly in layers 1 and 3. Cortical efferents course to the septum, thalamus and nucleus accumbens striati. Intracortical fibers pass from the lateral, dorsal and dorsomedial fields to the medial area, which in turn projects to the dorsomedial and dorsal cortices. The latter pathway is characterized by the high content of zinc in its preterminal boutons. Cells in the dorsomedial area and in the adjacent part of the dorsal cortex send fibers to layer 1 of the contralateral medial and dorsomedial areas. Nearly all cells in layers 1 and 3 are non-pyramidal and contain the inhibitory neurotransmitter gamma-aminobutyric acid (GABA). Some GABA-positive neurons are found also in layer 2. GABA-immunoreactive presynaptic boutons make symmetric synaptic contacts mainly with the somata and apical dendrites of the principal cells in layer 2.

Together with earlier published data on the cytoarchitecture, cytology and histochemistry of the cerebral cortex of lizards, our results on the cortical lamination, distribution of cell types and patterns of extrinsic and intrinsic fiber connections coincide surprisingly well with the corresponding data that have been reported for the hippocampal formation of the mammalian brain, and support earlier suggestions that areas of the telencephalic cortex may be homologous to areas of the hippocampal formation.

In detail, we find similarities between: the lateral cortex of lizards, and the entorhinal cortex of mammals; the medial cortex of lizards, and the area dentata of mammals; the dorsomedial cortex plus adjacent parts of the dorsal cortex, and the Ammon's horn of mammals.

85.12 AN IMMUNOCYTOCHEMICAL STUDY OF THE OPTIC TECTUM IN RATTLESNAKE.
P.H.Hartline and K.S.Rockland. Eye Reseach Inst. of the Retina Foundation, 20 Staniford St., Boston, MA 02114.

The optic tectum in the rattlesnake serves as the principal neural structure for integrating information from visual and infrared modalities. Its layered architecture, the substrate for multisensory integration, has been described, but mainly with conventional cell and fiber stains. With such stains, the tectum is subdivided into SO (stratum opticum: 50-75um thick), SFGSa,b,c (stratum fibrosum et griseum superficiale: 150-200um), SGC (stratum griseum centrale: 100-150um), and SAC (stratum album centrale: 400-500um). Recording sites yielding visual responses predominate in SO and SFGS; those yielding multisensory responses are concentrated in SGC, and those yielding infrared responses predominate in SAC.

We reexamined tectal organization for evidence of further subdivisions, using histochemical and immunoperoxidase techniques. We found immunoreactivity for several substances, in a pattern corresponding only approximately with classical Nissl-based lamination. GAD (glutamic acid decarboxylase) and AChE (acetylcholinesterase) reactivity are concentrated in 3 bands occupying the 250-350 um immediately below the SO: a band dense for GAD and light for AChE, one moderate for GAD and dense for AChE (this includes GAD reactive horizontal processes and small cell bodies), and one moderate for AChE and light for GAD. These 3 bands, exhibiting some complementarity between AChE and GAD, lie within the 4 cytoarchitectonic subdivisions of SFGS and SGC. The central band (dense AChE, moderate GAD) occurs near the border of SFGS and SGC, and also exhibits immunoreactivity that is weak for L-Enk (leu-enkephalin), moderate for neuropeptide Y (NPY), dense for 5-HT (serotonin), and dense for substance P. Substance P-like reactivity extends further into SFGS and SGC than do 5-HT, L-Enk, and NPY. In SAC, our results indicate a different, more diffuse organization. This zone is traversed by varicose fibers showing immunoreactivity for 5-HT, substance P, L-Enk, met-enkephalin, and (weakly) neuropeptide Y, as well as reactivity for AChE. None of these show obvious sublaminar segregation.

In addition to its layered chemoarchitecture, the SFGS/SGC border region exhibits some tangential zonal organization, which is most evident in AChE material. Concentrations of AChE occur in discontinuous islands 50-100um across (ca. 100um center-to-center). Thus, the middle layers (lower SFGS and upper SGC, corresponding to multisensory responses) show significant chemical diversification. Unlike species such as pigeon or frog, however, the rattlesnake seems to have only a modest degree of segregation of different peptide/neurotransmitter candidates in SFGS and SGC; most of those screened to date are compressed into a 100-150um wide zone that straddles the SFGS/SGC border. (supported by NSF BNS 8015839)

85.13 SUPRASPINAL CONNECTIONS OF A NECK MOTOR NUCLEUS (SSp) IN THE PIGEON.
J.J.A. Arends and R.W. Allan*. West Laboratory, American Museum of Natural History, NY 10024, and Biopsychology Program, Hunter College, CUNY, NY 10021.

The pigeon's collimotor system mediates both the control of head stabilization and the transport of a prehensile effector organ: the beak. We have identified supraspinal connections of neurons in the most rostral (C-1) extension of the neck motor column, the nucleus supraspinalis (SSp), following WGA-HRP injections covering this area.

Retrogradely labeled cells were observed (**1**) in various parts of the vestibular nuclei, (**2**) in the abducens nucleus and the medial reticular formation medially and ventrally adjoining this nucleus, (**3**) in the pre-/perihypoglossal region and (**4**) in the interstitial nucleus of Cajal. Vestibular nuclei containing clusters of retrogradely labeled cells included (**i**) the main (lateral) part of the tangential nucleus and the entire dorsolateral nucleus (VDL) contralaterally, (**ii**) the rostral part of the descending nucleus and the adjacent part of the medial nucleus (VeD/VeM: the "accessory" region) bilaterally, and (**iii**) the rostromedial part of the superior nucleus (VeS: group "A" of Wold) ipsilaterally. Scattered labeled cells were found in the lateral aspects of VeS and in the more caudal portions of VeD.

The distribution of anterogradely transported label observed after WGA-HRP injections into these putative premotor regions suggests that the vestibular region is the major source of axosomatic projections upon SSp. With the exception of the (lateral) tangential nucleus (the avian interstitial nucleus of the vestibular nerve), all vestibulomotor clusters projecting to SSp receive direct cerebellar corticovestibular projections (Arends, *Soc. Neurosci. Abs.*,1985; **11**: 692). With the exception of VDL, these vestibular regions also project to the midbrain oculomotor complex, presumably by way of collaterals. The remaining corticovestibular target nuclei —the infracerebellar nucleus and the medial part of the tangential nucleus— project exclusively upon the oculomotor complex and do not contribute afferents to SSp.

Although no retrogradely labeled neurons were observed among the giant cells of the lateral vestibular nucleus (VeL) following HRP injections covering SSp, collateral projections upon SSp were seen to emerge from ipsilateral lateral vestibulospinal tract (LVST) fibers after WGA-HRP injections involving VDL, VeL and extending into the subjacent border region of VeS, VeD and VeM. This finding indicates that some of the ipsilaterally projecting vestibulocollic neurons do so by way of the LVST rather than via the MVST, which contains the bulk of the vestibulospinal fibers from areas other than VeL.

The limited caudal extent (C1-2) of the bulk of direct vestibulocollic connections other than those originating in VeL (Cabot et al., *Progr. Brain Res.*,1982, **57**: 79-108 [pigeon]; Gross & Oppenheim, *J.comp.Neurol.*,1985, **232**: 162-179 [chicken]), taken together with their collateral projections upon the oculomotor system, suggest that SSp plays a major role in head stabilization subserving gaze control.

Supported by Grants BNS 85-07374, MH-08366 and NRSA # NS 07465.

85.14 STEREOTAXIC MAPPING OF VISUAL AND MONOAMINERGIC PATHWAYS IN THE HOUSE SPARROW BRAIN.
Vincent M. Cassone. Department of Neurology, State University of New York, Stony Brook, NY 11794-8121

The distribution of primary visual pathways, indoleaminergic and catecholaminergic cells and fibers were studied within the framework of a stereotaxic analysis of the house sparrow (Passer domesticus) brain. Adult sparrows (3 males, 3 females) were anaesthetized and received intraocular injections of 5 ug cholera toxin conjugated with horseradish peroxidase (CTHRP) in 5 ul 1% DMSO. After 48 hrs, sparrows were anaesthetized again and placed in a stereotaxic instrument while a series of bilateral needle tracks were placed in the brain. Sparrows were then perfused transcardially with a modified Zamboni's fixative. Brains were processed for CTHRP histochemistry, and immunohistochemistry localization of serotonin (5HT-LI) and tyrosine hydroxylase (TH-LI)cells and fibers.

Major visual projections were observed in the visual suprachiasmatic nucleus (vSCN),nucleus lateralis anterior (LA), ventral lateral geniculate (GLv) and the dorsolateral nuclei (DL) in the diencephalon, and in the mesencephalic lentiform nucleus (LM), ectomammilary nucleus (EM) and optic tectum (Te) in the mesencephalon. Large numbers of small retrogradely labeled cells were also observed in the isthmooptic nucleus (IO).

Diencephalic 5HT-LI cells were observed in the organum periventricularum (PVO), but most cells were observed in mesencephalic and metencephalic nuclei, primarily in the nucleus centralis superior (CS), tegmentum ventralis (TV), and nucleus annularis (NA). Scattered cells were observed in area ventralis (AVT), tegmentum pedunculopontis(TPc) and the substantia griseum centralis (GCT). Dense fiber distributions were observed throughout the telencephalon with the conspicuous exception of nucleus basalis (B). In the diencephalon, fibers were widely distributed but concentrated in the organum vasculosum lamina terminalis (OVLT), vSCN, nucleus paraventricularum magnocellularis (PVM), GLv and median eminence (ME). Fibers were also present in several layers of the Te.

TH-LI cells were widely distributed in the telencephalic lateral septal nuclei (LS), diencephalic preoptic area (PA), lateral hypothalamic area (LH), periventricular preoptic nucleus (PPM), posteriomedial nucleus (PMH) and nucleus tuberis (NT). Mesencephalic TH-LI cells could be divided into a dorsal tegmental group and a ventral tegmental group. The dorsal group included the GCT and locus coeruleus (LC). The ventral tegmental group was more extensive with cells in the AVT, TPc, nucleus pontis reticularis (RPO) and nucleus pontis lateralis (PL). Major TH-LI fiber distributions included the lo bus paraolfactorius (LPO), septum, paleostriatum, OVLT, PVM, PPM, ME and cerebellum.

These data will be analyzed and compared to existing immunohistochemical analyses of dopamine-B-hydroxylase and phenylethanolamine N-methyltransferase distributions. Supported by NSF 85-19660

85.15 EFFERENT PROJECTIONS OF THE PARABRACHIAL NUCLEI IN THE PIGEON. J.M. Wild, J.J.A. Arends and H.P.Zeigler. Department of Anatomy, University of Auckland, Auckland, New Zealand, and Biopsychology Program, Hunter College, New York City, N.Y., U.S.A.

The avian central viscerosensory system comprises the nucleus of the solitary tract (nTS) and a variety of brainstem, diencephalic and basal telencephalic nuclear targets of nTS, in particular the parabrachial nuclear complex (PB) of the dorsolateral pons (Wild, J.M. et al., Soc. Neurosci. Abstr., 11:1309, 1985). In order to determine the subsequent projections of PB, injections of either wheatgerm-agglutinin conjugated horseradish peroxidase (WGA-HRP) or tritiated amino acids were made into PB and surrounding regions and the projections charted following conventional histochemistry or autoradiography. Caudal to PB an extensive terminal field was observed throughout the medullary parvocellular reticular formation (Rpc) and the dorsal part of the central nucleus (Cnd) including the region of the nucleus ambiguus. A particularly dense and localized terminal field occupied the whole extent of the hypoglossal nucleus (Wild, J.M. and Arends, J.J.A., Brain Res., 407:191, 1987) but projections to nTS and DMN X were inconspicuous. Rostral to PB terminal fields were observed within many (but not all) of the adjacent coerulean nuclei (Kitt, C.A. and Brauth, S.E., J. comp. Neurol., 247:69, 1986)eg strata cellulare externus and internus (SCE, SCI) of the hypothalamus, dorsal thalamus, "ventral paleostriatum" (VP) and nucleus accumbens (Ac), and archistriatum (A). WGA-HRP injections into these and other regions of the forebrain and brainstem retrogradely labelled PB neurons and suggested the following pattern of projections from PB subnuclei: The ventrolateral PB subnucleus provides the major descending projection to the ventrolateral medulla and exclusively to nXII. The dorsolateral, dorsal and medial subnuclei largely project rostrally to SCI, SCE and rostral PVM of the hypothalamus, various dorsal thalamic nuclei, VP, Ac, the nucleus of the anterior pallial commissure (nCPa), and A. Since VP, Ac and nCPa also receive projections from nTS, and since VP also projects to PB and nTS, these three nuclei may form part of the bird's "visceral forebrain". In particular, some components of VP seem more appropriately comparable with the bed nucleus of the stria terminalis of mammals. In summary, the avian PB, like its mammalian counterpart, is a major center for the integration and distribution of visceral, and possibly gustatory, information.

PRESYNAPTIC MECHANISMS I

86.1 EVIDENCE THAT ACETYLCHOLINE RELEASE IS MEDIATED BY A PRESYNAPTIC MEMBRANE PROTEIN. Morel N, Israel M.*, Manaranche R.* and Lesbats B.*
Dept Neurochimie, lab. NBCM, CNRS, 91190 Gif/Yvette, France.

A protein (the mediatophore) which mediates the calcium dependent release of acetylcholine from proteoliposomes has been purified from the presynaptic plasma membrane. Removal of associated lipids inactivated the protein which became water soluble ; this permitted to evaluate its Stokes radius (53 A), its sedimentation coefficient (9.8 S) and hence an approximate molecular weight of 210 KDa. Electrophoretic methods showed that the protein is made of 17 KDa subunits, not linked by disulfide bonds. When observed after negative staining, it has an average diameter of 8 nm and seems pentameric (Israel et al, 1986, PNAS 83, 9226).

Proteoliposomes equipped with purified mediatophore showed a calcium dependent activation and a calcium dependent "fatigue" of ACh release similar to that of synaptosomes (Israel et al, 1987, J.Neurochem.in press).

The drug Cetiedil which inhibits acetylcholine release from intact tissue and synaptosomes by acting after the calcium entry step, was able to block with the same Ki the release mediated by the purified mediatophore (Morot-Gaudry Talarmain Y. et al, 1987, J. Neurochem., in press).

An antibody to the purified protein was raised in rabbits. By indirect immunofluorescence, it stained nerve terminals at motor end plates in Torpedo and rat.

86.2 **CONCENTRATIONS OF SYNAPTIC VESICLES AND CALMODULIN IN PRESYNAPTIC NERVE TERMINALS OF ELECTRIC RAY ELECTRIC ORGAN.** G. P. Miljanich and T. I. Prigozy*. Dept. of Biological Sciences, Univ. of Southern California, Los Angeles, CA 90089.

For both in vitro reconstitution and detailed modeling of various presynaptic functions, it is necessary to determine the relative and molar concentrations of the requisite presynaptic components. Toward that end, the molar concentrations of synaptic vesicles and the calcium-binding regulatory protein, calmodulin, have been determined in electric organ nerve terminals.

Two previously characterized monoclonal antibodies, which bind specifically to epitopes on two different integral proteins in the synaptic vesicle membrane (Carlson and Kelly, 1983; Buckley and Kelly, 1985), were used to assay the vesicle content of immunopurified electric organ synaptosomes (Miljanich, Brasier, and Kelly, 1982). With highly purified electric organ synaptic vesicles serving as a standard, synaptic vesicle protein was found to represent 19.4 $\pm$ 2.5% of the total nerve terminal protein. Scanning densitometry of electrophoretically separated nerve terminal proteins was employed to determine the calmodulin content of this nerve terminal preparation. Using affinity purified electric organ calmodulin as a standard, and measuring the integrated difference between densitometric scans of electrophoretograms run in the presence and in the absence of calcium, calmodulin was found to represent 7.1 $\pm$ 0.9% of the total nerve terminal protein. Applying the known protein particle weight of synaptic vesicles and the molecular weight of calmodulin in conjunction with the percentages of total synaptosomal protein for the two components, the molar ratio of calmodulin to synaptic vesicles was calculated to be approximately 90 to 1. This ratio includes an indeterminant number of vesicle membrane "equivalents" which are incorporated in the presynaptic plasma membrane and which are also detected by the anti-synaptic vesicle antibodies.

Morphometric analysis of micrographs of intact electric organ revealed that at least 11% of the total volume of nerve terminals is synaptic vesicle volume. Assuming that immunopurified synaptosomes are representative of intact nerve terminals, and using the above volume percentage in conjunction with the known volume of synaptic vesicles, the effective concentration of synaptic vesicles in electric organ nerve terminals was estimated to be at least 0.5uM. With this concentration and the calmodulin:vesicle molar ratio (and assuming that the fraction of vesicle membrane equivalents inserted into the presynaptic plasma membrane is negligible), the average concentration of calmodulin in the terminal is roughly 45uM.

Supported by NIH grant NS20138 to GPM.

86.3 SYNAPTOPHYSIN-CONTAINING VESICLES FROM RAT BRAIN AND PC 12 CELLS: A COMPARISON. H. Rehm*, B. Wiedenmann*, and C.-M. Becker* (SPON: W. Huttner). ZMBH and Department of internal medicine, University of Heidelberg, FRG.

Synaptophysin was initially discovered as a major Ca^2 - binding membrane protein of synaptic vesicles from brain (Wiedenmann, B., and Franke, W. Cell,. 41:1017, 1985; Jahn et al. PNAS, 82:4137-4141, 1985; Rehm et al. EMBO Journal, 5:535-541, 1986). Subsequently synaptophysin containing vesicles were also found in endocrine organs like the islets of Langerhans and the adrenal medulla or in tumors derived from these organs like the PC 12 cell line (Wiedenmann et al. PNAS, 83:3500, 1986; Navone et al. J. Cell Biol., 103:2511-1527, 1986)

The function of synaptophysin is unknown. The PC 12 cell line could be used for experiments designed to address this question. We therefore investigated whether the synaptophysin containing vesicles from brain and PC 12 cells are of similar type. To facilitate this analysis we have developed a simple dot immunoassay which allows a quick, specific and sensitive determination of synaptophysin. Synaptophysin containing vesicles from brain and PC 12 cells were compared by physical methods like density gradient centrifugation on Percoll and size exclusion chromatography on Sephacryl S-500 and controlled pore glass columns. For further analysis an immunoprecipitation method was established which allowed a preliminary investigation of the protein composition of these vesicles.

This work was supported by the Deutsche Forschungsgemeinschaft (SFB 317) and the Bundesministerium für Forschung und Technologie (BCT 381-5).

86.4 PRODUCTION OF PROTEIN III-SPECIFIC ANTIBODIES. M.D. Browning and P. Greengard. Laboratory of Molecular and Cellular Neuroscience, The Rockefeller University. New York, N.Y. 10021.

Acid extracts of all rat brain regions contain four prominent phosphoproteins: synapsin Ia (M_r 85,000), synapsin Ib (M_r 80,000), protein IIIa (M_r 74,000) and protein IIIb (M_r 55,000). We have previously shown that these four proteins possess significant strutural homology and that all four proteins appear to be co-localized to presynaptic terminals where they are associated with synaptic vesicles. However, previous studies of proteins IIIa and IIIb (collectively referred to as protein III) were hampered by the fact that all polyclonal antibodies raised against protein III exhibited significant cross-reactivity towards synapsin I. In an effort to obtain protein III-specific antibodies, we raised monoclonal antibodies against protein IIIb which had been purified by preparative SDS-PAGE. In some cases, protein III was proteolysed and the synapsin I-like fragments were removed by immunoprecipitaion with synapsin I antibodies and the remaining fragments were conjugated to thyroglobulin for immunization. We have been successful in obtaining a collection of monoclonal antibodies which exhibit a high degree of specificity for protein III in Western blots. One antibody (CII.21) has been utilized to develop a radioimmunoassay (RIA) for protein III that is sensitive to as few as 10 fmol of protein III. In this assay, synapsin I exhibits less than 1% cross-reactivity. We have used this assay in conjunction with an RIA specific for synapsin I to determine the amounts of synapsin I and protein III in various brain regions. In all brain regions examined, except for the olfactory bulb, the molar ratio of synapsin I to protein III was approximately 2:1. However in the peripheral nervous system, the concentration of protein III was higher than that of synapsin I. For example, in the superior cervical ganglion, the molar ratio of synapsin I to protein III was approximately 1:4. We have also succeeded in using antibody CII.21 to affinity purifiy protein III with a 50-fold greater yield than had been obtained with previously used procedures.

86.5 STIMULATION-DEPENDENT PHOSPHORYLATION OF TYROSINE HYDROXYLASE IN RAT CORPUS STRIATAL SYNAPTOSOMES. J.W. Haycock. Department of Biochemistry, Louisiana State University Medical Center, New Orleans, LA 70119.

Stimulation of intact peripheral noradrenergic and adrenergic tissues produces an increase in tyrosine hydroxylase phosphorylation, an activation of tyrosine hydroxylase, and an acceleration of catecholamine biosynthesis. In vitro, several protein kinases can phosphorylate and activate tyrosine hydroxylase purified from pheochromocytoma. Such observations have led to the hypothesis that the phosphorylation of tyrosine hydroxylase underlies the stimulation-dependent regulation of catecholamine biosynthesis. Although tyrosine hydroxylase purified from rat corpus striatum can be phosphorylated and activated by at least one protein kinase, evidence for the phosphorylation of tyrosine hydroxylase in intact brain and/or dopaminergic systems has been lacking. The present studies demonstrate that (1.) tyrosine hydroxylase is phosphorylated in dopaminergic nerve terminals from rat corpus striatum and (2.) agents which increase dopamine release and dopamine biosynthesis also increase the phosphorylation of tyrosine hydroxylase.

In the present studies, rat corpus striatal tissue was dissected and homogenized in sucrose. Synaptosomes were prepared by standard centrifugation techniques, and the synaptosomal preparation was preincubated with $^{32}PO_4$. Aliquots of the synaptosomal preparation were treated with secretagogues (elevated K+, veratridine, A23187), and the tissue was then solubilized with sodium dodecyl sulfate (SDS). Tyrosine hydroxylase was immunoprecipitated with an antibody which recognizes denatured tyrosine hydroxylase, and the immunoprecipitates were subjected to SDS-PAGE and autoradiography.

^{32}P was incorporated into tyrosine hydroxylase in a time-dependent manner, and each of the secretagogues increased the phosphorylation of tyrosine hydroxylase. Unlike systems such as adrenal chromaffin cells, PC12 cells or superior cervical ganglia, synaptosomes present no cell body associated tyrosine hydroxylase. As such, these data indicate that stimulation-dependent regulatory processes exist in brain dopaminergic nerve terminals to alter the phosphorylation state of tyrosine hydroxylase. Furthermore, these data raise the possibility that brain and/or dopaminergic tyrosine hydroxylase is regulated by processes similar to those previously described for peripheral adrenergic/noradrenergic systems. Studies comparing the site-specificity of tyrosine hydroxylase phosphorylation in striatal synaptosomes and adrenal chromaffin cells are currently being undertaken.

86.6 A SUBTYPE OF NEURONAL PROTEIN KINASE C ACTIVITY WITH UNIQUE SUBSTRATE SPECIFICITY. Phillip J. Robinson, C. K. Black* and W. Lovenberg*. Merrell Dow Research Institute, 2110 E. Galbraith Rd., Cincinnati, OH 45215.

Protein kinase C (PKC) is the Ca^{++} - activated, and phospholipid-dependent protein kinase found in high concentrations in brain. PKC is further stimulated by diacylglycerol (DAG), which increases its affinity for Ca^{++} and phospholipids. In addition, PKC can be activated by tumor-promoting phorbol esters, such as phorbol-12-myristate-13 acetate (PMA), which compete for the same binding site. Recently multiple forms of PKC have been recognised, and although it appears likely, it has not previously been demonstrated that these enzymes possess different substrate specificities. To address this question we have examined the effects of activators and inhibitors of PKC on the phosphorylation of endogenous substrates in rat brain. A cytosolic fraction from rat cortical synaptosomes was the source of both PKC and endogenous substrates. The proteins were labelled by incubation for 60 sec in the presence of [γ-^{32}P]ATP, 30mM tris/HCl pH 7.4, 1mM Mg^{++}, 1mM EGTA, 1mg/ml protein and the activators of specific protein kinases. Phosphoproteins were detected by polyacrylamide gel electrophoresis and autoradiography. In the presence of Ca^{++} and phosphatidyl- serine (Ca^{++}/PS) the phosphorylation of a number of specific proteins was stimulated, notably a 96,000 dalton protein termed P96 and another known substrate for PKC, termed P83. Neither phosphoprotein was phosphorylated by cAMP- or calmodulin-dependent protein kinase. However, in the presence of Ca^{++}, PMA stimulated the phosphorylation of P83, but not of P96, suggesting a limited substrate specificity for PMA-stimulated PKC. PMA activation also occurred in the absence of Ca^{++} (1mM EGTA). These distinct PKC activities were termed PKC1 (for PMA-stimulated) and PKC2 (for Ca^{++}/PS-stimulated) and could be further distinguished with two PKC inhibitors, sphingosine (SPH) and palmitoylcarnitine (PC). SPH more selectively inhibited PKC1 activity towards P83 (IC_{50} 26μM) than PKC2 activity towards P96 (IC_{50} 270μM). In contrast, PC was more selective towards PKC2 labelling of P96 (IC_{50} 96μM) than PKC1 labelling of P83 (IC_{50} 530μM). This is consistent with the known ability of SPH to compete for the phorbol ester binding site and of PC to compete with phospholipid for binding to PKC. Although these data do not yet prove that PKC1 and PKC2 represent distinct isoenzymes of PKC, they show that different activators and inhibitors of PKC can modulate two distinct substrate specificities of the enzyme. We propose that the multiple effects of phorbol esters in intact cells may be mediated only through a single form of PKC activity.

86.7 INHIBITION OF VOLTAGE-GATED K CHANNELS IN SYNAPTOSOMES BY sn-1,2-DIOCTANOYLGLYCEROL, AN ACTIVATOR OF PROTEIN KINASE C. K.A. Colby* and M.P. Blaustein, Department of Physiology, University of Maryland School of Medicine, Baltimore, MD. 21201

The effects of sn-1,2-dioctanoylglycerol (diC8), an analogue of diacylglycerol which activates calcium/phospholipid-dependent protein kinase (C kinase), were tested on K channel function in rat brain synaptosomes. At least four distinct classes of K channels can be measured in synaptosomes with ^{86}Rb efflux techniques (Bartschat & Blaustein, 1985, J. Physiol. 361:419). One type of channel maintains resting K conductance. There are three voltage-regulated K channels: A voltage-gated, rapidly inactivating channel; a voltage-gated, non-inactivating channel; and a calcium-gated channel. Incubation of synaptosomes prepared from rat hippocampus with diC8 does not affect resting K conductance. However, diC8 dramatically inhibits ^{86}Rb efflux stimulated by depolarizing concentrations of K^+ (see Table). This effect is due to inhibition of efflux through voltage-gated K channels (ΔK). DiC8 does not affect ^{86}Rb efflux through calcium-gated K channels (ΔCa). Time course experiments suggest that diC8 partially inhibits a rapidly inactivating K channel which may correspond to the "A" channel, and markedly inhibits a non-inactivating, voltage-gated K channel which may correspond to the delayed rectifier. The increase in neurotransmitter release which accompanies activation of C kinase (e.g. Malenka et al., 1987, Brain Res. 403:198) may result from inhibition of these voltage-gated K channels. (Supported by NIH grant NS-16106).

TABLE I. Inhibition of ^{86}Rb Efflux from Synaptosomes by DiC8

Hippocampal synaptosomes were preloaded with ^{86}Rb and incubated with 100 μM diC8 for 6 min. ^{86}Rb efflux was measured for 5 sec. as previously described. Resting efflux is the Rb efflux under nondepolarizing conditions (5 mM K) The K-stimulated efflux (ΔK) equals efflux into 50 mM K minus resting efflux. Ca-dependent efflux (ΔCa) is that which occurs into 50 mM K + 1 mM Ca, minus the efflux into 50 mM K alone. The means of 4 replicate measurements (±SE) from one experiment are shown. Similar results were obtained in two other experiments.

Efflux Component	^{86}Rb efflux/5 sec (% of Total ^{86}Rb Content)	Percent Inhibition
Resting efflux	10.84 ± 0.15	-
K-stimulated (ΔK)	11.66 ± 0.91	-
Δ K + diC8	6.26 ± 1.16	46%
Ca-dependent (ΔCa)	4.30 ± 1.38	-
Δ Ca + diC8	4.40 ± 1.17	0

86.8 MODULATION OF SPONTANEOUS SYNAPTIC CURRENTS IN CULTURED HIPPOCAMPAL NEURONS BY PHORBOL ESTERS AND BAY K 8644. D.M. Finch and M.B. Jackson. Departments of Neurology and Biology and Brain Research Institute, University of California, Los Angeles, CA 90024.

We performed patch clamp recordings in the whole cell mode from cultured embryonic mouse hippocampal neurons. The cells (in TTX-containing bath) showed spontaneous inward currents, with a rise time of 1-2 msec, decay time of 5-10 msec, and an amplitude that varied from just greater than the noise level (1-2 pA) to more than 40 pA. Recordings under current clamp showed that these currents corresponded to spontaneous depolarizations of up to several mV. The frequency of the spontaneous currents was usually less than 0.1/sec. The currents were blocked by bathing the cells in 1 mM of the glutamate receptor antagonist gamma-D-Glutamylglycine. Therefore, the source of the currents is thought to reflect spontaneous release of excitatory, glutamatergic transmitter substance by terminals contacting the cells from which recordings were obtained. Spontaneous outward currents (possibly due to spontaneous release of inhibitory transmitter substance) were seen only rarely, and were not blocked by gamma-D-Glutamylglycine. The frequency of the spontaneous inward currents was increased in high potassium bath (16 mM), but did not obviously depend upon holding potential. Incubating cells in tetanus toxin, which has been shown to block synaptic transmission, decreased or blocked the currents. These observations provided more evidence that the currents reflected activity of presynaptic terminals.

Application of micromolar concentrations of phorbol ester 12,13 dibutyrate (PDB, a protein kinase C activator) increased the frequency of the spontaneous inward currents. The latency of this effect varied from a few seconds to a few minutes. Local application (via puffer pipets) or bath application were both effective. The increase in the rate of the spontaneous currents was only slowly reversible after removal of PDB. Application of vehicle alone (0.1% DMSO) had no consistent effect. Local application of the calcium channel agonist BAY K 8644 also increased the frequency of the spontaneous inward currents, in about one third of the cells, indicating a modulating or mediating role for calcium. However, the currents were not abolished by bathing the cells in a solution containing 0 mM calcium, 5 mM EGTA (to chelate residual calcium), and 2 mM cobalt (to block external calcium channels). This suggests that internal release of calcium, perhaps from mitochondria or endoplasmic reticulum, may trigger these events.

Supported by NIH Grant NS 21908.

86.9 α-LATROTOXIN RAISES CYTOPLASMIC IONIZED CALCIUM IN XENOPUS OOCYTES INJECTED WITH RAT BRAIN mRNA. J.A. Umbach, A. Grasso, and C.B. Gundersen. Department of Pharmacology, UCLA School of Medicine, Los Angeles, CA 90024 and Institute of Cell Biology, Rome, Italy.

When Xenopus oocytes are injected with poly(A)$^+$mRNA from rat brain, they express a variety of receptors, channels and transport proteins in their plasma membranes. We hypothesized that this expression system might be of value toward further characterizing the binding site on nerve cell membranes for the polypeptide neurotoxin, α-latrotoxin. This spider venom toxin binds with high affinity and considerable specificity to an acceptor protein associated with the nerve endings of a wide variety of vertebrates and invertebrates. Within 7d of injecting Xenopus oocytes with 30-50ng of rat brain mRNA (isolated by chloroform-phenol extraction and oligo dT cellulose chromatography), two-electrode voltage clamp revealed the appearance of oscillatory chloride currents evoked by the bath application of α-latrotoxin (10-25nM). This chloride conductance appeared to be identical to the conductance activated by application of serotonin, glutamate or acetylcholine to these cells. Previous work has indicated that this chloride channel is activated by a rise of cytoplasmic ionized calcium. We used calcium-selective microelectrodes to confirm that α-latrotoxin (10-20nM) produced a significant change (from a resting level of 60-100nM to values above 700nM) of oocyte ionized calcium. (These measurements also showed that the chloride channels of the oocyte membrance were activated when cytoplasmic ionized calcium reached 650nM.) The α-latrotoxin effect was largely dependent on external calcium and was not reversed by washing. By contrast, the toxin had no effect on cytoplasmic calcium (or membrane currents) of uninjected oocytes or on oocytes injected with non-neuronal preparations of mRNA (eg., rat muscle). Moreover, if oocytes that had been injected with rat brain mRNA were pretreated with concanavalin A (5ug/ml), a lectin that is known to block α-latrotoxin action in other systems, no membrane currents were detected upon toxin application (up to 40nM α-latrotoxin). These results indicated that Xenopus oocytes can be induced to express on their surface the effector site for a highly selective presynaptic neurotoxin.

Supported by a contract from the ARO (DAMG29-85-K0113) and by a grant from the CNR.

86.10 ANESTHETICS ALTER INTRACELLULAR IONIZED CALCIUM CONCENTRATIONS IN SYNAPTOSOMES. L.C. Daniell and R.A. Harris. Dept. of Pharmacology, V.A. Med. Ctr. and Alcohol Res. Ctr., Univ. of Colorado Health Sci. Ctr., Denver, CO. 80262.

Previous work from this laboratory showed that ethanol (350-700 mM) increases resting intracellular ionized calcium concentrations (Ca_i) in mouse whole brain synaptosomes. Studies have also shown that various anesthetic agents enhance calcium-dependent potassium conductances and reduce calcium currents in neurons, indicating that calcium-dependent mechanisms are altered by anesthetics in neuronal tissue.

The effects of anesthetic agents selected from various chemical classes (n-alkanols, halothane, diethylether and pentobarbital) on Ca_i were assessed in synaptosomes isolated from mouse whole brains. Fura-2, a fluorescent calcium indicator, was used to quantitate Ca_i. Fura-2-loaded synaptosomes were incubated with drugs at 35°C in low calcium buffer containing approximately 70 uM calcium for 10 min prior to measurement of Ca_i. Measurements were corrected for autofluorescence and leak of Fura-2 from synaptosomes.

Resting Ca_i was approximately 280 nM following incubation of synaptosomes for 10 min. Resting Ca_i was significantly increased by n-alkanols (butanol, pentanol and hexanol), halothane (3-6 mM) and diethylether (100 mM). In contrast, pentobarbital (0.01-1 mM) did not alter resting Ca_i. Depolarization of synaptosomes by the addition of KCl (final concentration, 50 mM) significantly increased Ca_i by approximately 60 nM and this value of Ca_i was further increased by prior incubation with n-alkanols (pentanol and hexanol) or halothane. Pentobarbital (0.01-1 mM) and diethylether (10-50 mM) reduced KCl-stimulated values of Ca_i. Subtraction of resting Ca_i from KCl-stimulated values of Ca_i showed that KCl-stimulated increases in Ca_i were reduced by n-alkanols, pentobarbital and diethylether but unchanged by halothane.

These results show that anesthetics differentially alter Ca_i in brain tissue. These effects of anesthetics may have important consequences for neurotransmission, ion channel regulation and other calcium-dependent processes in brain tissue. Supported by the VA and AA06399 and AA03527.

86.11 EFFECTS OF ACUTE THALLIUM ADMINISTRATION ON TRANSMITTER RELEASE AND Ca INFLUX. W.D. Atchison, J. Thornburg, U. Joshi* and A.C. Barton, Dept. Pharmacol./Toxicol., Neuroscience Program and Center for Environ. Toxicol., Michigan State Univ., E. Lansing, MI 48824.

Thallium (Tl^+) like its neighboring elements in the periodic chart, Pb and Hg, is neurotoxic. However, while the effects of the inorganic divalent cations on synaptic transmission are well known, the effects of the monovalent Tl^+ are unknown. The goal of this project was to determine whether Tl^+ causes suppression of evoked release and stimulation of spontaneous release of transmitter as do inorganic divalent cations such as Pb or Hg. Effects of acute administration of micromolar concentrations of Tl^+ on synaptic transmission were measured electrophysiologically at the neuromuscular junction of the rat and neurochemically as determinations of ^{45}Ca influx in K^+-depolarized forebrain synaptosomes from the rat. Neurochemical studies of $^{45}Ca^{2+}$ influx into forebrain synaptosomes depolarized with elevated $[K^+]$ were used to determine if the Tl^+-induced suppression of synaptic transmission was related to diminished entry of Ca^{2+} into the axon terminal following depolarization. After a latent period, Tl^+ gradually reduced the amplitude of nerve-evoked endplate potentials (EPPs) and occasionally blocked them completely. The depressant effects of Tl^+ were more pronounced as the concentration was increased. When total block of the EPP occurred, it could usually be reversed by washing the preparation with Tl^+-free solutions. Tl^+-induced block of the EPP was sometimes preceded by a brief period during which EPP amplitude was increased. Block of the EPP was due at least in part to prejunctional effects of Tl^+, as mean quantal content was reduced in Tl^+-poisoned preparations. Tl^+ caused a biphasic effect on miniature endplate potential (MEPP) amplitude; initially mean MEPP amplitude was increased by Tl^+, but subsequently MEPP amplitude also declined. Decreased MEPP amplitude was not caused by depolarization of the postjunctional muscle membrane by Tl^+, because endplate membrane potential was not altered by exposure to Tl^+ for periods of up to 90 min. The frequency of occurrence of MEPPs was increased by Tl^+. This effect was not blocked by increasing the Mg^{2+} concentration nor by increasing the K^+ concentration. Studies of $^{45}Ca^{2+}$ influx into isolated synaptosomes depolarized by K^+ indicated that Tl^+ did not suppress depolarization-dependent uptake of Ca^{2+} into the nerve terminal; total uptake of $^{45}Ca^{2+}$ during 10 sec of depolarization was not reduced by Tl^+, nor was either the "fast" nor "slow" component of uptake reduced. Results of the present study suggest that acute application of Tl^+ suppresses synaptic transmission by both presynaptic and postsynaptic mechanisms, but the presynaptic component probably is not related to block of Ca^{2+} entry into the axon terminal. (Supported by BRSG funds from the College of Veterinary Medicine and by NIH grant ES03299. Dr. Joshi was supported by funds from the Center for Environmental Toxicology.)

86.12 THE PATTERN OF DEPOLARIZATION-INDUCED CHANGES IN INTRASYNAPTOSOMAL FREE Ca^{++} MEASURED WITH FURA-2 CORRESPONDS TO THE PATTERN OF ACETYLCHOLINE RELEASE INDUCED BY KCl BUT NOT VERATRIDINE. Kenneth A. Stauderman*, Paul Lundy*#, Phillip J. Robinson*, Walter Lovenberg*. (SPON: David J. Jones) Merrell Dow Research Institute, 2110 E. Galbraith Rd., Cincinnati, OH 45215, # Defense Research Establishment Suffield, Ralston, Alberta, Canada.

Recent advances in both the techniques for preparing synaptosomes and the instrumentation for measuring fluorescence changes of the Ca^{++} sensitive dye fura-2 have improved the speed and quality of measurements of intracellular free Ca^{++} ($[Ca^{++}]_i$) in purified synaptosomes. In parallel with a continuous chemiluminescent assay for acetylcholine (ACh) release, (Israel and Lebats, J. Neurochem, 39: 248-250, 1982) we compared at pH 7.4 the time course of depolarization-induced ACh release with depolarization-induced changes in $[Ca^{++}]_i$, using rat striatal synaptosomes loaded with fura-2. Purified synaptosomes, prepared using a percoll-gradient, were loaded with 5μM fura-2/AM by a modification of the procedure by Ashley et al. (Biochem. J, 219: 149-158, 1984). Fluorescence was measured by a dual-excitation spectrophotometer (Deltascan I, Photon Technology Int.) with excitation alternating between 340 and 380 nm thirty times a second. The fluorescence ratios (340/380) thus obtained were used to calculate the absolute $[Ca^{++}]_i$ which was expressed in nM concentrations ± SEM. Striatal synaptosomes had a resting $[Ca^{++}]_i$ of 137 ± 9.4 nM. Depolarization with 40 mM KCl produced two responses: a rapid increase in $[Ca^{++}]_i$ that peaked at 416 ± 21 nM within 3 seconds of the onset, followed by a gradual decline in $[Ca^{++}]_i$ until a new steady-state was reached at about 260 nM. Both responses were dependent on extracellular Ca^{++}. On the other hand, depolarization with 1μM veratridine caused only a slow rise in $[Ca^{++}]_i$ that equilibrated at 430 nM 2 minutes after application. Similar to the $[Ca^{++}]_i$ response, 40 mM KCl-induced ACh release consisted of two phases: a fast phase that peaked at 1-3 seconds, and a slow phase that peaked at 60 seconds. Both phases were dependent on extracellular Ca^{++}. Surprisingly, this pattern of ACh release was also observed in response to veratridine. Thus, KCl and veratridine produce similar patterns of ACh release, but only the KCl response corresponds to the observed changes in $[Ca^{++}]_i$. These results indicate there is not always a direct relationship between average $[Ca^{++}]_i$ (measured with fura-2) and ACh release.

86.13 EFFECTS OF BACITRACIN ON IN VITRO 3H-SEROTONIN RELEASE AND CALCIUM-45 UPTAKE IN RAT HYPOTHALAMUS. M. S. Saporito and R. O. Warwick.* Dept. of Pharmacology and Toxicology, Philadelphia College of Pharmacy and Science, Philadelphia, PA. 19104.

Serotonin (5-HT) release from nerve terminals is a calcium (Ca) dependent event which is regulated by a presynaptic autoreceptor (5-HT1b). This autoreceptor regulates voltage dependent Ca channels which couple Ca influx with 5-HT release (Gothert, N-S Arch. Pharmacol. 314:223, 1980). The peptide antibiotic bacitracin (BCN) is used as a peptidase inhibitor in radioligand binding assays. We have incorporated BCN into superfusion experiments designed to study peptide effects on 5-HT release in vitro. Since BCN also decreases binding affinity of 5-HT for 5-HT1 receptors in the rat hippocampus (Rostene et al., J. Neurosci. 3:2414, 1983) and can chelate Ca, it may alter calcium associated events such as 5-HT release and autoreceptor function.

In this study we assessed the ability of BCN to modify 5-HT release and autoreceptor activity in rat hypothalamic (HYP) slices. Additionally, we examined the effects of BCN on 3H-5-HT and 45Ca uptake in a crude synaptosomal fraction (P2) prepared from rat HYP. Superfused rat HYP slices preloaded with 3H-5-HT were stimulated with two 6 min periods of 25 mM K+. Stimulated release was calculated as the ratio of peak 2 to peak 1 (S2/S1). BCN (2 ug/ml) and/or 5-methoxytryptamine (5-MEOT; 1 uM) were included in the superfusion buffer for the second stimulation period.

Control S2/S1 ratios were 0.80 ± 0.05. 5-MEOT decreased the S2/S1 ratio by 20%. BCN had no effect alone, but enhanced 5-MEOT activity by 25%.

Stimulated 45Ca uptake was assessed by the method of Leslie et al. (Brain Res. 325:99, 1985). Following a 12 min preincubation period, synaptosomes were depolarized with 30 mM K+ for 3 sec in the presence of 60 uM Ca45. Uptake of Ca45 in nondepolarizing buffer (5 mM K+) was subtracted to yield stimulated uptake.

Control stimulated uptake was 576 ± 60 pmoles/mg protein which was significantly ($p < 0.05$) decreased by 55% with BCN (2 ug/ml). BCN had no effect on nonstimulated uptake. Uptake of 3H-5-HT (50 nM) by P2 fraction of rat HYP was not altered by 2 ug/ml BCN.

These data suggest that BCN enhances autoreceptor activity by blocking voltage operated Ca2+ channels involved in coupling Ca influx with 5-HT release.

86.14 [^{3}H]GABA RELEASE FROM STRIATAL SLICES CAN OCCUR VIA CALCIUM-INSENSITIVE, REVERSE TRANSPORT. Sandor Bernath* and Michael J. Zigmond, Dept. of Behavioral Neuroscience and Center for Neuroscience, University of Pittsburgh, Pittsburgh, PA 15260

The role of Ca^{2+} in mediating transmitter release is generally well established. However, its involvement in the release of GABA is controversial. To examine this issue, slices (350 um) were prepared from rat striatum, preincubated with [^{3}H]GABA (0.1 uM) in the presence of ß-alanine (1 mM), an inhibitor of GABA uptake into glia, and then superfused at 37°C with Krebs buffer containing aminooxyacetic acid (0.1 mM), an inhibitor of GABA transaminase. Total tritium efflux was used as an index of GABA release. Electrical stimulation (2 Hz, 20 mA, 3.0 msec pulse, 360 shocks) elevated resting release approximately 2-fold. Reducing external Ca^{2+} failed to abolish stimulus- induced tritium overflow, although the precise impact of altering Ca^{2+} was a function of external Ca^{2+} concentration and the period of superfusion. Thus, if external Ca^{2+} was lowered to 0.1 mM twenty min prior to depolarization, tritium overflow occurred at 49% of the control rate, while if Ca^{2+} was omitted and 1 mM EGTA added, tritium overflow occurred at or slightly above the control rate. Moreover, if slices were exposed at a Ca^{2+}-free medium plus EGTA throughout a 70-min period of superfusion overflow increased 3-fold. Reducing Ca^{2+} increased spontaneous tritium efflux under all conditions. Tetrodotoxin (5 uM) abolished the overflow of tritium during depolarization in both normal and Ca^{2+}-free conditions. Nipecotic acid (0.1 to 1mM), an inhibitor of neuronal and glial GABA uptake, enhanced both the spontaneous efflux and evoked overflow of tritium from control slices, indicating the important role of GABA uptake in removing GABA from extracellular fluid. Nipecotic acid also increased spontaneous release when external Ca^{2+} was reduced or totally removed. However, under these conditions the electrically-evoked overflow was greatly reduced. In contrast, adding ß-alanine (1 mM) to the superfusion medium increased basal efflux and depolarization-induced overflow under all conditions. These results suggest that the electrically-evoked release of [^{3}H]GABA from striatal slices is of neuronal origin and depends on voltage-dependent sodium channels, but can occur in the absence of Ca^{2+}. They further suggest that Ca^{2+}-independent release depends on the high affinity GABA transport system in nerve terminals. (Supported in part by USPHS grant NS19608. S.B. is on leave from the Institute of Experimental Medicine, Hungarian Academy of Science, Budapest, Hungary.)

86.15 CALCIUM-DEPENDENT POTENTIALS IN LIZARD MOTOR NERVE TERMINALS. E.F. Barrett and K. Morita*. Dept. of Physiology & Biophysics, Univ. of Miami Med. Sch., P.O. Box 016430, Miami, Fla. 33101.

A microelectrode was inserted into motor axons innervating the ceratomandibularis muscle of lizards (Anolis sagrei), within 1 mm of the motor terminals. Preparations were pretreated for 1 hour in 10 mM tetraethylammonium (TEA) to increase the duration of the action potential and the resting input resistance of the axon. Action potentials were evoked by stimulating the nerve trunk via a suction electrode; muscle contractions were blocked with 30-60 μM carbachol or by cutting the muscle fibers. In physiological saline containing 2 mM Ca, 2 mM Mg and 10 mM TEA, action potentials recorded near the motor terminals were followed by this sequence of afterpotentials: (1) a depolarizing plateau (D1) with an amplitude of about 30 mV, terminated after about 40 msec by a rapid partial repolarization, (2) a smaller depolarization (D2) that decayed over a time course of several hundred msec, and (3) a hyperpolarization of about 5 mV that decayed over a time course of seconds. These afterpotentials were not seen in axons separated from their terminals. These terminal-specific afterpotentials disappeared when the preparation was perfused with low [Ca]-high [Mg] solutions or with 1 mM Ni or Mn, and were enhanced when bath [Ca] was increased. The duration of D1 increased following addition of 1 mM 4-aminopyridine or 1 mM Ba, or after [TEA] was increased to 25 mM. The D1 plateau potential thus appears to be due to calcium influx into the motor terminals. The slow hyperpolarizing afterpotential was increased by K-free solutions or 1 mM caffeine; it was reduced when bath Ca was replaced by 2 mM Ba, but was not abolished by ouabain. Thus the slow hyperpolarizing afterpotential appears to be mediated by a Ca-sensitive K efflux. The configuration of these terminal-specific afterpotentials changed during repetitive stimulation, in a manner that varied with bath [Ca]. For example, an increase in stimulus frequency from 0.1 to 1 Hz transiently increased D1 duration in 1 mM Ca, but reduced D1 duration in 4-6 mM Ca. These results suggest that changes in Ca entry during successive action potentials may contribute to the changes in evoked transmitter release observed during repetitive stimulation. Supported by NIH grants NS 12404 and GM 30377.

86.16 ADRENERGIC EFFECTS ON CALCIUM-DEPENDENT POTENTIALS IN LIZARD MOTOR NERVE TERMINALS. K. Morita* and E.F. Barrett (SPON: R. Keane). Dept. of Physiology & Biophysics, Univ. of Miami Med. Sch., P.O. Box 016430, Miami, Fla. 33101.

We applied adrenergic agonists and antagonists to the lizard ceratomandibularis nerve-muscle preparation, and used an intra-axonal microelectrode to record the calcium-dependent afterpotentials originating in the motor nerve terminals (recording techniques described in preceding abstract, Barrett & Morita, 1987). All preparations were bathed in 10 mM TEA, plus 30-60 μM carbachol to prevent muscle contraction. Action potentials evoked by stimulating the proximal nerve trunk were followed by a multi-component depolarizing afterpotential and a slow hyperpolarizing afterpotential, both of which were Ca-dependent. The depolarizing afterpotential is due at least in part to Ca influx, and the slow hyperpolarizing afterpotential is due mainly to Ca-dependent K efflux (see preceding abstract). Exposure to epinephrine (10-100 μM) usually reduced the amplitude and duration of both these Ca-dependent afterpotentials in a dose-dependent and reversible manner. However, both afterpotentials were transiently enhanced during washout of the epinephrine. In some axons the afterpotentials were enhanced even during exposure to epinephrine. When epinephrine was applied in the presence of a beta-adrenergic antagonist, propranolol (1-10 μM), the afterpotentials were always inhibited, whereas when epinephrine was applied in the presence of an alpha-adrenergic antagonist, phentolamine (1-10 μM) or prazosine (1-10 μM), both afterpotentials were always enhanced. These calcium-dependent afterpotentials were also enhanced by a beta-adrenergic agonist, isoproterenol (10 μM). These results suggest that lizard motor nerve terminals possess both alpha-adrenergic receptors, which inhibit Ca entry, and beta-adrenergic receptors, which enhance Ca entry. Supported by NIH grants NS 12404 and GM 30377.

86.17 CALCIUM CURRENTS IN MAMMALIAN MOTOR NERVE TERMINALS. B.R. Hamilton and D.O. Smith. Department of Physiology, University of Wisconsin, Madison, WI 53706.

Depolarization of nerve terminals by invading action potentials is known to open voltage dependent calcium channels, resulting in an inward calcium current that leads to vesicular fusion with terminal membrane and consequently, the release of neurotransmitter. Calcium currents have been measured directly in squid giant synapse and mouse motor nerve terminals. Voltage dependent calcium channel characterization has been possible in tissue culture and dissociable cell systems, as in the case of DRG cells where L, N and T type calcium channels have been identified. To date these characterizations have not been extended to motor nerve terminals. We have undertaken studies utilizing loose-patch electrodes and patch-clamp amplifiers to examine calcium currents in motor nerve terminals of rat EDL.

Incubation of the EDL preparation in 10 μM 4-(4-diethylaminostyryl)-N-methylpyridinium iodide allows viewing of end-plates with epi-fluorescence at 400X magnification and subsequent placement of electrodes. Post-synaptic responses are blocked with appropriate levels of d-tubocurarine. Initial terminal recordings are dominated by outward K^+ currents which can be blocked with TEA (1 to 10 mM) and 3,4 diaminopyridine (50 to 250 μM). Stimulation of the nerve via a suction electrode, in the presence of these blocking agents, results in an outward capacitative spike attributed to the depolarizing influx of Na^+ at the last node, followed by a slowly developing inward current, 10 to 15 pA in amplitude and 4 to 6 ms in duration. The slow inward terminal current is blocked by the known inorganic calcium channel blockers Co^{2+} (10 mM) and Cd^{2+} (1mM), thus indicating that this is most probably a Ca^{2+} current. This terminal Ca^{2+} current appears to be relatively insensitive to dihydropyridine antagonists such as nifedipine (10 to 20 μM). Double pulse protocols, though, have not revealed any significant Ca^{2+} dependent inactivation.

It has been hypothesized that N type channels are located at active zones and are responsible for transmitter release, while L type channels may be present, but away from active zones. Relative insensitivity to nifedipine suggests the presence of N type channels, while the lack of inactivation would be considered a characteristic of L type channels. Thus, it would appear likely that the slow inward current that we have identified in rat EDL motor nerve terminals is the result of Ca^{2+} ion flux through both L and N type Ca^{2+} channels. Supported by NIH grant NS13600 and the Muscular Dystrophy Association.

86.18 THREE POTASSIUM CURRENTS IN MOUSE MOTOR ENDINGS. A. Mallart, N. Tabti* and C. Bourret*. Lab. Neurobiologie Cellulaire et Moléculaire, CNRS, F-91190 Gif sur Yvette, France.

Action potentials elicited by motor nerve stimulation promote conductance changes at the presynaptic terminals which give rise to local circuit currents flowing between the terminals and the parent axon. The recordings obtained using extracellular electrodes placed on motor endings or inside the perineurium of preterminal nerve bundles showed a large outward current which was demonstrated, by its sensitivity to K channel blockers, to correspond to an increase in gK at the terminals during the repolarizing phase of the action potential (Brigant, J. L. and Mallart, A., J. Physiol. 333:619, 1982). The use of adequate channel blocking agents allowed the separation of this K current into three distinct components: i) 3,4-diaminopyridine (3,4-DAP) in bath application (200-400 μM) suppressed a large fraction of the outward current which was supposed to correspond to IK. ii) A fraction of the 3,4-DAP resistant outward current was abolished in Ca^{2+}-free media and in the presence of inorganic Ca channel blockers, TEA (5-10 mM) or charibdotoxin (CTX, 20 nM) and was, thus, identified as a Ca-dependent K current (Mallart, A., J. Physiol., 368:577, 1985). iii) In 3,4-DAP and CTX treated preparations, where IK and IK(Ca) channels were expected to be blocked, addition of TEA caused a marked enhancement of the wave form component that signals ICa, which suggests the suppression by this agent of another type of IK, 3,4-DAP resistant but TEA sensitive, not hitherto described in presynaptic terminals. Further separation of these two types of IK was achieved by using first TEA (10 mM) to suppress both the TEA sensitive component of IK and IK(Ca). This treatment induced only a moderate ICa response which was greatly enhanced by subsequent addition of 3,4-DAP (300 μM) or UO_2 (50 μM). On the basis of this pharmacological analysis one can distinguish two distinct, voltage dependent, IK components: one being sensitive to TEA and the other sensitive to 3,4-DAP and UO_2. It is not clear what is the functional significance of these three K currents. IK(Ca) should be small under physiological conditions since CTX failed to affect the presynaptic signals in standard saline. Although the relative potency of each fraction of IK remains to be determined, one can say, from the large size of the presynaptic 'K signal', that the combined action of both components is able to induce a really sharp decay phase of the presynaptic action potential.

We wish to thank C. Miller for a gift of charibdotoxin.

87.1 THREE-DIMENSIONAL ORGANIZATION OF A BIDIRECTIONAL-EXCITATORY CHEMICAL SYNAPSE. Ulrike Grünert,* and Peter A. V. Anderson. (SPON: M. J. Greenberg). Whitney Lab. and Depts. of Physiology and Neuroscience, Univ. of Florida, St. Augustine, FL 32086.

Morphologically non-polarized, or bidirectional chemical synapses are common in cnidarians, and present in other phyla, including vertebrates, but only in the jellyfish Cyanea has their bidirectionality been confirmed physiologically (Anderson, P. A. V., J. Neurophysiol., 53: 821-835, 1985). In thin sections these synapses in cnidarians are characterized by very marked pre- and post-synaptic densities and by the presence of 3-4 large synaptic vesicles. Both terminals contain a similar number and the two vesicle clumps are usually directly opposed to one another. Cisternae are usually present. The scarcity of vesicles in a given thin-section of such a synapse has often been received with some scepticism, particularly since a typical post-synaptic potential might be of the order of 50 mV. This prompted us to determine the three-dimensional organization of these synapses with a view to ascertaining the total number of vesicles present at the synapses, the degree to which vesicles in the two terminals were opposed and the presence and organization of other organelles in the synapse.

Preparations of the motor nerve net of Cyanea were exposed by oxidation of the overlying epithelial layer, then fixed and embedded in the conventional way. 5 mM Cd was present during the early stages of fixation to minimize vesicle exocytosis. Serial section were then cut and the organization of the synapse determined by tracing the images from photomicrographs onto plexiglass. Four complete synapses were examined in this manner.

A typical terminal contains 40 to 50, 90 to 100 nm diameter, slightly irregularly shaped vesicles. These form a single layer against the cell membrane and are separated by electron dense material. The organization of the two terminals is the same and the vesicles form two opposing plaques. Immediately internal to the vesicles is an extensive cisternal network that covers the entire vesicle array. From reconstructions, it appears to form a single perforated sheet from which arise numerous processes, some of which are fine, others large and bulbous. Its appearance in reconstructed terminals was reminiscent of sarcoplamic reticulum. Occasionally, the cisternae appear to be connected to the vesicles by fine necks of membrane, suggesting that the vesicles bud-off from the cisternae.

The major conclusion of this work is that the organization of the bidirectional synapses in Cyanea is similar to that of most other synapses, with the exception that the cisternal network is far more extensive that is reported for other synapses. The significance of this is not known.

87.2 MEAN SYNAPTIC LENGTHS OF LAMINAE I-IV IN THE RAT DORSAL HORN ARE NOT HOMOGENEOUS. R.E. Coggeshall, R.P. Bolender*, K. Chung, C.E. Hulsebosch and D.L. McNeill*. Marine Biomedical Institute and Dept. of Anatomy & Neurosciences and Physiology & Biophysics, University of Texas Medical Branch, Galveston, TX 77550 and Dept. of Biological Structure, University of Washington School of Medicine, Seattle, WA 98195.

A knowledge of synaptic size and distribution is essential in order to understand spinal cord organization. One parameter of synaptic size we have examined is the mean length of the synaptic cleft (MLSC). In the present study the MLSC was determined for laminae I-IV in the right and left dorsal horns of normal rat spinal cord. Four 3 month old Sprague-Dawley rats were perfused and the second sacral (S2) spinal cord segment removed. Each S2 segment was cut into 3 transverse slices then embedded for transmission electron microscopy. A thin section was cut from each slice and a low power (X 1200) montage was constructed of the right and left dorsal horns. Laminae I-IV boundaries were drawn on each montage and a template consisting of an orthogonal grid with holes located 8 cm from each other was placed randomly over the montage. Pen marks were made on the montage through the holes. A high power (X 38,000) micrograph was then taken using the pen mark on the montage as the center of the micrograph. Micrographs were subsequently arranged by lamina and right or left dorsal horn. Synapses were identified in each micrograph and their lengths were measured using an acoustic plotter. The MLSC for combined right and left laminae I-IV are listed below.

Lamina	MSL + S.D. (μm)
I	.29 ± .10
II outer (o)	.28 ± .10
II inner (i)	.28 ± .10
III	.30 ± .12
IV	.30 ± .11

The MLSC of laminae IIo and IIi is significantly smaller than that of III and IV ($p < 0.05$). There is no significant difference in the MLSC of laminae I versus II-IV or between individual lamina when compared with the respective lamina on the contralateral side. In addition, there is no significant difference with respect to medial to lateral placement of the MLSC within each lamina. Serial section reconstructions confirmed that synapses in all laminae were disc shaped with widths varying between .15-.40 μm. These data will be useful in comparing the normal with experimental situations.

Supported by NIH grants NS20091, NS11255, NS17039, the Spinal Cord Research Foundation and the Florence and Marie Hall Endowment.

87.3 SUBSTRUCTURE IN THE POSTSYNAPTIC DENSITY OF PURKINJE CELL DENDRITIC SPINES REVEALED BY RAPID FREEZING AND ETCHING. D.M.D. Landis. Depts Neurology, Developmental Genetics and Anatomy, Case Western Reserve University School of Medicine, Cleveland, OH 44106

We have used rapid freezing, freeze-substitution fixation, and shallow etching after freeze fracture to examine the distribution and structure of proteins composing the postsynaptic density in Purkinje cell dendritic spines synapsing with parallel fibers in normal mouse cerebellar cortex. The density consists of thin protein filaments which insert on the true inner surface of the postsynaptic membrane and which bind a variety of globular structures that we interpret as cytoplasmic proteins. It has long been appreciated that the size of the postsynaptic density is different at different classes of synaptic junction, but our studies reveal the additional complexity that the structure of the postsynaptic density varies as different Purkinje spines are compared to one another.

Slabs of cerebellar cortex were quickly excised and the pial surface frozen by impact against a copper block cooled by liquid helium. In tissue prepared by freeze fracture and then etching to remove 20-30nm of water prior to rotary replication with platinum alloy, the number and packing density of the globular proteins varies from region to region within a single density, and is even more variable when different junctions are compared. While actin-like microfilaments and spectrin-like filaments are juxtaposed to the postsynaptic density, they do not appear to be continuous with the constituent filaments of the density. We did not detect neurofilaments or microtubules in the postsynaptic density.

The fine filaments of the postsynaptic density appear to form a supporting framework for the various globular proteins, and to position them in the region of the spine which has the greatest concentration of ionized calcium entering with the synaptic current and the greatest extent of postsynaptic depolarization. The heterogeneity of the globular proteins in the postsynaptic density indicates that constituent proteins vary from density to density and are not uniformly distributed across a single density. Present evidence suggests that the nature of the neurotransmitter and the mechanism of excitatory action are the same at all parallel fiber synapses with Purkinje cell spines. Perhaps the variations in structure of the postsynaptic density at different spines reflect different histories of synaptic activity, resulting in qualitative and quantitative changes in the protein composition of the density.

87.4 DISTRIBUTION OF CONTRACTILE AND CYTOSKELETAL PROTEINS IN THE DENTATE MOLECULAR LAYER. M. Morales* and E. Fifkova (SPON: J. A. Markham). Dept. of Psychology, Univ. of Colorado, Boulder, CO 80309.

Contractile and cytoskeletal proteins may be involved in important neuronal functions. In our previous work (Fifkova and Delay, J. Cell Biol., 95:345, 1982), we have shown that actin filaments are distributed through the neuron with the highest density in dendritic spines. Actin filaments are anchored to the spine apparatus and determine the characteristic shape of the spine. They are also responsible for the absence of cytoplasmic organelles from the spine. Labeling of actin filaments with the S-1 fragment of myosin necessitated membrane permeation with saponin. Since the permeated membrane may affect the organization of actin filaments, it seemed important to verify actin organization with another method which does not affect the integrity of the plasma membrane. Such a method involves immunogold labeled antiactin antibodies in a postembedding procedure which leaves the plasma membrane intact. Actin filaments are well preserved because the protocol uses low concentrations of glutaraldehyde (0.5%) and instead of OsO_4 uranylacetate as a secondary fixative during dehydration. The tissue was embedded in Lowicryl K4M, which does not require absolute dehydration and may be done at low temperatures, both of which help to retain antigenicity. The pattern of distribution of actin filaments in spines with the immunogold labeling in dendritic spines was similar to that we observed with the S-1 fragment of myosin. As with the latter method, actin is distributed across the neuron with the highest density in dendritic spines. Gold particles were clearly associated with the postsynaptic density (PSD), with the plasma membrane and membranes of the spine apparatus. Thus, with two different methods, we have confirmed the density and distribution of actin filaments in dendritic spines. Since the postembedding technique allows us to use more than one antibody in the same tissue, we stained alternate grids with the antitubulin and antiplatelet myosin antibody. The antitubulin antibody showed the expected heavy labeling of microtubules in dendrites, axons and perikarya. Labeling could be also seen in axon terminals, in their center or periphery, but not at the active synaptic zone. This observation confirms that of Cumming et al. (Neurosci. Lett., 37:215, 1983). The antitubulin antibody failed to localize tubulin in spines and the PSD. The antimyosin antibody was distributed in spines along actin filaments in a concentration far below that of actin, which agrees with observations in other nonmuscle cells. Myosin labeling was absent from the PSD, however, it was seen under the plasma membrane and membranes of the spine apparatus. Sparse myosin labeling could be seen in axon terminals and dendrites. Taken together, these observations localize actin and myosin as the main contractile proteins in dendritic spines. Supported by NIA grant AG04806. The antibodies were the gift of Dr. J. M. Scholey, Department of MCD Biology , University of Colorado.

87.5 DENDRITIC SPINES ARE SUSCEPTIBLE TO STRUCTURAL ALTERATIONS INDUCED BY DEGENERATION OF THEIR PRESYNAPTIC AFFERENTS.

G. Benshalom* (Spon: J. Mazliah) Unit of Morphology, Faculty of Health Sciences, Ben-Gurion University of the Negev, Beer Sheva, Israel.

The most common approach used to study thalamocortical (TC) connectivity involves the labeling of the thalamocortical afferents by lesion-induced degeneration. However, despite the plethora of information regarding the morphology of degenerating axon terminals and of their postsynaptic elements, no systematic morphological analysis is available regarding the possible effects of the degeneration of TC projections on the morphology of their cortical targets, which are mainly dendritic spines. The aim of the present study was to investigate which specific structural alterations, if any, occur in the dendritic spines of cortical neurons, following the degeneration of presynaptic TC axon terminals. TC afferents to SmI cortex of adult male CD-1 mice were lesioned electrolytically. Four days post-lesion, the brains were fixed with aldehydes and processed by the Golgi gold-toning method. Dendritic spines belonging to layer IV spiny stellate neurons were examined in series of thin sections. Structural features were compared for spines synapsing with degenerated TC terminals, and with unidentified intact axon terminals, on the same dendritic segments. Results showed that the heads of denervated spines are significantly wider (+11%, p=0.03) and less variable in width (-6%, p=0.03) than the heads of spines whose innervation is intact. In addition, the synaptic junctions of denervated spines typically are concave with respect to the spine head, whereas the majority of those belonging to innervated spines are convex (significance, p=0.01). Structural features typifying transneuronal degeneration were not detected within the spiny dendrites. A body of data exists which indicates that the structural differences observed in this study are not related to the identity of the presynaptic element, but instead result directly from denervation, and so it is concluded that changes in the structure of dendritic spines can occur soon after synaptic inactivity is induced. Supported by N.I.H. # NS 20149-04.

87.6 SV2 AND P38/SYNAPTOPHYSIN CO-PURIFY ON SMALL SYNAPTIC VESICLES FROM MAMMALIAN BRAIN. E. Floor, Dept. of Anatomy, Univ. of Wisconsin Medical School, Madison, WI 53706.

A transmembrane glycoprotein, SV2, of Mr ~100,000 has been identified by means of a monoclonal antibody, 10H3, isolated by K. Buckley and R.B. Kelly (J. Cell Biol. 100, 1284) and shown to be on purified synaptic vesicles from elasmobranch fish and to be present in mammalian neurons and endocrine cells. Another synaptic vesicle-specific protein, p38/synaptophysin, was shown to be a major protein on mammalian synaptic vesicles by Jahn et al. (PNAS 82, 4137), and Wiedenmann and Franke (Cell 41, 1017). These two proteins were localized to mammalian synaptic vesicles largely by immunocytochemical methods. In the present experiments, SV2 and p38/synaptophysin levels during purification of synaptic vesicles from rat brain (Soc. Neurosci. Abstr. 11, 644) were measured by radioimmunoassay (RIA) with antibodies 10H3 and R10, respectively. R10 is a rabbit antiserum against purified synaptic vesicles that recognizes predominantly a 39K protein on Western immunoblots that was shown to be p38/synaptophysin. The RIA results were confirmed qualitatively by Western immunoblot analysis.

During synaptic vesicle purification, single peaks of SV2 and p38/synaptophysin immunoactivities were found after equilibrium density sedimentation on 10-30% Nycodenz gradients and after sizing chromatography on Sephacryl S-1000 and controlled-pore glass bead CPG-3000 columns. The peaks of the two proteins corresponded after each of these separation techniques, and both proteins were shown to be associated with vesicles ~40 nm in diameter by chromatography on a calibrated CPG-3000 column. The overall purifications of these synaptic vesicle proteins after the CPG-3000 chromatographic step were 80-fold for p38/synaptophysin and 50-fold for SV2 with respect to their concentrations per total protein in the crude homogenate. The amount of SV2 in column fractions containing larger synaptic vesicles (~100 nm) after the Sephacryl S-1000 chromatographic step was <2% of that in ~40 nm vesicles, while ~15% of p38/synaptophysin was in larger vesicles at the same purification step. The reason for this difference in levels of the two proteins is not clear. These results do not exclude the possibility that one or both proteins are present on larger synaptic vesicles. However, these results indicate that most of the SV2 and also p38/synaptophysin in rat brain are selectively localized on small synaptic vesicles.

I thank Kathy Buckley for 10H3 antibody. Supported by NIH Grant NS24890.

87.7 CLONING AND SEQUENCE ANALYSIS OF cDNA ENCODING A MAJOR SYNAPTIC VESICLE PROTEIN, p38 OR SYNAPTOPHYSIN.

K.M.Buckley*, E.Floor§,and R.B.Kelly. Dept. of Biochemistry and Biophysics, UCSF School of Medicine, SF, CA 94143.§Dept. of Anatomy, University of Wisconsin Medical School, Madison, WI 53706

Synaptic vesicles in all parts of the nervous system share three integral membrane proteins: p65 (Matthew et al.,1981), SV 2 (Buckley and Kelly, 1985), and p38 (Wiedenmann and Franke, 1985; Jahn et al.,1985). The most abundant of these three proteins, p38, has recently been proposed as a major Ca^{++}binding protein of the synaptic vesicle (Rehm et al.,1986). To extend the study of these vesicle proteins we have recently isolated cDNA clones encoding the open reading frame and untranslated regions of the mRNA for p38 from a lamda gt11 rat brain cDNA library. The cDNA clones were initially identified by screening with a polyclonal serum to rat brain synaptic vesicles. Positive phage were further screened by using fusion proteins adsorbed to nitrocellulose filters to affinity purify monospecific antibodies from the original heterogeneous serum. Inserts from clones which selected for antibodies binding to p38 in western blots were subcloned into plasmid vectors and used to generate cDNA probes for Northern blot analysis. A major transcript of 2.5 kb was expressed specifically in brain and endocrine tissue but not in liver, spleen, or salivary gland, consistent with the tissue-specific expression of the protein detected by antibody techniques. Three overlapping clones were sequenced by standard dideoxy chain termination in M13. Approximately 85% of the cDNA was identified and sequenced in this manner. The remaining sequence at the 5' end of the mRNA was obtained by screening a second lamda gt11 library with a 5' cDNA probe. The open reading frame consists of 1100 bp that encode a protein of M_r=36,000. Since the unglycosylated protein has been reported to be 34,000, we assume the increase in molecular weight represents the addition of a signal peptide. The remainder of the transcript consists of 1.4 kb of 3' untranslated RNA and the poly A tail. The protein shares no sequence homology with other known (albeit predominantly cytoplasmic) Ca^{++}binding proteins, and may represent a new class of integral membrane proteins with Ca^{++} binding activity. The availability of a cDNA clone for this synaptic vesicle protein should facilitate studies of both its function in transmitter release as well as the regulation of a synapse-specific protein during development and regeneration of nerve terminals.

87.8 IDENTIFICATION OF A NOVEL SYNAPSIN I-LIKE PROTEIN IN DROSOPHILA.

J. Buxbaum*[1,2], Y. Dudai[1], R. Jahn*[2] and P. Greengard[2] (SPON: I. Ginzburg). The Weizmann Institute of Science, Israel[1] and The Rockefeller University, New York[2].

Synapsin I is a major substrate for cAMP- and Ca^{2+}-dependent protein kinases, which is associated with synaptic vesicles and is implicated in regulating transmitter release. Synapsin I has been extensively characterized in mammalian brain, where it is a doublet of MW 80 and 86 kDa. We have set out to identify and characterize synapsin I in Drosophila melanogaster, since this organism offers the possibility of genetic dissection of synapsin I structure and function. In addition, Drosophila mutants exist which are defective in second messenger cascades and in neuronal and behavioral plasticity, and these mutants could shed light on physiological roles of synapsin I. For detection of synapsin I in Drosophila, we have employed antibodies against the mammalian protein (e.g., Goelz et al J. Neurochem. 45: 63 (1985)). In Drosophila, a single major protein (synapsin I-like immunoreactive protein, SLIP) of MW 150±15 kDa cross reacted with 5 out of 7 monoclonal antibodies and with all the serum antibodies raised against mammalian synapsin I. We have compared several properties of SLIP to those of mammalian synapsin I. Zn^{2+}/acid extraction (pH 3), which is a method used in purification of mammalian synapsin I, extracted ca. 90% of the Drosophila protein. After immunoprecipitation, SLIP was phosphorylated by purified mammalian cAMP-dependent protein kinase. Immunoreactivity to the mammalian anti-synapsin I antibodies as visualized by cytochemistry was high in Drosophila nervous system. High concentrations of SLIP were also detected in the Drosophila Schneider L_2 cell line, which originated from embryonic cell dissociates. Using an antibody affinity column, we were able to purify SLIP to apparent homogeneity from adult flies. We have also detected synapsin I immunoreactivity in the moths, Manduca and Cecropia, and in the locust. The MW of the relevant polypeptides were 70 and 160 kDa (Manduca), 80, 140 and 190 kDa (Cecropia), and 4 proteins in the range of 155-225 kDa (Locusta). It thus appears that polypeptides which share antigenic epitopes and additional properties with mammalian synapsin I, but differ from the latter in their MW, exist in Drosophila as well as in other insects. The effects of Drosophila mutations in the cAMP cascade on the level and phosphorylation of SLIP are currently being investigated. (Supported in part by the Rockefeller University - Weizmann Institute Research Fund).

87.9 CHARACTERIZATION AND LOCALIZATION OF G_s AND G_o PROTEIN MOLECULES IN APLYSIA NEURONS. G.J. Chin, S.S. Vogel*, S.M. Mumby* and J.H. Schwartz. Howard Hughes Med. Inst., Columbia Univ. Col. of Phys. & Surg., New York, NY 10032 and Dept. of Pharmacology, Univ. of Texas Health Sciences Center, Dallas, TX 75235.

There is biochemical (Critz, Harper & Byrne, Neur. Lett. 64:145, 1986) and neurophysiological (Brezina, Eckert & Erxleben, J. Physiol., 1987) evidence for the transducers G_s and G_i in Aplysia. We now can detect two molecular forms of G protein molecules in nervous tissue. By Western blot analysis, a 100,000 x g membrane fraction from Aplysia neural components contained immunoreactive polypeptides that are similar in molecular weight to those of bovine brain. We used affinity-purified polyclonal antisera generated against synthetic peptides corresponding to bovine brain G protein sequences. These antisera specifically recognize 1) the α-subunit of G_s 2) the α-subunit of G_o 3) the common β subunit of the G protein family or 4) the α-subunits of G_i, G_o, and G_s (Mumby et al., PNAS 83:265, 1986). A M_r 45,800 protein was recognized by the G_{common} (α) antiserum and by two antisera directed against $G_s(\alpha)$, one against a sequence near the N-terminus and the other against a sequence near the C-terminus. A M_r 40,600 protein was recognized by both the $G_{common}(\alpha)$ and the $G_o(\alpha)$ antiserum. The $G(\beta)$ antiserum recognized a protein of M_r 36,300. We demonstrated specificity by using the original synthetic peptides to block the reactions. Aplysia $G_i(\alpha)$ was not detected, possibly because it was not resolved from $G_o(\alpha)$; alternatively it may not be present in sufficient quantity.

The subcellular distribution of Aplysia G proteins was examined using the synaptosome fraction developed by Chin, Shapiro & Schwartz (Soc. Neurosci. Abs. 11:29, 1985). Quantitation of Western blot immunostaining by densitometry revealed that the subunits recognized by the $G_o(\alpha)$, $G(\beta)$, and $G_{common}(\alpha)$ antisera are enriched 4-fold in synaptosomes. The [^{32}P]ADP-ribosylated pertussis toxin substrate with M_r 40,000 is enriched 2-fold. We are extending these studies by examining the distribution of immunoreactivity in complete sequential tissue sections of ganglia. Localization of G proteins to specific neurons is also being determined by Western blotting of dissected identified cell bodies. In parallel studies, we are also studying the localization of the effector enzymes (protein kinases and phospholipases) of the transduction pathways.

87.10 IDENTIFICATION OF NOVEL SYNAPTOSOMAL PROTEIN KINASES AND THEIR ENDOGENOUS SUBSTRATES. U.K. Misra*, O.B. McDonald* and N. Sahyoun* (Spon: Will W. Pugh) Dept. of Molecular Biology, Wellcome Research Labs., Research Triangle Park, NC 27709.

Rat forebrain synaptosomes contain one or more protein kinases whose activity is unmasked after partial purification of a Triton X-100 extract on DEAE-cellulose columns. Marked phosphorylation occurs on two endogenous polypeptides with Mr values of 78 and 50K and with the corresponding pI values of 5.3 and 5.6. Phosphate incorporation is mostly labile to KOH hydrolysis.

The phosphorylation reaction is not dependent on known protein kinase activators such as Mn^{2+}, Ca^{2+}, calmodulin, phosphatidylserine, phorbol esters, and cyclic AMP. Mg^{2+} is required at relatively low concentrations with an EC_{50} of about 0.5 mM. Phosphorylation of exogenous substrates revealed that protamine, but not histones or casein, is effectively phosphorylated. Gel-permeation analysis on AcA-34 columns results in partial separation between phospholipid/Ca^{2+}-dependent histone phosphorylation and protamine phosphorylation. The synaptosomal protein kinase(s) was further characterized by separation of the proteins from the DEAE-cellulose peak fraction on non-denaturing electrophoretic gels in the presence of Triton X-100. The protein kinase reaction was conducted in the gel itself resulting in the phosphorylation of two major components. These polypeptides may be protein kinases themselves displaying autophosphorylation or may form molecular complexes with a protein kinase.

Thus, synaptosomal protein kinases described here appear to be distinct from protein kinase C, calmodulin-dependent protein kinases, cyclic AMP-dependent protein kinases and casein kinases, and may represent a novel pathway in synaptic signalling.

87.11 ETHANOL-DEPENDENT STIMULATION OF SOLUBLE PIP-KINASE ACTIVITY IN RAT BRAIN. E.B. Stubbs, Jr.* and G.Y. Sun. Biochem. Dept. and Sinclair Research Farm, Univ. of Missouri, Columbia, MO 65203.

The primary CNS depressive effects of ethanol are considered to result from the purturbation of neural membrane biophysical and biochemical properties. Particularly affected are those enzymes which actively participate in neurotransmission. Through their involvement in signal transduction, polyphosphoinositides are considered as putative participants in neuromodulation. Capitalizing on the bimodal distribution of both phosphoinositide kinases between membrane and cytosol, we examined the effects of ethanol on both PI- and PIP-kinase activities present in purified synaptosomal and cytosolic fractions isolated from rat brain. In vitro phosphorylation of inositol lipid substrates progressed linearly in the presence of buffered medium (pH 7.4) containing Na_2ATP (0.5 mM), $MgCl_2$ (10 mM) and EGTA (1 mM) when assayed at 30°C for 60s. Under these conditions, cytosolic PIP-kinase phosphorylated exogenously added PIP at an initial rate of 24 pmol/min/mg. In comparison, purified synaptosomes, when assayed under similar conditions, phosphorylated exogenous PIP at an initial rate that was 3-fold greater than that in cytosol. Ethanol, at concentrations between 0-500 mM, enhanced cytosolic PIP-kinase activity in a dose dependent manner with maximal catalysis (2-fold) occuring between 300-500 mM ethanol. Interestingly, synaptosomal PIP-kinase activity remained uneffected by the same concentration range of ethanol. Likewise, neither cytosolic nor synaptosomal PI-kinase activities were effected by ethanol. These results demonstrate modulatory effects of ethanol on cytosolic PIP-kinase which are abolished when this enzyme is present in its membrane-associated state. (Supported in part by NS20836 and AA06661 from NIH)

87.12 IN SITU PROTEIN PHOSPHORYLATION IN CULTURED PYRAMIDAL NEURONS. W.K.Scholz and P.T.Kelly. Univ.Texas HSC, Houston, TX 77025

In situ studies using hippocampal neurons were undertaken to better understand the role of protein phosphorylation in neuronal function, especially synaptic transmission. Primary cultures of pyramidal neurons were established from 18E rat hippocampi. The time course of neuronal differentiation and synapse formation in homogeneous pyramidal cultures was similar to that observed in vivo. We have shown that Ca^{++}/calmodulin-dependent protein kinase II expression, subcellular distribution, activity, and substrate phosphorylation in differentiating pyramidal cultures display developmental changes similar to that observed in newborn rat brain. We have examined cAMP- and Ca^{++}/phospholipid-dependent protein kinase activities and endogenous substrates using in vitro phosphorylation in subcellular fractions from cultured pyramidal neurons. The potential role of each kinase in signal transduction was examined by modulating in situ protein phosphorylation using membrane permeable analogues of second messengers and conditions that affect membrane depolarization properties followed by analysis of phosphoproteins using 1-D and 2-D gels and peptide mapping. Phosphoproteins labeled in situ were then compared with endogenous substrates phosphorylated in vitro under conditions optimal for Ca^{++}/CaM-, Ca^{++}/phospholipid- or cAMP- dependent protein kinases. Pyramidal neurons cultured for 18 days were prelabeled with $^{32}P_i$ and then treated with Krebs-Ringer-HEPES buffer (KRH) alone or KRH containing 8-bromo-cAMP, 12-o-tetradecanoylphorbol 13-acetate (TPA) or tetrodotoxin (TTX). Cultures were also prelabeled and treated with Ca^{++}-free KRH/15 uM EGTA. Following the different in situ labeling conditions particulate and cytosolic fractions were prepared from each culture. Proteins which showed significant increases in ^{32}P-incorporation following treatment with 8-bromo-cAMP had M_rs of 270, 74, 52, 50-54, 37, 32 and 22K. Protein phosphorylation dependent on 8-bromo-cAMP treatment was also increased in Ca^{++}-free media. TPA stimulated the phosphorylation of 120, 87, 57, 48, 47, 46, 18 and 14K polypeptides. TTX treatment, used to block spontaneous neuronal activity, increased the labeling of 270, 87, 56, 48 and 18K proteins which were also phosphorylated under other conditions (above) and 120, 37, 33, 22 and 21K proteins which were unique to TTX treatment. Homogeneous astrocyte cultures were examined under the same conditions. Analysis of all proteins whose apparent phosphorylation was stimulated in situ, revealed only 4 that were also phosphorylated in vitro (M_r = 87, 48, 46 and 74K). The apparent subcellular distribution of in situ labeled phosphoproteins was different than those phosphorylated in vitro and suggests that certain treatments may modulate the intracellular translocation of substrates and/or kinases. Whereas both neuronal and astrocyte phosphoproteins showed different in situ labeling patterns that were altered by incubation conditions, most of the labeled proteins were cell-type specific.

87.13 INFLUENCE OF SYNAPTOSOMAL CHOLESTEROL ON DOPAMINE UPTAKE. Patricia A. Maguire* and Mary J. Druse-Manteuffel. Department of Biochemistry, Loyola University Stritch School of Medicine, Maywood, IL 60153.

During aging and development, there is an increase in the cholesterol/phospholipid ratio (c/p) of synaptic membranes, a decrease in membrane fluidity and alterations in the components of several neurotransmitter systems. Since many membrane-associated functions are profoundly influenced by membrane fluidity, it is possible that at least some of the age-related changes of the neurotransmitter systems are due to alterations in the c/p and fluidity of the synaptic membranes.

In an attempt to investigate this hypothesis, we examined the influence of the c/p on a membrane-associated function of the dopaminergic system. The cholesterol content of synaptosomal membranes was altered using a lipid transfer protein (North, P. and Fleischer, S., Methods Enzymol. 98: 599, 1983) which facilitates the rapid transport of cholesterol between liposomes and synaptosomal membranes. Synaptosomal uptake of 0-5000 nM dopamine was determined in the presence and absence of 10 μM of nomifensine. Fluorescence polarization was used to assess the fluidity of the hydrophobic core (DPH) and surface (ANS) of the synaptic membranes.

Alterations in the c/p were accompanied by changes in dopamine uptake and by changes in relative microviscosity at both the surface and core of the membrane. Many of these alterations were found at c/p within the range of values found during development and aging.

The data obtained using DPH and ANS appear to fit a sigmoidal relationship, with inflection points at c/p within 10% of the value for unmodified membranes. At 37 °C, a 10% increase above the control c/p produced a 75% increase in the relative microviscosity at the membrane core, while a 10% decrease produced a 30% decrease in microviscosity.

Within the physiological range of c/p (control value ± 30%), the K_m increased ∿3-fold, or decreased ∿50% depending on whether the c/p was increased or decreased, respectively. The V_{max} for dopamine uptake showed a similar relationship to c/p. As the synaptosomal c/p increased above 0.50, there was an approximately 35% decrease in the V_{max}. The first order rate constant (V_{max}/K_m) decreased with increasing c/p.

The results of the present studies demonstrate that the transmembrane process of dopamine uptake may be inhibited by elevated synaptic c/p and increased microviscosity. These results may be relevant to the changes in dopamine uptake observed with aged animals.

87PO CHARACTERISTICS OF A POSTSYNAPTIC DENSITY (PSD) FRACTION ISOLATED FROM ADULT CANINE HIPPOCAMPUS (H). P. Siekevitz and K. Wu*, Lab. Cell Biol., Rockefeller University, New York, N.Y. 10021

PSDs were isolated in a manner similar to that of cerebral cortex (CTX) PSDs (Wu et al., Mol. Brain Res. 1: 167, 1986) with a yield of 0.3 mg protein/gm wet weight. Electron micrographs and SDS-gel electrophoresis showed that the fraction was similar to CTX-PSDs except that the H-PSD had proportionally higher fodrin, calmodulin, and the major 51 KD protein content but lower actin content than the CTX-PSDs. The H-PSD have one specific GABA binding site, with a Kd of 89 nM (CTX-PSD=62) and a Bmax of 12.3 pmoles/mg (CTX-PSD=17.8). They also have a specific glutamate binding site, with a Kd of 640 nM (CTX-PSD=418) and a Bmax of 36.9 pmoles/mg (CTX-PSD=28.9). EGTA (0.2 mM), Ca^{2+} (0.5 mM) plus EGTA (0.2 mM), or Mg (1 mM) had no effect on this binding. Glutamate binding to H-PSD and CTX-PSD were similarly inhibited by 10 μM AP5 (66% and 61%), by 20 μM NMDA (61% and 52%), and by 5 μM quisqualate (41% and 38%), while AP4 gave no inhibition in both cases. Contrary to Kessler et al. (J. Neurosci. 6: 355, 1986) pre-incubation of our H-synaptic membrane (H-SM) or H-PSD preparation with 10 mM glutamate showed no effect on subsequent Cl^--dependent or Cl^--independent glutamate binding. The H-PSD bound the Ca^{2+} channel blocker, nitrendipine, with a Kd of 179 pM (CTX-PSD=207) and a Bmax of 216 fmoles/mg (CTX-PSD=196). Calmodulin was necessary for this binding, similar to CTX-PSD, since 10 μM R24571 inhibited it by 95%, and since EGTA-pretreated H-PSD lost 95% of the binding, and the addition of calmodulin plus 1.5 mM Ca^{2+} restored 90% of the binding. The Ca^{2+}/calmodulin-dependent and cAMP-dependent phosphorylations of H-SM and H-PSD proteins were the same as those of CTX-SM and CTX-PSD proteins. The data so far suggest that H-PSD may be useful in studies on the postulated involvement of the hippocampus in learning or memory.

SYNAPTIC STRUCTURE AND FUNCTION II

88.1 SYNAPTIC TRANSMISSION AT THE ONSET OF MORPHOLOGICALLY MIXED SYNAPSES. K.D. Peusner and C. Giaume*. Lab. de Neurobiologie Cellulaire, Institut Pasteur, 75724 Paris Cédex 15, France.

The tangential vestibular nucleus (TN) of the chicken is composed essentially of two types of neurons, principal cells (PC, 80%) and elongate cells (EC, 20%). The EC are innervated solely by vestibular fibers of small diameter, but the PC receive two types of vestibular afferents, the colossal vestibular fibers, which form the spoon endings (SE), and finer vestibular fibers. Ultrastructural quantitative data have shown that the SE form numerous chemical synapses on the PC in 15-16 day embryos (dE), but few gap junctions which first appear at this age. This numerical relation reverses at hatching time (Peusner, 1984). Thus, in an in vitro electrophysiological study, we asked (1) what are the membrane properties of the two neuron types in TN and (2) what is the mode of transmission between SE and PC when gap junctions first appear in 15-16 dE?

The two neuron types can be distinguished by their membrane responses to intracellular current application and their synaptic potentials evoked by vestibular stimulation. These identifications were confirmed by intracellular injections of Lucifer Yellow. Using KCl electrodes, EC have a membrane potential of -56 ± 10 mV (n=11) and an input resistance of 38 ± 18 MΩ (n=7); EC exhibit an inward rectification to hyperpolarization and repetitive discharge of action potentials when depolarized. The EC respond to vestibular stimulation with a monophasic EPSP (1.8 ± 0.3 msec latency) which increases in a graded way as a function of stimulus intensity. In contrast, PC (-56 ± 7 mV, n=14; and 25 ± 7 MΩ, n=7) demonstrate a linear current-voltage relationship for negative currents, and respond with at most one or two spikes to positive currents. Typically, on synaptic depolarization, PC show two responses with distinctive latencies and thresholds. The first response is all-or-none (latency 1.7 ± 0.3 msec) and is attributed to the firing of the colossal vestibular fibers via the SE, while the second response consists of graded synaptic potentials which may be due to the activation of the slower conducting fibers.

Thus, in 15-16 dE (i.e. when gap junctions first appear), synaptic transmission at the SE is predominantly of the chemical type, given: (1) the long latency of the synaptic response; (2) a dependency of the EPSP's amplitude on membrane potential; and (3) the absence of presynaptic fluorescence after Lucifer Yellow injection into the PC. In contrast, preliminary results obtained at 5 days after hatching show that the PC respond to vestibular stimulation with a shorter latency (<1 msec), suggesting that transmission may be in part electrical at this age. Supported in part by NIH grant R01 NS18108.

88.2 THE FATE OF SYNAPTIC VESICLE MEMBRANE FOLLOWING TRANSMITTER RELEASE. K. Ikeda and J.H. Koenig. Division of Neurosciences, Beckman Research Institute of the City of Hope, Duarte, CA 91010.

The present study investigates the fate of synaptic vesicle membrane following transmitter release. It is presently well accepted that transmitter is released by exocytosis of synaptic vesicles, which involves the insertion of the vesicle membrane into the plasma membrane. This membrane is then retrieved by the process of endocytosis and recycled into new vesicles.

In the temperature sensitive mutant, shibire^{ts}, of Drosophila melanogaster, synaptic vesicle recycling is blocked at the pit formation stage if the temperature is raised to 29°C. This causes a gradual depletion of synaptic vesicles if transmitter release is allowed to proceed normally. One explanation for this phenomenon would be that transmitter is released by synaptic vesicle exocytosis, and that in this mutant at 29°C the vesicle membrane cannot be recovered from the plasma membrane by endocytosis for recycling, so that depletion occurs. This implies that in a depleted terminal in shi, all of the vesicle membrane has been incorporated into the plasma membrane.

The terminals of the cervical muscle in Drosophila are normally packed with vesicles, so that the total vesicle membrane far exceeds the amount of plasma membrane of the terminal. Thus, if all the vesicle membrane were inserted into the plasma membrane, a very significant increase in the perimeter of the terminal should be observed. However, in shi at 29°C, no significant increase in the perimeters of depleted cervical muscle terminals was observed, although a small number of pits were observed on the terminal membranes at this time. As long as the temperature was kept at 29°C, no significant increase in membrane was seen. Serial sectioning did not reveal any increase in membrane away from the terminal (eg., axonal membrane) to compensate for this large loss of membrane. When the temperature was lowered to 19°C, a gradual increase in the perimeter of the terminal occurred in the form of large pits and invaginations. As recycling progressed, more and more membrane was observed, first in the form of invaginations, then cisternae, and finally vesicles.

These observations suggest that vesicle membrane may not be inserted into the plasma membrane upon transmitter release, but rather may dissemble when transmitter is released and reassemble at points along the plasma membrane of the terminal away from the active zone.

Supported by USPHS NIH grant NS 18856.

88.3 SYNAPTIC VESICLE NUMBER CORRELATED WITH EJP AMPLITUDE.
J.H. Koenig and K. Ikeda. Division of Neurosciences, Beckman Research Institute of the City of Hope, Duarte, CA. 91010.

The relationship between the number of vesicles in the terminal and the amount of transmitter released from that terminal was investigated using the temperature-sensitive endocytosis mutant of Drosophila, shibire^{ts1} (shi). In this mutant at 29°C, endocytosis is blocked at the pit formation stage. Thus, in the shi neuron at 29°C, depletion of synaptic vesicles occurs as a result of exocytosis (transmitter release) proceeding normally while endocytosis (recycling) is blocked. Using this mutant, the number of vesicles in the synapse can be controlled by bringing the temperature to 29°C and inducing transmitter release until the desired degree of depletion is reached. In this way, the number of vesicles in the synapse (measured by electronmicroscopy) was correlated with the amount of transmitter released (measured by e.j.p. amplitude).

The neuromuscular junctions of the dorsal longitudinal flight muscle (DLM) were used in this study. Intracellular recordings were made from DLM fiber #6, which has a length constant longer than the length of the muscle fiber and is therefore isopotential. This muscle fiber is multiterminally innervated by a single motor neuron. The excitatory junction potential (e.j.p.) was recorded at 29°C while stimulating at 0.5 Hz. A gradual reduction in the e.j.p. was observed, and at various e.j.p. amplitudes the muscle fiber was instantly fixed for electronmicroscopy. The average number of vesicles/synapse for many synapses on the muscle fiber was calculated and correlated with the e.j.p. amplitude for that fiber.

It was observed that as the e.j.p. amplitude decreased, the average number of vesicles in the synapse also decreased. Also, the number of synapses with no vesicles increased with decreasing e.j.p. amplitudes. Thus, a reduction in the e.j.p. amplitude correlated with a reduction in the number of vesicles in the synapses, and also correlated with a reduction in the number of functional (undepleted) synapses. These results suggest that synaptic vesicles are directly related to the release process.

Supported by USPHS NIH Grant NS 18856.

88.4 ACTIVE ZONE STRUCTURE AT LOBSTER HIGH- AND LOW-OUTPUT SYNAPSES.
J. P. Walrond* and C. K. Govind. Department of Anatomy and Neurobiology, Colorado State Univ., Fort Collins, CO 80523, and The Marine Biological Laboratory, Woods Hole, MA 02543.

Quantal neurotransmitter release occurs at discrete sites in the axon terminal called active zones. These sites are recognizable in freeze-fracture views as clusters of large intramembrane particles (active zone particles). The location of transmitter release sites within 50 nm of the particles, suggests that these particles affect transmitter release. To determine the relationship between the number of particles at the active zone and the amount of transmitter released, active zone particles were counted in freeze-fracture views of lobster neuromuscular synapses. In the lobster, Homarus americanus, a single excitatory axon innervates the distal accessory flexor muscle. This axon releases 3 to 10 times more transmitter from high-output synapses in the most distal portion of the muscle than from low-output synapses on the most proximal portion of the muscle. The most distal and proximal muscle fiber bundles were dissected from glutaraldehyde-fixed and glycerinated muscles and freeze-fractured. Axon terminals contained between 4 and 30 synaptic contacts each containing one or two active zones. The density of synaptic contacts and the number of active zones was similar in high- and low-output terminals. Active zone particles were counted in synapses in 6 high-output and 6 low-output axon terminals from 7 animals. High-output active zones contained 20 $\pm$ 5 (n=76) intramembrane particles arranged in a cluster 140 $\pm$ 36 nm long and 69 $\pm$ 10 nm wide. Low-output active zones contained 12 $\pm$ 2 (n=44) intramembrane particles arranged in a cluster 78 $\pm$ 12 nm long and 67 $\pm$ 10 nm wide. Although the longer high-output active zones can accommodate 50% more vesicles (6 vs. 4), this difference cannot account for the 3 to 10 fold difference in the amount of transmitter released from high- and low-output synapses. The correlation between the distribution of active zone particles and the amount of transmitter released is consistent with the active zone particles being the Ca^{2+} channels which couple the action potential to neurotransmitter release. One explanation for the nonlinear relationship between the quantity of transmitter released and the number of active zone particles is that the particles govern the local intracellular Ca^{2+} concentration at the active zone following a nerve impulse. If transmitter release depends on the fourth power of the Ca^{2+} concentration, increasing the Ca^{2+} concentration by 1.7 times (20 vs. 12 channels) would lead to a nearly 8 fold increase in the amount of transmitter released (1.7^4=8.3). This difference is in good agreement with the 3 to 10 fold difference in transmitter release observed physiologically.

88.5 MORPHOLOGICAL PROXIMO-DISTAL GRADIENTS ALONG THE FROG NMJ: A SCANNING ELECTRON MICROSCOPIC STUDY.
R. Robitaille, J.P. Tremblay, O. Martineau*, L. Grégoire*, C. Labrecque* and M.A. Fahim. Lab. Neurobiology, Québec, Qué., Canada and Gerontology Center, Univ. of Southern California, Los Angeles, CA 90089.

Compiling physiological evidence suggests the existence of proximo-distal gradients in spontaneous and evoked release probability along the frog NMJ (Robitaille and Tremblay, Br Res Rev 12, 95, 1987). Scanning electron microscopy permits to verify the existence of corresponding morphological gradients. Cutaneous pectoris muscles were fixed with 2.5% gluteraldehyde and presynaptic terminals removed by consecutive collagenase and HCl treatments. The complete endplate region of 34 NMJs were photographed at X3000 or X5000. Between 2 and 14 branches of primary cleft were observed per endplate. Postjunctional folds (PJFs) were present at the bottom of these clefts and were usually perpendicular to the long axis of the cleft. The length and the position of more than 14,000 PJFs were measured along the clefts (mean density: 2.12 PJFs/µm of cleft). For each junction, the one or two longest branches of primary cleft generally showed proximo-distal gradients in: 1) the number of PJFs/µm of cleft, 2) the average length of PJFs and 3) the total length of PJFs/µm of cleft. The longest branches (100-120µm) have a 4 times smaller total length of PJFs/um of cleft in the distal region than in the proximal one (near the motor axon entry). This gradient in the total length of PJFs reflect a similar gradient in the length of active zones along the nerve terminal since most of the folds are located in front of an active zone (AZ). This gradient may be responsible for the lower spontaneous and evoked release probability observed in the distal regions. The gradient in the average length of PJFs could be responsible for the smaller MEPP amplitude in distal regions (Robitaille et al., Neur. Lett., 74, 187, 1987). The crest of the PJFs is covered with ACh receptors sites at a density of 26,000/µm^2. It therefore takes a crest surface of 0.3 µm^2 to have enough receptor site to have a 1 to 1 relation between the number of ACh molecules (10^4) in a quantum and the number of receptor sites (Matthews-Bellinger and Salpeter, J Physiol 279, 197, 1978). The crest surface (0.3 to 0.4 µm^2) of the smaller PFJs (0.4 µm) is very close to this critical area. Therefore when a vesicle release its content near the edge of a fold or when anticholinesterases are present, the number of receptors within reach by diffusion may limit the size of the MEPP. This may be a postsynaptic mechanism partly responsible for reducing the MEPP size in the distal region. However according to the multivesicular theory (reviewed by Tremblay et al. Br Res Rev 6, 299,1983) these smaller MEPPs may also be due to limited capacity of small AZs (located in front of short PJFs) to liberate simultaneously several vesicles.

88.6 DIFFERENTIAL EFFECT OF α-LATROTOXIN ON THE RELEASE OF ACETYLCHOLINE AND OF CALCITONIN GENE-RELATED PEPTIDE AT THE FROG NEUROMUSCULAR JUNCTION.
M. Matteoli*, C. Haimann*, F. Torri-Tarelli*, J.M. Polak#, B. Ceccarelli* & P. De Camilli* (Spon. L. Vicentini) CNR Ctr. *Cytopharm. & Dept. Med. Pharm. Univ. 20129 Milano, Italy; #Dept. Histochem. Hammersmith Hosp. London W120HS, U.K.

Within axon terminals, classical neurotransmitters are stored in, and released from, the small synaptic vesicles (SSVs) that populate the terminals, whereas peptide neurotransmitters are stored in a different class of organelles, the large dense-core vesicles (LDCVs). LDCVs, in general, represent a minor component of the overall vesicle population. Co-secretion of classical and peptide neurotransmitters occurs in a variety of experimental conditions. However, the relative amounts of the two types of transmitter secreted appear to vary depending on the stimulation conditions.

Recently, the peptide neurotransmitter calcitonin gene-related peptide (CGRP) has been localized at mammalian motor nerve endings, and we have found by light and electron microscopy immunocytochemistry that CGRP immunoreactivity is also present at the frog neuromuscular junction (FNMJ), where it appears to be localized in LCDVs. The latter findings make it possible to study the differential release of a peptide and a classical neurotransmitter at one of the most well-characterized synapses. As a first step in identifying a possible difference in the regulation of the release of CGRP and of the quantal release of acetylcholine (ACh) at the FNMJ, we have investigated whether treatment with α-latrotoxin (α-LTx), which is known to induce complete depletion of ACh-containing vesicles, also induces depletion of CGRP. Frog cutaneous nerve-muscle preparations were incubated at low temperature (2°C) in the presence or absence α-LTx (1 µg/ml). The effectiveness of α-LTx treatment in depleting the terminals of quanta of ACh was assessed electorphysiologically. The preparations were fixed and processed either for CGRP immunofluoresecence or for conventional electron microscopy.

A prominent punctate pattern of CGRP immunofluoresence was observed not only in control terminals but also in terminals treated with α-LTx. Consistent with this observation, a morphometric analysis carried out on electron micrographs of terminals cut in cross section revealed no significant decline of the number of LDCVs in α-LTx-treated terminals compared to control terminals. In contrast, α-LTx-treated terminals were almost completely depleted of SSVs. These findings indicate that, at least under certain experimental conditions, the release of SSVs and of LDCVs from FNMJ can be dissociated and suggest the existence of differences in the cellular mechanisms that lead to the exocytosis of the two types of vesicles. (Supported by MDA grants to PDC & BC).

88.7 THE INFLUENCE OF CELL-CELL CONTACT ON THE DISTRIBUTION OF SYNAPSIN I IN HIPPOCAMPAL NEURONS IN CULTURE.
T.A. Lindsley*, P. De Camilli, and G.A. Banker. Department of Anatomy, Albany Medical College, Albany, NY 12208 and CNR Center of Cytopharmacology and Department of Medical Pharmacology, University of Milan, 20129 Milan, Italy

We have used light and electron microscopic immunocytochemistry to study the role of cell interactions in the localization of synapsin I, a synaptic vesicle-associated phosphoprotein, in hippocampal neurons developing in culture. Cells were prepared from 18 day old rat hippocampi by dissociation with trypsin, plated onto polylysine-treated coverslips, and maintained in serum-free medium. Under these conditions, cells elaborate extensive axonal and dendritic arbors and form numerous synapses.

In mature cultures, stained for synapsin I by immunoperoxidase, synapsin I immunoreactivity was localized in large puncta along neuronal cell bodies and dendrites. Non-neuronal cells did not contain synapsin I. Electron microscopic immunocytochemistry demonstrated that the synapsin I-containing puncta corresponded to vesicle-filled axonal profiles that were exclusively presynaptic. Double-label immunofluorescence experiments, using antibodies against MAP2 to stain somata and dendrites, demonstrated that foci of synapsin I accumulation occurred predominantly at the sites of contact between axons and either dendrites or cell bodies. This pattern of staining was already apparent after one week in culture.

At early stages of development, before cell contacts, synapsin I was expressed by neurons, but its distribution was different. At the level of resolution of light microscopy, it appeared rather diffusely distributed throughout the cell. To determine the influence of cell-cell contact on synapsin I localization, low density cultures were prepared, in which some cells develop without contacting other cells. Even after 2 weeks under such conditions, isolated cells failed to localize synapsin I into large puncta. Neighboring cells in the same cultures that had made contacts developed foci of synapsin I in their axons.

In conclusion, synapsin I is expressed in hippocampal neurons in culture even in the absence of cell-cell contact, but under such conditions synapsin I is diffusely distributed throughout the cells. It appears that the aggregation of synapsin I into large puncta within the axon follows contact between an axon and the somata or dendrites of other cells. This probably reflects the formation of synaptic specializations. (This research was supported by NIH grant NS17112 to G.B. and an MD grant to P.DC.)

88.8 REGULATION OF ACTIN ASSEMBLY IN SYNAPTOSOMES DURING DEPOLARIZATION.
BW Bernstein and JR Bamburg*. Department of Biochemistry, Colorado State University, Fort Collins, Colorado 80523.

Depolarization of synaptosomes from mouse whole brain causes a reversible polymerization of actin, the major cytoskeletal protein of terminals. Filamentous actin (F-actin) levels fluctuate 2-3 fold during a 9 sec depolarization with 75mM K^+/2mM Ca^{++} Hepes buffer, a procedure that elicits transmitter release. Depolarization was terminated after 0, 3, 6, and 9 sec by addition of glutaraldehyde, followed by staining with phalloidin conjugated to the fluorophor, rhodamine. Relative changes in F-actin levels were measured by quantitating fluorescence intensity, an indicator of phalloidin bound by the synaptosomes. F-actin cycling also occurs if synaptosomes are depolarized with calcium free buffer or are treated with a calcium containing, non-depolarizing buffer. However, F-actin levels are constant in non-depolarizing, calcium free buffer. Dioctanoylglycerol (an activator of protein kinase C) enhances the polymerizing effect of depolarization.

Phalloidin, a mushroom toxin and bicyclic heptapeptide, binds specifically and in a 1:1 molar ratio with only F-actin, not monomeric actin. Rhodamine phalloidin binding to these fixed synaptosomes is saturable and is reduced 50% by omission of membrane permeabilization, 30% by treatment with pancreatic DNase I (a specific depolymerizing agent of F-actin), and 100% by competition with unlabelled phalloidin. Others have found that phalloidin binds to both long and short actin filaments in all regions of fixed cells, regardless of the particular actin binding proteins regionally present. Therefore, the cycling of staining intensity herein reported probably reflects polymerization/depolymerization rather than filament severing or fluctuation in the accessability of filaments to stain due to depolarization induced changes in actin binding proteins. Earlier reports on lysed synaptosomes indicated that depolarization causes a net reduction in actin associated with the cytoskeleton and that both stabilizing and destabilizing factors are activated (Bernstein, BW and Bamburg, JR, J. Neurosci., 5:2565-2569, 1985; Bernstein, BW and Bamburg, JR, Neurochem. Res., in press). This report on intact synaptosomes shows that the net effect of stimulating these counterbalancing factors is a fluctuation in F-actin levels.

88.9 THE EFFECTS OF EXTRACELLULAR CALCIUM CONCENTRATIONS ON THE IN VITRO RAT HIPPOCAMPUS.
J.L. Stringer and E.W. Lothman. Department of Neurology, University of Virginia School of Medicine, Charlottesville, VA 22908.

In vivo the extracellular calcium concentration ($[Ca^{++}]_o$) is known to vary from its baseline level of 1.5 mM and in vitro brain slice studies have been done using various $[Ca^{++}]_o$. Therefore, we examined how $[Ca^{++}]_o$ affected synaptic excitability, membrane stabilization, response to paired-stimuli, and long-term potentiation (LTP) in the rat hippocampal slice. 500 µm slices were prepared and stored in an artificial CSF containing (in mM): NaCl 127, KCl 2, $MgSO_4$ 1.5, KH_2PO_4 1.1, $NaHCO_3$ 25.7, $CaCl_2$ 1.5, and glucose 10. $[Ca^{++}]_o$ was altered by perfusing slices with a solution in which only the concentration of $CaCl_2$ had been adjusted. Field potentials were recorded in the CA1 region while stimulating the Schaeffer collateral inputs.

In every slice tested, the input-output curve in 2.5 mM or 3.5 mM $[Ca^{++}]_o$ was shifted to the left of the corresponding one in 1.5 mM $[Ca^{++}]_o$. Increasing $[Ca^{++}]_o$ also reduced the tendency towards multiple spiking. Decreasing $[Ca^{++}]_o$ to 1.25 or 1.0 mM caused either no effect or a slight depressant effect on the input-output curve. Lowering $[Ca^{++}]_o$ from 1.5 to 0.75 mM led to epileptiform discharges in all slices.

Paired-pulse phenomena were studied at an interstimulus interval of 20 msec using two methods. The first method involved determining input-output curves for the population spikes in response to both the first (conditioning) and second (test) stimuli. The second method determined the threshold for action potential firing to both stimuli. The difference between the two thresholds is a sensitive and convenient measure of paired-pulse facilitation and inhibition. Using input-output curves, in 1.5 mM $[Ca^{++}]_o$ a population spike appeared in response to the test stimulus, and became maximal, before a population spike appeared in response to the conditioning stimulus, indicating facilitation. Inhibition was only seen at high stimulus intensities in 2.5 and 3.5 mM $[Ca^{++}]_o$. Only facilitation was seen using the single unit threshold method.

LTP was induced by a train of 25 stimuli (50 Hz/500 msec) at the stimulus intensity that produced a just maximal population spike. LTP was found to be very sensitive to $[Ca^{++}]_o$: maximal in 1.5 mM, absent in 1.0 mM and intermediate in 1.25 mM. LTP was present, but less prominent in $[Ca^{++}]_o$ greater than 1.5 mM. These studies show that a variety of synaptic processes are altered by changes in $[Ca^{++}]_o$ over the range in which $[Ca^{++}]_o$ varies in vivo.

88.10 HIGH CALCIUM INDUCED SPONTANEOUS ACTIVITY IN ISOLATED SPINAL CORD.
G. Czéh*, J.-C.A. Obih* and G.G. Somjen. Dept. of Physiology, Duke University Medical Center, Durham, NC 27710.

Calcium ions have multiple effects at synaptic junctions and their predominant action varies in different tissues. We exposed the spinal cords of infant mice in vitro to varying $[Ca^{2+}]_o$ levels. The mice were anesthetized with ether and their spinal cords were removed and hemisected. Dorsal and ventral root (DR and VR) responses were recorded with suction electrodes and interstitial calcium ($[Ca^{2+}]$) and focal potential (FP) was recorded in dorsal horn (DH) with ion selective microelectrodes. Control ACSF contained 3.5 mM K^+, 1.2 mM Mg^{2+}, 1.2 mM Ca^{2+}. Lowering $[Ca^{2+}]_o$ resulted in depression of the DR reflex, of the segmental VR reflex, and of slow DR potentials (DRP). Raising $[Ca^{2+}]_o$ to 1.8 mM resulted in enhanced reflex transmission. Further elevation of $[Ca^{2+}]_o$ caused selective increase of polysynaptic discharge. In some spinal cords at 2.4 mM and in all others at 3.6 mM $[Ca^{2+}]_o$ spontaneous irregularly recurring potential waves appeared, the amplitude and frequency of which increased further at 4.8 mM $[Ca^{2+}]_o$. The spontaneous waves were similar to evoked "slow" DR and VR responses and were reminiscent of paroxysmal discharges induced by penicillin in spinal cords in situ. They occurred in largest number in DR, but synchronized discharges were also frequent in VR and in FP of DH. The largest of the paroxysmal events approached in amplitude the maximal responses evoked by DR stimulation indicating high degree of synchronization among neurons. The NMDA antagonist APV (100µM) decreased the frequency and amplitude of the spontaneous discharges with little effect on synaptic transmission. After restoring normal bath $[Ca^{2+}]$, the paroxysmal discharges subsided more slowly than did tissue $[Ca^{2+}]_o$. The explanation of this type of paroxysmal activity may be that excess $[Ca^{2+}]_o$ may overload outward transport and thus gain access to cytoplasm; then inducing irregularly recurring inward current in interneurons with profusely branching terminal axon arbors, which then act as pacemakers to depolarize DR fiber terminals, resulting in primary afferent depolarization and simultaneously the release of excitatory transmitter onto postsynaptic cells including motoneurons. The slow subsidence of paroxysmal waves may indicate slow unloading of excess $[Ca^{2+}]_i$.

88.11 AFTEREFFECTS OF EXPOSURE TO VERY HIGH $[K^+]$ ON SYNAPTIC FUNCTION IN HIPPOCAMPAL TISSUE SLICES. K. Kawasaki*, G. Czéh* and G.G. Somjen (SPON: S.J. Schiff). Dept. of Physiology, Duke Univ. Med. Ctr., Durham, NC 27710.

This study explores whether Leão's spreading depression (LD) of extended duration causes lasting damage to neuronal function. Slices were cut from hippocampi of young rats and maintained in an interface chamber aerated with 95% O_2, 5% CO_2 and perfused with artificial cerebrospinal fluid (ACSF) at 36°C, containing 1.2 mM each of Ca^{2+} and Mg^{2+}, and 3.5 mM K^+, flowing at 2 ml/min. Interstitial potassium ($[K^+]_o$) and extracellular potentials evoked by stimulation of the Schaffer collateral-commissural fibers were recorded in st. radiatum and st. pyramidale of CA1 sector with ion selective microelectrodes. LD was provoked by high-$[K^+]$ ACSF (133 mM K^+) flowing from tubing positioned over the slice, at 0.6 ml/min, for periods ranging from 10 sec to several min. High $[K^+]$ exposure in excess of 25 sec reliably provoked LD, recognized by a sudden negative shift of extracellular potential and elevation of tissue $[K^+]_o$ above 20 mM. Potential and $[K^+]_o$ returned to control level after a variable time following cessation of high $[K^+]$ application. LD duration was defined as the time from onset of $[K^+]_o$ elevation until 1/2 decay of $[K^+]_o$ (return to 50% of maximal level). Synaptic recovery was tested for 60 or more min following high $[K^+]$-ACSF administration. After brief periods of LD, synaptic transmission either returned to control level, or showed hyperexcitability of CA1 pyramidal cells. Hyperexcitability was manifested by increased orthodromic population spike amplitude relative to unchanged or depressed fEPSP, and multiple population spikes evoked by single afferent volleys. After more prolonged periods of LD, synaptic transmission was impaired. In many cases synaptic transmission at first recovered from LD (with or without signs of hyperexcitability), but then failed. The amplitude of the recovered population spike (expressed as % of control, measured 60 min after high $[K^+]$ administration) was inversely correlated with the duration of LD (range 80 sec to 10 min). The results indicate that LD can cause lasting damage to synaptic function. The aftereffects of LD in well-oxygenated slices resemble those of oxygen withdrawal.

88.12 HYPOXIC DEPOLARIZATION AND LOSS OF SYNAPTIC FUNCTION IN CA1 AND DENTATE GYRUS OF HIPPOCAMPAL TISSUE SLICES. M. Balestrino and G.G. Somjen. Dept. of Physiology, Duke University Medical Center, Durham, NC 27710.

It has been reported that after transient oxygen withdrawal, synaptic transmission is more likely to recover in dentate gyrus (DG) than in CA1 sector of hippocampal tissue slices (Kass and Lipton, J. Physiol.378:313, 1986; Aitken and Schiff, Neurosci. Lett. 67:92, 1986); and that spreading depression (SD)-like hypoxic depolarization and the associated calcium loading of cells is a factor in irreversible loss of synaptic function after transient hypoxia (Balestrino and Somjen, Brain Res.385:219, 1986). We now compared the SD-like potential shifts, and the changes of extracellular calcium ($[Ca^{2+}]_o$) in CA1 and DG regions. Responses were evoked in CA1 by stimulating Schaffer-commissural fibers, and in DG by stimulating perforant path. Evoked potentials and $[Ca^{2+}]_o$ were recorded with extracellular ion selective microelectrodes. Oxygen was withdrawn from slices for variable times. In CA1, synaptic transmission was blocked sooner and tended to recover less often than in DG. During hypoxia, SD-like sustained potential shifts with associated decrease of $[Ca^{2+}]_o$ occurred in most slices in both DG and in CA1, and voltage and $[Ca^{2+}]_o$ returned to baseline upon reoxygenation. In 4 out of 19 slices, no SD-like sudden potential shift was recorded in DG, only a slow, gradual negative shift. The degree of post-hypoxic recovery of orthodromic population spike amplitude was inversely correlated with the duration of SD-like hypoxic depolarization. This correlation held for both DG and CA1, but even for equal time spent in SD, synaptic function recovered better in DG than in CA1. The magnitude of SD-related decrease of $[Ca^{2+}]_o$ was not different in DG from CA1. Addition of $CoCl_2$ (2 mM) to the bathing solution before and during hypoxia did not prevent the SD-related decrease of $[Ca^{2+}]_o$. We conclude that, even though SD-like depolarization is a factor in hypoxic neuron damage, the greater resistance of DG to hypoxia is not fully explained by a difference in susceptibility to SD-like depolarization.

88.13 PERSISTENT DECREASE IN INHIBITION AFTER RECURRENT HIPPOCAMPAL SEIZURES. J. Kapur, J.L. Stringer, E.W. Lothman. Department of Neurology, University of Virginia, Charlottesville, VA 22908.

It has been shown that GABA-mediated inhibition in the hippocampus decreases during electrically-induced seizures. Neither the duration of this alteration nor the effects of repetitive seizures on inhibition have been elucidated. These questions were examined in this study.

Adult albino rats were anesthetized with urethane. A stimulating electrode was positioned in one hippocampus and extracellular field potentials were recorded from the stratum pyramidale of the contralateral CA1. Stimuli (0.1 Hz, 0.4 msec) of increasing intensity were used to generate input-output curves for population spikes (PS). Inhibition was measured as the ratio of the amplitude of the second (test) PS to the amplitude of the first (conditioning) PS in a paired-pulse paradigm in which two equal intensity pulses were delivered at different (20-500 msec) interpulse intervals (IPI). Variation of inhibition as a function of the first PS amplitude was removed by appropriate adjustments of stimulus intensity. Input-output curves and inhibition vs. IPI curves were stable for 9 hrs.

Recurrent seizures were produced every 5 min for 6 hrs by 50 Hz, 10 sec stimulus trains of 1 msec pulses. There was a significant decrease in inhibition that persisted for 2 hrs after the last seizure (at which time the experiment was terminated). Typically there was also a rightward shift of the input-output curve. One seizure produced by delivering a single tetanus (50 Hz, 10 sec of 1 msec biphasic pulses) was followed by a decrease in inhibition 5-15 min later. The change in inhibition was smaller after the single seizure than after recurrent seizures and had returned to control values by 60 min. After a single seizure, the input-output curve was shifted to the left and remained so for at least 60 min. A less intense tetanus (50 Hz, 0.4 msec pulses for 400 msec) caused a leftward shift of the input-output curve but did not elicit a seizure and did not alter inhibition.

These results indicate that seizures cause a diminution of GABAergic inhibition in the CA1 region of the hippocampus that persists in the postictal period. After a single seizure, this diminution lasts less than an hour; after recurrent seizures, a greater diminution in inhibition persists for at least 2 hrs. The alterations in paired pulse inhibition can be dissociated from any particular change in input-output curves. We suggest that such a decrease of GABAergic inhibition may be involved in the development of various epileptic conditions such as kindling or status epilepticus.

88.14 CORRELATION OF DYE AND ELECTROTONIC COUPLING BETWEEN HIPPOCAMPAL NEURONS IN CULTURE. M. O'Beirne and B.A. MacVicar. Neuroscience Research Group, Univ. of Calgary, Calgary, Alberta, T2N 4N1, Canada

Dye coupling has been demonstrated in the in vivo hippocampus, in the hippocampal slice preparation and in dissociated culture of hippocampal neurons. Although electrotonic coupling has also been demonstrated in the slice and in tissue culture there is no study correlating the two in the hippocampus. These experiments have been designed to determine the extent of electrotonic coupling between dye-coupled hippocampal neurons in dissociated culture.

Hippocampi were removed from 18 day gestational rat fetuses and mechanically dissociated through a fire polished pasteur pipette. The cells were plated on polylysine coated glass coverslips and grown in DMEM + 10% HS at 37°C for up to 4 weeks. Neurons were impaled with glass microelectrodes filled with 5-carboxyfluoroscene (5-CFL). During the injection of 5-CFL, neurons were observed using a SIT video camera so that a low intensity of illumination could be used to visualize the fluorescent dye. If the cell was dye coupled to another, the second stained cell was simultaneously impaled with a microelectrode filled with 0.15 M KCL.

In 3/3 cases where neurons were dye coupled, the cells were also electrotonically coupled (with coupling ratios of .1, .2, .7). When released extracellularly into the dish, dye was never picked up by cells. Staining was observed only if dye was injected with current into the impaled cell. Stained cells quickly lost dye when damaged and mechanical movement of single stained cells did not cause artifactual dye coupling. Electrotonic coupling was never observed between non dye coupled cells. Stable recordings were obtained from neurons as long as the epifluorescence illumination was of low intensity. When the intensity was increased, action potentials broadened and neurites beaded and released dye. These events did not induce either dye or electrotonic coupling. These experiments demonstrate that dye-coupling indicates the presence of electrotonic coupling. Supported by MRC of Canada, AHFMR, and the Sloan Foundation.

88.15 COMPARATIVE SENSITIVITY ANALYSIS OF PARAMETERS FOR SYNAPTIC INPUT-OUTPUT FUNCTION

*J. L. Winslow** (SPON: W. MacKay) Dept. of Mathematics, U. of Toronto, Toronto, Ont. M5S1A8

For synapses, various structural and functional changes have been postulated or correlated with memory mechanisms. When a synapse is viewed as a sequence of signal processing steps, it can be described as a dynamic system with time functions. Using a computational model which describes presynaptic terminal shape, transmitter release, postsynaptic receptor site, and the cable equation for dendritic spines, a comparison of parameters is made as to their net result on postsynaptic response potential. Due to the nonlinear functions, the resultant equations are solved numerically.

With repeated use of a synapse, structural changes have been reported in the literature which correspond to parameters changes in the geometry on which the signals are carried. These changes may be the underlying mechanisms of memory. Initial calculations show that an increase in the number of postsynaptic receptor sites (hence maximum available postsynaptic conductance) and an increase in transmitter synthesis rate are more influential than volume changes of pre or postsynatic regions. Rate of change of transmitter release rate versus rate of growth of receptor sites determine which has more influence on overall synaptic transmission.

AUDITORY SYSTEM II

89.1 THE EFFECTS OF 8TH NERVE TRANSECTION ON THE NEURONAL AREA OF NUCLEUS MAGNOCELLULARIS IN THE RED-EARED TURTLE, CHRYSEMYS SCRIPTA ELEGANS. R.H. BROWNER, M. NIRENBERG AND B. WACHTEL. Dept. of Anatomy, New York Medical College, Valhalla, N.Y. 10595.

Turtles were anesthetized with sodium brevital (0.7mg/Kg) and placed on stereotaxic apparatus with continued anesthetized by a combination of oxygen (200ml/min), nitrous oxide (150ml/min), and halothane (1%) through a gas anesthesia machine. The skin and temporal muscle were removed by cauterization and the temporal bone over the ear was drilled away to expose the inner ear and 8th nerve. Under an operating microscope the right 8th nerve was cut with a fine micro-scissors with minimal disruption of the local blood supply. The wound was irrigated with thrombin and the bony opening was closed with dental cement. The area over the cement cap was filled with gelfoam and the skin closed with wound clips and dental cement. Three groups of turtles were allowed to survive along with a control group. They were 30,40, and 183 postoperative. Each group had 3 animals. At the appropriate survival time the animals were overdosed with nembutal and the animals were transcardically perfused first with Reptilian Ringers and then with Susa fixative without mercuric chloride. The brains were dehydrated in ethanol, cleared in benzene and embedded in Paraplast Plus. Serial transverse sections were made at 15um intervals through the brain stem. The sections were stained with Gallocyanin and coverslipped with Permount. Individual cell areas and perimeters were ,easired on a F. Haer Morphometry System. Individual cell areas was measured for the nucleus magnocellularis on every 4th section. The means derived from those values were used to estimate the variance of the neuronal area of the cell in the nucleus. The population variance was determined from differences among individual means of the cells with the F distribution using a one way analysis of variance. Based on these results an error term was obtained and used in a posthoc comparison according to the Neuman Keuls method. Data indicated significant differences between control, 30 and 40 day survivors; 183 and 30 and 40; 30 day and all groups; and 40 day and all groups. Control and 183 survivors had not significant differences. There was a decrease in mean neuronal area between 30 (203uM^2) and 40 (169.7uM^2) day survivors with a continued increase in 183 (219.4uM^2) day almost to control (227.9uM^2) levels. The numbers of neurons in the nucleus magnocellularis were compared between control and the different survival groups and there were no significant differences.

89.2 EVOKED AUDITORY RESPONSE ACTIVITY OF *HYLA GRATIOSA* - COMPARISON WITH OTHER ANURAN SPECIES AND REGULATING FACTORS. K.M. Mudry. Department of Biomedical Engineering, The Univ. Akron, Akron, OH 44325.

At an evoked potential level the central nucleus of the posterior dorsal thalamus in frogs has response characteristics that implicate this area in the processing of behaviorally important components of species-specific sounds. The response properties of *Hyla gratiosa*, the barking treefrog, were recently studied. A pronounced nonlinear facilitation to combination tones of 300 + 2000 Hz was found. When corrected for temperature effects, this spectral combination agrees with the frequencies required by the animal to detect its species-specific sounds.

Including this new species, three species of frogs, namely, *Hyla gratiosa, Hyla cinerea,* and *Rana catesbeiana* ,with known acoustic behavioral responses and whose calls and recognition of these calls involve the detection of a bimodal spectrum have now been studied. The thalamic evoked response characteristics of each species is distinct and is closely correlated to the spectral characteristics of each of the species' calls. Specific combination tones of 300 + 2000 Hz, 500 + 3000 Hz and both 200 + 1200 Hz and 600 + 1200 Hz produce good facilitation in respectively, *Hyla gratiosa, Hyla cinerea* and *Rana catesbeiana.* An inhibitory effect of a third tone with a frequency between the two facilitatory tones is found in both *H. gratiosa* and *H. cinerea.* A dependence on rise time of the stimulus has been found with *R. catesbeiana* showing a maximal response to sounds with slow onsets and the hylid species to sounds with rapid onsets. A good response to single tones only occurs at high stimulus levels. The facilitation found in the thalamic area is not found in the VIIIth nerve whole nerve response and in the torus semicircularis, the midbrain auditory area.

The responses in the thalamic area are very difficult to study because of non-auditory influences on this center. The area exhibits a long refractory period and the temperature of the animal affects the two-tone tuning and sensitivity. In some animals no evoked potentials can be recorded from this region. The reproductive state is also likely to influence the responses of this center.

This work was supported by NIH and U. Akron Faculty Research Grants.

89.3 NEURAL BASIS OF TEMPORAL PATTERN RECOGNITION IN THE FROG'S AUDITORY SYSTEM. J. C. Hall* and A. S. Feng. Dept. of Physiology and Biophysics, Univ. of Illinois, Urbana, IL 61801.

The spectral content and temporal pattern of frog mating calls are essential features for species recognition. The role of the frog's auditory system in the analysis and recognition of these signals in the frequency domain has been systematically studied. In contrast, only a few studies have addressed issues concerning the neural mechanisms which mediate temporal pattern recognition in frogs. To gain further insights into these processes we have chosen to systematically examine the neural basis of temporal pattern recognition in the auditory system of the northern leopard frog, Rana pipiens pipiens.

Single unit recordings were made to determine the response patterns of neurons at three different loci within the frog's auditory pathway; the 8th nerve, dorsal medullary nucleus (DMN) and central thalamic nucleus (CTN). Our results demonstrate an increasing selectivity for the temporal parameters (pulse repetition rate, pulse duration, pulse rise-fall time) of complex acoustic signals as one ascends the auditory pathway. Units of the 8th nerve and most of those in the DMN behave as envelope detectors, i.e., the stimulus envelope is accurately reflected in their discharge patterns. However, a few (<10%) DMN neurons behave as low-pass temporal filters with respect to pulse repetition rate or rise-fall time. All 8th nerve and DMN units show V-shaped frequency tuning curves and are narrowly tuned. In contrast, CTN neurons show broad frequency tuning but are highly selective for the temporal components of acoustic stimuli (pulse repetition rate and pulse duration). They do not reproduce variations in stimulus envelope, but respond with changes in firing rate. Low-, high-, and band-pass as well as band-suppression properties are evidenced. These neurons are probably important components of a pattern recognition system operating in the time domain.

Using both natural and synthetic stimuli it is clear that neural responses at lower levels are determined primarily by stimulus frequency rather than temporal features. At higher levels, such as the CTN, the converse is true.

89.4 DETERMINATION OF AUDITORY AND FREQUENCY DISCRIMINATION THRESHOLDS IN A FROG, XENOPUS LAEVIS, BY CONDITIONING. E.Günther*, B.Traub*, A.Elepfandt (SPON: H.Leppelsack). Dept Biol, Univ Konstanz, D-7750 Konstanz, FRG.

The study of the amphibian auditory system suffers from inability to test the animals' auditory capabilities with psychophysical methods: attempts of auditory conditioning in amphibians have failed so far. Recently one of us conditioned the aquatic clawed frog, Xenopus laevis, to discriminate between water waves (A.Elepfandt, Naturwissenschaften 72,492,1985). Using that paradigm, we succeeded to induce tone-discriminations in X.laevis, and present here the first psychophysically determined auditory threshold of a frog. In addition, we give initial data on the frog's frequency discrimination. Since Xenopus is purely aquatic, these data refer to underwater sound.

At or closely below water surface, Xenopus spontaneously responds to an impinging water wave by turning toward the wave origin. We trained the frogs to discriminate between stimulus waves that were or were not paired with a tone or, in the case of frequency discrimination, that were paired with tones of different frequency. The paradigm was go/no-go conditioning: responses to the one stimulus were rewarded by feeding the frog a small cricket, responses to the other were punished by a stroke with forceps on the animal's head. Nearly all animals learned the discrimination, about half of them within five sessions of 80 stimuli. Whenever discrimination was significant, the stimulus difference was reduced and testing continued until the threshold was attained.

The hearing range of the animals was 200-3600 Hz. In this range the threshold was relatively flat except that at 1000-1400 Hz it was lower by 15 dB. Interindividual differences were less than 5 dB.

Two types of frequency discrimination were compared at 1 kHz: in continuous-tone discrimination each wave was paired with a monofrequent tone of 3 s duration (interstimulus intervals were 1-5 min), in pulse-tone discrimination the tones consisted of 6 pulses with alternating or constant frequency. Surprisingly, there was no difference between these discriminations, neither in the speed of learning nor in the discrimination limen. On the other hand, their limen of 0.4 was considerably higher than known from other vertebrate classes.

89.5 STIMULUS PARAMETER ENCODING IS EQUAL IN LATERAL LINE AND IN LOW-FREQUENCY AUDITORY AFFERENT FIBERS OF VERTEBRATES. L.Wiedemer*, A.Elepfandt (SPON: E.Liske). Dept Biol, Univ Konstanz, D-7750 Konstanz, FRG.

Our recordings of afferent lateral line responses in the clawed frog, Xenopus laevis, to water waves revealed intriguing similarities of stimulus encoding to that in vertebrate low-frequency auditory afferents.

Two types of stimulus encoding were found: discharge modulation and firing rate. Low intensities are encoded by the degree of phase locking. It increases linearly with the logarithm of stimulus amplitude, the slope does not depend on wave frequency. Response phase is independent of stimulus intensity. From some intensity firing is completely suppressed for an increasing section of the wave cycle. Phase locking saturates at about 30 dB above threshold with vector strengths of 0.75-0.90. At high intensities response peaks get slightly skewed with the leading edge rising faster than the trailing edge falls.

20-30 dB above the threshold for phase locking, the mean firing rate begins to rise. Like in phase locking, the increase is a linear function of stimulus logarithm and the slope is independent of stimulus frequency. Further, sensitivity is positively correlated with the resting discharge rate, and the slope of the rate-intensity function is less when the threshold is higher.

This matches the response behavior of low-frequency auditory units below their characteristic frequency as described for mammals, birds and other vertebrates. There exists strong evidence that the mechano-electrical transduction is equal for all vertebrate sensory hair cells. The present data suggests that also the subsequent transformation to afferent discharge rates is done according to common mechanisms.

Alternatively to the mean firing rate, we determined the firing rate during the excitatory phase of the response cycle. This allowed to replace the two only partially overlapping codes, phase locking and mean firing rate, by one uniform code that over the whole intensity range follows Weber's law. We suggest that the same would be possible for auditory afferent encoding.

89.6 WAVE LOCALIZATION WITH LATERAL LINE: ORGANIZATION OF LEMNISCAL INPUT TO THE MIDBRAIN IN THE CLAWED FROG, XENOPUS LAEVIS. A.Elepfandt. Dept Biol, Univ Konstanz, D-7750 Konstanz, FRG.

The purely aquatic frog Xenopus can, by means of its lateral lines, detect the direction of impinging water waves. It responds to them by turning toward the wave origin. Previous investigation had shown peripheral redundancy of wave localization: many subsets of the lateral line organs, e.g. the organs of one side, are sufficient to allow the animal accurate localization of waves from any direction (A.Elepfandt, J Comp Physiol 148,535,1982). In the midbrain, however, a topology and lateralization was found: each midbrain side is responsible for localization of contralateral waves (A.Elepfandt, Brain Behav Evol, in press). The present investigation is concerned with the organization of the input ascending to the midbrain through the lateral lemniscus. The method is behavioral testing for detection of wave directions after unilateral lateral lemniscus dissection at isthmic level.

After that dissection, the frogs can still localize waves from any direction. Thus, lateral line input from either lateral lemniscus is conveyed not only to the ipsilateral but also the contralateral midbrain. A bilateral lateral-line connection above the level of the medulla was not known as yet. Wave localization was not impaired when the lemniscus dissection was combined with an ipsilateral hemisection between di- and mesencephalon. Thus, such a bilateral connection must exist at midbrain level, and this connection is sufficient to enable detection of all wave directions on the basis of input from only one lateral lemniscus.

When the lemniscus dissection was combined with unilateral destruction of the lateral line organs, all wave directions still could be detected, irrespective of whether deafferentation was made ipsi- or contralaterally of the dissected lemniscus. Thus, the duplicity described above for the lemniscal level is duplicated once more: not only is the input through either lemniscus sufficient for the detection of any wave direction, but even the input from the organs of either side through either lemniscus.

89.7 INDEPENDENT MAPS OF INTERAURAL TIME AND INTENSITY DIFFERENCES IN THE OPTIC TECTUM OF THE BARN OWL. J.F. Olsen* and E.I. Knudsen. (SPON: U.J. McMahan). Department of Neurobiology, Stanford Univ. School of Medicine, Stanford, CA 94305.

Neurons in the optic tectum of the barn owl respond to sounds from restricted areas of space, and form a map of azimuth and elevation. We investigated the binaural basis of the auditory space map. We compared the tuning of single units to the location of free-field noise with their tuning to interaural time (Δt) and interaural intensity differences (ΔI) of digitally controlled noise presented through earphones. Our sample consists of 63 units from 5 owls. Best azimuths ranged from 60° contralateral to 15° ipsilateral, and best elevations ranged from 70° up to 40° down. Most units responded only when Δt was within 50 microsec of the best Δt and when ΔI was within 20 dB of the best ΔI. Within these ranges, the best Δt was not altered by changes in ΔI, and vice versa. Varying stimulus level over a 20-40 dB range did not affect the best Δt, although, for most units, increases in level caused the best ΔI to increase in favor of the dominant ear. None of the units responded to monaural stimulation. Best azimuth varied with the anteroposterior location of the recording site and was strongly correlated with the best Δt ($r = 0.89$ to 0.96, depending on stimulus level; Fig. 1), but only weakly correlated with ΔI ($r = 0.14$ to 0.36). Conversely, the best elevation varied with the dorsoventral location of the recording site and was a function of ΔI (Fig. 2), but weakly correlated with the best Δt ($r = 0.55$ to 0.66). The data indicate that the auditory map of space is created primarily by the integration of two independently mapped acoustic parameters.

89.8 FLOW OF INFORMATION IN THE NETWORK THAT COMPUTES AZIMUTH IN THE BARN OWL. H. Wagner, T. Takahashi and M. Konishi. Div. Biology, 216-76, California Institute of Technology, Pasadena, CA 91125.

The central nucleus of the barn owl's inferior colliculus (ICc) is a major source of afferents to the neural map of contralateral space found in the external nucleus of the inferior colliculus (ICx). ICc itself consists of a centrally located "core," defined by the terminal field of nucleus laminaris (NL), surrounded by a "shell," defined, in turn, by the terminal field of nucleus angularis (NA). Interaural time difference (ITD), the binaural cue for the location of a sound source along the horizontal axis, azimuth, is systematically represented in ICc. ITDs corresponding to loci in the ipsilateral hemi-field are represented in the core, and ITDs corresponding to loci in the contralateral hemi-field are represented in the lateral portion of the shell. The representation of ipsilateral space in the core is simply explained. NL of the left, for example, which represents predominantly the right, or contralateral hemi-field, projects contralaterally thereby conferring upon the core of the right ICc selectivity for right or ipsilateral space. NA does not contain cells sensitive to ITD. How then, does the lateral shell acquire selectivity for ITDs corresponding to loci in the contralateral hemi-field?

Small quantities of horseradish peroxidase were iontophoresed into the lateral shell under guidance of extracellular recordings (four cases), and the distribution of retrogradely labeled somata was assessed by the tetramethyl benzidine method. Ipsilateral to the injection site, retrogradely labeled somata were scattered throughout ICc, with the greatest density occurring in the immediate vicinity of the injection site. The functional significance of this labeling pattern is difficult to interpret. Interestingly, however, contralateral to the injection, retrogradely labeled somata were concentrated in the core of ICc. This suggests that the core of the right ICc, for example, which contains a representation of right or ipsilateral space, projects to the lateral shell of the left ICc, thus presenting to it a representation of right or contralateral space. Finally, from the lateral shell, the representation of contralateral space is transmitted to the ipsilateral ICx.

89.9 BINAURAL PROPERTIES OF AUDITORY NEURONS IN THE GRANULE CELL LAYER OF THE POSTERIOR CEREBELLAR VERMIS IN THE CAT. C. Huang. Division of Structural and Systems Biology, School of Basic Life Sciences. University of Missouri-Kansas City, Kansas City, MO 64110.

There is an auditory area in the posterior cerebellar vermis. Within this area, neurons in the granule cell layer are sensitive to differences in sound intensity at the two ears. When the sound intensity at one ear was fixed, and that at the other ear was gradually increased, the response of a given neuron may increase, decrease, or show no change. Moreover, all three types of response pattern may be demonstrated in the same neuron depending upon the level of sound intensity at the other ear. The dynamic range of a given neuron ranged from narrow (10-20 dB) to wide (70-80 dB). The sound intensity at one ear strongly influenced its dynamic range for the other ear. By systematically varying the sound intensities at the two ears, it can be shown that a given auditory neuron in the cerebellum was most sensitive to a certain combination of binaural intensities but not to others. The limited excitation by binaural sound seems to code the direction of sound source in space. Three major types of neurons can be identified based on their binaural properties. Neurons located in the lateral part of a folium were more likely to be excited by sound from the contralateral ear. At the same time, these neurons were often inhibited by sound from the ipsilateral ear. Neurons located in the medial part of a folium were best excited by sound combinations in which the intensities at the two ears were equal or nearly equal. The third type of neuron generally showed a more complex binaural behavior and may actually contain several sub-types. Thus, neurons in the cerebellar auditory area were sensitive to the interaural intensity difference; as a collection of neurons, they were organized topographically according to their binaural properties. (Supported in part by NIH, ONR, MRAA, and the Lettie B. McIlvain Frederic Fund.)

89.10 RESPONSES OF CELLS IN THE INFERIOR COLLICULUS OF THE CAT TO INTERAURAL TIME DIFFERENCES OF CLICKS: COMPARISON WITH NOISE AND TONES AND AN ANALYSIS OF EXCITATORY AND INHIBITORY COMPONENTS. L.H. CARNEY* and T.C.T. YIN, Dept. of Neurophysiology, University of Wisconsin-Madison, Madison, WI 53706.

We have recorded responses of low-frequency cells in the central nucleus of the inferior colliculus (ICC) of the cat to 100 usec clicks presented binaurally with interaural time differences (ITDs). Previous work has characterized the cyclic properties of discharge rate vs. ITD in response to tones and wideband noise. Since low-frequency auditory nerve fibers have periodic responses to clicks as well as to tones and noise, we hypothesized that the responses to ITDs of these three sets of stimuli should be similar. For some cells in the ICC this prediction was confirmed, as the main features of the ITD curves for clicks agree with those measured in response to noise and tones. However, some cells that showed sensitivity to ITDs of tones and noise did not to clicks. Furthermore, unlike responses to noise and tones, the dynamic range of ITD sensitivity to clicks is often quite narrow, usually about 10-20 dB. This appears to be due to the fact that the responses to single clicks, either monaural or binaural, are no more than 2-3 spikes.

Click responses provide an interesting opportunity to study binaural interaction since one can attribute individual spikes to binaural facilitation, ipsilateral excitation or contralateral excitation based on monaural response properties. Thus, when studying responses to binaural clicks, it is possible to monitor the excitatory and inhibitory components of both inputs as ITD is varied. By changing the relative levels of the binaural inputs, we have been able to examine the laterality, strength, and time course of the various excitatory and inhibitory influences from each side. There is evidence for an early, short-lasting (usually < 1 msec) inhibition, followed by excitation, which is in turn followed by a late, long-lasting (from 2 to 50 msec or more) inhibition. These components may be present in both ipsilateral and contralateral inputs, and they vary in strength and duration from cell to cell. One effect of the early inhibition is to limit the range of ITDs, near 0 ITD, which produce facilitation or excitation, thereby keeping the central peak within the cat's physiological range of ITDs. The late, long duration inhibition following excitation is consistent with intracellular records of click responses (Nelson and Erulkar, 1963).

89.11 A COMPARISON OF INTERAURAL TIME SENSITIVITY OF NEURONS IN THE MEDIAL GENICULATE AND INFERIOR COLLICULUS OF THE UNANESTHETIZED RABBIT. T. R. Stanford*, R. Batra, and S. Kuwada. Dept. of Anat., Univ. of Connecticut Health Ctr., Farmington, CT 06032.

Low-frequency sounds are localized along the azimuth using the difference in the time of arrival of the sound at the two ears. Neurons in the binaural pathways respond preferentially to a particular range of interaural time differences (ITD's) reflecting their sensitivity to a range of azimuthal sound locations. The range of ITD's to which a cell is sensitive appears to decrease from the superior olive to the inferior colliculus (IC). We report here that low-frequency neurons in the medial geniculate body (MGB) of the unanesthetized rabbit are tuned to an even more restricted range of ITD's than neurons in the IC. Consequently, azimuthal sensitivity may be sharpened as binaural information progresses up the auditory pathway.

The rabbit was placed in a body stocking and its head immobilized by clamping to a bar fixed to its skull. Lidocaine was applied to the dura and a Pt-Ir electrode was lowered through a small hole in the skull. Acoustic stimuli were delivered dichotically through custom-fitted earmolds. Recordings were made from either single neurons or from small groups of neurons.

For each unit, interaural phase sensitivity was assessed at several frequencies. Interaural phase was continuously varied by delivering tones that differed by 1 Hz to the two ears. For all frequencies to which the neuron was sensitive to interaural phase, the response was plotted as a function of the equivalent ITD. At each frequency, one cycle on either side of zero was plotted to represent both ipsi and contralateral delays. These interaural delay curves were averaged to yield a composite curve. Using a parabolic fit to the upper 30% of the composite curve, the peak delay and the width of the composite curve were estimated. The peak delay corresponds to the point in space to which the neuron is maximally sensitive whereas the peak width reflects the sharpness of its azimuthal tuning.

Neurons in the MGB of the unanesthetized rabbit demonstrate a sensitivity to ITD that is qualitatively similar to that of cells in the IC. Neurons of both nuclei respond preferentially over a restricted range of ITD's. However, it appears that the widths of the composite peaks are on the average 30% narrower for neurons in the MGB. This implies that neurons in the MGB are tuned to a more restricted range of azimuths than those in the IC and supports the hypothesis that azimuthal tuning becomes progressively sharper at higher levels of the auditory system.

89.12 MONAURAL AND BINAURAL RESPONSES OF NEURONS IN THE RABBIT INFERIOR COLLICULUS: EFFECTS OF BARBITURATE ANESTHESIA. S. Kuwada, R. Batra, and T. R. Stanford*. Dept. of Anatomy, Univ.of Connecticut Health Center, Farmington, CT 06032.

Most neurophysiological studies of the auditory system have used barbiturate anesthesia. However, barbiturates are known to have a potent depressive action in the CNS, presumably through the potentiation of inhibitory GABAergic mechanisms. Furthermore, GABAergic cells have been observed in the inferior colliculus. Does barbiturate anesthesia affect the responses of neurons in the inferior colliculus? We have answered this question directly by testing the same neuron before and after the i.v. administration of sodium pentobarbital.

Rabbits were surgically prepared for recording under general anesthesia. A catheter was inserted into the external jugular vein to permit later infusion of barbiturate. A stainless steel rod was cemented to the skull and a small hole was drilled for entry of the electrode. The hole was capped with silastic and the animal was allowed to recover for several days. During recording, the rabbit was placed in a stocking and its head immobilized by clamping the steel rod. The silastic was removed, dura swabbed with lidocaine, and a Pt-Ir electrode was lowered using approximate stereotaxic coordinates. Sounds were delivered dichotically via custom-fitted earmolds.

At the start of the recording session, the rabbit was unanesthetized. Upon isolating a neuron, we measured the responses to monaural tone bursts at or near the neuron's best frequency. If the cell was tuned to low frequencies (<2000 Hz), we also assessed its sensitivity to interaural time differences using a binaural beat stimulus. We then injected sodium pentobarbital (10-25 mg/kg) through the catheter and repeated these characterizations. If time permitted, we injected supplemental doses to mimic procedures used in acute experiments employing anesthesia.

In most cases, anesthesia altered spontaneous activity, response rate, response latency, and discharge pattern. We have observed response latencies lengthening by tens of milliseconds, and monaural response patterns changing from sustained to onset, sustained to pauser, and build-up to pauser, among others. Sensitivity to interaural time differences was also changed. Barbiturate anesthesia often reduced the frequency range over which ITD sensitivity was observed, and measures such as the characteristic delay, characteristic phase, and composite delay were also altered.

This work was supported by NIH grant NS18027 to S. Kuwada.

89.13 THE FREQUENCY OF "OVER-REPRESENTATION" IN THE MUSTACHED BAT INFERIOR COLLICULUS. R.F. Huffman, D.C. Fitzpatrick*, A.W. Keating, Jr.* and O.W. Henson, Jr.* Curriculum in Neurobiology and Dept. of Anatomy, Univ. of North Carolina, Chapel Hill, NC, 27514.

The inner ear of the mustached bat (Pteronotus p. parnellii) resonates near a frequency of 61 kHz in response to echolocation signals. Large populations of neurons throughout the auditory system are sharply tuned near this frequency, resulting in an "over-representation" of 61 kHz within the CNS. A question of interest is the exact relationship of this over-represented frequency to the resonance frequency and to the resting frequency (the frequency which the bat emits while stationary).

For each bat studied the resting frequency was determined prior to surgery. The resonance frequency (RF) of the cochlea and best frequencies of single- and multi-units in the inferior colliculus (IC) were obtained from fully awake animals at least three days following surgery, and repeated for each bat over several days. The RF was obtained by FFT spectral analysis of cochlear microphonic potentials. Using glass microelectrodes, orthogonal and oblique penetrations were made in the IC. The best frequencies of units in the dorsal posterior division (DPD) of the central nucleus of the IC (Zook, et al., 1985, J. Comp. Neurol. 231:530) were determined with an accuracy of ± 25 Hz using an automated computer program.

To date, two bats have been studied. In one bat the RF was 63.47 kHz and the resting frequency was 63.11 kHz. Four penetrations into the DPD yielded 53 sharply tuned units with best frequencies within ± 300 Hz of the RF: 70% of these had best frequencies 100-300 Hz below the RF; 26% were tuned within 100 Hz of the RF; and 4% were tuned 100-300 Hz above the RF. The second bat had a RF of 61.55 kHz and a resting frequency of 61.49 kHz. Five penetrations yielded 61 units of which 28% were tuned 100-300 Hz below the RF; 51% were within 100 Hz of the RF; and 21% were tuned 100-300 Hz above the RF. Thus, one bat whose resting frequency was well below its RF had most units tuned below the RF; while the other bat whose resting frequency and RF were similar had the majority of units tuned near the RF. In both cases many units were tuned to a frequency other than the RF.

These preliminary results indicate that DPD neurons have best frequencies which are distributed within a range that encompasses both the RF and the resting frequency. Although emitted pulses and echoes cause the bat's ear to resonate, only a fraction of the neurons in the DPD appear to be maximally responsive to the resonance frequency. More animals are being studied to determine the range of variation among the resonance frequency, resting frequency and the frequency of over-representation within the IC. (Supported by NIH grant NS 12445)

89.14 MAJOR OUTPUTS OF THE FM_2 REGION OF THE MUSTACHED BAT INFERIOR COLLICULUS GO TO MEDIAL AND DORSAL DIVISIONS OF THE MEDIAL GENICULATE BODY. M.L. Zettel, W.E. O'Neill, and R.D. Frisina. Dept. of Physiology, Univ. of Rochester Sch. of Med. and Dent., Rochester, NY 14642.

The FM components of the multi-harmonic CF/FM mustached bat sonar cry carry target range information which is processed by delay-tuned neurons in the auditory cortex and medial geniculate body (MGB). A subpopulation of these units encodes time delays between the FM_1 and FM_2 components of the sonar pulse and the echo, respectively. HRP injections restricted to the physiologically-defined region representing FM_2 frequencies of the central nucleus of the inferior colliculus (ICC) revealed connections which are generally similar to the pattern seen in other mammals, except for the MGB.

Anterograde projections were examined in TMB- and DAB-stained sections from 5 bats. Aside from the MGB there were two major ipsilateral projection zones: the deep layers of the superior colliculus (SC) and the dorsal and ventral lateral pontine nuclei (LPN). The projections to SC course through the brachium of the IC (BIC) to merge with the brachium of the SC, within which small, simple, en passant endings are made by delicate fibers onto many cells. Fibers also ramify dorsally in the SC itself. Endings in LPN are dense and more complex than those in SC, and convergence is evident on individual cells. Minor projections can be seen entering the dorsal periaqueductal gray, ending in small clusters, usually ipsilateral to the injection.

Most intriguing were the projections to the MGB. Large numbers of labeled fibers travel ipsilaterally in the BIC and enter the MGB medially in a tract elongated dorsomedial-ventrolaterally. Large, complex endings occur on clusters of cells within the BIC as it courses through the medial division. Large numbers of fibers entering the dorsal division branch off laterally from the BIC to form complex endings onto many cells in rostral MGB. In DAB sections, individual fibers divide into several branches which terminate onto widely separated clusters of cells within the dorsal division.

In stark contrast to the pattern seen in other mammals where the ventral division receives the heaviest projection from the ICC, in the mustached bat few fibers were seen to enter this area, and no endings were visible. This suggests that the ventral division has a significant gap in its tonotopic axis for the FM_2 frequency band, the pathway for which is diverted to the dorsal and medial divisions where FM_1-FM_2 delay-tuned neurons are found (Olsen & Suga, SNS Abstr. 225.13, 1983). A lack of FM_2 representation in the ventral division may explain the lack of FM_2 representation in the tonotopic region of primary auditory cortex of this species. Supported by NSF grant BNS 8311627 to WEO and NIH-NRSA NS07343 to RDF.

89.15 ANATOMY OF THE MUSTACHED BAT'S MEDIAL GENICULATE BODY: CYTOARCHITECTONICS, NEURONAL ARCHITECTURE, AND GAD-IMMUNOREACTIVITY. Jeffery A. Winer and Jeffrey J. Wenstrup. Department of Physiology-Anatomy, University of California, Berkeley, California 94720.

As part of a study of the functional relations between the inferior colliculus and the medial geniculate body in the bat (*Pteronotus parnellii*), we classified thalamic auditory neurons in Golgi and Nissl preparations, and compared the architectonic scheme with the patterns of glutamic acid decarboxylase (GAD) or gamma-aminobutyric acid (GABA) immunoreactivity. We wished to provide an anatomical framework for parallel physiological experiments on midbrain afferents to medial geniculate subdivisions (J.J. Wenstrup and J.A. Winer, *Proc. Soc. Neurosci.*, 1987, **13**: in press), and to consider the organization of the mustached bat's medial geniculate body within the context of comparative neuroanatomy.

As in most species, three primary parts of the medial geniculate complex were recognized. The *ventral division* filled much of the ventrolateral two-thirds of the medial geniculate body. It contained medium-sized neurons (~10 μm in diameter) whose dendrites formed richly branched tufts which ran in long, parallel strips. Single dendritic tufts often ran parallel to the preterminal segments of midbrain afferents. In the *dorsal division*, which filled the superficial and caudal parts of the auditory thalamus, neurons with radiating dendrites and cells with tufted branches occurred. The former were numerous and had spherical dendritic fields and moderate numbers of branches, while the latter were bushier and common in the superficial dorsal nucleus. The *medial division* formed the medial limb of the auditory thalamus and had a heterogeneous neural population, including small (<10 μm), medium sized (10-12 μm), and large (>12 μm) neurons with radiating or weakly tufted dendrites. In each division, small neurons with thin, sparse dendrites were impregnated.

The distribution of GAD-immunoreactive puncta supported this architectonic parcellation. Thus, ventral division puncta were numerous and fine; their disposition confirmed the architectonic borders discerned in Nissl preparations. Puncta in the dorsal division were extremely small and few in number. Medial division puncta were much larger and coarser than in other medial geniculate divisions, and as plentiful as ventral division puncta. Few medial geniculate neurons were immunoreactive for GAD or GABA, even in sections where the superior colliculus or extrathalamic nuclei contained many such cells.

We conclude that three primary medial geniculate divisions exist in the mustached bat, each with a characteristic neuronal architecture and pattern of GABAergic innervation. These divisions are readily comparable to those in other mammals, with some important differences, especially in the relative reduction of the neuropil and the large size of the ventral division. The divisions are also distinguished by their differential input from funtionally defined inferior colliculus subdivisions, suggesting that even finer physiological and architectonic subregions might exist within the auditory thalamus.

This research was supported by USPHS grants R01 NS16832 to J.A.W. and F32 NS07733 to J.J.W. We gratefully acknowledge the GAD antiserum and generous advice of Drs. D.E. Schmechel and E. Mugnaini, and we thank D. Larue, T. McShane, and J. Popowits for technical assistance.

89.16 PROJECTIONS TO THE MEDIAL GENICULATE BODY FROM PHYSIOLOGICALLY DEFINED FREQUENCY REPRESENTATIONS OF THE MUSTACHED BAT'S INFERIOR COLLICULUS.
Jeffrey J. Wenstrup and Jeffery A. Winer. Department of Physiology-Anatomy, University of California, Berkeley, California 94720.

The projections of different frequency representations from the inferior colliculus to the medial geniculate body were examined in the mustached bat, *Pteronotus parnellii*. A goal of these experiments was to contribute to our study of the functional organization of the mustached bat's auditory thalamus. We placed small, iontophoretic deposits of HRP in regions of the inferior colliculus that were physiologically characterized by their best frequencies and sharpness of tuning. Axons and their terminals were visualized in alternate sections with either heavy metal-intensified DAB or TMB as chromogens.

Our preliminary observations showed that the projections of restricted frequency bands from the central nucleus of the inferior colliculus (ICC) to the auditory thalamus were divergent (*cf.* J.A. Winer and J.J. Wenstrup, *Proc. Soc. Neurosci.*, 1987, **13**: in press, for thalamic subdivisions). Low frequency ICC deposits, centered in regions with best frequencies between 30-35 kHz, produced a dorso-ventral crescent of labeled terminals in the lateral part of the *ventral division*. However, discontinuous groups of terminals were present in the medial part of the *ventral division*. HRP placed in the enlarged 60 kHz representation of the ICC produced heavy terminal labeling of the middle part of the *ventral division*. HRP deposits in the high frequency representation of ICC, centered at best frequencies between 91-96 kHz, labeled the medial and dorsal parts of the *ventral division*. These deposits resulted in tonotopic, retrograde labeling within the cochlear nuclei, the medial and lateral superior olives, and the nuclei of the lateral lemniscus. Deposits of HRP placed in the ICC often labeled other thalamic divisions as well. Thus, deposits centered near 30 kHz, 60 kHz, and 90 kHz each labeled axonal terminals in the *medial* and *dorsal divisions*. It is unlikely that these divergent projections resulted from damage to fibers passing through the midbrain deposit sites.

Axons from the brachium of the inferior colliculus, ranging from <1 μm to about 3 μm in diameter, entered the medial geniculate body dorsomedially. Viewed in the DAB material, their terminal ramifications were highly varied, ranging from extremely fine, widspread boutons, to axonal varicosities with irregular configurations, to dense clusters of coarse terminals.

These results, and those from our cytoarchitectonic studies, suggest that the mustached bat's medial geniculate body contains elements in common with other mammals (*e.g.*, the primary cytoarchitectonic subdivisions), and certain unique features (*e.g.*, the divergent terminal fields of the 30 kHz projection in the *ventral division*). This pattern of ICC projections to the medial geniculate body could underly the responses of some thalamic cells to combinations of frequencies in the mustached bat's sonar call (J.F. Olsen and N. Suga, *Proc. Soc. Neurosci.*, 1983, **9**:768).

This research was supported by USPHS grants F32 NS07733 to J.J.W. and R01 NS16832 to J.A.W. We thank D. Larue, T. McShane, Y. Nam, and J. Popowits for technical assistance.

89.17 COMPLEX RESPONSE PROPERTIES OF FM-FM COMBINATION-SENSITIVE NEURONS IN THE VENTRAL FRINGE (VF) AREA OF THE MUSTACHED BAT'S AUDITORY CORTEX.
H.Edamatsu*, M.Kawasaki and N.Suga. Dept. of Biology, Washington Univ., St.Louis, MO 63130

In the mustached bat, *Pternotus parnellii parnellii* , different types of combination-sensitive neurons are clustered in separate areas of the auditory cortex. In the FM-FM area, FM-FM combination-sensitive neurons are tuned to particular echo delays, i.e. target ranges. Anatomical studies with tritiated amino acids indicate that the FM- FM area projects to the DF area, which, in turn, projects to the VF area. The FM-FM area consists of three types of FM-FM neurons (FM_1- FM_2, FM_1-FM_3, and FM_1-FM_4) and has an axis representing echo delays of 0.4-to-18 ms (target ranges of 7- to-310 cm), while the DF area has the axis representing echo delays of 0.8-to-9 ms. [Suga,N. & Horikawa, J. Neurophisiol., 55,4:776- 805, 1986]. Since the VF area is two steps higher than the FM-FM area, neurons in the VF area are expected to be more specialized in processing biosonar signals than those in the FM-FM and DF areas.

In 8 unanaesthetized mustached bats, single unit activity was recorded with a tungsten-wire electrode from the VF area which is located along the sulcus and is very small (0.29-to-1.13 mm^2). As in the FM-FM area, there are 3 clusters of combination-sensitive neurons. Unlike the FM-FM area, however, these clusters are quite variable among bats in their relative locations, shapes, and sizes, and there is no systematic representation of echo delays, although best delays varied somewhat systematically in a few electrode penetrations. All VF neurons are tuned to short echo delays, 0.9-to-4.5 ms (2.87 ms on the average). Since these data suggest that VF neurons process target-range information only at short distances from the target, we delivered the pulse- echo pairs consisting of a short CF and FM components, mimicking biosonar signals in the terminal phase of target-directed flight. We then found that the facilitative responses evoked by combinations of two FM components in the pulse-echo pair were reduced by the CF component. This reduction of facilitative response was not evoked by a 30-ms-long CF component but only by a short CF component. Neurons in the FM-FM area did not show such a reduction of responses by CF sounds. Therefore VF neurons are more complex in response properties than those of the FM-FM area. The biological significance of this reduction remains to be explored. (This work was supported by PHS research grant NS 17333.)

89.18 PARALLEL-HIERARCHIAL PROCESSING OF RANGE INFORMATION IN THE MUSTACHED BAT: A SUBTHALAMIC NUCLEUS PRODUCES DELAY LINES.
N. Kuwabara* and N. Suga. Dept. of Biology, Washington Univ., St. Louis, MO 63130. (SPON: Y. Fukami)

The mustached bat, Pteronotus parnellii,emits orientation sounds (pusles) each consisting of eight components (CF_{1-4} and FM_{1-4}). In the medial geniculate body (MGB), neurons responding to the FM_1 of the pulse and those responding to the FM_n (n=2,3 or 4) of an echo are integrated to produce FM_1-FM_n conbination-sensitive neurons. These neurons are tuned to particular echo delays, i.e., target ranges. To produce such FM-FM neurons, delay lines are necessary. FM-FM neurons in the MGB often respond weakly to FM_1 and FM_n even when presented alone. The response latency for the FM_1 is usually longer than that for the FM_n. When the FM_n is presented after the FM_1 with a delay which is the same as the difference in latency, the FM-FM neurons show a strong facilitation. The response latency for the FM_1 is linearly related to the best delay for facilitation, while that for the FMn is the same regardless of the best delay, suggesting the creation of delay lines by neurons responding to the FM_1 (Olsen, 1986). To examine whether the delay lines are created within the MGB or a subthalamic nucleus, the distributions of the response latencies of brachial fibers of the inferior colliculus were studied.

In 6 unanesthetized mustached bats, action potentials were recorded from 1511 brachial fibers. The response of each neuron to a tone burst presented at its best frequency and amplitude was plotted as PST and PSTC histograms, and the latency and peak latency of the response were measured. The latencies of neurons tuned to the FM_1 ranged from 4.3 msec to 17.3 msec, and the distribution of the FM_1 latencies was very similar to that of best delays of FM-FM neurons in the MGB. On the contrary, the latencies of neurons tuned to the FM_n fell within a narrow range from 3.8 msec to 6.6 msec. Most of them were approximately 5 msec. Our data indicate that a subthalamic nucleus creates the delay lines, and then the thalamus produces FM-FM neurons to extract the range information. Thus, the processing of range information is parallel-hierarchial. (Supported by PHS research grant, R01-NS17333)

90.1 BINAURAL ORGANIZATION OF THE AUDITORY CORTEX IN THE ALBINO RAT. J.B. Kelly and S.L. Sally*. Lab. of Sensory Neuroscience, Psychology Dept., Carleton University, Ottawa, Canada K1S 5B6.

Microelectrode mapping techniques were used to determine the binaural response properties of cells in the auditory cortex of the albino rat. The animals were anesthetized with Equithesin (3.0 ml/kg i.p.), the surface of the cortex was exposed, and recordings were made with tungsten microelectrodes. A dissecting microscope was used to determine the position of electrode penetrations with respect to surface landmarks on the cortex. An enlarged photograph of the exposure allowed precise location of electrode penetrations by cross-reference to the vascular pattern on the cortex in individual animals. Pure tone pulses were delivered to each ear independently through sealed loudspeakers fitted to specula inserted into the external meatus. Sound pressure levels were determined by probe tube measurements within a few millimeters of the tympanic membrane. Characteristic frequency (the frequency for which excitatory thresholds was lowest) was determined for each neuron or neuron cluster encountered. Responses were obtained separately for contralateral alone, ipsilateral alone and binaural stimulation. In some cases detailed information was obtained regarding the responses to a wide range of interaural intensity differences. Results confirmed our previous findings with regard to frequency organization of the auditory cortex, namely, that the primary auditory cortex is tonotopically organized with high frequencies represented rostrally and low frequencies caudally. Isofrequency contours were aligned dorsoventrally. Also, secondary auditory areas were found dorsal and ventral to the primary auditory cortex. Binaural response types were classified as either summation (35.3%), suppression (42.2%), mixed (18.5%), or other (4%). Each of these response categories was represented at all frequencies within the rat's hearing range. Similar response types were grouped together within the auditory cortex forming binaural regions which cut across the isofrequency contours. The majority of neurons in the summation and suppression classes exhibited binaural interaction at interaural intensity differences around 0 db. Neurons in the mixed category typically showed binaural summation around 0 dB and binaural suppression when the ipsilateral intensity was greater than contralateral by 15-25 dB.

(This project was supported by NSERC operating grant 7654 to J.B. Kelly.)

90.2 POSTNATAL DEVELOPMENT OF CORTICAL CYTOARCHITECTURE AND LAMINA V PYRAMIDAL CELLS IN AREA 41 OF RAT. J. R. Coleman, J-M. Ding*, A. Wei*, and H. Dorn*. Departments of Psychology and Physiology, University of South Carolina, Columbia, SC 29208.

Area 41 of neocortex is the target of the core colliculo-geniculate system carrying tonotopically organized information. The present work demonstrates patterns of laminar and neural development in cortical area 41 during postnatal life in rat. The results show that substantial growth of auditory cortex occurs prior to onset of auditory function. Groups of five Sprague-Dawley rats were perfused with 10% formalin-saline on the first day postpartum (day 0) and on postnatal days 3, 5, 7, 11, 14, 16, 35 and 80. Coronal sections cut at 50 µm were stained with thionin for observations of cortical cytoarchitecture. Other groups were perfused at the same ages with 4% paraformaldehyde and the material postfixed in osmium tetroxide and placed in 0.75% silver nitrate solution then embedded in paraffin. In Golgi stained sections of 150 µm containing auditory cortex qualitative and quantitative observations were made on branching patterns of apical and basal dendrites of lamina V pyramidal cells and spine counts made on the apical dendrite and secondary branch in layer IV.

There is a dramatic growth of the six laminae of area 41 between birth and postnatal day 7 ($p < .001$). The sharpest growth occurs between days 5 and 7, which is followed by modest growth to postnatal day 11. A substantial increase in cortical thickness occurs by postnatal day 14 which includes the period of functional onset of hearing. Examination of individual laminae show that the growth spurt observed by postnatal day 7 is due to expansion in laminae II, III-IV, V and VI. Increments between postnatal days 11 and 14 largely correspond to enlargement of laminae III-IV.

In Golgi material, examination of pyramidal cells of lamina V show that emergence of the apical dendrite and axon precedes that of basal dendrites which accounts for the lack of pyramidal appearance of these cells at birth. During the period following birth, when the deep white matter exibits a transitional cascading appearance, the apical dendrite possesses thick varicosities probably associated with growth cones. Within the first three days postpartum branching of the apical dendrites occur, and by 5 days varicosities on the apical dendrite take on a more elliptical arrangement and some spines are observed. In 7-11 day-old animals varicosities are more associated with secondary branches off the apical dendrite. By 35 days spine counts/unit length on the apical dendrite and its branches are similar and adult-like in number. Branching of basal dendrites within 150 µm radius increases from 5 to 35 days from a mean of 3.8 to 4.3 for primary fibers, and from 0.3 to 5.6 secondary branches, and from no tertiary branches to 4.0. (Supported by NIH grant NS-20785).

90.3 DEVELOPMENT OF THE RAT MEDIAL GENICULATE BODY: QUANTIFICATION OF NEURONS IN THE VENTRAL DIVISION. W. J. Clerici, B. Maxwell*, D. R. Byrd* and J. R. Coleman. Departments of Psychology and Physiology, University of South Carolina, Columbia, SC 29208.

The rat medial geniculate body (MGB) contains ventral (MGv), dorsal (MGd) and medial (MGm) divisions. The present study examines cytoarchitectural features of the MGB in thionin stained material and quantifies somatic areas and densities in the MGv of rats at postnatal days (PND) 0, 5, 7, 11, 16 and 80+ (adult).

The adult MGv contains small dark staining round to almond shaped somata, the MGd has loosely packed pale cells; MGm is cytologically diverse and includes large, dark, vertically oriented triangular to oblate cells. In the MGv, the ovoid nucleus (OV) contains a double spiral of neurons in register with brachial axons sequestered from the ventral nucleus (LV) by a cell sparse zone; transition zone neurons align with radially ordered axons. MGd dorsal nucleus cells are sparsely packed and pale. The deep dorsal nucleus is cell sparse, lying within the midgeniculate bundle (MB); fusiform cells align with the MB. Suprageniculate neurons are vertically oriented, medium and large sized and medium darkly stained.

At PND 0 neurons within each MGB subdivision are homogeneous, very small and dark staining; nuclei and nucleoli are minimally discernable. At birth the MGv is relatively well formed, although the LV/OV distinction is not clear; the dorsal nucleus is very small. Between PND 0 and 16 nuclear differentiation involves cells aligning with afferent axons: DD fusiform cells strictly align with the MB, bipolar cell orientation in OV spirals and mediolateral orientation dominates the transition zone; OV double spirals are most distinct at PND 7-11. Dendrites of MGd stellate cells show no preferential orientation. Beyond PND 16, cell density is low, only somata stain and nuclear boundaries become less discriminable as adult patterns emerge. Diversity of somal shapes increase and alignment with fibers is less strict in the adult -- fusiform cells are a smaller proportion of the DD population, the OV double spiral is less obvious and somatic orientation in LV is less clear.

Somatic densities in LV, OV and DD are approximately three times greater at PND 0 as in the adult, and decrease exponentially. Densities decrease most rapidly between PND 0 and 5, with slightly less decline from PND 5-7 and PND 7-16; densities are almost at adult levels by PND 16. Somatic size increases exponentially during this same period; the most rapid increase in cell size is between PND 5 and 16, with only a slight further increase to adulthood. Somata measured from medial and lateral portions of the LV in register with brachial axons do not show differential growth rates. (Supported by grant NS-20785).

90.4 THE EFFECTS OF ACETYLCHOLINE ON SINGLE NEURON RESPONSES TO TONES IN CAT AUDITORY CORTEX. Raju Metherate, Josée F. Bourg* and Norman M. Weinberger. Center for the Neurobiology of Learning & Memory, Department of Psychobiology, University of California, Irvine, CA. 92717.

Cholinergic agents affect auditory perception and cognitive processes, and may do so by altering auditory sensory processing. To pursue this question, the present study examines the effects of iontophoretically administered acetylcholine (ACh) on single neuron responses to tones in the auditory cortex of barbiturate anesthetized cats. A further goal was to determine the extent to which pairing ACh with a single frequency tone would subsequently affect the cell's frequency receptive field (FRF).

Cats prepared for chronic recording sessions (performed at 1 week intervals) were initially anesthetized with sodium pentobarbital (35 mg/kg) and maintained areflexic by continuous infusion of barbiturate (1 mg/hr) and lactated Ringer's solution (12 ml/hr). Multibarrel glass or tungsten and glass microelectrodes were inserted through a burr hole into the auditory cortex. Drug barrels contained ACh chloride (1 M, pH 4), sodium glutamate (0.5 M, pH 8) and sodium chloride (1 M) for current controls. When a single neuron was initially isolated, its level of spontaneous activity and FRF were determined. The responses to a single, repeated tone were then noted before and during iontophoresis of ACh. Following this, the cell's FRF was re-determined.

ACh (5-70 nA) was applied to 51 neurons in 14 recording sessions. The spontaneous and/or tone-evoked activity of 39 cells (76%) was altered in the presence of ACh. The spontaneous rate increased in 34 cases, but never decreased during the ACh application. Responses to tones were increased by ACh in 16 cases and decreased in 11 cases. ACh often differentially affected a cell's activity, increasing, for example, the spontaneous rate while decreasing the evoked response. Six additional cells that did not respond to tones in the absence of drugs did so during ACh administration. When FRFs were determined following pairing of ACh with a single frequency tone, some cells displayed a decreased response to tones close to the paired frequency while responses to frequencies further away were less affected.

These data suggest that ACh can modify the activity of a large number of auditory cortical neurons. The differential effects on spontaneous and tone-evoked activity are consistent with previous observations from this laboratory (McKenna et al. 1986) using pressure ejection of ACh in unanesthetized cats. Finally, the observation of altered neuronal receptive fields subsequent to the ACh treatment bears significant implications for studies on auditory sensory processing.

90.5 LIGHT MICROSCOPIC EVIDENCE FOR THALAMOCORTICAL INPUT TO GABA-ERGIC NEURONS IN AUDITORY NEOCORTEX: COMBINATION OF PHA-L AND TARGET NEURON IMMUNOCYTOCHEMISTRY. N.T. McMullen and A.M. Prescott*. Dept.of Physiology, Univ. of Maryland School of Medicine, Baltimore., MD 21201.

We have combined anterograde labeling using PHA-L (Gerfen & Sawchenko, Brain Res., 1984) with GABA immunocytochemistry of presumptive target neurons (Wenthold et al, Brain Res., 1986) using procedures described by Wouterlood et al (J. Histo. Cyto., 1987). PHA-L was iontophoretically injected (20 um tip, 4 uA for 30 min.) into the MGB of NZW rabbits using stereotaxic procedures. Ten days post surgery, each rabbit was deeply anesthetized and intracardially perfused with 4% paraformaldehyde with 0.1% glutaraldehyde and 0.2% picric acid in 0.1 M PBS at 4° C (pH 7.4). Frozen sections (50 um) through the auditory cortex and injection site were collected in Tris buffered saline (TBS). We have found that incubation in pooled primary antibody solutions yielded optimal color differentiation of PHA-L-labeled afferents and GABA-ergic neurons in frozen sections. Free floating sections were incubated for 48 hours at 4° C in a solution of goat anti-PHA (1:2000, Vector Labs) and rabbit anti-GABA (1:3750) containing 1% normal donkey serum (NDS), 1% normal swine serum (NSS) and 0.3% Triton X-100 in 0.05 M TBS. Sections were then incubated for 2 hours in pooled secondary antisera consisting of donkey anti-goat IgG (1:40 Nordic) and swine anti-rabbit IgG (1:40 Nordic) with 0.3% Triton in 0.05M TBS followed by goat PAP (1:400 Nordic) with 1% NDS for 2 hours. Visualization of the PHA-L labeled afferents was carried out by incubation in a solution of .015% DAB, 0.6% nickel ammonium sulfate and .015% H_2O_2 in Tris buffer. After rinsing, sections were incubated in rabbit PAP (1:600) with 1% NSS (2 hours). Visualization of the GABA-labeled neurons was carried out using a solution of .04% DAB and .015% H_2O_2 in Tris buffer. With this protocol, PHA-L labeled fibers were labeled jet black and GABA positive neurons were labeled brown. PHA-L labeled terminal fibers within laminae III/IV form en passant and terminal varicosities on the somata and proximal dendrites of GABA-ergic neurons. Thalamocortical afferents also ascend to lamina I where they course tangentially for long distances and form en passant varicosities on the somata of GABA-ergic neurons in this layer. Because these methods are compatible with electron microscopy, the combination of anterograde tracing methods and target neuron immunocytochemistry will be a powerful method for future studies of synaptic circuitry in this sensory cortex. (Supported by NIH Grant NS17861)

90.6 SINGLE UNIT, EVOKED POTENTIAL AND MAPPING STUDIES OF GUINEA PIG AUDITORY CORTEX. J.W. Fleshman and S.A. Shamma*. Systems Research Center, Univ. of Maryland, College Park, MD 20742.

The guinea pig has long been used as the subject of studies of the peripheral auditory apparatus, but very little is known about the organization of its central auditory system, the cortex in particular. This study begins to provide a picture of the functional organization of the guinea pig auditory cortex.

Young adult guinea pigs (300-600 gm) were anesthetized with a combination of pentobarbital (12 mg/kg) and a mixture of fentanyl and droperidol (Innovar-Vet, 0.9 ml/kg). The pinnae were bilaterally resected and the temporal aspect of the cortex was exposed by craniotomy and covered with a 2% solution of agar in saline. A single-channel glass-coated platinum-iridium microelectrode or a multichannel silicon-based microelectrode was inserted normal to the cortical surface during presentation of contralateral sound stimuli.

Large evoked-potentials are characteristic of guinea pig auditory cortex and were used in conjunction with unit responses to perform mapping studies. In the area referred to as primary cortex, the evoked potentials were sharply tuned to sinusoidal stimuli and occurred at peak latencies of 18-28 ms. In agreement with Hellweg et al. (Exp. Brain Res. 29:467, 1977), we found that the gradient of tonotopic organization was reversed relative to cat primary auditory cortex, with low frequencies represented rostrally and high frequencies caudally, and isofrequency contours approximately parallel to the medio-lateral axis. The primary cortex was surrounded by areas responsive to auditory stimuli, but with different response characteristics. Preliminary results indicate the presence of at least two large fields, one temporal and one caudomedial to primary cortex, characterized by broad tuning and, at least in some locations, by rapidly adapting and highly variable responses evoked by sinusoidal stimuli. It was often possible to obtain more robust responses using broad-spectrum stimuli, such as low frequency square waves.

The most common unit responses were quite phasic, consisting of 1-5 spikes at the onset or offset of the stimulus or onset responses lasting about 100 ms during a 300-500 ms tone. Responses sustained for the duration of the stimulus were rare.

More detailed mapping and single unit studies of the primary and nonprimary cortices are proceeding.

90.7 REGION AND SPECIES SPECIFIC DISTRIBUTION OF SMI-32-IMMUNOREACTIVE (IR) NEURONS IN MONKEY AND HUMAN TEMPORAL LOBE (TL) NEOCORTEX. M.J. Campbell, K. Cox*, H.J. Noack*, J.H. Morrison. Scripps Clinic and Res. Fdn., La Jolla, CA 92037

SMI-32, a monoclonal antibody (Sternberger-Meyer) developed against rodent nonphosphorylated neurofilament protein, was used in immunohistochemical studies of cynomolgus monkey and human TL neocortex. A distinct subset of pyramidal neurons (PN) were SMI-32-IR in both primate species. Thus the epitope recognized by SMI-32 appears to be a molecular marker for a specific class of neurons. There were consistent differences between members of this subpopulation of PN in the degree to which they were completely and/or intensely immunoreactive. There were intensely immunoreactive PN that had a Golgi-like appearance where the soma and dendritic processes up to secondary and tertiary branches were visualized. In contrast, only the outline of the soma and limited portion of the apical and basilar dendrites were visualized in other SMI-32-IR PN. These observations suggest that even within a morphologically similar cell class like PN, distinct chemical phenotypes can be recognized by subtle differences in the molecular structure of their basic cytoskeletal proteins.

The size, density and laminar distribution of SMI-32-IR neurons differed substantially across TL neocortical areas in both species. A comparison of the two species revealed substantial differences in some TL areas, while other areas appeared somewhat similar. For example, the primary auditory cortex (PAC) of the human contained a substantial number of large, intensely reactive PN; the majority were located in deep layer III with the remainder in layer V. In addition, numerous examples of the less completely stained PN were found in layers II-III and V-VI. In contrast, there were no large intensely reactive PN observed in the monkey PAC, where deep layer III, V and VI contained a fair population of medium to small, less completely stained PN. Although differences in cell size were often less obvious in other areas, the species related differences in distribution were often even more dramatic than seen in PAC. For example, the posterior inferior temporal gyrus of the monkey had a striking bilaminar distribution of SMI-32-IR PN in layer III, a feature that was not observed in any human cortical areas. Areas that tended to be more similar in the distribution of SMI-32-IR PN included parahippocampal and perirhinal cortices, where the most intensely reactive PN were in layer V while the superficial layers contained only very lightly reactive PN. These observations suggest that detailed analyses of the distribution of different chemical phenotypes provide a powerful approach for further elucidation of regional and species related differences in neuronal organization of the primate neocortex. Supported by AG015131, AA07456.

90.8 PROJECTION PATTERNS AMONG THREE AUDITORY CORTICAL FIELDS A, AI, AND P IN THE CAT. W.A. Irons* and T.J. Imig (SPON: R. Bunag) Dept. of Physiology, Univ. of Kansas Medical Center, Kansas City, KS 66103.

The cortical projections among three tonotopic fields (anterior field, A; primary auditory field, AI; and posterior field, P) of cat auditory cortex were studied using retrograde axonal transport techniques. Horseradish peroxidase conjugated with wheat germ agglutinin was injected under pressure into one auditory field per experiment. Best frequency maps of the injected fields generated from microelectrode recordings were used to guide the placement of injections. All injections were confined to the middle (9-13 KHz) frequency representation within each field. The cortical locations of fields containing labeled neurons were identified by reference to previously obtained best frequency maps. The laminar architecture of cortical fields containing labeled cells was identified by microscopic examination of tissue sections reacted for peroxidase activity and counterstained with thionin. Outlines of brain sections and locations of labeled cells were transferred from slides to paper using a drawing tube attached to the microscope. Results from one injection into A, four injections into AI, and one injection into P indicate that each of the three fields receives projections from auditory areas in both hemispheres. Injection into field A resulted in labeling in ipsilateral fields AI and P and contralateral field A. AI injections labeled cells in ipsilateral fields A, AI, P and VP and contralateral field P and VP. Preliminary results indicate that projections from cells whose axons terminate in auditory fields within the same hemisphere (intrahemispheric) are confined primarily to cortical layers V and VI (70.4%), with fewer cells located in layers II (0.9%), III (12.3%) and IV (7.4%). Cells giving rise to projections which terminate in the opposite hemisphere (interhemispheric) are distributed primarily within cortical layer III (80.1%), with fewer cells found in layers IV (9.3%), V, and VI (10.6%). Few labeled cells were found in layer IV. Cells from fields AI, P and VP which gave rise to intrahemispheric projections to field P displayed a larger percentage of cells confined to layer III compared to cells projecting to other intrahemispheric fields. (Supported by NINCDS Grant NS17720)

90.9 CONNECTIONS OF PRIMARY AUDITORY CORTEX IN PRIMATES. L. E. Luethke, L. A. Krubitzer, and J. H. Kaas. Department of Hearing and Speech Sciences and Department of Psychology, Vanderbilt University, Nashville, Tennessee 37240.

The location, response characteristics and connections of the primary auditory cortex (A-I) were investigated in the tamarin (Saguinus fuscicollis), a New world monkey with a relatively smooth brain. Microelectrode multiunit recordings were used to determine the best frequencies for recording sites in A-I. In each case, A-I was defined by a characteristic pattern of tonotopic organization and lesions were placed to mark physiological borders for later correlation with cortical architecture. Following mapping, single injections of each of three tracers (wheat germ agglutinin conjugated with horseradish peroxidase, plus two of the following: fast blue, rhodamine, or diamidino yellow) were placed in different frequency representations within A-I. Three days later, animals were perfused and cortex was separated from the thalamus and brainstem, flattened and cut parallel to the surface. The thalamus and brainstem were cut in the frontal plane. Alternate sections were reacted with tetramethylbenzidine, mounted for fluorescent microscopy, or stained for fibers or cells. The recordings revealed that A-I has high frequencies represented caudally, low frequencies rostrally, and isofrequency contours oriented mediolaterally. The injections demonstrated tonotopic patterns of connections with a number of cortical and subcortical structures. Reciprocal connections were found between A-I and at least three adjoining architectonically distinct subdivisions of cortex of the same hemisphere, including subdivisions caudomedial, rostrolateral and lateral to A-I. Injections in the high frequency portion of A-I labeled caudal regions of both the caudomedial and lateral fields, injections in the middle frequency portion of A-I demonstrated connections with middle portions of the caudomedial and lateral fields, and the caudal and middle portions of the rostrolateral field, while injections in the low frequency portion of A-I labeled caudal portions of the rostrolateral field, and middle and rostral portions of the lateral field. Callosal connections of A-I were with A-I and adjoining cortical regions. Injections in the low, middle, and high frequency regions of A-I labeled lateral, middle, and medial regions of the principle division of the medial geniculate nucleus, respectively. Connections with the inferior colliculus and other subcortical structures were also evident. An injection confined to the lateral field of cortex exhibited dense reciprocal connections with A-I and less dense connections with surrounding cortex. Callosal connections of this lateral field were primarily with the lateral field. These results are consistent with the conclusion based on previous findings in other monkeys that auditory cortex of monkeys contains four or more tonotopically organized fields, and extend these findings by providing detailed information about the topographic organization of connections of primary auditory cortex in primates. (Supported by NIH Grant NS-16446).

90.10 A CONNECTIONAL ANALYSIS OF THE INTERHEMISPHERIC AND IPSILATERAL ASSOCIATION AFFERENT NEURONS OF THE SUPERIOR TEMPORAL REGION IN THE RHESUS MONKEY. P.B. Cipolloni and D.N. Pandya, ENRM VA Hospital, Bedford, MA 01730 and Depts. of Anatomy and Neurology, Boston Univ. Sch. of Medicine, Boston, MA 02118.

In order to determine if interhemispheric and ipsilateral association afferents of the superior temporal region (STR) originate from common neurons, flourescent retrograde tracer (FRT) dyes were injected in selected cortical regions of the STR of each hemisphere in four animals. Although there was considerable overlap of labeled neurons of both afferent systems, only occasional double-labeled neurons were found.

The interhemispheric afferents originated not only from the homotopic but also from heterotopic areas. The heterotopic areas giving rise to the interhemispheric projections corresponded to some of the ipsilateral projection zones. Whereas the laminar patterns of the ipsilateral neurons of origin varied considerably, the interhemispheric projections neurons were only in layer III.

For interpreting the distribution patterns of the projection neurons, the architectonic parcellation of the STR described by Galaburda and Pandya (J. Comp. Neurol., 221: 169-184, 1983) was utilized. They divided the STR into three distinct rostrocaudal lines, designated as "root", "belt" and "core" lines. Each of these three lines were subdivided into four rostrocaudal stages. Because of more restricted injections of FRT dyes, our study has provided additional information about the connectional organization of the STR. Thus, the primary auditory area (KA) receives projections not only from the "belt" and "root" areas of the same stage but also from all three components of the adjacent rostral and caudal stages. This means that a "core" region is connected with all adjacent cortical subdivisions. Unlike the "core" areas, the "belt" regions receive projections from "core" and "root" regions of the same stage, as well as from the "root" and "belt", but not "core", areas of adjacent stages.

On the basis of architectonic analysis, Sanides (The Primate Brain, Vol. 1, pp. 137-208, 1970) postulated that a highly differentiated "core", ie. primary cortical area, developed from a surrounding less-differentiated association region and conceptualized this as a growth-ring pattern of cortical development. Our connectional observations support this growth-ring concept since the "core" area, ie. KA, receives projections from all the immediately surrounding regions and since the "belt" area of a given stage connects more with the other association areas surrounding the "core" than with the "core" itself.

Supported by NIH Grants NS16841 and NS26841, the ENRM VA Hosp., Bedford, MA and the Institute for Neurologic Research, Inc.

90.11 AN ULTRASTRUCTURAL ANALYSIS OF PRIMARY AUDITORY CORTICAL AFFERENTS ONTO IDENTIFIED NEURONS OF THE LATERAL AUDITORY ASSOCIATION CORTEX OF THE RHESUS MONKEY. V.M. Knowlton(1), D.A. Pandya(1), B.A. Ekstein(1) and P.B. Cipolloni(2). Depts. of Anatomy(1,2) and Neurology(2), Boston Univ. Sch. of Medicine, Boston, MA 02118 and the ENRM VA Hospital, Bedford, MA 01730(1,2).

Architectonic parcellation and the ipsilateral connectivity patterns of the auditory cortices of the rhesus monkey have been described at the light microscopic level (Galaburda, A.M. and Pandya, D.N., J. Comp. Neurol., 221: 169-184, 1983). Using this study for guidance, cortical lesions of the primary auditory area (KA) were made by aspiration in a series of monkeys. In order to mark the various neurons of the lateral auditory association cortex (paAlt) for subsequent ultrastructural examination, several methods were employed including the retrograde transport of horseradish peroxidase (HRP), Golgi impregnation and NADPH-diaphorase staining. In the application of the HRP method, the enzyme was injected into area Ts3 (the cortical area immediately adjacent to area paAlt rostrally) filling pyramidal neurons in layers II and III of area paAlt. Since this labeling technique marks only pyramidal neurons, the Golgi-EM method (Fairen, A., et al., J. Neuorcytol. 6: 311-337, 1977) was employed to mark all neuronal types and the diaphorase stain was used to mark a subset of the nonspinous interneurons.

Survey of the degenerating axon terminals in area paAlt showed them to be distributed in cortical layers I-V, with the overwhelming majority found in layers III and IV. The synapses formed were always of the asymmetric type. Preliminary observations show that the postsynaptic elements found forming synapses with these terminals were spines (90%), dendrites (9%) and somas (1%). Using the cell marking techniques, in combination with lesion-induced degeneration, axon afferents from area KA were demonstrated forming asymmetric synapses on spinous and nonspinous neurons of area paAlt.

Supported by NIH Grant NS26841, the ENRM VA Hospital, Bedford, MA 01730 and the Institute for Neurologic Research, Inc.

90.12 AUDITORY INVASION OF "VISUAL" CENTERS IN THE MOLE RAT (SPALAX EHRENBERGI): EVIDENCE FROM 2-DEOXYGLUCOSE. P. Heil, G. Bronchti*, Z. Wollberg, H. Scheich. Depts. of Zoology, TH Darmstadt, 6100 Darmstadt, F.R.G., and Tel-Aviv Univ., 69978 Tel-Aviv, ISRAEL.

Mole rats (Spalacidae) live subterraneously in south east Europe, Israel, Egypt, and Libya. Their largely reduced eyes are covered by muscles, skin, and fur. The central visual system also shows numerous reductions: the optic nerve is very thin and has no myelinated fibers, of the lateral geniculate body (LGB) only the ventral part (LGBv) is developed, the superior colliculus has only 5 layers, the nerves N.oculomotorius, N.trochlearis, N.abducens, and their nuclei are absent (Leder,M.-L.,Zool.Jb.Anat. 94:74,1974). In spite of these observations it is not clear to what degree these animals can see. However, their acoustic and olfactory communication seems to be highly developed (Nevo,E., Ann.Rev.Ecol.Syst. 10:269,1979).

We have tested the hypothesis whether the remaining structures of the central visual system might have adopted auditory functions by analyzing (14C)-2-fluoro-2-deoxy-D-glucose (2DG) patterns in specimens of Spalax ehrenbergi, which had been subjected to unilateral cochlea destructions and thereafter been stimulated with noise bursts after 2DG-injection. Methods for preparation and evaluation of 2DG autoradiographs correspond to those in Heil and Scheich (J.Comp.Neurol. 252:279,1986).

The success of the cochlea destructions was controlled by asymmetric labeling in the auditory system. Reduced 2DG accumulation was seen in the dorsal (DCN) and ventral (VCN) cochlear nuclei on the side ipsilateral to the lesioned ear. The medial nucleus of the trapezoid body (MNTB), the ventral (LLv) and dorsal (LLd) nuclei of the lateral lemniscus, the inferior colliculus (IC), the medial geniculate body (MGB), and the auditory cortex all showed weaker 2DG labeling contralaterally. Interestingly, the LGBv also showed asymmetric labeling with reduced 2DG accumulation contralaterally. Moreover, an area of cortex, extending for about 2mm along the dorsoventral and 1mm along the rostrocaudal axis, and located dorsally and caudally to the auditory cortical fields, was found to be asymmetrically labeled, with weaker labeling ipsilateral to the lesion. In intact controls all of these structures were labeled symmetrically. According to the Spalax brain atlas (Leder,M.L.,Zool.Jb.Anat. 93:353,1974) this cortical area would correspond to fields A17 and A18a. Electrophysiological experiments revealed the presence of auditory units there.

Our data indicate that LGBv and the cortex area described above, which have visual functions in other rodents, receive auditory input. We are presently investigating the connectivity and functional anatomy of these structures. (Supp. by DFG-SFB45.)

90.13 COMPARATIVE STUDIES OF THE ACOUSTICAL COMMUNICATION BEHAVIOR AND ORIENTATION OF WILD RATS. M.Th. Kaltwasser* (SPON: S. Chang), Zoophysiology, Morgenstelle 28, D-7400 Tübingen, F.R. Germany

The purpose of this study was to determine the complete vocalization repertoire of two closely related species, RATTUS NORVEGICUS and RATTUS RATTUS, and to evaluate its functional significance. Wild trapped rats of both species were kept in the laboratory under seminatural coniditions. Behavior was monitored on a video tape, vocalizations were recorded on a high speed tape recorder. By means of a special synchronization set-up behavior and sounds were exactly correlated. Behavioral categories were scored from the video recordings, and sound analyses were done with a real time spectrum analyzer. Analyses of behavior and sound of well established and undisturbed groups of rats indicate that the vocalization repertoire consists of nine different types of sounds. TOOTH CHATTER, SNIFF-WHISTLE and BROADBAND PULSE were in the hearing range of man, and typically occurred during orientation behavior. While sniff-whistle and broadband pulse were characteristic for R. RATTUS only, the tooth chatter was also produced by R. NORVEGICUS. It occurred as an orientation signal and also during attack behavior of a dominant male. When attacked or bitten an animal of either species emitted a SREAM of 3 to 4 harmonics with the 1. harmonic at about 2 kHz. The 22-kHz-CALL and SHORT PULSES in the range of 50 to 80 kHz were typical for agonistic behavior as well as for sexual behavior. Additionally, LONG PULSES, ranging between 30 and 60 kHz, and WAVE-LIKE MODULATED PULSES of 40 to 70 kHz were recorded during mating. New born pups isolated from their mother, emitted a DISTRESS CALL in the range of 50 kHz. These sounds mature to the adult pattern within 3 weeks.

Out of all analyzed signals some were tested for their functional significance. In a four alternative forced-choice procedure with blinded rats the orientation sounds were tested for their use as echolocation signals when subjects are deprived of sensory cues other than hearing. As no correlation between sound production and target detection was found, the results do not support the hypothesis of echolocation in rats. In resident-intruder tests with sham operated and devocalized intruders the role of the 22-kHz-call was investigated. The data show that different hierarchically organized social and environmental factors influence defensive behavior and especially the use of the 22-kHz-call of a submissive rat. The intensity of defensive behavior is suggested to be a measure of the aggression level of the resident. Therefore, resident-intruder tests may serve as an ethological model for pharmacological investigation of aggression.

90.14 THE RAT'S HEART RATE AND AROUSAL RESPONSE AS A FUNCTION OF STIMULUS INTENSITY AND RISE TIME. K. Rudolph*. (SPON : B. Mambrito). Dept. of Zoophysiology, Univ. Tuebingen, Morgenstelle 28, D-7400 Tuebingen, West Germany.

Auditory stimuli can evoke motor as well as autonomous and centralnervous responses in an organism. Depending on the intensity of the stimulus, an orienting response (OR) or a defense response (OR) can be elicited. OR's are characterized by habituation upon repeated presentation of the same stimulus whereas DR's do not habituate. Another difference between these two types of response is the direction of the reponse: in humans the cardiac OR consists in heart rate (HR) deceleration, whereas the cardiac DR consists in acceleration (GRAHAM, 1979 and TURPIN, 1986) A third response type, the cardiac startle response (SR) which consists in HR acceleration can be elicited by high intensity stimuli with a sufficiently short rise time (TURPIN, 1986).

The present study thought to characterize the rat's cardiac OR, DR and SR and the accompanying cortical response under a well defined state of vigilance (slow wave sleep, SWS). Electrocardiogram (ECG) and electrocorticogram (ECoG) of unrestrained animals were transmitted via miniature telemetry. Additionally, respiration and motility were registered. Stimuli were 2-sec bursts of white noise with intensities between 40 and 100 dB SPL and either fast, uncontrolled rise time or a rise time of 100 ms. One session consisted of 10 stimuli with an interstimulus.interval between 45 and 75 sec.

The results of this study show that the rat's cardiac and arousal response is very similar to that of man. Low intensity stimuli evoked a HR deceleration and a cortical arousal response. Since both responses showed habituation within session, they can be considered as part of the rat's OR. No long-term habituation of the OR was observed: The response had recovered completely, when the same stimuli were presented one week later. High intensity stimuli, on the other hand, showed a non-habituating HR acceleration and an incomplete habituation of the cortical arousal response. This seems to reflect the rat's DR. Further data will be presented to describe the influence of stimulus rise time upon the rat's OR and DR. This work was supported by the Deutsche Forschungsgemeinschaft grant Schn. 138/13-15 and by the SFB 307 of the University of Tuebingen.

AUDITORY SYSTEM IV

91.1 LATE ONSET OF ACOUSTIC DEPRIVATION RETARDS DEGENERATION OF COCHLEAR NUCLEUS IN GERBILS. M.D. McGinn and B.T. Faddis. Department of Otolaryngology, University of California, School of Medicine, Davis, CA 95616.

Gerbils exhibit an unusual spongioform encephalopathy, characterized by extensive microcystic lesions that are most pronounced in the neuropil of the posterior ventral cochlear nucleus. These lesions become evident at 5 to 6 weeks of age, they are progressive and, eventually, result in neuronal degeneration.

We have recently reported that the progress of these lesions is slowed by neonatal acoustic deprivation (Assoc. Res. Otolaryngol. Abstr., Vol. 10, p. 208, 1987). A conductive hearing loss, induced prior to the onset of hearing (postnatal day 12), resulted in dramatic reductions in lesion area density and lesion number density in the cochlear nuclei ipsilateral to deprived ears. However, we now find that late onset of conductive block is as effective as early onset in retarding the progress of this disease.

We induced monaural deprivation in 4 gerbils, on postnatal day 35, by occlusive ligation of the right external auditory canal. Although gerbils of this age are still immature, their auditory sensitivity has reached adult levels. As in our earlier study, the gerbils were sacrificed on postnatal day 96, transcardially perfused with mixed aldehydes, and tissue blocks containing the brainstem were prepared for histology.

The late onset of monaural deprivation resulted in unilateral reduction of lesions. In the cochlear nuclei ipsilateral to the deprived ear lesion number density was only 14% of that in the non-deprived ear (number density; left CN, $\bar{x}$=11.86, right CN, $\bar{x}$=1.684; df=3, 't'=11.20, p=0.0012; two-tailed 't'-test for dependent samples). This compares to a 17% reduction in lesion number density with early onset of auditory deprivation. Thus, the course of this disease can be altered by a reduction in functional activity after lesions begin to develop. Whether this effect is restricted to immature animals is yet unknown.

91.2 AGING IN THE RAT LATERAL SUPERIOR OLIVARY NUCLEUS: QUANTITATIVE EM STUDIES OF AXOSOMATIC SYNAPTIC TERMINALS. M.A. Casey. Department of Cell Biology and Anatomy, School of Medicine, University of Alabama at Birmingham, Birmingham, AL 35294.

Recent studies have shown that principal cells and synaptic terminals in the medial nucleus of the trapezoid body (MTB) are significantly reduced in number in aged albino rats (Casey and Feldman, Neurobiol. Aging, 3:187-195, 1982; Casey and Feldman, Neuroscience, In press, 1987). The primary projection of MTB principal cells is to the ipsilateral lateral superior olivary nucleus (LSO), and the fibers terminate mainly on the cell bodies of LSO principal cells. Thus, an age-related loss of MTB principal cells would be expected to result in a significant loss of axosomatic synaptic boutons terminating on LSO principal cells, and the present study was done to test this hypothesis.

Twelve animals (four per age group) were studied at the following ages: 3-5 MO, 18 MO, and 24 MO. The animals were perfused with aldehydes, and brainstem slabs containing the LSO were prepared for transmission electron microscopy. Fifteen to twenty photographic montages of LSO principal cells from each animal were analyzed. Using a computerized planimeter, the perimeter of LSO principal cell profiles was measured, and the amount of somal surface in close contact with axosomatic synaptic terminals was determined. In young adult rats (3-5 MO of age) 75.7% (SEM = 1.5) of the surface of LSO principal cells is apposed to synaptic terminals. In rats aged 18 MO and 24 MO, the proportions are 59.5% (SEM = 3.1) and 64.7% (SEM = 2.1), respectively. These significant (ANOVA, $F = 12.6$, $p<0.001$) decreases in the amount of somal surface apposed to synaptic terminals may signify a partial deafferentation of LSO principal cells with aging. Whether this deafferentation is associated with other morphological changes, such as cell atrophy or cell loss in the aging rat LSO, is currently being studied.

Supported by NIH grant AG06188 and a grant from the American Federation for Aging Research.

91.3 ULTRASTRUCTURE OF THE ANTEROVENTRAL COCHLEAR NUCLEUS (AVCN) IN YOUNG AND OLD C57BL/6J MICE. W.E. Briner and J.F. Willott. Dept. Psychol., Northern Illinois Univ., DeKalb, IL 60115

The C57BL/6J mouse is a model of presbycusis, developing severe sensorineural pathology during the second year of life. We examined the AVCN of young (2-mo.-old) and old (24-mo.-old) C57BL/6J mice using transmission electron microscopy. The old mice had about a 50% loss of ganglion cells and eighth nerve fibers.

The young mouse's AVCN appears to have features similar to that of other mammals, with bushy and multipolar (stellate) cells being identified. The former are characterized by perinuclear endoplasmic reticulum cisternae and numerous terminal oppositions, including end bulbs of Held. The latter are opposed by fewer terminals, and these are non-end bulb types.

Compared to young mice, AVCN neurons of old mice typically had: (1) nuclei likely to be heterochromatic; (2) more and deeper invaginations of nuclei; (3) reduced perinuclear cisternae; (4) more and larger lipofuscin deposits; (5) a lower percentage of the cell occupied by mitochondria; (6) fewer terminal contacts and a smaller percentage of neuronal perimeter opposed by terminals; (7) more myelinated axons contacting the soma en passant; (8) fewer somatic spines. In spherical cells, buildup of lipofuscin and nuclear invaginations were most pronounced in the dorsal AVCN (the high frequency region, which is first to lose input due to progressing sensorineural degeneration). However, throughout the AVCN age-related differences were generally more pronounced in multipolar cells than in spherical cells.

AVCN neurons of old, presbycusic, C57 mice demonstrate a number of changes suggesting impairment of cellular function. However, different cell types, bushy and multipolar (and, presumably, the functions they mediate), and different AVCN regions (re: tonotopic organization) may be differentially vulnerable to aging and/or presbycusis.

91.4 RESPONSES OF INFERIOR COLLICULUS NEURONS IN C57BL/6J AND CBA/J MICE: CORRELATES OF AGING AND PRESBYCUSIS. J.F. Willott, K. Parham, and K.P. Hunter*. Dept. Psychol., N. Illinois Univ., DeKalb, IL 60115

Extracellular recordings were obtained from inferior colliculus (IC) neurons of C57 (1- to 15-mo.-old) and CBA (1- to 29-mo.-old) mice. C57 mice undergo progressive sensorineural hearing impairment (severe by 15-mo.); CBAs develop only moderate losses by 2-yrs.

Post-stimulus time histograms in young mice of both strains showed numerous examples of typical tone-evoked IC response patterns--phasic on, sustained excitation and/or inhibition, pauser, etc. These response types proved remarkably robust in the face of aging without severe presbycusis, being observed in very old (29-mo.) CBA mice. However, there were many examples of old neurons that were "sluggish" in their response to sounds or did not respond at all. Nevertheless, in those neurons that continued to respond well to tones, the relative proportions of neurons showing each response type changed little with age. Other response properties of these neurons (e.g., spontaneous activity, intensity functions) also showed little age-related change.

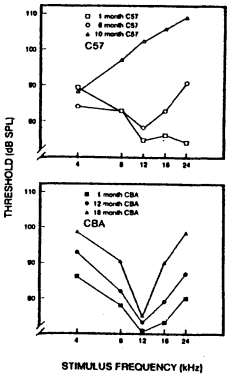
In severely hearing-impaired aging C57 mice many examples of "normal" PSTH response types were also found. However, the incidence of neurons responding with phasic on responses increased with aging. Many older neurons were auditorily "sluggish" or unresponsive to sound. It was often impossible to classify intensity functions in older C57s due to elevated thresholds and reduced dynamic range; nonmonotonic intensity functions were rare. Many older neurons responded to tones at unusually high rates within 10 dB of their (elevated) thresholds. The incidence of spontaneously active neurons increased in aging C57s.

The data indicate that extreme aging without severe presbycusis (CBA mice) is accompanied by an increasing number of IC neurons that respond poorly to tones; however, many "normal" response features persist. The same is true in the case of moderate aging with severe presbycusis (C57 mice); however, changes in the proportion of response types, intensity functions, and spontaneous activity are more pronounced. Thus, presbycusis appears to disrupt the coding of suprathreshold sounds more severely than aging per se.

Supported by NIH: R01 AG03069 and RCDA K04 AG00234.

91.5 THE ACOUSTIC STARTLE RESPONSE IN YOUNG AND AGING C57BL/6J AND CBA/J MICE. K. Parham, and J.F. Willott. Department of Psychology, Northern Illinois University, DeKalb, IL 60115.

C57BL/6J mice demonstrate progressive age-related hearing loss during the first year of life (threshold elevations at 4, 8, 12, 16, and 24 kHz: 4, 5, 4, 18, and 55 dB, respectively; from Willott, J.F., J. Neurophys., 56: 391-408, 1986). CBA/J mice lose little sensitivity through 18 mo of age. We measured the acoustic startle response (ASR) to determine behavioral correlates of aging with and without presbycusis. ASR thresholds (the minimum SPL required to elicit ASRs more than 50% of the time) of C57s increase dramatically at high frequencies, but remain unchanged at 4 kHz . CBA startle thresholds increase minimally at middle frequencies and moderately at high and low frequencies (see figure). The CBA data indicate that aging per se has little effect on ASR threshold; the C57 data show that hearing loss is a cogent factor. However, elevations of ASR thresholds are much greater than elevations of absolute thresholds. Both peripheral and central mechanisms can be proposed to account for the discrepancy. High intensity ASR stimuli must displace a considerable length of basilar membrane. The basal cochlear regions (e.g.; > 20 kHz) of aging C57 mice are severely impaired, reducing the number of sensory/ganglion cells providing input to the CNS. Higher frequencies would involve relatively greater proportion of impaired organ of Corti off the "center frequency". Alternatively, central factors (e.g., greater loss of potency of excitatory than inhibitory cells) might reduce the number of centrally excited auditory neurons that "drive" the ASR.



Supported by NIH grants R01 AG03069, and RCDA K04 AG00234.

91.6 AUDITORY BRAINSTEM RESPONSE DEVELOPMENT IN PRECOCIAL AND ALTRICIAL RODENTS. L.J. Hood*, E.K. Barlow*, and D.B. Webster. Kresge Hearing Research Lab, Department of Otorhinolaryngolgy, LSU Medical Center, New Orleans, LA 70112.

The development of auditory brainstem responses (ABR's) was measured in four rodent species chosen because of their difference in onset of hearing relative to time of birth. Guinea pigs and spiny mice develop detectable ABR's a few days before birth, cotton rats at birth and CBA/J mice at 14 days after birth.

ABR's were obtained for three subjects from each species at 1, 3, 6, 12, 24 and 48 days after onset of airborne hearing (which coincided with days after birth except for CBA/J mice where Day 1 of detectable ABR's was obtained at 14 days after birth). ABR's were also recorded for 3 adults of each species. Click stimuli were presented through an insert earphone beginning at 98 dB peak SPL and decreasing in 10 dB steps to 10 dB below ABR threshold. Data analyzed were: 1) intensity of the response threshold, 2) latency of the first vertex-positive wave (wave I representing the VIIIth Nerve CAP), and 3) the latency interval between the first and fourth vertex-positive waves (Waves I-IV).

Response thresholds indicated two distinct groups. Guinea pigs and spiny mice showed sensitivity at Day 1 which did not differ statistically from adult thresholds. Cotton rat and CBA/J mice thresholds reached adult values by 12 days after the onset of airborne hearing. Wave I latencies varied by species with latencies statistically consistent with adult values at Day 1 for guinea pigs, Day 3 for spiny mice, Day 6 for CBA/J mice, and Day 12 for cotton rats. Interwave latencies for Waves I-IV were consistent with adult values at Day 1 in guinea pigs and did not differ significantly from adult values by Day 12 for spiny mice and cotton rats and by Day 24 for CBA/J mice. Although CBA/J mice have a more rapid development than cotton rats, it must be remembered that airborne hearing onset as measured by the ABR is close to Day 1 after birth for cotton rats while CBA/J mice do not demonstrate ABR responses until 14 days after birth.

Since all the measures (sensitivity, Wave I latency, and Wave I-IV latency interval) are at adult values in 1 day old guinea pigs, it is evident that airborne hearing is not necessary for maturation of these parameters of hearing. However the very rapid maturation of these three measures in the altricial species (cotton rats and CBA/J mice) suggests that airborne hearing may accelerate both peripheral and central auditory maturation.

(Supported by a grant from the Deafness Research Foundation).

91.7 EFFECTS OF COCAINE ON THE BRAINSTEM AUDITORY EVOKED POTENTIAL (BAEP). P. Gritzke* and M.W. Church (SPON: M.J. Titmus). Research Institute on Alcoholism, Buffalo, NY 14203.

Because cocaine is both an abused substance and a central nervous system (CNS) stimulant, its effects on sensory function are of interest. For example, cocaine reportedly enhances auditory sensitivity and the acoustic reflex, can cause auditory hallucinations, and decreases cortical sensory evoked potential amplitudes. The present study examined the effects of an acute psychoactive dose of cocaine on the rat BAEP over a broad range of stimulus intensities as an objective quantitative measure of this drug's effects on subcortical auditory electrophysiology.

So far, data have been collected from 6 adult Long-Evans rats. The stimuli were 0.1 msec clicks (12.5/sec) with intensities ranging from 33-110 dB p.e. SPL. BAEPs were recorded before and after cocaine HCl treatment (10 mg/kg, i.p., 2% solution). Rectal temperatures were maintained within a narrow range to control for the possible influence of core temperature.

At the higher stimulus intensities, the rat BAEP had 6 components (labelled P1 through P6). Only components P2 and P4 were visible at lower stimulus intensities. All BAEP latencies were prolonged and all amplitudes were decreased as a function of decreasing stimulus intensities ($P<.002$). There were no significant main effects for the drug on BAEP latencies or amplitudes. There were, however, significant intensity-by-drug interactions for P2 and P4 latencies ($P<.05$). In brief, cocaine treatment prolonged P2 and P4 latencies at low stimulus intensities (60 dB and below) and shortened these latencies at high intensities (90 and 110 dB) in comparison to pre-drug levels. A similar trend was observed for P5 and P6 latencies, but not P1 (auditory nerve). The average BAEP threshold was also increased by cocaine treatment (37.3 vs. 41.0 dB, $P=.065$).

The various cocaine-induced changes in the BAEP were not strong. They do suggest, however, that the increased auditory sensitivity associated with cocaine use probably occurs only in response to loud sounds with the reverse effect occurring in response to soft sounds. Such a pattern is suggestive of a recruitment-type change (i.e., loudness recruitment) in auditory neural function. Our results with cocaine treatment are similar in some respects to the effects of amphetamine on auditory threshold (Delay et al., 1978) and theophylline on the BAEP (Church & Shucard, 1987).

91.8 EFFECTS OF MORPHINE, NALOXONE AND TEMPERATURE ON THE AUDITORY BRAINSTEM RESPONSE (ABR) IN THE GUINEA PIG. T.L.Sahley*, T.C.Chimento* and J.N.Gardi. Coleman Memorial Lab. HSE 871, University of California, San Francisco California, 94143.

Acetylcholine (ACh) is the major transmitter of the efferent olivocochlear system (OCS). Enkephalin and dynorphin-like activity also exist in the lateral OCS cells of origin, and in cochlear structures ascribed to the same system. There is also evidence of opioid-kappa and mu receptors in the cochlea, the significance of which is unknown. Amplitude reductions in N1 and ABR potentials, induced by electrical or chemical stimulation of the OCS have been well documented. To date, however, there are no published reports of opioid effects on cochlear outputs.

Changes in ABR interpeak latencies (IPLs) and amplitudes following morphine (10mg/kg) and naloxone (1mg/kg) administration were determined in a series of adult ketamine (40mg/kg) and rompun (20mg/kg) anesthetized guinea pigs. Stimuli were 100usec. rarefaction clicks, monaurally delivered at 20/sec. from 0 to 60dBSL in 10dB increments. Responses to 500 click presentations were averaged at each intensity level through a baseline period, and at 5 minute post-morphine and post-naloxone intervals. Ear temperature (ET) was continuously recorded by a thermister sealed in the contralateral ear canal. This method affords an accurate estimate of brainstem temperature (Williston & Jewett, 1982, Audiology 21:457), and ET changes are highly correlated with wave I-V or I-IV IPL shifts [$F(1,5)=29.35, p<.005; r=.92$; or $F(1,5)=17.62, p<.01; r=.88$] respectively. ET was kept to within ±0.1°F during all ABR recording.

With ET controlled, morphine and naloxone produced no measurable IPL changes. Preliminary analyses did indicate that morphine produced significantly larger (15%) wave I amplitudes at 60dBSL [$t(5)=3.98, p=.01$ but not at 30dB [$t(5)=1.81$, ns]. Naloxone injectio failed to reverse this significant effect of morphin on ABR peak amplitudes by 30 minutes [$t(5)=0.05$, ns]

91.9 EFFECTS OF ATROPINE SULFATE ON THE BRAINSTEM AND CORTICAL AUDITORY EVOKED POTENTIALS IN THE RAT. M.W. Church and R. Gritzke*. Research Institute on Alcoholism, 1021 Main Street, Buffalo, NY 14203.

Because brainstem auditory evoked potentials (BAEPs) are frequently recorded in anesthetized animals and humans, it is important to become familiar with the effects on the BAEP of drugs used during anesthesia, including pre-anesthetics. The dose-dependent and stimulus intensity-dependent effects on the BAEP of one pre-anesthetic, atropine sulfate, were studied in the unanesthetized rat. The animal subjects were 11 young adult female Long-Evans rats. BAEPs in response to 0.1 msec clicks (12.5/sec) were recorded from skull screw electrodes during a baseline period as well as after saline and atropine treatments while each animal was restrained in a fixed position relative to a piezoelectric speaker inside a sound isolation chamber. Click intensitities were 70, 90 and 110 dB p.e. SPL. Rectal temperatures were maintained within ± 0.2 °C of baseline to control for possible temperature-related effects.

Contrary to a prior report, doses in the standard pre-anesthetic range (i.e., 0.250 to 1.000 mg/kg) did not convincingly influence the BAEP. Only the highest dose (40 mg/kg) produced a significant and noteworthy change. This effect was characterized by significant amplitude increases in the P1, P2, and P3 components, but not in the P4, P5 and P6 components. This selective effect occurred at the highest stimulus intensity of 110 dB p.e. SPL, but not at lower intensities. There were no convincing atropine-induced changes in BAEP latencies. Atropine-induced changes in the cortical auditory evoked potential (CAEP) were characterized by amplitude decrements. Thus, atropine seemed to have an excitatory effect on the BAEP and an inhibitory or depressive effect on the CAEP. Atropine-induced changes in the routine electroencephalogram (EEG) were also noted. The atropine-induced changes were not attributable to changes in core temperature, circadian variation, stress associated with handling and restraint, or the tensing of middle ear muscles.

The results of the present study suggest that a standard pre-anesthetic dose of atropine sulfate does not influence the BAEP. Instead, a relatively massive dose is required. Research by others, however, suggests that low doses of pre-anesthetics might interact with other drugs to alter the BAEP (Bhargava et al., Neurosci., 1978, 3: 821-826).

91.10 EXAMINATION OF IRRELEVANT AUDITORY EVOKED POTENTIALS DURING AN AUDITORY ATTENTION TASK. L.C. Oatman. U.S. Army Human Engineering Laboratory, Aberdeen Proving Ground, MD 21005-5001.

This investigation was designed to examine whether selective auditory attention in cats involves a filtering or gating of irrelevant auditory stimuli at the peripheral stages in the afferent auditory pathway. Previously, we demonstrated that when cats were attentive to a visual discrimination task, the amplitudes of irrelevant auditory evoked potentials at the receptor and cortical levels were suppressed. Since suppression of the N1 response of the auditory nerve was observed under carefully controlled conditions and in the absence of middle-ear muscles, we suggested that, during attention to visual stimulation, a central inhibitory mechanism suppresses irrelevant auditory stimuli through the action of the olivo-cochlear bundle (OCB). Since these studies demonstrated a cross-modality gating effect during visual attention, perhaps a similar gating function occurs within the auditory modality during attention to auditory stimuli.

To examine this possibility, four adult female cats learned a two-tone (1000 Hz and 800 Hz) frequency discrimination using food reinforcement. The two tones (relevant stimuli) were presented successively at 85 dB SPL (re 0.0002 microbar). The auditory clicks (irrelevant stimuli) were presented at 1/sec at each 10-dB intensity step from 35 to 125 dB SPL (re 0.0002 microbar) during the presentation of the two-tone discrimination task.

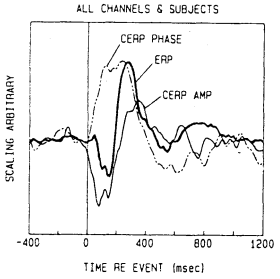
Click-evoked potentials were recorded from the round window (cochlear microphonic and auditory nerve), cochlear nucleus, and auditory cortex of unanesthetized cats during periods of auditory attention and non-attention. The clicks (irrelevant stimuli) of increasing intensity were presented continuously as background before, during, and after the presentation of a two-tone frequency discrimination task (relevant stimuli) which attempted to alter the attentive state of the cats. Amplitude measures of the auditory evoked potentials recorded concurrently at the receptor and the cortical levels were used to assess the effects of auditory attention on irrelevant auditory click stimuli. At all electrode sites (auditory nerve, cochlear nucleus, and auditory cortex) the mean peak-to-peak amplitudes of click-evoked potentials were not significantly different during attention to the two-tone frequency stimuli when compared with the pretest and posttest control sessions. The results suggest that during auditory attention, irrelevant auditory stimuli are not affected by inhibition of the olivo-cochlear bundle at the peripheral stages in the afferent auditory pathways. In contrast to a cross-modality gating effect during visual attention, a similar gating function does not occur within the auditory pathways during auditory attention.

91.11 EVENT-RELATED PERTURBATIONS IN 40 HZ AUDITORY STEADY-STATE POTENTIALS. S. Makeig* and R. Galambos. Childrens Hospital Research Center, 8001 Frost St., San Diego, CA 92123.

When a train of monaural clicks is delivered to the human ear at repetition rates near 40/s, a steady-state evoked response (SSR) is recorded from the scalp. An experimental event (such as changing the intensity of one of the clicks) may perturb the amplitude and phase of the SSR, and these perturbations can be quantified by averaging the responses time-locked to the events, narrow-band filtering at the stimulus rate, and measuring the amplitude and phase of the filtered response using a brief (circa 50 msec) moving window. A complex event-related potential (CERP) is the result. The CERP is a two-dimensional, narrow-band, frequency-domain analog of the usual one-dimensional time-domain event-related potential (ERP).

If a single click is omitted from the stimulus train the CERP amplitude drops for 200 msec then rises (peaking at 400 msec), whereas the phase shifts 40 or more degrees (at 100 msec), crosses the baseline near 400 msec, reaches a minimum at 600 msec and takes fully 900 msec post-stimulus to regain baseline phase. When the perturbing stimulus is a click to the ear contralateral to that receiving the probe train a similar CERP appears; however, when the perturbing stimulus is visual (checkerboard reversals), no CERP is observed.

The window on event-related brain dynamics provided by the 40 Hz CERP differs from that given by the conventional auditory ERP sequence; the CERP both parallels and complements the ERP. The CERP may index gating of events in cortical and subcortical structures, and we speculate that its initial 200 msec drop in amplitude may be related to the several 200 msec time constants characteristic of central auditory integration.



91.12 EFFECTS OF TEMPORAL AND PARIETAL LESIONS ON TEMPORAL COMPONENTS OF THE HUMAN AUDITORY EVOKED POTENTIAL. R. T. Knight, D. Scabini*, D. L. Woods and C. C.Clayworth* Neurology Dept., Univ. of California Davis, V.A.M.C., 150 Muir Rd., Martinez, Ca 94553

Based on scalp topography and dipole modelling data, the human auditory evoked potential (AEP) generated to a transient sound is felt to consist of superimposed neural activity from multiple intracranial sources. The T-component of the human AEP is a negative potential which is maximal over temporal recording sites and is proposed to arise from a radial dipole source situated in lateral regions of the superior temporal gyrus (STG). In order to assess the contributions of temporal and parietal cortex to the T-component, we recorded AEPs to tone pips (50 msec duration, 1Khz, 60 dbSL, 1/sec ISI) in controls and in patients with focal unilateral lesions centered in STG (n=10) or in lateral parietal cortex (PAR; n=6). Control subjects generated a T-component peaking at 128 msec with comparable amplitudes over T3 (-1.09 uv) and T4 (-1.33 uv) electrode sites. In controls the T-component was markedly enhanced in amplitude (by 88%) over the temporal lobe contralateral to the ear of stimulation ($p < 0.001$). Data from STG and PAR patients were analyzed as a function of whether the temporal electrode was ipsilateral (Ti) or contralateral (Tc) to the lesioned hemisphere. Latencies of the T-component were similar to controls for both STG and PAR groups (PAR, Ti=120 msec, Tc=128 msec; STG, Ti=124 msec, Tc=128 msec). The T-component was slightly reduced over lesioned and non-lesioned hemisphere in the PAR group but the amplitudes were not significantly different from controls (Ti=-0.66 uv, Tc=-0.82 uv). In contrast, a near abolishment of the T-component was observed over lesioned STG with normal amplitudes recorded over non-lesioned hemisphere (Ti=-0.13 uv, Tc=-1.27 uv, $p < 0.02$). These data support an origin of the human T-component in STG. The results will be discussed in relation to other lesion data concerning the origins of the human AEP.

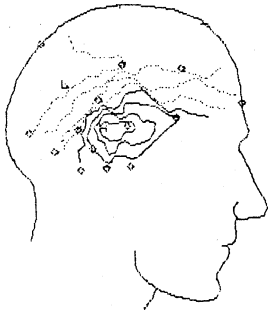
91.13 THE 45 MSEC TEMPORAL POSITIVE PEAK (TP45) OF THE HUMAN AUDITORY EVOKED POTENTIAL. A.T. Cacace* and J.R. Wolpaw (SPON: K.D. Barron). Depts of Surg, Neurol, & Anat, Albany Med Coll, Albany, NY 12208; and Wadsworth Labs, NYS Dept Hlth, Albany, NY 12201.

Detailed topographical analysis of middle latency (20-80 ms) auditory evoked potentials has received only limited attention. Knowledge of these distributions may allow development of significant new measures of CNS function. We studied these distributions in 30 normal adults (20-49 years, 15 male, 15 female). Monaural and binaural clicks were delivered at 0.3 Hz and recorded from 32 channels referred to a balanced noncephalic reference.

In addition to the expected central positive peaks, Pa and Pb, at about 30 and 50 ms, very localized positive activity occurred over posterior temporal scalp locations at about 45 ms. This TP45 peak, focused over auditory cortex, was simultaneous with frontocentral negative activity. TP45 was larger over the right hemisphere and over the contralateral hemisphere.

TP45 has probably been obscured in previous studies by use of active reference electrode locations, such as mastoid and earlobe, and possibly also by high stimulation rates. We are defining the intersubject variability of TP45 and evaluating electrode montages which may minimize variability for clinical applications.



Right-side isovoltage topography for TP45 to left ear stimulation. Solid lines indicate positive voltage, dotted indicate negative. "H" is the highest point, "L" is the lowest.

91.14 CONTRIBUTIONS OF MULTIPLE NEURAL ELEMENTS TO THE CLICK-EVOKED RESPONSE OF MONKEY AUDITORY CORTEX. C.E. Tenke, G.V. Simpson, C.E. Schroeder, J.C. Arezzo and H.G. Vaughan, Jr. Neuroscience and Neurology Depts., Albert Einstein Coll. Med., Bronx, NY.

Auditory koniocortex is the principal generator of surface-recorded auditory evoked potentials (AEP) in monkeys, and is thought to be a major contributor to scalp-recorded AEP in humans. Pyramidal cells have traditionally been identified as the major neural element contributing to surface responses. This study uses high resolution, intracortical recording techniques to examine the laminar distribution of neural activity associated with the AEP as well as the possible contribution of non-pyramidal elements. AEPs and concomitant multiunit activity (MUA) were recorded during electrode penetrations through the supratemporal plane (STP) in 2 alert monkeys (m. Fasicularis). Recordings were made using 16 channel, multicontact electrodes with intercontact spacings of 75 or 100uM. Current source density (CSD) was computed from the AEP depth profiles. To permit an accurate one-dimensional CSD, penetrations were made normal to STP. Stimuli consisted of binaural clicks (50usec rectangular pulses at 100db SPL) at repetition rates of 1.4/sec to 40/sec, varied across trial blocks.

The early portion of the cortical AEP consists of 4 components: an initial negativity (N9), a double lobed positive wave (P12/14), a small, second negativity (N18) and a later positivity (P24). Each component inverts in polarity within STP: P12/14, N18 and P24 within the middle laminae, while the inversion of N9 is completed only in the deepest cortical laminae. CSD analysis resolves three temporally and spatially separable sinks in the immediate vicinity of the thalamocortical terminations. The earliest sink is sharply localized to lamina IV and is coincident with N9 and with the initial burst of MUA recorded within A1 and the subjacent white matter. Both the initial sink and N9 are selectively spared at high repetition rates. The second sink, coincident with P12/14, is co-located with the N9 sink but is characteristically larger in amplitude and more widely distributed. A third sink peaking between 18 and 20 msec is centered within lamina III. The sources associated with the N9 sink are primarily confined to laminae IV and V, while those associated with P12/14 extend superifically to include laminae III and II.

These data are consistent with the localization of the major generators of the early AEP components to neural elements within lamina IV. Terminal depolarization of thalamocortical afferents and the initial activation of lamina IV stellate cells appear to be exclusively responsible for N9 and partially responsible for P12/14. The activation of pyramidal cells contributes to P12/14 and to the later components. Supported by MH06723, MH15788.

91.15 CONTRIBUTIONS OF AUDITORY CORTEX TO AUDITORY EVOKED POTENTIALS IN THE RAT. G. V. Simpson and R. T. Knight, University of California, Dept. of Neurology, V.A. Med. Ctr., Martinez CA 94553

Auditory evoked potentials (AEP) were recorded before and after bilateral ablations of auditory cortex to examine its contribution to the AEP in the rat. AEPs were recorded in the alert, unrestrained rat from screw electrodes implanted (under pentobarbital anesthesia) in the lateral skull directly over auditory cortex (ACx) 4.5 mm anterior to the interaural line; and in the dorsal skull over frontal cortex (FCx), at the vertex (Vx), and at the posterolateral edge of the dorsal skull (PL). AEPs were recorded to clicks (50 dB above BAEP threshold) in eight Fischer 344 male rats 12 months of age, twice in each of two pre-lesion sessions and at one and six days following bilateral auditory cortex lesions. Post-lesion data are reported for the 4 animals in which complete bilateral ablations of auditory cortex had been verified.

One series of components was maximal over the dorsal skull surface (at Vx) and consisted of a P13, N18, P25, N40, N50 and P70. The later components (N40, N50 and P70) were also recorded on the lateral skull (ACx). Another series of components was found to be maximal on the lateral skull over auditory cortex (ACx), the P7, P11, N14, and N32. Higher stimulation rates (10/sec.) diminish the P11 and increase its latency while the P7 is largely unaffected.

The P7, P11 and N14 components were eliminated on the first day following bilateral auditory cortex ablations and remained so at day six post-lesion. The N32 component was greatly reduced, but the percentage decrease could not be unequivically determined due to its overlap with the N40 component. In marked contrast, those components maximal at the dorsal skull were relatively unaffected by the lesions. The basic waveforms remained intact and only partial amplitude reductions were found, some not evident until the sixth day post-lesion.

The findings indicate that auditory cortex is the generator of the laterally recorded P7, P11 and N14 components and at least the major contributor to the laterally maximal N32. All AEP components recorded on the dorsal skull appear to receive relatively little, if any, direct contribution from auditory cortex generators.

91.16 FOURIER BESSEL DECOMPOSITION OF AUDITORY EVOKED POTENTIALS. F.M. Chen* and K.M. Mudry (SPON: L. Abel). Dept. Biomedical Engineering, The University of Akron, Akron, OH 44325.

A series of evoked potentials recorded in response to a sequence of stimuli are often difficult to quantitatively describe and to compare to each other if more than one or two predominant peaks occur in the signal. A method to decompose evoked potentials into orthogonal components which can approximate the original signal with a small number of basis components are being investigated. There are many orthogonal series which could be evaluated including the Fourier and Exponential series. The Fourier Bessel functions, because of their decaying oscillatory shape which resembles the auditory evoked responses, have the potential to be a more efficient descriptor of these signals than some other orthogonal series. Bessel functions of the 1st kind and above the 1st order have a shape related to the evoked reponses. The decomposition using the 1st kind, 1st order were used to analyze a series of whole VIIIth nerve responses to a series of tone bursts at different frequencies. Because of the latency of the evoked response, the optimal starting time used to decompose the signals was found to be important. The number of components needed to reconstruct the potentials was dependent on the shape with fewer components needed for signals with rapid onsets and more transient responses than signals which exhibited slower onsets and continued responses throughout the stimulus period.

FEEDING AND DRINKING II

92.1 **ABDOMINAL VAGAL PATHWAYS MEDIATING THE CEPHALIC PHASE INSULIN SECRETION IN THE RAT.** H.-R. Berthoud and T.L. Powley. Lab. of Regulatory Psychobiology, Purdue U., W. Lafayette, IN, 47907.

In contrast to the widely held belief that the celiac branch(es) of the abdominal vagus innervates the pancreatic B-cells to stimulate insulin secretion, we recently found that the plasma insulin response to electrical stimulation of the cervical vagi depends almost exclusively on the integrity of the two gastric branches and the hepatic branch (Berthoud et al., Soc. Neurosci. Abstr. 12, p. 766,1986). In order to test the validity of these observations in a more physiological situation (electrical stimulation activates all vagal fibers indiscriminately) we investigated the cephalic phase of insulin secretion in separate groups of rats that had received selective bilateral celiac vagotomies, bilateral gastric (plus hepatic) vagotomies, or sham operations.

Vagotomies and the implantation of chronic jugular vein catheters were performed in male SD rats of 320 - 360g which had been adapted during 2 weeks to a liquid sweetened condensed milk diet. Fifteen days later, testing began with either normal rat chow (2 trials), 20% α-D-Glucose (1 trial) or the maintenance diet (1 trial) given to the 10 - 15h food deprived animals. At the end of the testing period, the animals were injected i.p. with 3mg True Blue and 3 days later were sacrificed. Inventory of the fluorescently labeled dmnX cells was taken in order to verify the selective vagotomies, according to the method of Powley et al. (Am. J. Physiol., in press, 1987).

Controls and animals with verified bilateral celiac vagotomies, both significantly increased their plasma insulin levels at 2min when eating chow (+17.5 ± 3.1 μU/ml and +15.9 ±5.2 μU/ml above basal, respectively). In contrast, rats with verified bilateral gastric plus hepatic branch vagotomies showed only a small and nonsignificant increase (+1.4 ± 1.3 μU/ml, $p<0.01$). Plasma glucose changes at 2 min were small and non-significant for any group. Cephalic phase insulin responses to milk or glucose ingestion were confounded by the significantly elevated glycemia at 2 min, due to rapid absorption, but the same pattern emerged if insulin responses were corrected for glycemia. In other regulatory tests, gastric plus hepatic branch vagotomized rats exhibited (1) depressed intake of the maintenance diet for the first 7 days following vagotomy, (2) chronically reduced water intake, (3) lower body weight, (4) delayed gastric emptying of chow, and (5) accelerated emptying of fluids. Celiac vagotomized rats failed to show any of these disturbances and only displayed abnormally high plasma glucose and insulin levels between 10 and 20 min after the start of a chow meal, which was most likely due to changes in gastric emptying and/or absorption.

It is concluded that the integrity of the gastric and the hepatic abdominal vagal branches is necessary and sufficient for mediation of the cephalic phase insulin response. Together with our earlier electrical stimulation experiments, this is strong evidence that these branches innervate the endocrine pancreas. The targets and functions of the celiac branches remain to be indentified. (NIH Grant DK27627)

92.2 EFFECT OF NUCLEUS OF SOLITARY TRACT LESIONS ON FOOD INTAKE RESPONSES AND DIETARY CHOICES OF RATS FED DIETS CONTAINING PROTEIN IN EXCESS. P.M.B. Leung, D.W. Gietzen and Q.R. Rogers. Dept. of Physiological Sciences, School of Vet. Med., Univ. of California, Davis, CA 95616.

Bilateral electrolytic lesions were placed in nucleus of solitary tract (SOL) of adult Sprague-Dawley rats at rostrocaudal extent of medial and lateral aspects rostral to the area postrema (AP) (SOL 1, 13.3 mm posterior to bregma) and at the level of the AP (SOL 2, 13.8 mm posterior to bregma). Earlier we reported that rats with AP lesions showed chronic reduction in food intake (FI) and body weight. They also exhibited similar initial FI depression as did intact controls (INT) but showed facilitated adaptation when fed a high-protein (75% casein) diet (HP) (Leung, P.M.B., et al., Fed. Proc. 45:1091, 1986). Also when offered the choice between a low protein (6% casein) diet (LP) and the HP, rats with AP lesions consumed more HP in the choice-regimen than INT (Leung, P.M.B., et al., Soc. Neurosci. 12:1556, 1986). Since SOL has demonstrated neural and vascular connections with AP and contains both visceral and gustatory connections, animals with SOL 1 and SOL 2 lesions as well as INT were equilibrated with the LP and fed the HP for 23 days before refeeding the LP. Following LP re-equilibration, rats with SOL 1 and SOL 2 lesions as well as INT were offered the choice between the LP and the HP. The two identical spillage-proof food containers in choice-regimen were rotated daily at random from side to side and among all animals tested. Food and water were available ad libitum. An average of 3 days of LP intake just prior to the switching to HP was used as basal baseline intake (BL). When fed HP, animals with SOL 1 and SOL 2 lesions as well as INT showed similar marked initial reductions in FI (45.0±2.3%, 52.5±2.4% and 49.6±2.8% of respective BL of 24.6 g, 24.4 g and 24.5 g for the two lesioned and INT groups). Slow adaptation to HP was observed for all lesioned and non-lesioned animals reaching 80.3±3.1%, 75.8±6.4% and 83.4±5.2% of their respective BL for rats with SOL 1 and SOL 2 lesions as well as INT, respectively, in 23 days. All animals, whether lesioned or non-lesioned, showed transient hyperphagia on the 3rd day but returned to BL thereafter when refed LP. When offered the choice between LP and HP, the initial FI of HP comprised only 22.9±8.7%, 24.5±7.8% and 27.4±4.9% of their respective combined total FI in choice-regimen for SOL 1 and SOL 2 lesioned groups as well as INT. The initial protein-energy selected expressed as % of total caloric intake (PE%) were 22.6%, 23.6% and 25.4%, respectively, for SOL 1 and SOL 2 lesioned animals as well as INT. The preference for LH steadily increased while the reverse was true for HP. Averages of 7 days PE% for SOL 1, SOL 2 and INT groups were respectively 17.7%, 17.8% and 18.6%. These results indicate that the SOL and the AP responded differently to HP feeding. In contrast to AP, SOL is not involved in the adaptive FI of HP or normal avoidance for HP under dietary choice situations. (Supported by USPHS NIH grant #DK13252.)

92.3 STRIA TERMINALIS TRANSECTIONS PRODUCE DRAMATIC CHANGES IN TASTE REACTIVITY WITHOUT CONCOMITANT HYPER- OR HYPO-PHAGIA IN THE RAT. R. M. Black* and H. P. Weingarten. Dept. of Psychology, McMaster University, Hamilton, Ontario, Canada, L8S 4K1

An over-reactivity to the sensory qualities of a food (*i.e.* finickiness) is one of the defining features of the ventromedial hypothalamic (VMH) syndrome. The neural damage responsible for this disturbance is unknown. It is possible that finickiness results from damage to cell bodies in the VMH *per se*. In contrast, it may result from interruption of amygdaloid (AMY) inputs to the VMH via the Stria Terminalis (ST). This view is supported by evidence that: 1) AMY inputs to the VMH are destroyed in the classic VMH lesion; 2) hyperphagia and finickiness may be anatomically separable in the VMH; and 3) AMY damage results in feeding disturbances suggestive of an over-responsiveness to taste stimuli. To test the contribution of damage of amygdalo-hypothalamo connections via the ST to VMH induced finickiness, the taste responsiveness of four groups of rats (VMH lesion, ST transection, combined VMH/ST damage and controls) were assessed in a sham feeding paradigm.

When feeding palatable sucrose solutions of various concentrations, ST rats were as finicky as VMH rats. However, the effects of VMH and ST damage were additive suggesting that the taste disturbances induced by VMH and ST damage are independent. Neither VMH, ST nor VMH/ST rats over-respond to unpalatable tastes such as quinine. When the continuity of the gastro-intestinal tract was maintained, *i.e.* the fistula was closed, the excessive taste responsivity of the ST rats, but not the VMH or VMH/ ST rats, was completely masked. Similarly, when fed *ad lib*, ST rats were not hyperphagic compared to controls, whereas VMH and VMH/ST rats were. It was concluded that ST damage produces dramatic alterations in the sensory processing of sweet but not bitter tastes, independent of the VMH, and this effect is masked when the continuity of the gastro-intestinal tract is maintained.

Supported by grant funds from NSERC.

92.4 TASTE RESPONSES IN THE NTS OF NA-DEPRIVED RATS. G. P. Mark*, K. M. Jacobs* and T. R. Scott. Dept. of Psych. and Inst. for Neurosci., Univ. of Delaware, Newark, DE 19716.

Maintenance of sodium balance is crucial to mammals and is expressed in the innate salt appetite. With depletion, sodium preference is exaggerated, hypertonic solutions accepted, and salt balance restored. This compensatory behavior is thought to result from a centrally-induced change in taste responsiveness, a proposal we tested by recording taste activity from 94 single neurons in the nucleus tractus solitarius of sodium replete (N=44) and of deprived (N=50) rats. Twelve Wistar rats were given a nominally sodium-free diet for 10-13 days, and the resulting Na depletion confirmed by flame photometry of their urine. Nine rats provided control data. Taste stimuli included five concentrations of NaCl (.003-.3M) plus 8 other salts, acids, sugars and alkaloids. Taste responsiveness was generally reduced in Na-depleted rats. Spontaneous activity was 33% lower while responses to sodium salts lagged by a mean of 30%, to acids by 25% and to bitter salts and quinine by 17%. Remarkably, mean activity to sugars was 60% higher in the deprived group. Activity in sweet-sensitive and Na-sensitive neurons was most affected. In deprived animals responses to sodium salts were lower by 80% among Na-sensitive cells while among sugar-sensitive neurons activity to these stimuli was nearly 10 times greater than in controls. Multidimensional stimulus spaces based on average activity in each of the four identifiable neuron subgroups (sugar, sodium, acid, quinine) demonstrated a shift in the affiliation of Na-salts away from bitter stimuli and toward sugars. These results confirm earlier findings from the chorda tympani that Na-deprivation suppresses activity evoked by Na salts and augments responses to sugars. Beyond this, however, they reveal a shift in the major responsibility for encoding sodium from Na-sensitive neurons to those whose primary sensitivity is to sugars. The implication is either that sodium assumes a sweet taste in a deprived rat or that the underlying dimension we are measuring is one based on hedonics along which sodium is shifted toward the positive pole by deprivation and so toward the sugars that reside there.

92.5 TASTE REACTIVITY IN RATS WITH VENTROMEDIAL-HYPOTHALAMIC AND SEPTAL LESIONS
J. M. Dopp* and J. C. Mitchell, Psychology Dept. Kansas State University, Manhattan, KS., 66506.

The taste reactivity test (Grill & Norgren, 1978) was used to evaluate the magnitude of taste hyperresponsivity displayed by rats with lesions to the VMH and septum. Septal, VMH, and Control groups (n=6) received 1-ml intraoral infusions of solutions of sucrose (.01, .03, .3, 1.0 M) and quinine hydrochloride (.00003, .00003, .0003, .003 M). The resulting stereotyped behavioral responses or "fixed action patterns" (FAPs) were videotaped and analyzed frame-by-frame.

Responses were divided into three categories: ingestive, aversive, and neutral (neutral responses were those found to be negatively correlated with solution concentration).

Septal and VMH animals displayed significantly more ingestive responses to sucrose than did controls, and all groups of animals showed similar decreases in aversive responses as sucrose concentration increased. These results support the notion of positive finickiness (Weingarten, 1982) in septal and VMH animals.

Lesion animals did not show evidence of negative finickiness; there were no sigificant differences in numbers of aversive responses to quinine hydrochloride.

Additionally, ingestive responses were plotted against sucrose concentration and it was found that while septal animals showed more ingestive responses than controls at all concentrations, the slopes of the lines for the two groups were approximately the same. In contrast, the slope for the VMH group was significantly steeper than that of the septal group. This indicates that the nature of taste hyperresponsivity in septal animals is different from that in VMH animals: The septal lesion appeared to produce a constant increase in responsivity across the sucrose concentrations tested; the VMH lesion produced a multiplicative increase in responsivity as sucrose concentration increased.

92.6 ANGIOTENSIN II EVOKES DRINKING-LIKE JAW AND TONGUE MOVEMENTS IN THE ANESTHETIZED GUINEA PIG. L. J. Goldberg, K. De Bruyne* and G. E. Gerstner*. Depts. of Oral Biology, Kinesiology, Anatomy and the Brain Research Institute, UCLA, Los Angeles, CA 90024.

Angiotensin II (AII) has been shown to elicit drinking in a variety of water replete awake animals when administered either intravenously or directly into the cerebral ventricles. Its effects are presumably via activation of dopaminergic systems that initiate and maintain drinking motor movements. We have observed that the dopamine agonist apomorphine when administered intravenously in the anesthetized guinea pig induces drinking-like jaw and tongue movements (Lambert et al., J. Neurophysiol. 55,301, 1986). The purpose of the present study was to determine if AII could induce such drinking-like motor movements in the anesthetized guinea pig.

In ketamine anesthetized guinea pigs fine wire bipolar recording electrodes were inserted into the jaw opener digastric muscles for recording EMG activity. The movements of the mandible were monitored by a photoelectric position sensor placed in front of a small tungsten light source fixed to the inferior surface of the mandible. An infusion pump was used to deliver (i.v. through the external jugular vein) 1 μg of AII dissolved in 0.4 ml of normal saline at a rate of 0.02 ml/min for 20 min.

The level of anesthesia was adjusted so that all animals demonstrated spontaneously occurring rhythmic jaw movements prior to AII infusion. This previously described behavior (Lambert et al., J. Neurophysiol. 55,301, 1986) consists of prominent lateral excursions of the mandible occurring in association with both jaw opening and closing movements. From between 6 and 8 minutes after the beginning of AII infusion jaw and tongue movements and digastric EMG activity characteristic of drinking behavior were observed. This activity consisted of rhythmic jaw movements with the opening component of the cycle confined almost totally to the midline. In contrast to the spontaneous cycles, visually observed prominent tongue protrusions accompanied each jaw opening movement. The mean and standard deviation of the cycle times of the drinking-like behavior was 386±88 ms (n=96); the EMG burst durations of the digastric muscle were 128±23 ms, and there was a highly significant correlation between digastric EMG burst duration and cycle time ($r=0.47$; $p<0.001$). Cycles with drinking characteristics gradually replaced the spontaneous type. From 9 to 13 minutes after the onset of AII infusion the presence of drinking-like cycles increased to 70-95% of the total observed rhythmic jaw movements. Drinking-like cycles ceased to occur and all rhythmic jaw movements were of the spontaneous type 18 minutes after the beginning of AII infusion.

The jaw movement trajectories, tongue movement patterns, digastric EMG burst durations and cycle time-digastric burst duration correlations are similar for AII and apomorphine induced drinking-like behavior in the anesthetized guinea pig, as well as for actual drinking in the awake guinea pig. These results indicate that the regulatory peptide AII can drive motor systems responsible for drinking behavior in the unconscious animal.

92.7 PATTERNS OF FEEDING AND BITING ELICITED BY DEPRIVATION OR BY HYPOTHALAMIC STIMULATION *M. L. Volkov*, T. R. Maone, S. Mann, J. M. Kaplan* and S. M. Feldman.* Department of Psychology, New York University, New York, NY 10003.

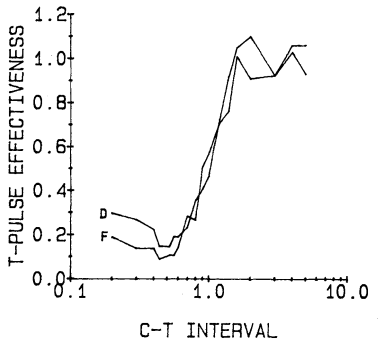
We used a discrete trials paradigm to study the microstructure of food intake in rats. A single daily feeding session consisted of 30 or 32 trials, during which a dish of wet mash (Purina rat chow and water, 3:2, w/w) was available for 30-sec feeding trials (bouts) separated by 2-min intertrial intervals. Feeding was achieved during experimental sessions either by using 30-sec trains of electrical stimulation of the lateral hypothalamus (ESLH: 0.1msec pulses @ 60pps) or by food deprivation. Intake during ESLH sessions was targeted by varying current intensity. Under deprivation conditions, animals were adapted to a feeding schedule in which food was available during trial-structured meals that always followed a 23-hr fast. Food intake was measured after each trial, and sessions were recorded on videotape for subsequent analysis of latency, duration and bite frequency. Deprived rats were studied either in an open field environment, or were suspended in a harness (Kaplan and Feldman, *Soc. Neurosci. Abstr.*, 9:190, 1983) during the feeding sessions to restrict their behavioral options. Harness restraint was also used for ESLH-induced feeding. Both restrained and open field subjects adapted to the paradigm and consumed a sufficient amount to maintain body weight. ESLH subjects and a comparable group of deprived subjects studied using harness restraint were matched for total session food intake.

Results showed that the shape of the intake curves were the same for food deprived and ESLH subjects. Analysis by linear regression of the eating curves produced by subjects under all conditions showed that intake rate decreased monotonically throughout the course of a feeding session (mean slope = -0.048 for deprived animals in harness, -0.050 for deprived animals in open field, and -0.040 for ESLH animals) with a high correlation between trial order and intake level (mean r = -0.83 for deprived animals in harness, -0.77 for deprived animals in open field, and -0.79 for ESLH animals). Microstructural analyses, carried out on ESLH and deprived animals in the harness, revealed that intake rate was a direct function of bite size, which declined through the course of the session for both groups, with a *constant* bite frequency. This constant bite frequency under ESLH conditions was earlier reported by Kaplan and Feldman, cited above. However, under ESLH conditions the number of bites was approximately double that seen under deprivation-induced conditions, even when intake rate was the same for both groups. We have shown that for both ESLH-elicited and deprivation-induced feeding, intake can be described by the same linear function. By sampling intake rate over time, this paradigm reveals a strong correlation between decreasing intake rate and meal progress.

92.8 A COMPARISON OF REFRACTORY PERIOD ESTIMATES FOR STIMULATION-INDUCED FEEDING AND STIMULATION-INDUCED DRINKING. M.B. Noel and R.A. Wise. Dept. of Psych., Concordia University, Montreal, Canada H3G 1M8.

Electrical stimulation of the same site in the lateral hypothalamic medial forebrain bundle (MFB) can induce a variety of behaviors including eating and drinking. It is not clear whether these two behaviors result from activation of two different fiber systems of the MFB, or whether the same MFB fiber population is involved in the mediation of the two behaviors. In the present experiment, the refractory periods (RPs) for the two behaviors were estimated and compared.

Rats were implanted with monopolar MFB stimulating electrodes. Subjects were four animals that both ate and drank in response to stimulation. Refractory periods for the substrates of stimulation-induced feeding (SIF) and for stimulation-induced drinking (SID) were estimated using a paired-pulse technique, in which the animal's latency to respond during a train of pulse pairs is compared to its latency to respond to a train of single pulses. The distribution of RPs in the population of behaviorally relevant fibers was inferred by varying the delay (C-T interval) between the two consecutive pulses (C and T pulse) of each pair in the paired-pulse condition. The initial rising portion of the RP curves of the two behaviors begins at C-T intervals of about 0.5-0.7 msec. In either behavior the RP curve approaches an asymptote at C-T intervals of 2.0-3.0 msec. It appears that the two behaviors are mediated at least in part by the same MFB fibers, or by different MFB fibers having similiar RP distributions.



92.9 STUDIES ON THE FEEDING AND DRINKING ELICITED IN RATS FOLLOWING INJECTIONS OF MUSCIMOL INTO THE MEDIAN RAPHE NUCLEUS. M.A. Klitenick and D. Wirtshafter, Dept. Psychology, Univ of IL at Chicago Chicago, IL 60680.

In previous studies we have demonstrated that injection of the GABA-A agonist muscimol into the median raphe nucleus (MR) leads to a pronounced increase in food and water intake. Mapping studies have shown that the MR is a more sensitive site for the elicitation of feeding and drinking than are either the dorsal raphe nucleus or the ventral tegmental area (Klitenick & Wirtshafter, 1986) and, in other studies, we have observed a similar pattern of anatomical sensitivity with respect to the ability of muscimol to increase locomotor activity. In the current report we attempted to investigate in more detail the ingestive behaviors produced by intra-MR muscimol injections.

Several authors have reported that the effects on feeding elicited by intra-hypothalamic injections of norepinephrine differ depending on whether the injections are made during the light or dark phases of the day/night cycle. In order to determine whether similar effects occur with muscimol injections, we prepared rats with chronic indwelling cannula aimed at the MR. Feeding and drinking in response to intra-MR injections of muscimol (0,6.25,12.5, 25ng/0.25ul) were then examined either during the first two hours of the dark phase or during the middle of the light phase. The results indicate that baseline intakes were much higher during the night than the day. Muscimol, however, produced equivalent, dose dependent, increases over baseline feeding and drinking regardless of the time of administration.

Since the MR is well known to contain a population of serotonergic cells, we next examined the effects of serotonin depletion on muscimol-induced feeding. Rats were prepared with chronic cannula aimed at the MR and feeding and drinking were measured for 2 hours after injection of vehicle or 25ng of muscimol. Subjects were then divided into two groups matched for previous intakes and given intra-MR injections of either 5,7-DHT (7.5ug/1.5ul) or its vehicle following DMI pretreatment. After 12 days of recovery, food and water intake and food spillage were again measured for 2 hours after intra-MR muscimol (0 & 25ng/0.25ul).

Preliminary results indicate that depletion of 5-HT does not attenuate muscimol-induced feeding behavior. The present results do not support a role for serotonergic systems originating in the MR in mediating the ingestive behaviors produced by intra-MR muscimol. In other studies we have obtained similar results with respect to muscimol-induced hyperactivity.

92.10 ONTOGENY OF POLYCOSE AND SUCROSE APPETITE IN INFANT RATS. M. Vigorito and A. Sclafani. Dept. of Psychology, Brooklyn College of CUNY, Brooklyn, NY 11210.

Rats taste starch and starch-derived polysaccharides and find the taste very attractive. Their starch taste is qualitatively different from their taste for sucrose and it appears that rats have two different carbohydrate taste systems. It is known that rats have an innate preference for sweet taste but whether their preference for starch taste is innate or conditioned by the postingestive effects of starch is not known. We addressed this issue by comparing the behavioral responsiveness of infant rats to Polycose (a starch hydrolysate) and sucrose using the intraoral infusion technique.

Infant rats were tested once with either water, Polycose or sucrose (.03 M or .3 M) at 3, 6, 9, 12, or 15 days of age. One hour prior to testing the pups were removed from the mother, implanted with an oral cannula and placed in a test incubator. Their behavioral responses (mouthing, general activity) to five infusions of the taste stimulus was measured during a 10 min test session; intake was determined by pre- and post-test body weight measures.

The pups consumed more .3 M Polycose and sucrose than water at ages 9 days and older, and more .03 M saccharides than water at 12 days and older. Their intakes of the two saccharides did not differ. The mouthing data revealed that the pups first discriminated the .3 M sucrose from water at 6 days and the .3 M Polycose at 9 days of age. However, the pups discriminated the .03 M Polycose at an earlier age (9 days) than they did the .03 M sucrose (12 days). These results are consistent with the findings that adult rats prefer Polycose at lower concentrations, but sucrose at high concentrations in two-bottle preference tests.

The findings demonstrate that polysaccharide appetite, like sucrose appetite, is present in rats at a very young age prior to any experience with starch. In fact, the rats' appetitive response to polysaccharides develops before they have the enzymes to digest starch (salivary and pancreatic amylase). The differential development of the mouthing response to Polycose and sucrose provides further evidence for the existence of two different taste (sub)systems for carbohydrates. 92.11 CONDITIONED FLAVOR PREFERENCES INDUCED BY INTRAGASTRIC POLYCOSE INFUSIONS: AN ELECTRONIC ESOPHAGUS PREPARATION
A. Sclafani and J.W. Nissenbaum*. Dept. of Psychology, Brooklyn College of CUNY, Brooklyn, NY 11210.

Rats are very attracted to the taste of starch-derived polysaccharides (e.g., Polycose). Some data suggest that the postingestive consequences of polysaccharides are also rewarding to rats. The present study assessed the relative importance of pre- and postingestive factors in polysaccharide appetite using an "electronic esophagus" preparation.

Adult female rats were fitted with two chronic gastric catheters. The catheters were connected to infusion pumps that were automatically operated whenever the rat drank from drinking tubes that were available 24 hr/day. On alternate days, as the rats drank one flavored nonnutritive solution (CS+ = cherry or grape Kool-Aid) 16% Polycose was infused intragastrically (IG) and when they drank a different flavored solution (CS- = grape or cherry Kool-Aid) water was infused intragastrically. (Approx. 1.3 ml was infused for each 1 ml orally consumed.) Chow was available ad libitum. After 4 training days the rats were given two-bottle preference tests (24 hr/day). The rats displayed a robust preference (95%) for the CS+ solution over the CS- solution. They also preferred the CS+ solution to water (87%) but did not prefer the CS- solution to water (56%). The rats continued to prefer (99%) the CS+ solution to the CS- solution even when both flavors were associated with IG water infusions (extinction tests).

In separate one-bottle tests the rats' oral intakes of 16% Polycose solution (paired with IG water), CS+ solution (paired with IG 16% Polycose), and .2% saccharin solution (paired with IG 16% Polycose) were compared. The rats consumed approximately twice as much of the Polycose and saccharin solutions as of the CS+ solution.

These results demonstrate that the postingestive effects of polysaccharides are reinforcing to rats and condition strong and persistent flavor preferences. Nevertheless, stimulation of the rats' polysaccharide or sweet taste receptors (with Polycose and saccharin, respectively) appears necessary in order to obtain maximal intakes. Thus, both taste and postingestive factors play a critical role in carbohydrate appetite.

92.12 OROPHARYNGEAL CORRELATES OF MEAL PROGRESS IN THE RAT.
J.M. Kaplan* and H.J. Grill. Department of Psychology and Institute of Neurological Sciences, University of Pennsylvania.

Because the ingestion rate for a given feeding bout is equal to the product of the swallow frequency and the average volume per swallow, any modulation of the rate of ingestion must be mediated by an adjustment of either or both of these swallowing parameters. Recently, using controlled intraoral infusions of sucrose solutions, Kaplan & Grill (1986) showed that both swallowing parameters covaried positively to accommodate adjustments, imposed by the experimenter, in ingestion rate (= infusion rate). In the present study, we sought to determine whether comparable swallow patterning mechanisms operate during normal meals of semi-solid food where ingestion rate varies systematically under the animal's voluntary control.

Prior to feeding tests, fine-wire electrodes were implanted into the inferior pharyngeal constrictor muscle of adult male Sprague-Dawley rats for chronic EMG recording. During test sessions, a video frame-splitter enabled simultaneous recording of the rat's oromotor behavior (biting, chewing) along with an oscilloscope screen displaying the EMG activity associated with swallowing. Rats were 20 to 24 hrs food-deprived and placed in an experimental chamber to which they had previously been adapted. Access to food (wet mash - 3:2 water:lab chow v/w) was limited to 60 sec test trials (inter-trial interval = 120 sec). Thus, meals taken were of the form of a series of consecutive 1 min feeding bouts.

For each meal studied: (1) there was a gradual decline in ingestion rate over trials, presumably reflecting the satiating consequences of the accumulating postingestive load and, (2) both swallow frequency and average volume per swallow declined over trials in direct proportion to reductions in the rate of ingestion. Correlation coefficients relating ingestion rate to either swallowing parameter ranged from 0.75 to 0.91 and were, for every subject (N=4), significant at or beyond the .05 level.

Comparing the present results with those obtained via the intraoral infusion method, we conclude: (1) swallowing is adjusted similarly for liquid and for solid foods and, (2) swallowing is adjusted similarly whether ingestion rate is manipulated by the experimenter or whether ingestion rate varies over the course of normal meals.

92.13 RELATION BETWEEN DIURNAL RHYTHM OF FEEDING AND NEURON ACTIVITY IN LATERAL AND VENTROMEDIAL HYPOTHALAMUS IN FREELY BEHAVING RATS.
R. Shibata* and T. Ono. (SPON: S. Mori). Dept. of Physiol., Fac. of Med., Toyama Med. & Pharmaceu. Univ., Toyama 930-01, Japan

The lateral (LHA) and ventromedial (VMH) hypothalamus are involved in control of circadian rhythm of feeding. We report here, recording of single unit LHA and VMH activity for 1-8 days through chronically implanted electrode in freely behaving rats, and relations between neuronal activity, circadian rhythm, and individual feeding acts and episodes. Activity of 55 of 64 LHA neurons varied with circadian rhythm, 49 increased activity during EEG arousal and decreased during slow wave sleep, and one reacted inversely. Activity of 5 was independent of sleep-wake conditions; 3 gradually increased activity in the dark to a maximum in the morning, then subsided rapidly in 1-2 h; and 2 increased intermittently, at night, prior to and during eating and drinking episodes. Activity of 23 of 50 neurons that were related to sleep-wake cycles decreased during individual feeding acts (consumption of each pellet), and that of one increased. Nine neurons had no relation to circadian rhythm; 4 responded to individual feeding acts; 5 did not. Of the 5 neurons that were unrelated to circadian rhythm and feeding, activity of 3 increased at light on and decreased at light off for 4-13 min. Activity of 74 of 78 VMH neurons recorded varied with circadian rhythm, and 4 had no relation to circadian rhythm or feeding. Activity of 31 of 74 increased during EEG arousal and decreased during slow wave sleep; that of 26 changed inversely. Of 17 neurons that were independent of sleep-wake patterns, 16 were more active in the dark than in the light; 8 of these increased activity during feeding and for 4-10 min after, 2 were depressed during feeding but recovered immediately, and 6 were not influenced by feeding. None responded to individual feeding acts. Activity of 1 of 17 was increased by photostimulation. Activity of 26 of 57 neurons related to the sleep-wake cycle decreased during feeding episodes, but none responded to individual feeding acts. Bilateral suprachiasmatic lesions abolished circadian rhythm that was sleep-wake dependent or independent, but did not affect relation to EEG change or feeding responses. The results suggest that the LHA processes external and internal signals while the VMH processes mainly internal signals in the control of short term feeding (feeding episodes), and that sleep-wake cycles are related to LHA (76.6% increased upon arousal) and VMH (39.7% increased, 33.3% decreased upon arousal, 20.5% increased in dark period) activity in the long term (circadian) control of feeding.

92.14 ADRENALECTOMY ALTERS CENTRAL MONOAMINE METABOLISM IN GENETICALLY OBESE MICE (ob/ob).
J. S. Sims, S. J. Meloni*, and J. F. Lorden. Dept. Psychol., UAB, Birmingham, AL 35294.

A role for adrenal cortical hormones in the obesity syndrome of the ob/ob mouse is suggested by the fact that adrenalectomy reduces weight gain, hyperglycemia, hyperinsulinemia and fat deposition in the mutant. These effects are reversed by glucocorticoids. The effects of adrenalectomy cannot be reproduced by food restriction, although adrenalectomy does reduce food intake. We have previously shown that in addition to the metabolic and hormonal abnormalities displayed by the ob/ob mouse, hypothalamic monoamine metabolism is altered. The present study examined the effects of adrenalectomy on this aspect of the ob/ob syndrome.

Female (C57BL/6J-ob/ob) and C57BL/6J control mice were subjected to bilateral adrenalectomy or sham surgery under ketamine/xylazine anesthesia at 6-7 wks of age. Prior to surgery, all animals were given 325 ug of corticosterone acetate, s.c. Following surgery mice were supplied with standard mouse chow, tap water and .9% sodium chloride ad libitum. The mice were weighed every three days for one month. During the last week of observation, food intake was measured twice. On Day 31 postsurgery, all mice were decapitated. Brains were removed and dissected. Trunk blood was collected for enzymatic assay of glucose and radioimmunoassay of corticosterone.

Adrenalectomy produced similar reductions in serum corticosterone in both lean and obese mice. As expected, adrenalectomy slowed weight gain in the obese mutants. Obese-adrenalectomized mice (ob-ADX) gained an average of 4.9 + 2.1g (SE) in comparison with obese sham controls (ob-SHM) that gained 15.4 + 2.1g. Food intake was reduced by an average of 16% in the ob-ADX group in comparison with sham-operated mice. Lean mice were not significantly affected by the treatment. Mean (+ SE) blood glucose levels in the ob-ADX group were reduced to 143.6 + 3.1 mg% in comparison with the ob-SHM mean of 216.1 + 43.7 mg%. In the lean groups, values did not differ significantly. In hypothalamic samples assayed by HPLC, norepinephrine levels were significantly elevated in the ob-SHM group in comparison with lean controls, but were reduced significantly in the ob-ADX group. Adrenalectomy also reversed a significant decrease in levels of the serotonin metabolite, 5-hydroxyindoleacetic acid (5HIAA) in the obese mice. 5HIAA levels in ob-ADX mice did not differ from lean control values. These effects on hypothalamic monoamines were not duplicated by weight reduction brought about by restricting food intake, nor were they seen in Lean-ADX mice. Thus, the CNS effects are due to the altered hormonal status of the ob-ADX mice and furthermore, the obese mice may be abnormally sensitive to the effects of adrenal hormones. (Supported by grant NS14744).

92.15 MICRODIALYSIS AND BEHAVIOR: FEEDING INDUCED BY DEPRIVATION OR HYPOTHALAMIC STIMULATION INCREASES DOPAMINE TURNOVER IN THE NUCLEUS ACCUMBENS. L. Hernandez and B. G. Hoebel, Dept. Psychology, Princeton Univ., Princeton, NJ 08544

Extracellular DA was measured in the accumbens of freely moving rats using a small, removable microdialysis probe[1]. Ten rats were implanted with 26 gauge guide shafts in the nucleus accumbens. Seven rats had lateral hypothalamic electrodes in addition. Microdialysis in the accumbens was performed in three experiments: (1) before, during and after a meal in rats at 80% body weight (n=5); (2) before, during and after bar pressing for food after 20 hours of food deprivation (n=5); and (3) before, during and after electrically induced feeding (n=7). Dopamine, DOPAC and homovanillic acid were measured in the dialysate by reverse phase high pressure liquid chromatography with electrochemical detection. In all three experiments feeding significantly increased extracellular dopamine, DOPAC and homovanillic acid (ANOVA $p<0.05$). This enhancement of dopamine turnover outlasted feeding behavior. This shows that the mesolimbic dopamine system is involved in some aspect of feeding behavior, and the increase in dopaminergic activity is a neurochemical event common to feeding induced by either food deprivation or electrical stimulation of the lateral hypothalamus.

92.16 FENFLURAMINE INCREASES EXTRACELLULAR SEROTONIN MEASURED BY MICRODIALYSIS IN THE LATERAL HYPOTHALAMUS OF FREELY MOVING RATS. D. H. Schwartz, J. B. Kloecker*, L. Hernandez & B. G. Hoebel, Dept. Psychology, Princeton Univ., Princeton, NJ 08544

Extracellular serotonin (5-HT) was measured in the lateral hypothalamus (LH) of freely moving rats using a small, removable microdialysis probe[1]. Animals received dexfenfluramine injections ip or directly into the lateral hypothalamus. Dialysis samples taken during 20 min intervals were analyzed by high pressure liquid chromatography with electrochemical detection before and after injection. Injection of ip dexfenfluramine increased extracellular 5-HT (3 mg/kg, 2 fold increase; 10 mg/kg, 6 fold* increase). Direct administration of dexfenfluramine (vehicle, 0.1, 1.0, 10 ug) to the LH caused dose dependent increases in extracellular 5-HT (0.1 ug, 8 fold; 1.0 ug, 52 fold*; 10 ug, 64 fold* increase). Similar results were obtained by infusing dexfenfluramine via the microdialysis probe itself. Dexfenfluramine (10 ug) depressed food intake when administered bilaterally to the same LH site. This dose, which increased extracellular 5-HT, also suppressed food intake with a similar time course. These findings support the view that the anorectic drug, dexfenfluramine, releases 5-HT in the hypothalamus, and that 5-HT is involved in the termination of feeding behavior.

*ANOVA followed by Dunnett's Test: $p<0.05$.

92.17 Comparison of Regional Cerebral Metabolic Rates for Bulimics vs. Normal Controls J.C. Wu, B. Blinder, M. Derrfler, T. Asavisanu, E. Hazlett, N. Sicotte, M. Buchsbaum, Psychiatry Dept., Univ. Calif. Irvine, Irvine, CA 92717

Introduction: This study assesses differences in the regional cerebral glucose metabolic rates in bulimics vs. normal controls.

Methodology: Six bulimic subjects (women, age 24.5 ± 3 yrs) and five normal controls (women, age 28.9 ± 4 yrs) were studied. Bulimic subjects met DSM-3 criteria for bulimia. Subjects were asked to perform the Continuous Performance Test (CPT) during 18F-2dg uptake. Subjects were scanned on CTI Neuroecat IV (FWHM = 7.6mm). Nine scans parallel to the CM line were obtained. Glucose use was calculated according to the Sokoloff model.

Results: A cortical survey will be performed to analyze anteroposterior, dorsal-ventral and hemispheric dimensions. Metabolic rates for caudate, putamen and thalamus will also be analyzed.

Discussions: Treatment response and family history have led some investigators to suggest the possibility that bulimia may be an affective variant. Recent PET scan studies of affective illness have independently found decreased relative caudate activity in depressed subjects. If bulimia is an affective variant, then bulimia may share a common neural metabolic substrate with depression.

92.18 HYPOTHALAMIC HYPERINSULINEMIA AND OBESITY: A COMPARISON OF RADIO-FREQUENCY AND ELECTROLYTIC LESIONS. B. M. King, P. M. Daigrepont*, M. F. Dallman* and L. A. Frohman*. Department of Psychology, University of New Orleans, New Orleans, LA 70148.

Electrolytic lesions of the ventromedial hypothalamus (VMH) result in overeating, obesity, and a marked increase in plasma insulin levels. Rats with VMH lesions become obese even when pair-fed with sham lesioned control animals, leading many to conclude that the obesity is primarily the result of the hyperinsulinemia. However, in addition to tissue ablation, electrolytic lesions leave deposits of metallic ions that can potentially irritate adjacent tissue. King and Frohman recently reported (Am. J. Physiol. 248: E669, 1985) that small, nonirritative VMH lesions resulted in no increase in basal insulin levels, but a moderate increase in weight gain (60% of that observed with electrolytic lesions). The present experiment compared the effects of large electrolytic and radio-frequency VMH lesions in female rats. The absence of metallic ion deposits was verified with a Perls' stain.

Both groups with VMH lesions became obese, but the weight gain was greater in animals with electrolytic lesions (189.8 g vs. 120.0 g). The rats with electrolytic lesions were markedly hyperinsulinemic both during food restriction and when given food ad libitum, but as in the previous experiment, the animals with nonirritative lesions displayed elevated basal insulin levels only when allowed to overeat. Both groups with lesions displayed elevations in morning plasma corticosterone levels.

In a second experiment, weanling female rats were given sham, electrolytic, or radio-frequency lesions when 28-days old and were then allowed food ad libitum for 30 days. Weanling rats with electrolytic lesions displayed a significantly greater weight gain and Lee Obesity Index than either of the other two groups. Their mean basal insulin level was double that observed in rats with radio-frequency lesions (99.3 μU/ml vs. 48.8 μU/ml).

Recent studies have found that like radio-frequency VMH lesions, electrolytic paraventricular lesions, parasagittal knife cuts between the VMH and lateral hypothalamus, and procaine injections into the VMH do not result in basal hyperinsulinemia unless the animals are allowed to overeat. Electrolytic lesions of the VMH is the only condition in which animals are found to be hyperinsulinemic during food restriction. It is concluded that VMH lesion-induced hyperinsulinemia (i.e., in absence of overeating is the result of irritative ion deposits rather than tissue ablation.

92.19 MONOCYTE PROLIFERATION FOLLOWING PVN KNIFE-CUTS IS NOT ADRENALLY MEDIATED. Patrice B. Evers, Richard M. Gold, and Sue Anne Assimon, Psychology Department, Univ. of Massachusetts, Amherst, MA 01003.

Parasagittal knife-cuts alongside the paraventricular nucleus (PVN) of the hypothalamus produce hyperphagia and obesity. These cuts also compromise adrenal regulation, presumably by cutting CRF positive axons going from PVN to median eminence, as well as projections to the intermediolateral column of the spinal cord. These cuts have recently been shown to also selective elevate the monocyte population of the white blood cells. This study asked whether the monocytosis is adrenally mediated.

Female albino rats were sequentially adrenally demedullated, knife-cut, and treated with the synthetic glucocorticoid Dexamethasone (DEX). Irregardless of the other treatments, the hypothalamic knife-cuts more than doubled the monocyte count while having a negligible impact on other leucocyte populations. Neither adrenal demed-ullation nor glucocorticoid (DEX) administration had any impact on the basal or knife-cut elevated monocyte count. (DEX has, however, been shown to block PVN knife-cut obesity.)

Monocytosis following obesifying knife cuts has been replicated, but the phenomenon is, surprisingly, not adrenally mediated.

Finally, ACTH (8 U bid) was admininstered for 8 days to determine whether the knife cuts might be producing monocytosis via a direct action of CRF elicited ACTH secretion on blood forming elements. ACTH completely blocked the monocytosis produced by PVN knife-cuts (but had no effect on body weight).

We conclude that PVN knife-cuts elicit monocytosis via a reduction in ACTH secretion, and that ACTH exerts this control extra-adrenally. Furthermore, monocytosis does not appear to mediate the hyperpagia and obesity associated with these knife-cuts.

ALCOHOL AND BARBITURATES I

93.1 ETHANOL PREFERENCE OF ADULT RATS CAN BE PREDICTED IN INFANCY BY DURATION OF ETHANOL-INDUCED ANESTHESIA. D.L. Kachele* and I.B. Johanson. Department of Psychology and the Institute for the Study of Drug and Alcohol Dependence. Florida Atlantic University, Boca Raton, Florida 33431.

McClearn and colleagues were among the first to report differences among inbred strains of mice in both ethanol preference and duration of loss-of-righting (or "sleep time") in response to an acute dose of ethanol. Subsequently, selectively bred lines of rats and mice have been developed based upon either ethanol preference or "sleep time". With some exceptions, it appears that these two traits are correlated, so that the alcohol-preferring lines display shorter "sleep times" than nonpreferring lines, and alcohol-resistant (short sleep) lines ingest more ethanol than alcohol-sensitive (long sleep) lines. An association between ethanol-induced sleep time and preference has been demonstrated, as well, in adult individuals of a heterogeneous population of rats.

In the present study, we determined that the ethanol-induced sleep time of infant Sprague Dawley rats was a reliable predictor of their adult ethanol preference. Infant rats (4, 10, and 16 days old) were given a hypnotic dose of ethanol (4.5 g/kg ip) and the duration of ethanol-induced loss-of-righting was recorded. Beginning at 60 days of age, "short sleepers" (less than 10 min sleep time as infants) and "long sleepers" (greater than 30 min sleep time) were tested for ethanol consumption, using a 2-bottle test of 15% ethanol vs. water over a 2-week period.

Duration of ethanol-induced anesthesia, even when measured at 4 days of age, was highly predictive of adult ethanol preference. Animals that displayed short sleep times as infants consumed large volumes of 15% ethanol when tested as adults (43-44% of total fluid intake by the end of 2 weeks of 2-bottle testing). Conversely, those animals that displayed long sleep times in infancy consumed very little ethanol as adults (< 5% of total fluid intake). These findings demonstrate that adult differences in ethanol preference can be predicted from differences in sensitivity to ethanol that exist in infants as young as 4 days of age. The establishment of a reliable predictor, in infancy, of adult ethanol preference makes it possible, for the first time, to study the ontogeny of experimental alcoholism in a heterogeneous animal population.

93.2 OPIOIDS MODULATE ETHANOL'S REINFORCEMENT. L. D. Reid, C. L. Hubbell*, S. H. Marglin*, M. L. Abelson* and K. D. Wild*. Department of Psychology, Rensselaer Polytechnic Institute, Troy, NY 12180.

Multiple procedures were used to assess the idea that surfeits of opiodergic activity enhanced rats' positive reactivities toward ethanol (E). In one set of procedures, water-deprived rats were given a daily opportunity of 1.5 hr to take water or sweet alcoholic beverage. Rats receiving placebos, across days, gradually increase their daily intakes to asymptotic values of 2.25 g/kg of E. Injections of morphine, 1.0 mg/kg, before the opportunity to drink (after asymptotic intakes are achieved) increase intakes to about 3.0 g/kg. Injections of morphine, day after day (up to 100 days), maintain enhanced intakes. When morphine injections are given across the first 20 days of opportunities to take water or E, morphine leads to greater increases in intake of E from the 3rd day forward. Rats fixed with osmotic pumps delivering constant infusions of morphine (0.6 mg/kg/hr) also have increased intakes of E during the development of and after asymptotic levels of intake are achieved. Small doses of morphine (1.0 mg/kg) in rats having pumps delivering morphine lead rats to take about 5.0 g/kg of E. Naloxone, the antagonist at opioid receptors, reduces intakes of E and blocks the development of high levels of intake. Naloxone also antagonizes morphine's enhancement of E-intake. Injections of morphine, in other procedures, were shown to be a setting condition for injections of E to establish a conditioned place preference i.e., morphine plus E established a larger place preference than either alone. Collectively, these data support the idea that high functional activity of opiodergic systems is a setting condition enhancing E's ability to reinforce behavior associated with E.

93.3 THE EFFECTS OF FLUOXETINE ON ETHANOL INTAKE IN THE ALCOHOL-NON-PREFERRING (NP) LINE OF RATS. G.J. Gatto*, J.M. Murphy, W.J. McBride, L. Lumeng* and T.-K. Li* (Spon: S.L. Morzorati). Depts. Psych. & Med., Inst. Psych. Res. and Regenstrief Institute, Indiana Univ. Sch. Med. and VA Med. Ctr., Indianapolis, IN.

Fluoxetine, a serotonin (5-HT) uptake inhibitor, attenuates ethanol consumption in the P line of alcohol-preferring rats (Murphy et al., Alcohol 2: 349, 1985). The present study examined whether fluoxetine has similar effects on ethanol intake in NP rats, which are selectively bred for their aversion to consume alcohol in a free-choice situation of 10% (v/v) ethanol, water and food. To overcome this aversion, a modification of the polydipsia design of Kulkosky (Pharm. Biochem. Behav. 10: 277, 1978) was employed. NP female rats (N=5) received an ad lib choice of food, water and a solution containing 3% polycose, 0.5% NaCl and 0.125% saccharin to which ethanol was gradually added until a concentration of 10% was reached. Two control groups of NP female rats (N=4 each) were given a polycose solution without ethanol: control group one (C-1) received a 3% polycose, 0.5% NaCl and 0.125% saccharin solution while control group two was given a 17.6% polycose, 0.5% NaCl and 0.125% saccharin solution (C-2) which had the same caloric content as the polycose-10% ethanol solution. Both control groups received water and food ad lib. After steady baseline intakes were established, rats were injected i.p. according to a counterbalanced design with sterile water or fluoxetine. Animals were allowed to return to baseline for at least five days before a subsequent injection. For the alcohol-drinking group, the mean ethanol intake was 8.7 ± 0.4 g/kg body wt/d (41 ± 2 ml/d); injection of the vehicle alone did not alter alcohol intake. The i.p. injection of 5 and 10 mg/kg of fluoxetine significantly reduced the intake of the alcohol-polycose solution to 77% and 36% of the control values, respectively. Food intake for the alcohol group was 12 ± 3 g/d. Fluoxetine decreased food intake to 72% and 32% of control levels at the 5 and 10 mg/kg doses, respectively. The control groups readily consumed the polycose solutions, reaching a maximum of 120 ml for group C-1 and 102 ml for group C-2. The dose of 10 mg/kg fluoxetine had no effect on the intake of group C-1 and only slightly reduced the intake of group C-2 to 86% of baseline. Food intake for C-1 and C-2 were 17 ± 1 and 9.5 ± 0.5 g/d, respectively. The dose of 10 mg/kg fluoxetine slightly reduced the food intake of groups C-1 and C-2 to 70 and 85% of baseline levels, respectively. The data support the contention that serotonin may be involved in alcohol drinking and also could suggest that chronic alcohol consumption may alter serotonergic control of food intake.

93.4 TASTE REACTIVITY TO ALCOHOL IN RATS. S.W. Kiefer and J.M. Dopp. Dept. of Psychology, Kansas State University, Manhattan, KS 66506.

Taste reactivity has been defined as the gustofacial and body movements elicited by the infusion of a taste solution directly into the mouth (Grill & Norgren, Brain Res., 1978, 143). In the present experiment, this technique was exploited to determine the rat's response to various concentrations of alcohol. The goal of such work is to complement studies already done which have looked at preference/aversion responses in rats using traditional consumption measures.

Eight naive male rats were anesthetized and implanted with intraoral fistulae. Following two weeks of postoperative recovery, the rats were tested for reactivity to four concentrations of ethyl alcohol (3%, 6%, 9%, and 12%, v/v) in addition to the following solutions: .1 M sucrose, .1 M sodium chloride, .01 M hydrochloric acid, and .0001 M quinine hydrochloride. On a given day, 1 ml of solution was infused into the oral cavity over a 1 min period and the subsequent responses were videotaped for later analysis. Rats received all eight solutions, 1 per day, according to a balanced Latin square design. Distilled water was tested the day before solution presentation was begun. Scoring of the tapes was done frame-by-frame where the gustofacial responses and body movements were tabulated using the technique described by Grill and Norgren (1978). The responses were categorized as either ingestive (e.g., tongue protrusions), aversive (e.g., gaping), or neutral (e.g., face washing).

The results indicated that the reactivity to alcohol in rats was concentration dependent. As concentration of alcohol increased, the number of ingestive responses steadily decreased. And, as anticipated, the number of aversive responses increased as concentration increased. Whereas the predominant response to 3% alcohol was mouth movements (the profile of which resembled that of the response to water), 12% alcohol elicited a number of gapes and body movements indicative of rejection. Responses to sucrose were primarily ingestive; the remaining tastants elicited a complex pattern of responses.

93.5 ETHANOL TOLERANCE DEVELOPED FOR DRL OPERANT BEHAVIOR IN RATS: RATE-INCREASING AND -DECREASING EFFECTS. D.C. Bird, and F.A. Holloway. (SPON: J. Criado) Univ. OK Hlth Sci. Ctr., Okla. City, OK 73190

We have reported that chronic exposure to ethanol resulted in the development of persistent tolerance for ethanol's rate-decreasing effects on rat operant behavior under VI or FR schedules of food reinforcement (Bird, D.C. & F.A. Holloway, Psychopharmacol., 87:414, 1985). We suggested that such data were compatible with a functional interpretation of tolerance in which animals acquired, through intoxicated practice, some compensatory response to counteract ethanol's rate-decreasing effects. The present study sought to examine tolerance acquisition in an operant task where one of ethanol's direct effects was to increase response rate (i.e., differential reinforcement of low rate of responding, or DRL).

Six male Sprague-Dawley rats were trained in standard operant chambers to lever press for food reinforcement under a DRL-20 sec schedule (i.e., reward only for presses with an inter-response time (IRT) interval of 20 sec or greater). After performance stabolized, an initial dose-effect curve (DEC-1) was obtained (0.375-3.0 g/kg ethanol). After completion of DEC-1, all animals received daily ethanol injections beginning with 1.125 g/kg, escalating as they became tolerant at each dose and continuing until no further tolerance was evident (3.0-3.75 g/kg). Maximum tolerance was achieved in a mean of 68.8 days. After the completion of this chronic injection phase, we obtained DEC-2 immediately and DEC3, 26 weeks later. Between DEC-2 and DEC-3, training continued with several intermittent 1.5 g/kg ethanol challenge tests.

The DEC-1 data indicated a significant rate-increasing effect on non-reinforced responses for doses up to 1.5 g/kg, with a peak rate at a mean dose of 1.18 g/kg. Reinforced responses declined mononically with increasing doses, with an ED50 (effective dose in reducing reinforcements 50% of baseline) of 1.48 g/kg. Tolerance effects were evident at both DEC-2 and DEC-3. At DEC-2, peak rate increased occurred at a mean dose of 1.81 g/kg and the ED50 for reduction in reinforcements was 2.14 g/kg. At DEC-3, some tolerance loss was evident with peak rate increases and the ED50 for reward loss both occurring at a mean dose of 1.63 g/kg.

These data clearly indicate that tolerance develops for both the rate-increasing and rate-decreasing effects of ethanol and that such tolerance, while declining somewhat over time, persists for up to six months. Fine-grain analysis of the IRT distributions at each DEC further indicates that the putative compensatory strategy developed by these animals during intoxicated practice appeared to be one of "rate-reduction." This analysis suggested that compensatory behaviors acquired through the development of tolerance may, in the DRL task, interact with the direct effects of ethanol to modulate performance efficiency with increases in efficiency at lower doses and decreases at higher doses.

93.6 VALPROATE POTENTIATES THE ANXIOLYTIC ACTION OF ETHANOL IN A NONSHOCK CONFLICT TASK. H.C. Becker and B. Bickerstaff*. VA Medical Center and Medical Univ. of SC, Charleston, SC 29403.

The inhibitory neurotransmitter, GABA, has been strongly implicated in mediating a variety of behavioral effects of ethanol (EtOH), such as its locomotor stimulant, motor incoordinating, and anesthetic properties, as well as altering seizure threshold after EtOH withdrawal. Recently, GABA has been implicated in the anxiolytic action of EtOH, as well (e.g., Koob and Thatcher-Britton, Alcoholism: Clin. Exp. Res. 9:204, 1985; Liljequist and Engel, Pharmacol. Biochem. Behav. 21:521, 1984). The purpose of this study was to examine the effects of the indirect GABA agonist, valproate (VPA), on the anti-conflict activity of EtOH in a nonshock task. This task, referred to as negative contrast, involves the quantification of how animals respond to an abrupt, unexpected reduction in reward. The depressed behavior engendered by reward reduction is accompanied by elevated plasma corticosteroid levels, and selectively antagonized by anxiolytic drugs (e.g., EtOH, benzodiazepines). Previous work indicated 1 g/kg EtOH to be an effective anxiolytic dose (Becker and Flaherty, Psychopharmacol. 77:253, 1982); the marginally effective dose of .5 g/kg was employed in this study. Male Sprague-Dawley rats were given brief (5 min) daily access to a 32% sucrose solution for several days, and then shifted to a 4% solution for 4 post-shift days. Unshifted controls received access to only the smaller 4% sucrose reward. Forty min prior to the second post-shift day session, shifted and unshifted rats were injected (IP) with either 0, 50, 100, or 200 mg/kg VPA, followed 30 min later by an injection of either saline or .5 g/kg EtOH. Results indicated that rats shifted from the 32% to 4% sucrose solution consumed substantially less of the latter in comparison to unshifted 4% controls, i.e. a significant negative contrast effect ($F(1,55)= 14.78$, $p< .01$). Moreover, while 0.5 g/kg EtOH did not significantly differ from saline treatment when given alone, co-administration of 100 or 200 mg/kg VPA reliably potentiated the marginally effective anxiolytic action of .5 g/kg EtOH, i.e. increased performance of shifted rats without significantly influencing that of unshifted controls ($F(4,55)= 2.65$, $p< .05$). VPA did not exhibit anti-conflict activity when given alone. These data are supportive of a role for GABA in mediating the anxiolytic activity of EtOH.

93.7 BIPHASICITY OF CENTRALLY AND PERIPHERALLY ADMINISTERED CAFFEINE ON ACUTE ETHANOL-INDUCED MOTOR INCOORDINATION IN MICE. M.S. DAR, Department of Pharmacology, School of Medicine, East Carolina University, Greenville, North Carolina 27858.

We have previously reported that brain adenosine plays a role in the motor disturbing effects of ethanol in mice (Dar et al., Life Sci. 33:1363, 1983; Dar and Wooles, Life Sci. 39:1429, 1986) and rats (Clark and Dar, Pharmacologist 28:287, 1986). Recently we also reported up-regulation of brain adenosine receptors following chronic caffeine with a corresponding increase in acute ethanol-induced motor incoordination. Caffeine has been reported to exhibit biphasic effects on locomotor activity (Katims et al., JPET 227:167, 1983) and sleep (Yanik et al., Brain Res. 403:177, 1987). The possible biphasic effects of caffeine on acute ethanol-induced motor incoordination by rotorod evaluation was investigated in CD-1 male mice. Caffeine, 2.5, 5, 25, 75, 150ug/5ul of artificial cerebrospinal fluid was administered icv to mice at least five days after they were implanted with permanent indwelling stainless steel guide cannulae followed 5 min later by a test dose, 2g/kg ip, of ethanol. The animals were evaluated for motor coordination at 15, 30, 45, and 60 min post ethanol. The test dose of ethanol was selected based on a separate dose response study and was subsedative but produced marked motor incoordination. A motor coordination study in which caffeine, 2.5, 5, 20, 62.5 and 150mg/kg ip, followed 10 min later by the same test dose of ethanol ip, was also conducted in noncannulated mice. Caffeine <25 ug icv, dose dependently attenuated while 75ug icv potentiated ethanol(ip)-induced motor incoordination. Similarly, caffeine <20mg/kg ip, dose dependently attenuated while 62.5mg/kg ip, potentiated ethanol(ip)-induced motor incoordination. The higher, 150ug and 150mg/kg caffeine, given icv and ip respectively, practically exhibited no effect on ethanol-induced motor incoordination. The data obtained showed that caffeine <25ug icv and <20mg/kg ip, antagonized while at higher doses potentiated ethanol-induced motor incoordination demonstrating the biphasicity of caffeine on motor incoordinating effect of ethanol. Blood ethanol data suggested no effect of caffeine pretreatment on the clearance of ethanol. At low doses, (<25ug icv; <20mg/kg ip), caffeine has been known to display high affinity for adenosine binding sites. Therefore, the present study further supports our earlier reports that adenosine mediates the motor impairing effect of ethanol. The biphasic effects of caffeine may also suggest that at lower doses, caffeine appears to have greater affinity with A_1/A_2 subtypes of adenosine receptors that mediate the excitatory effects of adenosine while higher caffeine doses may have greater affinity with the subtypes of A_1/A_2 that mediate depressant effects such as motor incoordination.

93.8 INTERACTIONS OF IMIDAZODIAZEPINES WITH ETHANOL IN A HOLEBOARD TEST. R.G. Lister. Laboratory of Clinical Studies, DICBR, National Institute on Alcohol Abuse and Alcoholism, Bldg 10 Room 3C218, Bethesda, MD 20892.

There have been several reports that Ro 15-4513 (ethyl 8-azido-5,6-dihydro-5-methyl-6-oxo-4H-imidazo-[1,5a][1,4]benzodiazepine-3-carboxylate), which is a partial inverse agonist at central benzodiazepine (BDZ) receptors, can reverse some of the behavioral effects of ethanol. The present studies investigate the behavioral effects of several imidazodiazepines with high affinities for BDZ receptors and their interactions with ethanol. Ro 17-1812 (cyclopropylmethyl (S)-8-chloro-12,12a-dihydro-9-oxo-9H,11H-azeto[2,1c]-imidazo[1,5a][1,4]benzodiazepine-1-carboxylate) is a partial agonist at BDZ receptors (Clin. Neuropharmacol. 7 (Suppl 1) S363, 1984). Ro 15-3505 (ethyl 7-chloro-5,6-dihydro-5-methyl-6-oxo-4H-imidazo[1,5a][1,4]benzodiazepine-3-carboxylate) is a BDZ receptor ligand that has been used to reverse the effects of benzodiazepines in humans (Br. J. Clin. Pharmacol. 18:541-547, 1984). In mice it lowers seizure thresholds to bicuculline suggesting that it is a BDZ-receptor partial inverse agonist (Nutt and Lister, in preparation). In all experiments, a holeboard test was used to examine the effects of each drug in mice. This test allows an animal's exploration (head-dipping) to be assessed independently of its locomotor activity.

Ro 17-1812 (0.75-6.0 mg/kg, i.p.), significantly increased locomotor activity but did not alter exploratory head-dipping. Ro 15-4513 (0.75-3.0 mg/kg) significantly reduced exploratory head-dipping but did not alter locomotor activity. Ro 15-3505, (0.75-6.0 mg/kg) caused a slight decrease in head-dipping but did not change motor activity. The effects of Ro 15-4513 on exploration could be partially reversed by Ro 15-3505, suggesting that Ro 15-3505 is a weaker partial inverse agonist than Ro 15-4513.

Ethanol (2 g/kg) increased locomotor activity and decreased exploratory head-dipping. Ro 17-1812 (0.75 and 1.5 mg/kg) enhanced the reduction in exploration caused by ethanol. Ro 15-4513 (1.5 and 3.0 mg/kg) and Ro 15-3505 (0.75 and 1.5 mg/kg) both partially reversed the ethanol-induced reductions in exploration. Ro 15-4513 (3.0 mg/kg) and Ro 15-3505 (1.5 mg/kg) also attenuated ethanol's locomotor stimulant effect. In neither case, however, was the reversal of ethanol's effects complete.

The results of these experiments indicate that BDZ-receptor ligands with varying intrinsic activities are capable of modifying the behavioral effects of ethanol. The direction of the effect appears to be related to the intrinsic effects of each drug. Thus the partial agonist Ro 17-1812 enhanced the effect of ethanol on exploration, and the partial inverse agonists Ro 15-4513 and Ro 15-3505 partially reversed ethanol's effects.

93.9 **DOSE-, TIME- AND SEX-DEPENDENT EFFECTS OF ETHANOL ON LOCOMOTOR ACTIVITY IN RATS. G.J. Schaefer and R.P. Michael. Department of Psychiatry, Emory University School of Medicine, Georgia Mental Health Institute, 1256 Briarcliff Rd, Atlanta, Georgia 30306.**

Adult male and female Sprague-Dawley rats (approx. 100 days old, n=20) were placed in a locomotor activity monitor (Digiscan RXY, Omnitech, Columbus, OH) and habituated to the apparatus for 30 minutes. Animals were then administered either saline or ethanol (0.1, 0.3, 1.0 and 1.7 g/kg) intraperitoneally (IP) and locomotor activity changes were recorded for the next 3 hours. The following measures are reported: (1) horizontal activity (total number of infrared beam interruptions), (2) time at rest (seconds), (3) time moving at a slow speed, and (4) time moving at a fast speed. Over the dose-range of 0.1-1.7 g/kg, biphasic effects were found and these depended upon the sex of the animal and the time of testing. Females were more active and spent less time at rest than males following saline administration. During the first hour after injection, the low dose (0.1 g/kg) increased horizontal activity nearly 60% above saline values in males, while the high dose (1.7 g/kg) reduced activity by 40%. In females the 0.1 g/kg dose increased activity by only 15%, while the 1.7 g/kg dose reduced activity by 55%. Under control conditions, animals spent greater than 85% of their time at rest and the effects of ethanol on this parameter were less dramatic. For example, during the first hour males spent only 3% less time at rest when administered 0.1 g/kg compared to saline values, and spend 2% more time at rest when administered 1.7 g/kg. In contrast, females spent 1% less time at rest following 0.1 g/kg and 6% more time at rest following 1.7 g/kg than their controls. Changes in time spent moving at the slow and fast speeds were similar in direction, but different in magnitude. For males during the first hour, ethanol increased movement at the slow speed by 47% and increased movement at the fast speed by 115% when administered 0.1 g/kg. At the 1.7 g/kg dose, slow speed was reduced by 34% and fast speed by 71%. For females, movement at the slow speed was increased by 1.0% and at the fast speed by 11% at the 0.1 g/kg dose, while at the 1.7 g/kg dose, slow speed was reduced by 48% and fast speed by 80%. During the third hour, the only consistent effects were those produced by 1.7 g/kg which continued to reduce horizontal activity as well as time spent moving at slow and fast speeds. Our results demonstrated that: (1) when rats were habituated to the apparatus, ethanol administered IP produced both increases and decreases in motor activity, (2) females showed less of an increase at low doses and more of a decrease at high doses than males, (3) movement at a fast speed showed greater changes in both increases and decreases than movement at a slow speed, and (4) while the increased activity with a low dose was a consistent effect only during the first hour, the decreased activity with a high dose of ethanol persisted throughout the entire 3-hour test session. Thus, these changes in motor activity paralleled the euphoric effects of low doses and the sedative properties of high doses of ethanol.

93.10 INTERACTIONS OF THE 5HT REUPTAKE INHIBITOR FLUOXETINE WITH SEDATIVE-HYPNOTICS IN TESTS OF LOCOMOTION, EXPLORATION AND ANXIETY IN MICE. M.J. Durcan,* R.G. Lister, M.J. Eckardt, and M. Linnoila*. (SPON: J. Rohrbaugh) Laboratory of Clinical Studies, National Institute on Alcohol Abuse and Alcoholism, Blg 10 Rm3C218, Bethesda, MD 20892.

In previous experiments we have noted that pretreatment with the 5-hydroxytryptamine (5HT) uptake inhibitor fluoxetine (20mg/kg i.p., administered 90min prior to testing) selectively attenuated the anxiolytic effects of ethanol (2.4g/kg i.p., administered 30min prior to testing) without affecting the locomotor stimulant effects (Durcan et al, Alcohol. Clin. Exp. Res. 1987, in press.).

The present series of experiments were performed in mice to investigate the behavioral interactions of fluoxetine with a number of sedative-hypnotics; including ethanol (2.4g/kg), chlordiazepoxide (2.5,5,7.5mg/kg), diazepam (0.5,1,2mg/kg), sodium pentobarbital (10,15,20mg/kg) and phenobarbital (15,30, 60mg/kg), which were administered (i.p.) 30min prior to testing. The behavioral tests used were the holeboard test, which measures locomotor activity and exploratory head-dipping independently; and the elevated plusmaze test of anxiety, which assesses anxiolytic effects (Pellow et al., J. Neuro. Sci. Meth. 14:149 1985).

Ethanol increased activity both in the holeboard and on the plusmaze, decreased both number and duration of exploratory head-dips, and increased the percentage time and percentage entries on the open arm of the plusmaze reflecting its anxiolytic effects. Pretreatment with 20mg/kg fluoxetine (which is without intrinsic behavioral effects in these tests) significantly attenuated ethanol's anxiolytic effects without affecting its locomotor stimulating properties. Chlordiazepoxide and diazepam had dose-related effects similar to those of ethanol but pretreatment with fluoxetine did not significantly interact with any of these behaviors. Both pentobarbital and phenobarbital also showed dose-related effects similar to those of ethanol in both the holeboard and plusmaze tests. Pretreatment with fluoxetine had no significant interaction with the phenobarbital effects whereas it potentiated the behavioral effects of pentobarbital on locomotor activity, exploratory head-dipping and entries onto the open-arms of the plusmaze.

These experiments suggest that fluoxetine may interact with ethanol and barbiturates in a qualitatively different manner. Furthermore the extent of the involvement of 5HT uptake inhibition requires further investigation using other 5HT uptake inhibitors.

93.11 RESPONSE SUPPRESSION TO SEROTONERGIC DRUGS IS ATTENUATED IN THE P LINE OF ALCOHOL-PREFERRING RATS. J.M. Murphy, S.L. Morzorati, J.N. Hingtgen, S.L. Matney*, L. Lumeng* and T.-K. Li*. Departments of Psychiatry and Medicine, and Program in Medical Neurobiology, Institute of Psychiatric Research, Regenstrief Institute and Veterans Administration Medical Center, Indiana University School of Medicine, Indianapolis, IN 46223.

Rats of the alcohol-preferring P line have a lower content of serotonin (5-HT) and 5-hydroxyindoleacetic acid in forebrain regions than the alcohol-nonpreferring NP line (Murphy et al., Pharmacol. Biochem. Behav. 26: 389, 1987). This finding suggests that P rats have a deficient functioning and/or density of forebrain 5-HT innervation. To test this possibility, the P and NP lines were compared in an operant task where response suppression is known to be a sensitive measure of increased activity within brain 5-HT systems (Hingtgen et al., Pharmacol. Biochem. Behav. 20: 425, 1984). Adult male P (n=6) and NP (n=6) rats were maintained at 80% of their free-feeding body weights and were trained to bar press for sweetened milk on a VI 1 min schedule of reinforcement. Three 90-120 min sessions were given each week until a stable baseline responding was established. Subsequently, two sessions each week served as control sessions during which the rats received intraperitoneal injections of saline. During the third session of each week, the animals were injected with 25 mg/kg D,L-5-hydroxytryptophan (5-HTP), a 5-HT precursor, 15 min into the session or were given an injection of 5 mg/kg of fluoxetine, a 5-HT uptake inhibitor, 60 min prior to the 5-HTP injection.

The baseline response rate of the P rats was approximately twice that of the NP animals ($p<0.05$; 41 $\pm$ 6 vs. 22 $\pm$ 5 responses/min, mean $\pm$ SEM). The behavioral responding of the NP rats was similar to that observed for stock Wistar rats in previous studies. The period of response suppression (min) following 5-HTP alone tended to be longer for the NP rats compared with the P line ($p<0.10$; 70 $\pm$ 19 vs. 30 $\pm$ 5 min). Fluoxetine plus 5-HTP produced a significantly ($p<0.05$) longer response suppression in rats of the NP line relative to the P line (87 $\pm$ 20 vs. 36 $\pm$ 5 min).

The findings indicate that the P rats are behaviorally more active and exhibit less response inhibition than the NP rats, and that the shorter response suppression seen after 5-HTP and fluoxetine in the P line is consistent with a lower functional capacity in 5-HT neuronal systems of these alcohol-preferring rats. (Supported in part by AA03243).

93.12 TESTOSTERONE-ALCOHOL INTERACTIONS AND AGGRESSIVE BEHAVIOR IN DOMINANT AND SUBORDINATE SQUIRREL MONKEYS. J.T. Winslow*, K.A. Miczek, and J. Ellingboe. Dept. of Psychology, Tufts Univ., Medford MA 02155 and Alcohol and Drug Abuse Research Ctr., McClean Hosp.-Harvard Med. Sch., Belmont, MA, 02178

Social status and reproductive cycle determine the effects of acute, low doses of alcohol on the social behavior of squirrel monkeys. Alcohol produces biphasic effects on the behavior of dominant but not subordinate monkeys, and only during the mating season. Alcohol (0.1, 0.3, 0.6 g/kg) increased the frequency of threats, grasps, and displacements, and a higher dose (1.0 g/kg) decreased these behaviors in dominant monkeys. Neither dominant nor subordinate monkeys are affected by these doses during the non-mating season. The change in alcohol sensitivity measured in dominant monkeys coincides with changes in plasma testosterone levels. In order to directly study the interaction between alcohol, testosterone, and aggressive behavior, testosterone propionate (TP, 25 mg/kg/day, s.c.) was administered to either dominant or subordinate male monkeys belonging to four separate groups. TP was administered daily at 6:30 h and the behavior of treated monkeys observed in group between 8:30-10:30 h. Treatment elevated significantly plasma levels of testosterone, in excess of levels measured during the mating season (e.g. 905$\pm$ 43 ng/ml in subordinates). Studies were conducted during three consecutive non-mating seasons, period when aggressive interactions between members of established groups are infrequent. Two to three weeks after beginning testosterone treatment, treated monkeys were administered doses of alcohol (0.1-1.0 g/kg). We have previously reported that the behavior of subordinate monkeys was unaffected by testosterone treatment(even after the dominant monkey was removed from each colony and housed separately for 6 weeks). TP altered the sensitivity of subordinate monkeys to the effects of alcohol. Low doses of alcohol increased the frequency of threats, grasps, and displacements exhibited by subordinate monkeys with exogenously elevated testosterone. Daily administration of TP to dominant monkeys during the non-mating season did not affect the behavior of treated animals in group, although treatment was associated with increased body weight similar to that measured during the mating season. The sensitivity of dominant monkeys to alcoholwas affected by testosterone treatment. Low doses of alcohol increased the frequency of threats, grasps, and displacements.

These findings strengthen previous correlative data indicating a relationship between plasma testosterone levels and the effects of alcohol on the aggressive behavior of squirrel monkeys. High levels of testosterone may activate alcohol sensitive brain substrates of aggressive behavior.

93.13 INTERNAL CUES PRODUCED BY ETHANOL OR ETHANOL WITHDRAWAL: GENERALIZATION TO ANXIOLYTIC AND ANXIOGENIC DRUGS. R.D. Harland*, J.R. Criado, R.C. Michaelis, and F.A. Holloway. (SPON: M. Hettinger) Univ. Oklahoma Health Sciences Center, Oklahoma City, OK 73190

In a new animal model of anxiety, rats are trained to detect the interoceptive discriminative stimulus (IDS) properties of pentylenetetrazol (PTZ) in a standard drug-saline discrimination paradigm (Lal, H. & M.W. Emmett-Oglesby, Neuropharmacol., 22:1423, 1983). The IDS properties of PTZ are thought to be anxiogenic and are blocked by anxiolytic drugs. Further, withdrawal from chronic benzodiazepines, a condition which is anxiety-provoking in humans, also produces a generalization to the PTZ-induced IDS. Ethanol (ETOH), also alleged to have anxiolytic actions, has a variety of behavioral effects which vary with dose, duration of exposure, and post-injection interval. The present study sought to examine the extent to which rate-increasing, rate-decreasing, and acute or chronic withdrawal actions of ETOH could produce IDS properties similar to that produced by chlordiazepoxide (CDP), an anxiolytic, or PTZ, an anxiogenic drug.

Rats (N=12) were trained to discriminate 3 mg/kg CDP from 20 mg/kg PTZ in a drug-drug discrimination paradigm (food reward on a VR5-10 schedule with 2-min extinction tests). Dose-dependent generalization to CDP and PTZ levers was found for CDP and PTZ respectively, with saline producing 46% CDP-lever responding. ETOH produced CDP-lever responding at doses of .5 and .75 g/kg when injected 4 min pre-test and at 1.25 g/kg when injected 15 min pre-test, and no PTZ-lever responding at any dose. At dose ranges of .25-1.25, ETOH did not block PTZ-lever responding produced by 10 mg/kg PTZ, but did produce dose-dependent blockade of the PTZ increases in overall response rates. Saline administered 9 or 12 hrs after a 3 g/kg ETOH dose of 12 hours after a 4 g/kg ETOH dose produced 80% or greater PTZ-lever responding. A .5 g/kg ETOH dose injected 15 min before tests, at 9 hr after a 3 g/kg ETOH injection, or at 12 hr after a 4 g/kg ETOH injection failed to attenuate PTZ-lever responding. The chronic ETOH regimen consisted of 7 days in an ETOH inhalation chamber (mean terminal BAL = 175.1 + 16.09 mg%). Saline tests 12 and 18 hrs after removal from ETOH chambers yielded 94% and 93% PTZ-lever responding, respectively.

The data confirm and expand the earlier finding of Lal and colleagues, showing that acute and chronic ETOH withdrawal produces IDS which generalize to the PTZ-induced cue. However, the data further suggest that while ETOH may mimic the CDP cue at certain doses and times of injection, ETOH does not have anxiolytic properties sufficient to block the strong "anxiogenic" effects produced by PTZ or by acute ETOH withdrawal. While these conclusions must be tempered by the dose ranges and conditions tested, ETOH's status as an anxiolytic remains questionable.

93.14 DEVELOPMENT AND MAINTENANCE OF ETHANOL TOLERANCE FOR OPERANT BEHAVIOR OF RATS: ROLE OF NUMBER AND PATTERN OF INTOXICATED PRACTICE OPPORTUNITIES AND ABSOLUTE ETHANOL EXPOSURE. F.A. Holloway, R.C. Michaelis, R.D. Harland, and J.R. Criado. Univ. Oklahoma Health Sciences Center, Oklahoma City, OK 73190

Prior work (Bird, D.C., & F.A. Holloway, Psychopharmacol., 87:414, 1986) suggested that the long-term shifts-to-the-right in ethanol (ETOH) dose-effect curves (DECs) for operant behavior resulted from development of functional tolerance to ETOH. The mechanism for such tolerance was thought to depend on the acquisition of some compensatory behavior which counteracted the rate-reducing properties of ETOH in this task. Learning of new instrumental behaviors generally is facilitated by increases in training trials and by the pattern of those training trials. The present study sought to examine the magnitude of ETOH tolerance for operant behavior or rats as a function of: (a) magnitude of ETOH exposure; (b) the relative extent of intoxicated practice (IXP) opportunities; and (c) the pattern of IXP sessions.

Seventy-eight rats were trained to stable performance on a FR30 (fixed ratio), food-reinforced operant task. Estimated blood ethanol levels were determined by a breath/GC procedure. DECs were obtained with a cumulative-dosing procedure prior to a period of daily injections and at selected points during and/or after the chronic injection period. The animals were randomly assigned to one of thirteen experimental conditions, defined by the frequency of IXP sessions (0%, 33%, 67%, 100%), by whether the IXP sessions were spaced (S) or massed (M), and by whether the daily pre-session injections were supplemented by post-session ETOH injections (Y) or not (N). The pre-session ETOH injection period lasted 45-60 days and the dose was incremented from 1-1.75 g/kg. Where daily ETOH was held constant, the combined pre- and post-session ETOH dose was 1.75 g/kg.

All groups receiving any IXP sessions displayed shifts-to-the-right in their DECs for operant behavior but not for peak ethanol levels (p's $<.05$). Generally, the more frequent the IXP sessions, the greater the magnitude of tolerance developed. Further, supplemental post-session ETOH injections appeared to weakly facilitate tolerance acquisition, particularly in groups with less IXP (p's $<.05$). A weak trend also was apparent for distributed practice groups to develop more tolerance than massed practice groups. Finally, all groups, which acquired any degree of tolerance, displayed persistence of these effects for up to 3 months (p's $<.05$).

These data are consistent with the learning interpretation discussed above, but also suggest: (a) that the extent of IXP and absolute amount of ETOH exposure interact in affecting tolerance development; and (b) that the magnitude of tolerance (and to some extent, tolerance persistence) varies as a function of number and pattern of IXP sessions.

93.15 RAPID TOLERANCE TO THE DISRUPTIVE EFFECTS OF ETHANOL ON HIGH-SPEED REACTION TIME IN RATS. R. D. Mayfield*, M. Grant*, W. W. Spirduso[a] and T. Schallert[b]. Institute for Neurol. Sciences, Depts. of Physical & Health Education[a] and Psychology[b], Univ. Texas at Austin, Austin, TX 78712

Behavioral tolerance to ethanol (EtOH) appeared within a 5-day period of chronic EtOH treatment (20% w/v, oral intubation). F344 male rats, 8 mos of age, were shaped to perform a high-speed lever-release task until they had reached a minimum success criterion of 80% (10 - 14 days). Prior to EtOH exposure, a complete test session was given in the absence of EtOH (saline control). The first challenge with EtOH represented the start of the chronic EtOH regimen. Each test consisted of a series of 10 trials at 5, 10, 20, 45, 65 and 90 min post-EtOH on each of 5 days. EtOH was administered 3 times per day at 8 hr intervals to provide moderately high blood alcohol concentrations (BACs). The EtOH doses were increased each day to insure that the BACs were greater than or equal to the BACs of the previous test session. EtOH doses ranged from 1.6 - 1.8 g/kg EtOH on the first day to 2.0 - 2.5 g/kg by the fifth day.

The average peak BACs for the 5 test days were 105.4, 138.0, 150.3, 167.0, and 185.9 mg/dl. BACs were 0.0 mg/dl prior to each EtOH test session. Although the BACs increased each day, lever-release reactions (measured in terms of percent success and mean latency of response) improved. On the first test day, successful performance at each of the time points (5, 10, 20, 45, 65 and 90 min) was 59.4, 66.3, 48.0, 52.6, 75.4, and 80.0% of their control (pre-EtOH) values. By the fourth day, however, their performance improved to 84.6, 96.0, 93.7, 73.7, 89.1 and 89.2% of their control values. Lever-release was faster on the fourth and fifth days of testing than on the first three days even though BACs were higher. In addition, on the first day of EtOH exposure, performance was better at 65 and 90 min than at 5, 10, 20 and 45 min even though BACs were higher at 65 and 90 min. Thus, both within-test session and between-test session tolerance was demonstrated independent of metabolic factors. Subsequent experiments indicated that the tolerance was not due to exposure to EtOH *per se*, but depended on practice during intoxication. The improved performance of the rats on this highly practiced, reaction time behavior occurred with doses of EtOH that were comparable to voluntary human EtOH consumption.

93.16 THE EXPRESSION OF A BEHAVIORAL EFFECT OF ETHANOL: NECESSITY OF THE BASAL FOREBRAIN (Ch4) CHOLINERGIC SYSTEM. J.A. Stidham and L.D. Devenport. Department of Psychology, University of Oklahoma, Norman, OK 73019.

Several considerations lead to the suspicion that ethanol's (ETOH) action on cholinergic projections to frontal and parietal cortex might be the basis of some of the drug's behavioral effects (1, 2). Ethanol disrupts eight-arm radial maze performance in predictable ways (3, 4), one of the least complicated cases being spatial dispersion among the arms of the maze (5). If animals are allowed to obtain eight rewards per trial, normal rats will visit at least 75% of the different arms on each trial, even though the rewards could be obtained by returning to previously visited arms. In contrast, animals injected with moderate doses of ETOH rarely exceed chance levels of arm visitation. This is not because ethanol exacts a spatial mapping deficit or memory impairment (6, 7). Instead, it seems to result from a strong tendency to revisit sites that recently yielded reward (4, 6, 7).

Such a task readily lends itself to a neural analysis as it requires almost no training and is insensitive to any unusual reaction to nonreward as "errors" are impossible to commit in the reward-replacement design. The effects of ETOH on this task were examined in 380 g rats pretreated with diazapam (13 mg/kg) and infused with kainic acid (1.5 ug in 1 ul saline, pH 7.6) via cannula in the Ch4 (nucleus basalis) region of the forebrain, or in animals prepared similarly but with sham lesions. After recovery from surgery, 16 daily radial maze sessions (3 trials/session) were conducted 13 min after ETOH (1.5 g/kg, i.p. as a 10% w/v solution in saline) or saline injection.

In CNS-intact rats, the results were as usual: Saline-injected animals dispersed their visits throughout the maze, injected animals restricted their movements to a few preferred arms. Ethanol's effect almost completely disappeared in acetylcholine-depleted rats. This occurred in spite of the fact that the lesion itself had no effect on radial maze performance. The Ch4 cholinergic sytem seems necessary for the expression of the particular behavioral effect of ETOH examined here. As to whether other ETOH effects rely on such an "enabling" mechanism remain to be seen.

93.17 INTERACTION BETWEEN RO15-4513 AND ETHANOL IN MICE P.J. Syapin(1), K.W. Gee, M. Bejanian, B. Jones*, and R.L. Alkana (1)Departments of Psychiatry and Neurology, School of Medicine and Institute for Toxicology, School of Pharmacy, University of Southern California, Los Angeles, CA 90033

The partial inverse agonist imidazobenzodiazepine Ro15-4513 has been shown to have a novel property as an ethanol antagonist in rats (Suzdak et al, 1986). This effect of Ro15-4513 appears to be mediated through its binding to brain benzodiazepine receptors. We have examined the ability of Ro15-4513 to antagonize other effects of ethanol using mice. Male C57BL/6J mice (6-8 weeks of age) were used in all experiments. We first examined the ability of Ro15-4513 to antagonize the hypnotic action of ethanol. Mice were given a hypnotic dose of ethanol (3.6 g/kg, 20% w/v in saline) and ten minutes later were injected with either vehicle (4% Tween 80 in saline) or a 20 mg/kg dose of Ro15-4513 (0.01 ml/gm body weight). All injections were made i.p. Ro15-4513 significantly antagonized the loss of righting reflex. Mice given ethanol+vehicle had a mean (± SE) sleep-time of 35.0 ± 3.6 minutes; mice given ethanol+Ro15-4513 had a mean (± SE) sleep-time of 17.8 ± 3.7 minutes ($p < 0.01$, 2-tail t-test). Blood ethanol concentrations at wake-up were also significantly higher following Ro15-4513 treatment ($p < 0.02$, 2-tail t-test) indicating that the drug was not acting by altering ethanol pharmacokinetics. In contrast, body temperature at wake-up was not significantly different between treatment groups; both groups were hypothermic upon wake-up. In a second experiment we examined further the effect of Ro15-4513 on ethanol-induced hypothermia. Mice were given either saline or 3.6 g/kg ethanol injections followed by vehicle, Ro15-4513, or Ro15-4513+Ro15-1788 injections 10 minutes later. Rectal temperature was measured for 120 minutes after the first injection. Significant and long-lasting hypothermia was seen at all time points in both the ethanol+vehicle and ethanol+drug groups when compared to either saline group, while no differences were found between the ethanol+saline and ethanol+drug groups. No significant hypothermia was seen in the saline+vehicle group, however, a small but significant hypothermia was seen in the saline+Ro15-4513 group up to 30 minutes post-saline. These results indicate that 20 mg/kg Ro15-4513 did not antagonize ethanol hypothermia. In summary, our studies show that a high dose of Ro15-4513 is effective in reducing the hypnotic, but not hypothermic, effect of ethanol in mice. These results suggests that ethanol's hypnotic, but not hypothermic, effects may be mediated through interaction with the GABA/benzodiazepine/chloride receptor complex. (Supported by NIAAA grant AA 03972 and BRSG S07 RR05792).

93.18 PHARMACOLOGICAL CHARACTERIZATION OF Ro15-4513 INHIBITION OF ALCOHOL-INDUCED BEHAVIORAL INTOXICATION IN THE RAT. S.M. Paul*, J. Crawley and P.D. Suzdak. (SPON: M. Kafka) Clinical Neuroscience Branch, NIMH, Bethesda, MD 20892

Both biochemical and behavioral evidence suggests that that depressant/anxiolytic effects of ethanol may be mediated via the GABA/Barbiturate receptor-coupled Cl^- ion channel. Recently, the ability of ethanol to both (A) stimulate $^{36}Cl^-$uptake in vitro via the GABA receptor complex, and (B) produce anxiolytic and motor incoordination in vivo have been shown to be antagonized by the selective imidazobenzodiazepine, Ro15-4513. (Suzdak et al, Science 234, 1243 (1986)).

The present study examined the ability of Ro15-4513 to prevent, or reverse, the behavioral intoxication produced by ethanol and related short chain length alcohols in the rat. Ro15-4513 dose-dependently (0.5-10 mg/kg i.p.) prevented ethanol-induced intoxication ($IC50=1.5$ mg/kg). The ability of Ro15-4513 to prevent ethanol-induced intoxication was reversed by the central benzodiazepine receptor antagonists Ro15-1788 (10 mg/kg) and CGS-8216 (10 mg/kg). However, the ability of Ro15-4513 to prevent ethanol-induced intoxication was not mimicked by other benzodiazepine receptor antagonists or inverse agonists (FG-7142 (10-30 mg/kg) or βCCE (10 mg/kg)). Ro15-4513 (2.5-10 mg/kg), administered six minutes after the administration of ethanol, dose-dependently reversed the ability of ethanol to produce behavioral intoxication ($IC_{50}=5$ mg/kg). This effect was blocked by either Ro15-1788 or CGS-8216, but not mimicked by other benzodiazepine receptor antagonist or inverse agonists. These data suggest that the ability of Ro15-4513 to prevent, or to reverse, ethanol-induced intoxication may be mediated by binding to the central benzodiazepine receptor. The lack of effect of other benzodiazepine receptor antagonists or inverse agonists suggests that the "alcohol reversing" properties of Ro15-4513 are mediated through a unique interaction with the GABA/benzodiazepine receptor-coupled Cl^- ion channel. Thus it appears that the "alcohol antagonist" properties of Ro15-4513 may be dissociable from its inverse agonist properties.

93.19 ACUTE INTOXICATION WITH ALCOHOL IMPAIRS COGNITIVE PROCESSING OF PROSE. T. V. Petros,* B. E. Beckwith, M. Haut,* and J. Stempel.* University of North Dakota, Grand Forks, ND 58202.

The present study examined the effects of intoxication with ethanol on encoding and retrieval of prose. Intoxicated and sober subjects read three narrative and three expository passages from a computer at their own rate. Immediately after reading each passage subjects were asked to orally recall it. Reading times and the proportion of idea units recalled were the primary dependent variables. Intoxicated subjects recalled fewer idea units than sober subjects, but both intoxicated and sober subjects favored the main ideas in their recall. A multiple regression analysis of the reading time data indicated that intoxicated subjects did not modify their reading times according to the cognitive demands of the text to the same degree as sober subjects. The results suggest that ethanol impaired the efficiency of specific components of text processing.

SEROTONIN: FUNCTIONAL STUDIES I

94.1 REGIONAL EFFECTS OF 5,7-DIHYDROXYTRYPTAMINE ON 5-HT-2 RECEPTORS AND PHOSPHOINOSITIDE TURNOVER IN THE RAT. P.D. Butler[1] M.R. Pranzatelli[2], A.L. Barkai[1*]. Departments of Psychiatry[1] and Neurology[2], College of Physicians and Surgeons of Columbia Univ., New York, NY 10032.

Behavioral supersensitivity (myoclonus) can be elicited in response to serotonin (5-HT) agonists from several hours to at least 12 months after 5,7-dihydroxytryptamine (DHT) injection in rats and has been attributed to denervation supersensitivity of post-synaptic 5-HT receptors. DHT lesions could induce changes in receptor ligand binding and/or second messenger activity in the post-synaptic cell. To pursue both possibilities, we measured regional 5-HT-2 receptor ligand binding and 5-HT-stimulated phosphoinositide turnover in rats with DHT lesions and their saline-treated controls. We selectively depleted 5-HT in rats with intracisternal injection of DHT after pretreatment with desipramine: 77% depletion in frontal cortex, 47% in brainstem, and 78% in spinal cord, without changes in norepinephrine (NE). In saturation studies (six concentrations from 10 to 0.1 nM) of fresh brain tissue two weeks after DHT injection, ^{3}H-ketanserin specific binding (using 10 uM methysergide to define non-specific binding) was unchanged in brainstem and spinal cord, and increased in frontal cortex (+12%) compared to controls (expressed as pmol/g brain). This represented a small significant change in Bmax but not Kd or Hill coefficient. In the same two groups of rats, cross-chopped brain and spinal cord slices were prelabeled with ^{3}H-myo-inositol. Accumulation of ^{3}H-inositol phosphates (IP) was measured in the presence and absence of 5-HT (10 uM) and NE (5 uM) to assess the function of 5-HT-2 and alpha-1-adrenergic receptors, respectively. DHT lesions did not affect basal levels of ^{3}H-IP accumulation but significantly increased 5-HT-stimulated ^{3}H-IP accumulation in the brainstem (+27%). Effects in spinal cord and cortex were in the same direction but were not significant. NE-stimulated ^{3}H-IP accumulation was not altered by DHT treatment in any of the regions studied. These data suggest a regional dissociation between changes in phosphoinositide metabolism and density of 5-HT-2 receptor recognition sites following DHT lesions. In view of the importance of the brainstem in DHT-induced myoclonus, the compensatory increase in 5-HT-stimulated phosphoinositide hydrolysis in brainstem following DHT lesions in the rat may be relevant to serotonergic behavioral supersensitivity. Further studies will assess the time course and subregional localization of these effects and their relation to myoclonus.

94.2 5HT-2 RECEPTOR-MEDIATED PHOSPHATIDYLINOSITOL (PI) HYDROLYSIS IN HUMAN PLATELETS:MODULATION OF PI TURNOVER BY PROTEIN KINASE C ACTIVATORS. M. Mikuni, H. Mori*, Y. Yoshida, I. Yamashita* and K. Takahashi*(SPON:K.Satoh) Div. of Mental Disorder Res. Natl. Institute of Neuroscience, NCNP, Tokyo, 187 and Dept. of Psychiat. Hokkaido Univ. Schl. of Med. Sapporo, 060, Japan.

The metabolism of inositol phospholipids in response to 5HT was investigated in human platelets using sensitive radioisotopic method of Berridge(1983). In platelets prelabeled with ^{3}H-myo-inositol, 5HT caused a dose-dependent accumulation of inositol-1-phosphate(IP-1) during 15min incubation in Ca^{++}free HEPES buffer containing 10mMLiCl and 1μM fluoxetine. A maximal increase in IP-1 formation was observed at 30μM of 5HT and its EC_{50} value was 4μM. Ketanserin was a potent inhibitor of 5HT-stimulated IP-1 accumulation with a Ki value of 12nM, but a 5HT-1 antagonist, propranolol(10μM) failed to block the 5HT response. Metergoline, a mixed 5HT-1 and -2 antagonist caused the almost same reduction in 5HT induced IP-1 formation as ketanserin, with a Ki value of 5.2nM. Moreover, chlorpromazine and imipramine inhibited 5HT-stimulated IP-1 accumulation, with Ki value of 124nM and 2.56μM, respectively. Spiperone(1μM) inhibited completely, and clozapine(1μM) and amitriptyline(1μM) reduced partially (50-70%) 5HT-induced IP-1 accumulation, but sulpiride(1μM) failed to block the 5HT response. The potencies of these compound to inhibit 5HT-stimulated IP-1 accumulation in human platelets was positively correlated with the affinities to 5HT-2 receptor as defined by radioligand binding in rat cerebral cortex membranes.

The biologically active phorbol ester was reported to inhibit the PI turnover stimulated by 5HT in rat aorta(Roth et al,1986). We investigated, therefore, whether or not phorbol-12,13-dibutylate(PDB) and mezerein which is tumor promotor and protein kinase C activator as well as PDB, but not phorbol ester, inhibit 5HT-stimulated IP-1 accumulation in human platelets. PDB(100nM) inhibited 5HT response in human platelets, and mezerein was also found to inhibit 5HT-induced IP-1 accumulation with a IC_{50} value of 1nM. These results suggest that an activation of protein kinase C may desensitize 5HT-2 receptor-mediated PI hydrolysis in human platelets.

94.3 ICS205-930 INHIBITS HIGH AFFINITY SEROTONIN BINDING AND SEROTONIN STIMULATED ADENYLATE CYCLASE IN THE RAT SPINAL CORD. S.R. GLAUM and E.G. ANDERSON. Department of Pharmacology, College of Medicine, University of Illinois - Chicago, Chicago, IL 60680.

Dorsal root ganglion cells (DRG's) have been used in intracellular recording as pharmacological models of dorsal horn afferent terminals. Individual DRG's of the frog and rat display multiple electrophysiological responses to perfusion with serotonergic agonists, suggesting the presence of multiple receptor subtypes. (Scroggs and Anderson., NS Abst. 12,1238 1986). Serotonin (5HT) binds with nanomolar affinity to two distinct receptor families, the $5HT_1$ and $5HT_3$. The $5HT_1$ class are broadly distributed within the central and peripheral nervous system. At this time, no previous examples of central $5HT_3$ receptors have been reported. The development of a specific antagonist at $5HT_3$ receptors, ICS205-930, has revealed that many of the peripheral excitatory effects of 5HT are mediated by $5HT_3$ receptors (Richardson and Engel., TINS 9,424 1986). We now report the presence of central $5HT_3$ receptors based on ICS205-930 displacement of high affinity ^{3}H-5HT binding in the dorsal horn of male Sprague-Dawley rats. Additionally, the ability of ICS205-930 to inhibit 5HT-stimulated adenylate cyclase (AC) in the dorsal cord was determined.

^{3}H-5HT binds with high affinity to the dorsal cord (K_d =1.2nM, B_{max}=40 fmol/mg protein). ICS205-930 maximally displaces 35% of the high affinity binding, suggesting the presence of residual high affinity sites, possibly $5HT_1$. Methiothepin antagonizes ^{3}H-5HT binding to $5HT_1$ and $5HT_2$ sites, but not $5HT_3$ sites. In the presence of 1nM methiothepin, ICS205-930 displaced ^{3}H-5HT binding with an IC_{50}=20nM (nH=1). AC was stimulated in a dose dependent manner by 5HT in rat dorsal cord. Maximal stimulation (136% of basal) occurred at [5HT]=100nM. Higher concentrations reduced stimulation, suggesting low affinity 5HT sites linked to the inhibition of AC. ICS205-930 inhibited 5HT-stimulated AC at concentrations as low as $10p^M$. The potency of ICS205-930 as an antagonist of 5HT-stimulated AC is similar to the pA_2 values reported by Richardson and Engel for its peripheral effects.

These data support the existence of centrally located $5HT_3$ receptors. We are currently investigating the neuronal subtypes where $5HT_3$ receptors predominate and their possible function in the CNS. (Supported by USPHS grant NS 17834-02)

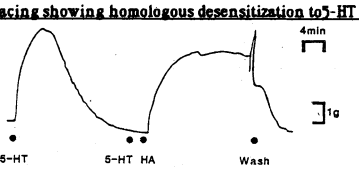
94.4 **COMPARISON OF THE AFFINITY OF SEROTONIN AGONISTS FOR THE 5-HT-1A RECEPTOR WITH THEIR POTENCY AT ELICITING A 5-HT-1A RECEPTOR-MEDIATED RESPONSE.** **S.J. Offord, T.M. DeAngelo*, H.L. Wang* and A. Frazer, Departments of Psychiatry and Pharmacology, University of Pennsylvania School of Medicine and VA Medical Center, Philadelphia, PA 19104.**

Multiple subtypes of the serotonin-1 (5-HT-1) receptor exist in the rat brain. For 5-HT-1A receptors, the radioligand agonist 3H-8-hydroxy-2-(di-N-propylamino)tetralin (3H-DPAT) has been used to determine affinities of drugs. In general, the affinity of serotonin agonists for the 5-HT-1A receptor as measured with 3H-DPAT is lower than that reported when affinities are measured using the non-selective agonist 3H-5-HT. In the 3H-5-HT assay GTP was included as was TFMPP, to prevent 3H-5-HT from binding to 5-HT-1B receptors (Sills et al., J. Pharmacol. Exp. Therap., 231:480, 1984). In particular, RU 24969, TFMPP and m-CPP have been reported to have higher affinity for displacing the binding of 3H-DPAT (Peroutka, J. Neurochem. 47:529, 1986) than that found using 3H-5-HT (Sills et al., 1984). To study this issue further, we determined the potency of these serotonin agonists for producing a 5-HT-1A mediated response, inhibition of forskolin-stimulated (F-S) adenylyl cyclase activity in homogenates of rat hippocampus. As reported by DeVivo and Maayani (J. Pharmacol. Exp. Therap. 238:248, 1986), we found that spiperone prevented the inhibitory effect of 5-HT on F-S adenylyl cyclase with a K_D of 26±3 nM, a value in agreement with the affinity of spiperone for the 5-HT-1A receptor (73±14 nM). By contrast, the selective 5-HT-2 antagonist ketanserin (1uM) was not able to block the inhibitory effect of 5-HT, consistent with this response being mediated by 5-HT-1A receptors. The inhibitory effect of 5-HT required GTP (25 uM) and was not mimicked by dopamine. 5-HT, DPAT, RU 24969 and 5-MeODMT were full agonists, producing a maximal inhibition of about 30%. TFMPP and m-CPP were partial agonists, causing about half the maximal inhibition produced by the full agonists. EC50 (nM) values for inhibiting F-S adenylyl cyclase were: DPAT, 15±2; 5-HT, 40±1; RU 24969, 124±12; 5-MeODMT, 380±63; TFMPP, 3530±1580; m-CPP, 18000±6000. We found that affinities obtained for drugs in the 3H-DPAT binding assay agreed with values reported by Peroutka (1986). For 15 compounds, the Pearson correlation coefficient was 0.97. The Ki (nM) values for DPAT, 5-HT, RU 24969 5-MeODMT, TFMPP and m-CPP were 1±0.3, 2±0.3, 1±1, 3±1, 56±9 and 113± 11, respectively. These values are 15-160 fold lower than the EC50 values measured in the cyclase assay. Several factors could contribute to these quantitative differences. Spare receptors could affect potency in the cyclase assay but this would be expected to increase potency in this assay, not lower potency. A second explanation could be that 3H-DPAT binds to multiple affinity states of the 5-HT-1A receptor. This seems likely as this receptor is linked to adenylyl cyclase through an inhibitory guanine nucleotide binding protein. Consistent with this is our finding that 3H-DPAT binding is inhibited by GTP. These results indicate that affinities of serotonin agonists obtained using 3H-DPAT should be interpreted cautiously. **(This research was supported by USPHS Grants MH 29094, GM 34781 and research funds from the VA).**

94.5 KINETIC CHARACTERIZATION OF DESENSITIZATION OF THE RESPONSE TO 5-HYDROXYTRYPTAMINE IN AIRWAY AND VASCULAR TISSUES. R.R.Ben-Harari*, B. Dalton*, J.Kaplan* and S.Maayani†. Departments of Anesthesiology and Pharmacology†, Mt. Sinai School of Medicine, City University of New York, New York, N.Y. 10029.

Desensitization and resensitization of a response to an agonist presents difficulties both experimentally, in characterization of receptors and receptor-effector interactions, and clinically, in therapeutic efficacy. Despite its obvious importance, desensitization in intact tissues has either been reported descriptively or tissue responses have been measured at steady-state. Both desensitization and resensitization are time-dependent which cannot be accurately analyzed under steady-state conditions. Kinetic analysis with novel pharmacologic protocols (J. Pharm. exp. Ther., 236, 48, 1986) allows us to characterize these two phenomena. In comparison to the rabbit aorta preparation (half lifetime for desensitization to 5-HT is 70 min), the response to 5-HT in guinea-pig trachea shows very fast rates of desensitization (t1/2 = 5min) and thus, kinetic studies become experimentally feasible. Tissue tension in guinea-pig trachea and rabbit aorta were measured isometrically in Krebs-Henseleit buffer, pH 7.4, gassed with 95% O_2 + 5% CO_2. Under steady-state conditions (concentration-response curves), the $5\text{-}HT_2$ antagonist, ketanserin (10µM) abolished the response to 5-HT and no responses were obtained to 8-OH-DPAT or to 5-carboxamidotryptamine on tissue precontracted with histamine (HA). 5-HT therefore acts at a single homogeneous receptor population. Experiments with 4mM $NaNO_2$ demonstrated that the contractile response of the tissue to 5-HT was not necessary for desensitization to occur. Desensitization to 5-HT was homologous and was not a result of monoamine oxidase activity, removal by neuronal or extraneuronal uptake or release of an endogenous inhibitor of contraction. Rate constants for the decay of the response (desensitization) to 5-HT were: a) reversible after 3h; b) slower at 15°C than at 37°C; c) increased with increasing concentrations of 5-HT; and d) faster than to N-methyl 5-HT (a partial 5-HT agonist) at equal occupancy of the receptor. The results demonstrate that homologous desensitization to 5-HT is operationally a time, concentration, temperature and efficacy dependent loss of tissue responsiveness in a functional system. (Supported by USPH GM-34852).

Fig. Original tracing showing homologous desensitization to5-HT on trachea.



94.6 FUNCTIONAL 5-HT RECEPTORS IN BRAIN AND PERIPHERY AND THEIR RELATED BINDING SITES: ACTION OF AGONISTS AND ANTAGONISTS. D.K. Hyslop[1], F.D. Yocca[1], and S. Maayani[2], [1]Preclinical CNS Research, Pharmaceutical Research and Development Division, Bristol-Myers Company, Wallingford, CT 06492, and [2]Department of Pharmacology, Mount Sinai School of Medicine, CUNY, NY 10029

The recognition sites of two distinct functional 5-HT receptors can be selectively labeled: the 5-HT-sensitive [^{3}H]8-OH-DPAT sites are indistinguishable from the $5\text{-}HT_{1A}$ receptor that is negatively linked to adenylate cyclase activity (DeVivo and Maayani, JPET: 238, 1986) and the methysergide-sensitive [^{3}H] ketanserin site (Leysen et. al., Mol. Pharmacol: 21, 1982) or the cinanserin-sensitive [^{3}H]DOB site (Lyon et. al., Mol. Pharmacol: 31, 1987), sites which are pharmacologically congruent with the $5\text{-}HT_2$ receptor that mediates contractility in vasculature, such as the rabbit aorta preparation (Maayani et. al., JPET: 229, 1984). 8-OH-DPAT is an agonist at the $5\text{-}HT_{1A}$ receptor, while DOET and DOI (the latter being an analog of DOB) are $5\text{-}HT_2$ agonists in the rabbit aorta preparation. Affinity values of 5-HT agonists at these two sites (EC_{50} at the $5\text{-}HT_{1A}$ and K_A at the $5\text{-}HT_2$) were determined in the functional systems and compared to reported K_i values at the high affinity sites. The EC_{50} and K_A values at the functional receptors are 20-30 times higher than their related affinity for the 5-HT-sensitive [^{3}H]8-OH-DPAT or cinanserin-sensitive [^{3}H]DOB binding sites. Also, the binding to the 5-HT-sensitive [^{3}H]8-OH-DPAT sites by spiperone and methiothepin, drugs that were reported to act as competitive $5\text{-}HT_{1A}$ antagonists (DeVivo and Maayani, JPET: 238, 1986) does not obey the simple Michaelis-Menten model (Hill coefficients of 0.59 ± .05 and 0.47 ± .03, respectively). Similarly, BMY 7378 (7,9-dioxo-8-[2-(4-o-methoxyphenylpiperazinyl)ethyl]-8-azaspiro[4.5]decane dihydrochloride), a buspirone analogue with high affinity, selectivity and low intrinsic activity at the $5\text{-}HT_{1A}$ receptor in rat and guinea pig hippocampal membrane (Yocca et al., E.J.P., submitted) (K_D = 10 nM), binds in a complex manner to the 5-HT-sensitive [^{3}H]8-OH-DPAT site (Hill coefficient of 0.69 ± .03). These data may be explained by the existence of interconvertible states of the 5-HT receptors (uncoupled, high affinity and coupled, low affinity states) or by two distinct binding sites. Because the binding of antagonists to the recognition binding sites labeled with agonists (8-OH-DPAT and DOB) is complex, while the binding of agonists at these sites seems to be simple, it is proposed that these 5-HT receptors and their related binding sites exist in two interconvertible states (supported in part by USPH GM 34852).

94.7 EFFECT OF 5,7-DIHYDROXYTRYPTAMINE-INDUCED LESIONS ON THE 5-HT_{1A} RECEPTOR NEGATIVELY COUPLED TO ADENYLATE CYCLASE IN RAT HIPPOCAMPUS. F.D. Yocca, A.S. Eison, E. Ryan* and J. Torrente*. Preclinical CNS Research, Bristol-Myers Company, Wallingford, CT. 06492-7660.

The 5-HT_{1A} receptor linked negatively to adenylate cyclase in rat hippocampal membranes has been shown to be pharmacologically indistinguishable from the 5-HT-sensitive [^{3}H]-8-OH-DPAT binding site in similar preparations. (Devivo and Maayani, JPET: 238, 1986). While measurement of the functional response to this receptor has proven to be a powerful tool for characterizing drug responses and identifying structural requirements necessary for activation of the 5-HT_{1A} receptor (Yocca et. al., Soc. Neurosci: 12, 1986), little is known about its location (pre vs. post-synaptic) or whether this receptor can demonstrate plasticity. To answer these questions, a study was performed which involved selective lesioning of central serotonergic neurons by 5,7-di-hydroxytryptamine (5,7-DHT), with the aims of 1) removing 5-HT terminals in the hippocampus (where these receptors may reside) and 2) denying putative postsynaptic 5-HT_{1A} receptors a source of 5-HT to determine if the phenomena of "receptor supersensitivity" can be induced.

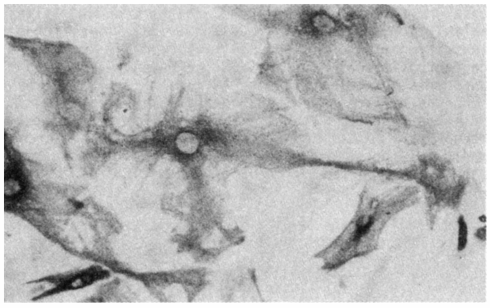
Lesions of 5-HT neurons were performed (Eison et. al., PBB: 24, 1986) five days after surgery when polyethylene cannula were inserted into the lateral ventricles of male Sprague-Dawley rats. Prior to lesioning, rats were pretreated with 25 mg/kg desipramine followed by 15 mg/kg pentobarbital treatment, after which 5,7-DHT (150 ug/20ul) was slowly infused (10ul per side). Seven and fourteen days after administration of the neurotoxin, rats were sacrificed and the hippocampus homogenized so as to measure 5-HT_{1A} inhibitory cyclase and 5-HT levels from the same preparation.

5,7-DHT lesions significantly depleted hippocampal 5-HT levels seven (88%), and fourteen (93%) days after administration of the toxin. The functional status of the hippocampal 5-HT_{1A} receptor was assessed using the potent agonist 5-carboxamidotryptamine. When compared to sham-operated controls, the functional parameters generated in lesioned hippocampi (EC_{50} = 5-10 nM; intrinsic activity=1.0) were not statistically different at any time point tested. These findings are consistent with the idea that the 5-HT_{1A} receptor is not located on presynaptic 5-HT terminals in the rat hippocampus. Furthermore, the lack of change in the sensitivity of the receptor 14 days after i.c.v. administration of 5,7-DHT suggests that this receptor may lack the ability to adapt to changes in synaptic 5-HT concentrations. Continuing investigations with partial 5-HT_{1A} agonists which exhibit a range of potencies and intrinsic activities may provide insight into this apparent lack of plasticity.

94.8 AUTORADIOGRAPHIC AND FUNCTIONAL STUDIES OF HIGH AFFINITY SEROTONIN RECEPTORS ON ASTROGLIAL CELLS. P.M. Whitaker-Azmitia and E.C. Azmitia. Dept. of Psychiatry, SUNY, Stony Brook, NY and Dept. of Biology, New York University, New York, NY.

Using neuronal cultures, we have shown that high affinity serotonin receptors modulate the development of serotonergic neurons (Neurosci. Letters 67:307, 1986). Some of these receptors occur on astroglial cells and their number varies with the age of the cultures and the region of brain from which the astroglial cultures originate (J. Neurochem. 46:1186, 1986). Together, these observations led us to investigate in more detail the characteristics of these receptors on astrocytes and how they might function in neurodevelopment.

Primary astroglial cultures were derived and maintained as previously described. For production of growth factors, cells were exposed to serum-free media or media containing serotonin, and the conditioned media added to cultures of dissociated serotonin neurons. These studies showed the presence of factors in the media from treated cultures which regulated neuronal growth. For autoradiographic studies, lightly fixed cells were rinsed and incubated for thirty minutes with 5-8 nM radiolabelled serotonin. Non-specific binding was determined in the presence of 1,000 nM serotonin. In some cases, cells were stained immunocytochemically with an antibody raised against GFA. Slides were dipped in emulsion and developed after two to three months. These studies showed that serotonin receptor labelling is not uniform over a cell. Moreover, not all cells within the culture were labelled with serotonin, although they were labelled for GFA. An example of this work, shown in a culture stained for GFA, is reproduced below.



94.9 RAPID DETECTION OF THE STIMULUS PROPERTIES OF 5-HYDROXYTRYPTAMINE (5-HT) AGONISTS. I. Lucki, J.A. South* and R. Berger*. Department of Psychiatry, University of Pennsylvania, Philadelphia, PA 19104.

Drug discrimination studies have shown that rats distinguish the stimulus properties of 5-HT agonists that are selective for different receptor subtypes (see R.A. Glennon: J. Med. Chem., 1987, 30:1-12). Establishing this discrimination generally takes extensive training procedures lasting 6 weeks or longer. However, using a discriminated conditioned taste aversion procedure, rats were trained to recognize the stimulus properties of 5-HT agonists after only 8 conditioning sessions.

Fluid-restricted rats were given access to 0.25% saccharin 30 min each day for 18 conditioning sessions. On 9 drug days, separate groups of rats (N=8) were administered one of the training compounds, either the 5-HT_{1A} agonist 8-hydroxy-2-(di-n-propylamino)-tetralin (DPAT; 0.4 mg/kg) or the 5-HT_{1B} agonist trifluoromethyl-phenylpiperazine (TFMPP; 0.8 mg/kg), 15 min prior to drinking saccharin. Saccharin drinking was immediately followed by administration of .15 M LiCl (1.8 mEq/kg). On 9 alternate nondrug days, 0.9% NaCl was administered instead of the 5-HT agonists and the LiCl. Two additional groups of rats (N=8) receiving either DPAT or TFMPP prior to saccharin without LiCl served as unconditioned controls.

Associating the injection of DPAT with LiCl, but not with NaCl, produced a discriminated conditioned taste aversion after only 4 pairings, as indicated by significant differences in drinking between NaCl and DPAT. During the last 3 acquisition sessions, rats drank 19.6 $\pm$ 1.7 ml (mean $\pm$ 1 SEM) following NaCl but only 4.8 $\pm$ 2.3 ml after DPAT (75% reduction). In generalization studies, DPAT produced a dose-dependent inhibition of saccharin drinking (ED50 = 0.25 mg/kg) in LiCl conditioned animals at doses that did not reduce drinking in unconditioned controls.

Rats trained to discriminate the 5-HT_{1B} agonist TFMPP from NaCl showed similar rapid acquisition of the discriminated aversion after only 4 pairings. During the last 3 acquisition sessions, conditioned rats drank 21.6 $\pm$ 2.1 ml after NaCl but only 6.4 $\pm$ 2.6 ml after TFMPP (70% reduction). TFMPP inhibited saccharin drinking dose-dependently in LiCl conditioned rats (ED50 = 0.31 mg/kg) at doses that failed to alter drinking in unconditioned controls.

Drug substitution studies were conducted with other agonists selective for either 5-HT_{1A} or 5-HT_{1B} receptors. The stimulus properties of DPAT were similar to the effects of other 5-HT_{1A} compounds, such as buspirone or ipsapirone. The stimulus properties of TFMPP were similar to the 5-HT_{1B} selective agonist m-chlorophenylpiperazine. This agrees with previous studies. Thus, discriminated conditioned taste aversion appears to be a useful method for establishing the rapid acquisition of the stimulus properties of selective 5-HT agonists in rats.

Supported by USPHS grants MH 36262 and GM 34781.

94.10 CHARACTERIZATION OF SYNTHESIS MODULATING SEROTONIN (5HT) AUTORECEPTORS IN BRAIN SLICES, M.P. Galloway, E.A. Novak*, and B.N. Mathews* Lafayette Clinic and Depts. Psychiatry and Pharmacology, Wayne State Univ. Sch. Med., DETROIT, MI 48207

Autoreceptor control of neuronal function is known to occur at the level of impulse flow, transmitter release, and transmitter biosynthesis. In serotonin (5-HT) containing neurons, relatively little is known about the pharmacological or physiological nature of autoreceptors that modulate tryptophan-5-monooxygenase (TRYP-H) activity. To determine the role of 5-HT autoreceptors in the regulation of 5-HT synthesis, we have measured 5-HTP accumulation (in the presence of NSD-1015) in either cortical or striatal brain slices (0.3 mm^2).

Basal 5-HT synthesis in cortical slices was inhibited by the 5-HT-1B agonist TFMPP (1uM) but not by the 5-HT-1A agonist 8-OHDPAT (10 uM). After activation of TRYP-H in the presence of 30 mM K, TFMPP and m-CPP dose dependently decreased 5-HT synthesis with a greater potency and efficacy when compared to effects on basal synthesis. In contrast, 8-OHDPAT had no significant effect on activated TRYP-H. Similar findings were obtained in striatal slices except that basal striatal 5-HT synthesis was unaffected by agonists. Methiothepin, propranolol and quipazine shifted dose response curves of 5-HT agonists to the right.

The results suggest that nerve terminal synthesis modulating 5-HT autoreceptors are of the 5-HT-1B subtype with little 5-HT-1A character. We, and others, have previously shown that 8-OHDPAT is an extremely potent inhibitor of 5-HT synthesis in vivo, an effect that can be prevented by axotomy of ascending 5-HT fibers. Earlier studies by others suggest that 5-HT autoreceptors modulating release also appear to be 5-HT-1B, however somatodendritic autoreceptors appear to be exquisitely sensitive to 5-HT-1A agonists such as 8-OHDPAT. Taken together, the results support the following model: Under normal conditions, nerve terminal TRYP-H is primarily regulated by impulse flow (thus 5HT-1A cell body ARs) and only under conditions of TRYP-H activation are terminal 5HT-1B autoreceptors recruited. This circumstance differs considerably from autoregulation of tyrosine hydroxylase activity in dopamine neurons. Moreover, the results underscore the utility of this slice preparation for measuring 5-HT-1B function and further suggest that 8-OHDPAT induced suppression of 5-HT synthesis in vivo may be a biochemical measure of somatodendritic autoreceptor stimulation. Supported by MH-41227 and DA-04120 (MPG) and the State of Michigan-DMH.

94.11 EFFECT OF TRYPTOPHAN AVAILABILITY ON RELEASE OF ENDOGENOUS SEROTONIN FROM RAT HYPOTHALAMIC SLICES, Judith D. Schaechter and Richard Wurtman (SPON: W.J.H. Nauta) Dept. Brain and Cognitive Sciences, Massachusetts Institute of Technology, Cambridge, MA 02139.

Brain serotonin (5HT) synthesis is influenced in vivo by brain tryptophan levels, and thus by the plasma [tryptophan]/[large neutral amino acid] ratio. This study examines the relationship between 5HT release and the level of tryptophan available to brain neurons in vitro, using a superfused rat hypothalamic slice preparation. The efflux of 5HT and its chief metabolite, 5-hydroxyindole acetic acid (5HIAA), from these slices is measured under basal conditions and with electrical stimulation; tissue tryptophan, 5HT, and 5HIAA contents are also measured.

Increases in brain tryptophan content (20-600%) caused by adding tryptophan to the superfusing medium caused elevations in tissue 5HT (10-30%) and 5HIAA (20-200%) levels. Spontaneous and evoked 5HT release were augmented in parallel to these elevations: When rat hypothalamic slices were superfused in the presence of 1, 2, 5, or 10uM l-tryptophan, the spontaneous release of 5HT increased in a concentration-dependent manner, by 10.82 ± 4.72%; 21.61 ± 6.42%; 48.79 ± 10.16%; and 150.61 ± 7.28% respectively, over a period of 80 minutes. Spontaneous 5HT release as a percent of final tissue 5HT content was independent (0.08%/minute) of tissue tryptophan levels. Electrical field-stimulation of the slices (1400 bipolar square pulses, 5 Hz, 2ms) caused 3.62 ± 0.012% of the tissue 5HT to be released over a 10 minute period. While the fraction of tissue 5HT released with electrical stimulation did not change when tryptophan was added to the medium, the rate of 5HT release was clearly elevated with increased tryptophan availability; superfusing the brain slices in the presence of 1, 2, 5 or 10uM tryptophan augmented electrically evoked 5HT release by 8.43 ± 2.04%; 25.73 ± 4.94%; 39.54 ± 8.46; and 61.09 ± 11.43% respectively. There were also corresponding increases in the rate of 5HIAA efflux, i.e., by 28.50 ± 5.52%; 60.38 ± 11.41%; 109.27 ± 31.31%; and 177.39 ± 45.40% respectively.

These data demonstrate that the release of 5HT from brain neurons, both spontaneously and during electrical stimulation, parallels the tryptophan concentration in the extracellular space of the brain. Moreover, the amount of 5HT released spontaneously and with neuronal depolarization is proportional to brain 5HT levels. It is noteworthy that the increase in brain tryptophan (20-150%), caused by superfusing slices with low (1-2uM) tryptophan concentrations is within the range that occurs physiologically after consumption of a carbohydrate-rich, protein-free meal. Our data thus provides additional evidence that food consumption can modify 5HT release.

94.12 K^+-EVOKED RELEASE OF [^{3}H]5-HT FROM THE GUINEA PIG FRONTAL CORTEX. M.E. Bremer* and D.N. Middlemiss* (SPON: J. Farah). Searle Research & Development, Chesterfield, MO. 63198.

The release of [^{3}H]5-HT from preloaded slices of rat brain tissue has been extensively reported but only limited studies have been carried out in other species. The present study has investigated the characteristics of the K^+-evoked release of [^{3}H]5-HT from slices of the guinea pig frontal cortex. Slices of frontal cortex were loaded with [^{3}H]5-HT, superfused and exposed to Krebs solution containing elevated K^+ ions and 10 µM fluvoxamine (Middlemiss, D.N., Naunyn-Schmiedeberg's Archives of Pharmacology, 327:18, 1984). Elevated K+ ions (10-50 mM) caused a concentration related release of tritium. Exposure of the slices to 30 mM K^+ Krebs increased the release of tritium from 0.42 +/- 0.02% tissue stores/min (mean +/- SEM, n=6) to 1.86 +/- 0.05%. This K^+-evoked release was reduced to basal levels by the exclusion of Ca^{++} ions from the Krebs solution. Thus the stimulated release of [^{3}H]5-HT from guinea pig frontal cortex slices bears the expected characteristics of Ca^{++} dependent neurotransmitter release.

5-HT (30 to 300 nM) caused a concentration related inhibition of 30 mM K^+-evoked [^{3}H]5-HT release with a maximum inhibition observed at 300 nM of 48 +/- 3% (mean +/- SEM, n=5). This inhibition was attenuated by methiothepin (pA_2 = 8.23), cyanopindolol (pA_2 = 6.47), and mesulergine (pA_2 = 6.20), but not by ICS 205-930 (1 µM). 8-OH-DPAT (30 nM to 1 µM) did not inhibit K^+-evoked release of [^{3}H]5-HT.

These findings indicate that the pharmacological specificity of the terminal autoreceptor in the guinea pig does not correspond to that of the rat (Engel et al. Naunyn-Schmiedeberg's Archives of Pharmacology, 332:1, 1986).

94.13 INTERACTIONS OF THE 5HT$_1$ ANTAGONISTS QUIPAZINE, SPIPERONE, AND MESULERGINE, AT THE SEROTONIN (5HT) NERVE TERMINAL AUTORECEPTOR IN THE RAT SPINAL CORD. L.M. Brown, G.M. Williams, J.B. Amedro*, and D.J. Smith. Depts. of Pharmacology/Toxicology and Anesthesiology. West Virginia University Medical Center, Morgantown, WV 26506.

The selective $5HT_{1B}$ antagonist quipazine, the $5HT_{1A}$ antagonist spiperone (Peroutka, J. Neurochem. 47:529, 1986) and the $5HT_{1C}$ antagonist mesulergine (Hoyer et al., Eur. J. Pharmacol. 118:13, 1985) were used to confirm that the nerve terminal 5HT receptor (autoreceptor) responsible for modulating the release of 5HT in the rat spinal cord corresponds to the $5HT_{1B}$ binding site. A superfused synaptosomal preparation of rat spinal cord tissue labelled with ^{3}H-5HT was used. In this preparation the non-selective agonists 5HT (30-100nM) and lysergic acid diethylamide (LSD) (0.1-1µM) and the $5HT_{1B}$ selective agonists 1-(m-trifluoromethylphenyl) piperazine (TFMPP) (0.3-1µM) and 1-(m-chlorophenyl) piperazine (mCPP) (1-3µM), (Peroutka, 1986; Sills et al., J. Pharmacol. Exp. Ther. 231:480, 1984) inhibited the K^+ (15mM)-evoked release of ^{3}H-5HT in a concentration-dependent manner. On the other hand, the $5HT_{1A}$ agonists 8-hydroxy-2-(di-n-propylamino) tetralin (8-OH-DPAT) (1µM) (Middlemiss and Fozard, Eur. J. Pharmacol. 90:151, 1983) and 5-methoxy-N, N-dimethyltryptamine (5-MEODMT) (1µM) (Peroutka, 1986) were ineffective.

Only quipazine (1µM), the $5HT_{1B}$ antagonist, was capable of reversing the effects of the autoreceptor agonists. This antagonist reversed the depressions in ^{3}H-5HT release induced by 5HT (30nM) and LSD (0.1µM) (73 and 83% of control to approximately 90 and 96% of control, respectively). In a similar manner the depressions in ^{3}H-5HT release caused by TFMPP (1µM) (79% of control) and mCPP (3µM) (75% of control) were reversed to 95 and 89% of control, respectively. Spiperone and mesulergine were both ineffective in reversing the effect of either 5HT or other autoreceptor agonists tested. Therefore, it appears that the rat spinal cord nerve terminal 5HT autoreceptor is of the $5HT_{1B}$ subtype. Supported by NIH grant 5 T32 GM07039 and the WVU Med. Corp.

94.14 SPECIES DIFFERENCES IN SEROTONIN AUTORECEPTORS. J. Schipper*, J.A.M.van der Heyden*, B.Olivier (SPON: L.D. Bradford). Dept. Pharmacology Duphar B.V., P.O. Box 2, 1380 AA Weesp, The Netherlands.

The release of serotonin (5-HT) from nerve terminals is frequently studied by measuring the [^{3}H]-5-HT overflow from rat brain slices in vitro. Administration of exogeneous 5-HT results in inhibition of 5-HT release, indicating the presence of a negative feedback via presynaptic 5-HT autoreceptors. Pharmacological characterisation with 5-HT agonists and antagonists has indicated that the 5-HT autoreceptor in rats resembles the $5\text{-}HT_{1B}$ receptors site as defined by receptor binding studies (Engel et al. N.S. Arch. Pharm. 332: 1, 1986). Recently however, it has been reported that the $5\text{-}HT_{1B}$ site is not present in human and pig brain tissues (Hoyer et al. Eur. J. Pharm. 118: 13, 1985; Heuring et al. Eur. J. Pharm. 122: 279, 1986). Therefore we were interested to see whether 5-HT autoreceptors were present in species, which lack the $5\text{-}HT_{1B}$ site.

Cortical tissue was obtained from rats, mice, guinea pigs, rabbits, pigs, rhesus monkeys and immediately chilled in cold Krebs-Ringer buffer (KRB). Slices (0.25x0.25x2mm) were prepared with a tissue chopper and prelabelled with [^{3}H]-5-HT (30 nM) during 15 min at 37°C under $95\%O_2+5\%CO_2$ atmosphere. Slices were transferred to a superfusion apparatus and superfused with oxygenated KRB containing 10 µM fluvoxamine (5-HT uptake inhibitor) at a rate of 0.2 ml/min. After 45 min presuperfusion, 15 min fractions were collected. Release was stimulated by a 5 min exposure to 20mM K^+. Drugs were added 15 min before stimulation. Effects on stimulated release were corrected for basal release and expressed as percentage of control.

In all species studied (including those which lack the $5\text{-}HT_{1B}$ site) 5-HT induced a dose dependent inhibition of K^+ stimulated 5-HT release. 8-OHDPAT ($5\text{-}HT_{1A}$ agonist) was inactive in all species studied. Trifluoromethylphenyl piperazine ($5\text{-}HT_{1B}$ agonist) was active in rat and mouse cortical tissue, but inactive as an agonist in the other species. Cyanopindolol (0.1µM), a $5\text{-}HT_{1B}$ antagonist, completely blocked the 5-HT effects in rat and mice, but was inactive in the other species. Methiotepine (1µM), a $5\text{-}HT_1$ antagonist, blocked the 5-HT effects in all species, whereas mianserine (0.1µM), a $5\text{-}HT_{1C}$ antagonist and ketanserine (0.1µM), a $5\text{-}HT_2$ antagonist were inactive.

In conclusion, serotonin autoreceptors are present in cortical tissue of all species studied, but the pharmacological characteristics differ between species. In rat and mouse the 5-HT autoreceptor is of the $5\text{-}HT_{1B}$ type. In the other species the 5-HT autoreceptor is a $5\text{-}HT_1$ like receptor but not of the 1_a, 1_b or 1_c type.

94.15 THE EFFECTS OF CHRONIC ETHANOL AND ETHANOL/LYSINE COMBINATION ON SEROTONIN RELEASE FROM PARIETAL CORTICAL BRAIN SLICES.
Hoau-Yan Wang*, Hing Char* and Eitan Friedman* (Spon: Wagner Bridger) Division of Neurochemistry, Departments of Psychiatry and Pharmacology, Medical College of Pennsylvania, Philadelphia, PA 19129.

Changes in brain serotonin transmission have previously been reported to alter alcohol-induced narcosis and tolerance and to reverse the cognitive dysfunction caused by ethanol ingestion. In the present investigation we have examined the effects of 2 or 7 weeks of treatment with a liquid diet containing 5% ethanol on K^+-stimulated ^{3}H-serotonin release from preloaded parietal cortical brain slices. Furthermore we examined the effect of treatment with l-lysine, which has previously been shown to prevent the hypnotic effect of ethanol (Toxicol. Appl. Pharmacol. 22, 422, 1972), on ^{3}H-serotonin release and on its interaction with chronic ethanol administration. Male Sprague-Dawley rats (100-125g) were divided into four groups. Two groups were fed Liquidiet with ethanol and two received the control diet. One of each of these groups also received oral l-lysine (1.5g/kg)daily. At the end of 2 or 7 weeks, 16 hr prior to killing, the respective diets were given by gastric intubation (3ml/100g body weight). Cortical slices were incubated with ^{3}H-serotonin, and superfused with oxygenated physiological solution. Depolarization was elicited by a brief (30 sec) pulse of 65mM K^+. Stimulated release and basal efflux of ^{3}H-serotonin were calculated as the % fractional release of the tissue content at the time of stimulation. The results show that 2-weeks of treatment with ethanol(a) diminished K^+-induced ^{3}H-serotonin release and basal efflux by about 30%, (b) the co-administration of l-lysine completely prevented the effect of ethanol on serotonin release and (c) in alcohol-treated animals the release-inhibitory response to d-LSD was significantly greater than that found in control or in alcohol plus lysine treated animals. Animals treated with ethanol for 7 weeks (a) exhibited an increase (17%) in ^{3}H-serotonin release which was also prevented by the co-administration of l-lysine and (b) this treatment period resulted in a decreased responsiveness to d-LSD which was not different in the ethanol/lysine treated group. The results suggest that chronic ethanol ingestion results in presynaptic serotonin autoreceptor and serotonin release changes. Furthermore, some of these effects may be prevented by the co-administration of the l-lysine.

94.16 SYNTHESIS AND SECRETION OF A TRANSFERRIN-LIKE PROTEIN BY RAT CHOROID PLEXUS. M. Tsutsumi,* M.K. Skinner,* and E. Sanders-Bush. Dept. of Pharmacology, Vanderbilt Univ. School of Medicine, Nashville, TN 37232

Serotonin (5HT) via the 5HT-1c receptor increases phosphoinositide hydrolysis 5- to 10 fold in choroid plexus (CP) (Conn et al., Proc. Natl. Acad. Sci. USA. 83, 1986). Interestingly, 5HT is the only known substance to induce this effect. Autoradiographic studies have shown that the 5HT-1c receptor is localized to the epithelial cells of the CP (Yagaloff and Hartig, Mol. Pharmacol. 29:120, 1986). Evidence also suggests that the receptor is under the influence of cerebrospinal fluid(CSF)-borne 5HT; however, the physiological significance of the receptor is not understood.

It is generally accepted that the CP has two major functions; 1) CSF production and 2) the blood/CSF barrier. Data suggest that the CP not only functions as a gateway for the transport of various substances between the plasma and CSF, but also synthesizes proteins that are selectively enriched in the CSF. Dickson et al. have shown that high levels of mRNA for transthyretin, transferrin, and ceruloplasmin are found in rat CP (see e.g., J. Biol. Chem. 261: 3475-3478, 1986). Furthermore, a significant portion of the total protein synthesized and secreted by rat choroid plexus is transthyretin.

In an attempt to better understand the function of CP and to elucidate a possible role of the 5HT-1c receptor, we have cultured isolated cells from CP of 20-day old male, Sprague-Dawley rats. The cultured cells retain functional 5HT-1c receptors as evidenced by enhanced phosphoinositide hydrolysis. We examined the profile of the proteins synthesized and secreted by radiolabelling the cells with various amino acids (^{3}H-glycine, 35S-methionine, 35S-cysteine) for 48 hours in medium lacking glycine, methionine, and cysteine. Proteins present in the medium were separated by gradient polyacrylamide gel electrophoresis and fluorographed. Preliminary results show that 4 major proteins with approximate molecular weights of 17k, 35k, 70k, and 130k Da are synthesized and secreted by these cells. Furthermore, the 70k Da protein can be specifically immunoprecipitated with rabbit anti-rat transferrin antisera, suggesting that these cells produce and secrete transferrin into the medium. If transport proteins such as transthyretin and transferrin are normally synthesized and secreted, this would suggest that CP plays a crucial role in maintaining the homeostasis of the environment of the central nervous system. (Supported by USPHS Grants MH-34007 and HD-20583).

CONTROL OF POSTURE AND MOVEMENT II

95.1 Modification of Responses to Postural Disturbances in Leg Muscles by Transcranial Motor Cortex Stimulation in Man. C. Van derLinden*, M.R. Dimitrijevic, W.J. Eaton*, A.M. Sherwood. Section for Restorative Neurology and Clinical Neurophysiology, Dept. of Rehabilitation, Baylor Coll. Med., Houston TX 77030.

Stretching the triceps surae (TS) muscle by dorsiflexion at the ankle while standing on a rotatable platform induces several EMG responses in the TS and its antagonist the tibial anterior (TA) muscle. The first response (M1, latency ~45 msec) in the TS muscle is comparable to the monosynaptic stretch reflex. A medium latency response (M2, latency ~70 msec) in the TS muscle and a long latency response (M3, latency ~130 msec) in the TA muscle are suggested to be mediated through a long loop circuitry. The M2 response destabilizes and the M3 response stabilizes posture. Transcranial electrical stimulation of the scalp at the vertex with high voltage (~300 V) short duration (100 us) pulses evokes motor EMG responses (MEPs) in bilateral distal and proximal leg muscles (with a latency of ~30 msec in TA and TS muscles). We studied the interaction between the postural responses which are primarily mediated through bulbospinal pathways and the MEPs which are primarily mediated through direct corticospinal pathways in four neurologically healthy subjects.

A platform on which the subjects stood was rotated with an initial posterior deflection of 10 degrees with a velocity of 100°/sec. M1, M2, and M3 responses were recorded in addition to the anterior-posterior (A-P) body sway. An electrical stimulus at the vertex was triggered at various delays after the onset of the posterior deflection of the platform. M1, M2, and M3 responses and MEPs were recorded in bilateral TA and TS muscles with surface electrodes.

MEPs recorded without platform rotation were more polyphasic and of larger amplitude in the TA Muscles than in the TS muscles, accompanied by an induced body sway in the forward direction. When the cortical stimulus was delayed, after the onset of the posterior deflection, so that the latency of the MEP was comparable to that of the M2 response, the M2 response was only partially suppressed and the A-P sway was not significantly altered. However, when the latency of the MEPs was comparable to that of the M3 response, the M3 response was completely suppressed and the A-P sway in the forward direction was significantly increased.

One possible interpretation of this study is that postural reflexes under bulbospinal control are suppressed by the more potent corticospinal system, and that activation of the TA Muscles in humans is predominantly under corticospinal control, whereas, the TS Muscles, may be more under bulbospinal control.

95.2 LOAD EFFECTS ON CORTICAL SOMATOSENSORY EVOKED POTENTIALS DURING POSTURE AND ACTIVE MOVEMENT.
B. Dimitrov*, M. Hallett and J. N. Sanes. Human Motor Control Section, Medical Neurology Branch, NINCDS-NIH, Bethesda, MD 20892.

Cerebral cortical somatosensory evoked potentials (SEPs) are generally depressed in amplitude during the execution of voluntary movement in comparison to SEPs evoked at rest. It has been reported that SEPs, evoked by cutaneous stimulation of nerves in the leg, are suppressed by voluntary movement and by tonic activation of leg muscles without joint displacement. The present study attempted to determine if this phenomenon also occurred with finger movements. Thus, we investigated the magnitude of SEPs during finger movements and when different constant loads opposed postural maintenance.

Humans had the right index finger coupled to the axle of a torque motor, permitting abduction-adduction movements about the metacarpophalangeal joint. Subjects maintained a steady position of 0° ±1° of abduction while using a video screen for visual guidance. Two somesthetic stimuli were delivered: a positional ramp of 20° towards adduction, 100 msec duration, or an electric shock, at 3x sensory threshold, delivered to the proximal phalanx of the index finger. In the first condition, the somesthetic stimuli were presented during maintenance of posture against no load or a load of 0.15 Nm opposing abduction. In the second condition, subjects performed a 20° abduction movement of the index finger, from -10° to 10°, in 200 msec. The somesthetic stimuli were delivered 10° into the movement in an unpredictable fashion on one-third of the trials. As with the posture experiment, movements were performed with or without load. The EEG was recorded from the scalp 2 cm in front and behind C3, digitized at 500 Hz, and epochs of 200 msec preceding and 300 msec following the stimulus onset were averaged off-line. Four major components were analyzed: P40-55 (P1), N85-115 (N1), P170-190 (P2), and N220-240 (N2).

The SEP components were affected differently when evoked during postural maintenance or active movement and with or without load. During postural maintenance, the ramp evoked a larger P1 than the shock, whereas the shock evoked a larger P2 and N2 than the ramp. Maintenance of posture against a constant load potentiated the ramp-evoked SEP for the P1 and N1 pre-central components and the N1 and P2 post-central components, but did not affect the shock-evoked SEPs. The SEPs evoked by either the ramp or shock stimuli during movement were generally smaller in comparison to SEPs evoked during postural maintenance. The suppressive effects of active movement were greatest for the shock-evoked SEPs and were observed most readily for the P2 and N2 components in the pre- and post-central recordings. Imposition of load during active movement did not affect the magnitude of the SEP.

These data demonstrate that SEPs related to deep and superficial somesthetic inputs are differentially sensitive to imposition of a constant load during postural maintenance, but are generated similarly during active movement. In particular, a constant load potentiated SEPs evoked by the ramp stimulus, whereas SEPs were uniformly suppressed during active movement. This suggests that a gating mechanism selectively enhances deep inputs to the cerebral cortex when humans tonically activate motor neuron pools, but that both deep and superficial inputs are suppressed equally by phasic activation of motor neuron pools.

95.3 HUMAN BODY SWAY IN AN OPTICAL FLOW. M. Flückiger* (SPON: M. Woollacott). Exp. Psych. Lab. of FPSE, Univ. of Geneva, 1211 Geneva 4, Switzerland.

Postural adjustments of standing adults were studied using a textured optical flow pattern projected on the ground and walls of a darkened room. The flow pattern was structured to correspond to textures encountered in open outdoor settings. The optical flow texture consisted of circular spots 9 cm in diameter, distributed at intervals of .5 meters. Body sway was determined by measuring both changes in vertical force on a platform on which the subject stood and by measuring the displacement of a diode attached to the chest. 16 adults (aged 19-30 years) participated in the study.

The experiment consisted of the successive presentation of 5 optical conditions of 20 seconds each. Conditions 1,3 and 5 consisted of a motionless texture, measuring baseline postural sway. Condition 2 consisted of an optical texture approaching the subject, while condition 4 consisted of a flow pattern receding from the subject. The velocity of the flow was 1.39 m/sec.

Results indicate that an approaching optical flow texture causes backward postural inclination, while a receding texture gives forward inclination. The backward sway, at the onset of an approaching texture, was also less important than the forward sway with a receding flow. In addition, at the offset of image motion, there is a large inverse resetting of body position extending beyond the initial equilibrium position. 75 % of both onset and offset sway responses occurred within the first 3 second interval of an experimental condition. As each 20 sec exposure condition progressed, the oscillations tended to decrease. These experiments provide a more precise approach to the analysis of visually driven postural sway in humans.

95.4 MECHANICAL AND COGNITIVE CONSTRAINTS ON STANDING INFLUENCE POSTURAL ADJUSTMENTS AND MAXIMAL FORCES DURING PULLING. W.A. Lee, M.W. Rogers*. Phys. Ther., Northwestern Univ., and Rehabil. Inst. of Chicago, Chicago IL 60611.

This study describes how biomechanical and EMG correlates of postural adjustments (PAs) which precede the onset of voluntary bilateral upper limb movement vary with the length of the support base under the feet and with cognitive constraints on posture.

Nine subjects exerted maximal force pulses under self-paced conditions by pulling against a rigid handle fixed at elbow height. The length of the support base and instructional set were varied. Support bases equaled 100%, 80%, 60%, 40% and 20% of foot length. For the first instructional set, subjects were told to maximize the pulling force and to keep balanced. Body movement (hip angle) was unconstrained. For the second set, subjects were told to maximize the pulling force, keep balanced, and also to keep the body straight. Each subject performed 10 trials for each combination of set and base length. We measured hip and trunk displacements in the sagittal plane, pulling force, and EMG activity in the gastrocnemius, biceps femoris, tibilais anterior, and quadriceps muscles. Hip angle was computed from displacement records. The force impulse (from force onset to peak force) and the change in hip angle (from before body movement to force onset) were measured.

Preliminary analysis of ensemble averaged records have yielded four major findings. (1) All subjects kept the body straighter when instructed to do so, but hip flexion always increased before initiation of the force impulse. Thus, instructions about posture influenced the PA pattern of hip movement quantitatively, not qualitatively. (2) About half of the subjcts exerted higher forces when body movement was unconstrained. The other subjects exerted higher forces when the body was straighter. (3) All subjects had complex, bi-phasic EMG patterns of PAs in the leg muscles. The first phase (P1) preceded movement of the hips, which led the force impulse by up to 1.0 sec. The second phase (P2) of the EMG pattern immediately preceded the onset of the pulling force. The P1 component accelerated the body away from the center of the support base and presumably helped to maximize the force impulse. Some qualitative differences between EMG patterns were noted for pulls made under the two instructions. (4) The force impulses produced by subjects generally decreased with base length, with a 50% decrement in force between the 100% and 20% base lengths. More complete analysis of individual trials is in progress.

The results show more complex patterns of PAs than have been previously reported and implicate a role for some PAs in generating voluntary force rather than in controlling balance. The mixed effects of support base and hip flexion on force magnitude suggest that dynamic aspects of PAs contribute to the maximal forces which subjects can produce.

95.5 THE EFFECT OF LEARNING ON THE ELECTROMYOGRAPHIC AND KINEMATIC PATTERNS IN A PERTURBED ARM MOVEMENT. C. Dugas and R.G. Marteniuk, Dept. of Kinesiology, University of Waterloo, Waterloo, Ontario, N2L 3G1, CANADA

There is evidence to show that motor learning and mental set or strategy can produce changes in reflex responses. Both factors can lead to facilitation, inhibition or even suppression of the medium and long latency reflexes to stretch, if this modulation is appropriate to the demands of the task. The purpose of this study was to investigate how reflex modulation and voluntary motor commands are integrated in order to achieve effective goal directed movements. The strategy used by the subjects was manipulated by changing the number of perturbed trials that were presented in each training session. Four independent groups, with four subjects in each group, were trained with 0%, 20%, 50% or 100% of perturbed trials on two consecutive days with 100 trials of practice per day. Subjects were instructed to perform a 70 degree forearm extension movement in 900 ms to a visual target. A perturbation in the flexion direction (90 ms, 13 Nm peak torque) was introduced 500 ms after the onset of movement on specific trials following a pseudorandom order in each group. Arm position and acceleration were recorded along with surface EMG's from the triceps and biceps muscles for specific blocks of trials on each day.

Average data and their variability for trajectories, acceleration and EMG profiles were used to assess the effects of learning and strategy in each group. The behavioral results from all four groups showed that there was a 15% improvement in performance, in terms of successful trials (when the target was reached), over days. The phase-plane trajectory data revealed that for all subjects there was a decrease in mean within subject trajectory variability with learning and that variability was affected by the level of uncertainty the subjects were facing. The associated EMG profiles showed changes with learning, in terms of decreases in the mean level of average EMG (AEMG) and mean within subject variability for agonist and antagonist muscles. More specifically there was a significant decrease of the AEMG in the M3 component (90-150 ms after onset of perturbation) over days for the groups with 20% and 50% of perturbed trials on each day. This decrease allowed subjects to change the speed of the movement after the perturbation in order to reach the target. Subjects seemed to be overcompensating for the disturbance on the first day, and with training they were able to modify the trajectory of the movement and accommodate to the demands of the task. In the 100% group, the subjects developed an anticipatory strategy that optimized the resistance to the perturbation. Subjects increased the stiffness of the limb 150 ms before the onset of the perturbation and decreased the M3 response in order to minimize the effect of the disturbance in the movement.

95.6 **THE ROLE OF GEOMETRICAL CONSTRAINTS IN THE CONTROL OF MULTI-JOINT POSTURE AND MOVEMENT.** F.A. Mussa-Ivaldi*, N. Hogan* and E. Bizzi (SPON: J.S. Barlow). Dept. of Brain and Cognitive Science, MIT, Cambridge, MA 02139.

The purpose of this investigation was to gain some understanding of the relative role of the mechanical and geometrical properties of the musculo-skeletal system in the control of multi-joint posture and movements. Recent work has indicated that muscles, in vivo, behave like tunable springs. A convenient way to represent the net spring-like behavior of the arm muscles at a given hand position was developed by Mussa-Ivaldi et al.(1985). Briefly, while subjects maintained a hand posture, small displacements of the hand along different directions were imposed. While the hand was maintained in the displaced position, the elastic restoring forces were measured. By relating the restoring forces to the displacement vectors, the net stiffness of the hand was derived. At each position of the workspace, the hand stiffness was then graphically represented as an ellipse characterized by three geometric parameters: size (the area), shape (the ratio of the major and minor axes) and orientation (the direction of the major axis). It was found that the postural hand stiffness followed a very consistent pattern as the hand location changed in the workspace: i.e., the major axis was oriented in a polar direction passing through the hand and the shoulder and the shape became less isotropic (more elongated ellipses) as the hand approached the distal boundary of the workspace. When the hand posture was maintained against externally imposed disturbances acting in different directions we observed that, while size increased, shape and orientation remained unchanged.

In the experiments reported here we investigated whether these invariances can be explained on the basis of a change in the pattern of neural input to the muscles or as a consequence of the geometrical properties of the musculoskeletal system. To this end we measured the hand stiffness as constant forces with different amplitudes and directions were applied to the hand. From the measured values of hand stiffness we derived, by geometrical transformations, the contributions to the hand stiffness from three muscle groups: muscles acting only on the shoulder, muscles acting only on the elbow and two-joint muscles. Finally we compared the actual variabliity observed in the hand stiffness parameters to the simulated variability of the same parameters computed from the muscle contributions in the hypothesis that these could vary independently of each other (e.g. with no coordination) within the measured range of values.

Our results indicate that the variations of shape and orientation of the hand stiffness field which were derived by randomly combining the measured stiffnesses from three muscle groups are of comparable magnitudes to the observed variations of measured hand stiffness. Hence, we conclude that the orientation and shape of the hand stiffness is poorly sensitive to changes in muscle stiffness. It follows that the CNS tuning of muscle properties is not a crucial factor in the expression of these invariances.

The significance of this finding became clear through simulations which show that the invariance of the pattern of hand stiffness shape and orientation has the effect of simplifying the generation of hand movements. This simplification is a consequence of the fact that the dynamic interactions of the spring-like forces with limb inertia and viscosity are more predictable if the muscle activity can affect the joint stiffness terms only by a common scaling factor.

To sum, our results are consistent with the view that biomechanical constraints arising from the geometrical structure of the arm instead of representing a problem for the motor controller provide simpler solutions for generating and representing multi-joint arm movements. 95.7 INFLUENCE OF LIGHT TOUCH INPUT FROM THE HAND ON POSTURAL SWAY. M.K. Holden, J. Ventura*, and J.R. Lackner. Ashton Graybiel Spatial Orientation Lab., Brandeis Univ., Waltham, MA 02254.

We have examined the possible contribution of light touch (and associated upper extremity proprioceptive) input from the fingers in the control of postural sway. That such input may be important is suggested by the informal observation that some patients with balance disorders can improve their standing and walking by simply lightly touching a wall.

Subjects(n=12) were tested under three conditions of support: no support(NS), touch support(TS), and pressure support(PS), with eyes open(EO) and closed(EC). A Kistler force platform measured reaction forces during unilateral stance over trials of 30s duration. Three measures of postural sway were derived from center of pressure coordinates: mean sway amplitude (MSA), path length (PL), and average velocity (AV). In the TS and PS conditions, subjects placed one index finger on a laterally adjacent metal bar. The amount of applied force was monitored via strain gauges. In TS trials, subjects were limited to a force of <100 g; in PS trials subjects could use as much force as desired.

The results showed a significant main effect on MSA, PL and AV for support and vision, and an interaction between the two factors ($p<0.001$). The reduction in MSA for TS vs NS with EC was significant ($p<0.05$); the reduction in MSA for PS was not significantly different from TS. For PL and AV, TS produced a significant ($p<0.05$) decrease vs NS for both EO and EC conditions. For PL and AV, TS was greater than PS. The mean force applied by the finger during TS trials was 39g and during the PS trials, 644g.

Although applied force was much greater in PS than TS trials, the concomitant decreases in sway measures relative to the TS trials were not impressive. The sensory input provided by TS decreased the sway associated with NS and EC by a magnitude similar to the decrease produced by allowing vision in the NS condition (about 60%). PS provided only about an additional 15% attenuation. These findings suggest that the decreases in MSA, PL and AV during the TS compared to the NS trials are not attributable to mechanical factors alone, and that sensory and motor information about arm position can play a significant role in the control of postural sway.

95.8 VISUAL INFLUENCES ON BODY SWAY IN STRABISMICS AND NORMALS. CR Fox, GT Petito*, C Mason*. SUNY Optometry and Veterans Administration.

Strabismics provide an opportunity to examine the unique contribution of both retinal and oculomotor factors to visual control of postural equilibrium. Binocular viewing in the strabismic does not imply fusion and the eye position information from the oculomotor system for the two eyes will not necessarily correspond. Therefore, the contribution of each eye may be significantly different for visual processing, this is particularl. true in constant, unilateral strabismics. Further, suppression, fixation nystagmus, and ARC may be present. The consequences of this for postural equilibrium are unknown. Few studies have been performed relating strabismus and postural equilibrium and they have major flaws which do not allow examination of postural sway control. None have attempted to assess the effect of eye position or movement which makes any attempt to examine the effect of fusio or lack of fusion merely speculative. None of these studies have attempted to separate the individual relative contributions of eac eye and because of a lack of proper clinical evaluation and control, the interpretation of the data presented is questionable.

With the present state of our knowledge, there is no reason to assume a difference in equilibrium between normals and non-neurologically induced strabismics when the eyes are closed. However, with eyes open, binocular viewing would be expected to have less effect on sway in the strabismic than the normal observer due to the fact that the strabismic has weakly or abnormally correlated retinal and/or oculomotor information between the two eyes. This should result in minimal stabilization with binocular vision. This is particularly true in constant strabismics, due to the semi-independence of the two eyes and lack of normal fusion. The degree to which the binocular condition attenuates sway in the strabismic should be related to the degree of independence between the two eyes.

This experiment examined visual control of postural equilibrium with specific attention to the effects of strabismus. The observers were either normal visioned, constant unilateral strabismics (both ARC and NRC), or constant alternating strabismics (both ARC and NRC). Sway was measured during quiet standing in a stable visual surround (ie, a static environment) which was either fully illuminated and structured or dark while the subject fixate a small, stationary target monocularly with each eye and binocularly. Sway with eyes closed and eyes open in complete darkness was also measured. Eye movements were objectively monitored throughout all postural measurements when the eyes were open.

Results are discussed in terms of retinal, oculomotor, and spatial abilities in the strabismic.

95.9 VESTIBULAR AND NECK PROPRIOCEPTIVE INPUTS MODIFY THE COORDINATE TRANSFORMATION OF VISUAL TARGET INTO BLIND POINTING POSITIONS. D.Ott* and R.Eckmiller (SPON: G.Q. Fox). Division of Biocybernetics, University of Düsseldorf, FRG.

Pointing to visual targets (presented sequentially at positions along a horizontal line in head coordinates) without seeing the pointing arm (blind pointing), which was studied in four healthy subjects yields a highly reproducible blind pointing characteristic (BPC). Whereas the BPC branch contralateral to the pointing arm is almost parallel to the line of targets, the ipsilateral BPC branch is typically rotated upwards relative to the target line by an angle τ ($0<\tau<20$ deg) thus indicating a dichotomy of the BPC.

The brain functions required to generate these blind pointing movements are assumed to include the following sequence of neural coordinate transformations (CT): CT_1 projects points in physical space onto a neural eye position map representing horizontal and vertical coordinates of eye position (while fixating the target) relative to head position. CT_2 projects points from the eye position map onto an internal space map (for neural internal representation of physical space). CT_2 is assumed to process multimodal signals regarding the head tilt angle. CT_3 projects points from the internal space map onto a pointing motor map representing desired pointing positions in physical space. CT_3 is assumed to be modified by neck proprioception proportional to the head-trunk tilt angle. Finally, CT_4 executes pointing movements in physical space based on points represented in the pointing motor map.

Results:

1) The sequence of coordinate transformations CT_1 to CT_4 is modified following stepwise lateral tilt (tilt angle 20 deg) of body, head, or trunk only in the ipsilateral pointing hemispace as evidenced by dynamic changes in angle τ. 2) For blind pointing with the right arm, body tilt (left ear down) causes a steplike increase of τ. Trunk tilt (right shoulder down) gradually decreases τ (with an average time constant of 5 min.), trunk tilt (left shoulder down) gradually increases τ. Head tilt (left ear down) leeds to a transient increase of τ, which then decreases again below the pre-tilt value (with an average time constant of 6 min.).

Conclusions:

A) The dichotomy of the BPC indicates a hemispherical subdivision of the underlying neural sensori-motor coordinate transformation process. B) The dynamic tilt-induced changes of τ seem to be caused by vestibular-otolith (body tilt), neck proprioceptive (trunk tilt), or combined (head tilt) stimulation, indicating a side-specific dynamic input of these afferents. C) Due to its high reproducibility and its reversible tilt dependance this paradigm is a powerfull tool to evaluate sensori-motor coordinate transformation performance in normal subjects and patients.

95.10 BIOMECHANICAL STRATEGIES FOR POSTURAL CONTROL IN HUMANS. J.F. Yang and D.A. Winter*. Department of Physiology, University of Alberta, Edmonton, Alberta, and Department of Kinesiology, University of Waterloo, Waterloo, Ontario, Canada.

A computer simulation model, representing the dynamics of a standing human, predicted specific joint torque strategies necessary to compensate for mechanical disturbances (J.F. Yang et al., Soc. Neurosci. Abstr., Vol 12, Part 2, p.1301, 1986). These joint torque strategies were represented as a solution space. The model suggested that an output principle in the form of proportional joint torque combinations could be used to control posture over a wide range of disturbance types. Three model predictions were experimentally validated: (1) the joint torque strategies in response to a knee-forward disturbance, (2) the change in response produced by a greater disturbance force, and (3) the change in response produced by a different starting posture. An apparatus capable of generating impulsive force disturbances was designed and constructed. The disturbance force was a triangular waveform of 20 ms, applied to the leg just below the knee. Film, force plate and surface electromyogram (EMG) from the rectus femoris, vastus lateralis, medial hamstrings, tibialis anterior, soleus and medial gastrocnemius on the right side were recorded from five subjects. Three experimental conditions were presented in a random order: a straight starting posture with a light disturbance force (170 N), a straight starting posture with a medium disturbance force (235 N), and a 20 degree knee flexed posture with a medium disturbance force. Subject joint torque responses were calculated using standard inverse dynamic solution methods, for the early response time period 40 to 125 ms from the disturbance onset. The EMG responses were averaged over five trials. Subjects responded with joint torques which fell within the solution space, in spite of intersubject differences in the individual joint torques and muscle combinations used. Different disturbance forces and different starting postures were responded to with a gain change, as predicted by the model. While the individual joint torques varied between subjects, a consistent total limb strategy was evident. The model was able to account for the different subject responses, and thus appears more general than those reported by others.

95.11 TASK DEPENDENCY OF MUSCULAR SYNERGIES EVOKED BY PERTURBATION OF COMPLEX MOVEMENT. W.E.McIlroy and J.D.Brooke, Human Biology /Biophysics, College of Biol.Sci., Univ. of Guelph, CAN. N1G 2W1.

Contrasting patterns of muscular synergies have been evoked at medium and long latencies following perturbation of rhythmic leg movement (McIlroy & Brooke Brain Res., 407:317-326, 1987). The two patterns were suggested to reflect pre-volitional and volitional outputs, respectively. This was based on the response latencies and the relationship between evoked whole limb movement and task requirements. The present study was designed to quantify the contribution made by volitional sources (including preparatory set and evoked volitional discharge), both which would be altered by task. Four subjects participated in the study. EMGs from six muscles of the right leg were sampled; soleus (SOL), lateral gastrocnemius (LG), tibialis anterior (TA), vastus medialis (VM), rectus femoris (RF) and semitendinosus. Subjects pedalled an ergometer at a rate of 0.8 Hz against a resistance of 15 N. A mechanical brake on the flywheel rapidly increased resistance. The brake was activated between 60° and 80° past top of the right crank. Subjects were instructed to either maintain movement velocity ('resist') or to relax the limb ('no resist'), with perturbation. The first experiment sampled 15 trials of both these conditions per subject. Perturbations were presented randomly (3 to 20 cycles apart). All subjects demonstrated inhibition of LG and SOL, and excitation of TA, VM and RF in the 'resist' condition at medium latencies (range 70-110 ms). Longer latency responses (range 140-180 ms) included excitation of SOL and LG. The longer latency response was also associated with a large increase in pedal force. In the 'no resist' condition a similar pattern of medium latency responses was identified, although with significantly smaller duration and magnitude. The longer latency responses were absent, consistent with the instruction set. This indicated that volitional contribution, by prior setting of CNS or by descending discharge in response to the perturbation, was modulating characteristics of both patterns. A second study was conducted in an attempt to distinguish between the two sources of volitional input. A choice reaction time task was used in the paradigm. Subjects were to resist when they saw a green light and not resist with a red light. For the initial study, the lights were triggered at the onset of perturbation, in an attempt to delay the preparation of instruction set. It is noteworthy that correct responses were only observed in 60% of the trials. Most responses evoked, correct or incorrect, did not differ from the data recorded in experiment 1. There were a few trials which appeared to differ, suggesting subjects did attend to the lights. However the small number of such samples limited quantification. (Supported by NSERC Grant #A40025).

95.12 KINEMATICS OF CEREBELLAR INCOORDINATION STUDIED WITH A 3-DIMENSIONAL MOVEMENT ANALYSIS SYSTEM R.G.Lee, W.J.Becker, B.L.Morrice*, D.G. White*. Department of Clinical Neurosciences, University of Calgary, Calgary, Canada, T2N 4N1

Lesions of the cerebellum result in errors in the trajectory, velocity and accuracy of target-directed limb movements. To quantitate these abnormalities and to investigate mechanisms responsible for incoordination, we studied four patients with cerebellar damage and four normal subjects using a Watsmart 3-dimensional movement analysis system.

Infrared emitting diodes (IREDS) were attached to the tip of the index finger, the wrist, the elbow and the shoulder. From a starting position with the arm at the side and the elbow flexed to 90°, subjects were required to move the finger tip to a target located at shoulder height and arm's length in front of them. This task required a movement of almost 90° at both the shoulder and elbow joints. Two infrared cameras recorded the position of each IRED at a rate of 200/sec. The results were converted into 3-dimensional coordinates which were used to generate plots of movement path, velocity, and joint angles.

In normal subjects the path followed by the tip of the index finger was a relatively straight line which remained fairly constant for trials made at a number of different velocities. In the cerebellar patients the paths were non-linear and highly variable from trial to trial. Part of the reason for this could be seen in the joint angle plots which revealed uncoupling of the normal precise relationship between elbow angle and shoulder angle. For example cerebellar patients would often begin the movement flexing the shoulder through a number of degrees before starting to extend the elbow, causing the finger to move vertically rather than directly towards the target. In addition, the symmetrical Bell-shaped velocity profiles which are a feature of normal movements of this type were distorted in the cerebellar patients.

95.13 VENTROFLEXED RIGHTING PRODUCED BY MEDIAN RAPHE' LESIONS. R. M. Chesire. Psychology Dept., Univ. Hawaii at Manoa, Honolulu, HI 96822.+

Electrolytic lesions of the median raphe' nucleus (MRN) can produce several forms of postural and locomotor abnormalities, including locomotor hyperactivity. Many such symptoms resemble those produced by lesions of the nucleus reticularis tegmenti pontis (NRTP; 1-3). This report describes a form of surface righting displayed by MRN-damaged rats that approximates the form of righting shown by NRTP-damaged rats. Because NRTP-damaged rats have been shown to be partially serotonergically controlled with respect to posture and locomotion, and because the MRN is a major serotonin-containing nucleus, (2-4), the results suggest a transmitter-mediated rather than a locus-mediated control for pronation from supination in rats with MRN or NRTP damage.

Twenty male Long-Evans hooded rats were given electrolytic lesions of the MRN (1 ma for 20 sec.). When locomotor hyperactivity developed (1-3 days postoperatively), they were tested for the ability to pronate from a supine position by being placed gently on a flat surface in the supine position. The form of pronation (e.g., ventro- or lateroflexion was videotaped). Ten undamaged rats and 4 sham-operated animals were tested in the same manner. Sham-operated and control animals righted to a prone position using a lateral rotation of the head and shoulder girdle. Rats with MRN lesions ventroflexed the upper torso (especially the head), and often did not complete the righting sequence. When pronation occurred in MRN-damaged rats, they rolled forward in the ventroflexed position rather than in the normal lateral rotation.

The ventroflexion displayed by MRN-damaged rats is displayed by NRTP-damaged rats. The results suggest that there is significant serotonergic mediation of the symptomatology displayed by the MRN and NRTP preparations.

95.14 TONIC VIBRATION REFLEXES ARE GRAVITOINERTIAL FORCE DEPENDENT. J. R. Lackner, P. DiZio, and J. Fisk. Ashton Graybiel Spatial Orientation Laboratory, Brandeis University, Waltham, MA 02254.

Tonic vibration reflexes (TVRs) can be elicited by mechanically vibrating the body of a muscle to activate the spindle receptors within it. The abnormally high level of spindle activity leads to reflex contraction of the vibrated muscle through activation of the alpha-motor neurons innervating it (Hagbarth & Eklund, 1966). If the action of a TVR is resisted by restraining the limb controlled by the vibrated muscle, illusory motion of the limb will be experienced in the direction that would be associated with lengthening of the vibrated muscle (Goodwin, McCloskey, & Matthews, 1972).

We have studied the influence of gravitoinertial force level variations on the illusory motion evoked by resisting TVRs. The experiment was conducted in a Boeing KC-135 aircraft that performed parabolic maneuvers to generate alternating periods of free fall, 0 G, and of high force, 1.8-2.0 G peak, each lasting approximately 20 s. Vibration of the restrained right arm (elbow angle=135°) began in 1 G and continued through 0 G or 1.8-2.0 G. Subjects (n=6) tracked with their left arm the apparent position of their right forearm during separate vibration (120 Hz) of the right biceps brachii and triceps brachii. An electrogoniometer on the left arm and a linear accelerometer permitted correlation of apparent limb position and force level.

The findings indicate that changes in apparent limb position associated with resisting TVRs are virtually eliminated in free fall and greatly increased in 1.8-2.0 G relative to straight-and-level flight, 1 G. The mean apparent displacements (in degrees) and ranges are presented below.

	0 G	1 G	1.8-2.0 G
Biceps Brachii Vibration (Apparent Extension)	2.9 (0-8.2)	16.6 (9.1-22.3)	36.1 (24.6-45.0)*
Triceps Brachii Vibration (Apparent Flexion)	1.3 (0-5.7)	7.4 (3.6-12.3)	11.7 (8.8-16.1)

* Two subjects reported hyperextension of the forearm beyond the physiologically possible limits; the maximum possible goniometer signal however was only 45°.

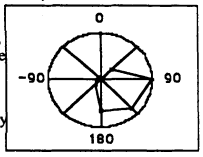
The G-force dependence is virtually immediate, being manifest generally within 1 s. These findings point to immediate vestibulo-spinal influences, and possibly proprio-spinal and somatosensory spinal, influences on postural tonus as a function of background gravitoinertial force levels.

Supported by NASA contract NAS 9-15147.

95.15 **DIRECTIONAL PREFERENCES OF HUMAN NECK MUSCLES DURING HEAD STABILIZATION.** E. A. Keshner, D. Campbell* and B. W. Peterson. Dept. of Physiology, Northwestern University Med. School and Sensorimotor Performance Program, Rehabilitation Institute of Chicago, Chicago IL 60611, USA. Supported by grants NS22490 and 1T32 NS07243.

The head-neck motor system is a highly complex musculoskeletal linkage composed of multiple joints, and more muscles than there are degrees of freedom of motion. Thus it is theoretically possible that a given movement could be produced by many different muscle patterns. However, animal studies have indicated that the CNS chooses a single muscle pattern for each movement. To see if this is also true in humans, w e measured the EMG response patterns of four muscles in the neck during isometric stabilization of the head. Surface electrodes were placed over the palpable areas for the right semispinalis capitis, splenius capitis, trapezius, and sternocleidomastoid muscles. Twelve seated subjects were given visual feedback of head position and instructed to hold the head still and upright at all times. A weight was lowered in 16 different directions within the frontal plane (including pitch and roll) from the top of a helmet worn on the head. Equal weights were also placed on either side of the helmet so that one pulled forward and the other pulled backward in order to produce rotational torques (yaw).

EMG responses of each muscle to the unidirectional forces suggested an orthogonal pattern of activation where the muscle was activated maximally in one specific direction and silenced in the orthogonal direction. A distinct pattern of activation was observed for each muscle, thereby supporting our supposition of having measured four different neck muscles. These preferred patterns of reciprocal activation to small unidirectional forces were consistent across the subjects and quantifiable. As seen in the figure, the right sternocleidomastoid muscle produced its greatest EMG activity when the subject stabilized against a leftward extensor force by pulling into rightward roll (90°) with some head flexion(135°). There was gradually diminished activity between the forces of pure head flexion (180°) and pure roll; no activation occurred in the extension (0°) and leftward roll directions. Subsequent recordings with bipolar needle electrodes confirmed that the results were representative of activity in individual muscles. When forces applied to the head were increased, the amplitude of the reciprocally activated response increased linearly in the preferred direction. Eventually, coactivation of the muscles appeared even in the null direction. Torsional forces increased the amplitude of response as much as threefold, producing cocontraction patterns with greater activation in one or the other direction of head turning. Our results show that each muscle has clearly defined spatial properties with consistent patterns of minimal and maximal activation for each muscle. The size of the response and its appearance in the null direction were altered when cocontraction rather than reciprocal activation occurred. Since the preferred directions do not align with the pulling directions described in anatomy texts, we suggest that the human neck muscles may be programmed like those in the cat where preferred activation and pulling directions differ (Peterson et al., Neurosci Abstr, 11: 83).



95.16 SPRING ACTIVATED HUMAN TILTING PLATFORM FOR THE STUDY OF BIPEDAL BALANCE CONTROL IN MAN. E.V. Lo Monaco*, C.W.L. Chan and D.G. Watt (SURG: G. Mandl). School of Physical and Occupational Therapy, McGill University, Montreal, Quebec, Canada, H3G 1Y5.

Evidence from human and animal studies indicates the presence of interactions between visual, vestibular and somatosensory afferent discharges in the control of posture and balance. However, the actual neural interactions and organizations of these sensory modalities in coordinated activation of lower limb muscles for the maintenance of normal human standing against external perturbation is yet to be fully understood. This in part arises from difficulties in discerning the specific contribution of a particular sensory modality during the regulation of bipedal balance. In normal human stance, the body behaves as a multi-link inverted pendulum with rotation at the ankle, knee, hip and neck. Experimental investigation of the direct action and interaction of vestibular and ankle somatosensory inputs in balance control therefore requires a technique, whereby the body can be modelled as a single link pendulum rotating only about the ankle joint. Accordingly, a tilting apparatus has been developed to produce vestibular stimulation alone, or in combination with ankle somatosensory stimulation, during rapid fore-aft tilts of the head and body about an axis colinear with the ankle joint.

The apparatus is composed of a tilting device attached to a structural base, and provides rotation in the antero-posterior plane. Mechanical rotation of the tilting device is achieved by a spring-activating system mounted at its base. Subjects are secured to the device's vertical support by a body and leg harness system with the head immobilized. Simultaneous application of dynamic vestibular and ankle somatosensory inputs are induced by rotating only the vertical back support, whereas vestibular input alone results from the concurrent rotation of both back support and standing surfaces. The maximum excursion of the back support is 15 degrees from the vertical midposition, with magnitudes of acceleration ranging from 0.1 to 0.5g as measured by a linear accelerometer mounted on a dental bite. During the testing session, electromyographic recordings will be obtained from the lower limb muscles bilaterally, with the subjects blindfolded and wearing earphones to minimize auditory stimulation.

This experimental technique will make possible the elucidation of neurophysiological mechanisms underlying the close functional relationship between vestibular and somatosensory reflexes in the regulation of standing balance. Such knowledge will provide a basis for further studies relevant to the understanding of equilibrium disorders.

95.17 **THE EFFECT OF FORCE ON THE PERCEPTION OF FINGER MOVEMENT.** L.A. Jones and I.W. Hunter. Faculty of Medicine, McGill University, Montreal, Canada H3G 1Y5

The perception of static limb position has recently been shown to be influenced by the forces generated as the limb moves from one location to another (Watson et al., 1984). Errors in the perceived position of a limb occur when subjects are required to generate a changing isometric force against a device moving the limb, the magnitude of these errors being proportional to the amplitude of the forces produced at the end of the imposed movement (Rymer & D'Almeida, 1980). Consistent with these findings, Roland and Ladegaard-Pedersen (1977) have demonstrated that the perceived amplitude of voluntary limb movements is affected by the external forces against which the limb has to move, but the precise relation between force and the perception of limb movement has not been determined.

The objective of the present experiment was to examine the influence of the force exerted during the course of a voluntary finger movement on the perception of movement amplitude. The hand was positioned in such a manner that the wrist was immobilized and the tip of the index finger rested on the end of a lever protruding from a galvanometer operating in a constant-force servo mode. Subjects were required to track a reference movement that was presented on a screen by flexing and extending the proximal interphalangeal joint of the index finger. Three different movement amplitudes were used ranging from 5 to 10 mm. Immediately after the finger returned to the rest position the subject was asked to reproduce the movement in the absence of visual feedback. The forces against which the reference and matching movements were made, varied from trial to trial and ranged from 0 to 4 N. Finger position was measured using a capacitive angular position transducer. The sequence of trials and the displacement of the finger were recorded on-line by a MicroVAX computer.

The results indicated that force had a small but consistent effect on the perceived amplitude of the reference movement. Although there was some inter-subject variability in the accuracy with which movements were reproduced when the forces in the two conditions were equal, when the force against which the matching movement was made was considerably greater (e.g. 3 N) than that of the reference trial there was a tendency to overestimate the amplitude of the reference movement. These findings indicate that the forces exerted during the course of voluntary limb movements can influence both the perceived amplitude of the movement and the perceived position of the limb. They also suggest that under some conditions sensory signals arising from muscles are unable to provide accurate information about the position of the limb.

95.18 ELECTROMYOGRAPHIC RESPONSES TO LOAD PERTURBATIONS IN A MULTI-JOINTED LIMB. J.F. Soechting and F. Lacquaniti, Laboratory of Neurophysiology, Univ. Minnesota, Minneapolis, MN 55455.

A force applied to the human forearm leads to angular motion at the elbow and shoulder. If the direction of force in the sagittal plane is varied, different combinations of angular motions can be induced (e.g. flexion at the elbow with flexion or extension at the shoulder) as can different combinations of changes in torque at the two joints (e.g. shoulder flexion with shoulder flexor or extensor torque). It thus becomes possible to ask the question: to which if any of the four variables (kinematic and dynamic) are the electromyographic responses to load perturbations related?

Force perturbations consisting of pseudo-random pulse trains were applied to the forearm and electromyographic responses of shoulder and elbow flexors and extensors were computed by cross-correlation with the input. It was found that the average response to a single pulse consisted of two components, an 'early' one 40-80 ms after pulse onset and a later one occurring with a latency of 80-120 ms. In any given muscle, the sign of these two components could differ and during these intervals, the sign of the response could also differ in the three main elbow and shoulder flexors examined. Thus, biceps activation could be accompanied by a depression in anterior deltoid or brachioradialis activity.

The amplitude of the 'early' components was found to be best correlated with the angular velocity of the limb resulting from the perturbation: for mono-articular muscles, the angular velocity at that particular joint and for bi-articular muscles, a combination of shoulder and elbow angular velocity. By contrast, the amplitude of the 'late' components was best related to changes in elbow and shoulder torque, with a weighting which could be predicted from results obtained under static conditions. Finally, a principal component analysis of the correlations among the activities in different muscles gave no evidence of a set of fixed synergies in the activation of shoulder and elbow flexors and extensors. The patterns of activity in each muscle resulting from a load perturbation depends in a unique manner on the kinematic and dynamic parameters describing the motion of the limb.

95.19 QUANTIFICATION OF PRECISION GRASP CAPABILITIES IN HUMANS. S.M. Drucker* and J.M. Hollerbach. Dept. of Brain and Cognitive Sciences, Massachussetts Institute of Technology, Cambridge, MA 02139.

Many attempts have been made to characterize human grasps. In particular it has been proposed that grasps can be classified primarily into two categories, precision grasps and power grasps. There exists, however, very little quantitative data on the exact capabilities of precision grasping in human hands. In robots hands, analyses have been performed to determine what capabilities are necessary to grasp and manipulate arbitrary objects. These studies have determined theoretically the grasp forces that ensure secure grasps, and mapped out primary and secondary work spaces for multifingered hands. In robotics, it is theorized that for fine motion control (which is necessary for interfacing grasped objects to the geometry of the environment), the robot must be able to impart arbitrary incremental displacements in six dimensions. This is equivalent to generating arbitrary force-torque vectors on an object.

Our hypothesis for this study is that during precision grasps humans can generate arbitrary force-torque vectors. To examine this, we use a 6-axis force-torque sensor in the shape of a sphere to collect data from subjects in a variety of manipulation tasks using three fingers. Initially the subject is directed to attempt to achieve certain target force-torque combinations. The subject receives constant feedback via computer graphics about what forces and torques are actually being applied to the sensor. The subject is then directed to manipulate the sphere in arbitrary directions in an attempt to characterize the natural workspace of human grasps. The forces and torques are recorded and analysed.

An attempt is made to compare the data collected to existing characterizations and theories on both human and robot hands.

Supported in part by an NSF Presidential Young Investigator Award.

95.20 THE EFFECTS OF VISUAL INFORMATION, OBJECT MOTION AND SIZE ON REACHING AND GRASPING KINEMATICS. C.L. MacKenzie & J. Van den Biggelaar*. Department of Kinesiology, University of Waterloo, Waterloo, Ontario, Canada, N2L 3G1.

The unified act of grasping requires processing information about the spatial location and specific features of the object such as shape, size, weight and texture. The motor system(s) must transport the limb to the appropriate location and control grip formation for effective prehension. Jeannerod (1981,1984) labelled these the transport and manipulative components, and suggested parallel visuomotor channels for their control. The purpose of this research was to evaluate visual information, object motion and target size on the transport trajectory and grip aperture.

Five right-handed adults were seated and instructed to grasp and lift small (3 cm) or large (6 cm) wooden disks 27 cm in front of the body midline. There were 3 grasping conditions: 1) "stationary central" - subjects looked at the target placed 27 cm in front of them; 2) "moving central" - subjects watched the target as it approached on a moving treadmill from left to right; 3) "moving peripheral" - subjects focussed on a point marked on the treadmill frame (body midline) and saw the target moving left to right in peripheral vision. Treadmill (target) speed was 53 cm/s. The WATSMART system produced 3 dimensional position coordinates for markers placed on the wrist, index and thumb (sampled at 200 Hz, filtered at 10 Hz). Differentiated wrist data indicated the transport component and the distance between thumb and index markers indicated grip aperture over the course of the movement.

For transport, results over both disk sizes indicated peak speed was fastest and most variable over 10 trials for moving peripheral, then moving central, then stationary central conditions. Aperture results showed larger and more variable maximum apertures in peripheral than in central vision conditions, regardless of whether the object was moving. Consistent with previous work, maximum apertures were larger for large than small disks. Thus the transport component was affected by whether the target was moving and type of vision, but not disk size. In contrast, the manipulative component was affected by type of vision and disk size, not whether the object was moving. Although instructed to grasp the disk between index and thumb, almost all subjects tried to use additional fingers in the moving peripheral condition.

95.21 **THE INFLUENCE OF MULTIDIMENSIONAL STIFFNESS AND VISCOSITY ON TRAJECTORY FORMATION AND CONTROL OF A MODEL HUMAN ARM.** S. A. Ellias* (SPON: W. Richards) Massachusetts General Hospital, and Massachusetts Institute of Technology, Cambridge MA 02139.

As a prelude to experiments on the influence of shoulder and elbow stiffness and viscosity on arm movement control and trajectory formation, numerical simulations were conducted on a model human arm executing planar point to point movements. The following experimentally relevant issues were addressed: Can the trajectories and velocity profiles of the end point [tip] of a two-link arm be used as discriminators of the orientation of tip stiffness and viscosity during an arm movement? (The stiffness orientation is defined as the direction of the greatest stiffness at the tip). For example, could stiffness and viscosity orientation vary in a way that would leave many trajectories unchanged in spite of large variations in the direction of maximal stiffness during a trajectory? Are there directions of trajectories which are more sensitive to these parameters?

Design issues for movement controllers with a moving "equilibrium point" and no inverse dynamics were studied: e.g., what are the advantages of feedback control laws which cause the tip stiffness to be isotropic, polar (directed from shoulder to the tip) or arbitrarily directed.

The planar nonlinear dynamical equations for a model two-link arm executing fast point to point movements were numerically integrated. The model was governed by a linear feedback controller with a straight line minimum-jerk reference trajectory in cartesian space. Two different control strategies were compared: constant stiffness and viscosity at the tip versus constant stiffness and viscosity at the joints.

These simulations suggest that if the tip orientations of stiffness and viscosity are kept constant during the trajectory, then the shape of the trajectory can be a very sensitive indicator of the stiffness orientation. This is true if the trajectories are oriented obliquely to the direction of maximal tip stiffness and if the tip viscosity orientation is not perpendicular or parallel to the stiffness orientation. However, a coordinated variation of tip stiffness and viscosity orientation may make the trajectory and velocity profiles insensitive to stiffness orientation. The straightest trajectories with constant tip stiffness and viscosity occur with isotropic values for both. Though, trajectories passing close to the shoulder may still be curved.

If the joint stiffness and viscosity orientation are kept constant (yielding variable tip parameters), then many trajectories are yet closer to the reference trajectory - even for trajectories passing close to the shoulder. Extremely straight trajectories have been obtained when the stiffness and viscosity orientations were polar. Thus, for point to point movements there are advantages to a control system or mechanical geometry which can create an almost constant relationship between the polar direction and the orientation of tip stiffness and viscosity: an arm with a linear feedback controller can create good straight line trajectories without computing detailed inverse dynamics.

96.1 COORDINATION OF THE HEAD AND BODY IN STANDING POSTURE IN NORMALS AND PATIENTS WITH BILATERALLY REDUCED VESTIBULAR FUNCTION. C. L. Shupert*, L. M. Nashner, F. B. Horak, and F. O. Black. Neurological Sciences Institute of Good Samaritan Hospital, Portland, OR 97209.

Control of body and head position during stance is achieved by combining sensory information from the somatosensory, visual, and and vestibular systems. Although these sensory systems all provide similar information about head and body motion, none of the three can, in isolation, completely specify the motion of the body's center of gravity. The task of correctly interpreting information from multiple sensory systems would be simplified, however, if the head's inertial sensors were kept at a constant angle with respect to gravity during body motion.

In order to determine whether a constant head angle with respect to gravity is maintained during postural adjustments, 5 normal subjects aged 30 to 56 were subjected to 3.6 cm backward translations of their support surface at 15 cm/sec with eyes open or closed. Subjects were tested both standing on a flat support surface, which typically elicits forward ankle sway, and standing crosswise on a 4-inch beam, which typically elicits forward hip sway. A group of 4 adults aged 49 to 69 with bilaterally reduced vestibular function (absent caloric responses bilaterally, and gains of less than .15 for .05 Hz and .2 for .2 Hz sinusoidal rotations) were also tested. Head, hip, and ankle angle were recorded during sway using a Watsmart system, and leg, trunk, and neck EMG were also recorded. Angular head velocity was recorded using a rate sensor attached to a snugly fitting helmet.

For translations on the flat surface (ankle sway), both normals and patients with bilaterally reduced vestibular function initiated postural responses before any measurable linear or angular changes in head position had occurred. During the active postural response to the induced forward sway, the head was rotationally displaced briefly, and was then restabilized. For ankle sway in normals and patients, neck EMG activity was minimal, but the small active neck response counteracted the inertial effect of upper body motion on the head. Finally, the rotational head stabilization of the patients was as complete, if not more complete, than that of the normals. However, none of the patients were able to use hip motions, which were required to maintain balance on the beam. For normals on the beam (hip sway), the earliest neck EMG appeared in the neck flexors with a latency of about 100 msec, and the subjects achieved good rotational head stabilization by coordinating the motions of the hip and neck. Finally, the results of both patients and normals were largely equivalent for eyes open and eyes closed. (Supported by grants NS-12261 to LMN and NS-19222 to FOB.)

96.2 MOVEMENT CONTROL IN THE ELDERLY. W.G. Darling and J.D. Cooke, Dept. of Physiology, Univ. of Western Ontario, London, Canada N6A 5C1.

In previous studies we have suggested that the relationship between velocity and position (phase plane trajectory) is controlled throughout simple limb movements. Recently it was shown that motor control processes of elderly subjects may differ from young adults in that they exhibit asymmetric movement profiles. In the present study we examined trajectory variability of movements made by young adults and elderly subjects to determine whether there is an effect of aging on movement-to-movement trajectory control.

Eight elderly subjects (aged 68-95 years) and six young adults (aged 21-24 years) performed elbow flexion and extension movements in a visual step tracking paradigm. Movement amplitudes ranging from 10° to 80° were performed under two instructions - "own speed" and "fast and accurate". In a second experiment 5 elderly subjects practiced 30° movements for a total of 180 flexion and 180 extension movements. Instructions were to make movements smoothly and accurately and to attempt to increase speed while maintaining accuracy during practice.

Trajectory variability increased with both movement amplitude and speed as expected from previous work. Trajectory variability was greater in the elderly subjects for both the acceleratory and deceleratory phases of the movements. With practice, the elderly subjects showed large decreases in trajectory variability with little change in movement speed.

Analysis of EMG patterns showed that although the first agonist burst appeared normal in elderly subjects, there was greater agonist-antagonist cocontraction. Control of the antagonist was abnormal. There were usually not clear antagonist bursts, or if present, their timing was inappropriate. With practice, there was little change in the overall EMG pattern, although a clear antagonist burst developed in a few subjects. Variability in agonist-antagonist EMGs was, however, clearly decreased with practice.

The results show that movement trajectories are less accurately controlled in elderly subjects. Substantial reductions in trajectory variability can, however, be attained during practice by elderly subjects. As indicated from the observed EMG patterns, motor control processes of the elderly are not the same as those used by young adults. In spite of these differences, the ability to improve performance with practice is clearly not lost in elderly subjects.
Supported by the Physician's Services Inc. of Ontario.

96.3 IMPAIRMENT OF MOTOR PROGRAMMING AND TRAJECTORY CONTROL IN A DEAFFERENTED PATIENT. J. Gordon, M. Iyer*, & C. Ghez. Ctr. for Neurobiol & Behav, Columbia Univ and NYS Psych Inst, New York, NY

Human subjects use a pulse height control policy to vary the amplitudes of targeted force impulses: the peaks of the time derivatives of force (dF/dt and d^2F/dt^2) are proportionally scaled to the target force while rise time is regulated around a preset value. Rapid force trajectories are controlled by alternating contractions in agonist and antagonist muscles. Peak force and the peaks of the derivatives of force are scaled to the magnitude of a first EMG burst in the agonist (AG1); termination of the rising force depends on a reciprocal burst in the antagonist (ANT-R) during the agonist silent period. Accurate control over peak force therefore requires the precise timing and scaling of commands to opposing muscles. In order to determine the role of somesthetic information in calibrating these feedforward commands, we have examined the control of isometric force trajectories in a 41 y.o. woman with a severe sensory neuropathy of unknown etiology involving the arms. Muscle strength is normal, and both muscle biopsy and clinical EMG studies show no evidence of motor involvement.

The patient was required to produce rapid uncorrected impulses of elbow flexor force to accurately match the amplitudes of target shifts of different sizes displayed on an oscilloscope along with visual feedback of her force. Her accuracy in this task was severely impaired: peak forces were highly variable and the range of peak forces constricted. Peak d^2F/dt^2 was poorly scaled to the target and was less predictive of peak force achieved ($r=.68$) than in normals (mean $r=.94$). Although mean force rise time was similar to that of normals and rise time was independent of peak force, its variability was twice as great in the patient. Thus, the patient's inaccuracy resulted from an inadequately programmed initial output and a lack of stereotypy of her trajectories. Although the patient used an alternating pattern of agonist (biceps) and antagonist (triceps) contractions, the EMG bursts were abnormal. AG1 magnitude was poorly related to trajectory variables. Whereas AG1 is normally truncated at the time of peak dF/dt by a silent period, in the patient it was twice as long in duration, lasting beyond peak force. Moreover, the agonist EMG never showed an initial pause or late bursts, as were always observed in the fastest force impulses of normal subjects. ANT-R was abnormally large and prolonged in duration. Its time of onset was highly variable and not, as in normals, precisely timed to the peak dF/dt.

Thus, the patient was able to produce isometric force trajectories at the elbow with a normal range of rise times, and she could program alternating contractions of opposing muscles. However, the accuracy of her control and the precision with which she could time muscle activation were severely impaired. These deficits have not improved with 6 sessions of practice. Our findings demonstrate the importance of somesthetic information for the calibration of motor programs that determine the size and timing of agonist and antagonist contractions. (Supported by NS22715)

96.4 REACTION TIME PROCESSING FOR NORMALS AND PARKINSONIANS (PKs) MAKING REACHING MOVEMENTS AVOIDING OBSTACLES IN VISUAL SPACE. M.C. Verrier* and W.G. Tatton. Departments of Rehabilitation Medicine and Physiology, University of Toronto, Toronto, Canada M5T 2S8.

Reaching movements to pseudo-randomly located parafoveal targets which avoid obstacles randomly-placed along the direct path to the targets show increases in mean reaction time (RT) of 48 msec compared to movements without obstacles when the targets and obstacles are simultaneously illuminated to cue the movements (Thompson et al., 1986). At least part of the increase can be attributed to the sensory processing and integration of the novel obstacle locations relative to those of the target and the kinesthetic information concerning initial limb and body position.

In the present studies subjects fixated on a yellow LED and 40 cm reaching movements were made from a microswitch to a suddenly-illuminated green (4 cm diameter) spherical target pseudo-randomly located within a $\pm$ 20 degrees visual angle. On random trials, one to four 4 cm diameter red spheres placed along the direct path to the target were illuminated with a target. The studies were carried out in a dark room so that target and obstacle position were not discernible prior to their illumination.

Limb trajectories were monitored, with LEDs on the shoulder, elbow, wrist, 5th metacarpalphalangeal, and 1st index finger, using a Selspot kinematic system. Studies were conducted in young PKs (<45 years $n=5$) and age-matched normal subjects. Although normal subjects showed increased RTs for the obstructed reaching as opposed to the unobstructed reaching, PKs showed similar mean increases in comparison to normals for both the obstructed and the unobstructed movements. Increased RTs were not related to number of obstacles in either PKs or normals. Vector velocities in PKs were decreased ($\bar{x}$ = 1.1 m/sec) compared to normals. In PKs vector velocities maintained a single maxima in both obstructed and unobstructed trials similar to normal subjects. However, analysis of individual X, Y, and Z velocity profiles demonstrated marked discontinuities in the Y (vertical) profiles. Position/velocity profiles describing the instantaneous vector velocity in extracorporeal space showed highly "stereotyped" movements. Therefore, the Y velocity discontinuities and the stereotyped nature of the the movements were the only features which distinguished the normal from the PK reaching movements.

These findings will be described in the context of a model proposing "defective" processing of sensory information relating the location of the target and obstacles to limb and body positions. The model suggests that PKs are not able to use previously acquired position information to "plan" either obstructed or unobstructed reaching movements.

96.5 ALTERATIONS IN MOTOR UNIT FIRING BEHAVIOR DURING ISOMETRIC CONTRACTIONS IN OLDER ADULTS. G. Kamen, D. Stashuk*, C.J. De Luca. NeuroMuscular Research Center, Boston University, Boston, MA 02215 USA.

We conducted an investigation to determine whether alterations in motor unit behavior accompany age-related changes in the neuromuscular system. Motor unit firing patterns were studied in the first dorsal interosseus (FDI) and the tibialis anterior (TA) muscles in aged (>65 yrs) individuals with no known neuromuscular disorders. Each individual performed a series of muscle contractions at 40-60% MVC, each contraction lasting approximately 20 secs. Motor unit activity was recorded by a specialized quadrifilar needle electrode and stored on FM tape. The signal was later digitized off-line at 50 khz. A previously-described decomposition algorithm was used to identify motor unit firing times, yielding 4-6 motor unit action potential trains during each contraction. A comparison with previously-published data using younger subjects revealed many similarities. For example, of the 70 motor units studied to date, there was a tendency toward higher peak firing rates in the FDI than in TA. Cross-correlational analysis of motor unit firing rates in both FDI and TA produced high correlations (.4 to .9) around a lag of 0 $\pm$10 ms, suggesting a common drive linkage between motor unit firing rates, as reported earlier. However, some highly unusual behavior was observed in both FDI and TA, particularly in high-threshold motor units. Some late-recruited units tended to continually increase in firing rate, even when force declined to very low levels. While peak firing rate is usually inversely related to recruitment threshold, there were some high-threshold units which fired steadily at high firing rates. While these results are still preliminary, they seem to support the idea that in order to produce contractions of moderate intensity requiring force feedback, older adults may use an alternative strategy to compensate for peripheral neuromuscular changes.

96.6 ABNORMAL ISOMETRIC ARM RESPONSES IN PARKINSON'S DISEASE. M.M. Wierzbicka*, A.W. Wiegner, E.L. Logigian*, R.R. Young. Clin. Neurophysiology Lab., Mass. General Hospital & Harvard Medical School, Boston, MA 02114

Force impulses produced during isometric quick flexion of the elbow were studied to gain insight into the pathophysiology of the abnormally slow movements (bradykinesia) characteristic of Parkinson's disease.

Four normal subjects and five Parkinsonian patients were seated with the shoulder abducted and elbow flexed at 90 degrees. The forearm was immobilized while a load cell measured force produced across the elbow. Each subject was asked to produce "brief, rapid force pulses" to match targets of 4, 8 and 12 kg presented on a CRT display. Surface electromyographic activity (EMG) was recorded from biceps and triceps. Twenty trials were acquired for each target. In addition, each subject's maximum voluntary contraction force was measured over a 2-second period.

All normal subjects were able to match all 3 targets by producing consistent, smooth force pulses with short rise times (65 $\pm$ 10 ms). In contrast, force records from patients (which showed large variability from subject to subject as well as within the same subject) ranged from nearly normal behavior to abnormally slow, staircase-like force patterns. Each force step within the staircase was produced with a brief rise time and corresponded to an EMG burst in the agonist (and usually a co-contraction burst in the antagonist). For a given target, the force increment per step varied among patients but was usually consistent for any one patient. Frequency of EMG bursting varied somewhat from trial to trial; most often bursts were separated by clear silent periods, but occasionally bursts merged and the resulting force was smoother. Average force rise times in all patients except one were substantially increased for all targets. This abnormally long rise time was approximately equal to the normal rise time multiplied by the number of force steps made. For one patient, rise times were within the normal range but his coefficient of variation was twice as large as normal. This patient's maximum voluntary force was only 15% less than normal (31 $\pm$ 1.8 kg) whereas other patients were only able to produce about half the normal maximum strength.

Slowness and segmentation of movements observed in patients with Parkinson's disease appear to be explained by their inability to produce smooth muscle contractions. It does not appear that the fast motor program has been replaced by the slow motor program (in which the antagonist is not activated and there is a longer agonist burst). Rather, there is failure to match the magnitude of the initial response to the required task.

96.7 THE EFFECTS OF BODY WEIGHT SUPPORT ON THE LOCOMOTOR PATTERN OF NORMAL AND SPASTIC PARAPARETIC SUBJECTS DURING TREADMILL WALKING. M. Visintin*, L. Finch*, N. Wainberg* and H. Barbeau. School of Physical and Occupational Therapy, McGill University, Montreal, P.Q., H3G 1Y5.

Neurological patients are unable to adequately bear weight through the affected lower extremities during ambulation resulting in gait abnormalities which often persist following conventional treatment strategies. An alternative approach might be to decrease body weight through the lower extremities by supporting the trunk while retraining gait. Animal studies have shown that the adult spinal cat could recover a near normal gait pattern following interactive locomotor training where the hindquarters were supported while walking on a treadmill (Rossignol S et al. In Development and Plasticity of the Mammalian Spinal Cord. Goldberger M et al (eds), III:323-346, 1986). During each training session the animals were given just the amount of weight they were able to support on the hindlimbs. Progressively the animals walked on the treadmill bearing their full weight. This training strategy has been proposed to retrain gait in neurological patients. Before validating this approach, the effects of decreasing body weight on the EMG, temporal distance and kinematic parameters of normal and neurological gait have to be determined.

In 7 normal subjects, 0, 30, 50 and 70% of body weight was mechanically supported by an overhead harness during treadmill walking. Maximum comfortable speed decreased with increasing body weight support (BWS) and % BWS trials were therefore compared to full weight bearing trials (0% BWS) at comparable speeds. Electromyographic (EMG) activity of Medial Hamstrings (MH), Vastus Lateralis (VL), Tibialis Anterior (TA) and Gastrocnemius (GA), footswitch and kinematic data were simultaneously collected. The results demonstrated significant decreases ($p<0.01$) in % stance, total double support time (TDST) and maximum hip and knee flexion angles with increasing BWS. At all BWS there was a significant decrease in mean burst amplitude for GA and an increase for TA. VL was unaffected by BWS and MH showed a significant decrease only at 70%.

In a preliminary study 6 spastic paraparetic subjects walked on a treadmill at 0, 20 and 40% BWS at a constant speed (mean=0.29 $m \cdot s^{-1}$). Data were collected as for the normal subjects with the addition of gluteus maximus (GM). A significant increase ($p<0.01$) in cycle duration was noted for all subjects from 0 to 40% BWS. A more symmetrical gait pattern was evident in 4/6 at 40% BWS as shown by a decrease in % stance difference between the two limbs ranging from 2.4% to 10.5%. 3/6 demonstrated an increase in single limb support time for the more involved lower extremity. TDST decreased in 2 of the 3 subjects who were able to walk independently on the treadmill. Qualitatively, 4/6 demonstrated a smoother locomotor pattern at 40% BWS. In 3 of these subjects this was manifested as an increase in knee flexion angle at toe-off (5° to 15°) and/or initial swing (5° to 10°). 5/6 demonstrated greater knee extension at initial foot-floor contact (5° to 12°) and/or at midstance (10° to 21°) during single limb support. An improvement in trunk alignment, with less forward flexion, was also noted. Analysis of EMG activity with increasing BWS revealed an overall trend of a decrease in peak amplitude for GA, MH, VL and GM while TA showed an increase in amplitude for peak activity. Some muscles with BWS produced an EMG profile with more appropriate phasing in relation to the gait cycle. 5/6 were able to walk at higher comfortable speeds with BWS with increases ranging from 0.06 to 0.1 $m \cdot s^{-1}$ at 20% BWS and 0.06 to 0.17 $m \cdot s^{-1}$ at 40% BWS.

It appears that in normal subjects BWS at levels below 70% modifies gait parameters without producing an abnormal gait pattern. However, decreasing body weight in spastic paraparetic subjects may elicit a more normal gait pattern as evidenced by the changes in EMG, kinematics and temporal distance parameters studied. The effects of BWS on the locomotor pattern is presently being investigated in subjects stratified according to the severity of spasticity. (Supported by Canadian MRC. H.B. is a FRSQ scholar.)

96.8 THE EFFECTS OF CLONIDINE ON CLINICAL SPASTICITY AND IN MODULATION OF THE LOCOMOTOR PATTERN IN CHRONIC SPASTIC SPINAL CORD PATIENTS. J.E. Stewart*, H. Barbeau, and S. Gauthier MD. School of P. & O.T., McGill University, Mtl, P.Q., H3G 1Y5 & M.G.H., 1650 Cedar Ave., Mtl, H3G 1A4.

Recent studies have shown that the noradrenergic agonist, clonidine, modulates locomotor function and reduces cutaneous excitability in chronic spinal cats (Rossignol et al. in: Development and Plasticity in the Mammalian Spinal Cord, Goldberger et al.(eds.), Spoleto, III:323-346, 1986). Based on these findings, a double-blind crossover study involving 6 spastic paraplegic and 3 paraparetic subjects, was developed to investigate the effects of clonidine (oral administration, dosage range: 0.15 - 5.0 mg/day) on spasticity and in modulation of the locomotor pattern of chronic spinal cord patients. Clinical measures of spasticity included the degree of evoked tonic stretch reflex (TSR) and foot/ankle clonus, as well as the use of a visual analog scale to record patients' perceived levels of spasticity. Locomotor function was evaluated as the subjects walked on a treadmill at 0.26 $m \cdot s^{-1}$ with bipolar surface electrodes recording the electromyographic activity of Vastus Lateralis (VL), Medial Hamstrings (MH), Tibialis Anterior (TA), Gastrocnemius (GA), and Gluteus Maximus (GM). Footswitches recorded the temporal parameters of gait. The subjects were supported in an overhead harness which allowed partial or complete support of body weight. The walking movements were passively manipulated in the paraplegics, and assisted in the paraparetics as necessary. Overground locomotion was also assessed in the paraparetics.

While on clonidine, TSR was diminished in 5/6 paraplegic subjects, whereas clonus was unchanged. Perceived levels of spasticity were reduced in 4/6 paraplegics. During treadmill locomotion, a reduction in the clonic discharge in GA during stance, or in the stretch reaction induced in MH during swing phase was observed in 4/6 paraplegics, with no evidence of drug induced locomotor pattern generation. Two examples are illustrated below: Ia) GA (placebo), Ib) GA (clonidine), IIa) MH (placebo), IIb) MH (clonidine). Arrows indicate the stance/swing transition. The decrease in spasticity was not reflected by an improvement in daily function except in 1/6 paraplegic. Moreover, 4/6 paraplegics experienced side-effects (eg. hypotension).

Among the paraparetic subjects (S.Q., S.H., M.H.), only S.H. demonstrated a reduction in TSR or clonus while on clonidine, however all reported a decrease in perceived levels of spasticity. S.H., initially non-ambulatory due to excessive spasticity, gained the ability to take 5-10 steps, while for S.Q. and M.H., already capable of overground locomotion, minimal changes in gait parameters were noted. During treadmill locomotion, all paraparetics demonstrated improved stance/swing ratios ($p<0.05$). Moreover, S.H. and S.Q. showed more appropriate phasing in the knee muscles (VL and MH). In addition, S.Q. and S.H. reported improvement in daily functioning while on clonidine, especially in locomotor abilities and transfers. All of the paraparetics experienced negative side-effects.

In conclusion, the effect of clonidine in the paraplegic patients was a decrease in stretch activation due to spasticity, without the generation of a locomotor pattern. In the paraparetics, clonidine had the effect of diminishing spasticity in addition to modulating the locomotor pattern. However, in light of the side effects, and the inconsistent functional benefits, further investigation is warranted into alternative methods of administration, or the combination of clonidine with substances acting on other descending systems. 96.9 A DYNAMIC EMG PROFILE INDEX TO QUANTIFY LOCOMOTOR SPASTICITY. J. Fung[1] and H. Barbeau (SPON:P.McKinley).School of Physical and Occupational Therapy, McGill University, Montreal, Quebec, H3G 1Y5.

Spasticity is a complex phenomenon characterized by hypertonia, hyperrefleria, clonus and impaired control of voluntary movement. Existing clinical and physiological measures of spasticity have mainly focused on the evaluation of clonus and reflexes. Subjected to the limitation of testing in a resting position, the results may not necessarily reflect the extent of functional impairment caused by spasticity. To evaluate spasticity in a dynamic,voluntary movement such as walking, a more objective and task-specific approach is essential. We therefore propose an index, 'I', as a functionally relevant measurement of spasticity in locomotion. Surface electromyography (EMG) in four lower limb muscles, simultaneous footswitches and video recordings were made from 5 normal male subjects and 5 spastic male patients of spinal origin during treadmill walking. The EMG signals were full-wave rectified, linear-enveloped and normalized to the gait cycle. The mean ensemble average amplitude ranges over 10 cycles were normalized to the peak activity for inter-subject comparison. The profiles were then divided equally into 2 'on' and 'off' domains defined from normal gait profiles (Winter D., The biomechanics and motor control of human gait, 1987). For the Vastus Lateralis (VL), the 'off' bin was chosen as 35% to 85% of the gait cycle; Medial Hamstring (MH), 30% to 80%; Tibialis Anterior (TA), 20% to 70% and Gastrocnemius (GA), 0% to 20% and 70% to 100%. Integral areas under the profiles were calculated for each bin (eg. a_1, a_2, a_3 in fig.D). 'I' was defined as the ratio of the area in the 'off' bin(s) to that in the 'on ' bin(s), i.e. $I=a_2/(a_1+a_3)$.

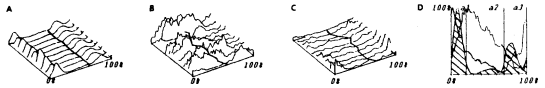

Fig.A depicts the ensemble average segments of a normal TA while the hatched area in fig.D illustrates the area under the mean profile of the same muscle. The 'I' of this muscle is 0.13. Fig.B shows a spastic TA with an 'I' value of 1.95 and fig.C, the same muscle after cyproheptadine administration, which drastically reduced the 'I' to 0.36. The superimposed profiles are shown in fig.D. The following table summarizes the 'I' range in each muscle in the normal and spastic group of subjects and the change of 'I' with two types of intervention, cyproheptadine and body weight support (BWS). Even with a small N (5) in each group, the data clearly demonstrate that the range of 'I' in spastic muscles falls completely outside that of the normal.

Group/Intervention	VL	MH	TA	GA
Normal (N=5)	0.10 - 0.21	0.10 - 0.16	0.10 - 0.21	0.07 - 0.13
Spastic (N=5)	0.48 - 1.24	0.35 - 2.99	0.52 - 1.95	0.17 - 0.89
Medication (pre→post)	1.02 → 0.57	2.99 → 0.79	1.95 → 0.36	0.86 → 0.70
BWS (0%→40%)	1.24 → 0.57	0.74 → 0.48	0.81 → 0.51	0.89 → 0.49

The marked decrease in 'I' observed in one subject after administration of an antispastic medication (cyproheptadine) corresponds to a decrease in spasticity and improvement in functional outcome. The effect of cyproheptadine on spastic paraparetic gait has been reported as a case study in the same subject (Wainberg M., Barbeau H. and Gauthier S., J. Neurol. 233: 311-314, 1986). 'I' is also sensitive to the change in muscle profile seen when a percentage of BWS is provided during walking, which is associated with a subjective and objective improvement in locomotion. We are now in the process of validating this index with respect to the severity of spasticity as well as the effect of different therapeutic interventions.

96.10 METHODS FOR ANALYSIS OF HUMAN MOVEMENT: DIGITIZED VIDEO IMAGES. BM Myklebust, JB Myklebust, JOB Greaves*. VA Medical Center and Medical College of Wisconsin, Milwaukee, WI and Motion Analysis Corp., Santa Rosa, CA.

Previous studies have identified myotatic reflex variations in children and adult subjects with cerebral palsy (Myklebust *et al.*, 1982), and some elderly subjects with spinal stenosis (Myklebust *et al.*, 1986); these subjects also have gait abnormalities by clinical examination. We are currently conducting objective studies in these subjects to determine if there are correlations between myotatic reflex abnormalities and the profiles of joint angles and velocity during gait. Kinematic analyses of human walking previously have been performed by hand-digiziting the movement of limb segments recorded on 16 mm film, videotape, or sheet film (using stroboscopic techniques). Alternatively, light-emitting diodes placed on the joints can be tracked under computer control.

We are currently using a computer-based system for digitizing limb movements recorded on videotape as the subject walks along a 15 ft walkway (Motion Analysis Corp., Santa Rosa, CA). A single camera is used to videotape (60 fields/s) trunk and limb motion in the sagittal plane (*i.e.*, flexion and extension movements in the plane of progression). Furthermore, using an overhead mirror system (Murray *et al.*, 1967), we can measure anterior-posterior and medial-lateral displacements of the head, shoulder, trunk, arm, and feet. To identify body landmarks for digital processing, 3-dimensional retro-reflective markers are secured to standard locations on the lateral aspect of the body.

The movement of the markers is digitized and analyzed to determine the paths of the targets as a function of time. From the path information, motion variables (*e.g.*, joint angles of the hip, knee, and ankle, and velocity profiles for each walking trial) are calculated and plotted with respect to time. External scaling is used to transform pixel (video) data to real-world dimensions. Stick figures are plotted to represent the movement of limb segments along the walkway. Gait patterns among subjects are compared using such study variables as walking speed, stride length, duration of the walking cycle, duration of the stance phase and swing phases, flexion-extension patterns of the hip, knee, and ankle, and the vertical trajectory of the heel and toe.

We will present data to compare myotatic reflex patterns and gait parameters in normal adult subjects, young normal children, children who walk on their toes, healthy elderly subjects, and adult patients with neurologic disease, including spinal cord injury, spondylotic myelopathy, and multiple sclerosis.

96.11 KINEMATIC PROPERTIES OF MOTOR SKILL ACQUISITION IN CHILDREN. T.J. Pincince* and K.L. Kerman*. (SPON: J.A. Anderson). Department of Brain and Cognitive Sciences, Massachusetts Institute of Technology, Cambridge MA 02139, and Pediatric Neurology Division, Massachusetts General Hospital, Boston MA 02114.

We examined the development of motor skill acquisition in children by studying the kinematic properties of visually guided planar arm movements. Right-handed boys and girls, ranging in age from 30 months to 14 years, were asked to execute a series of continuous arm movements from a start point to an end point through an intermediate via point. The start point and end point were located in front of the subject at the midline, and the via point was located 20 centimeters to the right, at the midpoint between the start and end points. Position and time information were collected during the movement and analyzed off-line to recover velocity, acceleration and higher derivitives. The children were instructed to make the movement as quickly and accurately as possible. Previous studies suggest that adults perform this type of movement using a strategy that minimizes jerk.

Our analysis indicate that children employed three age-dependent strategies. The first strategy (ages 2-6) was characterized by a multi-segmented path and a velocity profile with many small peaks. The second strategy (ages 6-10) was characterized by a bi- or tri-segmented path, composed of long straight movements. The velocity profile for this strategy was composed of two or three large peaks separated by zero-velocity troughs. The third strategy (starting at age 10) was equivalent to the minimum jerk strategy of adults. This strategy was characterized by a smooth, arced path and a velocity profile with two large peaks separated by a non-zero trough. Movement path lengths and total trajectory time shorten, while the mean and peak velocity increase with age.

The multi-segmented path strategy suggests that movement is closed loop, employing continuous visual and kinesthetic feedback. The bi- and tri-segmented path strategy is composed of two or three chained movements, with feedback used only at the end of these smaller movements. The minimum jerk strategy may be seen as a single, open loop movement.

All children improved their performance across repeated trials, using one of two learning methods. Children using the first learning method always made movements of a single strategy type, but improved within the strategy criteria. The second learning method was seen in children who initially made movements employing one strategy that, across repeated trials, developed into another strategy.

These data imply that as children get older they learn to more fully plan complete trajectories while optimizing a number of movement parameters. This improvement in movement planning may arise from the development of an increasingly accurate representation of body kinematics.

96.12 DEVELOPMENT OF INDEPENDENT SITTING IN INFANTS. C.A. Giuliani, R.T. Harbourne*, and J.C. Mac Neela*. Motion Analysis Lab., Dept. of Medical Allied Health, Sch. of Med., University of North Carolina, Chapel Hill, NC 27514 USA.

The development of postural control for independent sitting is poorly understood. The purpose of this study was to describe kinematic and EMG variables during the development of independent sitting in normal infants. Ten normal children were tested at three stages of sitting development. Children were tested at Stage I (2-3 mo. old and unable to sit), at Stage II (sits propped forward on extended arms), and again at Stage III (sits without support 30 sec. or more).

Infants were supported at the trunk in an erect sitting position. As the examiner released support, muscle activity and trunk movement responses were recorded by surface EMG and on videotape, respectively. Angular displacement and velocity of trunk movement were measured from an erect sitting position to the position of maximum trunk displacement. EMG from the upper paraspinals, lower paraspinals, gluteus maximus, hamstrings, abdominals, and quadriceps were recorded on FM tape along with an event marker to synchronize EMG and video events.

Significant differences were seen between Stages I and II in velocity of trunk movement and trunk displacement ($p < .05$). Muscle activation was inconsistent in Stage I, but by Stage II the infants showed a significantly greater percentage of organized muscle responses, and by Stage III a clear paraspinal-hamstring muscle pattern emerged ($p < .05$). The gluteus maximus and abdominal muscles did not participate during postural response.

Our data suggest that the paraspinal-hamstring muscle synergy may be necessary for the development of independent sitting posture. The increasing occurance of this synergy related to the child's ability to sit suggests that strategies of postural control emerge during the development of independent sitting. Identifying characteristics of postural control in the normal development of sitting may increase our understanding of control problems in infants with delayed motor development.

Supported in part by USPHS-MCH grant #149.

96.13 IMPAIRMENT OF BIMANUAL CO-ORDINATION IN PATIENTS WITH UNILATERAL SMA LESIONS. F. Viallet*, J. Massion**, R. Massarino** and R. Khalil*. *Service de Neurologie CHU La Timone, 13005 MARSEILLE and **LNF, CNRS, 13402 MARSEILLE CEDEX 9, FRANCE.

Unilateral lesions of supplementary motor area (SMA) result in an impairment in bimanual co-ordination. According to BRINKMAN (Brinkman, C., J. Neurosci., 4: 918, 1984), the effect of lesion in the monkey depends on the role played in the task by the contralateral hand: when it is acting as the "postural" hand, the co-ordination is impaired; whereas, when it is the "active" hand, the co-ordination remains rather preserved but compensatory strategies are observed.

A model of bimanual co-ordination has been tested in humans (Hugon, M. et al., Pflüg. Arch., 393: 292, 1982). In this task, one postural forearm, held in a horizontal position while supporting a 1 kg weight, was unloaded either by the experimenter's hand (imposed unloading) or by the subject's other hand in response to a tone burst (voluntary unloading). The variables recorded were reaction time, movement time, force changes and elbow angle. The EMG activity from the elbow flexors and extensors were recorded. The two arms were tested alternately as to which arm was "postural" and "active". In normal subjects, the voluntary unloading performed by the "active" arm was accompanied by a phasic decrease in EMG activity of the flexors of the "postural" arm. This anticipatory postural adjustment minimized the amplitude of the elbow rotation of the unloaded arm.

This bimanual task was tested in five patients with unilateral lesions including the SMA as confirmed by CT scan and/or NMR imaging. The results showed, that in all but one case, the co-ordination was impaired when the "postural" arm was contralateral to the SMA lesion. This disorder consisted in an increased elbow rotation of postural arm after voluntary unloading. By contrast, the co-ordination remained unimpaired when the "postural" arm was ipsilateral to the SMA lesion. In the same way, in two patients with spastic hemiparesis, no co-ordination was observed when the "postural" arm was the spastic arm. A specific role of the corpus callosum in this co-ordination could be excluded since a split-brain patient showed a normal co-ordination on both sides. It is suggested that in a bimanual task where one arm is active and the other is postural, the SMA contralateral to the "postural" arm, together with other parts of the motor-premotor areas, play a specific role in the control of the co-ordination between the two arms.

96.14 CHARACTERISTICS OF POSTURAL CONTROL ACCOMPANYING VOLUNTARY MOVEMENT IN THE ELDERLY. J.S. Frank, A.E. Patla and J.E. Brown*, Dept. of Kinesiology, University of Waterloo, Waterloo, Ontario, Canada, N2L 3G1.

Performance on standard balance tests, e.g., the Rhomberg test, have demonstrated that balance control declines with adult aging (cf. Fernie et al., Age and Aging, 11:11, 1982). However, few investigations have examined age-related changes in postural control when attempting to stabilize the body during a perturbation. Perturbations can arise from external forces, as well as, voluntary movements of the limbs and trunk. The purpose of this investigation was to examine the organization of postural control during movements of the right arm in young (n=9, $\bar{x}$ age = 22 years) and older (n=9, $\bar{x}$ age = 75 years) adults. The tasks performed included rapid arm flexion, pulling on a stiff lever and pushing on a stiff lever. Surface emg was recorded from 6 muscles: tibialis anterior (TA), lateral gastrocnemius (LG), rectus femoris (RF), biceps femoris (BF), anterior deltoid (AD) and posterior deltoid (PD). For each task, 10 trials were ensemble averaged prior to response analysis. The organization of the postural response was examined with respect to a) which of the 4 postural muscles was activated first and b) the onset time of that muscle with respect to activation of the focal (arm) muscle, i.e., the postural-focal latency (P-F latency).

Young subjects demonstrated a consistant pattern of postural control in all 3 tasks. Postural muscles were always activated prior to focal muscles. The first postural muscle activated and its P-F latency was: BF, 40 $\pm$ 20 ms for the arm raise task (8 subjects), LG + BF, 69 $\pm$ 38 ms for the pull task (6 subjects), and TA + RF, 54 $\pm$ 60 ms for the push task (7 subjects). In contrast to young adults, the organization of postural control was more variable for older adults. A small number of subjects displayed a postural control pattern similar to young adults; however the P-F latency increased. The results were: 6 subjects, 69 $\pm$ 43 ms for the arm raise task, 3 subjects, 110 $\pm$ 71 ms for the pull task, and 155 $\pm$ 95 ms for the push task (3 Ss).Remaining subjects displayed a change in the ordering of postural muscle activation, tonic co-contraction of postural muscles and/or activation of postural muscles following focal muscle activation.

In addition to the above findings older adults displayed longer reaction time, later onset of centre of pressure shift and smaller centre of pressure displacements for the 3 tasks. These results demonstrate that postural muscle coordination changes with age and may contribute to poorer balance performance by older adults.

96.15 MOVEMENT RELATED PHASIC EMG ACTIVITY IN HUMANS: RELATIONS WITH MOVEMENT ACCELERATION-DECELERATION CHARACTERISTICS. S.H. Brown[1] and J.D. Cooke, Dept. of Physiology, Univ. Western Ontario, London, Ontario, Canada.

We have investigated the relation between the magnitudes and durations of the various components of the triphasic EMG pattern and the accelerations/decelerations of the resulting movements. Utilizing phase plane tracking, subjects performed movements in which the amplitude, duration, peak velocity, temporal profile and acceleration/deceleration characteristics were explicitly controlled.

Initial agonist burst (AG1) - AG1 duration increased linearly with acceleration duration. Above mean accelerations of 400-500 deg/sec2, AG1 magnitude increased linearly with mean acceleration. This linear range corresponded to acceleration/deceleration duration ratios of less than approximately 0.8 which is the value seen in normal subjects performing step tracking movements. Below accelerations of 400-500 deg/sec2, there was little change in AG1 magnitude with acceleration magnitude.

Antagonist burst (ANT1) - The time of onset of ANT1 was linearly related to the duration of the acceleratory phase. ANT1 duration was relatively constant across all conditions. ANT1 magnitude, however, increased linearly with mean decelerations above about 500 deg/sec2. Below this level of deceleration, little change occurred in ANT1 magnitude.

Second agonist burst (AG2) - AG2 duration increased with increasing duration of the deceleratory phase. AG2 magnitude increased with deceleration magnitude for decelerations greater than 400-500 deg/sec2.

The data shows that the components of the triphasic EMG pattern are linked to the acceleration/deceleration characteristics of the movement rather than to the classic kinematic variables as movement amplitude and duration. Previously determined relations between EMGs and movement kinematics are explainable on the basis of changes in accelerations and decelerations associated with varying amplitude and/or durations of movements having a constant temporal profile. The data thus suggests that the triphasic EMG pattern, rather than being 'hard wired' centrally, is a consequence of the choice of a particular movement profile, a choice which is presumably based on energetic considerations.

96.16 AN EMG STUDY OF SCRATCHING IN CHICKS. M.B. Smith*, N.S. Bradley, and A. Bekoff (SPON: D. Whitlock). Dept. EPO Biology, University of Colorado, Boulder, CO 80309.

Scratching, a rhythmic grooming behavior, has been studied in both normal and spinal transected frogs, cats, and turtles. Here, we describe the behavioral and EMG characteristics for scratching in chicks 1 to 7 days after hatching.

Selected leg muscles are surgically implanted with chronic EMG electrodes in White Leghorn chicks. Muscles studied include the right gastrocnemius lateralis (GL, ankle extensor), tibialis anterior (TA, ankle flexor), sartorius (SA, hip flexor-knee flexor), and femorotibialis (FT, knee extensor). Recordings are made 24 hrs following implantation. To verify electrode placement prior to and between tests for scratching, EMG activity is also recorded during runway walking. Final position of the electrodes is determined by dissection at termination of the experiment. Computer-assisted methods are used to quantify EMG characteristics for scratching and include: cycle period, based on the onset of consecutive bursts in the reference muscle (GL); phase relationships of non-reference muscles; and burst durations for each muscle.

Scratching is most readily elicited by placing tape on or near the right external ear. To initiate scratching, a chick first shifts its weight to the contralateral leg. Occasionally, chicks abduct and extend the contralateral wing, while some also lower the wing toward the ground. The ipsilateral leg flexes to position the foot near the ear. During scratching, the leg then alternately flexes and extends in attempts to remove the tape. Younger chicks occasionally lose their balance during the alternating limb motions, but this does not always terminate scratching.

Preliminary findings indicate scratching is characterized by reciprocal activation of leg flexors and extensors. Some aspects of muscle activation resemble those for chicks during walking; for example, FT exhibits two bursts, one co-active with TA, the other with GL (Bekoff, A., *et al., J. Neurosci.,* in press). However, phase relationships of non-reference muscles appear shifted from those seen in walking. Also, activation of ankle antagonists (GL and TA) is asymmetric; extensor bursts are shorter in duration than flexor bursts. This pattern is the reverse of that for walking in chicks, but is similar to that for scratching in decerebrate cats (Deliagina, T.G., *et al., Brain Res.*, 100:297, 1975). Because scratching is ballistic (≤10Hz) and repetitive in the chick, it may prove a useful behavior to study to further understanding of neural-mechanical interactions in motor control. Funded by NIH grant NS 20310.

96.17 KINEMATIC ANALYSIS OF WALKING, SWIMMING AND AIRSTEPPING IN CHICKS. R.M. Johnston* and A. Bekoff (SPON: J. Werner). Dept. EPO Biology, University of Colorado, Boulder, CO 80309.

The present study was undertaken to compare the range and phasing of joint motions involved in intralimb coordination during walking, swimming and airstepping. Walking was chosen because it is the most common locomotor behavior in chicks. Swimming and airstepping were selected because sensory information due to weight bearing does not occur in either behavior. However, the conditions under which the latter two behaviors occur are different. That is, in swimming the buoyant chick floats and the leg movements occur in water. In airstepping, the chick is suspended, the legs are pendent and the leg movements occur in the air.

Kinematic analysis of free walking on a runway was performed in 1- to 7-day old chicks using video recordings. This was compared to swimming in a clear plastic pool and airstepping while supported by a ring glued to the chick's back. Black dots were placed on the lateral aspect of the right leg to mark the hip, knee, ankle and foot. The dots were digitized, and hip, knee and ankle joint angles were calculated for each behavior using a computer program. A cycle was defined from peak ankle flexion to peak ankle flexion for all three behaviors.

The results confirm that certain kinematic characteristics distinguish each behavior. Walking has the longest average cycle period, while airstepping has the shortest. The range of joint angular excursions and maximum joint angles also differ among the three behaviors. On the other hand, some features that are shared by swimming and airstepping are not seen in walking. For example, the flexion and extension phases within a cycle are similar in duration in both swimming and airstepping. In contrast, during walking, extension is longer than flexion. This suggests that the relative lengthening of the extension phase seen during walking is related to sensory information due to weight bearing (Bekoff, A., *Soc. Neurosci. Abstr.*, 12:880, 1986).

Finally, we also identified some features of the leg movements that were shared among the three behaviors. For example, knee extension (or flexion) always preceded hip and ankle extension (or flexion). This similarity may result from constraints imposed by the underlying CPG circuitry, supporting the idea that these movement patterns share common circuitry elements. Alternatively, this similarity may result from mechanical constraints present in the hindlimb of the chick. Supported by NIH grant NS 20310.

96.18 COMPARISON OF WALKING AND AIRSTEPPING IN CHICKS: HINDLIMB NEUROMUSCULAR PATTERNS. T.N. Anderson and A. Bekoff. EPO Biology Dept., University of Colorado, Boulder, CO 80309.

The purpose of this study was to examine the effect of sensory feedback due to weight support on stepping in chicks. Previously, a comparison of walking, swimming, and embryonic motility in chicks suggested that the relationship of extensor and flexor burst duration to cycle period is regulated by sensory information related to weight support (Bekoff, A., *Soc. Neurosci Abstr.*, 12:880, 1986). Sensory feedback due to weight support is eliminated during swimming and embryonic motility. However, sensory feedback resulting from increased resistance due to the aqueous medium and turbulence caused by the movements may be added. Sensory feedback due to weight support is also eliminated during airstepping, but the medium through which the limbs move during the flexion phase is the same as in walking. Therefore, a comparison of the activation pattern of hindlimb muscles in the chick during airstepping versus walking will further examine the effects of sensory feedback due to weight support.

The neuromuscular activity patterns of walking and airstepping were quantified using electromyogram (EMG) recordings in 0- to 4-day old chicks. Chicks spontaneously walked on a runway and airstepped when suspended by a shielded cable attached to their backs. Bipolar hook electrodes were surgically implanted in extensor and flexor muscles at the hip, knee, and ankle. Parameters used to quantify the neuromuscular activation patterns were: cycle period of the reference muscle, gastrocnemius lateralis (GL), phase relationships for non-reference muscles, and burst durations for all muscles.

A comparison of walking and airstepping in cats with thoracic spinal transections demonstrated that extensor burst durations are shorter during airstepping than during treadmill walking while flexor burst durations remain unchanged (Giuliani, C.A. and J.L. Smith, *J. Neurosci.*, 5: 1276, 1985). The role of feedback due to weight support cannot be readily studied in intact cats, however, as they only airstep during the first two postnatal weeks. At this time in development, kittens do not have the postural stability to maintain a mature walking gait (Bradley, N.S. and J.L. Smith, submitted). In contrast, both airstepping and mature walking can be elicited in intact chicks immediately after hatching. Therefore, the chick may be a good model for studying the regulation of neuromuscular patterns by sensory information related to weight support in vertebrates. Supported by NIH grant NS 20310.

96.19 INVOLVEMENT OF RED NUCLEUS GABAERGIC SYSTEM IN MOTOR PERFORMANCE IN THE CAT.

A.Schmied*,R.Allaf*,M.Amalric,J.F.Dormont*.
CNRS-Lab.Neurobiologie et Neuropharmacologie du Développement.Bat 440.Université Paris-Sud, 91405 ORSAY (France).

Injections of a GABA agonist (muscimol) and an antagonist (bicuculline) were made in the area of Red Nucleus (RN), in 3 cats. Each cat was trained to press a pedal with the contralateral forelimb and to release it after a randomly delivered go-signal with Reaction Times (RTs) less than 400ms. Prior to RTs testing, pressure injections (0.5 or 1ul in 1.5 or 3min) were made with an injection needle placed in a cannula implanted above the RN.

Injection of saline in the RN had no effect on RTs. Injection of 25ng of muscimol dissolved in saline increased the RTs (up to 25%), with force changes occurring later and more slowly after the go-signal. There was no effect on the tonic force measured at the go-signal. Higher doses (up to 200ng) were required to produce comparable effects for injections slightly above the RN. When 200ng of muscimol was injected directly in the RN, RT performance was blocked for hours and the blockage was associated with a permanent contralateral head torsiflexion. Surprisingly, injection of 200 ng of bicuculline in the RN also produced an increase of RTs (up to 25%) with delayed and prolonged force changes and, again, no effect on the tonic force. Higher doses of bicuculline (300ng) produced a transient blockade of RT performance associated with anxiety signs but no abnormality of head posture.

In one cat, the rubrospinal output was monitored with an electrode implanted in the medulla. An evoked potential was recorded in response to the go-signal with a constant latency of 10 ms and an amplitude correlated with the RTs. The rubrospinal response was unchanged by injection of saline in the RN, but was markedly decreased by injections of muscimol or bicuculline which produced an increase in RTs.

The known inhibitory action of muscimol on rubral activity is consistent with the depressant effects of muscimol injections on RT performance and rubrospinal output. As for bicuculline, its depressant effects could possibly be explained by a depolarization-block resulting from the suppression of the GABAergic hyperpolarizing influence which normally interacts with the strong depolarizing cerebellar control over rubrospinal neurons. In conclusion, the disruption of RT performance and rubrospinal output observed after injections in the RN of both a GABA agonist and an antagonist in the RN suggests that the triggering of a motor response after a go-signal requires a well-balanced rubral GABAergic activity.

96.20 DIFFERENTIAL TRANSNEURONAL LABELING OF SPINAL INTERNEURONS WITH WGA-HRP DURING DIFFERENT FORELIMB TASKS IN THE CAT. E. Sybirska*, J. Martin, J. Brennan*, C. Ghez. Ctr Neurobiol. & Behav., Columbia Univ. and NYS Psych. Inst., New York, NY 10032

Behavioral and physiological studies in the cat suggest that corticospinal (CS) and rubrospinal (RS) commands for reaching are transmitted to forelimb motoneurons (MNs) through C3-C4 propriospinal neurons (PNs) (Alstermark et al.,1981). The purpose of the present study was to determine if these PNs also participate when the cat performs a forelimb tracking task in which the CS and RS systems play critical roles (Martin and Ghez,1986). This question was addressed by injecting a 5% solution of WGA-HRP into a nerve to a forelimb extensor muscle (lateral head of triceps), and determining the locations of neurons showing retrograde and activity-dependent transneuronal uptake (Harrison et al.,1984). Two groups of cats were examined. One group (tracking cats) performed the forelimb tracking task used in the prior study and made 400 forelimb extensor responses per day. A control group (walking cats) walked 1.5 km per day. In both groups, the dorsal columns were transected two weeks before injections to exclude anterograde labelling of PNs via ascending collaterals of afferents in the injected nerves. Four days (100 h) after WGA-HRP injection the cats were anesthetized and perfused with saline and 4% paraformaldehyde. The spinal cord was then removed, sectioned and processed with a modified TMB method (Gibson et al.,1984).

Approximately equal numbers of MNs showed intense retrograde labelling in both tracking and walking cats. However, marked differences in both the longitudinal and the laminar distribution of transneuronally labelled neurons were present between groups. Whereas in the walking cats only scattered neurons were labelled in the upper cervical segments, in the tracking cats numerous PNs were seen from C2 through C4 . These PNs were located both ipsi- and contralaterally. Ipsilateral PNs were seen both laterally and medially within lamina VI-VIII; contralateral PNs were found only in the medial portions of the these laminae.

In both groups of cats the density of labelled segmental interneurons (INs) was highest ipsilaterally, but some contralaterally labelled INs were also present. The laminar distribution of labelled INs differed in the two groups of animals. In the tracking cats ipsilateral INs were located within laminae VI and the dorsal part of lamina VII, whereas in the walking cats the labelled INs extended ventromedially through lamina VII into lamina VIII.

Our findings indicate that PNs projecting monosynaptically to triceps MNs are preferentially active during the performance of simple targeted limb movements and not during walking which also requires activation of the triceps motoneurons. The specific task conditions that are associated with activation of PNs remain to be determined. Retrograde transneuronal labelling with WGA-HRP is a very useful tool for functional identification of different populations of neurons during different motor activities in awake animals. Supported by NS 19205.

99 SYMPOSIUM. PROTO-ONCOGENES IN THE NERVOUS SYSTEM. M.R. Hanley, MRC Molecular Neurobiol. Unit (Chairperson); J. Feramisco*, Cold Spring Harbor Lab.; J. Brugge*, SUNY at Stony Brook; W.E. Wille, Univ. of Cologne; J. Morgan*, Roche Inst. Mol. Biol.; S.P. Hunt*, MRC Molecular Neurobiol. Unit.

Genetic probes derived from acutely-transforming viral oncogenes have demonstrated that homologous genes, "proto-oncogenes", are present in normal vertebrate genomes. To date, the roles of proto-oncogenes have been considered in relationship to normal and aberrant growth. Many proto-oncogenes are now recognised to be expressed in high levels in developing and mature brain, and to exhibit both acute and long-term changes in expression in response to external stimuli. Thus, proto-oncogenes may have a wider significance in neural cell function than in control of proliferation. This symposium will introduce three major classes of proto-oncogenes; GTP-binding proteins, tyrosine kinases, and nuclear proto-oncogenes, and discuss their neural expression and possible functions.

Dr Hanley will introduce the topics by a brief discussion of the identified oncogenes and their relationship to proto-oncogenes. Dr Feramisco and his colleagues have been studying the roles of the GTP-binding proteins, ras p21, in cellular proliferation and neuronal differentiation. Results from micro-injection of ras and its antisera, and single-cell functional studies will be discussed. Prof. Brugge will describe the cellular src gene product; a membrane associated tyrosine specific protein kinase that is expressed in high levels in neural tissue. The factors regulating the neuronal expression and kinase activity of the c-src gene product, and the possibility that c-src may play a regulatory role in neuronal cell function will be considered. Prof. Wille will present results on expression of the nuclear proto-oncogenes, c-myc and c-fos, in developing and mature brain; emphasising hippocampus and cerebellum. Data on in situ hybridization, sensitivity of c-fos to injury induction, specific c-fos stimulation in cerebellar neurones by taurine treatment, and the intracellular localization of the c-fos gene product will be discussed. Dr Morgan will review recent evidence for regulation of c-fos expression in cultured neurones and in vivo. These results will then be discussed within the framework of a larger model of transcriptional regulation in neurones. It will be proposed that activation of a family of immediate early genes, such as c-fos, by extracellular stimuli presents one phase of a previously unsuspected signal transduction cascade that may be involved in long-term neuronal responses. Dr Hunt will focus on observations that expression of immunoreactive c-fos protein can be induced in neurones of adult nervous system by a variety of stimuli, but that synaptic induction of c-fos expression has so far been found only within neurones of the spinal cord following sensory stimulation. The relationship between induced c-fos expression and neuronal plasticity will be considered.

100 **SYMPOSIUM. PEPTIDE-MONOAMINE INTERACTIONS: FROM MOLECULAR MECHANISMS TO BEHAVIOR.** T.Reisine, Univ. Pennsylvania (Chairperson); R.A.North, Inst. Adv. Biomed. Res.; P.Magistretti, Univ. Geneve; M-F.Chesselet, Med. Col. Pennsylvania; J.Crawley, Clin. Neurosci. Branch, NIMH.

Neurotransmitters have been shown to interact in the brain to regulate neuronal activity. The functional role of the interaction of neuropeptides with classical transmitters, such as monoamines, in the brain has been carried out at various levels of resolution, ranging from single cell to behavioral analysis. This symposium is a multidisciplinary approach to examine the recent advances in peptide-monoamine interactions in the brain. **Dr. North** will present recent electrophysiological findings on the interaction of the peptides, somatostatin and the opiates, with the monoamines, norepinephrine (NE), dopamine (DA) and serotonin. He will discuss the molecular mechanisms by which these transmitters regulate potassium conductance channels. **Dr. Reisine** will speak on the biochemical interaction of somatostatin and NE receptors in electrically excitable cells. This talk will emphasize the role of GTP binding proteins in coupling receptors to multiple effector systems such as adenylate cyclase and ionic conductance channels. **Dr. Magistretti** will speak of the interaction of VIP and NE in the cerebral cortex. He will discuss the convergence of neurons containing these substances in areas of the cortex and how these transmitters act in a synergistic fashion to regulate cell activity. Specifically, he will discuss the mechanism through which NE stimulates alphal-receptors to potentiate VIP-induced cAMP formation. **Dr. Chesselet** will speak about the interaction of DA neurons originating form the substantia nigra with striatal peptidergic interneurons and efferents. She will present evidence that the interaction of these neurons is topographically specific in the striatum. This will be shown by in situ hybridization studies revealing the effect of alterations of DA transmission on the levels of mRNA's coding for peptides in the striatum. Furthermore anatomical and pharmacological evidence supporting the existence of a dual control of DA neurons and peptide neurons in the substantia nigra and presynaptically, in the striatum will be discussed. **Dr. Crawley** will speak of the behavioral implications of the coexistence of CCK and DA in the mesolimbic pathway of rodents and primates. She will present studies in which microinjection of CCK into the nucleus accumbens, but not into the striatum, potentiates DA-induced hyperlocomotion in the rat. The ability of selective antagonists of the CCK receptor to block this facilitatory behavioral action on the DA system will be discussed in terms of the potential development of novel antipsychotic treatments.

VISUAL CORTEX II

101.1 SOME NEURONS IN THE ADULT CAT WHITE MATTER ARE SUBPLATE NEURONS. J.J.M. Chun and C.J. Shatz. Dept. of Neurobiology, Stanford University School of Medicine, Stanford, CA 94305.

Subplate cells are the first postmitotic neurons of the neocortex, in the cat born on embryonic days 24-30 (gestation is 65 days) based on ^{3}H-thymidine studies. These cells are present in high density within the subplate during development, but then decrease in density during the first 2 postnatal months. During fetal and postnatal life, all ^{3}H-thymidine labeled subplate neurons are immunoreactive for the neuron-specific protein microtubule associated protein 2 (MAP2), as well as for GABA and the neuropeptides NPY, somatostatin and CCK. These immunophenotypes suggest that adult white matter cells observed in previous peptide immunohistochemical and Golgi studies may be the adult counterpart of the subplate neuron population.

To address this possibility, ^{3}H-thymidine was injected into three littermates at E27 to label those subplate neurons born on this day. Brains were then studied at postnatal day 49, 178 or 401 by using immunohistochemistry with the antisera mentioned above combined with autoradiography to identify the birthdated subplate neurons. At each age, all ^{3}H-thymidine labeled cells were MAP2 immunoreactive. These double-labeled cells were located in the subjacent white matter of all cortical areas examined. Some cells were also located at the base of cortical layer 6. No double-labeled (or ^{3}H-thymidine labeled) cells were seen in layer 1. The morphology of double-labeled cells varied from simple fusiform to more elaborate, multi-processed types. MAP2 immunostaining also revealed processes within white matter beneath gyri, some of which were probably dendrites belonging to the subplate neurons.

Somatostatin and GABA immunoreactive cells were also ^{3}H-thymidine labeled at each age. GABA double-labeled cells were the most common, occurring throughout the white matter and lowest extent of layer 6. Somatostatin double-labeled neurons were less frequently observed and tended to be located deep within or immediately subjacent to layer 6. No NPY or CCK double-labeled cells were found at any of the three ages studied, probably due to problems associated with sampling from these sparse populations.

These results confirm the suggestion that at least some of the adult white matter neurons are subplate neurons that persist into adulthood and show somatostatin or GABA immunoreactivity. At least some of the white matter neurons immunoreactive for NPY and CCK are also likely to be subplate neurons. These results further suggest that these earliest, peptide-immunoreactive neurons of the neocortex can exert their influence during development and into adulthood. We thank Drs. Evans, Luca, and Vallee for antibodies. Supported by NIH grants EY02858 to CJS and GM07365 to JJMC.

101.2 **INFUSION OF AN NMDA-RECEPTOR ANTAGONIST BLOCKS VISUALLY DRIVEN CORTICAL ACTIVITY IN CAT VISUAL CORTEX.** K.D. Miller, B. Chapman* and M.P. Stryker. Dept. of Neuroscience, Stanford University, Stanford, CA 94305, and Depts. of Neuroscience and Physiology, Univ. of California, San Francisco CA 94143.

Several lines of evidence from other laboratories suggest that the N-Methyl-D-Aspartate (NMDA) receptor (a subtype of glutamate receptor) may be involved in activity-dependent synaptic plasticity. Biophysical studies indicate that the receptor opens a conductance that passes Ca^{++} only in response to conjoint presynaptic activity and local post-synaptic depolarization. This suggests a possible molecular mechanism for a "Hebb"-type synapse in which conjoint pre- and post-synaptic activation (or depolarization) provides a signal resulting in potentiation of synaptic strength. In addition, studies in hippocampal slices have shown that NMDA receptor blockers will block some forms of long-term potentiation without apparent effect on the post-synaptic responses to single-pulse electrical activation of afferents.

To study the possible role of NMDA receptors in plasticity of visual cortex, we first chose to examine the effect of NMDA receptor blockers on normal visual activity. Cannulae (33 gauge; 200 μm diameter) were implanted in visual cortex of either adult cats or four-week old kittens. The cannulae were attached to minipumps containing 50 mM D,L-APV, pumping at a rate of 1 $\mu l/hr$. Multi-barrel glass electrodes were glued to tungsten recording electrodes. With this arrangement, we were able to assess the visually-driven activity, the threshold to NMDA iontophoresis, and the threshold to KA (kainic acid) iontophoresis at each recording site. Using the normal, untreated hemisphere as a control, we were able to ascertain in each animal whether the APV treatment had successfully and specifically blocked NMDA receptors without raising threshold to KA stimulation.

In animals studied 1-2 days after cannula implant, we have found that, in regions of cortex extending 2 mm and in some cases as far as 4 mm anterior to the cannula, such a specific block is achieved, and cortical activity is profoundly and often completely blocked. Partial blockades were evident in some cases at 5-6 mm. The activity block appeared to be lifted somewhat in animals studied after several days of APV exposure.

This result helps suggest an alternative interpretation of the role of NMDA receptors in cerebral cortex. Previous studies in other laboratories have shown that NMDA receptor activation results in a slow epsp; that APV, by blocking this slow epsp, can attenuate responses to high-frequency electrical stimulation in hippocampal slices; and that APV blocks responses to physiological, but not electrical, stimulation of afferents in rat ventrobasal thalamus. Together with our results, this suggests that a slow epsp mediated by NMDA receptors may be necessary for post-synaptic activation by the relatively weak, high-frequency, fast epsps associated with physiological afferent activity. Thus, NMDA receptors may play a role in regulating the temporal patterns of afferent activity that can successfully activate cortical cells. This hypothesis, if true, would not negate the hypothesis that passage of Ca^{++} through NMDA receptor-coupled channels provides a signal for plasticity; however, separating a specific plasticity signal from a more general effect on activity may present a difficult technical challenge.

Supported by grants from the NIH and System Development Foundation and by a fellowship from the NSF.

101.3 RESTORATION OF BINOCULAR VISION RETURNS GABA IMMUNOSTAINING TO NORMAL IN AREA 17 OF MONOCULARLY DEPRIVED ADULT MONKEYS. E.G. Jones and S.H.C. Hendry. Department of Anatomy and Neurobiology, University of California, Irvine, CA 92717.

Monocular deprivation or enucleation in adult macaques reduces the density of GABA immunostained neurons in area 17. The reduction is most prominent in layer IVC of columns dominated by the deprived eye (Hendry and Jones, 1986; Nature 320:750). In this study, monocular deprivation was produced in young adult monkeys (Macaca fascicularis) either by suturing the lids of one eye closed for 4 months (one monkey) or by injecting the sodium channel blocker, tetrodotoxin (TTX) into one eye for 2 or 3 weeks (two monkeys). The monkeys were then anesthetized and a biopsy, approximately 1 cm^2 wide and 3 mm thick was surgically removed from the occipital operculum and fixed by immersion in 2% paraformaldehyde and 0.2% glutaraldehyde. The visual deprivation was terminated by re-opening the eyelids or by halting the TTX injections, after which the monkeys were allowed to survive for 4-6 weeks. They were then sacrificed by barbiturate overdose and transcardial perfusion with the same fixative as above. Sections through area 17 from the biopsies and from the brains later fixed in situ were stained histochemically for cytochrome oxidase (CO) and immunocytochemically for GABA. In the biopsies, CO staining reveals alternating light and dark bands in layers IVA and IVC corresponding to columns dominated by deprived and non-deprived eyes respectively. The difference in CO staining between columns is greater in the TTX-injected monkeys. GABA immunostaining in layer IVC follows precisely the pattern of CO staining, with deprived-eye columns containing a low density of immunostained somata and processes and non-deprived-eye columns containing a normal, high density of immunostained somata and processes. In all three monkeys, there was a return to normal CO staining and GABA immunostaining after restoration of binocular vision. The CO staining in layer IVC is uniform and a high density of GABA immunostained elements is found uniformly throughout this layer. Preliminary quantitative analyses indicate that the density of immunostained somata after restoration is normal. These results indicate that the effects of monocular deprivation on GABA immunostaining in area 17 of adult monkeys can be reversed by restoration of binocular vision. The data suggest that the levels of GABA within cortical neurons are dependent upon activity: deprivation reduces the GABA concentration to a level where it is not detectable by immunoctyochemistry, but a return to binocular vision quickly increases the GABA concentration and GABA immunostaining to normal levels.

101.4 ACTIVITY DEPENDENT REGULATION OF TACHYKININ-LIKE IMMUNOREACTIVITY IN VISUAL CORTICAL NEURONS: INCREASED AND DECREASED IMMUNOSTAINING IN THE CYTOCHROME OXIDASE PATCHES OF MONOCULARLY APHAKIC MONKEYS. S.H.C. Hendry, E.G. Jones and N. Burstein*. Departments of Anatomy and Neurobiology and Ophthalmology, University of California, Irvine, CA 92717.

Monocular deprivation or enucleation reduces GABA and glutamic acid decarboxylase (GAD) immunostaining in neurons of adult monkey area 17 (Hendry and Jones, 1986; Nature 320:750). Many of the GABA neurons also display immunostaining for tachykinin-like substances (Jones and Hendry, 1985; Soc. Neurosci. Abstr. 11:83) and this staining is reduced by manipulations that either reduce the levels of light entering the eye or eliminate retinal activity (Hendry and Jones; Soc. Neurosci. Abstr. 11:16). In the present study, removal of the crystalline lens was used to impair pattern vision in one eye without reducing the level of light falling upon the retina. Three weeks, 3 months or 6 months following the surgical removal of one lens, monkeys (Macaca fascicularis) were sacrificed and blocks of area 17 were prepared for histochemical localization of cytochrome oxidase (CO) and immunocytochemical localization of tachykinins with a monoclonal antibody that recognizes substance P and other members of this neuropeptide family. Monocular aphakia produces little effect on CO staining of layer IVC but the rows of CO patches in layers II-III, IVB and V-VI exhibit marked changes, with rows at the centers of both the deprived and non-deprived eye columns being affected. In every other row, dominated by the aphakic eye, the patches shrink and become paler; in the alternating rows, dominated by the normal eye, the patches are no longer discrete, but widen and fuse to form expanded and continuous rows. These findings suggest that in non-deprived eye columns, neuronal activity is elevated within the regions that normally lie between CO patches. Tachykinin immunostaining is normally densest within the CO patches and equal staining is seen in each row of patches. However, in aphakic monkeys the immunostaining in the two sets of rows is uneven and follows precisely the pattern of CO staining. In rows of patches dominated by the aphakic eye, tachykinin immunostained somata and processes are restricted to the shrunken CO-stained patches, while in rows of patches dominated by the normal eye, high densities of immunostained somata and processes are present along the full length and width of the expanded patches. Quantitative analyses indicate the density of tachykinin somata is reduced by 60% in the deprived-eye rows and increased by 30% in the expanded rows; the density of the total (thionin-stained) population of neurons is not affected in either row. These results suggest that tachykinin-like immunoreactivity within single cortical neurons can be up- and down-regulated by activity.

101.5 DISTRIBUTION OF MAJOR NEUROTRANSMITTER RECEPTORS IN THE VISUAL CORTEX OF MONKEYS DEVOID OF RETINAL INPUT FROM EARLY EMBRYONIC STAGES. P. Rakic, M. Kritzer and D. Gallager, Section of Neuroanatomy, Yale Univ. School of Medicine, New Haven, CT 06510.

Recently, we demonstrated that ten major neurotransmitter receptors in areas 17 and 18 of adult rhesus monkeys display laminar and regional binding properties that in some instances correlate with the pattern of cellular layers and synaptic input-output relationships in these areas (Rakic et al., '87, J. Neurosci.; Kritzer et al., '87, J. Comp. Neurol.). In the present study, we examined the binding distributions of these same receptors in the visual cortex of animals that were binocularly enucleated at embryonic (E) days E63 and E81, prior to the ingrowth of geniculocortical fibers to the developing cortical plate (Rakic, '76, Nature, 261:467), delivered at term (E165) and sacrificed at 2 months. In vitro receptor autoradiography was performed using ligands selective for alpha-1, alpha-2 and beta adrenergic, serotonergic ($5HT_1$ and $5HT_2$), cholinergic, dopaminergic (D-2), GABAergic (GABA-A; muscimol and benzodiazepine) and cholecystokinin (CCK) binding sites. Nonspecific binding was assessed in the presence of appropriate unlabeled agonists or antagonists, and autoradiograms were examined using computer-assisted densitometry.

In both enucleates and age-matched controls each ligand demonstrated a unique laminar pattern, which changed abruptly at the border between areas 17 and 18. Consistent with cytoarchitectonic findings (Rakic and Williams, '86, Abst. Soc. Neurosci.), the pattern of labeling characteristic for area 17 occupied significantly less surface area in enucleates than in age-matched controls. Laminar specificity of ligand binding in area 17 was basically similar to that observed in controls. Although some blurring of stratified binding was observed among sublaminae of layer IV in autoradiograms generated with ligands selective for CCKergic, serotonergic, and alpha-1 adrenergic receptors, preservation of the basic laminar pattern was found in remaining cortical layers of area 17 and all layers of area 18. Thus, while a certain level of fine tuning for some receptor types in thalamorecipient layers may depend on normal or functionally active thalamic input, regional differences and characteristic laminar distribution of receptors in areas 17/18 develop in basically a normal fashion despite the absence of information from the periphery. These results are in harmony with our findings of normal cortical thickness, patterns of cellular laminae (Rakic and Williams, '86, Abst. Soc. Neurosci.), and normal synaptic density in early enucleated animals (Bourgeois and Rakic, '87, Abst. Soc. Neurosci.). Supported by NS22807 and EY02593.

101.6 DEVELOPMENTAL STUDIES OF SUBSTANCE P AND NEUROPEPTIDE Y NEURONS IN MONKEY VISUAL CORTEX. R. Mehra* and A. Hendrickson. Depts. Ophthalmology and Biological Structure, Univ. Washington, Seattle WA 98195

The localization pattern of two neural peptides, substance P (SP) and neuropeptide Y (NPY) was followed during development of Macaca monkey striate cortex, using light and EM immunocytochemistry. Ages studied ranged from 90 fetal days (F90) through the first 12 postnatal (PN) wks and the adult. Both neural antigens were localized to perikaryal cytoplasm, dendrites, and axonal processes including synaptic terminals. Although both peptides were present at all ages, considerable differences existed between neurons in different laminae as to the time of appearance of the antigens.

SP+ cell bodies were found deep to the cortical plate at F90; these were vertically-oriented, immature-appearing neurons, probably in the process of migration to superficial cortical layers. From late gestation to early PN ages, SP+ cells were found in II/III and V. At the border between layers V and VI, a well defined SP+ fiber plexus containing SP+ cell bodies was seen up to the first PN wk. SP+ axons of many of these cells could be traced to superficial, cortical layers, while dendrites arborized mostly in the neighborhood of the perikaryon. This layer V plexus became progressively less intensely stained after birth, until it was nonreactive by 12 PN wks. In contrast, SP+ cells in the white matter are not stained until after birth; these increase in intensity up to 12 PN wks and remain in the adult brain. Double-labeling experiments indicate many SP+ neurons in II/III, V, and white matter also contain GABA in PN cortex.

NPY+ neurons are located in layer I and deep to the cortical plate at F90. Layer I cells lose their immunoreactivity by 1 PN wk. NPY+ neurons appear in II/III by F113, and continue in this position to adult. Typical horizontal NPY+ neurons in the white matter appear in late gestation. By 1 PN wk, NPY+ axons from layer II/III cells descend to deeper cortical layers, giving collaterals at different sites, while axons of NPY+ white matter horizontal cells send their axons to superficial cortical layers. Double-label experiments show that both NPY+ populations contain some cells which also stain for SP+ in the adult. Hendry et al ('84) has previously shown that most NPY+ neurons also are GABAergic.

The functional significance of transitory or delayed peptide expression is not understood. Experiments are underway to determine whether these transient populations die, or remain but stop synthesizing peptides. Possibly these peptides have a trophic or modulatory influence on surrounding neurons during development; in particular the early appearance of both peptides long before significant numbers of synapses occur suggests such a role. EM studies are underway to determine the pattern of connections formed by SP+ and NPY+ neurons during cortical development.

(Supported by EY01208, EY04536 and EY01730)

101.7 NEUROPEPTIDE Y-CONTAINING NEURONS ARE SITUATED PREDOMINANTLY OUTSIDE CYTOCHROME OXIDASE-POSITIVE BLOBS IN LAYERS II-III OF MACAQUE STRIATE CORTEX. R.O. Kuljis and P. Rakic. Section of Neuroanatomy, Yale University School of Medicine, New Haven, CT 06510-8001.

Neuropeptide Y (NPY) is present in a small population of local circuit neurons in the striate cortex. In layers II-III, NPY-containing somata (NPYcs) tend to aggregate in loose clusters of 3-6 cells (Hendry et al., J. Neurosci. 4: 2497; Wahle et al., Exp. Brain Res. 61: 364). We analyzed whether the distribution of NPYcs was related to cytochrome oxidase (CO)-containing parcellations in layers II-III of the opercular region.

Four macaque monkeys were anesthetized and perfused with 4% paraformaldehyde, alone or with 0.08% glutaraldehyde and 15% saturated picric acid added. NPY-like immunoreactivity was revealed by the avidin-biotin-peroxidase technique (Hsu et al., J. Histochem. Cytochem. 29: 577). A histochemical procedure was used to reveal CO activity (Wong-Riley, Brain Res. 171:11). Computer-assisted plots of adjacent sections labeled for NPY or CO - and sections double-labeled for NPY and CO - were used to perform 3-dimensional computerized reconstructions of the distribution of 606 NPYcs (6 series of 6-20 serial sections). NPYcs display a low average density in layers II-III (30 cells/mm^3), with no apparent pattern in their spatial distribution. Most cells were found **outside** the CO-containing blobs (n= 513; 84.7%); 77 cells (12.7%) were found in the boundary between CO-rich and CO-poor zones. Only 16 NPYcs (2.6%) were found in the CO blobs, which comprise 35% of the volume of layers II-III. The uneven distribution of NPYcs in relation to CO compartments is highly significant (X^2= 366; A= <0.001; df= >30).

Most cells in the CO-rich blobs of layers II-III are color-coded, while CO-poor regions - where NPYcs are situated - contain many orientation-selective cells (Livingstone and Hubel, J. Neurosci. 4: 309). The present findings indicate that the circuits supporting orientation vs color selectivity may differ not only in their input-output relationships, but also in the transmitter/modulators their local circuit neurons contain.

101.8 **THE BIPOLAR CELL IN RAT VISUAL CORTEX.** A. Peters. Dept. of Anatomy, Boston Univ. Sch. of Med., Boston, MA 02118.

The bipolar cell of rat visual cortex has achieved prominence because it is visualized by a number of antibodies to neuroactive compounds, including antibodies to vasoactive intestinal polypeptide (VIP), cholecystokinin, choline acetyltransferase, and to α-aminobutyric acid (GABA). Reports in the literature show that the axon terminals labelled by these antibodies form symmetric synapses. Yet earlier Golgi-electron microscopic studies of bipolar cells in rat cortex showed them to have axons forming asymmetric synapses (Peters and Kimerer, J. Neurocytol. 10:921). In an attempt to resolve these conflicting data, bipolar cells in rat visual cortex have been examined further by using additional cells some prepared for Golgi-electron microscopy and others reacted with antibodies to VIP.

Additional Golgi-electron microscopic studies show that there are two types of bipolar cells. As previously described one type has axons forming asymmetric synapses, and these neurons most commonly synapse with dendritic spines. The other bipolar cell type has axons forming symmetric synapses, and these neurons preferentially synapse with dendritic shafts. This latter population must include these bipolar cells which label with the above mentioned antibodies, for the axons of some VIP labelled bipolar cells have been traced from cell bodies and shown to form symmetric synapses. Like the Golgi impregnated bipolar cells forming symmetric synapses, dendritic shafts are the most common postsynaptic element for VIP positive axon terminals, although some VIP labelled terminals synapse with cell bodies. Analysis of tissue labelled with VIP antibody shows that about 50 per cent of bipolar cells are VIP positive, and since about 80 per cent of all bipolar cells are GABA-positive, it is suggested that many VIP positive bipolar cells also contain GABA. The transmitter used by those bipolar cells with axons forming asymmetric synapses is unknown. Supported by NIH research grant NS 07016.

101.9 GABA RECEPTOR COMPONENTS IN VISUAL CORTEX OF CAT AND MACAQUE. D. Parkinson and E. Coscia* Dept. Cell Biol. & Physiol., Washington University Medical School, St. Louis, Mo

GABA is one of the major inhibitory neurotransmitters in the cerebral cortex. In visual cortex, GABAergic mechanisms contribute to the orientation and direction specificity of visually driven cells, as well as regulation of binocular input. Most of these conclusions are based on work with the GABA-A antagonist, bicuculline. Two types of GABA receptors have been identified. The GABA-A receptor is made up from three major components;the agonist binding site, the BZD binding site, and the chloride channel. The GABA-B receptor modulates adenylate cyclase activity and is selectively activated by GABA or baclofen. We used binding assays to measure the abundance of GABA receptor components and then receptor autoradiography to visualise their distributions across cortical layers.

[3H]Muscimol was used to label GABA-A agonist sites. Binding was saturable, of high affinity (Kd=9nM) and was potently inhibited by GABA and bicuculline, but not Ro 15 1788 or picrotoxin. The binding of the BZD antagonist, [3H]Ro 15 1788, was also saturable, of high affinity (Kd=1nM) and inhibited by clonazepam but not GABA. Binding of [35S]TBPS to the chloride channel required the presence of chloride ion, was saturable, of high affinity (Kd=12nM) and was inhibited by GABA and picrotoxin but not bicuculline. Bicuculline antagonised the inhibition seen with GABA but not with picrotoxin. Binding of [3H]baclofen was saturable (Kd=50nM), calcium-dependent and inhibited by GABA. The maximum number of sites for these ligands was measured. GABA-B sites were the least abundant (0.09-0.14 pmoles/mg.prot.). The concentrations of GABA-A sites and BZD sites were similar at 1.2-1.9 and 1.0-1.4 pmoles/mg. prot., respectively. The number of TBPS sites was about one third of these levels (0.3-0.6 pmoles/mg. prot.). The autoradiography patterns seen with [3H]muscimol and [3H]Ro 15 1788 were very similar. In cat visual cortex, both sites were present in all layers, highest in layers I-IV, intermediate in layer VI and lowest in layer V. In macaque, the pattern was different; specific label was seen in all layers, highest in layer IVc, intermediate in layer VI and a band composed of layers I-III. [35S]TBPS sites were seen in layers IV and VI in cat, but not in layers I-III. In macaque, the highest labelling was in layer VI and to a much lower level in layer IVc. No evidence was seen in macaque of association of these sites with "patches".

These results show that the three components of the GABA-A receptor complex are all present in cat and macaque visual cortex, but may not always be associated in a GABA-A/BZD/chloride ionophore complex. Whether there are complexes composed of GABA-A and BZD receptors, that can modulate neuronal activity, remains to be determined. Supported by NIH grant EY5904

101.10 Morphologically Distinct Subsets of GABAergic Neurons in Cat Area 17 Have Unique Patterns of Glycosylated Molecules On Their Surfaces. J. R. Naegele, L. C. Katz and C. J. Barnstable. Lab of Neurobiology, The Rockefeller University, NY, NY. 10021

The GABAergic neurons in the visual cortex form a morphologically and chemically heterogeneous group. A subpopulation of GABA cells were recently identified by their unique surface molecules, recognized by monoclonal antibodies VC1.1 and VC5.1 (J. Neurosci. 7: 1250, 1987; Soc. Neurosci. Abst. 12: 582, 1986). Here, we have asked whether the expression of particular cell surface molecules is related to characteristic morphological properties in these neurons.

Monoclonal antibodies and plant lectins were used to identify subsets of GABAergic neurons in cat area 17; these included VC1.1 and the lectin, VVA. VC1.1 recognizes a triplet of polypeptides with M_r 95-105 kd, 145 kd and 170 kd on immunoblots of polyacrylamide gels. VVA shows highly specific binding to terminal N-acetylgalactosamine residues. Both molecular probes revealed a meshwork pattern which enveloped the cell bodies and dendrites of a subpopulation of nonpyramidal neurons scattered through layers II-VI of Area 17. Immunocytochemical double-labeling with an antiserum to GABA, revealed that nearly all the VC1.1 or VVA-stained neurons were immunoreactive to GABA. VC1.1 positive cells were morphologically heterogeneous and included bitufted and multipolar varieties. VVA positive cells were a more homogeneous group and closely resembled the large Basket cell class of cortical interneurons. Neither reagent labeled axons which limited more precise identification of their morphological subclasses.

To obtain this information, we prepared living slices from cat visual cortex and injected cells intracellularly with Lucifer Yellow (J. Neurosci. 7: 1223, 1987). The slices were then fixed, sectioned, incubated in VVA and visualized using peroxidase immunohistochemistry. When sequentially viewed with epi-fluorescent and bright-field illumination, a subset of the intracellularly-filled neurons were labeled by VVA. Fifty to 70 cells were injected per experiment and of these, approximately 5% were double-labeled with the lectin. Of the double-labeled cells recovered so far, all were morphologically similar, with extensive and highly varicose dendrites. None of the other kinds of neurons intracellularly stained, which included spiny pyramids and sparsely spiny varieties, were labeled by the lectin.

These studies have identified a unique subset of GABAergic neurons with a distinct topography of glycosylated molecules across their surfaces. By this combined approach, we are beginning to link molecular composition to cellular architecture in specific subsets of cortical neurons.

101.11 NICOTINIC CHOLINERGIC INPUT TO CAT PRIMARY VISUAL CORTEX. Nigel W. Daw, Kenneth E. Kratz and David Parkinson Dept. Cell Biology, Washington Univ. Med. School. St Louis, MO 63110.

Last year we reported that, in area 17 of the cat cerebral cortex, ^{3}H-Nicotine binds almost exclusively to layer IV (Parkinson and Daw, Soc. Neurosci. Abstr. 12: 162.1). This observation raised two questions: whether the binding was located on geniculocortical afferents, and whether the ^{3}H-nicotinic binding sites represent a physiologically relevant cholinergic receptor. We tackled the first question by making lesions in the lateral geniculate nucleus and the second by iontophoretic techniques.

To determine the location of the binding, we made lesions in the lateral geniculate nucleus. An electrode was angled at 20° to the vertical in the parasaggital plane, to pass through the same part of the field of view in all layers of the geniculate, and a lesion of approximately 1mm diameter was made in all layers. Two to four weeks later the animal was sacrificed, and the cortex frozen and sectioned for autoradiography. A gap was found in the nicotinic binding in layer IV of primary visual cortex. The location coincided with the loss of visual input to primary visual cortex determined elecrophysiologically. Staining with cytochrome oxidase revealed a gap in the same location. The pattern of labelling seen with ligands binding to the following receptors was not affected: muscarinic, GABA-A, benzodiazepine, and the GABA chloride channel.

To look for nicotinic effects on the activity of cells in the cortex, we recorded from single cells and iontophoresed acetylcholine, atropine, mecamylamine and hexamethonium. Results were obtained from 21 cells. In 17 of these cells the effect of acetylcholine was excitatory and/or the effect of an acetylcholine antagonist was inhibitory. In the other four acetylcholine had an inhibitory effect and/or an antagonist had an excitatory effect. Nicotinic antagonists were applied to 14 of these cells. In 7 cases activity was reduced by mecamylamine, usually both spontaneous and light-driven activity. In 6 of these cells atropine also reduced the activity: in the other case there was a slight increase in activity with atropine. Hexamethonium was applied to 6 cells, but a definite effect was not seen.

We conclude that there are nicotinic receptors in primary visual cortex; that these receptors appear to be located on the terminals of afferent fibers; and that the activity of cells in layer IV can be affected by nicotinic antagonists. It seems likely, therefore, that acetylcholine fibers have a nicotinic influence on primary afferent fibers at the level of their entry into the visual cortex.

101.12 THE NORADRENALINE, DOPAMINE AND SEROTONIN INNERVATION OF THE RAT VISUAL CORTEX. J.G. Parnavelas*[1], G.C. Papadopoulos*[2] and R.M. Buijs*[3] (SPON: T. Harrison). [1]Dept. of Anatomy, University College London, London WC1, U.K., [2]Veterinary School, University of Thessaloniki, Greece and [3]Netherlands Institute for Brain Research, Amsterdam, The Netherlands.

The monoaminergic innervation of the rat visual cortex was examined by light and electron microscope immunocytochemistry using antibodies against noradrenaline (NA), dopamine (DA) and serotonin (5-HT).

Observations with the light microscope confirmed earlier reports concerning the density and distribution pattern of the noradrenergic fibers in the rat neocortex. Briefly, fibers running parallel to the pia predominate in layers I and VI, relatively straight radial fibers traverse layers II & III, and short tortuous or obliquely oriented axons prevail in layers IV and V. In addition, detailed examination revealed the striking presence of NA-immunoreactive fibers running in the mediolateral direction and "oscillating" regularly between layers II through IV. The DA innervation of the visual cortex was characterized by the differential density of labelled fibers within individual visual areas. Thus, area 18 contained a modest density of DA-labelled axons but areas 17 and 18a were sparsely innervated. All layers of area 18 appeared to be innervated by collateral branches emanating from fibers ascending from layer VI to layer I. These axons were thin and tortuous bearing irregularly spaced varicosities. The 5-HT innervation of the visual cortex appeared dense in all layers. Most axons, bearing numerous intensely-stained varicosities of various sizes, followed a tortuous path.

The ultrastructural features of the monoaminergic terminals in the cerebral cortex have been the subject of controversy in recent years. Systematic analysis of serial ultrathin sections, immunocytochemically stained with antibodies against NA, DA or 5-HT, has shown that nearly all stained terminals formed synapses characterized by specialized junctional appositions. These findings suggest that monoamines exert their influence in the cortex through conventional synaptic junctions.

CHEMICAL SENSORY SYSTEMS I

102.1 RAT ORAL TASTE SYSTEMS: COMPARISON WITH HUMAN. J.C. Boudreau. Sensory Sciences Center. Graduate School of Biomedical Sciences. University of Texas at Houston. Texas, 77030.

Almost all mammalian taste research is directed toward rodents and the results are usually interpreted in terms of an assumed human taste model. In our studies, oral taste systems of the rat were investigated by recording spikes from single sensory neurons in the rat geniculate ganglion (GG) and petrosal ganglion (PG). Utilizing stimulus-response measures, the neurons were parcelled into six different groups (GG salt, PG salt, GG acid, PG acid, Sugar-amino acid and X units--alkaloid and alkaloid plus). Only the latter two neural groups of units were found in both ganglia. On the basis of active stimuli, these neural groups were compared to humans where elicited sensations were utilized. Only the GG salt units (Na responsive) seem to clearly have a human counterpart. GG acid units of the rat were activated by a more restricted group of acids than those eliciting a sour sensation, and in addition, these rat units also fired to salts, which do not elicit a sour sensation. No clear human sensation exists as a counterpart for the rat PG salt and PG acid systems. No neural response was shown to glutamate (umami sensation) apart from GG salt units which fire to Na. No nucleotide responsive system has been found in the rat. Although some X units respond to a narrow range of alkaloids (atropine best), most bitter compounds are relatively inactive or inhibitory. No rat (or any other mammalian) excitatory neural analog exists for a general human bitter taste. The sugar-amino acid units do not discharge to some amino acids humans find sweet, nor do they innervate the front of the tongue. Little rat response has been shown to many of the intense sweeteners. Other human sensations (e.g., metallic) have been inadequately characterized to compare with rat units. Although the rat is frequently depicted in terms of a four basic taste model, this model and its accompanying simplistic chemistry improperly characterize the rat (and human). Since the rat's taste systems differ markedly from those of the human, it can be assumed that so also do its nutritional and metabolic systems.

102.2 TASTE UNITS RESPONDING BEST TO NACL, SUCROSE OR KCL ARE FOUND IN SEPARATE LOCATIONS WITHIN THE SOLITARY NUCLEUS OF THE HAMSTER. M. McPheeters, S.C.Nuding*, T.P. Hettinger* and M.E. Frank. Dept. of BioStructure and Function, University of Connecticut Health Center, Farmington, CT 06032.

In mammals, the solitary nucleus is the first taste relay in the brain. Taste information from the tongue is carried via cranial nerves VII, IX, and X which synapse on second-order taste neurons in the solitary nucleus of the medulla. The information is then relayed to the parabrachial nucleus in the midbrain or to the thalamus. Knowledge of the physiological and anatomical properties of the solitary nucleus is necessary to understand the processing of taste information at this level. We are studying the response properties of single cells within the solitary nucleus in relation to their location.

We record from single taste responsive units in the solitary nucleus of of hamsters (Mesocricetus auratus) with glass microelectrodes filled with 0.5M KCl and 4% HRP. The rostral pole of the nucleus which receives afferent input from the anterior tongue via the chorda tympani is approximately 500 x 500 x 250um. Each unit is characterized by its response to NaCl (0.03M), sucrose (0.1M) and KCl (0.1M) presented to the anterior tongue. These chemicals identify three distinct populations of afferent inputs to the solitary nucleus. A unit is then classified as NaCl, sucrose or KCl best based on which stimulus evoked the maximal response measured by highest spike frequency. The location of the unit is marked with a small iontophoretic injection of HRP. Following sectioning of the brain and histological processing to visualize the location of the HRP reaction product (50 um in diameter), a three-dimensional reconstruction of the medulla is made either with clear plastic sheets or by computer simulation. We are then able to clearly see the location of each functionally identified unit within a model of the solitary nucleus. NaCl units tend to cluster in one location, sucrose units in another and KCl units in yet a third location. Thus we conclude that there exists a spatial organization of taste qualities at the second-order neuron level. This finding suggests that the organization of the gustatory system may be analogous to other lemniscal sensory systems.

102.3 L-ARGININE-ACTIVATED CATION CHANNELS FROM THE CATFISH TASTE EPITHELIUM. J.H. Teeter and J.G. Brand* (SPON: R. Bruch). Monell Chemical Senses Center, University of Pennsylvania, and Veterans Administration Medical Center, Philadelphia, PA 19104.

L-Arginine is a highly effective stimulus for the taste system of the channel catfish (Ictalurus punctatus) in electrophysiological and behavioral experiments. In addition, binding studies using a sedimentable fraction from catfish taste epithelia (Fraction P2; Krueger and Cagan, J. Biol. Chem. 251:88, 1976) display specific binding of L-arginine with affinities of 10^{-7} and 10^{-5} M.

We have incorporated membrane fragments from a nucleotidase-enriched portion of Fraction P2 into artificial phospholipid bilayers (soybean phospholipids) formed over the tips of patch pipettes. Single-channel records revealed a variety of current fluctuations which resembled openings and closings of ion channels. Most of the channel activity was voltage-dependent and slope conductances ranging from 8 pS to 230 pS were observed. In 7 of 14 patches, which showed no channel activity at potentials between -100 mV and +100 mV, concentrations of L-arginine greater than 1 µM elicited single channel fluctuations. The amplitude of the open channel current varied approximately linearly with voltage between -80 mV and +80 mV, corresponding to a slope conductance of about 40 pS. Both individual openings and bursts of openings lasting several seconds were recorded. The frequency of openings increased with increasing concentrations of L-arginine (1-100 µM). The L-arginine-activated currents reversed at about 0 mV (-8 mV to +12 mV) with Ringer in the bath (mM: 110 NaCl, 2.5 KCl, 1.6 $MgCl_2$, 1 $CaCl_2$. 5 HEPES, pH 7.4) and a pseudo-intracellular solution in the pipette (85 KCl, 12.5 NaCl, 1.6 $MgCl_2$, 0.25 $CaCl_2$, 0.5 EGTA, 5 HEPES), indicating that the channel was cation selective with similar permeability to Na^+ and K^+. L-Arginine-activated channels were not observed in preparations derived from previously frozen samples of Fraction P2, which exhibit little specific binding of L-arginine. However, spontaneous channel activity was frequently observed in previously frozen preparations.

These results demonstrate the presence of L-arginine-activated cation channels in membranes from the catfish taste epithelium. Although modulation of these channels occurred in the absence of added second messengers or substrates, suggesting that L-arginine may directly gate channel openings, it is possible that sufficient second messenger substrate was present in the preparation to mediate the observed responses.

102.4 **ADENYLATE CYCLASE AND GTP BINDING PROTEIN IN RAT SWEET TASTE TRANSDUCTION.** Doron Lancet§, Benjamin J. Striem*†, Umberto Pace*§, Uri Zehavi*† and Michael Naim*† (SPON: Sara Fuchs). †Dept. of Biochemistry and Human Nutrition, Faculty of Agriculture of the Hebrew University of Jerusalem, Rehovot, Israel, and §Dept. of Membrane Research, the Weizmann Institute, Rehovot, Israel.

The response of vertebrate olfactory epithelial neurons to many odorants has been shown to involve activation of adenylate cyclase via a stimulatory GTP-binding protein (olfactory G_s) (Lancet and Pace, Trends Biochem. Sci. 12:63, 1987). Taste transduction has long been proposed to be similarly mediated by cyclic nucleotides, but direct evidence has been lacking. Such evidence is provided here through the demonstration that rat lingual adenylate cyclase is activated by sweet tasting compounds. Membranes were prepared from the anterior dorsal rat tongue (tip), rich in fungiform papillae, by polytron homogenization in hypotonic buffer, followed by differential velocity centrifugation. Tip membranes, but not control ones from a non-sensory tongue region, tongue muscle or olfactory cilia, showed a significant (91±14%) elevation of adenylate cyclase activity by 1.0M sucrose. cAMP production was dose-dependent (8-142% enhancement for the physiological range of 0.2-1.2M sucrose) and required the presence of GTP or its non-hydrolysable analogue GTPγS. The latter observation suggests that a G_s-like protein couples sweet taste protein receptors and adenylate cyclase. Other disaccharides, all eliciting appealing taste in rats, were also activatory. Maltose was roughly a half as effective as sucrose, in agreement with with its potency relative to sucrose in eliciting chorda tympani nerve electrophysiological responses (Hagstrom and Pfaffmann, J. Comp. Physiol. Psychol. 52:259, 1959). Non-sugar sweeteners, aspartame and neohesperidine dihydrochalcone (NHD), which are essentially non-tasting for rats, did not significantly affect adenylate cyclase levels in tip membranes. Saccharin, a strongly appealing compound, gave about 100% enhancement at 20mM, but such activation was observed also in muscle membranes, and its specificity needs yet to be established. Adenylate cyclase measurements in tongue membranes could thus be used to assess the effectiveness and kinetics of sweet-tasting compounds in different species. Our results suggest that sweet disaccharides induce an elevation of intracellular cAMP in taste cells. This could give rise to the documented membrane depolarization by modulating ion channel conductance directly (as in olfactory cilia) or indirectly, via cAMP-dependent protein phosphorylation. The second possibility is supported by recent patch clamp recordings in isolated frog taste cells (Avenet, Hofmann and Lindemann, Pflugers Arch. 408:R35, 1987).

Supported by grants from NIH (NS22063), Minerva Foundation (Munich), Weizmann-Rockefeller Trust, Fragrance Foundation, Gutwirth Foundation and Ann Kaplan Mandell Fund.

102.5 MECHANISM OF TRANSDUCTION OF BITTER TASTE IN RAT TASTE BUD CELLS. M.H.Akabas*, J.Dodd & Q.Al-Awqati* (SPON: J.Ripellino). Dept. of Medicine & Physiol., Columbia Univ., New York, N.Y. 10032

Since most poisonous plant alkaloids are intensely bitter, taste permits animals to avoid potentially toxic foods. We have studied the mechanism of bitter taste transduction in rat taste cells. We developed a procedure to dissociate the rat lingual epithelium into single cells and to identify the taste cells using a fluorescently labelled antibody. Using fura 2, to measure single-cell intracellular calcium levels, and patch clamping, we have characterized the response of the taste cells to denatonium, the most bitter substance known. In a small subset of taste cells, denatonium induced a rise in intracellular calcium due to release from intracellular stores. Potassium induced depolarization did not alter cell calcium levels. This implies that voltage-dependent calcium channels are not involved in the transduction process.

Using patch clamp recording, delayed rectifier K^+ currents have been identified in the taste cells. Single channel studies have shown the presence of two types of K^+ channels, a voltage-dependent channel and a calcium-dependent channel. Using cell-attached patch clamping, we have shown that denatonium induces the closure of the voltage-dependent K^+ channels in a small subset of the cells. Since denatonium has no direct access to these channels, its effects must be mediated by a second messenger. The role of channel closure in the transduction process is unclear, however, since K^+ induced depolarization had no effect on cell calcium.

These results suggest that bitter taste transduction occurs via a biochemical pathway, not an electrophysiologic one. The initial event involves binding of a bitter substance to an apical cell surface receptor. This interaction leads to the generation of an intracellular second messenger which causes release of calcium from intracellular stores and the closure of a class of K^+ channels. Presumably, these events lead to neurotransmitter release.

102.6 ODORANT- AND SECRETAGOGUE-INDUCED CHANGES IN THE CATION CONCENTRATION OF OLFACTORY MUCUS. H. Joshi*, M.L. Getchell*, B. Zielienski* and T.V. Getchell. Department of Anatomy and Cell Biology, Wayne State University School of Medicine, Detroit, MI 48236.

Atomic emission and absorption spectrophotometry was used to determine [Na], [K] and [Ca] in olfactory mucus of grassfrogs. Samples were obtained at 10-min intervals for 70 min using a modification of the "filter paper" technique. In untreated frogs, the mean (N=72) ion concentrations (mEq/L) were: Na, 52.7 ± 4.1; K, 10.6 ± 1.9 and Ca, 10.7 ± 1.7. These concentrations did not change appreciably during the 70 min period. This stability suggested that representative mucus samples were obtained without substantial cellular or extracellular fluid contamination. The odorant 1,8-cineole was delivered to the epithelial surface at 10, 20 and 30 min after an initial sample was obtained by moistening filter paper with 0.4 ul of 1 mM cineole in deionized water. [Na] increased transiently to 88.3 ± mEq/L at t-30 followed by a systematic decrease to within 15% of initial values. The changes in [Na] were statistically significant ($P<0.001$). Similar results were obtained for [Ca], but not [K], that were significantly different ($P<0.02$) from control values. The secretagogues methacholine (5 mg/ml, topical) and isoproterenol (30 mg/kg, i.p.) caused transient increases in [Na] at t-20 to 68.1 ± 26.4 mEq/L for the cholinergic agonist and 58.8 ± 28.4 mEq/L for the B-adrenergic agonist; due to the high variability in the data as evidenced by the standard deviations, mean values were not significantly different from control values. The [K] and [Ca] were not affected significantly. Histological examination of tissue from experimental animals showed signs of mucus and electrolyte/water secretion from sustentacular cells that included formation of apical domes and vacuoles and from acinar cells that included secretory granule depletion. Effects ranging from disaggregation of the mucociliary matrix to partial deciliation were also observed. The results show that the cation concentrations in frog olfactory mucus resemble those found in human nasal and tracheobronchial secretions, perilymph of the inner ear and gastrointestinal mucus. The transient increases in [Na] and [Ca] induced by the application of an odorant and secretagogues reflect secretory activity associated with perireceptor events. Supported by NSF-BNS-07949 (MLG) and NIH-NS-16340 (TVG).

102.7 PROPERTIES OF VOLTAGE DEPENDENT IONIC CURRENTS IN ISOLATED SALMON OLFACTORY RECEPTOR CELLS Gabrielle Nevitt, Department of Zoology, University of Washington, Seattle, Washington, 98195

Salmon offer a unique opportunity to study the biophysical basis of olfaction as it relates to behavior. Their keen ability to discriminate between specific chemicals by smell has been shown to play a key role in homing as well as predator avoidance. Here, I present a characterization of ionic currents present in olfactory receptor cells of Coho salmon (Oncorhynchus kisutch) using the whole-cell recording technique of Hamil, et al (1981).

Receptor cells were isolated from 2 year old fish by gently agitating rosette tissue in 0 Ca/0 Mg ringer, followed by an incubation in papain (.5 mg/ml / 15 min). Ciliated rod receptor cells retained their morphology and were easily recognizable. 10-20 G Ohm seals were routinely obtained, and in cell-attached configuration, spontanious action potentials were frequently observed.

Under voltage clamp recording conditions, both inward and outward currents were observed. Transient inward currents occurred in response to depolarizations from holding potentials of -60 to -120 mV. Amplitudes ranged from 200 to 700 pA and peak currents occurred at voltages between -5 and -30 mV. Peak currents activated within 1 ms and ½ inactivation times were of the order of 3 ms. This current is most likely carried by Na ions because it was blocked by TTX, and absent when choline replaced Na in the external ringer. Using CsCl-filled pipets and 10 mM Sr substitution for 3 mM Ca externally, a second inward current was observed during depolarizations from a holding potential of -40 mV. Peak current occurred at voltages between +5 and +15 mV. This current did not inactivate during an 800 ms pulse, and completely disappeared within 3-6 min following the establishment of whole-cell configuration. It is likely that this current is carried by Sr ions passing through Ca channels.

In addition to inward currents, an outward Ca-activated K current occurred in response to depolarizations from holding potentials of -120 to -40 mV. Amplitudes ranged from 200 to 1000 pA with peak currents occurring in a similar voltage range to the peak Ca current. This current was not present when Sr replaced Ca in the external ringer. Preliminary studies in which .15 mM cyclic GMP has been added to the control pipet solution suggest that cyclic GMP activates a second outward current in addition to an approximately 10% increase in steady state membrane conductance. Further investigations will focus on elucidating the details of these effects, and possible roles that these currents may play in the olfactory response to behaviorally relevant odorants.

102.8 **MOLECULAR CORRELATES OF OLFACTORY ADAPTATION: ADENYLATE CYCLASE AND PROTEIN PHOSPHORYLATION.** **Umberto Pace*, Judith Heldman*, Iris Shafir*, Galia Rimon* and Doron Lancet (SPON: Michael Y. Spiegelstein). Dept. of Membrane Research, the Weizmann Institute, Rehovot, Israel.**

Olfactory adaptation is manifested at two levels: 1) A slow (~ 1 min), often complete loss of odor sensation, most probably centrally mediated; 2) A faster (~ 1 sec) partial diminution of odorant-induced electrophysiological activity in the sensory epithelial neurons, possibly analogous to hormone and neurotransmitter receptors desensitization. We studied molecular correlates of olfactory adaptation using an in-vitro assay: odorant activation of adenylate cyclase in a rat olfactory cilia preparation. Olfactory epithelia (whole turbinates) were dissected after quick decapitation, and incubated in isotonic buffer, with or without odorant cocktail (1 mM each, n-amylacetate, l-carvone, 1,8-cineole and citral) for 60 min at 30°C. Subsequently, a cilia-enriched preparation was obtained by 5 sec sonication and differential centrifugation (Shirley et al., Biochem. J. 240:605 ,1986). This preparation displayed the same odorant activation of adenylate cyclase as olfactory cilia obtained by calcium shock, although the specific activity of the enzyme in it was ~ 5 times lower. We found that preparations from epithelia pre-exposed to odorants and washed, gave an appreciably diminished GTP-dependent odorant effect on cyclic AMP (cAMP) production: 41±38% enhancement above basal level, compared to 98±45% activation in untreated controls ($N=17$, $p<0.002$). Such decreased efficiency of stimulation was not due to constitutive, lingering activation, as odorant pre-exposure had no effect on basal adenylate cyclase levels, i.e. odorant preactivation was fully reversible. The desensitization of olfactory receptor (OR) coupling to adenylate cyclase may be of the homologous type, stemming from odorant-induced receptor phosphorylation by hypothetical olfactory receptor kinase (ORK), akin to β-adrenergic receptor kinase (βARK) (see Lancet and Pace, Trends Biochem. Sci. 12:63, 1987), or by cAMP-dependent protein kinase. cAMP-regulated transmembrane phosphoproteins, recently identified in olfactory cilia of rat and cow incubated with $\gamma[^{32}P]$-ATP may be substrates for such odorant-activated modifications. This possibility is currently examined by studying protein phosphorylation in epithelial explants incubated with $[^{32}P]$-phosphate under conditions that promote desensitization. Other sites at which phosphorylation related to heterologous desensitization could occur are the stimulatory GTP-binding protein (olfactory G_s) and the cAMP-gated ion channels. Cross adaptation studies with different odorants, studies of olfactory G_s modification and attempts to identify and examine the phosphorylation of the ciliary cation channel would be instrumental in determining the molecular sites of chemosensory adaptation.

Supported by grants from NIH (NS22063) and Minerva (Munich).

102.9 MOLECULAR ASPECTS OF OLFACTORY RECEPTION. P.B. Sklar, R.C.A. Pearson, J.C. Venable*, and S.H. Snyder. Department of Neuroscience, The Johns Hopkins University School of Medicine, Baltimore, Maryland 21205.

Recent advances in the study of the initial events which transduce odorant signals across the olfactory epithelium suggest 1) that a wide variety of odorants interact with an odorant-sensitive adenylate cyclase (Pace et al., Nature 316:255, 1985) and 2) the presence of a cyclic nucleotide gated channel in isolated ciliary membrane patches (Nakamura and Gold, Nature, 1987).

In the bullfrog Rana catesbeiana, many fruity, floral, minty, and herbaceous odorants stimulate adenylate cyclase activity in isolated olfactory cilia, while numerous putrid odorants and odorous chemical solvents do not (Sklar et al., J. Biol. Chem. 261:15538, 1986). We now report that mammalian cilia (rat) display a similar response profile to odorants. In rat olfactory cilia odorants such as citralva, 2-isobutyl-3-methoxypyrazine, carvone, menthone, and hexylpyridine all activate enzyme activity as in amphibian cilia. Odorants which had no effect in frog cilia similarly were ineffective when tested in our rat cilia preparation.

We wondered if the regeneration of olfactory neurons into adulthood might result from oncogene expression. To investigate this we examined mRNA expression in the olfactory epithelium by in situ hybridization. Preliminary experiments suggest that the message for the c-fms, c-cis, c-abl, H-ras, N-ras, and K-ras oncogenes are present in the olfactory epithelium. Currently, we are investigating the changes in oncogene expresion following unilateral bulbectomy.

102.10 ODORANT-BINDING PROTEIN: cDNA CLONING AND HOMOLOGY TO RAT α2-MICROGLOBULIN. J. Pevsner, R.R. Reed* and S.H. Snyder. Depts. of Neuroscience, Pharmacology and Molecular Sciences, and *Howard Hughes Medical Institute, The Johns Hopkins University School of Medicine, Baltimore, MD 21205.

An odorant-binding protein (OBP) has been purified from nasal epithelium of rat and cow. OBP has a subunit molecular weight of 19 kDa (bovine) or 20 kDa (rat). The protein binds several odorants with micromolar affinities, and has been immunohistochemically localized to bovine mucus-secreting glands in the nasal epithelium. We now report the cloning and sequence analysis of two cDNAs encoding rat OBP.

The sequence of the N-terminal 14 amino acids of rat OBP was determined. A set of oligonucleotide probes was synthesized corresponding to the first seven amino acids. These probes were used to screen a λgt10 cDNA library derived from rat olfactory epithelium (provided courtesy of Dr. E. Barbosa, Johns Hopkins). Two clones (800 and 850 base pairs) which were recognized by the probes were isolated and sequenced by the Sanger chain termination method. Initial results suggest that the cDNA clones encode OBP because amino acid sequences of the protein adjacent to the region used to generate the oligonucleotide probes are identical to those determined from DNA sequencing of that region.

Based on preliminary sequencing results, OBP is homologous to rat α2-microglobulin, an abundant 18 kDa protein secreted by the liver. Both of these proteins appear to be members of a supergene family that includes retinol-binding protein (which binds retinol), apolipoprotein D (which binds cholesterol), and protein BG, a 20 kDa soluble protein present in the Bowman's glands of frog olfactory epithelium. The homology between OBP and members of this gene family supports the hypothesis that OBP serves as a carrier for odorants within the nasal epithelium.

102.11 CORRELATIONS BETWEEN 2DG ACTIVITY AND MONOCLONAL ANTIBODY STAINING IN THE OLFACTORY SYSTEM OF THE FETAL RAT. P.E. Pedersen, B. Friedman, R. Smith*, C.A. Greer, G.M. Shepherd and S. Hockfield, Secs. of Neuroanatomy and Neurosurgery, Yale University School of Medicine, New Haven, CT 06510.

The accessory olfactory bulb (AOB) is the site of intense 2-deoxyglucose (2DG) activity in E(embyronic day)22 fetal rats in utero. Together with behavioral and anatomical evidence, this finding has suggested that fetuses may use this pathway to sample and detect their chemical milieu. We now report the use of monoclonal antibody Rat 204 generated in this laboratory in combination with 2DG autoradiography to compare the biochemical and functional differentiation of components of the peripheral olfactory pathways.

In the adult rat, Rat 204 recognizes a subset of olfactory receptor neurons situated in the dorsal recess of the main olfactory epithelium and in the vomeronasal organ and their respective axonal projections. In the fetal rat, at E15, the immunoreactivity is similarly spatially restricted to the dorsal recess and to the vomeronasal organ. In contrast to this selective staining of a subset of receptor neurons, another monoclonal antibody, Rat 203 (Friedman et al., 1986), recognizes receptor neurons throughout the embryonic olfactory epithelium.

Fetuses that receive 2DG in utero according to previously reported methods (Pedersen et al., 1983) exhibit differentially dense areas of metabolic activity throughout the neuraxis. At the earliest age examined, E15, areas of dense 2DG uptake are evident within the olfactory mucosa and presumptive olfactory bulb. Within the olfactory mucosa, these areas appear in the dorsal recess. There is also dense uptake in the vomeronasal organ. Of interest is the finding that the areas of high metabolic activity in the mucosa overlap with the areas that are recognized by Rat 204.

The early expression of antigens in subcomponents of the olfactory system, correlated with metabolic activity, suggests that the neurons in the dorsal recess and in the vomeronasal organ may undergo early functional differentiation. This may be significant for the development of odor detection.

102.12 **Olfactory marker protein (OMP)-like immunoreactivity in discrete nuclei of rodent brain.** H. Baker and F. L. Margolis*. Dept. Neurology, Cornell Univ. Med. Col., New York, NY 10021 and *Roche Inst. Molec. Biol., Nutley, NJ 07110

Olfactory marker protein is a major cytoplasmic protein present in mature olfactory receptor neurons. Antibodies prepared against the SDS-PAGE homogeneous protein have been reported to exhibit exquisite specificity for olfactory receptor neurons in several vertebrate species. Immunoprecipitates of *in vitro* translations driven by mRNA isolated from olfactory tissue manifest a single band of 35S-met labeled material which co-migrates with authentic isolated OMP on SDS-PAGE. Only a single band is observed on immunoblots of olfactory tissue extracts. OMP has not been detected by radioimmunoassay in several grossly dissected non-olfactory brain regions or in a variety of peripheral tissues. Similarly on Northern and slot blot hybridization, RNA isolated from 14 non-olfactory tissues gave no reaction when probed with an OMP cDNA clone. The amino acid sequence of isolated rat OMP has not evidenced any significant homology within the N.B.R.F. data base. Thus, it was with some surprise that we observed OMP-like immunoreactivity in very restricted, discrete groups of neurons in both mouse and rat CNS. Major areas of CNS such as neocortex, cerebellum and basal ganglia, among others, were unstained. However, staining was seen in several auditory related structures such as medial geniculate, inferior colliculus and lateral lemniscal nuclei. Several medullary nuclei contained labelled perikarya including area postrema, nucleus of the solitary tract-motor vagal complex and spinal trigeminal nucleus, pars zonale. The preoptic area and hypothalamus also manifested reactive neurons. In the latter, the most heavily stained neurons were located peri- and para-ventricularly. Similar staining patterns were observed with OMP antisera prepared in both rabbit and goat. In the hypothalamus the mouse exhibited more robust immunoreactivity and a somewhat wider distribution of fibers and terminals than in the rat. The staining in hypothalamus and preoptic region was abolished by preincubation of the antierum for one hour with 1μM purified OMP. Among the possible interpretations of these observations are: 1) OMP or a closely related protein is present in these neurons, 2) these antisera cross react with a hypothalamic peptide/protein, or 3) OMP antisera contain immunoglobulins directed against a previously unsuspected, highly immunogenic contaminant. The extensive use, by several laboratories, of these antisera as reagents has prompted this preliminary report. Evaluation of these diverse possibilities is under investigation as are the implications of these observations with regard to the function of OMP.

EPILEPSY I

103.1 **KINDLED SEIZURES EVOKED BY REPEATED EXPOSURE TO BICUCULLINE: CROSS-KINDLING TO LIDOCAINE AND A NON-CONVULSANT BETA-CARBOLINE, (FG7142).** M. Fabrazzo*, P. Noonan*, and K. Gale, Dept. of Pharmacology, Georgetown University, Schools of Medicine and Dentistry, Washington D.C. 20007

For the generation of convulsive seizures induced by GABA antagonism, an epileptogenic site within the deep prepiriform cortex, "area tempestas" (AT), has been shown to be crucial (1). This area is subject to electrical kindling and exhibits bi-directional transfer ('cross-kindling') with electrical stimulation of amygdala (2,3). As the latter, in turn, exhibits bi-directional transfer with kindling induced by repeated systemic treatment with lidocaine (LIDO) (4), we expected transfer of 'kindling' between LIDO and the GABA antagonist, bicuculline (BIC). To test this, rats were kindled with LIDO (**Group I**) (60 mg/kg/day i.p. for 21 days) or BIC (**Group II**) (14 daily s.c. injections starting at 2 mg/kg and reducing the dose until ≤1 mg/kg was given during the last 4 days). Approximately 30% of **Group I** became kindled as indicated by the appearance of clonic seizures in response to LIDO (60 mg/kg i.p.); no control rats (receiving injections of saline for 21 days) exhibited seizures with this challenge. LIDO-kindled rats also exhibited an enhanced seizure sensitivity to BIC in comparison either to LIDO-treated rats that did not become kindled or to saline treated controls. In **Group II**, over 70% became kindled as indicated by clonic seizures in response to a dose of BIC (≤ 1mg/kg) less than half the convulsive threshold dose in controls. 100% of BIC-kindled rats exhibited clonic convulsions with acute LIDO (60 mg/kg i.p.) challenge. BIC- and LIDO-kindled seizures typically included facial and forelimb clonus, rearing and falling (Stage 5, using the scoring system applied to amygdala-kindled seizures). These resemble seizures induced by application of BIC into AT as well as those induced by electrical kindling of amygdala ('limbic motor seizures'), but they are distinct from the seizure pattern observed in response to an acute challenge with BIC in non-kindled rats. BIC-kindled rats were also tested for their response to a beta-carboline (FG7142, 15 mg/kg i.p.) and 100% exhibited Stage 5 motor seizures; parallel controls did not show these seizures in response to FG7142 (15, 30, or 60 mg/kg i.p.). Days or weeks without convulsant exposure did not appear to diminish the kindled seizure responses.

In BIC-kindled rats, the threshold dose of BIC methiodide for eliciting motor seizures when placed directly into AT was decreased and the resulting seizures were more prolonged in comparison either to non-kindled rats or to pre-kindling baseline responses.

Thus, chemical kindling with LIDO and drugs which interfere with GABA transmission may share a common substrate. It is likely than an alteration in limbic circuitry with which amygdala and AT are interconnected is responsible for this kindling process.

103.2 **CHOLINERGIC-GABAERGIC INTERACTIONS IN THE GENERATION OF LIMBIC MOTOR SEIZURES IN RATS.** M. Garnett*, M. Fabrazzo *, and K. Gale, (spon: J. McConnell) Department. of Pharmacology, Georgetown University, Schools of Medicine and Dentistry, Washington D.C. 20007

Blockade of GABA receptors, as well as stimulation of muscarinic receptors locally in area tempestas (AT, an epileptogenic site within the deep prepiriform cortex) elicits clonic convulsions that are prevented by the local application of a GABA agonist (1). Moreover, inhibition of excitatory drive within AT blocks limbic seizures induced by systemic treatment with the muscarinic agonist, pilocarpine (2). Based on this, we expected that the GABA antagonist, bicuculline (BIC) would potentiate the convulsant action of pilocarpine. To test this, rats were given a dose of pilocarpine (100 mg/kg i.p.) that was less than one-third the convulsant threshold. Ten min later, BIC was given in a dose (0.5 or 1.0 mg/kg s.c.) less than 25% of the convulsant threshold. At 20-30 min after BIC, 50% of the pilocarpine-treated rats exhibited clonic seizures. These seizures resembled the 'limbic motor seizures' induced by high doses of pilocarpine (400 mg/kg), consisting of facial and forelimb clonus, rearing and falling (Stage 5 according to the scoring system applied to amygdala-kindled seizures). Over 25% of the rats exhibiting convulsions also exhibited status epilepticus lasting over 3 hrs. These results are in contrast to those reported by Turski et al (3) who found that injection of BIC 10 min **prior** to pilocarpine did not potentiate convulsions. It is likely that the relatively brief duration of action of BIC and the 20-30 min latency for the convulsive action of pilocarpine does not allow for synergism when BIC is administered **prior** to pilocarpine.

To further explore a BIC-pilocarpine interaction, rats were 'kindled' by daily treatments (for 14 days) with BIC (starting at 2 mg/kg s.c. per day and reducing the dose by 0.5 mg/kg every 4-5 days). After this period, the threshold convulsive dose of BIC was <50% of that required in non-kindled (saline-treated) controls. After 10 days drug-free, these rats were challenged with 200 mg/kg pilocarpine, a subconvulsive dose in controls, and 50% of the BIC-kindled rats exhibited full Stage 5 convulsions.

Thus, the epileptogenic effects of BIC and pilocarpine probably share one or more common substrates. We have shown that not only does BIC potentiate the convulsant action of pilocarpine, but rats sensitized to BIC by repeated exposure, show cross-sensitization to pilocarpine. As the AT is a site at which both GABA antagonists and muscarinic agonists act to elicit limbic motor seizures, this site is likely to mediate BIC-pilocarpine synergism. In addition, pilocarpine convulsions can be potentiated by a reduction of GABA transmission within substantia nigra (4), so this is another site at which BIC may act to enhance pilocarpine seizures. Finally, as repeated application of muscarinic agonists (but not GABA antagonists) into amygdala can induce kindled seizures (5), a combined action of pilocarpine in amygdala and AT may contribute to the generation of seizures with pilocarpine in BIC-treated rats.

103.3 DEPTH INJECTION OF INHIBITION-BLOCKING CONVULSANTS SUGGESTS THAT PROPAGATING EPILEPTIFORM RESPONSES REQUIRE THE POTENTIATION OF THALAMOCORTICAL CIRCUITRY IN NEOCORTICAL LAYER 4. A.B. Chatt* and J.S. Ebersole. Epilepsy Center, VA Medical Center, West Haven, CT 06516 and Department of Neurology, Yale University School of Medicine, New Haven, CT 06510.

Simultaneous recordings from three laminae within the cat visual cortex following differential intralaminar injections of strychnine (a putative blocker of glycine, taurine and beta-alanine) 1) confirmed that low strychnine concentrations (5 mM) induce intrinsically-mediated epileptiform abnormalities preferentially when injected into the superficial cortical layers, 2) reveal that these abnormalities are generated locally and 3) that they remain local phenomena by not spreading vertically into other cortical layers. Higher strychnine concentrations (20 mM), however, 4) obscure this differential laminar sensitivity by potentiating middle layer sensitivity to this agent, and further 5) reveal vertically propagating abnormalities following layer 4 injections which are associated with the potentiation of the thalamocortical circuitry that is prevalent within this layer.

In our previous experiments where the GABA-blocker, penicillin has been used as the convulsant agent, response changes induced in any layer were always preceded by a thalamocortically mediated response from layer 4 which generally recruited intrinsically-mediated activity there and in adjacent layers (Brain Res 1984: 290, 361-366; Brain Res 1984: 298, 253-272), a condition clearly unlike the 5 mM but similar to the 20 mM strychnine foci observed in this study.

These results suggest that convulsant action upon the thalamocortical circuitry of layer 4 is essential for the development of propagating as opposed to local epileptiform activity. While we do not know the mechanism of action of layer 4 thalamocortical activation many minutes following 20 mM strychnine injection, the absence of similar effects at 5 mM would suggest a non-specific mechanism perhaps on the axonal membranes of the multitude of thalamic terminals within this layer. What is clear is that only when this activation is present does strychnine induce propagating epileptiform abnormalities in the neocortical column and perhaps between columns as well. Further, the inability of strychnine to induce propagating abnormalities at concentrations where some specificity of action can be inferred makes this agent much less useful than the GABA-blockers in investigating epileptogenesis.

103.4 **POSSIBLE MECHANISM FOR THE TRANSITION FROM INTERICTAL TO ICTAL ACTIVITY IN HIPPOCAMPAL SLICES BATHED IN HIGH EXTERNAL POTASSIUM.** S.F. Traynelis* and R.J. Dingledine. Dept. of Pharmacology, Univ. North Carolina, Chapel Hill, NC 27514.

We have previously reported that rat hippocampal slices bathed in 8.5 mM $[K^+]_o$ display both interictal activity and spontaneous electrographic seizures. Interictal bursts arise in the CA3b or c region (frequency ~1 Hz) and propagate to the CA1 region, triggering bursts which gradually increase in intensity. At some threshold level an incoming CA3 burst triggers a tonic-like seizure component in CA1 which lasts 5-10 sec, consists intracellularly of a 8-12 mV depolarization capped by a train of action potentials, and appears extracellularly as a long train of population spikes superimposed on a 4 mV negative envelope. This is followed by a clonic-like phase lasting tens of sec in which CA3 interictal bursts trigger large amplitude CA1 afterdischarges. Seizures occur in 22% of bursting slices, last 52.0 ± 1.9 sec (mean ± SEM, n=192 slices), occur at intervals of 2.6 ± 0.1 min for up to three hours, and are dependent on CA3 interictal input, elevated $[K^+]_o$, and elevated temperature.

Throughout the duration of the seizure and the interseizure interval, the CA3 region generates interictal bursts apparently unaltered in intensity or frequency. The focal nature of the electrographic seizure suggests that development of hyperexcitability occurs within the CA1 region itself. In the 30-60 sec preceding a seizure, both CA1 pyramidal cells and glia depolarize, and the extracellular DC potential drifts negative. These results are all reflective of an increase in baseline $[K^+]_o$. Seizures could be blocked by the competitive NMDA antagonist D-APV (5-10 uM), but not its inactive isomer L-APV (25 uM).

We suggest that a positive feedback loop develops in high $[K^+]_o$, in which several initial consequences of elevated potassium bring about an increase in the number and/or synchrony of CA1 neurons firing during each interictal burst. This in turn increases the amount of potassium released into the CA1 interstitium following each interictal burst, and the entire cycle becomes regenerative. Consequences of increased $[K^+]_o$ include decreased IPSPs and AHPs, cellular swelling, neuronal depolarization, and decreased spike threshold. The actual initiation of a seizure may occur when the CA1 region fails to clear the potassium from its interstitium before the next interictal burst arrives; the resulting threshold-level of K^+ enables the next burst to synchronize or enlist a sufficient number of neurons to become the leading edge of the tonic phase of the seizure. This work supported by NS17771 and a predoctoral fellowship from the National Science Foundation.

103.5 TONIC ELECTROGRAPHIC SEIZURES IN THE CA3 REGION OF RAT HIPPOCAMPAL SLICES BATHED IN HIGH POTASSIUM. N.L. Chamberlin* and R. Dingledine. (Spon: J.L. Giacchino) Dept. of Pharmacology, Univ. North Carolina at Chapel Hill, Chapel Hill, N.C. 27514

Hippocampal slices bathed in 8.5 mM potassium exhibit spontaneous interictal burst discharges. Events that resemble tonic-clonic electrographic seizures often occur in CA1 but rarely in CA3. We have found that treatment of slices with 2 μM phorbol ester 12,13 diacetate can produce activity in CA3 that resembles the tonic phase of a CA1 electrographic seizure. Treatment with phorbol ester significantly increased the rate of spontaneous interictal bursts from 47±2 to 69±3 per minute prior to the onset of tonic electrographic seizures in CA3 (paired "t" test, p<.01, n=26). Since burst intensity was slightly decreased (CA3) or unchanged (CA1), we suggest that an increase in interictal burst frequency was responsible for the interictal to ictal transition in CA3. Under control conditions, interictal bursts usually began in CA3b or c and spread to other pyramidal cell regions. In phorbol esters the interictal pacemaker could shift, but usually remained in CA3b or c. Tonic seizures in phorbol esters were initiated in any subfield of the hippocampus proper, as judged by onset latency in simultaneous recordings from multiple sites. Often they appeared in all regions of the slice simultaneously. These events were associated with a negative DC shift of -2.4±0.4 mV (n=10) in CA3 and -3.6±0.7 mV (n=7) in CA1. Tonic seizure components lasted 10-53 seconds and occurred every 15-150 seconds. The frequency and duration of tonic seizures was fairly constant within a given slice.

Phorbol esters have been shown to have a number of effects on hippocampal neurons, including reduction of burst afterhyperpolarizations (AHPs) in CA3 neurons (Williamson and Alger, Soc. Neurosci. Abst. 12(1):728,1986). Preliminary results suggest that the AHP was reduced in CA3 neurons prior to the onset of ictal events with no change in resting potential or input resistance. These findings are consistent with the idea that AHPs limit the rate of spontaneous interictal bursting and thereby prevent the appearance of electrographic seizures in CA3. Supported by NS-17771.

103.6 GRAFTS OF FETAL NORADRENERGIC NEURONS FROM LOCUS COERULEUS SUPPRESS DEVELOPMENT OF KINDLING EPILEPSY EVOKED BY ELECTRICAL STIMULATION IN THE HIPPOCAMPUS OF THE RAT. O. Lindvall*, D. Barry*, I. Kikvadze*, P. Brundin*, T. Bolwig* and A. Björklund. Dept. Histology, University of Lund, S-223 62 Lund, Sweden and Neurobiology Research Group, Dept. Psychiatry, Rigshospitalet, DK-2100 Copenhagen, Denmark.

Lesions of the ascending noradrenergic projections from the locus coeruleus facilitate the development of kindling (i.e. the number of stimulations needed to reach generalized seizures) caused by electrical stimulation in the amygdala, hippocampus or neocortex. The objective of the present study was to investigate if grafts of fetal locus coeruleus neurons could reverse this lesion-induced facilitatory effect on hippocampal kindling. Three groups of rats were prepared: (1) Normal control group; (2) Lesion group, which received 6-hydroxydopamine (6-OHDA) in the lateral ventricle; (3) Transplant group, which first received 6-OHDA in the lateral ventricle and then bilateral injections of cell suspension grafts of locus coeruleus from fetuses (crown-rump length 10-12.5 mm) into the hippocampus. All animals were subjected to electrical kindling daily in the CA1-CA3 region of the dorso-caudal hippocampus.

The development of seizures was considerably faster in the noradrenaline (NA)-depleted rats than in the control rats. Both the onset (number of stimulations to first grade 1 seizure) and the progression (number of stimulations from first grade 1 to first grade 5 seizure) of kindling was affected. In the grafted rats the onset and progression of kindling was markedly retarded compared to the NA-depleted animals. There was a clear graft-derived NA fiber ingrowth with a normal terminal pattern in all subfields of the dorsal two-thirds of the hippocampal formation. The extent and density of the graft-derived NA innervation varied, however, markedly between the individual animals. The number of stimulations to first grade 5 seizure was significantly correlated with the degree of reinnervation of the stimulated hippocampus.

Our data show that grafted noradrenergic locus coeruleus neurons can retard the development of kindling induced seizures. This study is the first demonstration that intracerebrally grafted neurons can modulate the excitability of epileptic brain regions. Intracerebral implantation of inhibitory neurons may, therefore, provide a new strategy to control the generation or spread of seizure activity.

103.7 THE SPREAD OF EPILEPTIFORM DISCHARGES IN RAT SOMATOSENSORY CORTEX MEASURED WITH A VOLTAGE SENSITIVE DYE. J.A. London, J.-Y. Wu,* M. Rioult,* M. Cattarelli,* and L. B. Cohen. Dept. of Physiology, Yale University School of Medicine, New Haven, CT 06510.

Optical recordings were used to study the propagation and spatial distribution of epileptiform discharges in somatosensory cortex. Adult male rats were anesthetized with equithesine, paralyzed, and artificially ventilated. The cortex was stained with the fluorescent styryl dye, RH795 (kindly supplied by R. Hildesheim and A. Grinvald) at a concentration of 1 mg/ml for 1 hr, followed by a 30 min saline wash. The stimulus consisted of brushing a thin nylon filament across mystacial whiskers. Optical signals were recorded via a 12 X 12 element photodiode array. A ball electrode was placed on the somatosensory cortex adjacent to the region of optical recording.

To measure the optical signal in response to whisker movement in the control preparations, 32 trials had to be averaged. Epileptiform discharges were then induced by application of 1 mM bicuculline to the cortex. After bicuculline, optical signals could be recorded in single trials. Two general classes of responses were recorded, those evoked by whisker stimulation and spontaneous interictal discharges. The evoked response originated from the same site as the control signal, but propagated over a much larger area. It was relatively stereotypic from trial to trial in one animal. In addition to the increase in size of the evoked response after the addition of bicuculline, the signal after bicuculline was also both longer lasting and it occurred with a larger latency after the whisker movement. The spontaneous response was much more variable in signal size, origin, propagation direction, and spatial location than the evoked response.

The electrical activity recorded with the ball electrode was sometimes not well correlated with the optical signals. On several occasions the optical signals disappeared even though there was little change in the ball electrode signal. The optical signals returned following the readdition of bicuculline to the cortex. Optical recording appears to provide detailed information about the location and propagation of epileptiform discharges.

103.8 RAPID CESSATION OF FOCALLY-INDUCED GENERALIZED SEIZURES IN THE RAT VIA DIRECT ANESTHETIZATION OF THE FOCUS. Douglas C. Smith and Ronald A. Browning, Department of Psychology and School of Medicine, Southern Illinois University-Carbondale, Carbondale, Illinois 62901-6502

In this report we will demonstrate the rapid cessation of behavioral and electroencephalographic (EEG) seizures induced by application of bicuculline into the deep prepyriform cortex (DPC) or hippocampus (HC) of the rat. Such rapid cessation is accomplished via infusion of 2% lidocaine hydrochloride into the focal discharge area. While lidocaine delivered intraveneously is well-known to produce seizures, direct application of lidocaine into neural tissue produces a complete, and reversible, cessation of all action potentials in neurons to which it is applied. This is due to the blocking of sodium channels caused by this local anesthetic.

In eight Long-Evans hooded rats, we delivered 1.0 µl of 100 ng/µl bicuculline (BIC) unilaterally into the DPC through an implanted cannula. As has been reported by Piredda and Gale (1986), such infusion initiates seizures which begin unilaterally and increase in intensity to bilateral clonus with rearing and falling (Stage 5 on Racine's [1972] scale). As soon as the seizure became generalized, 1.0 µl of 2% lidocaine was infused unilaterally at a maximum rate of 1 µl/min. In all cases, behavioral seizures were stopped (Racine Stage 0) within 30 seconds following infusion of lidocaine. Saline infusion had no effect on these BIC induced seizures. EEG recordings indicate a return to pre-BIC baselines following lidocaine, but not saline.

In four additional rats, wet dog shakes were produced via unilateral BIC infusion into the HC. During BIC the mean number of wet dog shakes/min was 5.9. For the minute following administration of lidocaine, $\bar{X} = 0$.

In summary, we have shown that infusion of the local anesthetic, lidocaine, into a focal discharge area rapidly terminates behavioral and EEG generalized seizures which are induced by focal application of bicuculline. We are currently exploring whether lidocaine will arrest focally-induced generalized seizures when other methods of inducing such seizures are employed. If this proves to be the case, the delivery of lidocaine into a focal discharge area, once we perfect the technology, may hold promise for the control of seizures in human epileptics which are unresponsive to conventional anticonvulsant drug therapy.

103.9 DECREASED NEUROTRANSMISSION IN HIPPOCAMPAL-SUBICULAR PATHWAYS OF HUMAN TEMPORAL LOBE EPILEPSY. M. Isokawa-Akesson, C.L. Wilson and T.L. Babb. Brain Research Institute and Department of Neurology, UCLA, Los Angeles, CA 90024-1761.

Although studies in both animal models (Wong & Traub, J. Neurophysiol., 49:442,1983) and humans (Prince & Wong, Brain Research, 210:323, 1981; Schwartzkroin & Haglund, Epilepsia, 27:523, 1986) have characterized the way hippocampal bursts were altered under conditions of epilepsy, how epileptic properties expressed by individual neurons propagate into seizures remains unknown. The present study was designed, in chronic temporal lobe epilepsy patients, to investigate interictal physiological characteristics of an existing limbic pathway, i.e. the hippocampal-subicular path, using electrical stimulation to test for response-differences in normal and epileptic connections. The hypothesis tested was that the presubicular (PRESUB) neurons activated by stimulation of epileptic hippocampus (HC) would exhibit "hyperexcitability" compared to PRESUB neurons activated from non-epileptic HC.

In vivo extracellular single units were recorded bilaterally from 56 HC and 41 PRESUB neurons in 17 patients with a unilateral HC epileptic foci. Neurons located in the hemisphere contralateral to epileptic foci were considered as normal and used as a comparison control. In epileptic HC, burst firings were observed with high probability, and the pattern of those bursts were found to be stereotyped using auto-correlation analysis. Synchronized firings were also characteristic of HC bursting neurons as previously reported in human epileptic amygdalae (Isokawa-Akesson, et al. Epilepsy research, 1:17, 1987). In contrast, PRESUB neurons neither fired as a burst nor showed synchronized firings even though they were located near the HC epileptic focus. Single electrical stimulation (0.1Hz) to non-epileptic HC evoked responses of initial excitation followed by inhibition in 40% of the PRESUB neurons, which agrees with the intracellular responses in rat subiculum following HC stimulation (Finch et al., Brain Research, 197:11, 1980). However, electrical stimulation of epileptic HC failed to evoke any response in PRESUB neurons (0 of 20). Within the epileptic HC, however, 25 of 54 neurons responded with excitation-inhibition to local epileptic HC stimulation, indicating the stimulus strength was effective and that the cell-poor HC is not electrically inexcitable. Furthermore, the PRESUB neurons near the epileptic HC were equally activated by stimulating locally or stimulating parahippocampal gyrus.

The present results demonstrate that, in the interictal period, the epileptic hippocampal outputs to cytologically-normal PRESUB (Babb et al., Epilepsia, 25:729, 1984) appear to be poorly transmitted, possibly due to HC sclerosis and its own restructured (Davenport & Babb, NS Abstr. 343, 1986) epileptic circuitry.

103.10 DIFFERENT THALAMOCORTICAL EXCITABILITY PATTERNS UNDERLYING STATE DEPENDENT SEIZURES IN FELINE MODELS OF PETIT MAL AND TEMPORAL LOBE EPILEPSY. M.N. Shouse.* (SPON: M.B. Sterman). Lab. of Sleep Disturbance Res., VA Med. Ctr., Sepulveda, CA 91343 and Dept. of Anatomy, UCLA Sch. of Med., Los Angeles, CA 90024.

Little is known about neural mechanisms underlying the important relation between biorhythms and epilepsy. This report summarizes three studies in cats suggesting thalamic mediation of sleep-activated seizures in the amygdala kindling model of secondary generalized temporal lobe epilepsy; in contrast, cortical hyperexcitability was implicated in the timing of "absences" and generalized tonic-clonic convulsions in the systemic penicillin model of primary generalized petit mal epilepsy. Amplitudes of centrally evoked neural responses in ventral lateral thalamus and motor cortex provided indices of thalamic and motor cortex excitability, respectively, in 18 cats. Six cats were kindled, six received 300,000 or 400,000 IU/kg sodium penicillin G intramuscularly, and six cats were nonepileptic.

Major results were: 1) During kindling, thalamic excitability increased with seizure generalization from the limbic system, especially during slow-wave-sleep (SWS) and transitions from SWS to rapid-eye-movement sleep when seizure susceptibility is highest in this model; cortical excitability accompanied penicillin epilepsy, particularly during SWS and drowsiness after awakening when vulnerability to these seizures peaks. 2) Sleep deprivation (24h) exacerbated seizures and increased thalamocortical excitability nonspecifically. 3) A temporal lobe anticonvulsant (carbamazepine) suppressed thalamic excitability and generalized seizures in kindled cats, whereas a petit mal anticonvulsant (ethosuximide) suppressed only cortical excitability and penicillin epilepsy.

The data suggest that thalamocortical excitability provides a final common pathway for the expression of sleep-waking state dependent generalized seizures. The results may also explain consistent sleep deprivation and differential anticonvulsant drug actions in these two quite dissimilar seizure models.

103.11 MORPHOLOGICAL ANALYSIS OF THE TEMPORAL LOBE OF AN EPILEPTIC PATIENT WITH A TUMOR IN THE ENTORHINAL CORTEX: NEUROTRANSMITTERS AND ELECTRON MICROSCOPY. C.E.Ribak[1], S.H.C.Hendry[1], E.G. Jones[1], B.H. Choi[2], J.W. Geddes[3], C.W. Cotman[3] and L.D. Cahan*[4]. Depts. of Anatomy and Neurobiology[1], Pathology[2], Psychobiology[3], and Surgery[4]. Univ. of California, Irvine, CA 92717.

A four year old girl with intractable epilepsy had a tumor removed from her left temporal lobe to stop her seizures. The brain tissue was blocked at the time of removal into small pieces that contained the hippocampal formation and associated parahippocampal structures, and it was immersed into fixative for light and electron microscopic preparations. Frozen sections (40 um thickness) were processed for Nissl staining and immunocytochemical localization of GABA, cholecystokinin, substance P and neuropeptide Y. In addition, Vibratome sections (100 um thickness) were dissected so that identified regions of the temporal lobe were embedded in plastic for electron microscopy. Light microscopy revealed a ganglioglioma in the entorhinal cortex where pyramidal cell bodies were apposed by tumor cells. The dentate gyrus displayed a decrease in the number of granule cells whereas the CA1 region (Sommer's sector) was devoid of virtually all pyramidal cells. In contrast, CA3 appeared normal. Cortical interneurons labeled in the immunocytochemical preparations were decreased in the entorhinal cortex and dentate gyrus. However, the basket plexus of axon terminals was labeled in CA3 but not in CA1 where the pyramidal cells were lost.

Electron microscopic observations have been limited to the dentate gyrus and hippocampus. The granule cells of the dentate gyrus were enveloped by profiles of reactive astrocytes. The terminal axons of granule cells, the mossy fibers, were rarely observed in the hilus and stratum lucidum of CA3. Very few axosomatic symmetric synapses were found whereas asymmetric axodendritic synapses were more numerous in the adjacent neuropil. Pyramidal cells in CA3 displayed numerous axodendritic asymmetric synapses. Many spines were compressed into dendritic shafts by the radially-oriented glial processes. Expanded, watery dendrites were also found. These dendritic observations are consistent with previous Golgi results that showed reduced numbers of spines and the presence of dendritic nodulations. Terminals of the basket plexus were packed with synaptic vesicles and were also compressed against the somata of pyramidal cells by glial processes. Finally, CA1 displayed only a few pyramidal cells and they contained many large dense-core (autophagic) vesicles in their perikaryal and dendritic cytoplasm. These remaining neurons in CA1 were encapsulated by glia and may be involved in the early stages of degeneration. These findings suggest that the most severe degeneration of neurons in the hippocampal formation occurs in CA1 and the dentate gyrus, the regions that receive the most excitatory afferents. The presence of some interneurons in these regions may indicate that they are more resistant to the excitotoxic effects of these afferents, including those from entorhinal cortex. This work was supported by NIH grants NS 15669, ES 02928 and NS 22317.

103.12 HIPPOCAMPAL SOMATOSTATIN, CCK, AND VIP LEVELS IN PATIENTS WITH TEMPORAL LOBE EPILEPSY. R.J. ROBBINS, T. ADRIAN*, N. de LANEROLLE, J. KIM*, S. HALVONIK* and D. SPENCER (SPON: S.Spencer). Sections of Neuroendocrinology and Neurologic Surgery, and The Yale Epilepsy Center, Yale Univ. School of Medicine, New Haven, CT 06510

The presence of peptide containing interneurons in various limbic structures has been well established in many species. Receptors for these peptides, and specific electrophysiologic effects have been demonstrated. Since immunohistochemical methods have localized such interneurons in hippocampal fields, where they may modify ongoing electrical activity we hypothesized that levels of specific peptides would be altered in states of abnormal electrical activity. We measured three neuropeptides, known to be present in the human hippocampus, in patients with medically refractory complex partial seizures (CPS) who were undergoing medial temporal lobectomy. As soon as the hippocampus was removed intact from the surgical field it was cut coronally into 2-3mm slices which were rapidly frozen and kept for up to 2 weeks at -80C. Slices were then allowed to warm to -10C and punch biopsies of various hippocampal regions were made using a dissecting microscope. Tissue was weighed, boiled in water, acidified, sonicated, centrifuged and the supernatants were stored at -80C until radioimmunoassay. Controls included tissue removed from patients dying of non-neurologic causes (NC), and tissue removed from patients with epilepsy due to glial tumors of the temporal lobe (TC). In the dentate granule cell layer, and in the CA4 field we found a significant reduction of immunoreactive somatostatin (IRS) in the CPS patients compared to NC or TC. No such changes in CCK or VIP were present. In the CA1 region IRS in TC was increased compared to CPS patients or NC. CCK levels in CA1 were much higher in both CPS patients and TC than in NC. VIP levels in CA1 were similar in all groups. No significant differences in peptide levels have been detected in the subiculum or entorhinal cortices to date. We conclude that specific alterations of somatostatinergic and CCK-ergic interneurons are occuring in the hippocampal regions of patients with epilepsy. Whether these changes are important in the pathophysiology of the seizures or simply reactions to the abnormal electrical signals remains to be determined.

PROCESS OUTGROWTH: GROWTH CONE BEHAVIOR

104.1 TURNING OF *APLYSIA* GROWTH CONES AT SUBSTRATE BORDERS *IN VITRO*. D.W. Burmeister and D.J. Goldberg, Dept. of Pharmacology, Columbia Univ. College of Physicians & Surgeons, N.Y., NY 10032.

Cultured *Aplysia californica* neurons can extend axons on either poly-lysine treated or untreated glass coverslips. When they are confronted with a border between the two, however, growth cones approaching from the treated side will turn and continue to grow only on the poly-lysine side. Recently we have em - ployed video enhanced contrast - differential interference contrast microscopy to examine, in detail, the behavior of growth cones on homogeneous substrates (Goldberg, D.J. & Burmeister, D.W., J. Cell Biol. 103:1921, 1986). We ob - served that growth always took place through the same sequence: vesicle-free veils formed between filopodia, these were invaded by vesicles from the growth cone center, and the veil was progressively transformed into the growth cone center. The growth cone center, in turn, rounded into the axon cylinder. Because substrate cues are thought to play an important role in directing neurite growth *in vivo* we were curious to observe how this developmental sequence was modified as growth cones approached and turned at a defined substrate boundary.

Turning neurites advanced through the same sequence observed previously. Turning occurred because the growth cones upon reaching the border generally started to split, developing two separate active growth areas, areas where new filopodia and veils formed. This behavior was similar to that seen when neurites branched at substrate obstructions. At the borderline, if one of the active areas extended onto treated and the other onto untreated glass, both areas usually continued to advance for a time, but the regions growing on the untreated glass would eventually, without initially losing adhesive contact with the substrate, wither, dying back to the point where the growth cone had originally split. Growth cones that approached the border at angles where both active regions formed on glass, stopped growing and eventually withered entirely, retracting back to a previous branch point, even if this was well back from the substrate boundary. Turning was not the result of differential filopodial adhesion. Because new filopodia tended to be at the front of approaching growth cones, and because growth cones tended to initially grow beyond the substrate boundary, often more filopodia were attached to the untreated substrate than the treated substrate during the early stages of turning.

Neurite turning was largely the result of asymmetric regression of developed areas of the growth cone, rather than asymmetric elongation. The selective re - gression of branches was competitive in that growth cones, or active areas, could survive and advance on untreated glass, but only if nearby areas or branches were not growing on the treated side. Both because of its competitive nature, and because withering occurred back to the branch point, growth cone turning may be analogous to, and may share mechanisms with, the pruning of exuberent branches seen during many stages of neural development.

104.2 LOCAL EFFECTS OF CALCIUM IN VEIL FORMATION AND MAINTENANCE IN APLYSIA GROWTH CONES IN VITRO. D.J. Goldberg. Dept. of Pharmacology, Columbia U. Coll. of P. & S., N.Y., NY 10032.

Our recent observations of the growth cones of Aplysia neurons in vitro using high resolution video microscopy have defined stages in the growth of an axon (Goldberg, D.J. and D.W. Burmeister, J. Cell Biol. 103:1921, 1986). Initially, there is protrusion on a filopodial framework of an organelle-free veil of membrane, followed by the morphological transformation in place of this veil eventually into the neurite. The filopodia clearly direct the growth of the neurite by defining the pathway along which veil protrudes, but it is unclear what causes veil protrusion or what determines along which of many filopodia the protrusion will occur.

The possibility of the involvement of Ca^{++} in the formation or maintenance of veils in Aplysia growth cones in vitro was investigated using video microscopy. Reduction of $[Ca^{++}]_o$ from the normal concentration of 11 mM to 0.3 - 20 μM through the use of Ca^{++} - EGTA buffers caused retraction of veils within minutes without visibly affecting filopodia or the bidirectional transport of membranous organelles in the neurite. Reduction of $[Ca^{++}]_o$ to 0.2 - 1.3 mM (without EGTA) usually, though not always, caused veil retraction. Addition of 20mM Co^{++}, which blocks Ca^{++} channels, to a solution containing the normal $[Ca^{++}]_o$ also caused rapid veil retraction. Perfusion with normal medium after any of the aforementioned treatments usually caused reformation of veils. Ba^{++}, which is known to readily permeate Ca^{++} channels, could substitute for Ca^{++} in causing veil reformation. Concentrations of trifluoperazine which should block calmodulin- and protein kinase C-dependent protein phosphorylation and concentrations of calmidazolium which should block only the former both caused veil retraction. Taken together, these data indicate that Ca^{++} plays a role in veil formation and maintenance, perhaps via calmodulin, and that, in these Aplysia neurons in vitro, substantial influx through the Ca^{++} channel is needed to maintain the requisite $[Ca^{++}]_i$ for this role. Whether changes in $[Ca^{++}]_i$ normally act as the trigger for veil formation is unclear.

Evidence was also obtained that Ca^{++} acts quite close to the site of veil formation. Microelectrodes containing either 1M $CaCl_2$ (for diffusion or iontophoresis) or 20 mM Ca^{++} in medium (for puffing) were moved to within a few μm of large (>10 μm) growth cones in low Ca^{++} medium. When veils formed in response, they were almost always restricted to the filopodia close to the orifice of the microelectrode (which was usually no larger than the space between neighboring filopodia). This suggests that, if veil protrusion is triggered by Ca^{++}-dependent exocytotic membrane addition, this occurs at or near the site of protrusion and determines where on the growth cone protrusion occurs.

104.3 PROPERTIES OF THE RETROGRADE MICROTUBULE-BASED TRANSLOCATOR FROM SQUID AXOPLASM. B.J. Schnapp, T. Schroer, M.P.Sheetz, and T.S. Reese. Laboratory of Neurobiology, NINCDS, NIH, at the Marine Biological Laboratory, Woods Hole, MA. 02543.

Two microtubule-based translocators have been identified in squid axoplasm and implicated in rapid axonal transport. Kinesin is a 600 kd, soluble protein thought to promote vesicle movement in the anterograde direction by associating with appropriate organelles and promoting their translocation along microtubules; the retrograde translocator is a different protein first identified in Triton extracts of low speed axoplasmic supernatants by examining bead movement on an oriented population of microtubules in vitro (Vale et al, Cell 43: 623, 1985). We now show that the retrograde activity is present in high speed, soluble supernatants from axoplasm in the absence of Triton, indicating that some of the retrograde protein, like kinesin, is in a soluble form in the axoplasm. The soluble retrograde activity appears to be part of a large complex because it can be separated from kinesin activity by sedimentation for 45 min in an airfuge; the resuspended pellets show retrograde activity. SDS-PAG electrophoresis of the soluble axoplasmic supernatant before and after the airfuge spin indicates that most proteins are not sedimented under these conditions. When supernatants containing retrograde activity are exposed to AMP-PNP in the presence of microtubules (conditions which promote tight binding of kinesin to microtubules and which provided the means for first purifying kinesin), no retrograde activity is recovered after the supernatant is desalted into ATP-containing buffer. Thus, a number of high molecular weight proteins, which we have suspected to participate in retrograde movement because of their AMP-PNP dependent binding to microtubules, are ruled out as retrograde factors. The role of the retrograde activity in organelle transport still remains unclear, as suggested by the following experiments. Soluble supernatants from squid axoplasm support both anterograde and retrograde movement of salt-stripped organelles as well as bidirectional bead movement. When these supernatants are depleted of kinesin using a monoclonal affinity resin specific for the 110 kd subunit, retrograde but not anterograde bead movement remains; movement of salt-stripped organelles in both directions, however, is lost. This suggests that the retrograde translocator by itself can not support organelle movement and that kinesin (which mediates the movement of beads in the anterograde direction only), or some protein binding to kinesin, is required for retrograde organelle movement.

104.4 PRUNING OF HIPPOCAMPAL PYRAMIDAL NEURON DENDRITIC ARCHITECTURE IN VITRO BY GLUTAMATE AND A PROTECTIVE EFFECT OF GABA PLUS DIAZEPAM. M. P. Mattson, P. Dou* and S. B. Kater. Program in Neuronal Growth & Development, and Dept. of Anatomy, Colorado State Univ., Ft. Collins, CO 80523

Glutamate is believed to be the major excitatory amino acid (EAA) neurotransmitter, and GABA the major inhibitory transmitter impinging upon hippocampal pyramidal neurons (HPN). In the hippocampus, glutamate, acting at synapses on HPN dendrites, is believed to be involved in a variety of normal and pathological processes including: learning and memory, epilepsy, Alzheimer's disease, and stroke. In each of these cases neuroarchitectural changes have been documented. In the present study we tested the possibility that interactions of **excitatory and inhibitory neurotransmitters can regulate the outgrowth status of pyramidal neurons**; these experiments were based upon preceding studies in Helisoma neurons which revealed roles for neurotransmitters in the regulation of neurite outgrowth (Science 226:561). Isolated, cultured HPN (obtained from 18 day rat fetuses) in which the axon and dendrites are morphologically distinct were used to demonstrate a new role for EAAs and GABA in the regulation of hippocampal architecture.

Glutamate selectively pruned, in a dose-dependent manner, the dendritic arbors of these neurons. With increasing concentrations of the EEAs glutamate, kainic acid (KA), and quisqualic acid (QA) we observed the following graded sequence of morphological changes in HPN: 1) Dendritic elongation was suppressed; axonal elongation was unaffected (10 uM glutamate). 2) Dendritic retraction; axons unaffected (50 uM glutamate). 3) Dendritic retraction; suppression of axonal elongation (100 uM glutamate); under these conditions cell death was often induced which occured over a period of 6 to 24 hr. 4) Rapid cell death ($\leq$ 1 hr) with somal swelling and process fragmentation ($\geq$ 1 mM glutamate). Outgrowth was insensitive to mM concentrations of N-methyl-D-aspartic acid (NMDA). The effects of the EAAs were prevented with the general glutamate antagonist d-gamma-glutamylglycine but not with the NMDA receptor-specific antagonist DL-2-amino-5-phosphonovaleric acid suggesting mediation by receptors of the KA/QA types. Co^{2+} (100 uM) prevented both the dendritic pruning and cell death induced by glutamate, KA, and QA. Furthermore, the calcium ionophore A23187 caused dose-dependent graded process retraction in HPN (100 nM - 1 uM) and was toxic at high levels ($\geq$ 10 uM). Calcium influx thus appears to play an important role in mediating the EAA effects on neuroarchitecture. Given these negative effects of EAAs on dendritic outgrowth, we next examined the effects of the inhibitory neurotransmitter GABA alone or in combination with glutamate on the outgrowth of HPN. GABA alone ($\leq$ 100 uM) had no significant effect on dendritic or axonal elongation. Neither did GABA alter the ability of glutamate to selectively prune dendrites. However, the combination of GABA (10 uM) and the benzodiazepine Diazepam (10 uM) was able to prevent the dendritic pruning and cell death caused by glutamate.

Taken together, these findings suggest roles for excitatory and inhibitory neurotransmitters in the regulating the growth status of neurons in the mammalian brain. The graded pruning of dendrites of isoalted HPN in response to increasing levels of EAAs is strikingly similar to the graded reductions in HPN dendrites seen in the brains of patients with increasing severities of epilepsy and Alzheimer's disease. Our finding that Diazepam is effective in countering the neurodegenerative effects of EAAs in HPN suggests that such inhibitory agents might be effective in preventing the kind of dendritic pruning of HPN associated with various neurodegenerative disorders. (Supported by NIH grants NS 08054 [MPM]; NS 24683, NS 2456, NS 15350 [SBK]).

104.5 GROWTH CONE-TARGET CELL INTERACTIONS IN DEVELOPING CEREBELLUM IN VITRO. C.A. Mason, J. Sanchez*, and M.E. Hatten, Dept. of Pharmacology, New York University School of Medicine, New York, NY 10016.

One of the tasks of the axonal growth cone is to select and make synapses with specific target cells. We have developed a model culture system, using mouse cerebellum, to characterize growth cone behavior, membrane appositions, and synaptic morphology during axon-target cell interactions.

Two afferent systems (mossy and climbing fibers) derive from separate brainstem sources (pontine and inferior olivary nuclei, respectively) and in mature brain contact granule cells or Purkinje cells, respectively. Granule neurons and Purkinje cells were purified into highly homogeneous cell populations by gradient separation and preplating, and plated as microcultures (30 µl) on polylysine-coated coverslips, in medium containing horse serum and FGF (Hatten, '85, JCB 100:384; Hatten et al., '87, SfNA). Olivary and pontine nuclei were excised from brain slices and subdivided into small chunks, which were placed as explants onto a sparse monolayer of their appropriate target cells. Within 24-36 hrs, neurite outgrowth from the explant is profuse, and target cells extend neurites. During this period, we focused on growth cones about to approach target cells. Neurites were identified as being afferent by either following them back to the explant, or by injecting the explant with HRP or rhodamine. Target cells were identified by specific antigen markers and by characteristic morphology.

The behavior of growth cones as they associate with target cells was monitored in real time with video-enhanced differential interference contrast optics, coupled with a time-lapse optical memory disc recorder. When a growth cone meets a target cell, within minutes, filopodia and ruffles on both the growth cone and target cell actively extend and withdraw. Filopodia from each cell often appear to be continuous. Such interactions precede either growth cone binding to, or withdrawal from, the target cell. After a growth cone forms a stable attachment to a cell via filopodia and veils, other projections extend and further probe the cell. We are currently determining the time course from first interactions to stabilization of contacts, by performing a periodic time-lapse study. The cytology, membrane interactions and synaptic morphology of identified growth cones will be analyzed in the EM and with antisera to synaptic vesicle antigens.

This model system forms an assay for future studies on the molecular basis of target cell selection and synapse formation. (Supported by NIH grants NS-16951 and NS-21457).

104.6 AXON INGROWTH AND TARGET CELL INTERACTIONS IN DEVELOPING CEREBELLUM. S. Catalano* and C.A. Mason, (SPON:L.A. Greene), Dept. of Pharmacology, New York University School of Medicine, New York, NY 10016.

During the assembly of neural circuitry, different groups of axons enter target regions and interact with specific populations of target cells. Demonstration of the temporal and spatial features of axon-target cell interactions has been impaired by the difficulty of labeling identifed immature afferents and localizing target cells, particularly before cell migration is completed. To address this issue, we have a) labeled cerebellar afferents (mossy and climbing fibers) from their brainstem sources (pontine and inferior olivary nuclei respectively), with rhodamine, a dye that densely labels axons and their growth cones over a long distance, and b) localized Purkinje cells, the target cell of climbing fibers, with antisera to the 28,000 M_r vitamin D-dependent calcium binding protein (gift of S. Christakos, NJ Med. Sch., Newark), which selectively stains Purkinje cells, including dendrites and growth cones.

At birth, climbing fibers extend well into the cerebellar anlage, reaching to the external granule cell layer as relatively unbranched fibers tipped by small growth cones. Purkinje cells are either still migrating into position, or have grouped in a multi-layered tier, and bear radiating somatic processes and growth cones. The majority of pontine mossy fibers at this age are just entering the cerebellum, and also have a simple shape, but have larger growth cones. There is considerable overlap in the projection of both axon groups at P2-3. By P3-4, climbing fibers form profuse finely branched arbors that extend laterally over several Purkinje cells, which now form a more condensed multilayered tier. Mossy synaptic boutons within the granule layer become enlarged, and some mossy fibers send fine branches into the Purkinje cell zone, that are tipped with climbing fiber-like endings. This latter finding confirms our original prediction that such HRP-labeled fibers derive from a mossy source (Mason and Gregory, '84, J. Neurosci. 4:1717). At P5 climbing fibers that have focused onto individual Purkinje neurons with a 'nid' formation, do so on Purkinje cells that have settled into a monolayer.

These first observations raise several issues: the placement and role of afferent axons during migration of their target cells; the relationship of axonal exuberance to the multiple layering and somatic protrusions of target cells; the rationale for mossy fiber projections to the Purkinje cell layer. Experiments are in progress to label cerebellar afferents and to localize Purkinje cells at embryonic ages, to further understand the whereabouts and morphology of immature axons and target cells, and their early interactions. (Supported by NIH grant NS 16951).

104.7 INFLUENCE OF SUBSTRATE ON THE DISTRIBUTION OF CALCIUM CHANNELS IN SPROUTS OF IDENTIFIED LEECH NEURONS IN CULTURE. H. Arechiga, J.G. Nicholls, and W.N. Ross, CINVESTAV-IPN, Mexico 14, D.F. Mexico, Biocenter, Basel 4056, Switzerland, and Dept. of Physiology, New York Medical College, Valhalla, N.Y. 10595.

When leech neurons are plated on two different substrates, the plant lectin Con A and an extract of extracellular matrix (ECM), they grow very differently (Chiquet and Acklin, PNAS 83: 6188-6192, 1986): on Con A the sprouts are thick with broad flattened growth cones; on extract the sprouts are long, straight, extremely fine, and branched. The aim of the present experiments has been to determine whether these two substrates have different effects on membrane properties, particularly the distribution of calcium channels.

A mixture of arsenazo III (a sensitive indicator of calcium concentration changes) and Lucifer Yellow (to indicate membrane area) was injected into the soma of an identified neuron and allowed to diffuse into the fine processes. The cell was imaged onto a 10x10 array of photodiodes and each element detected changes in light intensity at 660nm corresponding to changes in intracellular calcium. Each array element detected calcium changes in an area 40x40 um^2. Earlier work with cells on Con A (Ross, Arechiga, and Nicholls, J. Neurosci., in press) had shown that calcium entry following impulses was pronounced in the soma and initial segment but rarely detectable in thick processes or broad flat growth cones. These results have now been confirmed. By contrast, the same types of cells (Retzius, P, or AP) grown on ECM extract showed clear calcium signals, not only over the cell bodies and initial segments but also over the slender processes. The membrane area was far smaller than that for processes on Con A. The amplitudes of the calcium signals are proportional to the number of calcium channels in each pixel. Hence, the larger calcium signals and smaller membrane area on ECM extract imply a greater density of calcium channels. These results indicate that the laminin-like molecules of the ECM extract which neurons of the CNS contact in situ can have pronounced effects on the distribution of calcium channels.

We thank Ms. H. Niederer for excellent technical assistance. Supported by USPHS grant NS16295 and the Whitaker Foundation (WNR), and the Swiss National Fund and the U.S. Navy (JGN).

104.8 ANALYSIS OF GROWTH CONE MORPHOLOGY AND AXONAL BRANCHING IN INITIAL LIMB INNERVATION. M. Hollyday, Bryn Mawr College, Bryn Mawr, PA, 19010.

Previous studies have demonstrated that motor axons grow to the periphery with a high degree of precision. It is not known how axons make these accurate pathway choices. One possibility is that axons are guided by specific chemotrophic cues. An alternative mechanism of axon guidance might involve branching at the growing tip and maintenance of only those portions of the growth cone in contact with a suitably adhesive substrate. In order to gain insight into this issue in vivo, anterograde transport of WGA-HRP was used to selectively label individual axons and their associated growth cones during the stages of initial innervation of the chick embryo wing (stages 17-28). Labeled axons were studied with the light microscope in 40-60 µm thick sections reacted with DAB and intensified with cobalt. Axon identity was determined either directly by tracing into the ventral root or the dorsal root ganglion, or indirectly by inferring from the HRP injection site. More than 300 axons and their associated growth cones were reconstructed and drawn with a camera lucida.

Both motor and sensory axons terminated in growth cones which could be classified as either filopodial, lamellopodial, lamellopodial with associated filopodia, or club shaped. No blunt or rounded growth cones were observed at the ends of axons except in the "waiting zone" at the base of the dermomyotome, and even here they did not predominate. Many lamellopdial growth cones had complex shapes and were divided in ways which suggested the incipient formation of branches. Branched axons, terminating in two or more separate growth cones separated by axon segments as long 50-70 µm, were observed at all stages examined. These were found distributed all along the outgrowth pathway, from the ventral root or dorsal root ganglion, to the spinal nerve, in the plexus region, and further distally in the limb bud. Identification of "branched" axons (as opposed to divergence of two tightly fasciculated axons) was based on the presence of a distinctive triangular or "tricorne" shaped structure. The frequency of axon and growth cone branching was higher in decision regions than along spinal nerve pathways or in nerve trunks in the limb bud. The decision regions examined most thoroughly were in the limb plexus region and proximally in the ventral nerve pathways where n. pectoralis diverges from n. inferior brachialis, and where n. inferior brachialis splits into median and ulnar nerves. Similar patterns of growth cone and axon branching were observed among both identified sensory and motor axons in the same decision regions.

Examination of the labeled material revealed beaded and even fragmented, apparently degenerating, axons and growth cones among both motor and sensory populations in decision and non-decision regions alike. It is unlikely that these structures resulted from HRP cytotoxicity since other axons and growth cones in the same or adjacent sections appeared perfectly healthy. Rather they may be the remnants of inappropriately directed exploratory growth cones and axonal branches. Taken together, these observations suggest that one important determinant of accurate pathfinding is the formation of exploratory growth cones which not infrequently produce axonal branches. The mechanisms which act to select and maintain an appropriately directed branch and to withdraw inappropriately directed branches are presently unknown.

104.9 INTRINSIC POSITIONAL INFORMATION GUIDES THE EARLY FORMATION OF THE RETINOTECTAL PROJECTION OF XENOPUS. S. E. Fraser. Dept of Physiology & Biophysics, University of California, Irvine, CA 92717.

The lower vertebrate visual system has served as an important testing ground for the cellular processes that underlie patterned neural connections. A wide range of evidence is consistent with a role for cell-autonomous positional cues in the shaping of the retinotectal projection, but definitive tests have not been possible. The work presented here provides a test of this proposal by demonstrating that single retinal cells can project appropriately to the tectum, even when grafted to inappropriate regions of the eyebud.

The experiments use the axonal transport of fluorescent dextrans to follow the patterning of retinotectal connections in living, intact Xenopus embryos and larvae (O'Rourke & Fraser, Dev Biol 114:265). Lysinated fluorescein dextran (LFD) or lysinated rhodamine dextran (LRD) was injected into a fertilized egg, the animals were allowed to develop to eyebud stages, and were then used as donors for embryonic grafts of eyebud tissue to unlabeled hosts. The labeled optic nerve fibers arising from the grafted eyebud cells were then followed in the intact animal using epifluorescence microscopy. A refinement of this technique permits grafts of as few as one cell from each of the labeled donor animals. In animals with small grafts, individual optic axons and their growth cones were clearly visible, and the terminal arbors were easily distinguished from the axons leading to the terminal arbors.

In this set of experiments, LRD and LFD labeled cells were grafted to a single unlabeled host in either an equivalent location to which they were removed (homotopic grafts) or to non-equivalent locations (heterotopic grafts). The grafting of both LFD and LRD labeled cells to a single host permitted unambiguous evaluation of the topography of the projection. The animals were then raised either in the dark or in light filtered to remove wavelengths that could bleach the fluorescent dyes.

The results from homotopic grafts were in agreement with our previous work on labeled half-eye grafts. Homotopic dorsal and ventral grafts projected to the ventral and dorsal tectum at all stages examined. Homotopic anterior and posterior grafts initially projected indistinguishably, and then slowly sorted into a topographic order by stage 48.

Axons from heterotopic grafts always behaved in a fashion appropriate for their position of origin in the donor, independent of their final position in the host. Donor-specific behavior persisted under all conditions examined, including: 1. dark rearing, 2. light rearing, 3. grafts performed in "full-strength" embryological medium, 4. grafts performed in dilute artificial pond water, 5. grafts performed in artificial pond water intentionally titrated to an inappropriate pH (from pH6.5 to pH8). The results from grafts performed on animals ranging from stage 26 to stage 34 were indistinguishable, and the topography of the projection remained stable until at least stage 52.

These observations indicate that small groups of eyebud cells (as small as a single cell) possess positional information that helps to guide the optic nerve fibers to the correct site in the tectum. This positional information can be autonomously expressed and acted upon even when the cells are confronted with inappropriate neighbors. (Supported by NSF and the McKnight Found.)

104.10 CHANGES IN OPTIC FIBER MORPHOLOGY DURING DEVELOPMENT. N. A. O'Rourke , B. E. S. Fox and S. E. Fraser. Dept. of Physiology & Biophysics, Univ. of CA, Irvine, CA 92717.

In the lower vertebrate visual system, the axons of retinal ganglion cells form a topographically ordered projection in the tectum. The optic fibers respond to a number of different cues in the tectal environment during both development and regeneration of this ordered projection. A common link in these interactions is the ability of fibers to respond to these cues by extending and retracting branches and changing their position within the tectum. Neuronal activity appears to be involved in dynamic refinement of the projection during regeneration. In this study, we have investigated the role of neuronal activity in a similar refinement process which occurs during the initial formation of the topographic projection in *Xenopus* tadpoles. In addition, we have evaluated the role of dynamic changes in the morphology of individual retinal ganglion cell axons in the tectum during early fiber ingrowth as well as later stages of development.

We have utilized the fluorescent vital-dyes, fluorescent dextrans, to directly visualize dynamic changes in the retinotectal projection in live *Xenopus* larvae over a period of weeks. In a recent study, we described the technique and used it to follow the initial anteroposterior patterning of the projection. Fibers from nasal and temporal poles of the eye first overlapped in the tectum and then sorted out into the normal topographic pattern over a period of days (O'Rourke & Fraser, Dev. Bio., 1986). We have used this early refinement paradigm to test the role of neuronal activity in the initial development of topographic order. From other studies, we have results suggesting that glutamate is the primary neurotransmitter in the *Xenopus* retinotectal system (Fox & Fraser, Neur. Sci. Abst., 1987). Tadpoles which had recieved grafts of fluorescently labeled nasal and temporal retinal ganglion cells were reared in solutions of agonists and antagonists of NMDA-type glutamate receptors. These treatments block visually-evoked activity in the tectum. Preliminary results show that perturbing the NMDA class of glutamate receptors in this way delays the onset of the initial segregation of optic fibers.

To further investigate dynamic behavior in the retinotectal projection, we have refined the fluorescent dextran technique to follow changes in the morphology of single optic fibers in the tectum. In a parallel approach, the fluorescent carbocyanine dye, diI, was also used. In both cases, the dyes label the axons completely and diffusely, permitting visualization of terminal branches and growth cones of single fibers. An image intensifying camera and image processing system have allowed us to observe the fibers several times over a period of a week or more without phototoxic effects on the fibers. Morphological changes in the optic nerve terminal arbors were observed not only during initial ingrowth of the younger fibers into the tectum but in older fibers as well. These observations support the idea that axons display dynamic behavior during early stages and then maintain this behavior during later development.(NSF Grant BNS 8608356).

104.11 DISTRIBUTION OF IPSILATERALLY-PROJECTING AXONS IN *XENOPUS* OPTIC NERVE. S.G. Hoskins. Dept. of Biol. Sci., Columbia Univ., NY, NY 10027.

The ipsilateral retinothalamic projection in *Xenopus* is formed during metamorphosis by axons of a subset of ganglion cells which lie interspersed with contralaterally-projecting cells in the retina. The development of the ipsilateral projection is thyroxine-dependent (Hoskins and Grobstein, *Nature 307*: 730, 1984), and contralateral projections to the thalamus and tectum are present well before ipsilaterally-projecting fibers begin to develop. Developing ipsilaterally-targeted axons thus initiate growth toward the brain in a contralaterally-projecting nerve. The mechanism(s) which controls the accurate routing of ipsilaterally-projecting fibers is unknown. One possibility is that such axons might fasciculate selectively in the optic nerve, and be routed as a group at the optic chiasm.

To examine the routes taken by ipsilaterally-projecting fibers, I injected HRP into the thalamus of juvenile frogs, and examined the distribution of retrogradely-labelled fibers in the ipsilateral optic nerve and tract. Pressure injections of concentrated HRP were made into the thalamus on one side of the brain. Two to three days later, the animals were anaesthetized and killed, the optic nerves severed behind the eye, and the brains and attatched nerves fixed, processed, and sectioned serially. The positions of HRP-labelled fibers in the optic nerve and tract were reconstructed from frozen or paraffin sections using a camera lucida. 1. At the level of the eye, the nerve is cylindrical in cross section, with glial cell bodies concentrated centrally and the periphery essentially cell-free. All HRP-labelled fibers lie in the periphery, the majority at the extreme posterior or postero-ventral periphery, interspersed with unlabelled, presumably contralaterally-projecting axons. No labelled fibers are seen in the anterodorsal periphery. 2. Near the brain the nerve widens along the antero-posterior axis and glial cells are distributed heterogenously. Labelled axons occupy more of the peripheral circumference, appearing in ventral and dorsoposterior regions as well as posteriorly. As in distal nerve, labelled axons are interspersed with unlabelled axons. 3. In the optic tract, ipsilaterally-projecting fibers form a closely associated bundle lying anteriorly and do not appear to be interspersed with unlabelled fibers, suggesting that substantial reorganization of fibers occurs in the optic chiasm. 4. In contralateral nerves, in contrast, labelled fibers are found centrally as well as throughout the entire periphery, at all levels. The central vs peripheral distribution of labelled retinothalamic fibers thus correlates with the birthdates of their cells of origin, as is to be expected based on studies of fiber organization involving central or peripheral retinal lesions (Taylor, *Development 99*: 393, 1987).

In summary, ipsilaterally-projecting axons do not form a closely associated group in the optic nerve, and instead are scattered throughout much of the periphery. It is thus unlikely that routing of ipsilaterally-projecting axons at the optic chiasm can be achieved by deflection of a particular fascicle. The mechanism controlling pathway selection at the chiasm appears to be one which affects axons individually, perhaps on the basis of cell-surface differences, rather than routing them as a group. Since the development of ipsilaterally-projecting axons requires thyroxine, and the early establishment of the contralateral projections does not, it is possible that hormone-associated molecular differences between the two groups of axons might underly their divergent routing at the chiasm. As a first step in pursuing this possibility, I have constructed a cDNA library from metamorphosing retina, and am in the process of screening it for thyroxine-regulated genes.

104.12 TARGET RECOGNITION AND PATHWAY CUES IN THE PRIMARY DEVELOPMENT OF THE RETINOTECTAL PROJECTION. J.S.H. Taylor,* (Spon. G. Fink), MRC Neural Development and Regeneration Group, Dept. of Zoology, University of Edinburgh, West Mains Road, Edinburgh, EH9 3JT.

It has been shown that in the normal Xenopus embryo, retinal ganglion cell axons grow directly toward their target cells in the optic tectum. Harris (Nature, 320, 1986) has shown that axons from displaced eyes, which enter the caudal part of the ipsilateral midbrain still grow directly to the tectum.

By translocating the midbrain rudiment of stage 24 Xenopus embryos, the eventual midbrain target cells of the developing retinotectal projection can be moved to novel sites. In these experiments the tectal anlage, contained within the developing midbrain, has been placed rostral or caudal to its normal position, or separated into two spatially distant parts, or removed altogether. By using the axonal tracers Horseradish peroxidase and Di-i, the pathways of the first growing optic axons in such preparations have been examined. It is shown that retinal ganglion cell axons follow well defined pathways, in spite of the abnormal structure of the brain. In cases where the target has been removed, the normal optic tract is followed to a point just ventral to the tecto-diencephalic border; here the axons turn caudally, and extend into the hindbrain where they enter spinal tracts. Where the target has been displaced caudally a similar pathway is initially followed, however, in these cases the axons turn dorsal at the level of target and terminate. In cases where the targets have been displaced rostrally, the axons follow the normal optic pathway to the level of the target and then turn to innervate the tectal anlage. In these cases no axons are found growing caudally away from the tectum. Where dual targets have been made, the optic tract bifurcastes, such that both structures are subsequently innervated.

These experiments clearly show that optic axons can seek out and form terminal arbors in ectopically placed target structures. It is suggested that retinal ganglion cell axons preferentially grow along stereotyped pathways which, in the normal animal lead them towards the optic tectum. In these experimental preparations and most probably in normal animals, a target derived trophism acts as an important short range guidance cue, directing the axons from the pathway towards the tectal anlage and their target cells.

104.13 REGULATION OF THE PHOSPHORYLATION AND STEADY-STATE LEVELS OF MAP1.2 BY NERVE GROWTH FACTOR. J.M. Aletta, N.J. Cowan*, S.A. Lewis* and L.A. Greene. Depts. of Pharmacology and Biochemistry, NYU Medical Center, New York, NY 10016.

MAP1.2 is a phosphorylated microtubule-associated protein whose relative level is increased during NGF-mediated neurite outgrowth in cultured PC12 cells (Greene et al. JCB:96; 76-83, 1983). Although the NGF-induced accumulation of MAP1.2 protein in these cells has been purported to be 10-20 fold (Drubin et al. JCB:101; 1799, 1985), quantification of MAP1 mRNA levels during NGF treatment revealed a much more modest increase (Lewis et al. JCB:102; 2106, 1986). To resolve this apparent discrepancy, we have now further characterized the NGF-dependent regulation of MAP1.2 in PC12 cells during process outgrowth.

MAP1.2 was identified in lysates of whole cells by its comigration with immunoprecipitated material on low percentage SDS-polyacrylamide gels. The gels were either silver-stained or dried for autoradiographic detection of proteins previously labeled metabolically with ^{35}S-methionine (3 days) or ^{32}P-orthophosphate (2 hrs). Using quantitative densitometry of gel autoradiograms generated from sister cultures, we found that over a time course of 15 min to 2 weeks or more of NGF-treatment, the steady-state levels of MAP1.2 protein, relative to total cell protein, were increased only 3.5x (±0.4 SEM; n=5). This was corroborated by the silver-stained material. Phosphorylation of MAP1.2 in cells treated with NGF for at least 2 weeks, when corrected for these increases in protein levels, was elevated an average of 4.1-fold per molecule (±1.0) above that in untreated cells. The increase in phosphorylation commenced rapidly (2.6x ±0.3 within 15 min.) followed by a slower increase over days to weeks; in contrast, the increase in protein level commenced only after 2-3 d of treatment, rising slowly thereafter. NGF also evoked a progressive decrease in the mobility of MAP1.2 on gels. This appeared due to enhanced phosphorylation since MAP1.2 from NGF-treated cells could be converted to the more mobile form characteristic of untreated cells by exposure to alkaline phosphatase.

Our results demonstrate that under the influence of NGF both the steady-state levels and the phosphorylation of MAP1.2 are increased. The level of phosphorylation is elevated prior to the induction of protein levels and continues to increase afterwards as well. Activators of kinases A or C were much less effective than NGF with regard to MAP1.2 phosphorylation, although with respect to a Triton-insoluble cytoskeletal substrate, they were equally or more effective mediators of phosphorylation.

105.1 STOCHASTIC ANALYSIS OF THE CENTER OF PRESSURE MOVEMENT IN QUIET STANDING Z. Ladin*, M.H. Hanno*, S.H. Roy and C.J. De Luca (SPON: H. Voigt) NeuroMuscular Research Center, Boston University, Boston, MA 02215

The momentary movements of the center of pressure (COP) of a standing subject, as measured by a force platform, produce a trace called a stabilogram. This trace represents the output of a complex sensorimotor system aimed at maintaining an erect posture of a human subject standing still. Some global aspects of this trace (e.g. total distance traveled, minimum bounding radius, etc.) have been studied, but only recently was it attempted to extract some quantitative information from the momentary movements of the COP. This study presents another step in that direction and describes the stochastic nature of the direction changes in the COP trajectory.

A series of stabilogram studies were conducted on human subjects of a young age-group (20's to early 30's) and an old age-group (70's). The subjects were asked to stand still on a force-platform in a comfortable posture while looking at a picture on the wall opposite them. Data were collected for a period of 15 seconds at a sampling-rate of 200Hz. Experiments were repeated for a total of eight times interchanging between "eyes-closed" and "eyes-open" states. An algorithm to calculate the angle change occuring between two samples was developed. The histogram of the angle changes in the range of $\pm 180^{\circ}$ was calculated and displayed, excluding stationary points, i.e. the sample points which represented movements smaller than the resolution of the measurement system.

Preliminary results suggest the existence of qualitative differences between the histograms of the two age-groups. The histogram for the young age-group had a U-shape with peak values at $\pm 180^{\circ}$ and a uniform distribution in-between. such a distribution is indicative of a movement which occurs mostly along a straight line. The histograms of the older age group showed significant deviations from the above. The main feature we observed included two peaks at angles close to $\pm 130^{\circ}$. Such a distribution suggests that the minute sway motions which are along a straight line for the young age-group, are replaced by deviations from a straight line in preferred directions for the older age-group.

An interesting finding involved the percentage of time spent in a stationary manner (i.e. - sample points which moved a total distance smaller than the resolution of the system). Stationary samples were in the range of 0.2-6% of the total time. No correlation with age was found for the specific group of subjects in our study. Hence, the results suggest that age affects the nature of the CP movement, rather than its ability to be stationary. The study was supported by Liberty Mutual Ins. Co.

105.2 IDENTIFICATION OF AN M2 LATENCY RESPONSE TO POSITIONAL STRETCH. J. S. Thomas, Department of Physiology, Meharry Medical College, Nashville, TN 37208

During behavioral tasks requiring maintenance of a defined posture (of elbow, wrist, or finger) against an expected load change, a step increase in load evokes a characteristic pattern of EMG response peaks usually labeled "M1" (25-50 msec.), "M2" (50-100 msec.), and "M3" (100+ msec). Flutter frequency (8 - 50 Hz) square wave modulation of torque load produces similar M1/M2 response peaks (as timed from the onset of the loading phase of the forcing), but this evolving pattern is truncated by the inhibition resulting from the subsequent unloading phase of the load modulation. If the periodic load modulation is terminated by the omission of the unloading half of the last cycle, the result is a step increase in net load equal to one half the periodic amplitude whose onset is timed from the point where the missing unloading torque step would have occurred. As tested in six human volunteer subjects, such "Missing Unload" termination of periodic forcing produces an M2 latency peak of EMG response as timed from the point of the missing unload. Using various frequencies of terminated forcing it can be demonstrated that this "Missing Unload Response" (MUR) bears no constant latency relationship to the M1/M2 latency events evoked by the loading transient of the periodic forcing and thus must derive from a different reflex mechanism.. Responses to other waveforms of terminated periodic forcing (i.e., 'sawtooth' vs 'inverse sawtooth' waveforms which shift the onset of the periodic load termination by 180 deg. with respect to the phase of the kinetic parameter variations induced by the preceding periodic torque) show that the MUR is NOT a response to the detection of the onset of deviation from an accommodated forcing pattern, but seems instead to be timed from achievement of a critical level of positional stretch away from the minimal length associated with the preceding periodic fluctuations in joint angle. This conclusion is reinforced by tests which vary the waveform of the terminal cycle so as to retard or accelerate the resulting positional excursion and which produce corresponding changes in the latency of the MUR burst. Missing Unload termination of periodic forcing thus demonstrates an M2 latency response component to load change which is independent of the afferent source of the M1/M2 latency responses to acceleration and which can be conveniently used to assess the static components of behavioral reflex gain in human and animal subjects. Supported by NIH grant RCMI 03032

105.3 ABSENCE OF DISTINCT MUSCLE SYNERGIES DURING POSTURAL RESPONSES IN CATS TO TRANSLATION OF THE SUPPORT SURFACE. J.M. Macpherson. Dept. of Anatomy, Queen's University, Kingston, Ont. Canada K7L 3N6

It has been suggested that the computational problems faced by the nervous system in producing controlled movements could be simplified by controlling several muscles as a unit, a muscle synergy, thereby reducing the number of degrees of freedom (Bernstein, 1967). This study was designed to explore the synergic organization of muscle activation patterns in limb muscles during postural reactions to movements of the support surface in the horizontal plane.

Cats were trained to stand on a moveable support surface, with each paw on a miniature, triaxial force plate. The animals were required to keep their weight about equally distributed between the left and right sides. Trials consisted of ramp-and-hold movements of the platform in one of sixteen different directions in the horizontal plane, with 0° being tailward, 90° leftward, 180° headward and 270° rightward. Recordings consisted of 50 ms of quiet stance followed by the platform movement and postural response, for a total of 500 ms. The data included the three components of force exerted by each paw, vertical, longitudinal and lateral, the position of the platform, and electromyographic (EMG) activity. Eight EMGs were recorded from each of 6 cats using implanted pairs of wire electrodes, and included 6 muscles of the left forelimb and 9 of the left hindlimb.

During quiet stance, all cats exerted tonic horizontal forces directed backward and outward for the hindlimbs and forward and outward for the forelimbs. The maximum corrective forces exerted by any limb were observed for translations that were directly opposite to the horizontal force vector of quiet stance. Thus, the left hindlimb was maximally loaded, and exerted the largest horizontal forces for translations of the platform that were forward and to the right (225°).

Each muscle was active over a broad range of angles of platform movement, showing a gradual increase in activity to a peak and then a decrease, as angle of translation increased, the 'tuning curve'. While the tuning curves of many muscles overlapped, they were not identical. For example, gluteus medius was active between 157° and 315°, with maximum activity at 225°. Gracilis was active from 135° to 247°, with a maximum at 180°. The tuning curve for each muscle appeared to be related to its biomechanical action on the limb. The postural response in any one direction consisted of a unique blending of activity of many muscles such that the limb exerted the appropriate force vector to correct trunk position. Therefore, for postural responses, muscles appear to be controlled independently rather than in distinct synergic groupings.
Supported by MRC of Canada and Queen's University.

105.4 INDEPENDENT ACTIVATION OF COMPARTMENTS OF FELINE BICEPS FEMORIS DURING POSTURAL RESPONSES TO TRANSLATIONS OF THE SUPPORT SURFACE. C.M. Chanaud and J.M. Macpherson. Lab of Neural Control, NINCDS, NIH, Bethesda, MD 20892 and Dept. of Anatomy, Queen's Univ., Kingston, Ontario K7L 3N6.

A recent glycogen depletion study of biceps femoris (BF) in the cat has revealed three separately innervated compartments: anterior (BFa), middle (BFm) and posterior (BFp) (English & Weeks, J. Morph. 19:161-175, 1987). Recordings of EMG during various natural behaviors have demonstrated differential activation of these three regions (Chanaud et al., Neurosci. Abstr. 12:686, 1986). The current study explores the differential functions of BF during postural responses to translations of the supporting surface in the horizontal plane.

Each of two cats were implanted with a chronically indwelling Silastic patch containing 8 pairs of electrodes that were evenly spaced across the width of the BF muscle of the left hindlimb. The cats were trained to stand quietly on a hydraulically-driven, moveable platform with each of the four paws placed on separate, triaxial force plates (Macpherson et al., J. Neurosci. Meth., in press). The platform was moved in a linear trajectory in any of 16 directions in the horizontal plane (presented in varying orders), with 0° defined as a tailward translation, 90° a leftward translation, 180° a headward translation and 270° a rightward translation. The EMGs, the forces exerted by each paw, and the position of the platform were recorded on-line for 100 ms before and 900 ms after the onset of platform movement. At each new direction, several practice trials were presented before data collection.

During those perturbations that loaded the left hindlimb (203°-270°), BFa was activated along with other hip extensors and abductors (Macpherson, Neurosci. Abstr. 13, 1987) while BFp was inactive. In contrast, perturbations that unloaded the left hindlimb (45°-135°) resulted in inhibition of tonic BFa activity and activation of BFp, the latter presumably for knee flexion. BFm was activated at angles in between those for which BFa and BFp were involved, but was most similar to BFa.

Activation of the various compartments of biceps femoris depended on the direction of translation of the support surface in the horizontal plane, and could be related directly to the differential biomechanical actions of BFa and BFp at the hip and knee joints, respectively, as required for the postural correction.

105.5 KINESTHETIC COORDINATION OF A MULTI-JOINT ARM MOVEMENT. P.J. Cordo. Neurological Sciences Institute Good Samaritan Hosp. & Med. Ctr., Portland, OR 97209

To control targeted movements of the whole arm, the nervous system must coordinate the motions of different joints. Coordination might be learned and then implemented via open-loop control or it might be produced by reafferent sensory input. Sensory control of coordination might be preferable to open-loop control, because sensory input could compensate for variability in motor output and changes in the mechanical environment. This experiment examined whether the nervous system can use kinesthetic input from the arm to coordinate a throwing-like movement of the elbow and hand.

In a movement task resembling frisbee throwing, subjects extended the elbow horizontally at 16 deg/s through an arc of 40-50 deg and opened the hand as the elbow passed through a 2 deg wide target zone. The target zone was located approximately half way between the starting and ending angles. The forearm was placed in a cuff that resisted elbow extension with a standard stiffness of 0.3 Nm/deg. In randomly presented trials, the stiffness was either increased to 0.5 Nm/deg or decreased to 0.1 Nm/deg just before the subject began to extend the elbow. The function of stiffness changes was to speed up or slow down the elbow rotations.

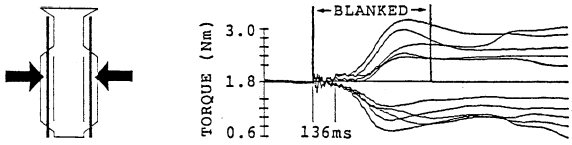
The experiment was designed to determine whether subjects were able to open the hand in the target zone independent of the changes in elbow velocity. To do this, subjects would have to employ kinesthetic input from the moving limb since no visual feedback of elbow angle was provided, and the changes in stiffness and velocity were unpredictable.

Subjects were able to open the hand in the target zone with a high degree of accuracy, independent of the imposed changes in elbow velocity. Subjects compensated for the changes in elbow velocity with two distinct mechanisms. Approximately 250 ms after subjects initiated their elbow rotations, the first mechanism corrected for errors in elbow velocity by adjusting the level of agonist muscle activity and elbow torque. Nevertheless, the elbow passed through the target zone at distinctly different times due to early leads and lags produced by stiffness changes. Subjects compensated for these timing differences with a second mechanism that adjusted the timing of the hand movement.

105.6 KINESTHETIC CONTRIBUTIONS TO HUMAN BIMANUAL COORDINATION. M. Flanders and P.J. Cordo. N.S.I., Good Samaritan Hosp. & Med. Ctr., Portland, OR 97209

Although our everday experience suggests that kinesthetic sensory input helps to coordinate voluntary movement, experimental evidence for this is incomplete. For example, Cole et al. (Exp. Brain Res.,56:582,1984) showed that during pinching, perturbation of one finger increases the agonist muscle activity of both fingers. Our research (Flanders et al., J. Motor Behav.,18:427, 1986) suggested that this type of increase in activity may be similar to a startle response. A kinesthetically driven system that coordinates movement should be capable of evoking accurate decreases as well as increases in muscle activity. The present study was designed to demonstrate that kinesthetic input from a perturbed elbow can evoke graded increases or graded decreases in the muscle activity of the other elbow.

Five subjects were trained to respond to an imposed rotation of the right elbow by quickly changing the torque of the isometric left elbow. All rotations and torques were in the horizontal plane. Subjects began each of 50 trials by producing flexion torque at both isometric elbows. As shown below, this torque moved left and right, visually displayed, tracking lines toward each other and into their respective target zones. After 1-3s, the display was blanked and the right elbow was randomly extended or flexed 4,6,8,10, or 12 deg. The correct response was a corresponding 0.4,0.6,0.8, 1.0, or 1.2 Nm increase (for extension) or decrease (for flexion) in the torque of the left elbow. Knowledge of results was provided by the reappearance of the display, 700ms after its disappearance.



The averaged (N=5 trials) torque responses of one subject are shown above. For all subjects, the average latency for responding in the correct direction was 123ms (SEM=8ms). Kinesthetically evoked responses were graded with stimulus amplitude before the visual display reappeared. Further data analysis was focused on the latency of accurately graded muscle activity and on improvement of this activity during motor learning.

105.7 EMG MEASUREMENTS SIGNIFICANCE IN THE EVALUATION OF FATIGUE. A.B. Arsenault, D. Gagnon*, S. Nagata* and G. Smyth*. Ecole de réadaptation, Université de Montréal and Centre de recherche, Institut de réadaptation de Montréal, Montréal, Qc, Canada H3S 2J4.

Ten normal subjects participated in a study designed to contrast results obtained pre and post-fatigue. The measures contrasted were; the slope of the EMG/Torque relationship, the mean and the median frequencies of the EMG power spectrum and the IEMG ratios of agonist/antagonist pairs of muscles. The experimental task was a 8 second ramp isometric elbow flexion ranging from 0 to 100% maximal voluntary contraction (MVC) (elbow angle = 90°). IEMG ratios and power spectra statistics were obtained over 1024 points of data at levels of 20, 40, 60 and 80% MVC. The following muscles were recorded from with miniature Beckman surface electrodes and TECA MarkIII pre-amps and amplifiers; Biceps-brachii (BB), Brachio-radialis (BR), Triceps-brachii (TB) and Anconeus (AN). The torque was measured at the wrist using a CybexII dynamometer. Fatigue was induced using a 60% MVC of elbow flexion maintained during at least 5 minutes. The data were collected on-line using a PDP 11/23+ computer and a sampling rate of 1kHz. The results were as follows. The expected increase, post-fatigue, of the EMG/Torque relationship for both BB and BR was found in only half of the subjects. In the other half, a drastic loss of the linearity of this relationship was observed with a levelling off of the EMG at 40% MVC. The statistics of the power spectra showed significant shifts (ANOVA for repeated measures, $p<.05$) towards the low frequencies at the levels of 40, 60 and 80% MVC. Finally, the IEMG ratios (BB/TB and BR/AN) presented a marked decrease at the levels of 40, 60 and 80% MVC at the post relative to the pre-fatigue state. The BB/BR ratios remained stable. It appears that these changes in the post-fatigue ratios disclose an increased level of contraction of the antagonists which may exert an inhibitory effect on fatigued agonist. Furthermore, while the torque and the statistics of the power spectra are sensitive, as measures, to the fatigue state, it appears that the EMG/Torque relationship cannot be considered a reliable measure for this physiological state, as has been suggested previously.

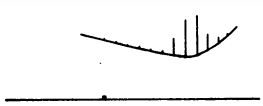
105.8 MOVEMENT MODULATION OF A HUMAN Ib INITIATED HETERONYMOUS REFLEX. J.D. Brooke, W.E. McIlroy, Human Biology/Biophysics, College of Biological Sci., University of Guelph, Guelph, Ont. Can. N1G 2W1.

Modulation of the electromyographic (EMG) response to stimulation of flexor reflex afferents occurs over the locomotor cycle in cat and human. There is also modulation of responses to group I stimulation during fictive locomotion in the mesencephalic cat. The present study reports that, following transcutaneous stimulation of Ib fibres in humans, a heteronymous reflex from ankle afferents to knee extensors shows substantial modulation over the cycle of leg movement. Subjects pedalled an ergometer instrumented for angular position of the pedal crank and for pedal reaction force. EMG responses were evoked in vastus medialis (VM) muscle, following low threshold, 1 ms square wave, stimulation of the common peroneal nerve serving the dorsiflexors of the ankle. The stimulus was applied at different points in the 360° rotation of the pedal crank, with 20 to 50 samples taken per point, for each subject. The direct activation (M wave) of the tibialis anterior muscle (TA) was also recorded and compared against M max obtained separately for each movement point, to control for variations in the intensity of stimulation. During normal pedalling, VM was active from approx. 290° to 110° of pedal crank rotation (0° being top dead centre for the crank).The burst in rectus femoris started earlier, closer to 220° of rotation. TA ranged approx. 163° to 7°, soleus 25° to 155° and lateral gastrocnemius 25° to 250°. In response to stimulation, reflexes were observed in VM at short latency (22-30 ms), with maximum peak to peak amplitudes up to 35% of those seen in maximum voluntary contractions. Around the movement cycle, the substantial modulation of this VM reflex was uncorrelated with changes in the magnitude of the M wave. The modulation was strongly associated, in timing and magnitude, with the locomotor burst normally occurring in VM, reducing from its peak to the extent that, between approx. 110° and 245°of pedal crank rotation, no VM reflex occurred. The threshold for the reflex was approx 10% ongoing contraction in VM. If bursts of VM activity were voluntarily intruded into the movement phase when VM normally was quiet, the reflex reappeared. In contrast, no effect of the group I stimulation on contralateral VM or TA was observed, with or without contraction of the target muscles. This supports the view that the contralateral path involves higher threshold interneurones. It is concluded that this ipsilateral reflex depends on the contraction of the target muscle. This is probably through facilitation of the motoneuron pool, similar to the locomotor drive potential described for the mesencephalic cat. However, the reflex modulation is not specific to the patterning of normal locomotion. Supported by NSERC (Canada) Grant #A0025.

105.9 NEURONAL CONTROL OF MOTOR BEHAVIOR IN THE ELECTRIC FISH Eigenmannia

K. Behrend Zool. Inst. Abt. Biophys. der Univ. D-65 Mainz, FRG

The segmental motor activity during so-called "probing" (Behrend, K., Neurosci., 13:171, 1984) of the electric fish Eigenmannia was investigated. When probing the fish bends its tapering caudal end (see fig.) presumably to fully exploit the dynamic properties of its sensory brain centers which in turn leads to an improved perception of objects of interest. The fish swam in a 10 x 20 cm channel and was stimulated at various positions in the channel by a short between a point electrode and a distant ground. The motor activity was monitored by a specially developed optical method with a time resolution of 20 msec. As a measure of motor activity the curvature of the fish was calculated every 8 mm along its longitudinal axis and interpreted as the activity of the motoneuron pool of the particular segmental muscles. The data show that the bending pattern is fairly uniform: the distribution of activity always has one peak and its amplitude decreases smoothly to the right and left (see fig.). Activity always starts simultaneously - within the limits of temporal resolution - in the segments involved in the movement. The center of activity may be shifted along the body axis to meet the needs of the fish. In the brainstem each body segment is represented in eight different nuclei by only one neuron in most cases (Behrend, K., Donicht, M. in prep.). Electrical stimulation in two of these nuclei elicits bending albeit in different contexts (Behrend, K., Neurosci. Abstr., 1985). The pattern may then be explained by assuming an excitatory coupling of each neuron to its neighbours weighted decreasingly as the distance between the neurons increases.



Fish (continuous line) seen from below; head is to the left. The amplitude of curvature is represented by the bars. The small square marks position of stimulation.

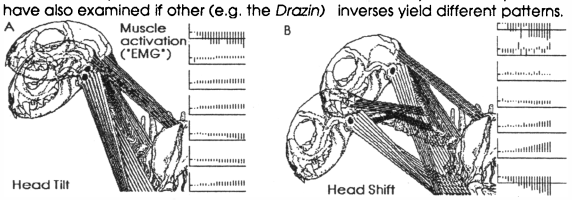
105.10 MULTIDIMENSIONAL SENSORIMOTOR "PATTERNS" ARISING FROM A GRAPHICS-BASED TENSORIAL MODEL OF THE NECK-MOTOR SYSTEM. **J. Laczkó***, KFKI/MSZKI Budapest, Hungary, 1525, **A. J. Pellionisz,** Dept. Physiol. Biophys., New York Univ. Med. Ctr. New York, NY, 10016, **B.W. Peterson,** & **T.S. Buchanan***, Dept. Physiol., Northwestern Univ. Med. School, Chicago IL, 60611. (SPON: G. Ostriker)

The general problem of how sensory reception is transformed, via neuronal networks, into motor execution led us to build a multidimensional tensorial model of the neuro-musculo-skeletal head control system of the cat *(Pellionisz & Peterson, 1987, in: "Control of Head Movement", Oxford U.P.).* The structuro-functional basis of the model is the availability of general (non-orthogonal, overcomplete) coordinates that are intrinsic to neural, muscular and skeletal expressions of sensory and motor events. With the numerical values of muscle orgin and insertion points and a single center of head-rotation revealed *(cf. Baker & Wickland, Ibid)* the tensorial model can provide experimentally verifiable predictions *(cf. Peterson et al., 1987, Proc. Symp. Biomech. & Neural Contr.).* When further developing this model, one of the considerations is that the center of rotation of the head/neck system is not fixed. This necessitates accurately modeling the skeleton. A further phenomenon to be accounted for by the model is that animals may use different muscle patterns when making a head movement in different paradigms *(Keshner et al., Soc Neurosci. Abstr, 1986).*

Thus, the tensor approach was extended with a graphics-based computer model *(Pellionisz,1987, In: "Comp. in Brain Sci.", Cambridge U.P.).* 2D diagrams of the skeletomuscular system were inputed. By specifying joints and muscle origin and insertion-points, the overcomplete non-orthogonal systems of coordinates were calculated. Predictions were made by the *Moore-Penrose* inverse, since the model requires the solution of an overdetermined system of equations. We have also examined if other (e.g. the *Drazin)* inverses yield different patterns.



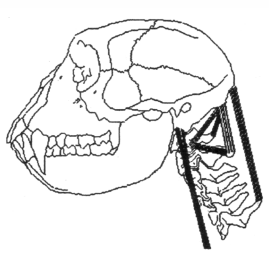
A surprising result gained by this generation of tensor models is that with only slightly different movement-intentions the emerging movement-patterns can be drastically altered (see *tilt* around a *single* center in **A**, versus *shift* around *two* centers in **B**). The emergence of different CNS patterns is of great interest because it provides insight into how a single neuronal mechanism might yield different "synergies", "schemas" or "strategies" to coordinate the multitude of degrees-of-freedom of multi-joint movements given a desired trajectory.

Such tensor models are research tools for the interpretation of sensorimotor experimental data in several species. They can also be used to predict muscle activity which can be used both for direct comparison with EMG data and for studies related to functional neuromuscular stimulation. — Supported by NS 22999

105.11 ROLE OF THE SUPERFICIAL & DEEP NECK MUSCLES IN THE CONTROL OF MONKEY HEAD MOVEMENT: APPLICATION OF THE TENSOR ANALYSIS APPROACH. F. Lestienne*, Ph. Liverneaux* CNRS Lab. Neurosensorielle, Paris, France 75270, A. Pellionisz, Dept. of Pysiol. & Biophys. New York Univ. Medical Center, New York, NY, 10016, USA. (SPON: A. Berthoz)

The understanding of structuro-functional principles of sensorimotor systems hinges on a proper quantitative knowledge of the complex anatomical features of the system and on the power of mathematical concepts and formalisms applied to the explanation of its functioning. On the basis of a recent multidimensional geometrical approach applied to model cat's head control system *(Pellionisz and Peterson 1987, In: "Head Control", Oxford U.P.)* our aim was to interpret, by this kind of a tensorial model, the complex neck muscle synergies acting on a multisegmental skeletal-cervical column of the monkey *Macaca Mulatta.*

The sub-occipital muscles (rectus capitis posteror major and minor, obliquus capitis superior and inferior) and the medial superficial neck muscles (semispinalis capitis, splenius capitis and trapezius) were implanted with bipolar electromyographic electrodes in female rhesus monkeys. X-ray opaque markers were placed in the two rectus capitis posterior major and in the two splenius capitis muscles to allow visualization, using successive X-ray exposures made in synchronization with a dedicated digital hardware system, for movement-analysis via real-time video signal processing. Head movements and the electromyographic activities were recorded during free voluntary head movements. A computer modeling technique was adapted that is applicable even if anatomical data are available only in graphical form: the computer was utilized to extract the quantitative information *(cf. Pellionisz, 1987, In: "Computers in Brain Sci.", Cambridge U.P.).* As the first step of such modeling, 2D diagrams of the cervical column and the neck muscles of *Macaca Mulatta* were inputed to a widely available graphical processor. By selecting joint-points and muscle origins and insertion points, the overcomplete system of coordinates of individual muscle contractions were automatically calculated. Since tensor network theory postulates a unique distribution of muscle activities even in such overdetermined systems, activations of mucles (EMG) and movements, according to any movement-intention in the 2D, could be calculated and displayed.



From EMG data it has been found that sub-occipital muscles and medial superficial muscles are simultaneously activated during pitch movent, whereas during yaw movements these two groups of muscles are activated in a sequential order. The tensorial modeling approach is able to predict the pitch-pattern of motor activation of the 7 pairs of deep and superficial neck muscles in its present form, and work is in progress to model full 3D rotations also including yaw and roll.— Support: CNES /87 /1228 and NS 22999 &NS13742

106.1 LATERAL MOBILITY OF CHICK ACETYLCHOLINE RECEPTORS IS UNAFFECTED BY FACTOR THAT INCREASES THEIR DENSITY. J.M. Dubinsky, D.J. Loftus*, G.D. Fischbach, E.L. Elson.* Washington University School of Medicine, St. Louis, Mo. 63110.

The mobility of acetylcholine receptors (ACHR) in rat myotubes and Xenopus myocytes has been measured by fluorescence photobleaching. Similar data are not available in chick muscle cells. In rat and Xenopus, a high fraction of the diffusely distributed receptors are mobile (rat=75% Axelrod et al 1976, Xenopus=68% Kidokoro et al 1985). The estimated diffusion coefficients (D, at 22°C) are $5*10^{-11}$ cm^2/s in rat and $2.5*10^{-10}$ cm^2/s in Xenopus. In contrast, few if any ACHRs are mobile within high density receptor clusters.

We have assayed the mobility of diffuse and clustered receptors in control chick myotubes and in myotubes treated with a partially purified factor known to increase ACHR density (Usdin & Fischbach 1986). Chick cells were grown on glass coverslips and the ACHRs were labeled with rhodamine-alpha-Bungarotoxin (RdBTX). Receptor mobility was assayed by monitoring the recovery of fluorescence within a 4um circle after bleaching the same area with an intense laser flash. 38% (±19% s.d., n=15) of the diffusly distributed ACHRs were mobile, with calculated D of $7.3*10^{-10}$ cm^2/s ($\pm 1.2 * 10^{-10}$). Less than 10% of the ACHRs within clusters were mobile. Similarly, in ciliary ganglion-muscle cocultures, few if any receptors within neurite-associated receptor patches (NARPs) were mobile, even if the NARPs were located at growth cones. The fact that the mobile fraction of chick ACHRs is significantly less than that estimated in Xenopus and rat is consistent with the observation that receptor migration and trapping does not make a significant contribution to the initial accumulation of ACHRs at developing NARPs in chick myotubes. The role of local insertion of new ACHRs was evident when cell surface ACHRs were blocked with unlabeled BTX and new ACHRs were visualized with RdBTX between 1-6 hr later. Digitized images revealed new receptors distributed throughout NARPs rather than in a rim around their perimeter.

As expected, the RdBTX fluorescence intensity of myotubes treated with a partially purified factor from chick brain extract, was greater than that of controls. However, the mobile fraction of diffuse ACHRs in treated cells (44% ± 15%, n=8) and diffusion coefficient ($5.7*10^{-10}$ cm^2/s ± $1.8*10^{-10}$) were comparable to control values. Significantly, the intensity of RdBTX fluorescence increased more at hotspots (5.7x) than at non-hotspot regions (2.1x). This is consistent with the notion that brain factor influences ACHR insertion in the vicinity of clusters more than eleswhere.

106.2 SPONTANEOUS FORMATION OF ACETYLCHOLINE RECEPTOR CLUSTERS TRIGGERED BY BRIEF EXPOSURE TO EXTRACELLULAR ELECTRIC FIELD. B. Podbilewicz* and M-m. Poo (SPON: J. Dani). Department of Cell Biology and Section of Molecular Neurobiology, Yale University School of Medicine, New Haven, CT 06510

Application of an extracellular electric field to culture cells may result in a redistribution of membrane-bound molecules in the plane of plasma membrane, a phenomenon termed in situ electrophoresis (Poo, M-m. 1981. Ann. Rev. Biophys. Bioeng., 10:245). It was found previously that prolonged (>3 hrs) exposure of embryonic Xenopus myocytes in 2-d old primary culture to a field of 10 V/cm caused formation of large immobile acetylcholine (ACh) receptor clusters on the cathode-facing side of the cell, as shown by the clustered distribution of binding sites for fluorescently labelled α-bungarotoxin. Brief exposure to the same field for durations less than 1 hr produced low levels of ACh receptor accumulation and formation of small receptor clusters on the cathodal side. Here we report a surprising finding that when the cells briefly treated with the field were incubated at culture conditions in the absence of the field for a duration of 6 hrs prior to the labelling of fluorescent α-bungarotoxin, the percentage of cells showing asymmetry of receptor distribution became higher and the average size of cathodal-facing receptor clusters became larger than those of similar field-treated cultures that were not incubated. Apparently small clusters of ACh receptors induced by brief treatment of the field served as a nucleus for the spontaneous formation of larger clusters at the same site, a process analogus to crystal formation in aqueous solution. For a field of 10 V/cm, the minimum duration of field exposure that can induce detectable post-field spontaneous clustering was found to be about 10 minutes. The resolution of the present technique does not allow us to determine whether this minimum duration corresponds to the time required for the formation of a small cluster of a certain critical diameter.

A field of 10 V/cm corresponds to a potential drop of 20 mV across a Xenopus myocyte 20 μm in width. Fields of similar strength could be generated at an active synapse by synaptic currents that occur at high-frequency. It seems possible that in the early stages of development brief bursts of synaptic current could produce a relatively long-term effect in the distribution or the density of membrane receptors and ion channels by a physicochemical mechanism similar to that described here. Work supported by NIH grant NS-22764.

106.3 DEVELOPMENT OF THE ACHR CLUSTERS: COMPETITION BETWEEN TORPEDO ELECTRIC ORGAN BASEMENT MEMBRANE EXTRACT AND POLYCATION-COATED LATEX BEADS. Ding-Liang Zhu*. H. Benjamin Peng and L.L. Rubin. Dept. of Anatomy, Univ. of North Carolina, Chapel Hill, NC 27514 and Rockefeller Univ., New York, NY 10021.

Molecules in the basement membrane of Torpedo electric organ have been shown to induce the formation of acetylcholine receptor (AChR) clusters in cultured chick myotubes. In our laboratory, we have found that polycation-coated latex beads induce the AChR clustering in cultured Xenopus muscle cells. In order to further understand the nature of the stimulation which leads to this postsynaptic differentiation, we examined the effect of the Torpedo electric organ basement membrane extract on Xenopus muscle cells and its competition with the latex beads. A high salt-soluble extract was prepared from the Torpedo electric organ basement membrane. At a protein concentration of 50 μg/ml, this extract caused a two-fold increase in the number of AChR clusters in cultured Xenopus muscle cells within 24 hr. Although individual clusters in extract-treated cells were somewhat smaller in size than those in the untreated cells, the total area occupied by the clusters in each cell was clearly larger in the extract-treated cells. When the cells were treated with polyornithine-coated latex beads, AChR clusters formed at the bead-muscle contacts. However, when the beads were applied in the presence of the extract, the bead-induced AChR clustering was suppressed. If the extract was applied first and followed by the addition of the beads, the latter failed to induce the cluster formation. Furthermore, if the extract was applied after the clusters were first induced by the beads, it caused a reduction in the number of bead-associated clusters and an increase in the number of extra-bead clusters. However, extract covalently linked to latex beads failed to exert any AChR clustering activity. These results indicate that the extract reversed the cluster-inducing effect of polycation-coated latex beads in Xenopus muscle cells. This may be due to an interference by molecules in the extract on the bead-induced local specializations responsible for the formation and the maintenance of the clusters. An understanding of this phenomenon should help elucidate the mechanisms of the postsynaptic induction by the basement membrane and by the latex beads. 106.4 MOLECULES SIMILAR TO AGRIN ARE CONCENTRATED IN MOTOR NEURONS. C. Magill, B.G. Wallace & U.J. McMahan. Department of Neurobiology, Stanford University School of Medicine, Stanford, CA 94305.

Monoclonal antibodies against agrin, which is extracted from the synapse-rich electric organ of Torpedo, selectively stain cell bodies of motor neurons in embryonic and adult spinal cord. Agrin causes the formation of several components of the postsynaptic apparatus on cultured myotubes, including aggregates of acetylcholine receptors (AChRs). These findings lead to the hypothesis that molecules similar to agrin are released by motor axon terminals to cause the formation of postsynaptic apparatus in embryonic muscle and the maintenance of the apparatus in adult muscle. It also suggests that motor neurons provide the molecules stably bound to basal lamina at the adult neuromuscular junction, that direct the formation of postsynaptic apparatus on regenerating muscle fibers in the absence of axon terminals. The experiments described here were aimed at determining if motor neurons contain and release agrin-like molecules with AChR-aggregating activity.

First we made extracts of the electric lobe of the brain of Torpedo, the region containing the cell bodies of the motor neurons that innervate the electric organ, and of spinal cords from adult Torpedo and frog and embryonic chick. Each of the extracts caused the formation of AChR aggregates on cultured myotubes. Monoclonal antibodies against agrin immunoprecipitated the AChR-aggregating activity indicating that the active molecules were antigenically similar to agrin. Extracts of regions of CNS that contain relatively few motor neurons had relatively little activity. Since anti-agrin antibodies selectively stain motor neuron cell bodies and since regions of the CNS in which cell bodies of motor neurons are concentrated are enriched for agrin activity, we conclude that motor neurons contain molecules similar to agrin.

Second, we made extracts from cultures containing dissociated chick spinal cord cells. The spinal cords were taken from a developmental stage when motor neurons are numerically predominant. As expected, such extracts contained AChR-aggregating activity. Moreover similar activity was detected in medium conditioned by the spinal cord cells, consistent with the hypothesis that motor neurons release molecules similar to agrin.

106.5 PURIFICATION AND CHARACTERIZATION OF AGRIN. M.A. Smith, B.G. Wallace, Y.-M.Yao, J. W. Schilling, P. Snow and U.J. McMahan. Depts. of Neurobiology and Biology, Stanford Univ., Stanford, CA 94305. Calif. Biotech. Inc., Mountain View, CA 94043.

Extracellular matrix-rich extracts of Torpedo electric organ contain agrin, which causes the formation of patches on cultured chick myotubes that resemble the postsynaptic apparatus at the neuromuscular junction; they contain high concentrations of acetylcholine receptors (AChRs), acetylcholinesterase (AChE), and butyrylcholinesterase (BuChE). We now have found that other components of the postsynaptic apparatus are concentrated at agrin-induced patches and have purified to homogeneity four structurally related polypeptides, two of which have agrin activity.

Incubation of cultured chick myotubes with agrin-containing extracts induces the formation of patches at which six components of the postsynaptic apparatus are concentrated: two extracellular matrix molecules, a heparan sulfate proteoglycan and an asymmetric form of AChE; three membrane components, AChRs and globular forms of AChE and BuChE; and a cytoplasmic molecule, a 43kDa receptor-associated protein. All of the aggregating activities were immunoprecipitated by each of four different anti-agrin monoclonal antibodies. All four of the monoclonal antibodies immunoprecipitated polypeptides of 150, 135, 95, and 70 kDa. To determine which of the activities was associated with each of the polypeptide species, extracts were chromatographed on a gel filtration column and the fractions analyzed for each aggregating activity and for agrin-like polypeptides. Our results indicate that both the 150 and 95 kDa polypeptides cause aggregation of all of the postsynaptic components, while the 135 and 70 kDa polypeptides have no detectable aggregating activity.

To characterize agrin further, we have purified each of the antigenically related polypeptides to homogeneity by preparative polyacrylamide gel electrophoresis. N-terminal amino acid sequencing indicates that the 95 (active) and 70 kD (inactive) polypeptides are identical at their N-terminus, as too are the 150 (active) and the 135 kD (inactive) polypeptides.

Thus, we have used anti-agrin monoclonal antibodies to purify four structurally related polypeptides from electric organ extracts. Two of these, agrin-150 and agrin-95, cause the formation of patches on cultured myotubes at which at least six components of the postsynaptic apparatus at the neuromuscular junction are concentrated.

106.6 AGRIN-INDUCED ACETYLCHOLINE RECEPTOR AGGREGATION: Ca^{++} DEPENDENCE, INHIBITION BY PHORBOL ESTER, AND EFFECTS ON RECEPTOR DEGRADATION. B.G. Wallace. Dept. of Neurobiology, Stanford Univ. Sch. of Med., Stanford, CA 94305.

Agrin, a protein extracted from Torpedo electric organ, is similar to molecules that direct the formation of the postsynaptic apparatus at the neuromuscular junction. For example, agrin causes the formation of patches on cultured chick myotubes at which several components of the postsynaptic apparatus are concentrated. The studies reported here were aimed at characterizing further agrin's effects on acetylcholine receptor (AChR) distribution and metabolism as a step toward determining its mechanism of action.

When agrin was added to the medium bathing chick myotubes it initially induced the formation of small ($< 4\ \mu m^2$) aggregates of AChRs. Aggregates began to appear within 2 hrs and increased rapidly in number until 4 hrs. Over the next 12-20 hrs the number of aggregates per myotube decreased as the mean size of each aggregate increased to approximately $15\ \mu m^2$. The large aggregates remained as long as agrin was present in the medium; if agrin was removed the aggregates disappeared slowly. For at least the first 6 hours of agrin-induced receptor aggregation all AChRs detected in aggregates accumulated there by lateral migration of AChRs present in the myotube plasma membrane at the time agrin was added. Agrin did not alter the rate of appearance of new AChRs.

Agrin-induced AChR aggregation required Ca^{++}; a half-maximal response occurred at 0.2 mM Ca^{++}. Co^{++}, Mn^{++}, and Ni^{++} inhibited agrin-induced AChR aggregation. Mg^{++} and Sr^{++} could not substitute for Ca^{++}, but did not block receptor aggregation in the presence of Ca^{++}. Agrin-induced receptor aggregation also was inhibited by the phorbol ester TPA, an activator of protein kinase C. Brief exposure (30 min-2 hrs) to 20 nM TPA completely prevented AChR aggregation. Two dimensional SDS-PAGE of extracts of cultures identified several polypeptides that were phosphorylated in response to TPA treatment. Agrin itself did not change the pattern of phosphoproteins.

Agrin-containing extracts of electric organ did cause a change in the rate of receptor degradation. In untreated cultures, two populations of AChRs were detected on the surface of cultured myotubes; most AChRs were rapidly turning over ($t_{1/2}$~1d), ~15% turned over more slowly ($t_{1/2}$~10d). Agrin-containing extracts increased the proportion of slowly turning over receptors to ~20%.

Thus agrin induces AChRs in the myotube plasma membrane to accumulate into aggregates by a rapid, Ca^{++} dependent process that is inhibited by protein kinase C-mediated protein phosphorylation and is accompanied by a decrease in the rate of degradation of a fraction of AChRs.

106.7 LOCALIZATION OF A SYNAPTIC ORGANIZING MOLECULE IN DEVELOPING MUSCLE. J. R. Fallon. Worcester Foundation for Experimental Biology, Shrewsbury, MA 01545.

Agrin is a molecule derived from the extracellular matrix of Torpedo electric organ that organizes AchR and AchE on cultured muscle cells. Immunocytochemical studies with monoclonal anti-agrin antibodies have established that in normal and damaged muscle molecules closely related if not identical to agrin ('agrin-related molecules') are localized in the synaptic basal lamina (Fallon et al., Nature 315; 571-574, 1985; Reist et al.; Magill et al., Soc. Neurosci. Abstr.12(1): 189;190, 1986). These results provide strong evidence that agrin or related molecules play a role in directing the regeneration of the neuromuscular junction.

The present studies are aimed at determining the role of agrin in the development of the synapse. As a first step towards this goal the localization and time of appearance of agrin-related molecules has been compared to that of AchR clusters in the developing chick hindlimb. The dorsal muscle mass and two muscles derived from that structure, the fast posterior iliotibialis (PITB) and the predominantly slow iliofibularis (IFIB), were examined in detail. Frozen sections were double-labelled with monoclonal antibodies directed against Torpedo agrin and rhodamine-coupled α-bungarotoxin. Examination of serial sections of the entire thigh from embryos of stage 24-30 (embryonic day 4.5-7) revealed that anti-agrin staining was present throughout the dorsal muscle mass from as early as stage 24. AchR clusters were first detected at stage 25. At this stage and at all subsequent stages examined greater than 95% of the AchR clusters co-localized with agrin-related molecules. This co-localization was also observed in unpermeabilized whole mount preparations of stage 32-34 muscles, indicating that the agrin-related molecules as well as the AchR clusters were on the external surface of the cells. At all stages of development the distribution of agrin-related molecules in muscle was wider than that of AchR clusters. The extent of anti-agrin labelling on the muscle cell surface increased until at stage 42-44 (embryonic day 16-18) the entire surface of all myofibers was stained. At these later stages the level of extrajunctional staining was greater in the IFIB than in the PITB. However, in the mature chicken, agrin-related molecules in both muscles were restricted to the region at and immediately adjacent to the endplates.

These experiments demonstrate that in developing muscle agrin or a closely related molecule is 1) expressed before AchR clusters are detected and 2) co-localized with the earliest AchR clusters formed. These results suggest that agrin may play a role in directing the initial events of synapse formation during development.

106.8 DISTRIBUTION OF PRE- AND POSTSYNAPTIC SPECIALIZATIONS DURING THE NORMAL DEVELOPMENT OF AN AMPHIBIAN MUSCLE. M.W. Cohen. Dept. of Physiology, McGill University, Montreal, Quebec H3G 1Y6.

The development of spatial alignment between pre- and postsynaptic specializations was examined in Xenopus myotomal muscle. Sites of clustered acetylcholine receptors (AChRs) were visualized after staining with fluorescent α-bungarotoxin. To view sites of presynaptic specialization in the same muscles indirect immunofluorescent staining was employed using a monoclonal antibody (generously provided by J. Bixby and L. Reichardt) directed against a synaptic vesicle antigen.

In mature myotomes the immunofluorescence was restricted to the ends of the muscle cells and aligned precisely with the sites of high AChR density. This immunofluorescence was not observed a) after denervation, b) in the absence of cell permeabilization, or c) when the monoclonal antibody was omitted from the staining protocol. These results, considered with those of previous studies, suggest that the monoclonal antibody is effective in revealing clusters of synaptic vesicles in Xenopus neurons.

At the onset of innervation of embryonic myotomes the presynaptic stain revealed nerve fibres coursing across the developing muscle cells. The nerve fibres were usually stained more intensely distally than proximally and their immunofluorescence terminated in broad expansions presumed to be growth cones. Co-localized with a few of these presumptive growth cones were small sites of postsynaptic (AChR) stain. More often sites of postsynaptic stain were situated more proximally along the path of nerve growth or were not present at all in the same myotome. More rostral myotomes of the same embryos exhibited larger numbers of stained sites but co-localization of both stains was still relatively low. With further development the incidence of co-localization increased. In further contrast to the pattern in mature myotomes, co-localized as well as individual sites of pre- and postsynaptic stain were not restricted to the ends of the muscle cells.

These observations suggest that growing axons contain clusters of synaptic vesicles in their growth cones. Clusters of AChRs form shortly after axon-muscle contact but synaptic vesicles do not initially remain at the majority of these postsynaptic sites. As development progresses the incidence of spatial alignment between clustered AChRs and clustered synaptic vesicles increases, presumably by the formation of new clusters at previously non-aligned sites as well as by unclustering of AChRs or synaptic vesicles at non-aligned sites. In addition, aligned as well as non-aligned sites eventually disappear from the central portions of the myotomal muscle cells, leaving neuromuscular junctions only at their ends. (Supported by MRC).

106.9 THE RELATIONSHIP BETWEEN PRE- AND POSTSYNAPTIC ELEMENTS DURING SYNAPTIC COMPETITION AT DEVELOPING NEUROMUSCULAR JUNCTIONS. R.J. Balice-Gordon and J.W. Lichtman, Anatomy and Neurobiology, Washington University School of Medicine, St. Louis, MO 63110.

During the first few weeks after birth, polyneuronal innervation of mammalian muscle fiber endplates is eliminated by retraction of motoneuron axon branches. The postsynaptic regions of acetylcholine receptors change shape during this period, from simple plaques containing a uniform distribution of receptors to a more complex distribution containing receptor rich and receptor poor regions. To determine how the alterations in axonal convergence and in postsynaptic receptor distribution are related, techniques were developed to study the pre- and postsynaptic elements of the same endplates in living mouse sternomastoid muscle during the first month of postnatal life, using a flourescent marker for motoneuron nerve terminals, 4-Di-2-Asp (J. Neurosci. 7: 1215), and flourescently tagged alpha-bungarotoxin to label acetylcholine receptors. Both nerve terminals and the postsynaptic distribution of receptors were observed to undergo rapid changes during the time synapse elimination occurs. In 1 to 2 day old mouse pups, the distribution of acetylcholine receptors on most muscle fibers is simple and doughnut shaped and has a relatively uniform staining intensity. Nerve terminal staining with 4-Di-2-Asp is diffuse at this age and is observed over most, if not all of the receptors. To verify that 4-Di-2-Asp exclusively stains nerve terminals and not other components of the endplate, the sternomastoid muscle was permanently denervated by nerve section in 2-4 day old mice. No endplate staining was seen, indicating that even in neonatal animals this marker is specific for components of nerve terminals. By 3-6 days, many of the receptor plaques have broken up into branched regions which contain receptors and regions which do not. Similarly, 4-Di-2-Asp staining indicates that nerve terminals become progressively more well-defined; the diffuse staining observed at earlier ages is replaced gradually by a pattern of distinct terminal branches. Interestingly, at many endplates at these ages it appears that some receptor regions no longer have nerve terminals overlying them. By 2 weeks of age, however, endplates have receptors distributed in a highly branched pattern which the nerve terminal staining matches completely. To investigate more precisely whether receptor-rich regions of endplate become vacated as axons are eliminated and to determine the relationship between the remaining axons and receptors, we have begun first, to examine the same endplate at multiple time points and second, to differentially label axons innervating the same endplate with flourescent markers that can be internalized by active terminals. Our results argue for rapid changes in the distribution of motoneuron terminals and postsynaptic receptors as competitive synaptic reorganization occurs.

106.10 AN ANTIGEN CONCENTRATED IN THE BASAL LAMINA OF THE NEUROMUSCULAR JUNCTION. D.D. Hunter*, J.R. Sanes, and A.Y. Chiu[1]. Department of Anatomy and Neurobiology, Washington University School of Medicine, St. Louis, MO 63110, and [1]Division of Neurosciences, City of Hope Medical Center, Duarte, CA 91010

Axons preferentially reinnervate original synaptic sites in denervated muscle, a selectivity mediated in part by cues associated with synaptic portions of the muscle fiber's basal lamina (BL) sheath. Molecular correlates of this functional specialization are provided by antibodies that selectively stain synaptic BL (Sanes and Chiu, Cold Spring Harbor Symp. Quant. Biol. 48: 667, 1983). To learn whether the synaptic antigens thereby defined are recognized by axons, it is necessary to purify and characterize them.

Four monoclonal antibodies, C1, C4, D5, and D7, stain synaptic BL far more intensely than extrasynaptic BL. All 4 also stain BL of arteries but not veins in muscle, and BL of glomeruli but not tubules in kidney, suggesting that they recognize the same antigen(s). Biochemical results support this suggestion. On immunoblots of reduced kidney glomerular extracts, C4 and D5 intensely stain a protein of ~185 kD and faintly stain a protein of >400 kD. D7 stains the >400 kD band more intensely than the ~185 kD band. C1 recognizes no proteins on blots, but immunoprecipitates a ~185 kD, C4-reactive protein. Thus, these antibodies recognize at least 3 different epitopes on a common set of polypeptides. The relationship of the >400 kD to the ~185 kD band is unknown: we have no evidence for conversion, and C4, D5, and D7 recognize only material of $>10^6$ kD when gels are run without reducing agent.

C4-reactive material of ~185 kD is present in rat muscle and cultured muscle cells, as well as in kidney. However, kidney was chosen as a source for purification because of its higher apparent content of antigen. Kidney cortices or glomeruli were pulverized, and depleted of cellular components by extraction with a series of detergent- and high salt-containing buffers; antigen was then solubilized in guanidinium with dithiothreitol, and detected by dot blot or Western blot. This selective extraction procedure results in a 50-100-fold purification over the starting material, but the extract still contains many proteins detectable by gel electropheresis. For further purification, C4-agarose was used. Over 75% of the antigen, but less than 2% of the protein, bound to the column; antigen was then eluted with chaotropic agents. We are now maximizing the yield and assessing the purity of eluted antigen; preliminary results suggest that sufficient material can be obtained for sequence determination. (Supported by NIH grant NS19195.)

106.11 FIBROBLASTS FROM DENERVATED MUSCLE SYNTHESIZE NCAM, J1 AND FIBRONECTIN. C.L. Gatchalian* and J.R. Sanes (Spon: C.J. Forehand). Department of Anatomy and Neurobiology, Washington University School of Medicine, St. Louis, Missouri 63110.

We have previously studied the distribution of several adhesive macromolecules, including NCAM, J1, and fibronectin (FN), in rat skeletal muscle. NCAM is present on denervated but not innervated muscle fiber surfaces, FN on both, and J1 on neither. However, all 3 molecules accumulate in interstitial spaces near synaptic sites following denervation (Sanes et al., J. Cell Biol. 102: 420, 1986). Because regenerating axons traverse these spaces, and may therefore be influenced by these molecules, as they reinnervate original synaptic sites (see accompanying abstracts), we have sought the source of these perisynaptic, extramuscular deposits of NCAM, J1 and FN.

Immunoelectron microscopy revealed that J1 is associated with collagen fibers in interstitial areas near denervated endplates. FN is also matrix-associated, at least in part. NCAM, however, is associated with the surface of a major class of cells in interstitial spaces. These cells are likely to be fibroblasts, in that they are rich in rough ER, free of basal lamina, and bear long processes. The processes frequently abut J1- and FN-rich matrix. Mast cells, macrophages, capillary endothelial cells, perineurial cells, and endplate-associated Schwann cells bear little or no NCAM. Autoradiography following administration of ^{3}H-thymidine showed that at least some NCAM-bearing fibroblasts arise by proliferation following denervation. Thus, fibroblasts that proliferate and accumulate near denervated endplates are a leading candidate for the source of interstitial NCAM, FN, and J1.

To study these cells further, we cultured small pieces (~2mm^2) of endplate-rich regions of denervated muscle on collagen substrata. Cells that migrated from the explants were stained after 2-5 days in vitro. More than 90% of these cells were typically fibroblastic in morphology; <2% were myoblastic (spindle-shaped or myosin-positive). More than 80% of the fibroblastic cells were FN-positive; of these, >50% were NCAM-positive and >70% were J1-positive. When monensin, a drug that inhibits glycoprotein secretion, was added to the cultures, NCAM, J1, and FN accumulated inside the cells. This result demonstrates that fibroblasts from denervated muscle synthesize multiple cell adhesion molecules. These perisynaptic cells will be compared with fibroblasts from other sources to determine whether they comprise a unique cell type, or whether they are conventional fibroblasts responding to a localized, nerve-dependent signal. (Supported by NIH grant NS19195.)

106.12 NEURITE OUTGROWTH ON CRYOSTAT SECTIONS OF INNERVATED AND DENERVATED MUSCLE. J. Covault and J.R. Sanes, Department of Anatomy and Neurobiology, Washington University School of Medicine, St. Louis, MO 63110.

Axons implanted in innervated skeletal muscle grow little and form no neuromuscular junctions; however, if the muscle is denervated, the axons readily sprout and form synapses. Regenerating axons preferentially reinnervate original synaptic sites, although "ectopic" synapses sometimes form. Several molecules have been proposed as mediators of these interactions; some are distributed throughout denervated muscle, some are concentrated perisynaptically, and some are localized precisely at synaptic sites (Sanes et al., J. Cell Biol. 102: 420, 1986; and preceding 2 abstracts). However, tests of these candidates in vivo have not been feasible. To bridge the gap between studies of axon guidance in animals and in culture we have studied neurite outgrowth on cryostat sections of muscle.

Chick ciliary ganglion neurons (known to form cholinergic skeletal neuromuscular junctions) were plated on cryostat sections of innervated and denervated rat diaphragm; 1-3 d later, cultures were fixed and neurons stained with anti-chicken NCAM. Our main results are as follows: 1) On both innervated and denervated muscle, neurons extended neurites that grew preferentially along cell surfaces. 2) On average, neurites regenerating on denervated muscle were longer, broader and more highly branched than those on innervated muscle. The ratio of neurite lengths on endplate-rich areas of denervated and innervated diaphragms was 1.7±0.1 in 29 experiments. 3) Average neurite length was greater on sections taken from endplate-rich areas than on sections from endplate-free areas of denervated diaphragm (1.4±0.1; n=20), although both were greater than that on endplate-rich areas of innervated muscle. 4) In 80% (24/30) of the cases in which neurites contacted original synaptic sites (marked with rhodamine-α-bungarotoxin), neurites terminated within 1 μm of the site. These results support the idea that denervated muscles use cell surface and extracellular matrix molecules to modulate axon growth.

Our aim is to study effects of antibodies to putative recognition molecules on neurite behavior in this "cryoculture" system. In preliminary experiments, we have found that anti-NCAM inhibits neurite outgrowth on sections of brain but not on sections of peripheral nerve, while antibody to a laminin-proteoglycan complex (INO; Chiu et al., J. Cell Biol. 102: 1383, 1986) inhibits outgrowth on nerve but not on brain. These results encourage us to test these and other antibodies, singly and in combinations, on muscle. (Supported by NIH and MDA).

107.1 ANTIBODIES TO GABA RECEPTOR RECOGNIZE FUSION PROTEINS ENCODED BY CLONED BRAIN cDNAs. M. Khrestchatisky*[1], R.W. Ransom*[2], R.W. Olsen[2,3], and A.J. Tobin[1,3,4]. Departments of [1]Biology and [2]Pharmacology, [3]Brain Research Institute, and [4]Molecular Biology Institute, University of California, Los Angeles, CA 90024.

We have screened three bacterial expression libraries with a polyclonal antiserum raised against purified rat GABA receptor. The antibody used to screen these libraries reacts principally with a single 52 kD polypeptide of affinity purified GABA receptors, with 52 and 66 kD polypeptides in extracts of rat and bovine cortex and whole rat brain, and with a 52 kD polypeptide in extracts of rat or bovine cerebella.

The libraries screened, all in lambda gt-11, contained cDNAs copied from poly (A) RNA from fetal human brain (obtained from R. Neve), from mouse cerebellum (prepared in this laboratory by T. Wood), and from rat brain (obtained from D. Chikaraishi). We isolated nine immunoreactive clones from the human library, three from the mouse library, and 16 from the rat library. We used fusion proteins from lysogens of these recombinants to select antibodies ("epitope selection"). These affinity purified antibodies were then tested for their reactivity to purified GABA receptor. The fusion proteins encoded by several rat clones appear to share epitopes with the 52 kD, benzodiazepine binding, polypeptide of purified GABA receptor.

One of the cloned human cDNAs, 4.3 kb long, encodes a polypeptide that shares epitopes with a 31 kD polypeptide that copurifies with the 52 kD and 56 kD components of GABA receptor. Partial nucleotide sequence of this cDNA shows no significant homology with other reported sequences in the NIH Gene Bank Database. Southern blot analysis indicates that the genomic sequence corresponding to this cDNA is 10-15 kb long.

This cDNA hybridizes to several rare RNAs in adult rat and human brain, as well as in two central neuroblastoma lines (B103 and B65) known to have GABA binding activity. No hybridizable RNAs are detectable in the rat pheochromocytoma cell line PC12. After two days exposure to purified nerve growth factor or dexamethasone, however, hybridizable RNAs appear. Their concentration increases after further treatment with NGF.

This work was supported by a grant to AJT from NINCDS (#NS 22256), a program project grant to Dr. A.V. Delgado-Escueta (#NS 21908), and a fellowship to MK from the Fondation de l'Industrie Pharmaceutique pour la Recherche.

107.2 DISTRIBUTION OF ACETYLCHOLINE RECEPTOR mRNA AT THE NEUROMUSCULAR JUNCTION OF SKELETAL MUSCLE LOCALIZED BY IN SITU HYBRIDIZATION. J.H. Caldwell and D.M. Chikaraishi. Dept. of Molecular and Cellular Biology, National Jewish Center, Denver, CO 80206 and Neuroscience Program, Tufts Univ. School of Medicine, Boston, MA 02111.

Skeletal muscle fibers are long, cylindrical, multinucleated cells. Some membrane proteins, such as the acetylcholine receptor (AChR), acetylcholinesterase, NCAM and the sodium channel, are highly concentrated at the neuromuscular junction. This distribution could be a consequence of differential insertion or accumulation of these proteins at endplates or different transcriptional programs in junctional versus nonjunctional nuclei. In this regard Merlie and Sanes (Nature, 317:66, 1985) demonstrated by RNA blot analysis more AChR RNA near endplates. We have tested this with in situ hybridization by using anti-sense RNA probes to the BC_3H1 muscle α subunit of the AChR.

Frozen sections of adult rat muscle were labeled with alpha-bungarotoxin to identify the neuromuscular junction and with Hoechst dye 33258 to identify nuclei. These same sections were then used for in situ hybridization performed with ^{35}S labeled riboprobe.

Preliminary results indicate that (1) denervation produces a large increase in the amount of αAChR mRNA, in agreement with Merlie et al., J. Cell Biol., 99:332, 1984 and Goldman et al., J. Neurosci., 5:2553, 1985). (2) At exposure times at which denervated muscle shows heavy labeling, innervated muscle is unlabeled even at the endplate. This implies that the endplate nuclei are not making 10-100 fold more message than extrajunctional nuclei. (3) At longer exposure times both endplate and non-endplate nuclei appear to synthesize αAChR mRNA. In all cases this hybridization seems to be perinuclear.

The results suggest that AChR mRNA is associated with endplate and non-endplate nuclei and implies that intracellular trafficking may be an important factor in the localization of AChRs.

107.3 Glucose Dependent Regulation of the Glucose Transporter mRNA in Rat Glial and Neuronal Cells in Primary Culture. P.S. Walker*, B. VanNess*, R.E. Fellows and J.E. Pessin*. Dept. of Biochemistry and Physiology & Biophysics, The Univ. of Iowa, Iowa City, IA 52242.

Although the brain depends on glucose as an extrinsic metabolic energy source, the regulation of glucose transport activity in the brain is not completely understood. To directly assess the regulation of glucose transport in neuronal and glial cells, in the absence of complications due to the endothelial cell blood brain barrier, we have developed methods to isolate and culture these cells from fetal and newborn rat brains. Neuronal cultures were prepared by enzymatic dissociation and plated onto polylysine coated dishes at $8x10^5$ cells/cm^2 and maintained in a serum free defined medium. Glial cultures were prepared in an analogous manner, plated at $1x10^5$ cells/cm^2, and maintained in DMEM plus 10% fetal calf serum. These cultures were determined to be at least 90% homogeneous based upon immunofluorescent staining by tetanus toxin (neuronal) or glial acidic fribrillary protein (glial), respectively. Total cellular mRNA was isolated by homogenizing the cells in 4M guanidine isothiocyanate, cesium chloride ultracentrifugation and ethanol precipitation. Northern blot analysis was performed by RNA glyoxylation, agarose gel electrophoresis, transfer to ABM paper and hybridization against the ^{32}P labelled rat brain glucose transporter cDNA.

Northern blot analysis revealed the presence of a single band at 2.9Kb corresponding to the expected rat glucose transporter mRNA from both neuronal and glial cultures. However, glial cells incubated for 24h with 25 mM fructose instead of 25 mM glucose (starved cells) in the culture medium displayed a 4-6 fold induction of the steady-state glucose transporter mRNA content. In contrast, starvation of the neuronal cultures under the same conditions only demonstrated a 1.5-2 fold induction of the glucose transporter mRNA. This effect was found to be concentration dependent, with half-maximal induction occurring at 5 mM glucose, maximal induction at 0.5 mM and maximal inhibition occurring at 25 mM glucose. These results demonstrate that the regulation of the glucose transporter by hypo and hyperglycemia in the rat brain is cell type specific. These results further suggest a role for glucose transport regulation in glial cells by altered metabolic states.

107.4 DIFFERENTIAL EXPRESSION WITHIN NEURONS AND GLIA OF mRNA ENCODING A PUTATIVE THYROID HORMONE RECEPTOR (cerbA1). S.R. Fox and D.W. Pfaff. The Rockefeller University, New York, NY 10021.

Thyroid hormone (T3) affects many functions of the adult central nervous system. However, the cells containing T3 receptors remain poorly described due to the high nonspecific binding of T3 analogs and the absence of T3 receptor antibodies. Therefore, we sought to identify cells containing T3 receptors by using in situ hybridization to measure T3 receptor mRNA within individual cells with a probe thought to be specific for this mRNA (cErbA1).

In situ hybridization was performed on frozen 10um tissue sections postfixed in paraformaldehyde and taken from forebrain areas of 6 female rats. Sections were prehybridized for 24 h. Putative T3 receptor mRNA was identified by incubating sections at 42°C for 72 h in 30ul of buffer containing 50,000 cpm of a tritiated cRNA complimentary to 3Kb of the human cerbA1 mRNA and hydrolyzed to 0.2Kb. Sections were then RNAse treated, rinsed in 0.1 x SSC for 24 h at R.T., dehydrated and dipped in emulsion. Autoradiograms were developed after 20-60 days and stained with cresyl violet. Cells were identified as glia or neurons on the basis of their size, shape and staining intensity.

Neurons in all parts of the brain examined appeared to contain many more copies of putative T3 receptor mRNA than did glia. To see if this difference was due to the smaller size of glia compared to neurons, the relative concentration of putative T3 receptor mRNA within individual cells was determined. We assumed that the number of reduced silver grains was a measure of the number of copies of the putative T3 receptor mRNA contained within a cell. Grain counting was performed as follows: a grid was positioned over cells magnified 100x in coronal sections of forebrain, and the number of reduced silver grains over each cell was counted. The cell areas were then measured and the relative concentration of silver grains calculated for each cell. Cells in three brain regions were compared: primary olfactory cortex, anterior cingulate cortex deep to the molecular layer, and corpus callosum. The mean concentration of grains found over neurons in different brain regions did not differ among themselves; neither did the grain concentrations over different glial populations. However, the mean concentration of grains over glia was about five-times less than that found over neurons in all brain areas studied. These observations suggest that neurons and not glia contain the majority of T3 receptors in the forebrain. Moreover, most neurons may constitutively express putative T3 receptor mRNA, since this mRNA was found at similar concentrations within neurons varying widely in their location and function.

107.5 THYROID HORMONE CONTROLS THE EXPRESSION OF SPECIFIC mRNAs IN THE FETAL AND NEONATAL MOUSE BRAIN. S. A. Stein*(Sponsor: P.M. Adams), Dept. of Neurol., Univ. of Tx. Hlth. Sci. Cent. at Dallas, Dallas, Tx. 75235.

Thyroid hormone(s)(TH), thyroxine(T4) and triiodothyronine(T3), play critical but only partially understood roles in the development of normal peripheral and central nervous system function. In the rodent, reduction in thyroid hormone levels (hypothyroidism) during the fetal and early neonatal period leads to significant behavioral abnormalities and anatomical abnormalities in the developing cerebral cortex and cerebellum. We have characterized a useful model of fetal and neonatal hypothyroidism, the hyt/hyt mouse on a BALB/cBY background, which has profound primary hypothyroidism, starting after 15 days(d) post conception (pc)(Stein, S.A. et al, Ann. Neurol., 20:402,1986). This model demonstrates many of the TH related anatomical and behavioral abnormalities seen in other rodents. The onset of rodent TH function after 15 d pc corresponds with cerebral cortex neuronal differentiation and new brain mRNA synthesis. Given the function of TH in regulating specific gene expression in adult rodent brain(Stein, S.A. et al, Ann. Neurol.,18:385,1985) and in a variety of tissues and developing systems, it is possible that some of the behavioral and anatomical abnormalities that are observed in the hypothyroid rodent might be due to alteration of fetal brain gene expression by hypothyroidism. We have isolated and characterized a group of rat and mouse cDNAs which are reflective of specific thyroid hormone regulated mRNAs by sequential colony hybridization, and northern gel hybridization(NGH). These cDNAs represent abundant but unknown mRNAs that are present in adult, fetal, and neonatal mouse and rat liver, brain, and cerebral cortex. Along with other cDNAs reflective of known and common brain mRNAs, including actin and tubulin, we have used our unknown TH regulated cDNAs to construct developmental mRNA abundance profiles using mixed cDNA probes from developing fetal(12 d pc to 19 d pc) and neonatal[1 day of age(Day of birth)] total brain and cerebral cortex in the BALB/cBY mouse and the hyt/hyt hypothyroid mouse. In comparing mRNA abundance in the normal and hyt/hyt animals for these 40 mRNAs at 1 day of age(DB), mRNAs that are potentially altered by hypothyroidism in the hyt/hyt animal have been identified. Of these potential fetal brain TH regulated mRNAs, cDNA MNB1 is present in 10-20 fold greater abundance in the normal total brain compared to the hyt/hyt total brain on slot blot(SBH) and NGH. MNB1, a 2300 b.p. mRNA, is detected at 12 d pc, rises in abundance at 18 d pc in total brain, and is also found in cerebral cortex(DB). The fact that fetal and neonatal mouse brain MNB1 might be regulated by thyroid hormone is suggested by: 1)The combined results of the SBH and NGH; and 2)The rise in MNB1 abundance corresponding with the endogenous fetal mouse rise in thyroid hormone after 15 d pc. mRNAs such as MNB1 may have relevance for understanding how thyroid hormone works in the normal and hypothyroid developing brain.

107.6 EXPRESSION OF THE THY-1 GENE IN TRANSFECTED NEUROBLASTOMA CELLS AND IN THE NERVOUS SYSTEM OF TRANSGENIC MICE. G. L. Andreason*, H. A. Ingraham*, S. Chen*, Florence Botteri*, Herman van der Putten* and G. A. Evans. Gene Expression and Cancer Biology Laboratories, The Salk Institute for Biological Studies, San Diego, CA 92138

The Thy-1 glycoprotein is a developmentally regulated cell surface antigen structurally related to the immunoglobulin superfamily of cell surface proteins. Thy-1 is expressed at high levels on the surfaces of most neurons; in mice, it comprises 2.5 to 7.5% of the neural cell surface protein and is induced in the central nervous system at 2 to 3 weeks after birth. In addition, Thy-1 gene expression is induced in PC12 pheochromocytoma cells upon treatment with nerve growth factor (NGF). Previous studies from our laboratory demonstrated that the mouse Thy-1 gene has two promoters which initiate transcription from one of two alternate first exons (Ingraham, H. A. and Evans, G. A., *Mol.Cell. Biol. 6*:2923-2931, 1986). S-1 nuclease protection assays and RNAase protection studies of RNA isolated from murine tissues and cell lines, as well as construction of hybrid genes using Thy-1 promoter and the CAT (chloramphenicol acetyl transferase) indicator gene, have demonstrated that these promoters lack tissue specificity and are equivalently induced when PC12 cells are grown in the presence of NGF. To evaluate the possibility that additional *cis*-acting regulatory sequences might be important for the expression of the Thy-1 gene in the brain, hybrid genes were constructed in which fragments of the Thy-1 gene were attached to the CAT or Luc (firefly luciferase) indicator genes. These constructions were introduced into neural cell lines by calcium phosphate-mediated transfection or electroporation and activities of the indicator genes determined as CAT activity or light production. These studies suggest that sequences downstream of the Thy-1 promoters have the properties of transcriptional enhancers and may be important for developmental control of gene expression in the developing mouse nervous system.

To extend these studies, we have begun studying expression of the native Thy 1.2 gene or a modified Thy 1.2 gene in transgenic mice. Results of these experiments should corroborate *in vitro* studies and allow us to localize sequences involved in brain-specific regulation of the Thy-1 gene expression.

107.7 L7 IS A MARKER FOR THE TERMINAL DIFFERENTIATION OF PURKINJE CELLS IN MOUSE CEREBELLUM. J. Oberdick*, F. Levinthal* & C. Levinthal (SPON: S. Schuetze). Dept. of Biological Sciences, Columbia Univ., NYC, NY 10027.

Three cDNA clones from a λgt10 library were isolated on the basis of reduced expression in Lurcher (Lc) cerebellum vs. wild-type. Lc is a mutation affecting post-natal viability of Purkinje cells (PC). Hence these sequences are likely to be PC specific or regulated by the presence of PC's.

By Northern analysis the three clones correspond to RNA's of about 500 bases in length. Clone L7 shows expression only in the cerebellum, L19 is brain specific but not cerebellum specific, and L14 is expressed in every tissue examined.

By primer extension the 5' end of the L7 RNA has been mapped relative to the end of the clone and the tissue distribution has been verified by repeating the experiment with RNA's from multiple tissues. In addition L7 has been completely sequenced. L7 could code for either a 131 amino acid protein or one of about 80 aa's, depending upon the start Met. This protein has no significant homology to other proteins; however its amino acid content and distribution is similar to several known peptide hormones. We are in the process of using both fusion proteins and synthetic peptides to raise antisera against L7 for immunocytochemical experiments.

By in situ hybridization L7 has been shown to be PC specific as predicted on the basis of its method of selection. By in situ hybridization as well as by primer extension L7 RNA first appears between post-natal days 4 and 8 (P4 and P8) and remains into adulthood. Perhaps most striking is the observation that not all PC's on P8 express L7 whereas all PC's at later stages do (see poster by F. Levinthal, et al.). Hence L7 is a marker for the terminal stages of PC differentiation. Similar experiments are in progress with L14 and L19.

Isolation of the corresponding genomic clones is in progress. We are searching for shared elements in the control regions of these three genes which might impart PC specificity. Differences between the three are also of obvious interest in that they all have different tissue distributions.

107.8 THE USE OF THE SELECTIVE NEUROTOXICANT, TRIMETHYLTIN AND A NOVEL AVIDIN-BIOTIN SUBSTRATE HYBRIDIZATION TECHNIQUE TO ISOLATE mRNAS UNIQUE TO SUBCLASSES OF RAT BRAIN NEURONS. J.K. Krady* and M.L. Billingsley. Department of Pharmacology and Center for Cell and Molecular Biology, Hershey Medical Center, Pennsylvania State University, Hershey, PA 17033.

Trimethyltin (TMT) is a neurotoxicant which selectively destroys subclasses of neurons in the rodent limbic system and neocortex. We have used a sensitive silver degeneration stain to map specific neurons which were destroyed by intoxication with TMT (8 mg/kg, i.p.). After 7 days, the greatest neuronal damage was seen in the CA3-4 fields of the hippocampus, the pyriform and entorhinal cortices. In order to determine whether there were mRNAs or gene products common to cells destroyed by TMT, we used the following selection and subtractive hybridization protocol. On day 7 post TMT, poly(A) mRNA was isolated from vehicle and TMT-treated Long-Evans rats using guanidine isothiocyanate extraction and enrichment via oligo d(T)-cellulose chromatography. Poly(A) mRNA from control rats was made into single-stranded ^{32}P-cDNA using reverse transcriptase; poly(A) mRNA from TMT-treated rats was biotinylated using photobiotin. Solution hybridization using control ^{32}P-cDNA and 20-fold excess of biotinylated mRNA from TMT-treated rats proceeded at 50°C for 24 hr. Avidin was added, and complexes of avidin-biotin-nucleic acid were retained on an imidoacetic acid chelating Sepharose column; unique, single-stranded ^{32}P-cDNA was not retained on this matrix. This procedure resulted in a 1000-fold enrichment of mRNA/cDNAs unique to neurons destroyed by TMT. The unique ^{32}P-cDNAs were made double stranded, annealed into the Pst I site of pBR322, and used to transform either E.Coli HB101 or the recA positive strain RR1. Positive transformants were tetracycline resistant and ampicillin sensitive (Pst I inserts). A total of 15 clones were isolated; slot blot hybridization analysis with total mRNA probes from both TMT-treated and control rats revealed that 5 of the 15 clones reacted only with mRNA from control rat brain but not with mRNA probes from TMT-treated brain. Studies are currently underway to sequence these 5 clones, and to examine the pattern of in situ hybridization in brain tissue with the unique cDNA probes. These results indicate that specific populations of neuronal mRNA can be selectively enriched by using a combination of selective neuronal elimination and avidin/biotin-based subtractive hybridization. We are currently using other selective neurotoxicants to enrich for brain region-specific mRNAs. Supported by a research grant from the International Life Sciences Institute Research Foundation and by EPA grant CR-200576 to MLB

107.9 mRNA EXPRESSION OF CYTOSKELETAL PROTEINS FOLLOWING β, β'-IMINODIPROPIONITRILE INTOXICATION. I.M. Parhad, E.A. Swedberg*, D.I. Hoar*, C.A Krekoski*, A.W. Clark. Depts. of Pathology and Medical Biochemistry, University of Calgary, Calgary. Alta, Canada, T2N 4N1.

β,β'-iminodipropionitrile (IDPN) when given to experimental animals produces a disorganization of the cytoskeleton, followed by a selective impairment in the transport rate of neurofilament (Nf) proteins. This impairment in transport produces in turn an accumulation of Nfs in the proximal axon, and a depletion of Nfs distally. The redistribution of Nfs along the axon results in marked changes in axonal caliber. Even with chronic IDPN intoxication, there is no neuronal death, and the lesions are reversible when the agent is discontinued. In this study we asked whether IDPN produces an alteration in mRNA expression of cytoskeletal components following acute or chronic intoxication. Female rats (Sprague-Dawley, 6 week old, 130-170 gms) were treated with IDPN (1.5gm/Kg of body weight intra-peritoneally, followed by 0.02% in drinking water) and killed 2, 7 or 30 days later. Total RNA was isolated from the spinal cord of each rat and 20μg resolved by electrophoresis on a 1.2% agarose/ 2.2M formaldehyde gel, transferred to nylon membranes and hybridized with ^{32}[P]-dCTP labeled cDNA probes. The following probes were used: Nf-M for the 145Kd Nf protein (Julien et al., Mol Brain Res: 1, 243, 1986), Nf-L for the 68Kd Nf protein (Lewis & Cowan, J Cell Biol: 100, 843, 1985), bαl tubulin (Cowan et al., Mol Cell Biol: 3, 1738, 1983), and GFAP (Lewis et al., Proc Nat Acad Sci: 81, 2743, 1984). Our results show that the total RNA remains unchanged in the spinal cords of the IDPN treated group as compared to the controls at each time point (2-ANOVA, p>0.05, n=4/group). Northern blots revealed bands at approximately 3.5 Kb for the Nf-M, 2 bands at 2.5 and 4.0 Kb for Nf-L, 1.8 Kb for b-αltubulin, and 3.0 Kb for GFAP in control and IDPN treated rats. Quantitation of mRNA bands by densitometry showed no alteration in Nf-M, Nf-L, bαl tubulin or GFAP in the IDPN groups as compared to their controls. Cytoplasmic dot analysis of IDPN and control groups at 7 days following intoxication confirmed these observations and showed no difference in the levels of the mRNAs evaluated. These results indicate that abnormalities at various stages of cytoskeletal processing such as 1) the early disorganization of the cytoskeleton, 2) the impairment of Nf transport, or 3) the long-term redistribution of Nfs along the axon are not directly due to, nor do they affect the mRNA expression of Nf or tubulin components in this model.

Supported by the Alberta Heritage Foundation for Medical Research, and the Alberta Mental Health council.

107.10 OPIOID PEPTIDE mRNA IN STRIATUM: DIFFERENTIAL EXPRESSION AND EFFECTS OF CORTICAL LESIONS. G.R. Uhl, B. Navia* and J. Douglas. Neurology Dept. and Howard Hughes Medical Institute, Massachusetts General Hospital and Harvard Medical School, Boston, MA 02114 and IABS, Portland, OR 97201.

Preproenkephalin and preprodynorphin are the principle opiate peptide genes expressed in the brain. Since expression of one or the other gene could exert substantially different influences on brain function, we have developed an approach to quantitative assessment of the levels of expression of each of these genes and applied it in the striatum, where both are expressed at high levels.

Hybridization to several ^{35}S-labeled oligonucleotide cDNAs complementary to specific regions of each mRNA but displaying similar length, guanine/cytosine content, and specific activity characteristics reveals densities of hybridization corresponding to each probe in serial sections of the rat striatum. The hybridization of each probe fulfills several anatomic and biochemical criteria for specificity. Testing in a model system in which known amounts of mRNA sense RNA are immobilized to a filter and subject to the same hybridization and wash conditions confirms that hybridization densities increase as added mRNA increases.

Studies of serial striatal sections hybridized with cDNAs directed against each of the mRNAs reveal that preproenkephalin-expressing neurons are more numerous than cells expressing preprodynorphin. Hybridization densities above enkephalin-positive neurons are also more than twice those noted above preprodynorphin expressing cells. Northern analyses of mRNA extracted from the striatum are consistent with these relationships.

In order to examine the regulation of the expression of these striatal enkephalin-expressing neurons, we assessed striatal cellular enkephalin mRNA hybridization densities at various times following unilateral cerebral cortical aspiration lesions. The mid-striatal preproenkephalin hybridization densities are decreased ipsilateral to these lesions. This change evolves largely between one and five days following the insult. Cellular hybridization densities in positive neurons of the adjacent central nucleus of the amygdala, on the other hand, are unaffected. Striatal preproenkephalin mRNA is thus more prominent than preprodynorphin mRNA, and depends on cerebral cortical inputs for its full expression.

107.11 CHRONIC LESIONS DIFFERENTIALLY DECREASE MESSENGER RNA IN DOPAMINERGIC NEURONS OF RAT SUBSTANTIA NIGRA. G.M. Pasinetti, S.P. Lerner*, S.A. Johnson, D.G. Morgan, N. Telford, M.M Myers* and C.E. Finch. Gerontology Ctr. USC, Los Angeles, CA 90089

Chronic lesions of rat substantia nigra pars compacta were produced by a single 6-hydroxydopamine injection (6-OHDA) that caused striatal depletion of dopamine (DA) by 65% . Morphological changes and effects on messenger RNA (mRNA) of tyrosine hydroxylase (TH) and β-tubulin by in situ hybridization in the remaining dopaminergic neurons were evaluated 9 months after lesion. Adult Fisher 344 male rats (250-275 g) were injected stereotaxically with 6-OHDA into the right substantia nigra pars compacta (8 μg in 3 μl volume of 0.1 % ascorbic acid). Three weeks later rats were tested for rotational behavior (amphetamine 5 mg/kg i.p.). Nine months after 6-OHDA lesions, rats were sacrificed by decapitation. Striata were dissected for estimation of DA and dihydroxyphenylacetic acid (DOPAC) by HPLC and midbrain fixed and embedded in paraffin. Immunocytochemistry (ICC) was performed using an ABC-PAP kit (Vector) with a primary antibody to TH (Eugene Tech). TH (PSTI/KPNI) cDNA (D. Chikaraishi) and B-tubulin (PSTI/HINDIII) cDNA (D. Cleveland) fragments, were recloned in PGEM I vector allowing single strand cRNA transcripts. In situ hybridization was performed on 10 um paraffin sections and the sections were treated first for TH-ICC. Neuronal content of mRNA for TH and β-tubulin was assayed by in situ hybridization in TH-positive neurons. A computerized grain counting system was used to quantify the grain density over neurons. Both mRNA types were reduced per TH-positive neuron, but TH mRNA showed a relatively greater loss (-60% ; P<.001), either per cell or by density per neuron area, compared with the contralateral nigra. TH mRNA was correlated with the loss of the ipsilateral striatal DA levels (P<.05). β-tubulin mRNA in TH positive cells did not correlate with the loss of ipsilateral striatal DA and did not differ with lesioned induced reduction in cell size. Among the remaining TH-positive neurons, cytoplasm, nuclear and nucleolar area were reduced by 30-40% (P<.001). The nigra contralateral to the lesion contained fewer TH neurons <20 um in diameter than the ipsilateral side. This apparent increase in number of small neurons after lesioning, must have resulted from the shrinkage of large neurons. These results confirm the findings that the remaining nigral neurons at the death of Parkinson's victims have less RNA and smaller nucleoli (Mann D. et al., J. Neuropathol. Exp. Neurol. 36:379-383, 1977). We hypothesize that genes for neuron specific proteins, such as enzyme for neurotransmitters, are more susceptible to neuronal damage in contrast to generally expressed genes like β-tubulin. 107.12 EXPRESSION OF THE GLIAL FIBRILLARY ACIDIC PROTEIN (GFAP) GENE IN THE MOUSE RETINA. P.V. Sarthy and M. Fu*. Department of Ophthalmology, Univ. of Washington, Seattle, WA 98195.

In response to photoreceptor degeneration, Müller cells, the predominant glial cell type in the retina, undergo 'reactive gliosis'. In normal mouse retinas, immunocytochemical studies show that polyclonal anti-GFAP sera stain the astrocytes while the Müller cells remain unstained. Photoreceptor degeneration resulting from rd, nr, and pcd mutations or constant light exposure (cld), however, lead to the appearance of GFAP-immunostaining in Müller cells. Since Müller cells in normal retina contain large numbers of intermediate filaments, what is the mechanism of GFAP expression in Müller cells from retinas with photoreceptor degeneration? Is the appearance of immunoreactivity due to depolymerization, proteolysis, or chemical modification of existing GFAP filaments, or is it due to formation of new GFAP molecules? We have used Western and Northern blotting and in situ hybridization techniques to address these questions. Our immunoblotting data show that there is an increase in the GFAP content in the rd, nr, and light-damaged retinas. Northern blot analysis with a GFAP cDNA probe shows that there is a 10 to 25-fold increase in the GFAP mRNA level in the rd, nr and cld retinas. Hence the increase in GFAP content probably results from de novo transcription of the GFAP gene and not from enhanced translation of pre-existing mRNA. In order to locate the sites of mRNA synthesis, in situ hybridizations were carried out with ^{35}S-labeled DNA and RNA probes. Both aldehyde-fixed and frozen sections were used for localization and DNA probes were 80-150 bases or 1.5Kb long. In normal retinas, silver grains were concentrated on cell bodies located just below the ganglion cell layer, the area where astrocytes reside. Few grains were found in other parts of the retina. In retinas with photoreceptor degeneration, silver grains were found on cells in the inner nuclear layer and on astrocytes. Furthermore, silver grains were also seen in the inner plexiform layer, and the density of silver grains was higher in astrocytes. These studies establish that reactive gliosis leads to transcriptional activation of the GFAP gene in Müller cells and astrocytes of the mouse retina. A similar mechanism is probably responsible for the increased GFAP-staining in Müller cells observed following photoreceptor degeneration in other mammalian retinas.

108.1 SYNAPTIC CONNECTIONS OF THE AXON TERMINAL OF ROD BIPOLAR CELLS IN THE RABBIT RETINA. E. Strettoi*, E. Raviola and R.F. Dacheux*. Dept. of Anatomy, Harvard Medical School, Boston, MA 02115.

The synaptic connections of the axonal arborization of rabbit rod bipolar cells were reconstructed at the electron microscope from continuous series of thin, radial sections using computer graphics. The axonal arborizations of four adjacent rod bipolars were reconstructed from the mid-periphery of the ventral retina.

Rod bipolar axons crossed the scleral portion of the inner plexiform layer (IPL) without branching. In the vitreal region of the IPL they gave rise to a small number of large endings arranged in a row at the boundary between IPL and ganglion cell layer. All synaptic contacts were confined to the vitreal portion of the axon and to the endings. Rod bipolar terminals were presynaptic exclusively at ribbon synapses and usually contacted a dyad of postsynaptic processes; monads were very infrequent. As a rule, the postsynaptic processes were dendrites of amacrine cells (99.4%, 159 processes); only one instance was observed of a ganglion cell dendrite postsynaptic to a rod bipolar (0.6%, 1 process). In about three quarters of the dyads, one of the postsynaptic dendrites had dark matrix and few vesicles; it contained a heterogeneous collection of cytoplasmic organelles. When these processes were followed through the IPL, they conformed in course, size, pattern of branching and fine structure with the dendrites of the narrow-field, bistratified (NFB) rod amacrine cell. There was a high degree of overlapping in the connections between rod bipolars and NFB rod amacrine cells: a large proportion of the ribbon synapses of an individual rod bipolar cell converged onto a single NFB rod amacrine; often, each amacrine cell dendrite received multiple synapses from the same rod bipolar ending. In two thirds of the dyads, one of the postsynaptic processes had pale matrix and numerous vesicles; it returned one or several punctate synapses onto the bipolar ending. These features are typical of wide-field, unistratified (WFU) rod amacrine cells. Most commonly, dyads resulted from the association of dendrites from NFB and WFU rod amacrines. In places, however, one of the postsynaptic dendrites belonged to other unidentified types of amacrine cells.

In addition to the reciprocal synapses, the axonal arborization of rod bipolars received a substantial input from a heterogeneous population of unidentified amacrine cell dendrites.

Thus, in both rabbit and cat retinas, transmission from rod bipolar to ganglion cells is mediated by an amacrine that is narrow-field and bistratified, and is modulated by the input of other varieties of amacrine cells onto the rod bipolar.

108.2 MORPHOLOGY AND DISTRIBUTION OF SYNAPSES ONTO A LARGE-FIELD GANGLION CELL (TYPE 1.2) IN THE RETINA OF THE GOLDFISH. Peter F. Hitchcock, The University of Michigan, Department of Ophthalmology, W.K. Kellogg Eye Center, Ann Arbor, MI 48105

As the retina of the goldfish grows by expansion, new synapses are continually added to the inner plexiform layer (Fisher and Easter (1979) J. Comp. Neurol., 185: 373-380), and the dendritic arbors of ganglion cells grow interstitially (Hitchcock and Easter (1986) J. Neurosci., 6: 1037-1050). I have established the morphology and dendritic distribution of synapses ending on the Type 1.2 ganglion cell in preparation for quantitatively determining the relationship between dendritic growth and synapse addition for this cell.

Type 1.2 cells were stained using retrogradely transported horseradish peroxidase, drawn with a camera-lucida attachment and a light microscope, embedded in plastic, and thin-sectioned parallel to the plane of the dendritic arbor. (The dendrites of these cells are unistratified within the outermost zone of the inner plexiform layer.) Every fifth section through the dendritic arbor was photographed at scanning magnification with the EM. With the low-power photmicrographs serving as guides, the HRP-filled dendrites were inspected at 8200 X magnification, and the type and location of each synapse ending on the dendritic arbor was marked on the low-power photomicrograph. From these photomicrographs, the dendritic location of each synapse was determined and marked onto the camera-lucida drawing of the cell.

Preliminary results (3 cells; 468 synapses) show that this cell receives synaptic contacts from ribbon and 3 morphologically distinct types of conventional synapses. The ribbon synapses (n=115) were found in large terminals with relatively electron dense cytoplasm, evenly distributed vesicles, and numerous mitochondria. The HRP-filled dendrites were generally one of a pair of post-synaptic elements at each ribbon synapse. For the conventional synapses (n=353), ninety-six percent were in relatively small, oval, relatively electron lucent terminals that contained a few unevenly distributed vesicles, and few mitochondria; three-percent were found in small terminals that had relatively electron dense cytoplasm, densely packed vesicles and generally no mitochondria; and slightly less than one-percent were en passant synapses, made by large, electron lucent processes that lay adjacent to the HRP-filled dendrites.

With respect to dendritic distribution, both the ribbon and the conventional synapses were distributed homogeneously throughout the dendritic arbor of these cells. Both types of synapses made contacts on all orders of dendrites, as well as onto dendritic appendages. No synapses were observed to contact somata.

108.3 MORPHOLOGY AND DISTRIBUTION OF DENDRITIC BEADS IN THE MAMMALIAN RETINA. Cesare USAI*, Silvia Bisti°* and Silvana Vallerga* (SPON: A.E.Del Bo). Istituto di Cibernetica e Biofisica, CNR, Genova and °Istituto di Neurofisiologia, CNR, Pisa, Italy.

The presence of beads on dendrites appears to be a general characteristics of neuronal morphology in the retinae of different animals. A detailed analysis of the properties of dendritic beads has been reported only for the amacrine cells of the fish retina.

Here we report results concerning the presence and distribution of beads in mammalian retinae. HRP or Golgi stained retinae of rat, cat and monkey were analyzed.

Almost all retinal neurons in the three species present dendritic beads differing in size and linear occupancy according to cell type and dendritic architecture. The same class of retinal neuron shows interspecies similarity in bead distribution.

An interesting exception are the ganglion cells. The type I ganglion cells of the rat retina and the α-type of the cat retina have dendrites devoid of beads, whereas all ganglion cells in the monkey retina are richly beaded.

This observation provides further evidence that the cat α-cells do not have any correlate in the ganglion cell populations of the monkey retina.

The results we present indicate that dendritic beads are indeed an outstanding feature also in mammalian retina, and they can be used as a tool to determine analogies among retinal neurons in different species.

108.4 AXO-DENTRITIC POLARITY IN RETINAL GANGLION CELLS. L. Maffei* and V. H. Perry* (SPON: V.K. Nielsen). Dept. of Experimental Psychology, Univ. of Oxford, England and Istituto di Neurofisiologia CNR, Pisa, Italy.

We have studied the relation between axons and primary dendrites of ganglion cells in wholemount retinae of rats, cats and monkeys. Ganglion cells were backfilled following injection of horseradish peroxidase (HRP) either in the optic tract or optic nerve. The retinae were prepared as wholemounts and the HRP revealed with a modification of the Hanker-Yates method (Perry and Linden, Nature, 297:683, 1982).

It is well known that retinal ganglion cells are polarized in the vertical plane, since the optic fiber layer lies vitread and the inner plexiform layer sclerad to the cell body.

We have found that the trajectories of the primary dendrites are biased away from the axon initial segment (AIS) also in the plane of the ganglion cell layer. This axo-dendritic polarity is also evident in that the majority of primary dendrites originate from the side of the cell body opposite to the axon initial segment. Higher order dendrites do not show this bias, so that the whole dendritic tree presents only a weak tendency to be oriented away from the AIS.

The axondendritic polarity is present in all the three species studied, suggesting that this could be a general rule in the organization of ganglion cells.

We then looked at the AIS and its orientation with respect to the optic disk. We found that in the cat the vast majority of ganglion cells have AISs directed towards the optic disk. This orientation is less clear in rats and monkeys.

The axondendritic polarity of retinal ganglion cells could be correlated to other cytological features of the cells. No clear relationship was observed between the position of the cell nucleus and the AIS either in adult rat and monkey, where the nucleus is eccentric, or in the adult cat, where the nucleus is at the center of the cell body. In the kitten however, the nucleus lies opposite to the AIS during the first 3 weeks of life and then moves to its adult central position. This period corresponds to a time of rapid growth of the ganglion cells axon terminals.

108.5 MORPHOLOGICAL CLASSIFICATION OF GANGLION CELLS IN RABBIT RETINA. E. V. Famiglietti. Dept. of Anat. and Lions' Sight Ctr., Univ. of Calgary, Calgary, AB, Can. T2N 4N1.

Ganglion cells (GCs) were studied in a large collection of whole flat-mounted and sectioned, Golgi-impregnated rabbit retinas. In the region of the visual streak 34 distinct morphological types could be recognized, and it is estimated that the number of types has an asymptote near 40. The following criteria were applied in order of importance: 1) dendritic morphology (a. branching pattern, b. contour, c. appendages), 2) dendritic stratification (a. sublamina a or b, b. stratum 1-5, c. substratum - 3 per stratum), 3) dendritic field size (DFD) and its regional variation, 4) cell body size and axon diameter (generally covarying). GCs were grouped in 4 classes. Class I GCs have large cell somata, large DFD, regular radiate branching with few appendages, and type a and b counterparts [3 types]. Class II GCs have medium somata, medium DFD, branching pattern like class I, a & b types [4 types]. Class III GCs have medium to small somata, small to large DFD, a heterogenous variety of dendritic morphologies, and a & b types [10 types]. Class IV GCs have small to large somata, small to large DFD, heterogenous dendritic morphologies, and include unistratified, bistratified, multistratified, and broadly stratified GCs with no type a & b counterparts [17 types]. The 4 part classification reflects a bias toward single-unit physiological studies using elementary visual stimuli. Class I is presumed to include physiological Y cells, large-field units and possibly some X cells, class II cells to include the majority of X cells, class III cells to correspond to "sluggish-concentric" GCs, and class IV to include the GCs with "complex" responses, such as direction and orientation selective GCs, and local edge and uniformity detectors. Some correlations in the last group have already been made (e.g. Amthor et al., '84).

It is unlikely that this diversity of types signals imprecision in the organization of the visual system, particularly in view of the complex but orderly arrangements of their neurotransmitter-selective presynaptic amacrine cells. At least 3 possibilities may underlie such diversity among rabbit GCs. GCs with similar receptive field (RF) properties could have unique sets of neurotransmitter-specific inputs, which give rise to unique responses under selected physiological conditions. GCs cells with similar RFs, but different morphology and slightly different inputs, may well project to different parts of the visual brain, or to different sets of neurons within the same target regions. Diversity might thus support the divergence of similar, but not identical information to different brain regions, and the convergence of pathways mediating slightly disparate information for integration at common targets in higher visual centers.

108.6 **INVESTIGATION BY INTRACELLULAR RECORDING OF PUSH-PULL MICROCIRCUIT IN CAT RETINA** Michael A. Freed and Ralph Nelson Laboratory of Neurophysiology, NINCDS, National Institutes of Health, Bethesda, MD 20892

Electron microscopic investigation of the cat retina has yielded a detailed wiring diagram for synaptic input to the on-beta ganglion cell of the cat retina. About half of this input is from two types of cone bipolar: type b_1 is depolarizing to light on but hyperpolarizing to light off and type b_2 is hyperpolarizing to light on but depolarizing to light off. The push-pull hypothesis states that during light on in the on-beta receptive field center the type b_1 confers excitation (the push)upon the on-beta cell while the type b_2 confers disinhibition (the pull); thus a synergy of excitatory and inhibitory inputs causes a depolarizing response in the on-beta cell. During light off in the on-beta receptive field center, type b_2 confers inhibition, causing a hyperpolarization in the on-beta cell.

In order to investigate the light-evoked resistance changes within this microcircuit we have recorded intracellularly from four on-beta cells in a perfused eyecup preparation using sharp high-impedance (400 MΩ) microelectrodes. The dark membrane potential was changed in steps by injecting currents (-1 to 1 nA, 0.1 nA steps) into the cells and then bars of light (100-200 μm wide) were shown over the receptive field center for 1 second. The photic response was recorded for each membrane potential step. All responses were recorded under mesopic conditions. Each cell was stained with horseradish peroxidase after recording and identified in the light microscope by well-accepted anatomical criteria. For three different times during the photic response the slope resistance was calculated (dV/dI) and the reversal potential was extrapolated. The three times were: 1) at the peak of the depolarization in response to light on (On-transient) 2) during the subsequent sustained depolarization (On-sustained) and 3) at the peak of the hyperpolarizing response to light off (Off-transient).

All three times were associated with a small resistance decrease (mean = 3.4 MΩ) compared to the dark resistance (mean = 45 MΩ). The reversal potential for each time period varied widely between cells; this may be due to variation in the strength of excitatory and inhibitory inputs which contribute to each response. There was, however, a consistent relation between reversal potentials: the On-transient reversal potential (-31 to 66 mV) was more positive than the On-sustained reversal potential (-56 to -40 mV), which was more positive than the resting potential (-21 to -58 mV). The Off-transient reversal potential (-69 to -53 mV) was more negative than the resting potential.

These results expand on the push-pull hypothesis by suggesting predominant excitatory input at light on and predominant inhibitory input at light off. These results do not demonstrate, however, the source of these inputs; assuming that the conductances measured are synaptically controlled these inputs may originate from either bipolar or amacrine cells. The reversal potentials lie inside the range of conventional Nerst potentials, which suggests some antagonism (strongest at the On-sustained time) between excitatory and inhibitory inputs. Our finding of antagonism differs from the original push-pull hypothesis which suggested synergy between such inputs. The source of this antagonism is uncertain: it may reflect the presence of the surround mechanism in the center of the receptive field.

108.7 LOCALIZATION OF SOMATOSTATIN-LIKE AND NEUROPEPTIDE Y-LIKE IMMUNOREACTIVITY IN THE TURTLE RETINA AND CHOROID. Charles L. Zucker and Alan R. Adolph. Eye Research Institute of Retina Foundation and Harvard Medical School, 20 Staniford St., Boston, MA 02114.

Immunoreactivity for both somatostatin (SS-like IR) and neuropeptide Y (NPY-like IR) has been described in retinal amacrine cells of a wide variety of vertebrate species (Tornqvist et al. 1982; Bruun et al. 1986). In most species, the processes arising from SS-like IR cell bodies give rise to three, more or less evenly spaced plexuses in sublamina 1,3 and 5 of the inner plexiform layer (IPL). Several distinct cell body morphologies are usually evident in any one species. Similarly, NPY-like IR cells typically give rise to a tri-laminar pattern of processes in the IPL. Additionally, NPY-like IR fibers have been observed to innervate the choroidal vasculature in the Guinea-Pig (Bruun et al. 1984) In the present study, using several well characterized antisera to each peptide, we have identified several unique features of SS-like and NPY-like IRs in the choroid and retina of the turtle (Pseudemys scripta). In the choroid, NPY-like IR fibers are seen throughout the stroma with extensive contacts onto the vasculature. In the retina, SS-like IR is seen only in cell bodies of the ganglion cell layer and a very restricted plexus at the proximal-most IPL. Since no immunoreactive axons were observed, we could not discern if these are ganglion or displaced amacrine cells. NPY-like IR staining showed amacrine cell bodies giving rise to plexuses at about the 30%, 60% and 90% levels in the IPL as has also been described by Adolph and Bruun (1987). In addition, a fourth, less prominent but very consistent plexus occurs in the ganglion cell layer. Within this most proximal layer, several NPY-like IR varicosities are evident in juxtaposition to most cell bodies in the ganglion cell layer. These juxtapositions are highly suggestive of synaptic contacts onto ganglion cells, especially since a greater number of cells appear to be contacted than can be accounted for by displaced amacrine cells. Electron microscopical immunohistochemistry is being used to confirm the exact nature of these contacts. The relationship of both SS-like IR and NPY-like IR to the ganglion cell layer is suggestive of a neuromodulatory role of these two peptides in ganglion cell function; this is a possibility we are currently investigating.

108.8 THE PHYSIOLOGY OF SOMATOSTATIN IN THE RABBIT RETINA. R.A. Zalutsky* and R.F. Miller (SPON: A.I. Cohen). Dept. of Ophthalmology, Washington University School of Medicine, St. Louis, MO 63110.

Somatostatin (SS) is present in amacrine and, possibly, interplexiform cells of the rabbit retina (Sagar et al., 1986). Since this neuropeptide has a wide spectrum of actions in the CNS and periphery, we have examined its effects on rabbit retinal neurons using an in vitro eyecup preparation designed for peptide pharmacology. The effects of SS and related peptides on neurons' light responses were monitored with ERG, single unit extracellular, intracellular, and whole cell recording.

SS affects virtually all types of ganglion cells in one or more of three ways. The first effect is a general excitation with a latency a few seconds longer than that of fast transmitters. The threshold concentration is less than 100 nM. The second effect is a simultaneous suppression of spontaneous activity and augmentation of light evoked spiking, resulting in a substantial increase in the ratio of light evoked to spontaneous firing. The third effect is a strong shift in center-surround balance toward a more dominant center. The latter two effects have threshold concentrations of less than 1 nM, latencies of tens of seconds, and durations of tens of minutes.

SS does have direct effects on ganglion cells evaluated during synaptic block with cobalt. The peptide also affects most amacrine cells causing a slight hyperpolarization and a pronounced increase in the amplitude of light evoked responses. The amacrine cell effects of SS also persist during synaptic block and are accompanied by an increase in input impedance. SS does not noticeably alter the behavior of horizontal cells. However, SS substantially reduces the influence of horizontal cells upong ganglion cells as demonstrated with dual intracellular-extracellular recordings of horizontal cell ganglion cells pairs with current injections into horizontal cells.

SS 28 has qualitatively and quantitatively similar effects to SS 14. The non-degraded SS analog SMS 201-995 is approximately equipotent with SS suggesting that SS may "act at a distance" in the rabbit retina. Cysteamine, which specifically depletes SS in rabbit retina (Sagar and Martin, 1982) increases the sensitivity of retinal neurons to SS.

We suggest that SS may be a neuromodulator in the rabbit retina with effects at multiple levels of the retinal circuitry, converging to produce a coordinated change in retinal output.

Supported by NEI grant EY03014.

108.9 THE EFFECTS OF APB ON THE CONTRAST SENSITIVITY OF CAT RETINAL X CELLS. E. P. Chen* and R. A. Linsenmeier. Departments of Biomedical Engineering and Neurobiology and Physiology Northwestern University, Evanston, IL 60201

Slaughter and Miller demonstrated in the mudpuppy retina that 2-amino-4-phosphonobutyric acid (APB), a glutamate analog, is very selective in mimicking the effect of the cone transmitter on the ON bipolar cells (Science, 219:1230-1232, 1981). This selectivity offers a unique opportunity for studying the contribution of ON bipolar cells to the receptive field circuitry of more proximal visual neurons. Our primary interest is the cone pathway to X-type cat retinal ganglion cells. Bolz et al. (Neurosci., 12:875-885, 1984) found that APB modifies the maintained discharge rate of cat retinal ganglion cells differently depending on the cell's center polarity; it reduced the discharge of the ON-center cells and increased that of OFF-center cells. In addition, the center response of ON-center cells to light was reduced in the presence of APB. The effect of APB on the light response of OFF-center cells, however, was small and variable. We have reexmined the effects of APB on the center mechanism of ON- and OFF-center X cells and studied its effect on center-surround spatial summating properties.

Our experiments were performed on the intact retina of anethetized cats with double-barreled electrodes. An X cell's activity was monitored extracellularly at the soma by one barrel, while 2-50 mM APB was delivered from the other by pressure ejection. The spatial summating properties of each X cell were characterized by using 2 Hz stationary or drifting sinusoidal gratings of various spatial frequencies at a photopic mean luminance, allowing us to estimate the strength and summating radius of the center and surround. Then APB was ejected until its effect reached a steady-state. At this time, the activity of the X cell was quantified in a similar fashion. Using this protocol, we were able to compare the strength and summation radius of the two mechanisms before, during, and after the application of APB. Our results confirmed Bolz et al.'s observations on APB's effects on X cells' maintained discharge. APB, however, reduced the responsivity of the center mechanism of not only ON-center, but also OFF-center X cells. There was no change in the size of the center mechanism. We also found an APB-induced phase advancement in the center response of both types of X cell, which may reflect a modification of the dynamic properties of these cells. APB seems also to reduce the surround responsivity of X cells, but further studies are required to determine whether center-surround balance or the surround radius have been altered by this agent. Supported by R01 EY00206 to C. Enroth-Cugell, R01 EY05034 and training grant T32 NS07223.

108.10 SPATIAL CONTRAST SENSITIVITY DEFICITS PRODUCED BY ON-CHANNEL BLOCKADE IN THE RHESUS MONKEY. E.L. SMITH III, G.C. DUNCAN, R.S. HARWERTH, AND M.L.J. CRAWFORD. College of Optometry, University of Houston and Sensory Sciences Center, University of Texas at Houston, Houston, Texas 77004.

One of the presumed advantages of processing information in parallel ON and OFF pathways is that the combined activity within these reciprocal systems facilitates the detection of simultaneous contrast. Logically it would be expected that inactivation of either the ON or the OFF pathway would result in a decrease in spatial contrast sensitivity. To examine this hypothesis, 2-amino-4-phosphonobutyric acid (APB) was used to reversibly inactivate the retinal ON channel and psychophysical procedures were employed to determine the effects of the ON-channel blockade on the rhesus monkey's spatial contrast sensitivity function.

The behavioral paradigm was a temporal interval detection task in which the subjects were required to respond to the appearance of a vertical sinusoidal grating pattern. Contrast detection thresholds for spatial frequencies between 0.25 and 16 cycles per degree were measured using a descending method of limits. Approximately three hours before the behavioral experiments, the retinal ON channel was inactivated by intraocular injections that produced estimated vitreal APB concentrations that ranged from 200 to 500 uM. The effectiveness of the APB injections was confirmed via the electroretinogram.

In agreement with a previous report by Schiller et al. (Nature, 322:824, 1986), APB-induced, ON-channel blockade resulted in a reduction in spatial contrast sensitivity. We found, however, that the magnitude of the contrast sensitivity deficit varied as a function of spatial frequency. The smallest changes in contrast sensitivity were observed for the lowest spatial frequencies; there was a systematic increase in the contrast sensitivity deficit as the spatial frequency of the grating pattern was increased.

108.11 SPATIAL PROPERTIES OF CONTRAST SIGNALLING BY Y RETINAL GANGLION CELLS OF CAT. John B. Troy, Christina Enroth-Cugell and John G. Robson. Biomedical Engineering and Neurobiology & Physiology, Northwestern University, Evanston, Illinois 60201 and Physiological Laboratory, University of Cambridge, U.K.

Since the middle sixties, it has been known that spatial summation within the receptive fields of Y retinal ganglion cells of cats is nonlinear (Enroth-Cugell, Ch. & Robson, J.G. J. Physiol. 187: 517-552, 1966). The elegant studies of Shapley and his colleagues have since provided us with first a quantitative model of the spatial properties of the Y cell's receptive field primarily founded on the cells' responses to single sinusoidal gratings (Hochstein, S. & Shapley, R.M., J. Physiol. 262: 265-284, 1976), and secondly a description of the dependence of the temporal transfer function on contrast (Victor, J.D. & Shapley, R.M., J. Gen. Physiol. 74: 671-689, 1979).

While Shapley and his coworkers have, in these earlier studies, examined the responses of Y cells to a number of non-sinusoidal spatial patterns, their investigations were focused more on the temporal properties of the Y cell receptive field than on its spatial properties. We have lately studied the responses of Y retinal ganglion cells to spatial patterns formed from more than one sinusoid; one of which was of high enough spatial frequency that it produced no first harmonic response from the cell. We found that the cell's response could not be predicted from a linear combination of the responses to each sinusoid presented alone, as might have been expected from Hochstein and Shapley's classic model. In fact, the presence of a second spatial sinusoid shifted the response versus contrast relationship of the Y cell for stimulation with another sinusoidal pattern along the logarithmic contrast axis. These results extend the description of contrast gain control in the retina provided by Shapley and Victor. It is clear that considerable work remains to unravel the mysteries of the spatiotemporal properties of the receptive field of the Y cell. Supported by NIH R01-EY00206 and R01-EY06669.

108.12 SPATIAL FREQUENCY ANALYSIS OF CAT RETINAL W-CELLS. M.H. Rowe and J.F. Cox*. Dept. Zoology & College of Osteopathic Medicine, Ohio University, Athens, OH 45701.

An important first step in understanding the afferent circuitry of retinal ganglion cells is the identification and characterization of distinct receptive field components. Although a great deal is known about the spatial components of X-and Y-cells of the cat retina, relatively little is known about the structure of W-cell receptive fields. We have begun to use spatial frequency analysis to identify spatially distinct components of cat retinal W-cells.

Our sample to date includes on and off tonic and phasic, as well as directionally selective and one suppressed by contrast cell. Both on and off tonic and phasic cells appear to have spatially linear center mechanisms, i.e. their response to a stationary, sinusoidally counterphased sine wave grating contains a fundamental component whose amplitude is a sinusoidal function of spatial phase. The responses of all phasic W-cells and some tonic W-cells also contain a second harmonic component whose amplitude is independent of spatial phase. Furthermore, in these cells drifting gratings at a spatial frequency above the resolution of the center elicit an unmodulated elevated maintained discharge. Thus, these cells appear to receive input from excitatory rectifying subunits similar to those described for Y-cells.

The spatial resolution of the center mechanism, measured with drifting sine wave gratings, varies considerably among W-cells, but can be as high as 2.5 c/d in phasic W-cells, 1.5 c/d in directionally selective cells and over 3 c/d in tonic W-cells. Second harmonic components, when present, invariably have higher spatial resolution than the center. Most cells in both groups show a clear fall off in contrast sensitivity at low spatial frequencies, indicating the presence of a surround. Contrast thresholds for phasic W-cells were often an order of magnitude higher that for X- or Y-cells in the same animals. Thresholds for tonic W-cells were much lower, but still higher than for X- or Y-cells.

The response of the suppressed by contrast cell to drifting gratings included both a modulated and an unmodulated suppression which were proportional to contrast. The modulated suppression was dominant at low spatial frequencies and the unmodulated suppression at high spatial frequencies, suggesting that the unmodulated suppression represents inhibitory subunits with higher spatial resolution than the center.

109.1 THE N-METHYL-D-ASPARTATE ANTAGONIST MK-801 POTENTLY INTERACTS WITH THE BRAIN PHENCYCLIDINE/σ RECEPTOR. R. Sircar, M. Rappaport*+, R. Nichtenhauser* and S.R. Zukin, Departments of Psychiatry and Neuroscience, Albert Einstein College of Medicine, Bronx, NY, +University of Cincinnati School of Medicine, Cincinnati, OH.

MK-801 ((+)-5-methyl-10, 11-dihydro-5H-dibenzo[a,d] cyclohepten-5, 10-imine maleate) is a novel anticonvulsant agent reported to antagonize CNS actions of the excitatory amino acid N-methyl-D-aspartate (NMDA) non-competitively (Wong et al., Proc. Nat. Acad. Sci. USA, 83:7104, 1986). The question arises of the mechanism underlying the anti-NMDA effects of MK-801. In this study we show MK-801 to be an extremely potent inhibitor of the binding of [^{3}H]N-(1-[2-thienyl] cyclohexyl) piperidine ([^{3}H]TCP) to brain PCP/σ receptors. Its IC_{50} value of 3.8 ± 0.8 nM in this assay ranks it as the most potent known ligand of the brain PCP/σ receptor (MK-801 > PCE > dexoxadrol > PCP > ketamine > levoxadrol). Addition of 1 μM MK-801 altered the apparent K_d of [^{3}H]TCP binding from 20.8 nM in the control situation to 291.3 nM in the presence of MK-801 without altering the apparent B_{max}. MK-801 strongly inhibited the binding of [^{3}H](+)N-allylnormetazocine ([^{3}H](+)SKF10,047) to the PCP/σ receptor but its effect on [^{3}H](+)SKF10,047 binding to the non-PCP haloperidol-sensitive σ binding site was weaker by several orders of magnitude. Functionally, MK-801 mimicked the inhibitory action of PCP on NMDA-stimulated [^{3}H]norepinephrine ([^{3}H]NE) release from rat hippocampal slices. For inhibition of NMDA-stimulated neurotransmitter release, MK-801 was significantly more potent than PCP; half maximal inhibition with MK-801 was observed at 1.47 nM against 75.9 nM for PCP. Our findings are consistent with those of a recent study (*Ibid.*) in which it was reported that MK-801 antagonized NMDA-induced depolarization in the rat cortical slice preparation, and that [^{3}H]MK-801 labeled a single population of binding sites from which it could be displaced by PCP and ketamine. All of those results can be interpreted on the basis of our determination that MK-801 exerts its anti-NMDA effects by potently binding to PCP/σ receptor. In fact, MK-801 appears to be the best available molecular probe of the PCP/σ receptor.

109.2 A NEW POTENT NMDA-TYPE RECEPTOR ANTAGONIST - CGS 19755. J. Lehmann, A.J. Hutchison, S.E. McPherson, C. Tsai, C.M. Sinton, D. Murphy, M. Williams, D.J. Steel, and P.L. Wood. Neuroscience/Cardiovascular Research, Pharmaceuticals Division, CIBA-GEIGY Corp., Summit, NJ 07901.

CGS 19755 (1-(cis-2-carboxypiperidine-4-yl)methyl-1-phosphonic acid) potently inhibited N-methyl-D-aspartate- (NMDA-)evoked, but not KCl-evoked, [^{3}H]acetylcholine release from slices of the rat striatum. The concentration-response to NMDA was shifted to the right by CGS 19755, consistent with a competitive interaction with NMDA-type receptors. CGS 19755 inhibited [^{3}H]CPP binding to NMDA-type receptors with an IC_{50} of 67 nM, making it the most potent NMDA-type receptor antagonist yet reported. CGS 19755 did not affect the binding of 21 other ligands to their receptors. In crude P_2 fractions, no evidence was obtained to suggest that radiolabeled CGS 19755 is taken up by an active transport system. Furthermore, CGS 19755 failed to affect the uptake of [^{3}H]L-glutamate, or to interact with aconitine-induced inhibition of [^{3}H]L-glutamate uptake, the latter finding consistent with a lack of membrane-stabilizing or local anesthetic properties. CGS 19755 selectively antagonized the excitation by iontophoretically applied NMDA in the red nucleus of the rat, without affecting the excitation by quisqualate. CGS 19755 inhibited the harmaline-induced increase in cerebellar cGMP levels completely at a dose of 4 mg/kg i.p., with a duration of action exceeding 2 hours. CGS 19755 therefore is a competitive NMDA antagonist which is active in vivo and may be a useful therapeutic and investigative agent.

109.3 [3H]-CPP BINDING TO NMDA RECEPTORS IN HIPPOCAMPAL MEMBRANES. David T. Wong and Penny Threlkeld*. Lilly Research Laboratories, Eli Lilly and Company, Lilly Corporate Center, Indianapolis, IN 46285.

CPP, 3-((±)-2-carboxypiperazin-4-propyl-1-phosphonic acid, has been identified as a potent and selective antagonist of NMDA receptors (Davies et al, Brain Res. 382:169, 1986). We describe here the specific binding of [3H]-CPP with properties similar to those of the N-methyl-D-aspartate-sensitive glutamate receptors in hippocampal membranes (P. Threlkeld, P. Ornstein and D. Wong, this volume, 1987). Crude synaptosomal preparations (P2 fraction) isolated from hippocampus of rat brain were suspended in 50 mM Tris-acetate (pH 7.4) containing the detergent Triton X-100 in a final concentration of 1%. After standing at 4°C for 15 min, the suspension was centrifuged at 50,000 x g for 10 min. The detergent was removed by repeating the process of suspension and centrifugation 5 times. The resulting membranes in 150 µg protein were incubated at 25°C for 15 min in a medium containing 50 mM Tris-acetate buffer (pH 7.4) and various concentrations (1-50 nM) of [3H]-CPP. L-Glutamate at 10 µM was included in separate samples to assess nonspecific binding at each concentration of [3H]-CPP. Specific binding represented 67-73% of total binding. [3H]-CPP binding was saturable with a maximum density (Bmax value) of 3.4 pmole/mg protein and a dissociation constant (Kd value) of 22 nM. L-Glutamate at 25 nM lowered the Bmax and Kd values by 54 and 28%, respectively, suggesting a noncompetitive nature of inhibition. L-Glutamate was most potent as an inhibitor with concentration required to lower 50% of [3H]-CPP binding at 25 nM (IC50 value). D-AP5 and D-AP7 were stereospecifically more potent (IC50's of 47 and 320 nM, respectively), than their corresponding L-isomers by 45 and 11 times. Glutamate diethylester, homocysteate, l-aspartate and NMDA also inhibited [3H]-CPP binding, with IC50's of 180, 240, 1000 and 1700 nM, respectively, but quisqualate, kainate and quinolinate inhibited only at 10,000 nM or higher concentrations. [3H]-CPP binding was inhibited by the guanine nucleotides GTP, GDP and GMP, with IC50's of 4.1, 10 and 100 µM, respectively. The adenosine nucleotides ATP, ADP and AMP were inert at 10 µM. Thus, these studies show that [3H]-CPP is an ideal 3H-ligand for studies of the NMDA receptors of excitatory amino acids in vitro.

109.4 **ANATOMICAL AND PHARMACOLOGICAL EVIDENCE FOR TWO CLASSES OF NMDA RECOGNITION SITES.** D.T. Monaghan[1], C. Chung*[1], H. Olverman*[2], J. Watkins*[3], and C.W. Cotman[1]. Dept. Psychobiology[1], Univ. California, Irvine, CA 92717, Dept. Pharmacology[2], Univ. Edinburgh, Edinburgh, U.K. and Dept. Pharmacology[3], The Medical School, Bristol BS81TD, U.K.

The excitatory amino acid receptor which is selectively activated by N-methyl-D-aspartate (NMDA) plays a critical role in synaptic transmission, neuronal plasticity, epileptiform activity, and excitotoxicity. Using electrophysiological and radioligand binding methods, pharmacological studies of the NMDA receptor generally indicate that this receptor represents a homogeneous population exhibiting a unique pharmacological profile. However, there is some evidence that there may exist multiple receptor populations. The relative potency of quinolinic acid as an NMDA agonist varies between regions. In radioligand binding experiments, agonists are more potent displacers of L-[^{3}H]glutamate binding (at the NMDA site) than of [^{3}H]3-((±2-carboxypiperazine-4-yl)propyl-1-phosphonic acid ([^{3}H]CPP) which also binds at the NMDA site. In contrast, antagonists are better displacers of radiolabelled antagonist binding.

To evaluate the possibity of multiple NMDA sites we have compared the distribution of NMDA-sensitive L-[^{3}H]glutamate binding sites to that of [^{3}H]CPP binding sites in the rat brain with the use of quantitative autoradiography. Autoradiograms of NMDA-sensitive L-[^{3}H]glutamate and [^{3}H]CPP binding sites were prepared as previously described (P.N.A.S. 83 (1986) 7532, Eur. J. Pharmacol. 131(1986) 161).

Relative to L-[^{3}H]glutamate, [^{3}H]CPP binding is low in the striatum, septum and cerebellar granule cell layer and relatively high in the thalamus. If two populations of NMDA binding sites exist, then the slower dissociating ligand L-[^{3}H]glutamate might label both populations in autoradiographic preparations, and various glutamate analogues may display regional variations in their ability to displace NMDA-sensitive L-[^{3}H]glutamate binding. We have found that D-2-amino-5-phosphonopentanoate, 2-amino-7-heptanoate, and D-aminoadipate more potently displace L-[^{3}H]glutamate binding from the cerebral cortex than other brain regions and are relatively weak at displacing binding in the cerebellar granule cell layer and the medial striatum. In contrast, the agonists, NMDA, quinolinate, and L-aspartate were more potent displacers of binding in the medial striatum than in other regions, and relatively weak displacers of binding in the thalamus. Thus, binding sites in the thalamus preferentially recognize NMDA antagonists while binding sites in the cerebellum and medial striatum preferentially recognize NMDA agonists.

These results suggest that there exist either two distinct NMDA receptor types or two states of the NMDA receptor which differ by their relative affinity for agonists and antagonists. Thus it remains to be determined whether these sites can interconvert or are distinctly different receptor populations.

109.5 MODULATION OF EXCITATORY AMINO ACID TRANSMISSION BY PHENCYCLIDINE AND GLYCINE IN THE RAT CEREBELLUM STUDIED IN VIVO. W. Danysz*, J.T. Wroblewski*, G. Brooker* and E. Costa. (SPON: M. Miyata). FIDIA-Georgetown Institute for the Neurosciences, Georgetown University Med. Sch., Washington, D.C. 20007.

It has been shown previously that excitatory amino acid responses induced by N-methyl-D-aspartate (NMDA) as measured electrophysiologically, biochemically and behaviorally can be attenuated by administration of phencyclidine (PCP). Our recent studies have demonstrated that ionotropic (G_C) and metabolotropic (G_P) excitatory amino acid receptors are present in primary cultures of cerebellar granule cells. One subclass of each receptor category (G_{C1} and G_{P1}) undergoes negative allosteric modulation by ligands acting at PCP recognition sites. This interaction may be of a physiological significance since an endogenous ligand for PCP recognition sites has been identified (Quiron et al., Peptides, 5, 967-973, 1984). Recent electrophysiological findings suggest that excitatory responses to NMDA can be modulated in a positive manner by glycine, acting at specific strychnine-insensitive recognition sites, possibly associated with G_C receptors (Johnson and Ascher, 1987, Nature, 325, 529-531).

In the present study, we have demonstrated that signal transduction at excitatory amino acid receptors present in the cerebellum can be modulated in opposite directions by PCP and glycine. For this purpose, male Sprague-Dawley rats (200 g) were implanted with plastic cannulae into the lateral cerebral ventricle. Four days after surgery, rats were used for the experiments. NMDA (G_{C1} and G_{P1} agonists) and PCP were injected i.c.v., while glycine was injected both i.c.v. and i.p. The animals were sacrificed by microwave irradiation 1-15 min after NMDA injections. The concentrations of cyclic GMP in brain tissues were measured by RIA.

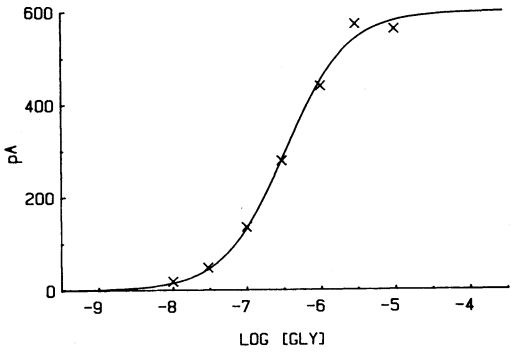
Injections of NMDA resulted in an increased content of cyclic GMP in the cerebellum, which was dose- and time-dependent. The co-administration of 2-amino-5-phosphonovaleric acid abolished this response confirming the specificity of NMDA action. PCP, injected (50 ug i.c.v.) together with NMDA inhibited the increase of cyclic GMP content elicited by NMDA. PCP also decreased cGMP content in the cerebella of saline-injected rats. Glycine, injected i.c.v. (1 ug) together with low doses of NMDA (1 ug) produced a 6-fold potentiation of NMDA action. The administration of glycine alone had no effect on cerebellar cGMP content.

These results indicate that PCP and glycine may act in opposite ways in modulating the responses of G_{C1} receptors. The possibility that modulatory sites for PCP and glycine may be located within the supramolecular complex of these receptors is in agreement with the present finding.

109.6 INTERACTION OF GLYCINE WITH THE N-METHYL-D-ASPARTATE RECEPTOR. J.W.Johnson* and P.Ascher* (SPON: C.KORDON) Laboratoire de Neurobiologie, Ecole Normale Supérieure, Paris.

The potentiation by glycine of the response activated by NMDA was studied using patch-clamp techniques on cultured brain neurons from mouse embryo. Dose-response curves for glycine were fit with the Hill equation by using a simplex algorithm to find the best values for n (Hill coefficient), Km (apparent dissociation constant), and maximum response. In the example shown below ([NMDA]=10 uM, [Mg]=0, V(h)=-50 mV) the value found for n was 1.04 and for Km 340 nM.

The high affinity of glycine for its receptor suggests that the glycine unbinding rate may be relatively slow. When the solution bathing a neuron is quickly changed from NMDA + glycine to NMDA alone, the decay of the response requires several seconds. The rate of this slow decay should approximate the glycine unbinding rate if NMDA channel closing rate is fast relative to both channel opening and glycine unbinding rates, as is suggested by data from outside-out patch recordings. Similar experiments in which a change is made from NMDA to NMDA + glycine (with glycine concentration below its Km) should allow estimation of the glycine binding rate. The validity of this simple approach can be tested by comparing the glycine affinity deduced from dose-response curves with that calculated from the on and off rates of glycine binding.



109.7 POTENT AND COMPETITIVE ANTAGONISM AT NON-NMDA RECEPTORS BY FG 9041 AND FG 9065. T. Honoré*[1], S.N. Davies*[2], J. Drejer*[1], E.J. Fletcher*[2], P. Jacobsen*[1], D. Lodge*[2] and F.E. Nielsen*[1] (SPON: L.H. Jensen). [1]Ferrosan Research Division, DK-2860 Soeborg, Denmark. [2]Royal Veterinary College, London NW1 OTU, UK.

Investigations of functions mediated by quisqualate receptors have been difficult due to lack of potent and selective antagonists. Here we report a new type of potent and competitive quisqualate antagonists.

FG 9041 and FG 9065 are potent inhibitors of ^{3}H-AMPA binding to rat cortical membranes with IC_{50}'s of 475 and 275 nM, respectively. Y-D-glutamyl aminomethyl sulphonic acid (GAMS), which has been reported to be a selective antagonist for non-NMDA-receptors gave an IC_{50} of 190,000 nM in the same assay.

FG 9041 and FG 9065 gave IC_{50}'s for the ^{3}H-kainate binding site of 2250 and 1700 nM, respectively and were very weak or inactive on NMDA-receptors as measured by ^{3}H-CPP binding (IC_{50} > 25 µM). No affinity of the compounds were detected for 5-HT-, NA-, Muscarinic-, DA-, opiate-, benzodiazepine-, GABA- or glycine-receptors.

In the following the antagonistic activities are exemplified for FG 9041, but generally FG 9065 has similar selectivity with a higher potency.

FG 9041 is a potent competitive antagonist of quisqualate induced ^{3}H-GABA release from cultured mouse cortical neurons (pA_2 = 6.25 corresponding to an EC_{50} = 560 nM). In this assay the EC_{50} of GAMS was > 200 µM. The EC_{50}'s of FG 9041 and GAMS as antagonists of kainate and NMDA induced ^{3}H-GABA release were 1300 and 4000 nM, and 185 and 235 µM, respectively. Detailed discussion of the activities of excitatory aminoacid antagonists on cell cultures will be presented elsewhere (Drejer et al. This meeting).

After electrophoretic application in rat spinal cord of FG 9041 to 15 cells the responses to quisqualate and kainate were reduced approximately equally with relatively little effect on the response to NMA. The effect of FG 9041 on the responses to L-glutamate and L-aspartate were tested on 11 cells which had selectivities to quisqualate and NMA as above. In these cells FG 9041 blocks the responses to L-aspartate most efficiently.

The above mentioned results indicate that FG 9041 and FG 9065 are selective and competitive antagonists of non-NMDA receptors with preference for the quisqualate receptors.

109.8 SINGLE CHANNEL PROPERTIES ESTIMATED FROM EXCITATORY AMINO ACID INDUCED CURRENT NOISE IN ISOLATED FISH HORIZONTAL CELLS. B.N. Christensen and T.J. O'Dell. Dept. Physiology and Biophysics, Univ. Texas Medical Branch, Galveston, TX. 77550.

Several of the excitatory amino acids produce increases in membrane permeability in fish horizontal cells. Glutamate (GLU), quisqualate (QA) and kainate (KA) are depolarizing agonists in both catfish (Ictalurus punctatus) and stingray (Dasyatis Sabina) whereas aspartate (ASP) and n-methyl-d-aspartate (NMDA) are effective only on catfish horizontal cells. We have used the fluctuations in the agonist induced current noise to measure the single channel conductance and mean channel open time in the presence of these agonists in an attempt to determine any differences that may exist between these two preparations of the agonist action.

Following enzymatic isolation, horizontal cells were voltage clamped at the resting membrane potential using patch electrodes. The cells were positioned by displacement of the electrode into a small isolation chamber with a volume around 25 uL to facilitate rapid exchange of solution containing the agonists to be studied. A background power spectrum was measured and subtracted from the agonist spectrum and this difference spectrum was used to estimate single channel conductance and mean open time. Open time was calculated from the corner frequency of a single Lorentzian fitted to the subtracted spectrum. Single channel conductance was calculated from the variance of the agonist induced current noise.

There was little difference in channel open time for the four agonists KA, QA, NMDA, or ASP in the catfish. They ranged from, 1.1 mSec to 1.3 mSec respectively (8 cells). The mean open times for KA and QA in stingray horizontal cells were about two times longer; 2.4 mSec for KA and 1.7 mSec for QA (12 cells). The single channel conductances were quite similar for the two preparations for the same agonist. KA produced the smallest conductance of 4.4 and 4.9 pS, QA the largest conductance of 9.9 and 10.1 pS for the two preparations. The single channel conductance for NMDA and ASP in the catfish was 6.7 and 5.0 pS. The single channel conductance measured under these conditions are similar to those measured in other CNS neurons except for the NMDA channel which has been reported to be as large as 50 pS in some preparations (Cull-Candy and Usowicz, Nat., 325, 1987 and Jahr and Stevens, Nat., 325, 1987). However, these authors reported that the NMDA channel had substates with conductances as low as those reported here. Our results suggest that under the conditions of these measurements, the large NMDA channel conductance state does not exist in the catfish horizontal cells.

109.9 INTERACTION OF EXCITATORY AMINO ACIDS AT A SINGLE NON-NMDA TYPE RECEPTOR IN ISOLATED CATFISH HORIZONTAL CELLS. T.J. O'Dell* and B.N. Christensen. (SPON: J. Blankenship) Dept. of Physiology and Biophysics, Univ. Texas Medical Branch, Galveston, TX. 77550.

While the excitatory amino acids glutamate (GLU) and quisqualate (QA) are generally considered to be agonists, these compounds can inhibit kainate (KA) responses in horizontal cells isolated from fish retina. Although the mechanism responsible for this inhibition is unknown, it has been suggested that uncompetitive kinetics are involved (Ishida and Neyton, P.N.A.S., 82, 1985). To better determine the mechanism(s) responsible for the GLU and QA inhibition of KA responses we have studied the actions and interactions of these compounds using horizontal cells isolated from catfish (Ictalurus punctatus) retina.

Whole-cell currents were recorded from enzymatically isolated cone horizontal cells using the single electrode patch-clamp technique to voltage-clamp the cells. Known concentrations of agonist were rapidly bath applied onto the cells using the "concentration-clamp" technique (Akike et al., J. Physiol., 379, 1986).

Dose-response curves for GLU, QA, KA, and alpha-amino-3-hydroxy-5-isoxazole-4-propionic acid (AMPA) were parallel to one another, suggesting that the agonists may be acting at a common site. The rank order affinity of the agonists was QA>AMPA>GLU>KA (EC50's = 2.3, 15.4, 23.0, and 85.0 (uM) respectively). Although KA had the lowest affinity of the agonists tested, at saturating concentrations KA produced 4-7 times more current than the other agonists. To examine the QA and GLU inhibition of KA responses, we applied 70 uM KA alone with concentrations of QA, GLU, or AMPA from 1 to 500 uM. QA, AMPA, and GLU all inhibited the KA response, the rank order potency for the inhibition being QA>AMPA>GLU (IC50's = 20.0, 88.0, and 150.0 uM respectively). Our results suggest that GLU, AMPA, KA, and QA act at a common receptor site. Although KA has the lowest affinity for this site it is more efficacious than the other agonists (i.e. produces the largest current response at saturating concentrations). When QA, AMPA, or GLU are applied with KA these agonists can displace KA from the receptor (due to their higher affinity) but they in turn produce much less current than KA. Thus the KA response appears to be inhibited by the other agonists. Our results suggest that the QA, GLU, and AMPA inhibition of KA responses arises from the interaction of agonists with different affinities and "efficacies" at a common receptor site.

109.10 NONCOMPETITIVE N-METHYL-D-ASPARTATE ANTAGONISTS AFFECT MULTIPLE ION CHANNELS. S.M. Rothman. Departments of Anatomy & Neurobiology and Pediatrics, Washington University School of Medicine, St. Louis, MO 63110.

Understanding the mechanism(s) of action of phencyclidine (PCP) and the related compounds ketamine (KET) and MK-801 has become an important problem in neuropharmacology. Considerable evidence suggests that these compounds are noncompetitive N-methyl-D-aspartate (NMDA) antagonists, while other experiments have demonstrated that at least PCP blocks voltage-gated potassium currents. We have examined the actions of PCP, KET, and MK-801 in cultures of dispersed rat hippocampal neurons. The whole cell patch clamp technique was used to record from single neurons under either voltage clamp or current clamp.

When neurons were stepped from -80 mV to -10 mV in buffer containing TTX and Cd and lacking added Ca, they produced a rapidly inactivating outward current which decayed by 100 msec (I_A) and a non-inactivating outward current which remained constant over 500 msec (I_K). The former current was partially blocked by 5 mM 4-aminopyridine (4-AP). PCP reversibly reduced both current in a concentration-dependent manner. At 100 µM, I_A decreased by 22.4±7.2% and I_K by 12.8±14.3% (n=12). At 3 mM, I_A and I_K diminished by 71.4±9.6% and 52.8±21.5% (n=5), respectively. Similar concentrations of KET or MK-801 produced equivalent reductions in I_A and I_K. However, the competitive NMDA antagonist D-2-amino-5-phosphonovalerate (APV) did not affect I_A and I_K.

Under current clamp, 4-AP increased the peak of the action potential and its maximum rate of rise while decreasing its rate of fall. PCP and MK-801 produced a concentration-dependent reduction in the action potential, its maximum rate of rise and rate of fall. Thus, both drugs likely block voltage-gated sodium channels as well as potassium channels.

At 100 µM, PCP and MK-801 decreased the inward current produced by a 200 msec application of NMDA (100 µM) by 74.5±6.2% and 71.2±8.9%, respectively (N=5). The NMDA blockade developed slowly but was at least partially reversible. It was present at holding potentials of -50 mV and +50 mV. APV (100 µM) produced an immediate and almost complete blockade of NMDA responses (92.0±6.1%, n=3). 4-AP had no effect on NMDA responses, even at 5 mM.

Potassium channels in intact hippocampal neurons are far more sensitive to 4-AP than neurons in culture. If there is a similar difference in their sensitivity to PCP, KET, and MK-801, then the behavioral effects associated with these drugs are likely due to actions at both potassium channels and NMDA-gated channels.

109.11 **IONOPHORETIC MAPPING OF GLUTAMATE RECEPTORS ON CULTURED CHICK SPINAL NEURONS.** L.O. Trussell & G.D. Fischbach. Washington U. Sch. of Medicine, 660 S. Euclid, St. Louis, MO 63110.

There is now abundant evidence for the localization of neurotransmitter receptors at sites of synaptic contact in the neuromuscular junction. In contrast, little is known about receptor distribution on neurons, especially in regard to glutamatergic neuronal synapses. We have used micro-ionophoretic application of glutamate to map receptors over the surface of cultured chick spinal neurons. Neurons were voltage-clamped with patch electrodes containing Cs_2SO_4 to improve the spatial clamp. Spatially restricted application of 250 mM glutamate was achieved with 0.5-1.0 msec pulses of less than 100 nA and a retaining current less than 10 nA. The position of the electrode was monitored using a 40X objective and DIC optics.

With careful positioning of the electrode and control of ejection and backing current, a transient inward current was observed in response to a pulse of glutamate. This response ranged from 10-90 pA in amplitude, peaked within 1-3 msec, and decayed within 10 msec. In amplitude and timecourse, these fast responses strongly resembled spontaneous synaptic currents observed in the same cells. The fast responses were critically dependent on electrode position: movement as little as 1-2 um away from or along the neurite sharply reduced and slowed this response. These local areas of high sensitivity were most often observed where neighboring neurites crossed or ran parallel to the recorded neuron's processes or soma. The relative insensitivity of this glutamate-activated conductance to 2-amino-5-phosphonovalerate (APV) and to voltage implies that it is predominantly mediated by G2 (kainate/quisqualate) receptors. Its discrete localization suggests that such receptors are tightly aggregated on these neurons, possibly at synaptic sites.

Following the rapid response discussed above, a slow inward tail was often observed which decayed over hundreds of msec. This slow response was markedly reduced by 0.5mM APV and by holding potentials more negative than -40mV, suggesting that it reflects G1 (NMDA) receptor activation. The slow response was much less sensitive to electrode position, suggesting that such receptors may have a wider spatial distribution than the receptors producing the rapid response.

Other studies in the spinal cord and hippocampus show that fast and slow components of evoked glutamatergic transmission may correspond to G2 and G1 receptor activation, respectively. The present work suggests that this may result from a tight localization of G2 receptors and a diffuse distribution of G1 receptors both responding to synaptically released glutamate.

109.12 **THREE TYPES OF EXCITATORY AMINO ACID INDUCED CURRENTS IN mRNA INJECTED XENOPUS OOCYTES.** T.A. Verdoorn* and R.J. Dingledine. (SPON : Anthony T. Dren) Dept. Pharmacology and Curriculum in Neurobiology. Univ. of North Carolina, Chapel Hill, NC 27514.

Total mRNA was prepared from rat brain tissue and injected into Xenopus oocytes. The oocytes were incubated for at least 24 hours in modified Barths solution before voltage clamp experiments were done. Injected oocytes responded with inward currents to bath applied excitatory amino acid (EAA) agonists while uninjected or water injected oocytes had very small or no responses to these agonists. Three distinct types of inward currents were seen in the injected oocytes corresponding to the three subtypes of EAA receptors thought to exist in mammalian brain. The response to N-methyl-D-aspartate (NMDA) was smooth and nondesensitizing. Its physiological properties and sensitivity to modulators are consistent with the neuronal NMDA receptors studied previously (see Kleckner et. al., this meeting). The EC50 for NMDA was 39±13 µM (n=4) and D-2-amino-5-phosphonovaleric acid (10 µM) reduced the response to 100 uM NMDA by an average of 83 % (n=6). Ibotenate and glutamate could also activate this current.

Another type of response to EAA agonists was elicited by quisqualate and glutamate and consisted of a inward current with large current oscillations superimposed. The oscillations are thought to be due to a chloride channel and desensitize rapidly leaving only the smooth part of the response.

The kainate induced current represents the third type of EAA response that we see in mRNA injected oocytes. Kainate causes a smooth current that does not desensitize and is insensitive to Mg++ ions. The kainate conductance and EC50 do show a slight voltage dependency. The response can be reduced by the antagonist kynurenic acid (50 µM). The reversal potential for kainate is -5.3± 2.0 mV (n=15) which suggests that the kainate channel is nonselectively permeable to cations in the oocyte. At a holding potential of -60 mV the EC50s for kainate and its more potent analogue domoate were 89±8 µM (n=10) and 14± 0.5 µM (n=4) respectively. The EC50s (measured as the smooth response) for glutamate and quisqualate were found to be 14±4 µM (n=5) and 0.44±0.03 µM (n=4) respectively.

These experiments show that the oocyte can be used to study the properties and structural relationships of brain EAA receptors. In the future we will determine the potencies of the various EAA receptor antagonists with Schild analysis as well as begin to study the receptor inter-relationships by using mRNA purified by size fractionation.

110.1 **HEPATIC PORTAL AND GASTRIC AFFERENT PROCESSING IN NUCLEUS OF THE SOLITARY TRACT OF THE RAT**

W. B. Laughton, L. A. Campfield, and D. O. Nelson Department of Physiology, Northwestern University Medical School, Chicago Il, 60202 and Hoffman-LaRoche Inc., Nutley, NJ 07110

Vagal gastric and hepatic mechano- and chemo- receptors monitor the entry of nutrients into the gastrointestinal tract and blood stream, respectively. This information, which is of crucial importance in the control of food intake, is relayed over subdiaphragmatic branches of the vagus, which ultimately synapse on neurons in the caudal and medial nucleus of the solitary tract (NTS). Given the importance that has been attributed to detection of changes in levels of blood glucose, and the possible peripheral monitoring of these changes, we wanted to assess the ways in which the central nervous system (CNS) processes changes in the glycemia, and how this is integrated with other afferent information, such as activity of gastric mechanoreceptors.

Chloralose/ urethane-anesthetized male rats instrumented for physiological recording were used in all studies. In order to devise a stimulus that would selectively influence peripheral (i.e. hepatic portal) glucose-sensitive structures, we employed simultaneous on-line recording of blood glucose levels in both the jugular and hepatic portal veins before, during, and after graded infusions of different volumes of glucose into the hepatic portal vein. A volume was found which produced significant transient increases in portal glycemia, but had no effect on systemic (jugular) levels.

In another series of experiments, this search stimulus was combined with graded distension of the gastric lumen (0-10cm H_2O). Single and multi-unit activity was recorded through glass microelectrodes in the caudal/medial NTS during application of these stimuli (and in some cases to electrical stimulation of the subdiaphragmatic branches). Chicago Sky Blue dye was iontophoretically applied at selected sites to permit histological reconstruction of the recording elctrode placements. Numerous units were found with tonic or phasic responses to gastric distension in the NTS regions receiving gastric branch afferents. Most were excited by distension, although a significant number (~10%) were inhibited. Units were also encountered that responded to increases in hepatic portal glucose concentrations--so far these responses have all been inhibitory. In addition, the cells receiving hepatic portal afferents also received convergent input from gastric mechanoreceptors. Cells that were inhibited by increases in portal glucose were excited by gastric distension.

This convergence of information at the first synapse in the vagal sensory pathway is consistent with our previously reported finding of extensive convergence of afferents in the hepatic and gastric branches of the vagus onto single NTS neurons. It is also consistent with the extensive integration of metabolic afferent information that is believed to take place in the hindbrain. (Supported by HL29033 and NS23432)

110.2 BRAINSTEM UNITARY RESPONSE TO ELECTRICAL STIMULATION OF VENTRAL AND DORSAL GASTRIC VAGAL BRANCHES IN THE CAT. W.D. Barber, C.S. Yuan* and T.F. Burks. Departments of Anatomy and Pharmacology, College of Medicine, University of Arizona, Tucson, AZ 85724.

Gastric vagal projections to the dorsomedial region of the caudal brainstem were examined electrophysiologically in cats anesthetized with halothane and nitrous oxide supplemented with oxygen. Single shock stimulations (0.3 msec, 500 uA, 0.5 Hz) were applied to the ventral and/or dorsal gastric vagal branches to activate C fibers which serve the proximal stomach. Single unit activity was recorded extracellularly from 290 neurons in both sides of the caudal brainstem during gastric vagal nerve stimulation. Based upon stereotaxic coordinates and electrophysiological correlates, the results showed that the units responding to gastric nerve stimulation were located in the region of nucleus solitarius, similar to the location of the responses to gastric distention reported previously in our laboratory (W.D. Barber and T.F. Burks, 1983). The latency of the unitary discharges ranged from 185 to 420 msec with a mean of 293 $\pm$ 52.7 msec. The conduction velocity was less than 1 m/sec based upon the latency of the brainstem responses. The majority of the unitary responses contained multiple spikes. Decreasing the stimulus strength reduced the number of spikes in the unitary discharges, with the first spike showing jitter, suggesting an orthodromic response. Geographically the brainstem projections of the ventral and dorsal gastric branch stimulations were similar. Out of a total of 290 responses recorded, the ventral and dorsal gastric branches projected to the same recording area in 53 cases, and projected to the same neuron in 42 cases. Of the latter 42 convergent projections, there were 30 excitatory and 12 inhibitory responses when the ventral and dorsal gastric branches were stimulated simultaneously. These data indicate that there is a substantial amount of convergence in the brainstem of vagally mediated sensory information from the proximal stomach. The specific nature of the information and its role in the regulation of gastric function remains to be resolved. However, these data have identified some very basic functional characteristics of brainstem neuronal mechanisms in response to electrical stimulation of gastric vagal afferent fibers. (Support by USPHS Grant AM 31804).

110.3 **PATTERNS OF FACILITATION AND INHIBITION IN SOLITARY TRACT (NTS) NEURONS IN CAT PRODUCED BY CONVERGING SOMATIC AND VAGAL AFFERENTS.** R. J. Person. Dept. of Physiology and Biophysics, Univ. Okla. Health Sci. Ctr., Oklahoma City, OK 73190

This laboratory reported data showing convergence of vagal and hindlimb somatic Group II-IV sensory afferents on NTS neurons (Neurosci. Abst. 12:1324). Described here are intra- and inter-afferent interactions producing facilitation and inhibition of sensory input defined by conditioning-test (CT) paradigms. NTS unit responses to afferent stimulation were recorded with tungsten (10 MΩ) microelectrodes in acute, artificially respired, α-chloralose anesthestized, pancuronium paralyzed cats. Recording and stimulating electrodes were placed on the cutaneous sural (S), muscular common peroneal (P), and cervical vagus (V) nerves. Compound action potentials were recorded in response to single 100 μs shocks to define threshold for each nerve. Stimulation was applied in units of threshold in the 1-30X range for Group II and III responses and in trains of five 500 Hz stimuli at 100X threshold for Group IV responses. Units were recorded and histologically localized to the NTS and DMV area contralateral to hindlimb stimulation. Peristimulus histograms (PSTs) were generated for both single and paired stimuli with interstimulus intervals (ISIs) for stimulus pairs of 10-2000 ms and various permuations of P, S, and V shocks as conditioning (C) or test (T) stimuli (eg., CTs of P-S, P-V, and P-P stimuli).

NTS unit responses to single somatic Group II and III stimuli have been described and conform, with an earlier latency, to single and multi-fiber somatosympathetic responses (cf, Terui and Koizumi, J. Auton. Nerv. Sys., 10:73). CT testing demonstrated a common period of inhibition of both subsequent vagal and somatic input at ISIs of 10-500 ms with maximal inhibition of input to 0-50% of control responses in an ISI range of 25-100 ms. At ISIs greater than 500 ms various patterns of facilitation and inhibition of T input were observed with a return to control T response amplitude only after 1500-2000 ms. In some units, early facilitation of T responses were seen particularly with sural C input. Inhibition of T input was often observed with C input excitation below threshold for unit action potential generation. Sensory afferents to NTS neurons therefore elicit a prolonged inhibition during which subsequent somatic and vagal input is substantially or completely blocked.

This central NTS period of inhibition corresponds to the peripheral sympathetic "silent" period and parasympathetic excitation elicited by somatic stimulation. The results suggest that Group II-IV somatic sensory afferents are capable of modulating NTS activity to match cardiopulmonary adjustments for movement and exercise with peripheral tissue demand for blood flow and substrate delivery and support the NTS as the central site of somato-autonomic reflex mediation. Supported by American Heart, Oklahoma Affiliate, OK-85-G-11.

110.4 **INFLUENCES OF VAGAL AFFERENTS ON RAPHESPINAL NEURONS IN THE CAT.** R.W. Blair, U.T. Oh*, S.F. Hobbs, and R.D. Foreman. Dept. Physiology and Biophysics, Univ. Okla. Hlth. Sci. Ctr., Oklahoma City, OK 73190.

Excitation of vagal afferents often inhibits, and sometimes excites, thoracic spinothalamic (STT) and spinoreticular (SRT) neurons. One central site that may mediate these effects is the midline raphe complex; stimulation of raphe magnus inhibits STT, SRT, and other dorsal horn neurons. The purpose of this study was to determine the effects of electrical stimulation of cervical vagal afferents on raphespinal (RAS) neurons in raphe magnus. Fourteen cats were anesthetized with α-chloralose (40 mg/kg) and paralyzed with bolus doses of pancuronium bromide (0.3 mg). Adequacy of anesthesia was tested once paralysis wore off and before the next dose of pancuronium was given. A bipolar platinum electrode was attached to the right cervical vagus nerve after removal of the cervical sympathetic nerve. A laminectomy exposed the T_2-T_4 spinal segments, and concentric bipolar electrodes were placed bilaterally in white matter for antidromic activation of RAS cells. Pulses of 0.1 ms duration and 3-5 mA delivered at 1 Hz were used to search for antidromically-activated neurons. Individual RAS neurons were recorded extracellularly with tungsten microelectrodes. To date 18 RAS neurons have been tested for responses to vagal stimulation. Six neurons (33%) were responsive. All 6 cells were excited if single pulses or brief (10 ms) trains of high frequency (333 Hz) pulses were delivered at 1 Hz. However, if single pulses were delivered at higher frequencies, spontaneous cell activity was often inhibited; this pattern occurred for 3 neurons. A fourth cell's activity was unaffected if pulses were delivered at 20 Hz. The remaining two cells were not tested for responses to tonic trains of vagal stimuli. RAS neurons responsive to vagal stimulation had conduction velocities (CV) ranging between 43-97 m/s; unresponsive neurons had CV between 2-107 m/s. Results indicate that at low frequencies vagal stimulation may increase cell activity, but at higher frequencies inhibition occurs. About a third of RAS neurons respond to vagal afferent stimulation. Thus, vagal afferents can modulate activity of RAS neurons; this effect may then elicit altered activity of spinal neurons. (Supported by NIH grant # HL29618).

110.5 **LONGITUDINAL COLUMN OF GASTRIC BRANCH NEURONS IN THE DORSAL MOTOR NUCLEUS OF THE VAGUS IS COMPOSED OF SUBCOLUMNS CORRESPONDING TO DISTAL DIVISIONS OF GASTRIC BRANCH** T. L. Powley, E.A. Fox, E. Baronowsky*, D.L. Keller*, and H.-R. Berthoud. Lab. of Regulatory Psychobiology, Purdue University, W. Lafayette, IN, 47907.

The motor neurons of the abdominal vagus are organized into longitudinal columns within the dorsal motor nucleus of the vagus (dmnX) (Fox and Powley, Br. Res. 341:269, '85; Powley et al. AJP, in press). Specifically, the rat has five major columns, one corresponding to each of the primary branches of the subdiaphragmatic vagus. The possibility that these separate columns are composed of more punctate topographic elements has not been directly addressed. To evaluate this possibility and to characterize more fully the dmnX columnar organization, we mapped the central topographies associated with two secondary branches arising from the ventral (anterior) gastric branch.

Two complementary strategies were employed. In the first, either one of the two largest secondary gastric branches in the rat (cf. Prechtl and Powley, JCN, 235: 182, '85) as well as all other branches of the ventral vagus were cauterized, and then True Blue (TB) was injected IP (n = 15). [In this protocol all abdominal vagal terminals are exposed to TB, but only the intact secondary branch can transport it centrally--Powley et al., Soc. Neurosci. Abstr. 12, P. 1058, 1986.] In the second labeling strategy, one of the secondary gastric branches was cut and encapsulated in a small HRP-filled styrofoam cuff for a 48 hr survival period (n = 12 for each secondary branch).

Both TB and HRP experiments demonstrated that the ventral gastric branch column in the medial two thirds of the left dmnX was composed of separate, parallel, and longitudinal subcolumns. The axons of the secondary branch issuing onto the antrum/pylorus region of the stomach originated from a subcolumn constituting the medial half of the overall column. In contrast, the efferent fibers in the secondary branch issuing to the corpus/fundus region originated from a subcolumn forming the lateral half of the primary column. The subcolumns extended rostrocaudally throughout the full length of the dmnX. Like the major columns of the primary branches, the subcolumns were spatially more discrete in the caudal two thirds of the dmnX and overlapped more in the rostral pole of the nucleus.

Although to date we have only examined systematically the secondary branches of one of the five primary branches, it would seem parsimonious to hypothesize that the other major columns of abdominal efferents in the dmnX may also be composed of sets of finer subcolumns corresponding to secondary branches of the nerve. Further, the parallel longitudinal pattern of dmnX subunits, when considered in conjunction with the organization of the nucleus of the solitary tract, suggests that the specificity of vagal reflexes may be generated by the sensory-motor lattice which is formed by the orthogonal functional maps of the two nuclei. (NIH Grant DK27627)

110.6 EFFERENT PROJECTIONS OF THE NUCLEUS OF THE SOLITARY TRACT TO THE AMYGDALA, BED NUCLEUS OF THE STRIA TERMINALIS AND SUBFORNICAL ORGAN IN THE RAT EXAMINED USING THE PHA-L ANTEROGRADE TRACING METHOD. A.M. Zardetto-Smith and T.S. Gray. Dept. Anat., Loyola Univ., Maywood IL 60153.

The caudal, medial part of the nucleus of the solitary tract (NTS) receives the majority of general visceral afferent input carried by the vagus and glossopharyngeal nerves. Previous work in the cat has demonstrated that peripheral afferents terminate within the subnuclei of the NTS in a viscerotopic manner. The NTS projects to several forebrain areas in the rat, including the central nucleus of the amygdala (Ce). To examine whether NTS efferents terminate in a topographic manner within the Ce, small unilateral deposits of the sensitive anterograde tracer Phaseolus vulgaris leucoagglutinin (PHA-L) were iontophoretically placed within the caudal subnuclei of the NTS of male Long-Evans rats. After 14 d, the animals were overdosed with sodium pentobarbital and perfused according to the method described by Gerfen and Sawchenko ('84). Coronal sections (20 um) of the brainstem and forebrain were processed for visualization of PHA-L using the avidin-biotin immunoperoxidase technique.

Deposits of PHA-L were confined entirely within the NTS in some animals, or also included the NTS as well as the dorsolateral edge of the dorsal motor nucleus of the vagus in other animals. In the Ce, PHA-immunoreactive fibers were noted throughout all subdivisions of the Ce. The innervation of the ventral subnucleus was especially dense. At rostral levels, the bed nucleus of the stria terminalis contained labeled fibers throughout its medial and lateral subnuclei, with a particularly dense innervation present within the ventral lateral subnucleus. A new observation was the presence of PHA-L immunoreactive fibers within the subependymal and central parts of the subfornical organ. The same deposits of PHA-L resulted in widespread axonal labeling throughout other forebrain regions previously demonstrated to receive direct projections from the NTS. These areas included the paraventricular, supraoptic, dorsomedial and lateral hypothalamic nuclei, median and medial preoptic nuclei.

The present study demonstrates that the same population of cells within the caudal medial NTS send axons to terminate topographically within the Ce, bed nucleus, SFO and other areas of the forebrain. The relative density of terminal labeling within the ventrolateral bed nucleus suggests this region is a major forebrain target of the medial NTS. To our knowledge, the present study is the first to demonstrate direct efferent connections from the NTS to the subfornical organ. This projection may simultaneously relay blood pressure and body fluid volume changes to forebrain autonomic regions. Funded by NS 20041.

110.7 **EVIDENCE FOR DIRECT INHIBITION OF VISCERAL SENSORY NEURONS BY NORADRENERGIC SYMPATHETIC NEURONS.** D.L. Kreulen, and T.L. Anthony* (SPON: J. Angevine). Dept. Pharmacology, Univ. Arizona, Coll. of Med., Tucson, AZ 85724.

Sensory neurons (mechanoreceptors) located in the wall of the large intestine of guinea pig synapse on neurons in the inferior mesenteric ganglion. Transmission in these pathways is both cholinergic and noncholinergic, giving rise to fast, nicotinic excitatory postsynaptic potentials (e.p.s.p.s) and slow noncholinergic depolarizations. In this study we investigated the relationship between the patterns of contractile activity in the colon and the synaptic activity in the IMG. IMGs attached by mesentery and nerve supply to a 2 cm segment of distal colon were removed from guinea pigs and placed in a two-chambered recording bath which allowed separate superfusion of the ganglia and colon. Intracellular recordings in principal ganglionic neurons of responses to colon distension and subsequent contractile activity provided a means to evaluate the effects of postganglionic nerve stimulation and norepinephrine administration on the activity of colonic mechanoreceptors. Rapid distension of the colon to a basal intraluminal pressure of 20 cm H_2O results in an increase in the frequency and amplitude of fast e.p.s.p.s and a slow noncholinergic depolarization in neurons in the IMG. Distension also induced vigorous segmenting activity in the colon which was interrupted 4-7 times/min by sustained propulsive contractions of the entire colonic segment. 73 % of neurons tested received fast cholinergic e.p.s.p.s associated with colonic contractions. In all of these neurons the sustained colonic contractions following distension were associated with cessation of fast cholinergic e.p.s.p.s and partial repolarization of the slow noncholinergic e.p.s.p. Repetitive stimulation of postganglionic nerve trunks that innervate the colon (lumbar colonic nerves) during the distension, resulted in a decrease in the frequency and amplitude of fast cholinergic e.p.s.p.s and cessation of sustained propulsive contractions. Administration of norepinephrine (10^{-5}M) to only the colon had similar effects on both the colon and synaptic input to ganglionic neurons. The inhibitory effects of norepinephrine were antagonized by phentolamine (10^{-5}M). Administration of the smooth muscle relaxant papaverine ($5x10^{-5}$M) also resulted in cessation of sustained propulsive contractions of the colon but synaptic activity to the ganglion was not diminished. These experiments suggest that sympathetic noradrenergic outflow to the colon directly inhibits colonic mechanoreceptors so that they become less sensitive to colon distension. Support: HL 27781, DK 36289.

110.8 **CONVERGENCE AND COLLATERALIZATION OF NON-CHOLINERGIC AFFERENT NEURONS IN THE INFERIOR MESENTERIC GANGLION OF THE GUINEA PIG.** K.D. Keef*, P. Crowe* and D.L. Kreulen. Department of Pharmacology, University of Arizona, Tucson, AZ 85724.

The purpose of these studies was to determine the pattern of non-cholinergic afferent input to neurons of the inferior mesenteric ganglion (IMG). IMG neurons of control or surgically altered guinea pigs (175-275 g) were studied. Under halothane anesthesia IMGs were decentralized and two of three peripheral nerves sectioned. Animals were allowed to recover for 7 days to allow time for nerve degeneration. The IMG was removed and the intracellular responses to nerve stimulation compared. Repetitive stimulation (20 Hz, 4 s) gave rise to a non-cholinergic slow EPSP. In surgically altered ganglia, slow EPSPs were obtained with stimulation of each nerve trunk regardless of the nerve trunk left intact. The amplitudes of these slow EPSPs were significantly less than those recorded in control ganglia. These data suggest that non-cholinergic neurons arise in the periphery, synapse on principal ganglion cells and send collaterals out other nerve trunks. Thus two possibilities exist for the origin of synaptic activity in a single cell in response to stimulation of different nerve trunks, namely; 1) Collateralization and/or 2) Convergence.

Given the extent of collateralization demonstrated in the surgically altered IMG, we proposed that all activity recorded from a single cell in control ganglia with stimulation of the four nerve trunks arises from neurons entering the ganglion from a single nerve trunk (i.e., via collateralization). To test this hypothesis, two nerve trunks were stimulated simultaneously while recording the activity from single cells in control ganglia. Supramaximal stimulation (17 V, 0.2 ms dur) of two nerve trunks never produced slow EPSPs of larger amplitude than that recorded from stimulation of one nerve trunk. Thus each neuron exhibited a maximum level of activation. Simultaneous stimulation with submaximal stimulus intensities (1-6 V) produced variable results ranging from no summation to summation to maximum response. Lack of summation was predicted if neural input from the different nerve trunks occurred exclusively via collateralization whereas summation suggests convergence of neurons originating from different locations.

The experiments provide evidence that the apparent convergence of afferent synaptic input to ganglion cells in the IMG results from 1) the collateralization of axons of afferent neurons and 2) the convergence of multiple afferent neurons, coursing in different nerve trunks, on an individual ganglion cell. Convergence of sensory input on to single IMG neurons from distinctly different regions of the periphery has important physiological implications in terms of the reflex control of viseral function. Support NIH HL27781, HL34449.

110.9 **BIDIRECTIONAL CONNECTIONS BETWEEN ROSTRAL VENTROLATERAL MEDULLA (RVL) AND AUTONOMIC NUCLEI IN THORACIC SPINAL CORD.** *R.L. Stornetta, D.A. Ruggiero and D.J. Reis.* Div. of Neurobiology, Cornell Univ. Med. Coll., New York, NY 10021.

Adrenergic (C1) neurons of the RVL project bilaterally to the intermediolateral (IML) and intermediomedial (IMM) cell columns of thoracic spinal cord and are believed to be crucial to the regulation of arterial pressure (Ross et al., *J. Comp. Neurol., 228*:168, 1984). Neurons of the C1 area receive afferents from dorsal horn neurons of lumbar cord presumably mediating the pressor response to somatic stimulation. It is not known if C1 neurons also receive projections from segments of thoracic cord containing sympathetic preganglionic neurons (SPN's). We examined the projections from thoracic spinal cord to C1 area by injecting anterograde tracers (^{3}H-amino acids or wheat germ agglutinated horseradish peroxidase (WGA-HRP)) into thoracic spinal cord of anesthetized rats. Tissues were processed by autoradiography or WGA-HRP histochemistry and, in double-label studies, C1 neurons were identified with antibodies against phenyl-ethanolamine-N-methyltransferase (PNMT). Anterogradely labeled terminal fields were localized in autonomic brainstem areas including NTS, both RVL and caudal ventrolateral medulla, the A5 area and parabrachial complex. In the C1 area of RVL, spinal afferents intermingled with PNMT labeled neurons and dendrites. The cells of origin of spino-bulbar afferents from thoracic cord were retrogradely labeled following pressure injections of 5% WGA-HRP into the RVL of anesthetized rats. Retrogradely labeled cell bodies and anterogradely labeled terminals were confined bilaterally to laminae VI, VII and X of thoracic cord, i.e. those laminae which contain SPN's in IML and IMM and which do not receive primary sensory afferents. This pattern of retrograde labelling contrasts with projections from lumbar cord where retrogradely labeled cells are concentrated in laminae I, II, IV and V of dorsal horn, areas which receive primary sensory afferents (Stornetta et al., *Neurosci. Abstr. 12*: 1156, 1986). To determine whether the spino-bulbar neurons in IMM and IML were SPN's, the SPN's were identified by dipping the proximal end of the transected cervical sympathetic trunk into a microvial of Fast Blue (FB) in anesthetized rats. 48 h later, rats were reanesthetized and 5% WGA-HRP was pressure injected into RVL. Another 48 h later, rats were killed and tissues processed with WGA-HRP histochemistry. WGA-HRP labeled neurons and terminals were simultaneously visualized with FB labeled SPN's. While some SPN's were seen in juxtaposition to WGA-HRP retrogradely labeled cells in IMM and IML, no double labeled cells were seen. Bulbo-spinal projections from RVL exactly overlapped SPN's bilaterally. We conclude (a) the C1 area of the RVL receives projections from neurons which are not SPN's in the vicinity of the IMM and IML (b) these same spinal neurons are in turn innervated by neurons of RVL. This two-way anatomical connection between spinal and bulbar autonomic centers raises the possibility that information from SPN's is conveyed to RVL neurons. (Supported by HL 07379 & HL 18974)

110.10 NEURALLY EVOKED ELECTRODERMAL RESPONSES (EDR) ARE INHIBITED BY CLONIDINE BY AN ACTION AT THE SPINAL LEVEL. M.C. Koss and J.A. Hey. Departments of Pharmacology and of Ophthalmology and Dean A. McGee Eye Institute, University of Oklahoma Health Sciences Center, Oklahoma City, OK 73190.

Clonidine inhibits function in a variety of autonomic systems by acting in the central nervous system. A spinal cord site of action for sympatho-inhibition in the cardiovascular system is well documented. A spinal locus of action has also been reported for centrally evoked electrodermal responses (Koss, Europ. J. Pharmacol. 37:381, 1976). In a recent series of articles it has been reported that clonidine inhibition of sudomotor responses is unique, in that the primary site of action is at the level of the sympathetic ganglion (Walland, Europ. J. Pharmacol. 102:39, 1984; 102:47, 1984). The present experiments were designed to determine the neural site(s) of action for clonidine inhibition of sympathetic-cholinergic electrodermal responses in anesthetized cats by comparing the effects of clonidine on electrodermal potentials when administered by a variety of routes (intravenous, intra-arterial to the stellate ganglion, and intrathecal). In these experiments electrodermal responses were evoked by stimulation of the posterior hypothalamus as well as from the pre- and postganglionic peripheral nerves. Administration of clonidine (0.3-3.0 µg i.a.) directly to the stellate ganglion did not significantly decrease the amplitude of responses evoked by submaximal hypothalamic stimulation but did inhibit EDR when administered intrathecally at the C_6 to T_2 spinal levels. Administration of clonidine to the ganglion, however, did depress EDR evoked by the nicotinic ganglionic stimulant DMPP (10 µg i.a.). Intravenous clonidine (1-30 µg) also reduced EDR amplitude evoked by single pulse stimulation of both the pre- and postganglionic sympathetic nerves with responses elicited from both sites inhibited to an equal extent. Yohimbine (0.5 mg/kg i.v.) uniformly antagonized clonidine's depression of EDR regardless of the site or mode of activation. These results indicate that clonidine depresses centrally evoked sudomotor responses by activation of alpha$_2$-adrenoceptors in the spinal cord and to a limited extent by direct action at the neuroeffector junction. Although a possible DMPP-clonidine interaction takes place at the level of the sympathetic ganglion, it is unlikely that ganglionic blockade contributes significantly to clonidine inhibition of EDR evoked by electrical activation of the nervous system. (Supported by NSF Grant GII-8610676)

110.11 PRESYNAPTIC α_2-ADRENOCEPTORS MEDIATE SUPPRESSION OF THE PERIPHERAL SYMPATHETIC-CHOLINERGIC SYSTEM. T. Ito* and M.C Koss (SPON: J.P. Farber). Dept. of Pharmacology, Univ. of Oklahoma Health Sciences Center, Oklahoma City, OK 73190.

The sweat glands have a unique sympathetic-cholinergic innervation, activation of which is associated with electrical potential changes of the skin or electrodermal responses (EDRs). The present study was undertaken to investigate adrenergic control of the peripheral sympathetic-cholinergic system by utilizing peripherally evoked EDRs in rats anesthetized with pentobarbital and chloral hydrate (40 mg/kg and 200 mg/kg, i.p., respectively). EDRs evoked by electrical stimulation of the sciatic nerve were recorded from the hindfoot pads with Beckman miniature biopotential skin electrodes. Drugs were administered through a cannula inserted into the jugular vein. Electrical stimulation of the sciatic nerve (4-16 V) produced frequency dependent EDRs with threshold frequency below 1 Hz and maximal response at 16-32 Hz. In the following experiments stimulations of 8-12 V and 2-4 Hz were used to obtain submaximal electrodermal responses of approximately 40-80% of maximal amplitude. dl-Epinephrine (dl-Epi, 0.3-30 µg/kg, i.v.) suppressed evoked EDRs in a dose dependent manner, totally abolishing the response at the highest dose and with an ED_{50} of 4.4 µg/kg. l-Epi, d-Epi and l-norepinephrine also inhibited EDRs in a dose-related fashion with ED_{50}s of 1.7, 28.5 and 31 µg/kg, respectively. Isoproterenol (0.03-30 µg/kg, i.v.) partially decreased EDR amplitude, however, the maximal inhibitory effect obtained was only 34%. Yohimbine (0.75 mg/kg, i.v.) shifted the dose-response curve for dl-Epi to the right with the maximal inhibitory effect of 30 µg/kg of dl-Epi being 26%. Prazosin (0.3 mg/kg, i.v.) and propranolol (1 mg/kg, i.v.) did not alter the effect of dl-Epi. The selective α_2-adrenergic agonist B-HT 920 (1-1000 µg/kg, i.v.), suppressed EDRs with an ED_{50} of 66 µg/kg. This action of B-HT 920 was antagonized by the selective α_2-adrenoceptor blocker, idazoxan (0.1 mg/kg, i.v.) but not by prazosin (0.3 mg/kg, i.v.). In order to directly stimulate the postjunctional muscarinic receptors, methacholine (1 µg) was injected into the femoral artery. Methacholine evoked EDRs of about 1 mV with l-Epi (1-3 µg/kg, i.v., 30-60 sec before methacholine, i.a.) having no inhibitory effect. Taken together, the present results suggest that presynaptic α_2-adrenergic mechanisms are involved in the suppression of the peripheral sympathetic-cholinergic system in the rat. (Supported by NSF Grant GII-8610676. T. Ito was supported by fellowships from Uehara Memorial Foundation and Kao Corp.)

110.12 LOWER BRAINSTEM REGULATION OF ROSTROCAUDAL SPECIAL VISCERAL FUNCTION. B. Graber. Dept. of Psychiatry, Univ. of Nebraska Med. Ctr., Omaha, NE 68105.

A synthetic explanation of essential caudal evacutive processes including micturition, defecation and ejaculation is now possible due to rapid advances in neuroscientific techniques including labelling and tracing of individual neurons and pathways. The traditional passive structural model of neuroanatomy are being revised by a more functional, active, neurochemcial explanations of vital processes. In this presentation I propose to extend and defend my hypothesized synthetic model of anogenitalurinary function described in "A Thirteenth Cranial Nerve: The Cloacal Nerve" (Medical Hypotheses, 1987, in press). Strict adherence to Sherrington's spinal reflexology and Langley's craniosacral fragmentation of the autonomic nervous system has delayed or distracted such a synthesis in spite of accumulating evidence. Put simply, both ontogeny and phylogeny provide evidence that the caudal sphincteric mechanisms seen in cloacal derivatives are anatomically and physiologically similar to rostral special visceral efferent (SVE) branchiomeric derivatives and that the function of these rostral and caudal structures may be at least partially integrated. In this presentation I will utilize this hypothesis and supporting evidence to explain some of the continuing controversies about human sexual function by elaborating on "orgasmic dimorphism".

111.1 BEHAVIORAL CHOICE IN THE ISOLATED LEECH NERVOUS SYSTEM: SHORTENING VS. SWIMMING. G. Wittenberg and W. B. Kristan, Jr. Dept. of Biology, University of California at San Diego, La Jolla, CA 92093.

The leech, *Hirudo medicinalis*, responds to moderate tactile stimuli by producing one of several behaviors, among which are whole-body shortening and swimming. Motor patterns characteristic of these two behaviors can be recorded from segmental nerves of brainless, isolated nerve cords, and can be elicited by electric shocks to a small patch of attached body wall. Such stimulation results in a reproducible train of sensory cell action potentials. Using simultaneous intracellular recording of identified neurons, we are investigating how identical sensory activity leads to the selection of one or another behavior or a sequence of the two. This may lead to an understanding of how a simple nervous system makes a behavioral choice.

Whole-body shortening is a defensive withdrawal in which the leech's length is rapidly reduced by contraction of both dorsal and longitudinal muscle fibers in several segments, whereas swimming is produced by antiphasic contractions of dorsal and ventral longitudinal fibers. The intensity and duration of a shortening response depends on the number of shocks in the stimulus train, and shortening is produced by stimuli below the threshold for swimming. As expected, several of the excitatory motorneurons innervating both dorsal and ventral longitudinal muscle fields are active during whole-body shortening, while the inhibitory motorneurons to those muscles are inhibited. Surprisingly, the L cells, motorneurons which are effective at exciting all the longitudinal muscle around an entire segment, are inhibited during both swimming and shortening.

Cell 204, a swim-initiating interneuron, also increases its activity during a shortening response, but not to the same degree as when swimming is produced. Direct intracellular stimulation of cell 204 that is subthreshold for swim initiation excites many of the same motorneurons which participate in shortening. Thus, depending on its level of activity, this neuron may help to produce both behaviors. In addition, increased cell 204 activity causes a lasting increase in the probability that the isolated CNS will produce a swim pattern in response to a stimulus that previously elicited only shortening. Besides the effect of cell 204, serotonin is known to increase the likelihood of swimming and several serotonin-containing neurons can initiate swimming. Bath-applied 10^{-5} M serotonin also affects the shortening response by increasing the intensity, duration, and intersegmental extent of the motorneuron bursts. Thus two different forms of escape locomotion appear to share common neuronal elements and mechanisms of modulation.

111.2 **IDENTIFIED CELLS CAUSE HETEROSYNAPTIC FACILITATION AND HETEROSYNAPTIC DEPRESSION OF THE LEECH LOCAL BENDING REFLEX.** S.R. Lockery and W.B. Kristan, Jr. Dept. of Biol., Univ. of Calif., San Diego, La Jolla, CA 92093.

Focal mechanical stimulation of the leech *Hirudo medicinalis* causes a local withdrawal from the stimulus (local bending). The reflex can be elicited in a semi-intact preparation that consists of a segment of body wall innervated by two mechanosensory neurons, two motor neurons and a small number of interneurons from a single ganglion. Repeated stimulation of mechanosensory neurons causes a decline in reflex strength (habituation). Excitation of a nociceptive pathway (by pinching or stimulation of the nociceptive N cell) increases response strength (sensitization). We used this preparation to investigate the possible role of heterosynaptic modulation in these simple forms of learning.

The sensitizing effect of N cell stimulation is mimicked by bath application of serotonin, and the N cell excites two pairs of identified serotonin-containing neurons, cells 61 and 21. We therefore tested the strength of local bending before and after stimulation of single serotonin cells (8 Hz for 10 s). Activation of cell 61 did not elicit local bending. However, immediately following stimulation of cell 61, the local bending response was significantly increased. This effect was associated with an increase in the response of the motor neurons. Response strength was again normal 1 min after cell 61 stimulation. Activation of cell 21 produced similar results.

The opposite effect was achieved by stimulation of Leydig cells which, in a closely related species, contain and release octopamine. A single Leydig cell was impaled and hyperpolarized to stop tonic firing. Following a 10 min rest, the cell was fired at 5.0 Hz for 8 min. Leydig cell stimulation itself did not produce local bending. However, this treatment produced a 75% decline in the strength of the local bending response, and the decline outlasted Leydig stimulation by more than 25 min. The effect was detectable at frequencies as low as 0.5 Hz and was associated with a decline in the motor neuron EPSP's elicited during production of behavior. Spontaneous firing in unimpaled Leydig cells (recorded extracellularly from somata) ranged from 0.1 to 0.9 Hz. Thus the Leydig cell may exert tonic control over reflex strength. Repeated trains of sensory cell stimulation sufficient to cause habituation increased Leydig activity. We are currently testing the hypothesis that the Leydig cell contributes to habituation.

111.3 CENTRAL CORRELATES OF TASTE-DISCRIMINATION IN THE TERRESTRIAL SLUG *LIMAX MAXIMUS* *K. Delaney and †A. Gelperin *Dept. of Biology, Princeton Univ., Princeton, NJ 08544 and †Dept. Molecular Biophysics, AT&T Bell Laboratories, Murray Hill, NJ 07974

Using an *in vitro* preparation consisting of lips, cerebral ganglia (CG) and buccal ganglia (BG) we have identified a group of cerebral to buccal interneurons (CB's) which have powerful initiating and modulating effects on fictive feeding rhythm (Delaney and Gelperin, 1986;Gelperin, 1986;King et al., 1987). CB's receive synaptic input from lip mechanoreceptors and chemoreceptors, feedback from the BG during fictive feeding and strong inhibitory input from stimuli which elicit withdrawal in the whole animal such as electric shock of the foot. Thus, they provide neural loci from which to study convergence and processing of sensory information in a situation where the result of this processing has implications for the control of motor output by the central pattern generator for ingestion.

Fictive feeding is monitored *in vitro* with suction electrodes attached to several BG nerves. Application of potato extract, which is attractive to intact slugs, to chemoreceptors on the lips, triggers fictive feeding. When potato extract is applied to the lip and BG are attached CB_1, CB_{EC}, CB_3, CB_4 and CB_{EPSP} receive a mixed but predominantly excitatory input before and during the initiation of fictive feeding. Application to lips of 0.7% quinidine sulfate (QSO_4), a bitter tasting substance which produces withdrawal responses as opposed to ingestion in intact slugs, produces a predominantly inhibitory response in these CB's. With the BG removed there is no fictive feeding pattern but the response to potato is strongly excitatory with few inhibitory inputs apparent while there is no response or inhibition to QSO_4. In contrast, CB_{ST} receives strong excitation to potato extract when BG are attached and fictive feeding is initiated but is weakly or not at all excited by potato when BG are removed. CB_{ST} is also unique in that without BG attached it is strongly excited by QSO_4. Several putative lip motor neurons are excited by QSO_4 with and without BG attached. Effects of QSO_4, including inhibition of spontaneous excitatory inputs in CB_{EPSP} and tonic excitation of CB_{ST} can persist for tens of minutes following a single 30 second application.

We have also begun to study a group of 5 CG interneurons presynaptic to CB's which have contralateral projections via the sub-cerebral commissure. Responses of these neurons to potato and QSO_4 are similar to the responses of $CB's_{1,3,4}$ and CB_{EC}. We hope to use this system to examine both central mechanisms of discrimination as well as for studies of associative and non-associative conditioning *in vitro*. 111.4 A CLEANING REFLEX AND ITS MODIFICATION BY EXPERIENCE IN DROSOPHILA. G. Corfas* and Y. Dudai, Department of Neurobiology, Weizmann Institute, Rehovot 76100, Israel.

Mechanical stimulation of thoracic bristles in Drosophila melanogaster elicits a characteristic reflex in which a leg cleans the sensory field covered by the stimulated bristles (Vandervorst and Ghysen, Nature 286:65, 1980). We have set out to analyze and quantify this reflex and its modification by experience. Stimulation of immobilized decapitated flies was performed by a series of air puffs (280 msec each, 0.2 pulses/sec) directed at the tegular, antero-notopleural (ANP) and humeral bristles, which elicit cleaning response by the ipsilateral foreleg. Leg movement was observed under a dissecting microscope. The quantified variable was the number of stimuli required for the fly to stop responding (SSR). SSR in naive flies was 40.5±2.4 (n=62). Following a resting period (1-15 min), SSR was measured again. Response after 1,5 and 15 min was 33.9±5.1%, 15.1±5.1% and 69.1±12.9% of the naive fly's SSR, respectively. When a fly that has stopped responding after training was immediately stimulated by a different stimulus (4x1 sec trains of 20 pulses/sec each, every 3 sec, directed at the thoracic dorso-central area), and then tested with the original training stimulus, its response, quantified as SSR, recovered. The experience-dependent modification of the cleaning reflex satisfies accepted criteria for habituation (Thompson and Spencer, Psychol. Rev. 73:16, 1966). Thus, in addition to 1) Response decrement with repeated stimuli (SSR), 2) Spontaneous recovery and 3) Dishabituation, we observed that 4) Higher frequency stimuli produced quicker habituation and 5) Weaker stimuli led to more rapid habituation. The experimental advantage of studying the cleaning reflex lies in the ability to identify sensory and motor neurons mediating the response and to study the reflex by neuroanatomical and electrophysiological methods. We have characterized by HRP backfilling the fine anatomy of a single sensory neuron which is involved in the reflex by mediating information from the ANP bristle to the thoracic ganglion, and found that a mutation that affects the cAMP cascade (rut) increases the number of axonal varicosities while a mutation in a presumptive K^+ channel (Sh^{133}) decreases the number of varicosities. We have also initiated recording of evoked field potentials from the responding leg. The cleaning reflex thus yields itself to multidisciplinary research methods that might contribute to out understanding of the effect of mutations on plasticity of identified cellular components underlying behavioral alteration in Drosophila.
