CHRONOLOGICAL LIST OF SESSIONS

(see page xi for Thematic List of Sessions)

WEDNESDAY

THURSDAY

FRIDAY

SATURDAY

Thematic List of Sessions

(Includes slide and poster sessions, symposia, and workshops only.)

Theme A: Development and Plasticity

Session Number	Session Title	Type	Day and Time
408.	Aging and dementia: anatomy	Slide	Fri PM
124.	Aging and dementia: function I	Poster	Wed AM
452.	Aging and dementia: function II	Slide	Sat AM
230.	Aging and dementia: molecular biology I	Slide	Thu AM
366.	Aging and dementia: molecular biology II	Poster	Fri AM
316.	Aging and dementia: plaques, tangles, amyloid	Poster	Thu PM
123.	Aging and dementia: transmitters	Poster	Wed AM
191.	Autonomic nervous system	Poster	Wed PM
257.	Biochemical and pharmacological correlates of development I	Poster	Thu AM
313.	Biochemical and pharmacological correlates of development II	Poster	Thu PM
339.	Biochemical and pharmacological correlates of development III	Slide	Fri AM
55.	Cell lineage and differentiation I	Slide	Tue PM
195.	Cell lineage and differentiation II	Poster	Wed PM
248.	Cell lineage and differentiation III	Poster	Thu AM
309.	Cell lineage and differentiation IV	Poster	Thu PM
409.	Cell lineage and differentiation V	Slide	Fri PM
200.	Development and plasticity: aging	Poster	Wed PM
168.	Development of invertebrates I	Slide	Wed PM
314.	Development of invertebrates II	Poster	Thu PM
442.	Developmental disorders	Poster	Fri PM
192.	Endocrine control of development I	Poster	Wed PM
423.	Endocrine control of development II	Poster	Fri PM
449.	**Hormonal Organization and Reorganization of Neural Circuits**	**Symp.**	**Sat AM**
315.	Limbic system	Poster	Thu PM
217.	**Molecular Genetic Analysis of Neuronal Development**	**Symp.**	**Thu AM**
74.	Morphogenesis and pattern formation I	Poster	Tue PM
308.	Morphogenesis and pattern formation II	Poster	Thu PM
419.	Motor systems	Poster	Fri PM
280.	Neural plasticity in adult animals I	Slide	Thu PM
341.	Neural plasticity in adult animals II	Slide	Fri AM
441.	Neural plasticity in adult animals III	Poster	Fri PM
462.	Neural plasticity in adult animals IV	Poster	Sat AM
269.	Neural plasticity in adult animals: hippocampus	Poster	Thu AM
47.	Neural plasticity in adult animals: spinal cord	Poster	Tue AM
7.	Neuronal death I	Slide	Tue AM
255.	Neuronal death II	Poster	Thu AM
220.	Neurotoxicity I	Slide	Thu AM
258.	Neurotoxicity II	Poster	Thu AM
466.	Neurotoxicity III	Poster	Sat AM
24.	Neurotoxicity: MPTP and ethanol	Poster	Tue AM
194.	Neurotoxicity: metals	Poster	Wed PM
193.	Nutritional and prenatal factors I	Poster	Wed PM
416.	Nutritional and prenatal factors II	Poster	Fri PM
6.	Process outgrowth I	Slide	Tue AM
75.	Process outgrowth II	Poster	Tue PM
130.	Process outgrowth III	Poster	Wed AM
337.	Process outgrowth IV	Slide	Fri AM
413.	Process outgrowth V	Poster	Fri PM
414.	Process outgrowth VI	Poster	Fri PM
104.	Process outgrowth: growth cone behavior	Slide	Wed AM
82.	Regeneration I	Poster	Tue PM
291.	Regeneration II	Slide	Thu PM
331.	Regeneration: PNS	Poster	Thu PM

Theme B: Cell Biology

Theme C: Excitable Membranes and Synaptic Transmission

Theme D: Neurotransmitters, Modulators, and Receptors

471.	Opiates, endorphins and enkephalins: anatomy and chemistry III	Poster	Sat AM
64.	Opiates, endorphins and enkephalins: physiological effects I	Slide	Tue PM
211.	Opiates, endorphins and enkephalins: physiological effects II	Poster	Wed PM
254.	Opiates, endorphins and enkephalins: physiological effects III	Poster	Thu AM
278.	Opiates, endorphins and enkephalins: physiological effects IV	Slide	Thu PM
361.	Opiates, endorphins and enkephalins: physiological effects V	Poster	Fri AM
284.	Peptide: receptors I	Slide	Thu PM
424.	Peptide: receptors II	Poster	Fri PM
83.	Peptides: anatomical localization I	Poster	Tue PM
273.	Peptides: anatomical localization II	Poster	Thu AM
381.	Peptides: anatomical localization III	Poster	Fri AM
437.	Peptides: anatomical localization IV	Poster	Fri PM
11.	Peptides: biosynthesis, metabolism and biochemical characterization I	Slide	Tue AM
299.	Peptides: biosynthesis, metabolism and biochemical characterization II	Poster	Thu PM
355.	Peptides: biosynthesis, metabolism and biochemical characterization III	Poster	Fri AM
39.	Peptides: opiate receptors	Poster	Tue AM
356.	Peptides: physiological effects I	Poster	Fri AM
362.	Peptides: physiological effects II	Poster	Fri AM
402.	Peptides: physiological effects III	Slide	Fri PM
463.	Peptides: physiological effects IV	Poster	Sat AM
155.	Peptides: receptors	Poster	Wed AM
118.	Peptides: substance P receptors	Poster	Wed AM
61.	Receptor regulation I	Slide	Tue PM
201.	Receptor regulation II	Poster	Wed PM
202.	Receptor regulation: cholinergic	Poster	Wed PM
324.	Receptor regulation: neuropeptides	Poster	Thu PM
198.	Regional localization of receptors and transmitters I	Poster	Wed PM
311.	Regional localization of receptors and transmitters II	Poster	Thu PM
358.	Regional localization of receptors and transmitters III	Poster	Fri AM
461.	Regional localization of receptors and transmitters IV	Poster	Sat AM
342.	Serotonin	Slide	Fri AM
458.	Serotonin and biogenic amines	Poster	Sat AM
323.	Serotonin receptors: radioligand binding studies	Poster	Thu PM
370.	Serotonin: behavioral and physiological effects	Poster	Fri AM
459.	Serotonin: electrophysiological studies	Poster	Sat AM
94.	Serotonin: functional studies I	Poster	Tue PM
224.	Serotonin: functional studies II	Slide	Thu AM
335.	**Stimulant-Induced Sensitization—Behavior and Pharmacology**	**Symp.**	**Fri AM**
66.	Transmitters and receptors in disease I	Slide	Tue PM
156.	Transmitters and receptors in disease II	Poster	Wed AM
300.	Transmitters and receptors in disease III	Poster	Thu PM
412.	Transmitters and receptors in disease IV	Poster	Fri PM
453.	Transmitters and receptors in disease V	Slide	Sat AM
16.	Transmitters in invertebrates I	Slide	Tue AM
70.	Transmitters in invertebrates II	Poster	Tue PM
298.	Transmitters in invertebrates III	Poster	Thu PM
349.	Transmitters in invertebrates IV	Slide	Fri AM

Theme E: Endocrine and Autonomic Regulation

Session Number	Session Title	Type	Day and Time
79.	Cardiovascular regulation: CNS pathways I	Poster	Tue PM
80.	Cardiovascular regulation: CNS pathways II	Poster	Tue PM
227.	Cardiovascular regulation: CNS pathways III	Slide	Thu AM
288.	Cardiovascular regulation: CNS pathways IV	Slide	Thu PM
345.	Cardiovascular regulation: CNS pathways V	Slide	Fri AM

205.	Cardiovascular regulation: heart, blood flow, nerves	Poster	Wed PM
206.	Cardiovascular regulation: hypertension	Poster	Wed PM
336.	**A Heart–Brain Peptide: The Atrial Natriuretic Factor**	**Symp.**	**Fri AM**
380.	Neural control of immune system I	Poster	Fri AM
400.	Neural control of immune system II	Slide	Fri PM
438.	Neural control of immune system III	Poster	Fri PM
115.	Neuroendocrine controls: other I	Poster	Wed AM
306.	Neuroendocrine controls: other II	Poster	Thu PM
450.	Neuroendocrine controls: other III	Slide	Sat AM
10.	Neuroendocrine controls: pituitary I	Slide	Tue AM
60.	Neuroendocrine controls: pituitary II	Slide	Tue PM
119.	Neuroendocrine controls: pituitary III	Poster	Wed AM
186.	Neuroendocrine controls: pituitary IV	Poster	Wed PM
233.	Neuroendocrine controls: pituitary V	Poster	Thu AM
301.	Neuroendocrine controls: pituitary VI	Poster	Thu PM
378.	Neuroendocrine controls: pituitary VII	Poster	Fri AM
425.	Neuroendocrine controls: pituitary VIII	Poster	Fri PM
276.	**Neuropeptides/Neural Systems in Fever, Inflammation and Immune Responses**	**Symp.**	**Thu PM**
78.	Regulation of autonomic function I	Poster	Tue PM
110.	Regulation of autonomic function II	Slide	Wed AM
203.	Regulation of autonomic function III	Poster	Wed PM
204.	Regulation of autonomic function IV	Poster	Wed PM
439.	Respiratory regulation I	Poster	Fri PM
456.	Respiratory regulation II	Slide	Sat AM
4.	**Visceral Afferents: Signaling and Integration**	**Wksh.**	**Tue AM**

Theme F: Sensory Systems

Session Number	Session Title	Type	Day and Time
17.	Auditory system I	Slide	Tue AM
89.	Auditory system II	Poster	Tue PM
90.	Auditory system III	Poster	Tue PM
91.	Auditory system IV	Poster	Tue PM
149.	Auditory system V	Poster	Wed AM
150.	Auditory system VI	Poster	Wed AM
151.	Auditory system VII	Poster	Wed AM
350.	Auditory system VIII	Slide	Fri AM
410.	Auditory system IX	Slide	Fri PM
102.	Chemical sensory systems I	Slide	Wed AM
387.	Chemical sensory systems II	Poster	Fri AM
388.	Chemical sensory systems III	Poster	Fri AM
389.	Chemical sensory systems IV	Poster	Fri AM
218.	**Information Processing in the Macaque Retina**	**Wksh.**	**Thu AM**
40.	Invertebrate sensory processing I	Poster	Tue AM
41.	Invertebrate sensory processing II	Poster	Tue AM
33.	Pain modulation I	Poster	Tue AM
84.	Pain modulation II	Poster	Tue PM
272.	Pain modulation III	Poster	Thu AM
283.	Pain modulation IV	Slide	Thu PM
440.	Pain modulation V	Poster	Fri PM
34.	Pain: central pathways I	Poster	Tue AM
164.	Pain: central pathways II	Slide	Wed PM
329.	Pain: central pathways IV	Poster	Thu PM
386.	Photoreceptors	Poster	Fri AM
12.	Retina I	Slide	Tue AM
108.	Retina II	Slide	Wed AM
293.	Retina III	Poster	Thu PM
294.	Retina IV	Poster	Thu PM

360.	Retina V	Poster	Fri AM
57.	Somatic afferents I	Slide	Tue PM
214.	Somatic afferents II	Poster	Wed PM
73.	Somatosensory cortex and thalamocortical relationships I	Poster	Tue PM
131.	Somatosensory cortex and thalamocortical relationships II	Poster	Wed AM
132.	Somatosensory cortex and thalamocortical relationships III	Poster	Wed AM
144.	Spinal cord I	Poster	Wed AM
382.	Spinal cord II	Poster	Fri AM
271.	Subcortical somatosensory pathways	Poster	Thu AM
145.	Subcortical somatosensory pathways: trigeminal	Poster	Wed AM
62.	Subcortical visual pathways I	Slide	Tue PM
122.	Subcortical visual pathways II	Poster	Wed AM
241.	Subcortical visual pathways III	Poster	Thu AM
399.	Subcortical visual pathways IV	Slide	Fri PM
5.	Visual cortex I	Slide	Tue AM
101.	Visual cortex II	Slide	Wed AM
177.	Visual cortex III	Poster	Wed PM
178.	Visual cortex IV	Poster	Wed PM
292.	Visual cortex V	Poster	Thu PM
404.	Visual cortex VI	Slide	Fri PM
451.	Visual cortex VII	Slide	Sat AM

Theme G: Motor Systems and Sensorimotor Integration

Session Number	Session Title	Type	Day and Time
13.	Basal ganglia I	Slide	Tue AM
376.	Basal ganglia II	Poster	Fri AM
435.	Basal ganglia III	Poster	Fri PM
436.	Basal ganglia IV	Poster	Fri PM
270.	Basal ganglia: electrophysiology and behavior	Poster	Thu AM
231.	Circuitry and pattern generation I	Slide	Thu AM
428.	Circuitry and pattern generation II	Poster	Fri PM
8.	Control of posture and movement I	Slide	Tue AM
95.	Control of posture and movement II	Poster	Tue PM
96.	Control of posture and movement III	Poster	Tue PM
105.	Control of posture and movement IV	Slide	Wed AM
199.	Control of posture and movement V	Poster	Wed PM
244.	Control of posture and movement VI	Poster	Thu AM
321.	Control of posture and movement VII	Poster	Thu PM
72.	Cortex: motor cortex I	Poster	Tue PM
188.	Cortex: motor cortex II	Poster	Wed PM
304.	Cortex: prefrontal and premotor areas	Poster	Thu PM
117.	Disorders of motor systems and neural prostheses I	Poster	Wed AM
470.	Disorders of motor systems and neural prostheses II	Poster	Sat AM
295.	Invertebrate motor function	Poster	Thu PM
69.	Motor systems and sensorimotor integration: cerebellum I	Poster	Tue PM
171.	Motor systems and sensorimotor integration: cerebellum II	Slide	Wed PM
351.	Motor systems and sensorimotor integration: cerebellum III	Poster	Fri AM
49.	Motor systems and sensorimotor integration: oculomotor system I	Poster	Tue AM
112.	Motor systems and sensorimotor integration: oculomotor system II	Slide	Wed AM
303.	Motor systems and sensorimotor integration: oculomotor system III	Poster	Thu PM
179.	Motor systems and sensorimotor integration: vestibular system I	Poster	Wed PM
338.	Motor systems and sensorimotor integration: vestibular system II	Slide	Fri AM

363.	Motor systems and sensorimotor integration: vestibular system III	Poster	Fri AM
332.	Muscle I	Poster	Thu PM
333.	Muscle II	Poster	Thu PM
296.	Reflex function I	Poster	Thu PM
426.	Reflex function II	Poster	Fri PM
21.	Spinal cord and brainstem I	Poster	Tue AM
232.	Spinal cord and brainstem II	Slide	Thu AM
239.	Spinal cord and brainstem III	Poster	Thu AM
469.	Spinal cord and brainstem IV	Poster	Sat AM

Theme H: Structure and Function of the CNS

Session Number	Session Title	Type	Day and Time
247.	Amygdala and limbic cortex	Poster	Thu AM
125.	Basal forebrain and cholinergic pathways	Poster	Wed AM
37.	Brain metabolism I	Poster	Tue AM
228.	Brain metabolism II	Slide	Thu AM
390.	Brain metabolism III	Poster	Fri AM
454.	Brain metabolism IV	Slide	Sat AM
352.	Clinical CNS neurophysiology I	Poster	Fri AM
353.	Clinical CNS neurophysiology II	Poster	Fri AM
85.	Comparative neuroanatomy: amphibians, reptiles and birds	Poster	Tue PM
38.	Comparative neuroanatomy: fish and below	Poster	Tue AM
146.	Comparative neuroanatomy: mammals, etc.	Poster	Wed AM
137.	Diseases of the nervous system I	Poster	Wed AM
138.	Diseases of the nervous system II	Poster	Wed AM

2 WORKSHOP: VISCERAL AFFERENTS: SIGNALING AND INTEGRATION. **M. Kalia**, Thomas Jefferson Univ. (Chairperson), and **L. Kruger**, UCLA (Chairperson), **K. Fuxe**, Karolinska Inst. (Sweden), **A.R. Light**, Univ. North Carolina, **W.C. deGroat**, Univ. Pittsburgh, **G.F. Gebhart**, Univ. Iowa, **C. Sternini**, UCLA, **M. Kalia**, Thomas Jefferson Univ., **D.A. Ruggiero**, Cornell Univ. Med. Ctr.

Recent developments in the neurobiology of visceral and somatic afferents have provided new insights into their central organization and patterns of discharge. These studies have utilized multidisciplinary approaches to examine functional and morphological aspects of visceral and somatic afferents. Such an approach is of great value in understanding sensorimotor coordination. Investigators working on central projections of visceral and somatic afferents have seldom directed their attention to addressing issues that are common to both sensory systems. The main aim of this workshop is to bring together neurobiologists working on central projections of visceral and somatic afferent projections so that current knowledge of these two sensory systems can be compared.

Dr. Kruger will introduce the symposium by providing a general overview of somatic and visceral afferents. Similarities and differences between these systems will be discussed in broad terms. **Dr. Fuxe** will lay the groundwork for subsequent talks by presenting the neurochemistry of peptidergic and monoaminergic neurons in the medulla and spinal cord where primary visceral and somatic afferents are known to terminate. The question of coexistence between monoamines and neuropeptides (NPY) will be addressed for both medulla and spinal cord. The distribution of these putative neurotransmitters in relation to specific cytoarchitectonically distinct regions of the central nervous system will be described. **Dr. Light** will discuss similarities and differences between primary afferent innervation by somatic vs. visceral afferents. He will describe the distribution and synaptology of somatic nociceptive primary afferents in the trigeminal nuclei and spinal cord based on data derived from single unit recording coupled with intraaxonal and intracellular staining with horseradish peroxidase and other neuronal tracers. Recent results on the activation of substantia gelatinosa neurons by muscle and visceral afferent inputs will also be presented. **Dr. deGroat** will review the anatomical and physiological properties of afferent pathways from pelvic viscera. He will focus on the examination of receptive fields of these visceral afferents, their termination and processing of their inputs in the lumbosacral spinal cord, as well as the colocalization of peptidergic neurotransmitters in visceral afferent neurons. **Dr. Gebhart** will present the results of electrophysiological studies examining responses of spinal neurons in the thoracolumbar and lumbosacral spinal cord following colorectal distension. Characterization of these spinal neurons was also done with respect to converging receptive fields, rostral projections and chemosensitivity to intraarterial injections of bradykinin. The responses of these neurons in relation to sensations such as nociception will be discussed. **Dr. Sternini** will focus her presentation on an analysis of afferent innervation of the enteric nervous system with particular emphasis on the distribution of spinal afferent fibers containing calcitonin gene-related peptide and substance P immunoreactivity in the stomach and pancreas and their perikarya in dorsal root ganglia. **Dr. Kalia** will present ultrastructural analyses of the central terminals of primary pulmonary afferents, originating from slowly and rapidly adapting receptors and compare this data on visceral afferents with results derived from Dr. Light's work on somatic afferents. **Dr. Ruggiero** will focus his presentation on cardiovascular afferents. He will present data relating to the following anatomical substrates underlying tonic and reflex control of arterial blood pressure: the cardiopulmonary subdivisions of the nucleus of the tractus solitarius, dorsal horn of spinal cord, brain stem cholinergic neurons and bulbospinal projections from the rostral ventrolateral medulla to the intermediolateral cell column of the spinal cord.

3 SYMPOSIUM. A NEURAL SYSTEMS APPROACH TO THE ANALYSIS OF FEAR AND ANXIETY. M. Davis, Yale Univ. (Chairperson); R.F. Thompson (Stanford Univ.), P.G. Henke (St. Francis Xavier Univ.), B.S. Kapp (Univ. of Vermont), J.E. LeDoux (Cornell Univ. Med. Ctr.), T.S. Gray. (Loyola Med. Ctr.).

Over the last several years a great deal of new, compelling, and highly consistent data have shown that the central nucleus of the amygdala along with its direct connections to hypothalamic and brainstem target areas appears to form a crucial component of a central fear system in a variety of animal species. Electrical stimulation of the central nucleus of the amygdala elicits a pattern of changes in blood pressure, gastric ulceration, respiration, heart rate, and ongoing motor and reflex behavior that normally occur during fear and anxiety. In fact, this pattern of behavioral changes is typically used to define the presence of generalized anxiety clinically, and many of the individual components listed above form the basis of various animal models that are used to study anxiolytic drugs (e.g., cessation of ongoing bar-pressing in the operant conflict test). Electrolytic or chemical lesions of cell bodies in the amygdala prevent stressful or conditioned fear stimuli from producing this pattern of behavioral changes. Local infusion of different psychoactive compounds into specific nuclei within the amygdala produce anxiolytic effects in several different behavioral tests of anxiety. Electrophysiological studies show that aversive or conditioned fear stimuli preferentially alter single unit activity in the amygdala. With the advent of sensitive and selective anterograde and retrograde anatomical tracing techniques it has become possible to delineate efferent pathways and specific target areas of the amygdala that might mediate each of the various symptoms seen in fear and anxiety. Data from several laboratories have now shown that direct connections from the central nucleus of the amygdala to specific target areas mediate specific symptoms of fear. Thus projections to the hypothalamus and dorsal motor nucleus of the vagus mediate changes in blood pressure and heart rate. Projections to the parabrachial nucleus may mediate changes in respiration. Projections to the central grey and pontine reticular formation are critical for freezing and increased startle, respectively. New assay techniques have shown that these efferent projections utilize one or several different neurotransmitters, including several peptides which are known to be abundant in the amygdala. Taken together, the data indicate that the central nucleus of the amygdala and its direct projections to the hypothalamus and brain stem comprise a critical neural substrate of fear. This conclusion has been reached using anatomical, behavioral, physiological and pharmacological approaches and will ultimately have considerable impact on the design of more selective anxiolytic drugs.

4 WORKSHOP: CHEMICAL ARCHITECTURE OF THE CEREBELLAR CORTEX: STRUCTURE AND FUNCTION. J.S. King The Ohio State Univ. (Chairperson) E. Mugnaini, Univ. of Connecticut, A.J. Beitz, Univ. of Minnesota, N.H. Barmack, Good Samaritan Hospital, J.C. Strahlendorf, Texas Tech. Univ.

The neuronal circuitry of the cerebellum, as defined by anatomical and physiological techniques, has been well characterized. The cerebellar cortex is generally described as a uniformly layered structure in which the neural components are organized in a repetitive geometric arrangement. Recent studies of the intrinsic circuits and afferent systems have utilized immunohistochemistry and the iontophoretic application of putative neurotransmitters to provide new insights into cerebellar structure and function. Dr. Mugnaini will show that most, if not all, Purkinje cells, stellate/basket cells, and Golgi cells are GABAergic. In addition, glycine and several neuropeptides can be localized in certain cerebellar inhibitory neurons. The notion that the cerebellar nuclear outflow is exclusively excitatory is no longer tenable. Apparently most, if not all, small and a few medium-size nerve cells are GABAergic projection neurons. Dr. King will describe a differential distribution of enkephalin, cholecystokinin and corticotropin releasing factor within distinct populations of climbing fibers, mossy fibers, and/or a beaded plexus of axons located at the Purkinje cell-granule cell border. These data indicate that classic cerebellar afferent systems are chemically heterogeneous. Dr. Beitz will discuss the localization of two putative excitatory amino acid transmitters, glutamate within pontocerebellar and trigeminocerebellar projections and aspartate within the olivocerebellar projection. In addition, the localization of glutamate-like and aspartate-like immunoreactivities to certain populations of granule cells in the cerebellar cortex will be described. Finally, the localization of the amino acid taurine and its synthesizing enzyme, cysteine sulfinate decarboxylase, in certain Purkinje cells and Golgi cells will be considered. Dr. Barmack will describe cholinergic mossy fiber projections; monoclonal and polyclonal antibodies to the cholinergic synthesizing enzyme, choline acetyltransferase have been used in this study. The importance of this cholinergic projection in visual-vestibular interactions will be discussed. Dr. Strahlendorf will discuss the direct and modulatory actions of serotonin on Purkinje cells. Direct effects are pentobarbital-sensitive and dependent on the firing rates of these cells. Modulatory actions include attenuation of glutamate-elicited excitation, and augmentation of inhibitory effects of GABA mimetics at $GABA_A$ and $GABA_B$ receptors. The predominant action of serotonin appears to be modulatory, serving to suppress Purkinje cell activity by interacting with endogenous inhibitory and excitatory processes within the cortex.

5.1 IN VIVO DEMONSTRATION OF PRESUMPTIVE BLOB AND INTERBLOB REGIONS BY MANIPULATION OF STIMULUS SPATIAL FREQUENCY IN MACAQUE STRIATE CORTEX. *Roger B. H. Tootell and Gary G. Blasdel.* Dept. Med. Physiol., Calgary Sch. Med., Calgary, Alberta, Canada, T2N4N1.

Previous studies in macaque striate cortex have demonstrated a horizontal segregation in the responsiveness of cortical neurons to achromatic, sinusoidal gratings of high vs. low spatial frequency (Tootell et al, submitted). The anatomical segregation appears so far to be binary, with some regions preferring high spatial frequencies and others preferring low spatial frequencies. In layers 2 + 3, regions tuned to low spatial frequency correlate with the blobs revealed by cytochrome oxidase staining, and regions tuned to high spatial frequency correlate with the interblob regions. This anatomical segregation also extends beyond layers 2 + 3, vertically through cortex. In layers 4B, 5 and 6, where the blobs are faint or absent, patchy deoxyglucose patterns are produced in response to high vs. low spatial frequency gratings which are in vertical registration with those seen in the upper layers.

Given these previous deoxyglucose results, and the availability of optical techniques for visualizing cortical activity *in vivo* (Blasdel and Salama, 1986), we decided to try to visualize the cytochrome oxidase blobs *in vivo* by manipulating stimulus spatial frequency. Such a demonstration would be useful for a number of reasons. It would allow deliberate introduction of microelectrodes, tracers, etc. into blob and interblob areas, it would permit correlations of blob position to other anatomical organizations in optical studies, and it would function as a further test of the deoxyglucose findings related to spatial frequency.

In these experiments, paralyzed, anesthetized macaques were prepared as for single unit recording, with both eyes converged and focused on a stimulus display screen. The dye NK 2367 was superfused over parafoveal striate cortex via a recording chamber implanted earlier, and illuminated with light of 720 nm. A television camera recorded changes in absorbance of the dye in response to achromatic, sinusoidal gratings of either low (0.5-1.5 c/deg) or high (6.5 c/deg) spatial frequency. For each orientation (in 45^{o} steps), the absorbance topography produced by the low spatial frequency was subtracted from that produced by the high spatial frequency grating.

At each orientation, this difference topography showed patches which looked like thinner versions of orientation columns, spaced regularly over striate cortex. Control comparisons of high-minus-high (or low-minus-low) spatial frequency gratings produced no periodicities in the absorbance topographies within the same area. The sum of topographies from all high-minus-low comparisons, at all orientations, produced a composite topography which strongly resembled that produced by deoxyglucose uptake in response to high spatial frequency gratings at all orientations: a repetive annular pattern, as if all the interblob area was labelled. The "holes" in the annulae (the areas absorbing most light in response to low spatial frequencies; the presumptive blobs) lay in the center of the ocular dominance strips, when the strips were produced by dye manipulations in the same piece of tissue. The similarity of these patterns to those seen earlier in deoxyglucose studies strongly suggest that the presumptive blobs seen in this study correspond to the blobs revealed by cytochrome oxidase staining *post mortem*. These dye results also support the idea of a segregation of cells according to peak spatial frequency tuning in the blob vs. interblob regions of primate striate cortex. Supported by NRSA 5F32 EY05786.

5.2 STUDIES OF ORIENTATION AND MOTION SELECTIVITY IN MONKEY STRIATE CORTEX USING OPTICAL TECHNIQUES. Gary G. Blasdel and Roger B.H. Tootell. Department of Medical Physiology, University of Calgary, Calgary, Alberta, Canada.

We used optical techniques based on video imaging technology and the voltage sensitive dye NK2367 to analyze the functional anatomy of orientation and motion selectivity in monkey striate cortex (macaca Nemestrina). Previous work using this approach (Blasdel and Salama, 1986) revealed a close relationship between the continuity of orientation mapping and the centres of ocular dominance columns: orientation shifts most continuously in patches of cortex that lie between O.D. column centres. Further analysis of this organization reveals that regions of greatest orientation continuity coincide with regions displaying the greatest selectivity for orientation. Since the boundaries of these regions, where orientation selectivity is much weaker, lie at the centres of ocular dominance columns, they include cytochrome oxidase blobs, the cells of which have been shown previously (Livingston and Hubel, 1984) to lack orientation selectivity. There is also the suggestion, from our optical data as well as from results achieved with 2-deoxyGlucose, that some of the observed differences in orientational selectivity may derive from differences in the absolute responsiveness of different regions of cortex to elongated black/white edges.

Since it is conceivable that end-stopped inhibition plays some role in the observed differences in responsiveness we assessed the effect of edge length on orientation preference and tuning by comparing patterns of activity generated by moving black and white edges with those generated by a field of random white dots (2% density with each dot subtending 0.1 degree of visual angle) moving uniformly in the same direction. Although the results of this comparison proved inconclusive with respect to our original question - effects on responsiveness and orientation tuning - they nevertheless revealed a surprising and robust difference in the direction of preferred movement for each of the two patterns. Maps of orientation/movement selectivity generated by moving fields of elongated edges (oriented perpendicular to the direction of motion) and random dots appear strikingly similar if the motional direction for one is rotated by 90 degrees. A cortical region responding best to the horizontal movement of black and white bars, for example, responds best to random dots moving vertically. And similar differences are apparent for all other possible orientations and directions of movement.

One possible explanation for this finding is that it derives from orthogonal direction selectivities for separate but co-mingling populations of neurons - one responsive to elongated edges, the other to dots. Alternatively, it could derive from some intrinsic property of all or most cortical cells - some property that causes them to prefer different directions of movement for different classes of stimuli. Preliminary studies, using micro-electrodes, of well isolated, single cells support the second possibility. All cells isolated to date, that responded well to elongated edges, also responded well to fields of moving random dots and preferred radically different (usually orthogonal) directions of movement for each.

5.3 ORGANIZATION AND CONNECTIVITY OF COLOR-SPECIFIC CELLS IN CYTOCHROME OXIDASE-RICH PATCHES OF MONKEY STRIATE CORTEX. D.Y. Ts'o, C.D. Gilbert, and T.N. Wiesel. Laboratory of Neurobiology, The Rockefeller University, NY, NY 10021

We have been studying the functional organization, receptive field properties and connectivity of color-selective cells found in the cytochrome oxidase-rich blob regions of the monkey striate cortex. Using multiple closely spaced penetrations into individual blob regions, we have previously shown that an individual blob seems to be dedicated to one color opponency system, either red/green or blue/yellow. In the present study, we examined the cells of layer 4C directly underneath blob regions to reveal relationships between the functional specificity of the cells in the two layers. Electrode penetrations first entered into blob regions and the functional properties of the blob cells were characterized. The electrode was advanced through a layer of oriented, non-color selective cells in layer 4B and then to layer 4C, where cells had monocular, unoriented, concentric receptive fields that were often color selective. In most cases (94%), the color opponency of the cells in layer 4C was identical to the blob cells found more superficially in the same penetration. These findings are consistent with idea that color-selective layer 4c cells contribute input to layer 2+3 blob cells with matching color selectivity. In addition, a few penetrations beginning in the superficial layer blobs and extending into layer 4C did not encounter oriented non-color selective cells in layer 4B, but instead encountered a continuous column of blob-like (unoriented, often color-selective, monocular) cells. Closely spaced neighboring penetrations did encounter the expected oriented cells of layer 4B. These penetrations suggest that there may exist a narrow columns of blob-like cells, perhaps centered in the middle of blobs, that span from layer 2+3 to layer 4C.

We have also done a preliminary study on the connectivity between color-selective blob cells and color-selective oriented cells. Using cross-correlation analysis between recordings from two electrodes, we have observed correlated firing between color-selective unoriented blob cells and oriented cells with matched color selectivity. The correlations reflect both monosynaptic and common input connectivity. The blob cells involved in these correlations had either Type I (color opponent center surround) or modified Type II (center color opponent with surround antagonism). No correlations between blob cells and oriented cells of different color selectivity have been found. These results suggest that color-selective unoriented blob cells may contribute to the construction of color-selective oriented fields in the monkey striate cortex.

5.4 COMPARATIVE STUDIES OF THE COLOR CELLS IN LAYER IVC_b AND IN THE BLOBS OF THE MONKEY'S STRIATE CORTEX. Charles R. Michael, Dept. of Cellular and Molecular Physiology, Yale University School of Medicine, 333 Cedar St., New Haven, CT. 06510.

Long, oblique tungsten electrode tracks were made through the monkey's striate cortex to examine the relationship of the double opponent color cells in layer IVC_b to the neurons in the cytochrome oxidase blobs in layers III and II. Small lesions marked the clusters of color cells in IVC_b; cytochrome oxidase (CO) stain revealed the blobs. The clusters were in register with the overlying blob pattern. As with the blobs, the cells within each color cluster were confined to a single ocular dominance column. When two oblique electrode tracks were made successively in the same plane through the same region of cortex, one in layer II/III and the other in IVC_b, the color properties of the blob cells were related to those of the cells in the clusters directly underneath them. The vertical blob/cluster pairs contained cells which shared the same chromatic organization, e.g. red on, green off center double opponents. Some blobs appeared to be entirely color specific while others apparently contained a mixture of color types. Oriented color cells were generally confined to the immediate area around the blobs but sometimes they formed bridges between adjacent blobs.

Intracellular recordings were made from double opponent color spiny stellate cells in IVC_b with micropipette electrodes filled with horseradish peroxidase (HRP). A double stain procedure for CO and HRP revealed that the axons of these cells terminated in the blobs. An axon arborized in the blob directly above its cell body. The terminals were confined within the blob. Sometimes an axon branched to end in two adjacent blobs which were probably in the same ocular dominance column. The contrast-sensitive cells in IVC_b were also spiny stellate cells. Their axons projected to layer III where they terminated in single interblob regions, spanning the boundary between two adjacent ocular dominance columns. Their arborizations sometimes extended into the blobs. These specific projection patterns indicate that the properties of the color cells in the blobs are influenced by the inputs from the spiny stellate double opponent cells in IVC_b.

5.5 ORGANIZATION OF HUMAN VISUAL CORTEX DEMONSTRATED WITH MONOCLONAL ANTIBODY CAT-301. S. Hockfield and R.B.H. Tootell.[#] [$]Section of Neuroanatomy, Yale Univ. Sch. Med., New Haven, CT and [#]Dept. of Neurobiology, Harvard Sch. Med., Boston, MA.

Monoclonal antibody Cat-301 recognizes a surface-associated antigen on a subset of neurons in the mammalian CNS. Previously we have shown that in monkey cortical area V1 (area 17) patches of Cat-301 positive neurons line up to form rows that are in vertical register with the center of the ocular dominance stripes (Hockfield, et al, CSH Symp. Quant. Biol. 48:877). Cat-301 also demonstrates a substructure in monkey area V2 (area 18), as antibody positive neurons lie predominantly within the thick strips demonstrated with cytochrome oxidase histochemistry (DeYoe, et al, this volume). Conservation of antigens through evolution potentially allows reagents like Cat-301 to be used to analyze the organization of human cortical areas where electrophysiological and tracing techniques can not be employed.

In an effort to study the organization of human striate and extrastriate visual cortex, the occipital third of human post-mortem brains was flattened, sectioned tangential to the pial surface and stained immunohistochemically for Cat-301. The subcellular localization of the Cat-301 antigen in human was identical to that previously described in cat and monkey, on the surface of cell bodies and proximal dendrites. Throughout the human cortex, Cat-301 recognizes only a subset of neurons. In area V1, antibody positive neurons are found in layers IV and VI. In flattened, tangentially cut sections, antibody positive cells lie in patches that form rows across the area. The rows of Cat-301 neurons show a periodicity of 1mm within an area approximately 4cm in width. At the border of V1, a continuous line of Cat-301 positive cells is found, marking the boundary between V1 and V2. In V2, Cat-301 recognizes cells that form broad strips, approximately 1-2mm in width, separated by gaps of 4-6mm. These antibody-demonstrated strips in the human are likely to represent the thick cytochrome oxidase positive strips in monkey that have been demonstrated to contain Cat-301 neurons and neurons that project to area MT.

These studies demonstrate an organization of human cortical areas V1 and V2 that is analogous to the organization previously demonstrated in monkey. The functional properties of the human areas are likely to be related to, if not identical to, the properties of the monkey areas.

5.6 CONNECTIONS OF MODULAR SUBDIVISIONS OF CORTICAL VISUAL AREAS 17 AND 18 WITH THE MIDDLE TEMPORAL AREA, MT, IN SQUIRREL MONKEYS, L. A. Krubitzer and J. H. Kaas. Vanderbilt University, Department of Psychology Nashville, TN 37240.

Modern methods for revealing patterns of connections have the potential for defining aspects of modular organization within areas of cortex, and suggesting functional roles for such modules. In the present study, small, single injections of wheat germ agglutinin conjugated with horseradish peroxidase (WGA-HRP) were injected in the middle temporal visual area (MT) of four squirrel monkeys, Saimiri sciureus. The cortex was removed, flattened, and cut parallel to the surface in order to reveal surface-view patterns of connections. Sets of alternate sections were processed for HRP, cytochrome oxidase (CO), or myelin. The CO and myelin sections identified the borders of areas 17, 18, and MT, and revealed CO-dense bands alternating with CO-light (and myelin dense) interbands in area 18. The injections were restricted to portions of myeloarchitectonically defined MT. In each case only portions of areas 17 and 18 contained labeled neurons and terminals. The label in area 17 was concentrated in several short, closely spaced, meandering rows (columns). Since area 17 is subdivided into systematic arrays of orientation selective neurons, and area MT is similarly subdivided into arrays of direction selective neurons, a logical interpretation of the connection pattern is that given direction selective columns in MT receive inputs from a limited number (4-6) of matched orientation columns in area 17. In area 18, label was in rows of punctate patches which were superimposed on the CO-dense bands. Label was largely confined to a limited number (3-5) of adjacent bands. This pattern appears to differ somewhat from that reported for macaque monkeys, where thick and thin CO-dense bands alternate, and the projection to MT seems to be largely restricted to the thick CO-dense bands. Nevertheless, in both squirrel and macaque monkeys connection patterns implicate the CO-dense bands and not the interband regions of area 18 in the visual subsystem related to MT. The injections also revealed patchlike patterns of interconnections with other visual areas and cortical regions including the superior temporal area, the rostral division of the dorsolateral area, the dorsomedial area, cortex in the superior temporal sulcus, the frontal eye field, and the frontal ventral visual region. In the contralateral cerebral hemisphere, foci of label were predominately in MT, but sparser connections were in the superior temporal area and the rostral division of the dorsolateral area. Supported by NIH Grant EY-02686.

5.7 SUBPOPULATIONS OF AXONS FROM AREA V1 TO V2 IN MACAQUE MONKEY, VISUALIZED BY PHASEOLUS VULGARIS (PHA). K.S. Rockland. Eye Research Inst. of the Retina Foundation, Boston, MA. 02114.

In macaque monkey, the connections from area V1 to V2 (or area 17 to 18) terminate in and around layer 4. This information is based on bulk injections of 3H-amino acids or HRP into area V1, with subsequent orthograde transport to area V2. No data are currently available, however, concerning the exact geometric configuration of individual cortical axons from V1 to V2: what is their lateral spread? is there any sublaminar stratification, such as described for geniculocortical terminations in V1? To address these questions, we have injected the orthograde tracer PHA in area V1 of 3 monkeys. This technique can produce a Golgi-like delineation of axons issuing from the injected area (V1 in this case). To date, we have evidence for 4 morphologically distinct types of cortical axons terminating in V2. The most common configuration (5 out of 12 reconstructed profiles) is a horizontally oriented profile, traveling 600u obliquely through the deeper cortical layers, bifurcating in layer 5, and then sending 2 daughter branches mainly to layer 4. In layer 4, these 2 branches overlap to some extent. They have a lateral spread of 350u, and are sparsely studded with both spines and beads. Two other distinct axonal profiles are associated with layer 4: one is characterized by strikingly parallel main branches, which run along the 3C/4 and 4/5A boundaries for 350u. Delicate sprays sparsely studded with spines dip about 30u into layer 4 from each branch. Another profile terminates in both layers 3 and 4, in a compact, bushlike shape, forming a cylinder of 400u diameter. Unlike the previous two types, this is densely studded with grape-like appendages. A fourth category has a parent trunk rising 600u obliquely from the white matter, which bifurcates in layer 5, and sends 2 daughter branches selectively to layer 3. In layer 3, these have separate terminal arborizations (100u across), with a center-to-center spacing of 300u. This spacing is reminiscent of autoradiographically demonstrated periodic peaks of label in layer 3. Interestingly, these PHA-delineated axons have lateral spreads of 350-400u in layer 4. This is one-half or one-third the width reported for different cytochrome oxidase (CO) compartments in area V2. This dimensional discrepancy may support other evidence suggesting the existence of tangential subdivisions within CO compartments. Whether these 4 axonal types can be associated with specific CO compartments in V2 is still under investigation. Preliminary results suggest that at least 2 occur in projection zones associated with all 3 CO compartments. These results emphasize the likelihood of precise stratification within the middle, input layers of V2, and suggest that each of the physiologically identified functional "streams" may be built-up from anatomically diverse cortical connections. (EY07058)

5.8 POSTNATAL DEVELOPMENT, STRUCTURE AND POSSIBLE FUNCTION OF LONG-RANGE HORIZONTAL INTRINSIC CONNECTIONS IN CAT AREA 17. H.J. Luhmann[$], J.M. Greuel* and W. Singer. Max Planck Institute for Brain Research, P.O. Box 710662, 6000 Frankfurt 71, F.R.G.

It has been shown in kitten striate cortex that an exuberant intrinsic system of far-reaching horizontal connections is already present in the 2nd postnatal week (Luhmann et al., Exp. Brain Res., 63:443, 1986). Single extracellular intracortical injections of different fluorescent dyes or horseradish peroxidase conjugated with wheat-germ agglutinin revealed in frontal, tangential and parasagittal sections a characteristic patchy pattern of retrogradely filled pyramidal cells and anterogradely labeled terminals. The spatial expression and the maximal lateral extent of these connections were strongly age- and experience-dependent. In 2- to 5-week-old normally reared (NR) and visually deprived (VD) kittens patches often fused to beaded, medio-laterally running bands and tangential connections of up to 11 mm length could be demonstrated in the superficial layers. During the critical period this exuberant pattern is reduced by an activity-dependent process. Selective cell death and/or elimination of long axonal collaterals are likely mechanisms. In adult NR cats horizontal intrinsic connections are limited to 2-3 mm in their lateral extent, whereas in adult VD animals they are no longer demonstrable. The spatial structure, columnar arrangement and postnatal development of these connections suggest a functional relation to the cortical system of orientation columns.

In order to test the hypothesis that tangential excitatory interactions are involved in the formation of large or unconventional receptive fields (RF), the RF properties of 608 neurons were studied in area 17 of 4- to $8^1/_2$-week-old kittens and adult cats at eccentricities between 0-20°. The width of the dominant discharge region and the overall size of the RFs of simple and complex cells were significantly (U-Wilcoxon-test, $p<0.01$) smaller in adult cats than in kittens. Furthermore, 18% (n=28) of the quantitatively investigated cells in kittens and 2.6% (n=1) in adult cats showed one or two facilitatory, often direction-selective ectopic fields, which were more than 4° separated from the classical RF. These neurons were mainly located in the superficial layers suggesting a relation to the system of long-range horizontal connections.

Current source density analysis of field potential responses to intracortical electrical stimulation in NR and VD kittens and in adult cats confirmed most of the anatomical data and revealed a layer-specific organization of tangential excitatory connections.

5.9 **RELATIONSHIPS BETWEEN CORTICO-CORTICAL PROJECTIONS, INTRINSIC CORTICAL CONNECTIONS AND ORIENTATION COLUMNS IN CAT PRIMARY VISUAL CORTEX.** C. D. Gilbert and T. N. Wiesel, Laboratory of Neurobiology, The Rockefeller University, New York, NY 10021.

A common pattern of cortico-cortical connections is their clustered or patchy distribution, with clusters of cells in one area projecting to patches of terminals in the target area. When projected onto a plane parallel to the cortical surface, the cell clusters are seen as systems of branching bands, reminiscent of the orientation and ocular dominance columns. To determine the relationship between the clustering pattern and the orientation columns, we combined retrograde labeling of the cells participating in cortico-cortical connections with labeling of orientation columns by 2-deoxyglucose autoradiography.

We labeled the cells projecting from area 17 to area 18 in the cat by injecting rhodamine filled latex microspheres (beads) in area 18. Prior to injecting the label we mapped the distribution of orientation columns in area 18 over a small area (approximately 1mm in diameter), and injected 0.5µl of the beads in a column of identified orientation preference, maximizing the distance from columns of orthogonal orientation preference. After allowing sufficient time for retrograde transport of the beads to area 17, the animal was reanesthetized and infused with 14C 2-deoxyglucose (100 µC). During the infusion the animal was presented with a visual stimulus consisting of vertical lines of varying thickness, thus labeling the vertical orientation columns. The cortex was flattened and sectioned in a plane tangential to its surface and exposed to X-ray film. The sections were then used to map the distribution of retrogradely labeled cells, allowing us to compare directly the distribution of cortical projection bands and vertical orientation columns in the same sections. The two patterns corresponded very closely: when the injection was placed in a horizontal orientation column in area 18, the labeled cells in area 17 lay between the labeled vertical orientation columns. With injections placed in a vertical orientation column in area 18, the labeled cells in area 17 were in register with the labeled vertical orientation columns. These findings indicate that cortico-cortical connections relate columns of like functional specificity.

We used a similar approach to relate intrinsic cortical connections to orientation columns. In these experiments, the orientation preferences of cells were determined by intracellular recording and their axons and dendrites were labeled by fluorescent dye injection. Preliminary results have revealed a correspondence between the distribution of the axons of the injected cells and the orientation columns.

(Supported by grants EY05253, BNS9318794 and 8351738)

IS THERE A TOPOGRAPHICAL RELATION BETWEEN OCULAR DOMINANCE AND ORIENTATION COLUMNS IN THE CAT STRIATE CORTEX? S. Löwel* and W. Singer (SPON: European Neuroscience Association). Max-Planck-Institut für Hirnforschung, P.O. Box 710662, D-6000 Frankfurt a.M. 71, F.R.G.

In order to visualize the topographic relationship between ocular dominance (OD) and orientation (OR) columns, the two systems were mapped with (3H)proline and (14C)deoxyglucose (2-DG) autoradiography. Two weeks after intravitreous injection of (3H)proline, cats were stimulated 1. binocularly with moving square wave gratings of one orientation or 2. monocularly through the right (injected) eye with one orientation in the left visual hemifield (HF) and all orientations in the right HF. The resulting patterns of increased 2-DG uptake and of terminal labeling were analyzed in flat-mount sections of the visual cortices.

Both columnar systems have the tendency to form regularly spaced parallel bands whose main trajectory is perpendicular to the 17/18 border. However, they differ in their spatial frequencies: adjacent OR-columns are more widely spaced than OD-columns. The graphical superposition of the two systems failed to show correlations beyond the degree that is expected from the superposition of independent but similarly organized patterns: none of the organizational features of OR-columns (start and stop points, bifurcations or beads) was specifically related to the centers or borders of OD-columns. Interestingly, monocular stimulation with many orientations failed to induce the pattern of OD-columns observed by Kossut, M. et al. (Acta Neurobiol. Exp., 43:273, 1983), but resulted in a more or less homogeneous increase of radioactivity over the entire extent and throughout all layers of the visual cortex. In addition, monocular stimulation with one orientation induced a pattern of OR-columns similar to that obtained after binocular stimulation (Löwel, S. et al., J. Comp. Neurol., 255:401, 1987). In both cases, regions of increased 2-DG uptake were not restricted to columns of neural tissue above and below the (3H)proline labeled OD-bands in layer IV.

Thus, in contrast to the striate cortex of macaque monkeys (Kennedy, C. et al., Proc. Natl. Acad. Sci. USA, 73:4230, 1976), visual stimulation through one eye seems to be sufficient to induce activity in the entire visual cortex of the cat. These results indicate that area 17 of cats and area V1 of macaque monkeys have a fundamentally different organization of binocular information processing.

5.11 TOPOGRAPHY OF CALLOSAL PROJECTIONS OF RAT PRIMARY VISUAL CORTEX. A. Burkhalter[1], J.P. Doyle*[2], R. P. Haugland*[3], and J.M. Nerbonne[2]. Depts. of Neurosurgery[1] and Pharmacology[2], Washington University School of Medicine, St. Louis, MO 63110. Molecular Probes Inc.[3], Eugene, OR 97402.

In rodents the main callosal projection of primary visual cortex (area 17) originates from layers 2/3, 5 and 6 at the border of area 17 and 18a, where the vertical meridian (VM) is represented, and terminates at a homotopical site in the opposite hemisphere. In addition, this projection receives a contribution from layer 5 and 6 outside the 17/18a border region, representing peripheral parts of the visual field, which could lead to topographical mismatch in the terminal zone on the opposite side.

To study the topology and simultaneously compare the callosal fiber terminals originating from the 17/18a border and the interior of area 17, we used anterograde tracing with fluorescent dextrans (Molecular Probes Inc.). The left area 17 of the hooded rat (3-5 weeks old) was injected at the VM with FITC-labeled dextran (D-1821, 25% in H_2O, 0.05ul) and a second similar injection labeled with Texas Red (D-1828) was placed into the peripheral representation (20-40°). After 2-4 days survival animals were perfused, the brains removed and sectioned.

Injection sites were 0.1-0.2 mm in diameter and included all layers. From the injection sites, green and red labeled fibers coursed through grey matter, descended into the optic radiation or crossed via the corpus callosum. Terminal arbors were observed in many cortical regions of the left (in areas 18a and 18b) and right (in areas 17 and 18a) hemispheres, visualizing red and green endings and enabling direct comparison of their distributions. Similarly, anterograde labeling was found in all known subcortical projections of area 17 (LGNd, LGNv, LP, pretectal nuclei, SC). Several of these were also marked with retrogradely labeled cells, confirming known reciprocal connections.

Across the corpus callosum, VM injections on the left side with green tracer resulted in terminal labeling in layers 1, 2/3 and 5 in a 0.1-0.3mm wide strip within right area 17 overlying the 17/18a border. This border was never labeled with red fibers nor have we ever seen red terminals within area 17 that originated from peripheral area 17. Instead, red terminal arbors mapped exclusively onto area 18a lateral to the 17/18a border and never overlapped the green callosal projection to the VM.

This is the first demonstration of anterograde and retrograde neuronal tracing with fluorescent dextrans in mammalian CNS. Specifically the results show, unlike Miller and Vogt's (Brain Res., 297:75, 1984), that injections away from the VM are not connected to mirror-symmetrical points of area 17 in the opposite hemisphere. Such transcallosal connections, however, do exist between areas 17 and 18a. (Supported by NIH grant EY05935).

5.12 **IN VIVO VISUALIZATION OF CALLOSAL PATHWAYS: A NOVEL APPROACH TO THE STUDY OF VISUAL CORTEX ORGANIZATION.** R. Malach* (Spon: T. Flash). Center for Neurosciences, Weizmann Inst. of Science, Rehovot, Israel 76 100.

A major challenge in cortical research is to directly relate the structure and function of cortical modules. An important step towards this goal is to reveal aspects of cortical organization while the animal is alive. I describe here the successful visualization of callosal pathways in the live mammalian cortex. The technique, called vital tract tracing, was prompted by the finding that cortical neurons, when labeled with fluorescent tracers under optimal conditions, stain sufficiently intensely to be visible even through the intact cortical hemisphere.

In the experiments reported here, rats had their left cortical hemisphere extensively injected with the fluorescent tracer bisBenzimide. After appropriate survival, the animals were reanesthetized and the right cortical hemisphere was exposed. Upon illumination with UV light, the fluorescing callosal pattern could be discerned under the network of blood vessels even with the unaided eye. The visualized callosal pattern was then used to guide WGA-HRP injections into a minute cortical region - the central callosal ring (CCR)- a 0.4 mm zone, whose boundaries are completely invisible under normal viewing conditions, situated rostral to area 17. The exposed cortex appeared normal in nissl stained material, and the presence of doubly labeled neurons indicated that the fluorescence labeling and UV exposure did not interfere with WGA-HRP transport.

By making precise injections into the CCR it was found to be reciprocally connected mainly to two zones: one on the lateral edge of area 18a and the other medially in 18b. Other, more minor projections were to posterior area 8, area 3 and the posterior edge of area 18a. Since these zones had fixed spatial relationship with the callosal system, vital tracing was used to guide WGA-HRP injections into the CCR- connected zone in area 18a. Again, there were two main labeled regions, one overlapped the hollow in the CCR, while the other was situated within area 18b. These results demonstrate the feasibility of using vital tract tracing to achieve great precision in studies of cortical organization.

6.1 NORMAL PATHFINDING BY PIONEER MOTOR GROWTH CONES IN MUTANT ZEBRAFISH LACKING FUNCTIONAL ACETYLCHOLINE RECEPTORS. M. Westerfield, C.B. Kimmel, and C. Walker*, Institute of Neuroscience, University of Oregon, Eugene, OR 97403.

The formation of orderly nerve connections during development of the nervous system requires correct pathfinding, synapse formation, and, in some cases, the elimination of extra synapses. A variety of studies have suggested that one or more of these processes is dependent upon neuronal activity since altering the normal pattern of electrical activity affects the final organization of nerve connections. Recent studies using tetrodotoxin to block sodium channels have shown that action potential activity is not required for normal pathfinding or synapse formation by developing neurons. Spontaneous release of transmitter from growth cones or from growing neurites, however, is usually not blocked by these procedures. Hence it is unclear if non-impulse mediated signalling between pre- and post-synaptic cells is a required component for appropriate pathfinding and synapse formation.

We have used a heritable mutation that eliminates functional ACh receptors in the embryonic muscles of the zebrafish to investigate the role of one aspect of neuronal activity, cholinergic neuromuscular transmission, on the establishment of peripheral nerve pathways by pioneer motoneurons. The mutation is a recessive lethal that was induced by gamma irradiation. It segregates as a single gene among progeny obtained parthenogenetically from heterozygous females.

Homozygous mutant embryos, although normal in outward appearance, are paralyzed and die a few days after hatching. Moreover, they are nonresponsive to tactile stimulation or to electrical stimulation of the spinal cord and no spontaneous or evoked neuromuscular activity can be recorded in mutant muscle fibers. Direct stimulation of the muscles, however, produces a contraction. Muscle fibers in mutant embryos do not bind bungarotoxin and fail to respond to cholinergic agonists. These observations suggest that the mutation eliminates functional ACh receptors.

To examine the accuracy of pathfinding by motor growth cones in mutant embryos, we studied the initial outgrowth of motoneurons by staining them with a neuron specific monoclonal antibody. We found that identified motoneurons are present and have axons in the muscles. Moreover, the growth cones of these pioneer motoneurons follow the same cell-specific pathways into the muscles that they establish in normal embryos. Thus, although motoneuron growth cones normally release transmitter and communicate with muscle fibers via ACh receptors during their initial outgrowth, this signalling is not required for the establishment of proper nerve projections. Supported by NS21132, GM22731, DCB8317049 and BNS12370.

6.2 THE EARLY DEVELOPMENT OF ROHON-BEARD NEURONS IN EMBRYONIC ZEBRAFISH. Paul Z. Myers*, Judith S. Eisen, and Charles B. Kimmel. (SPON: W.K.Metcalfe). Institute of Neuroscience, University of Oregon, Eugene, OR 97403.

Young zebrafish possess a small set of distinctive large neurons that mediate the simple, reflexive behaviors of the embryo. These neurons, called primary neurons, initiate axogenesis at roughly the same time, prior to 24 hours after fertilization (h) and quickly establish the basic framework of the embryonic nervous system. The development of one class of primary neurons, the primary motoneurons, has already been described. Primary motoneurons are characterized by a segmental distribution of their somata within the spinal cord and a precise, stereotypic pattern of axonal outgrowth. We describe here the morphology and early development of another class of primary neurons, the Rohon-Beard cells, which, together with trigeminal sensory neurons, form the tactile sensory component of the primary neuronal network.

Like the other primary neurons, Rohon-Beard cells begin axogenesis very early in development, at approximately 16 h. Their cell bodies are large (10-15 μm in diameter), and their peripheral arbors become extensive. Unlike the primary motoneurons, however, Rohon-Beard neurons are not individually identifiable and are not distributed segmentally. In contrast to the stereotyped growth of the primary motor axons, Rohon-Beard axons grow into the periphery in an apparently random fashion, with no recognizable pattern, and in particular, no segmental specificity. Thus, despite their initial similarities in size and time of development, Rohon-Beard neurons and primary motoneurons follow profoundly different programs of development.

We conclude that even among the set of primary neurons that develop synchronously within the spinal cord, there are at least two distinctly different patterns of neuronal organization and development: primary motoneurons are segmental and have stereotyped and specific axon morphologies, while Rohon-Beard neurons are nonsegmental and have seemingly nonspecific peripheral arbors.

Supported by NIH-NS 17963, the American Heart Association, and NIH-NS 23915-01.

6.3 TRANSIENT COUPLING BETWEEN IDENTIFIED MOTONEURONS IN ZEBRAFISH EMBRYOS DURING AXONAL PATHFINDING. J. S. Eisen and B. Debu. Institute of Neuroscience, University of Oregon, Eugene, OR 97403.

Dye-coupling between neurons and other cells has been described during axonal pathfinding in several invertebrate systems, but not in vertebrates. We studied dye-coupling between identified motoneurons in embryonic zebrafish to learn whether it occurs during axonal pathway selection. In zebrafish each side of every trunk muscle segment is innervated by three large identified motoneurons, referred to as primary motoneurons because they are the first motoneurons to develop. During embryogenesis the growth cones of the three primary motoneurons exit the spinal cord in an invariant sequence in which CaP (Caudal Primary) precedes MiP (Middle Primary) and MiP precedes RoP (Rostral Primary). Thus CaP acts as a pioneer in establishing the motor nerve of each segment.

We investigated coupling between identified primary motoneurons by injecting low molecular weight fluorescent dyes (Lucifer yellow or sulforhodamine) directly into motoneuronal somata. We found that, prior to initiation of axonal outgrowth, many cells within the spinal cord are dye-coupled. Primary motoneurons become uncoupled from their neighbors at the time they initiate axonal outgrowth. The CaP growth cone then exits the spinal cord and extends ventrally, into the periphery. At about the time the CaP growth cone leaves the spinal cord, the MiP growth cone extends caudally within the spinal cord, growing towards CaP. Because the CaP growth cone extends into the periphery before the MiP growth cone, the CaP axon is well established in the periphery before the MiP growth cone contacts it. When the MiP growth cone contacts the CaP axon, MiP and CaP become dye-coupled. Dye-coupling is bidirectional, resulting from dye injection either into CaP or MiP. After coupling with CaP, the MiP growth cone turns ventrally, leaves the spinal cord, and extends into the periphery, following the pathway previously pioneered by the CaP growth cone. MiP and CaP become uncoupled at about the time the MiP growth cone leaves the spinal cord, or shortly thereafter.

Our results indicate a correlation between the temporal appearance of transient dye-coupling between CaP and MiP and the change in direction of the MiP growth cone, from growing caudally within the spinal cord to growing ventrally into the periphery. This correlation suggests that coupling may play a role in pathway selection by the MiP growth cone. Supported by NIH NS23915, the AHA, and an NSF PYI award to JSE.

6.4 ANTIBODIES TO THY-1 PROMOTE NEURITE OUTGROWTH FROM RAT SYMPATHETIC NEURONS IN VITRO, AND PROMOTE NEURITE INITIATION BY RAT ADRENAL CHROMAFFIN AND PC12 CELLS IN THE ABSENCE OF NGF. N. K. Mahanthappa* and P. H. Patterson. Division of Biology, 216-76, California Institute of Technology, Pasadena, CA 91125.

Thy-1 is considered to be a member of the immunoglobulin gene superfamily (Williams and Gagnon, Science 216:696, 1982), and is expressed on the surface of mouse T lymphocytes and certain neurons (Reif and Allen, J. Exp. Med. 120:413, 1964). While the function of Thy-1 in the immune and nervous systems is unknown, monoclonal antibodies (MAbs) to Thy-1 induce mitosis and lymphokine secretion by T lymphocytes (Gunter et al., J. Exp. Med. 159:716, 1984; MacDonald et al., Eur. J. Immunol. 15:495, 1984), and substrates coated with anti-Thy-1 MAbs promote neurite regeneration from dissociated rat retinal ganglion cells (Leifer et al., Science 224:303, 1984) and mouse cerebellar Purkinje cells (Messer et al., Cell. Molec. Neurobiol. 4:285, 1984).

We have found that affinity purified anti-Thy-1 MAbs promote neurite outgrowth from neonatal rat superior cervical ganglion neurons, and that this effect is not simply a product of enhanced substrate adhesion or nonspecific membrane perturbation. Addition of any of three anti-Thy-1 MAbs (OX-7, 19XE5, and 2G12) to serum-free neuronal cultures increases the percentage of process-bearing cells by 40-50% over controls in 24 h, and crosslinking with secondary Ab enhances this effect. Simple preincubation of the collagen substrate with MAbs is insufficient, and the addition of antibodies to other cell surface antigens (NILE, heparan sulfate proteoglycan, and class I histocompatibility antigen) at similar concentrations (5 μg/ml), with or without secondary Ab, has no effect. Furthermore, anti-Thy-1 MAbs also promote neurite initiation, in the absence of NGF, from both neonatal rat adrenal chromaffin cells and the PC12 cell line over the course of 4-7 d: a three-fold increase over controls for chromaffin cells, and a fourfold increase for PC12 cells. In a different approach to the question of function, we are generating Thy-1 deficient mutant PC12 cells. Preliminary observations reveal that the deficient cells show a very high incidence of spontaneous neurite extension in the absence of NGF. This finding suggests that Thy-1 may play a role in the stabilization of processes and/or the inhibition of new outgrowth, and that MAbs to this molecule may be blocking normal function in our experiments.

This work is supported by grants from the NINCDS and the McKnight Foundation to P.H.P., and a NSF Graduate Fellowship to N.K.M.

6.5 **MOLECULAR GENETIC ANALYSIS OF DROSOPHILA LAMININ.** D.M. Johnson* and C.S. Goodman (SPON: S. Glatzbach). Dept. Biol. Sci., Stanford University, Stanford, CA 94305.

Laminin is a high molecular weight glycoprotein complex present in extracellular matrices. The complex is comprised of three disulfide-bonded subunits, A, B1, and B2, of 400, 220, and 220 kD respectively. A variety of functions, including neurite outgrowth, cell migration, epidermal growth, and cell attachment, have been proposed for laminin based primarily on in vitro assays. However, it has not been possible to directly assess what roles laminin plays during embryonic development. To test its role it promoting or directing neurite outgrowth during development, we have turned to a molecular genetic analysis of laminin function in Drosophila. We report here on the purification and cloning of all three subunits of Drosophila laminin.

Antibodies against mammalian laminin do not cross-react with Drosophila. Thus, laminin was purified from Drosophila embryos using lectin affinity chromatography. Each of the subunits (A, B1, B2; 400, 220, and 180 kD respectively) was purified, and antisera raised against them. We used these antisera to screen a Drosophila embryo cDNA expression library. cDNA clones were isolated for all three subunits. We confirmed the identity of the B1 and B2 cDNA clones by (i) cross-hybridization between the Drosophila and mouse B1 and B2 clones (the kind gift of Y. Yamada), (ii) cross-hybridization between the Drosophila B1 and B2 clones, and (iii) sequence analysis of a 1.9 kb partial cDNA clone encoding the Drosophila B1 subunit. This sequence has 25% amino acid identity with the mouse B1 sequence. We are presently determining the complete structure of the Drosophila B1 and B2 subunits by cDNA sequence analysis.

Northern analysis reveals that the A, B1, and B2 subunits have mRNAs of ~9, 4.6 and 4.5 kb, respectively. All three mRNAs are coordinately expressed during development, and yet polytene chromosome localization by in situ hybridization shows that the three laminin subunit genes are not clustered in the genome. We have begun a genetic analysis to test the function of laminin during development by searching for mutations in the B2 subunit.

6.6 LOCALIZED INO ANTIBODY BINDING IN THE WING OF DROSOPHILA DURING PERIOD OF AXONAL OUTGROWTH. S.S. Blair and J. Palka. Dept. of Zoology, Univ. of Washington, Seattle, WA 98195

The wing of Drosophila melanogaster is formed from the metmorphosing wing imaginal disc. During the first few hours of this process, identifiable sensory neurons arise within the wing. These neurons initiate axon outgrowth, forming stereotyped nerves which project towards the CNS along very precise pathways through the longitudinal veins of the wing. A series of experiments has shown that the epithelium underlying the neuronal pathways is in some manner specialized for the promotion and guidance of growing axons. If neuron-containing tissues are tranplanted into mutant, aneural host wings, axons grow out of the implant into a host wing lacking both its normal neurons and any indication of physically defined channels or veins. Nonetheless, implant neurons project axons in the correct, proximal direction and along the approximate course of the epithelium of the third longitudinal vein, one of the two normal nerve paths in wild-type wings. The cues are fairly non-specific, as neurons derived from leg, eye, antenna, and wing, as well as wing tissue from different Drosophila species, can follow them.

We have therefore examined a wide variety of antibodies to see if any bind to wings in a pattern similar to that expected of a putative guidance molecule. One of the antibodies examined was the INO-3 antibody (kindly provided by Dr. P.H. Patterson). This antibody was originally isolated for its ability in mammalian cell culture to block neurite-promoting factors derived from non-neuronal cells; in that system it recognizes a complex of laminin and heparan sulfate proteoglycan. We find that it also binds to Drosophila tissue. In developing wings INO binding first appears during the initial stages of axon outgrowth. Its spatial distribution becomes increasingly restricted, and eventually is limited to the nerve pathway of the radius and the third vein. By 24 hr after pupariation, when axon outgrowth is complete, the antibody no longer binds.

Thus, the INO antibody marks the pathway followed by both normal and implant axons. However, the earliest pattern of binding does not exactly match the course taken by the first axons, and in preliminary experiments the antibody did not appear to disrupt outgrowth under our wing culture conditions. Therefore, the role of the INO-binding antigens in axonal guidance in the wing is not clear.

6.7 RAT RETINAL NEURITES GROW ON SCHWANN CELL SURFACES BUT NOT SCHWANN CELL-ORGANIZED EXTRACELLULAR MATRIX. N. Kleitman, P.M. Wood*, M.I. Johnson, and R.P. Bunge. Dept. Anatomy & Neurobiology, Washington Univ. Sch. Med., St. Louis, MO 63110.

Despite evidence that both glial cell surfaces and components of the extracellular matrix (ECM) support neurite outgrowth in many culture systems, the relative contribution of these factors has rarely been compared directly. Specifically, it remains to be determined which components of peripheral nerve support growth of central nerve fibers. We have directly compared neurite outgrowth from embryonic day 15 rat retinal explants placed onto 1) Schwann cells without ECM, 2) Schwann cells expressing ECM (including a basal lamina), 3) cell-free ECM remaining after removal of the cellular components of neuron-Schwann cell cultures, 4) nonglial cells (fibroblasts), 5) purified laminin, 6) rat tail type I collagen prepared by air-drying after exposure to ammonia vapors (ammoniated) or 7) collagen which was air-dried without exposure to ammonia (ADC). Length estimates were made from a subset of cultures fixed 5-6d after plating of retinal explants and stained with Sudan black. Results are summaried as follows:

Substratum	Length in mm[1] (n)	% w/growth	(no. tested)
Schwann cell only	3.4 ± 0.4 (5)	82%	(33)
Schwann cell + ECM	2.9 ± 0.2 (4)	100%	(12)
ECM only	0.5 ± 0.4 (2)	10%	(58)
Fibroblasts	0	0	(12)
Laminin	0	5%[2]	(62)
Ammoniated collagen	0	0	(64)
Air-dried collagen	3.4 ± 0.1 (18)	92%	(111)

[1]mean ± SEM of maximum neurite length from each explant
[2]neurites extended on laminin retracted before fixation

Outgrowth on Schwann cells expressing ECM was extensive, but not obviously different from that on Schwann cells alone. Neurite extension on isolated ECM was poor to nonexistent. Ultrastructural observations revealed that in cultures containing Schwann cells with ECM, 95% of the shafts of retinal neurites contacted other neurites or Schwann cell surfaces exclusively; they were not seen in contact with the basal lamina. Finally, retinal explants were placed onto a small (3 mm) island of ADC in a laminin-coated coverslip to provide more secure explant attachment. Neurites grew on the ADC but none extended onto the laminin. Growth on ADC may be related to the 3-dimensionality of this substratum. We conclude from these experiments that neurite extension from embryonic rat retina is supported by a factor found on Schwann cell surfaces; neither organized ECM nor several isolated ECM components provided comparable growth support. (Supported by NIH grants NS09923, NS21771, NS07071.)

6.8 8D9 ANTIGEN IS A SUBSTRATE FOR NEURITE OUTGROWTH. V.P. Lemmon and C.F. Lagenaur. Dept. of Neurobiology, Anatomy and Cell Science and Ctr. for Neuroscience, Univ. of Pittsburgh, Sch. of Med., Pittsburgh, PA 15261.

Using an assay system in which integral membrane proteins are attached to the surface of petri plates, it has been possible to directly assess the ability of purified cell adhesion molecules to promote cell attachment and neurite outgrowth. 8D9 antigen, a chicken derived molecule that is cross-reactive with mouse L1 (Lemmon, V. and McLoon, S., J. Neurosci., 6:2987, 1986) was able to promote rapid attachment and neurite outgrowth of both chick retinal neurons and mouse cerebellar neurons. Non-neuronal cells were unable to attach to 8D9 coated surfaces. In contrast, 1A6 antigen, a chicken derived molecule related to N-CAM (ibid.) was unable to attach cells derived from either chick retina or mouse cerebellum. Since 8D9 is strongly expressed by neuronal axons, these findings support the hypothesis that 8D9 and related antigens are important in axon fasciculation and in outgrowth of axons along existing axons. The detection of the related molecule L1 on Schwann cells distal to sciatic nerve transsections (Nieke, J. and Schachner, M., Differentiation, 30:141, 1985) and the activity of 8D9 in promotion of neurite outgrowth detected in the studies presented here suggests that one function of Schwann cells in regeneration is to provide a substrate for axon outgrowth.

6.9 IDENTIFICATION OF TWO DISTINCT NEURONAL RECEPTOR SYSTEMS THAT MEDIATE PROCESS OUTGROWTH ON ASTROCYTE SURFACES. K.J. Tomaselli*, K.M. Neugebauer, J.L. Bixby, L.F. Reichardt and J. Lilien*. Dept. of Physiology and Howard Hughes Medical Institute, UCSF, San Francisco, CA and Dept. of Zoology, Univ. of Wisconsin, Madison, WI.

Neuronal process outgrowth by chick ciliary ganglion (CG) neurons of two different developmental ages was examined in vitro on extracellular matrix (ECM)-derived substrates and on the surfaces of primary cortical astrocytes. E8 CG neurite outgrowth on laminin (LN) or astrocyte-conditioned medium (CM) substrates was prevented by monoclonal antibodies that block the function of ECM receptors (CSAT and JG22) while process outgrowth on astrocytes was not. E14 CG neurons were unable to extend neurites on LN or astrocyte CM but grew neurites on astrocyte surfaces; this reveals the presence of a neurite-promoting activity on astrocytes that is distinct from LN. This activity is unlikely to be a soluble factor since E14 growth cones were unable to transit from astrocyte surfaces onto surrounding LN substrates as E8 growth cones often did.

To identify the interactions mediating process outgrowth on astrocyte surfaces, E8 and E14 CG neurons were grown 16-20 hours on astrocyte monolayers in the presence of antibodies to ECM receptors or to the Ca^{2+}-dependent and -independent cell adhesion molecules N-Cal-CAM and N-CAM. N-Cal-CAM is a member of the cadherin family and is involved in the Ca^{2+}-dependent aggregation of avian neural retinal cells. Antibodies to N-Cal-CAM had dramatic and specific effects on both E8 and E14 CG growth on astrocyte surfaces, reducing the percentage of neurons with neurites by about 70% and the average neurite lengths of those neurons that did respond by about 60%. On E8 neurons, ECM receptor antibodies reduced the average length of neurites and when combined with anti-N-Cal-CAM had roughly additive inhibitory effects. E14 neurite outgrowth was not inhibited by anti-ECM receptor antibodies. Antibodies to N-CAM had no detectable effects either alone or in combination with ECM receptor antibodies on process outgrowth by neurons of either age.

Thus, E8 CG neurons use primarily two receptor systems for growth on astrocytes: ECM receptors belonging to the integrin family and a Ca^{2+}-dependent cell adhesion molecule belonging to the cadherin family. E14 neurons that have lost ECM receptor function use primarily the latter system for growth on astrocytes. The results presented here suggest that expression of the cadherins and ligands to which they bind play a role in nervous system development and regeneration. Supported by NIH grant NS-19090, NSF grant DCB 8511052, March of Dimes Birth Defects Foundation grant I-774 and the Howard Hughes Medical Institute.

6.10 TISSUE ENVIRONMENT INFLUENCES THE TIMING OF PREGANGLIONIC AXONAL OUTGROWTH IN THE SYMPATHETIC SYSTEM OF THE CHICK. J.W. Yip. Dept. of Physiol., Sch. of Med., Univ. of Pittsburgh, Pittsburgh, PA 15261.

The spatio-temporal patterns of preganglionic outgrowth in the chick sympathetic system are highly specific. Preganglionic axons arising from the T1 spinal segment project predominantly in the rostral direction, whereas T4 preganglionic axons project predominantly in the caudal direction. Moreover, the timing of this outgrowth proceeds in the rostral to the caudal direction. Axonal outgrowth begins at stage 27 (5-5½ days). By stage 28 (5½-6 days) preganglionic axons arising from the T1 spinal level already project 3 segments, whereas T4 preganglionic axons project less than 1 segment.

Previous spinal cord rotation studies (T1 to T4 spinal cord segments were rotated 180° along the anterior-posterior axis) show that translocated neurons project in directions appropriate to their new locations. This suggests that there are specific cues in the tissue environment providing the guidance for these axons. Similar spinal cord rotation studies were recently performed to examine the effect of the tissue environment on the temporal pattern of axonal outgrowth. My results show that translocated neurons project on a schedule consistent with their new location. That is, T4 preganglionic neurons which have been translocated to the T1 spinal level extend their axons into the sympathetic trunk at stage 27 and by stage 28 they project 3 segments rostrally. Thus, the tissue environment determines not only the direction but also the timing of preganglionic axonal outgrowth.

To examine the influence of tissue environmental factors on preganglionic axonal outgrowth at different times, heterochronic spinal cord transplantations were performed. A segment of the spinal cord from the T1 to the T4 spinal levels was removed from donor embryos (stages 18 and 19) and transplanted into younger hosts (stages 13 and 14) from which an equivalent length of the upper thoracic spinal cord was previously removed. Even though the donor cord is at least 24 hours older than the host, preganglionic axons from the T1 level of the donor were not observed in the sympathetic trunk until stage 27 of the host. Furthermore, they also project 3 segments rostrally by stage 28 of the host.

These results suggest that the tissue environment outside the spinal cord influences not only the spatial pattern but also the temporal pattern of sympathetic preganglionic outgrowth.

Supported by NIH NS 23916

6.11 THE ROLE OF GLIAL "ANTI-CHANNELS" IN COMMISSURAL AXON GUIDANCE. D. Snow*, J. Dodd, T. Jessell, J. Silver. (SPON: Michel Kliot) Department of Developmental Genetics and Anatomy, Case Western Reserve University, Cleveland, Ohio 44106. The Center for Neurobiology and Behavior, Columbia University, New York, New York 10032.

Axons have been shown to grow through preformed glial channels in several areas of the developing nervous system. A glial region, the roof plate, is located at the dorsal midline of mouse and rat embryonic spinal cord. Axons never cross this area, but the reasons for this are unknown. Is there a specialized substructure present within the roof plate that acts as a boundary during development? In order to address this question, we have analyzed the developing dorsal spinal cord midline in mice with 1 um plastic serial sections and with EM. In addition, we have examined a particular subpopulation of commissural axons using a monoclonal antibody, 1C12, which is specific for a cell surface glycoprotein. Commissural fibers show a stereotypical trajectory away from the dorsal midline. During early stages of their outgrowth, we have observed a system of large extracellular spaces, surrounded by glial processes, which are strategically located in the roof plate.

A spatio-temporal analysis was done to visualize the developmental sequence of formation of the roof plate channels on embryonic days 8-14 in cervical cord. The alar commissural fibers, generated before E9, near the roof plate, course laterally away from the dorsal midline in close juxtaposition with the edges of this channel system, but never travel through it. The roof plate channels are transient. They are first observed as a single row of extracellular spaces at E9. After E11, as the dorsal root afferents approach the midline, the morphology of the roof plate undergoes a series of dramatic changes, but continues to serve as a boundary.

Our data suggest that the mere physical presence of large extracellular channels is not always predictive of a future axon pathway. Indeed, in the present case, the roof plate spaces seem to function as "anti-channels" to orient the ventrally-bound commissural fibers away from the midline. What makes anti-channels inhibitory? Previous studies in chick forebrain have shown that a glycosoaminoglycan, chondroitin-6-sulfate, is present in large quantities in channels beneath the cortical plate region where axons are not found (Palmert et al., Neurosci. Abs., Vol. 12, 1986). Whether this component of the extracellular matrix, or others, are inhibitory to axons and actually present in the anti-channels is currently under investigation (Supported by NIH EYO 5952, the Spinal Cord Society, and the Case Alumni Brumagin Memorial Fund).

6.12 ABNORMAL PURKINJE CELL HISTOGENESIS IN HUMAN RENAL AGENESIS. A GOLGI STUDY. Miguel Marin-Padilla. Department Pathology, Dartmouth Medical School, Hanover, New Hampshire 03756.

The neuronal differentiation/maturation of the cerebellum of four premature infants with bilateral renal agenesis (Potter's syndrome) has been studied with the rapid Golgi method. The infants were born at 32,33,33, and 36 weeks of gestation, and survived for only a few (3-7) hours. Their cerebelli were considered to be anatomically normal. Golgi preparations were made of the lateral lobes. Histologically, all cases show a 2-3 weeks delay in their differentiation and neuronal maturation, and abnormal Purkinje cell histogenesis. These neurons have retained their basal and perisomatic dendrites which should have disappeared by the 31st week of gestation (Marin-Padilla, J. Comp. Neurol. 235: 82-96, 1985). Subsequently, the basal/perisomatic dendrites undergo a pronounced hypertrophy, growing into the internal granular layer where they reach a considerable length. Some of these long dendrites give off apical branches that enter the molecular layer. The progressive growth of basal/perisomatic dendrites coincides with a reduction in the number and length of the original Purkinje cell apical dendrites. These Purkinje cell dendritic changes show a distinct developmental gradient. These developmental modifications are quite apparent when younger and older cases are comparatively studied. The anomalies are more pronounced in proximal than in distal regions of the same folium, and in older than younger infants. The appearance of these developmental dendritic changes coincides with the arrival of climbing fibers at the Purkinje cell plate. These fibers seem to retain their contacts with the basal/perisomatic dendrites failing to ascend the apical branches. In addition, these Purkinje cell dendritic anomalies could be related to maldevelopment of basket cells, since these neurons fail to establish recognizable pericellular nests around the Purkinje cell soma. The Purkinje cell anomalies found will be discussed in relation to other neuronal and fibrillar components of the cerebellum. Somewhat similar Purkinje cell dendritic changes have been reported in renal dysplasia and infantile polycystic kidneys (Kornguth et al., Acta Neuropath. 40:1-9, 1977).

Supported by NINDS grant-22897.

6.13 **THE ROLE OF PROTEIN KINASE C IN GOVERNING NEURITE OUTGROWTH IN CULTURED ADRENERGIC CELLS.** F. L. Hall*, P. Fernyhough*, P. R. Vulliet, and D. N. Ishii (SPON: K. Beam). Department of Physiology, Colorado State University, Fort Collins, Colorado 80523.

The formation of vertebrate neural circuitry is regulated in part by neurotrophic factors, such as nerve growth factor (NGF) and insulin; however, the biochemical mechanisms controlling neurite outgrowth remain incompletely understood. Both NGF and insulin initiate neurite outgrowth in addition to enhancing the survival of cultured sympathetic neurons. Phorbol ester tumor promoters (such as 12-O-tetradecanoyl-phorbol-13-acetate: TPA) are also known to alter or influence the extension of neurites in a variety of cultured adrenergic cells; and protein kinase C, the major phorbol ester receptor, is implicated in this process. To further assess the role of protein kinase C in the elaboration of neurites, sphingosine, a specific pharmacological inhibitor of the enzyme, was employed in a variety of in vitro adrenergic neurodevelopmental systems. In PC12 rat pheochromocytoma cells, SH-SY5Y human neuroblastoma cells, and embryonic chick sympathetic neurons, the extension of neurites was found to be reversibly inhibited by sphingosine in a dose-dependent manner (micromolar concentrations), whether the neuritogenic stimulus was NGF, insulin, or TPA. The antagonism observed between the effects of TPA and sphingosine was indicative of competitive inhibition. Previous studies have shown that the induction of neurites by NGF (Fernyhough and Ishii, Neurochem. Res., in Press, 1987) and by insulin (Mill et al., Proc. Natl. Acad. Sci. U.S.A., 82:7126, 1985) is correlated with an increase in the levels of tubulin messenger RNA; therefore, the effects of sphingosine on tubulin transcript levels were examined in an effort to delimit the locus of action. Sphingosine did not inhibit the NGF-directed elevation of tubulin mRNA levels in PC12 cells. Nor did sphingosine inhibit the insulin-directed elevation in tubulin mRNA levels in SH-SY5Y cells. Taken together, these results obtained from both normal and neoplastic cells 1) reveal the presence of a sphingosine-sensitive pathway in neurite outgrowth; 2) indicate that protein kinase C plays a regulatory role in mediating the neuritogenic effects of both NGF and insulin in cultured adrenergic cells; and 3) suggest that protein kinase C acts at a distal segment of the neurite growth pathway.

Supported by NINCDS grant RO1 NS24787 and by USAF-OSR grant 86-0117.

NEURONAL DEATH I

7.1 CELL DEATH AND SENSORY FIBERS IN THE TROCHLEAR SYSTEM OF LARVAL AND ADULT AMPHIBIANS. B. Fritzsch and R. Sonntag*. Fac. Biol., Univ. Bielefeld, P.O. Box 8640, 48 Bielefeld 1, FRG.

The development of the trochlear system and its adult diversity was studied in Xenopus laevis and Ambystoma mexicanum . The trochlear nerve was selectively exposed under anesthesia and cut in adults. Larvae were enucleated. HRP was briefly applied to the cut nerves. After survival times of 2 - 7 days, the animals were reanesthetized and perfused. The brains were subsequently removed and reacted with diaminobenzidine either as sections or as wholemounts. Labelled trochlear motoneurons were counted and the numbers corrected. Myelinated trochlear nerve fibers were counted in semithick epoxy resin sections of the proximal nerve and unmyelinated nerve fibers were counted in the electron microscope.

A significant reduction ($p<0.05$) of the initially higher numbers of labelled larval trochlear motoneurons in A. mexicanum (8 +- 4, N = 7, stage 40; 4 +- 2, N = 13, stage 44/45) and X.laevis (11 +- 3, N = 24, stage 42; 7 +- 4, N = 19, stage 46) was followed by a numerical increase to adult values. HRP-labelled degenerating trochlear motoneurons were present only at the time of numerical decrease. More than twice the numbers of fibers were found in the trochlear nerve of adult X. laevis (73 myelinated fibers) as compared to larvae (35 myelinated and unmyelinated fibers; stage 49). This suggests a late larval formation of trochlear nerve fibers and motoneurons. The development of the trochlear system of amphibians may show both cell death and long term proliferation.

Numbers of retrogradely labelled motoneurons (60 +- 8, N = 8) were slightly lower than those of myelinated trochlear nerve fibers (73 +- 11; N = 17) in adult X. laevis but much lower in adult A. mexicanum (19 +- 5; N = 13; 51 +- 6; N = 6). In the latter species a group of Mesencephalicus V cells (20 +- 7; N = 6) was consistently labelled via the trochlear nerve. The combined numbers of the two groups of labelled cells (39) related rather well to the numbers of trochlear nerve fibers (51) in A. mexicanum . These data indicate the presence of sensory Mesencephalicus V fibers in the trochlear nerve of some amphibians but not in others. Supported by the DFG, SFB 223.

7.2 DE NOVO TRANSCRIPTION AND TRANSLATION OF NEW GENES IS REQUIRED FOR THE PROGRAMMED DEATH OF THE INTERSEGMENTAL MUSCLES OF THE TOBACCO HAWKMOTH, Manduca sexta. L.M. Schwartz and B.K. Kay*. Department of Biology, University of North Carolina, Chapel Hill, N.C. 27514

The intersegmental muscles (ISM) of the moth Manduca undergo a developmentally programmed cell death following adult emergence. The trigger for cell death is a decline in the haemolymph ecdysteroid titer. We have sought to define some of the molecular events associated with the muscle's commitment to degenerate.

Animals at different developmental stages were injected with ^{35}S-methionine and after equilibration, muscle proteins were separated by 1 or 2 dimensional polyacrylamide gel electrophoresis and visualized by autoradiography. At each stage examined prior to the muscle's commitment to degenerate, the pattern of newly synthesized proteins was identical. However, coincident with committment, a set of approximately 5 new proteins could be resolved (25-100 k daltons). When animals were treated before commitment with actinomycin D or 20-hydroxyecdysone, the muscles failed to degenerate at the normal time. Both of these treatments also blocked the appearance of the new proteins. Interestingly, actinomycin D (0.5ug/animal) did not disrupt development or block adult eclosion.

Poly A$^+$ RNA was isolated from muscles at various stages and translated in vitro in the the presence of ^{35}S-methionine. The protein patterns obtained from all pre-commitment staged RNAs were identical. Translations with later mRNA samples however, revealed an additional set of 5 new proteins. Taken together, these data suggest that the de novo transcription and translation of a small set of "cell death" genes is required for muscle degeneration. We are curently attempting to clone these sequences for expression and analysis.

7.3 DIFFERENTIAL SENSITIVITY OF TRANSMITTER-IDENTIFIED NEURONES TO THE LETHAL EFFECTS OF INHIBITION OF ELECTRICAL ACTIVITY IN DISSOCIATED CULTURES OF MOUSE SPINAL CORD AND DRG. G.A. Foster and D.E. Brenneman. (SPON: P.J.Roberts). Lab. of Developmental Neurobiology, NICHD, NIH, Bethesda, MD 20892.

The survival of cells in vivo and in vitro is dependent on a variety of trophic factors. Differential survival of the same neurons transplanted to ectopic regions of the central nervous system illustrates that not all cells are equally sensitive to this trophic support. The level of refinement of this discrimination for specific neuron types is at present unknown. We have been using primary neuronal cultures to investigate the sensitivity of mouse spinal cord and dorsal root ganglion (DRG) cells to the neuron-depleting effects of tetrodotoxin (TTX), and their rescue by vasoactive intestinal polypeptide. There is now considerable evidence that approximately 30% of the spinal cord/DRG neurons are lost after treatment with TTX over the sensitive period of 9-14 days in culture (Brenneman, D.E. et al., Brain Res., 9:13, 1983). It was questioned, therefore, whether this attenuation represented the complete loss of one or more specific transmitter-identified sub-populations of neurons, rather than a partial reduction of all neurons in general.

Dissociated cultures of mouse spinal cord and DRG were treated with 10^{-6} M TTX, as described previously (Brenneman, D.E. et al., Brain Res., 9:13, 1983), and then fixed with 4% paraformaldehyde in 0.1M phosphate buffer (pH 7.4) for 30 min at room temperature. After rinsing in phosphate buffered saline (PBS), 10% normal goat serum in PBS containing 0.1% triton was applied for 1h at room temperature. The cultures were then incubated with rabbit antibodies against either neuron-specific enolase (NSE), neurofilament (NF), met-enkephalin (ENK) or calcitonin gene-related peptide (cGRP), diluted in PBS containing 1% normal goat serum and 0.1% triton, at 4^{0}C overnight. The ABC-peroxidase method was used for visualization (Vector Labs.). Positive neurons were counted in at least 100 fields per culture dish.

As described previously, approximately one third of all NSE- and NF-immunoreactive cells, ie. neurons, were depleted by the TTX treatment. In control cultures, ENK-positive cells constituted almost 10% of the total number of neurons, and their proportionate decrement after TTX treatment was 95%. There was also a large proportionate reduction in cGRP-containing neurons after TTX application: despite constituting only 1.5% of the neurons in control cultures, their number was depleted by 70% in TTX-treated dishes. When the cGRP-immunoreactive neurons from spinal cord were distinguished from those derived from DRG (on the basis of their morphology), there was found to be an almost 100% decrease in the former, and no significant change in the latter.

The present data show that TTX blockade of electrical activity in primary neuronal cultures can lead to a differential loss of transmitter-identified neurons. Cells containing ENK, and spinal cord cells storing cGRP are essentially depleted entirely, whereas cGRP-positive neurons from DRG are not reduced. The reduction in neuronal number resulting from the TTX-induced loss of ENK and cGRP cells amounted to approximately 20% of the overall decrement caused by this drug: the transmitter identity of the remainder is still unknown.

7.4 NMDA ANTAGONISTS INCREASE NEURONAL DEATH WITHOUT BLOCKING ELECTRICAL ACTIVITY IN DEVELOPING CULTURES. P.G. Nelson, D.E. Brenneman, I. Forsythe, T. Nicol* and G. Westbrook. Lab. Developmental Neurobiology, NICHD, NIH, Bethesda, MD 20892

Activation of the NMDA receptor, a glutamate receptor subtype, has been implicated in several animal models of acute neuronal death. We have explored the possibility that excitatory amino acid receptors may also modify activity-related neuronal survival and loss during normal development. We have shown previously that blockade of electrical activity with tetrodotoxin (TTX) increases neuronal death in spinal neurons. This effect was apparent when conditioning substances were removed and when electrical activity was blocked during a two week period in development when 50% of the neurons normally die. Since excitatory amino acids mediate a large proportion of the synaptic interactions in spinal cord cultures, we have investigated the possibility that NMDA antagonists might increase neuronal death similar to that shown for TTX. A comparison of the effects of (±) 2-amino-5-phosphonovalerate (AP5) and (±) 5-methyl-10, 11-dihydro-5H-dibenzo(a,d)cyclo-hepen-5,10-imine (MK-801) was made.

Dissociated spinal cord cultures were prepared from 13 day old fetal mice. Cultures were maintained in defined medium supplemented with 5% horse serum. Prior to drug treatment, a complete change of nutrient medium was performed. Drugs were added to the culture medium on day 9 and treatment was continued for 5 days. To assay for neuronal survival, the neurons were immunocytochemically identified with antibodies to neuron specific enolase and then counted. On day 14, electrical activity was assayed using the whole cell patch clamp method.

The survival of spinal cord neurons was significantly influenced by both NMDA antagonists. With the addition of 10 μM AP5 or 0.1 μM MK-801, the number of surviving neurons was reduced to 65% of that for controls. In sister cultures, 1 μM TTX treatment reduced neuronal survival to 55% of control. There was no additivity with TTX treatment plus AP5. A significant increase (15-25 %) in the number of neurons was observed with 0.1 μM AP5 or 0.01 nM MK-801 as compared to control cultures. Spontaneous excitatory post synaptic potentials were observed in all control cultures and in all cells treated with 30 μM AP5. Spontaneous action potential bursting was observed in 12 of 15 cells from control cultures but in 0 of 15 cells treated with 30 μM AP5. These data indicate that chronic NMDA receptor blockade can, depending on concentration, either enhance or decrease neuronal survival during development. These data suggest that the pattern of electrical activity rather than activity per se may be an important determinant for neuronal survival during development.

7.5 DIRECT EVIDENCE FOR AN INCREASE IN INTRACELLULAR FREE CALCIUM IN AMINO ACID NEUROTOXICITY OF SELECTIVELY VULNERABLE HIPPOCAMPAL NEURONS. L.S. Stodieck and J.J. Miller. Dept. of Physiology, Univ. of British Columbia, Vancouver, B.C. V6T 1W5.

Amino acid neurotoxicity has been proposed as a mechanism underlying selective vulnerability in the mammalian brain following such disorders as ischemia and status epilepticus. Indirect evidence has suggested that excitatory amino acids exert their cytotoxic effects by causing an increase in intracellular free calcium concentration ($[Ca^{2+}]_i$). In the current study, direct measurements of $[Ca^{2+}]_i$, using Fura-2 fluorescence, were made in cultured hippocampal cells exposed to 0.5 mM l-glutamate for periods ranging from 5 to 30 min. Measurements of $[Ca^{2+}]_i$ were correlated with cell death quantified 24 hours after glutamate exposure using the fluorescent compounds ethidium bromide and acridine orange. Ethidium bromide stains DNA from cells with disrupted plasma membranes while acridine orange stains nuclear material in viable cells. Appropriate excitation and emission filters were selected such that photographs could be taken of either dead or viable cells in the same microscope field. The percentage of dead cells were readily determined from these photographs.

During exposure to 0.5 mM l-glutamate, $[Ca^{2+}]_i$ was found to increase rapidly from a mean of 83nM to 1020nM in the neuronal cell bodies. Non-neuronal cells, identified by morphological criteria, exhibited only very slight increases in $[Ca^{2+}]_i$ from 72nM to 131nM and, surprisingly, $[Ca^{2+}]_i$ measured in areas consisting of neurites alone also increased only slightly from 114nM to 135nM. Following glutamate exposure, $[Ca^{2+}]_i$ returned to resting levels (mean 92.6nM) in many neuronal cell bodies. However, some neuronal somata continued to exhibit elevated $[Ca^{2+}]_i$ (mean 1080nM). $[Ca^{2+}]_i$ appeared to either remain above 800nM or drop to less than 150nM with very few cell bodies exhibiting intermediate calcium concentrations. The number of neuronal cell bodies with $[Ca^{2+}]_i$ remaining elevated varied from less than 10% to greater than 90% depending on the duration of glutamate exposure and correlated strongly with the percentage of dead cells at 24 hours.

Results from this study demonstrate a form of selective vulnerability in cultures of hippocampal cells; neurons are more vulnerable to amino acid toxicity than non-neuronal cells and some neurons are more vulnerable to glutamate exposure than others. Selective vulnerability in these cultures correlated strongly with elevated $[Ca^{2+}]_i$. Further work is still required to determine whether or not elevated $[Ca^{2+}]_i$ is the actual cause of death in the vulnerable cells.

7.6 LONG-TERM CHRONIC ELECTRICAL STIMULATION OF SPINAL CORD AND MOTONEURON SURVIVAL IN THE CHICK EMBRYO. (Spon: J.F.Toole) D.Prevette*, C.Fournier-LeRay*, G.Le Douarin*, R.Oppenheim and D. Renaud*. Dept. of Anatomy, Wake Forest Univ. Med. Sch., Winston-Salem, NC 27103 and Group de Physiologie cellulaire, Faculty Sci., Nantes-Cedex, France F-44072.

Previous studies have indicated that the survival of limb-innervating motoneurons (MNs) during periods of normally occurring cell death (E6-E15) is influenced by neuromuscular activity. Blockade of neuromuscular function by a variety of pre- and post-synaptic acting pharmacological agents or neurotoxins during the cell death period increases MN survival whereas short-term (< 24 hrs) direct electrical stimulation of the hind-limb musculature in ovo anytime between E6 and E8-9 significantly decreases MN survival. In the present study, we now extend this work and examine the effects of longer periods of chronic electrical stimulation of spinal cord on MN survival.

Chick embryos were prepared for in ovo spinal cord stimulation on E7 according to the methods of Renaud, D., et al., (Exp. Neurol., 60:189, 1978) in which two 60 μm silver wires are inserted around the still cartilagenous rudiment of the vertebral column rostral and caudal to either the brachial or lumbar enlargement. Continuous spinal cord stimulation was delivered by a constant current stimulator (5 ms, 0.5 H_z). Efficacy of the stimulation was verified daily by observing that limb movements were induced by each electrical pulse. Control embryos received electrode implants but no stimulation. Stimulation was begun either on E7 or E10 and embryos sacrificed on E10 or E14. Only embryos without grossly observable or histologically detectable abnormalities of spinal cord development were used for further morphometric examination. Spinal cords were processed histologically and cell counts carried out according to standard procedures.

Stimulation of either the brachial or lumbar spinal cord from E7-E10, E10-E14 or E7-E14 had little, if any, effect on the survival of brachial or lumbar MNs. For instance, following stimulation of the brachial region from E7-E14 MN numbers on E14 were 6,206 vs 6,737 for control embryos; and following stimulation of the lumbar region from E7-E10 MN numbers were 12,739 vs 13,181 for controls. Preliminary results also indicate that neither MN size nor the survival of three other populations of spinal cord neurons known to undergo normal cell death during these stages (dorsal root and sympathetic ganglia, and sympathetic preganglionic neurons) were affected by electrical stimulation of spinal cord. Experiments are planned to investigate the factors responsible for the apparent difference between spinal cord and direct muscle stimulation on MN survival.

7.7 DIRECT NEUROTOXIC EFFECTS OF COLCHICINE ON CHOLINERGIC NEURONS IN MEDIAL SEPTUM AND STRIATUM. G.M. Peterson, M.L. Stover*, and J.F. McGinty. Dept. Anatomy, East Carolina Univ. Sch. Med., Greenville, NC 27858.

Neurons in the medial septal nucleus die following transection of the fimbria-fornix and supracallosal stria through which they project to the hippocampal formation. It has been suggested that the septal cell death is due to interruption of retrograde transport of a neurotrophic factor (NTF) which is necessary to maintain viability of neurons in the medial septum. Indeed, several groups have reported that nerve growth factor preserves the viability of medial septal neurons after fimbria-fornix transections. Walsh and Schmechel (personal communication) have observed that colchicine-induced destruction of granule cells in the dentate gyrus (the target neurons of septohippocampal afferents) leads to neuronal death of up to 40% of the cholinergic neurons in the medial septum. Such an indirect, or retrograde degeneration would be predicted if the granule cells are a source of NTF for the septohippocampal neurons. We have investigated the direct neurotoxic effects of colchicine on the medial septal neurons. Ten adult Sprague-Dawley rats were implanted with chronic cannulae in the right lateral ventricle and injected 5-7 days later with colchicine (10 ug in 2.5 ul saline) or an equal volume of saline. Eight days later the rats were perfused with a 4% paraformaldehyde-picric acid solution and the brains were removed. Frozen sections of the brain were cut through the septal region and the hippocampus. Cholinergic neurons were identified immunocytochemically. Sections were incubated in antisera to choline acetyltransferase (Boehringer-Mannheim) at a dilution of 1:2000 for 3 days followed by the avidin-biotin immunoperoxidase method. Sections through the hippocampus were stained for acetylcholinesterase. Adjacent sections were Nissl stained. Of the six rats which received infusions of colchicine, 5 showed an almost total loss of cholinergic neurons ipsilateral to the injection. Furthermore, lateral to the injection site, there was a gradient of cholinergic cell death in the striatum. The cell loss in medial septum was barely detectable in the Nissl-stained sections, that is, the colchicine did not affect all septal neurons. We conclude from these observations that colchicine injections into the lateral ventricle in the immediate vicinity of the medial septal neurons produce a direct neurotoxic effect on the cholinergic neurons in both the medial septum and in the adjacent striatum. Supported by N.C. United Way grant # 5-80272 (GMP) and DA 03982 (JFM).

7.8 DELAYED NEURONAL NECROSIS IN NEONATAL HYPOXIA-ISCHEMIA. W.F. Massarweh*, H.V. Vinters*, P.H. Schwartz, B.E. Dwyer*, D.G. Fujikawa, and C.G. Wasterlain*. (SPON: A. MORIN). Epilepsy Res. Lab., VAMC, Sepulveda, CA, 91343, Depts. of Neurology, Pathology and Neuroscience, UCLA Sch. of Med., Los Angeles, CA 90024.

Following ischemic insults in adult animals, neuronal necrosis is often delayed by 24-72 hr, and it has been suggested that this delayed cell death is calcium-dependent. We recently reported that the inner layers of the dentate gyrus (DG) are selectively vulnerable to hypoxia-ischemia in 7-day old rats (Neurology, 37, Suppl. 1:88, 1987). Using the same model we now report that the histological appearance of neuronal necrosis is delayed by 24-72 hr in dentate granule cells but not in CA1 pyramidal cells of the hippocampus.

Twenty-three 7-day old rat pups underwent bilateral carotid ligation followed by exposure to an atmosphere of 8% O_2, 92% N_2 for 60 min. They were perfusion-fixed at the end of hypoxic exposure (time 0) or 4, 24 or 72 hr later. Serial sections (8 u) were stained with hematoxylin-eosin. Total number of necrotic neurons and total neuronal numbers in dorsal hippocampus were counted in one section per animal. In DG, where all necrotic neurons were located in the internal granular layer, the number of cells showing ischemic changes evolved from 1 per section (0 hr, 4 hr) to 30 (24 hr, over 95% from one rat) and finally 104 $\pm$ 31 (72 hr). CA3 neurons followed a similar progression (2-2-8-51) but CA1 pyramids and subiculum displayed ischemic cell change much earlier (CA1: 3-15-16-15; subiculum: 0-54-32-14 at 0-4-24-72 hr respectively). In cortex, at time 0 there were a few ischemic neurons scattered through layers 3 and 4, with vacuolation and ballooning. At 4 hr, numerous "halo" cells with condensed nuclei surrounded by pale, dilated cytoplasm were often seen in aggregate. At 24 hr, these were replaced by aggregates of ischemic neurons with fragmented nuclear material. At 72 hr, frank infarcts were present in most animals. Similar evolution of the ischemic insult was observed in basal ganglia and thalamus (VPL and reticular nucleus).

These data indicate that delayed cell death following hypoxic-ischemic insults is seen in neonates as well as in the adult. The predominance of this insult in the most immature cells of the DG suggests that some protective factor may appear during cell differentiation and confer resistance to hypoxia-ischemia. In other brain regions, the evolution from selective neuronal necrosis toward full infarction appeared as a continuum rather than independent processes.

7.9 PRESERVATION OF GABAERGIC INNERVATION IN THE GERBIL HIPPOCAMPUS EXHIBITING ISCHEMIA-INDUCED DELAYED NEURONAL DEATH. C. Nitsch*, G. Goping* and I. Klatzo Anatomy Dept., Munich University, D-8000 München, FRG and Lab. Neuropathology, NIH, NINCDS, Bethesda, MD.

In gerbils, 5 min occlusion of carotid artery results after a delay of 4 days in selective loss of hippocampal pyramidal cells of the field CA1. This so-called delayed neuronal death was postulated to be caused either by excessive excitatory synaptic activity or by a loss of inhibitory input. The major source of inhibition in hippocampus is derived from the local basket cells and the polymorphic neurons of the field CA4 which use GABA as transmitter. In an attempt to examine whether or not the GABAergic innervation in the hippocampus remains intact, vibratome sections of hippocampus were collected from gerbils submitted to 5 min ischemia and perfusion fixed 6 h, and 1, 2, 4, 6, and 14 days after the insult. Presence of GABAergic neurons and nerve endings was visualized immunocytochemically using an antiserum directed against the GABA-sythetizing enzyme GAD (courtesy of W. H. Oertel). The sections were further processed for light and electron microscopical analysis.

No change in the structure or innervation pattern of GABAergic elements was found 6 h, and 1 and 2 days after the ischemic event. After 4 days, the non-immunoreactive CA1 pyramids were severely shrunken, but the perikarya were still covered by GAD-immunoreactive boutons. After 6 days and even more impressive after 14 days, the CA1 pyramidal cells had virtually disappeared; GABAergic neurons and terminals, however, were still present and clearly delining the former stratum pyramidale. At the ultrastructural level, these terminals were seen to synapse with remnants of the degenerated neurons or with preserved GABAergic neurons, but most frequently, apposing membrane specializations were absent.

The present findings reveal that neither the GABA-synthetizing capacity nor the GABAergic innervation pattern is impaired by the ischemic episode. Thus, it may be suggested that delayed neuronal death is probably not caused by a loss of GABA-mediated inhibition.

7.10 EARLY POLYAMINE TREATMENT CAN ENHANCE SURVIVAL OF SYMPATHETIC NEURONS DURING DEVELOPMENT AND AFTER INJURY. V.H. Gilad,* M. Dornay* and G.M. Gilad.
The Center for Neuroscience and Behavioral Research, The Weizmann Institute of Science, Rehovot, Israel.

It was previously demonstrated that following injury of their axon sympathetic neurons of the rat superior cervical ganglion become dependent on polyamine (PA) synthesis for their survival. This is probably the basis for their enhanced regeneration after PA treatment. In addition treatment of newborn rats with biogenic polyamines can prevent the naturally occurring death of these neurons. In the present study, we sought to determine the effect of early PA treatment on the survival of developing sympathetic neurons after injuries. Groups of newborn rats were subjected to postganglionic nerve crush (axotomy) or to treatment with antiserum to nerve growth factor (NGF) (immunosympathectomy), two treatments which result in a massive loss of neurons in the ganglion. Another group was castrated at birth, a treatment which results in nerve cell loss to below normal levels. Daily injections of a PA combination (putrescine, spermidine and spermine, 10 mg/kg each), for 7 days after axotomy and for 9 days starting with the first NGF antiserum injection, attenuated the nerve cell loss. In castrated rats PA treatment, for the first 9d after birth, not only prevented the castration-induced cell loss, but resulted in increased cell numbers as was previously observed in intact PA-treated animals. These results further indicate that polyamines are important for the survival of sympathetic neurons and, while their mechanism of action is unknown, an indirect effect on the neurons via the testes or interaction with testosterone can be ruled out, but an interaction with NGF cannot be excluded. The increase in neuron numbers within the ganglion after PA treatment was not accompanied by changes in their axon terminals in one of their target organs, the iris. Furthermore, the reduction observed in the iris in [^{3}H]-norepinephrine uptake, a functional marker of innervation, after axotomy or immunosympathectomy was unproportionally small when compared to the large drop in the number of parent neurons. These results suggest that compensatory mechanisms exist which act to adjust the number of functional axon terminals per neuron so that the number of terminals innervating the target remains relatively constant.

7.11 **NON-NEURONAL CELLS PARTICIPATE IN REGULATING LOCAL CEREBRAL PERFUSION AFTER NEURONAL DEATH BY EXCITOTOXINS.**
C. Iadecola, S.P. Arneric, M.D. Underwood, H.D. Baker, J. Callaway and D.J. Reis,*
Div. of Neurobiology, Cornell Univ. Med. Coll., New York, N.Y. 10021

In brain, a major factor regulating local cerebral blood flow (lCBF) is local neuronal activity. However, we have recently discovered that, in rat, 5 days after selective elimination of local neurons in a restricted region of the primary sensory-motor cortex (SMI) by local microinjections of the excitotoxin ibotenic acid (IBO), local cerebral blood flow within the lesion, is unchanged. (Iadecola et al., Am. J. Physiol, 1987 in press). In this study we sought to determine whether the maintenance of lCBF after neuronal death correlates with the appearance of non-neuronal cells within the lesion and/or local changes in microvascular density. Rats were anesthetized (halothane 1-2%), IBO (10μg in 1 μl) was locally microinjected in SMI, and animals were allowed to recover. Three, 5, 7, 11, and 30 days later lCBF was measured autoradiographically under chloralose anesthesia (40 mg/kg, s.c.) by the ^{14}C-idoantipyrine technique. Cellular density was determined on Nissl-stained sections by using a microscope equipped with an ocular grid (140x140μm) and microvascular area (MVA) was measured by computer-assisted image analysis on sections processed for the endothelial marker alkaline phosphatase. Reactive astrocytes and macrophages were identified, respectively, by glial fibrillary acidic protein (GFAP) immunocytochemistry and acid phosphatase histochemistry. By 24 H after IBO, no neurons were detected within the area of the lesion. From 3 to 11d after IBO, lCBF within the lesion did not differ from that of the homotopic cortical area of sham lesioned controls (lesion at 3d: 120±23 mlx100g/min, n=4; control: 119±6, n=5; p>0.05, analysis of variance). However at 15d (n=5) lCBF was reduced by 22±6% and 30d (n=5) by 48±6% (p<0.05). After IBO, the number of cells increased dramatically reaching a plateau at 7-11d (17.5 fold increase at 11d; p<0.01) declining to a 11.7 fold increase at day 30 (p<0.01). The cells were mostly macrophages, endothelial cells and, at the periphery of the lesion, GFAP reactive astrocytes. MVA increased from 3d up to 4.2 fold at 11d (p<0.01), and then declined to 2.7 fold increase at 30d (p<0.01). To determine whether the microvessels were patent, the red blood cells (RBC) within the microvasculature of the area of the lesion were detected by endogenous peroxidase histochemistry and the RBC area (RBCA) determined by image analysis. In contrast to MVA, RBCA did not increase until after 7d, reaching a 3.2 fold increase at 11d. In summary, after neuronal death, lCBF is maintained in normal range during the period in which cellular and microvascular density increases. However, the increased vascular density does not participate to maintain lCBF since the, presumably newly-formed, vessels become patent at the time when lCBF begins to decline. The findings suggest that after neuronal death, non-neuronal cells, most likely activated macrophages, participate in the regulation of local cerebral perfusion, possibly, by releasing vasoactive substances and/or by-products of their metabolism.

7.12 NEUROPATHOLOGY IN ALZHEIMER'S AND DOWN'S DISEASES: THE LOCUS COERULEUS. V.M.Ingram, Z.Aslamy*, S.Jhaveri*, C.H.Miller*, H.M.Moore*, B.J.Blanchard* and D.F.Parry*, Department of Biology, Massachusetts Institute of Technology, Cambridge, MA 02139.

The noradrenergic neurons of the locus coeruleus [LC] suffer massive degeneration in the early-onset type of Alzheimer's disease [AD] and in Down's syndrome [DS], accounting perhaps for the losses in arousal and attention in these conditions. The degeneration of the LC and its subdivisions are best investigated quantitatively by computer-assisted 3-dimensional reconstructions.

Autopsy material [brain stem] was cross-sectioned sequentially, and neurons of the locus coeruleus were easily visualized by immunocytochemistry with a polyclonal antibody to tyrosine hydroxylase, the regulating enzyme in the biosynthesis of noradrenaline. The X-Y coordinates for every tenth or every thirtieth section were entered with a microcomputer into the Bioquant three-dimensional reconstruction program. Rotation of the assembly of neurons allowed us to perform quantitative analysis and quantitative comparisons between specimens.

We have to date analyzed the LC from 5 normal [27-85 yrs], 4 AD [66-82 yrs] and 4 DS brainstems [37-64 yrs]. We find degeneration of the posterior, central and anterior locus coeruleus ranging between specimens from mild to extremely extensive. Two early onset AD specimens show extreme degeneration, while a much older AD shows mild degeneration [?late onset AD]. Two DS brainstems [37,57 yrs] have LCs that are largely intact, but two other DS brainstems [48,64 yrs] are extensively degenerated in their LC. Contrary to expectation there is no correlation between age and degree of degeneration of the LC nuclei in these 4 DS specimens.

We find complete or relative sparing of the ventral LC which connects to the spinal cord and cerebellum [reported also by Marcyniuk et al. (1986) J Neurological Sci 76:335]. Interestingly, the trigeminal motor nucleus which is adjacent to the caudal part of the LC shows no loss of neurons at all in either the AD or the DS specimens. Thus there appears to be considerable selectivity in the degeneration of the LC in Alzheimer's and Down's diseases, at least in these specimens.

In our present normal LC reconstructions we see a considerable excess of LC neurons in the right caudal part of the LC[central] over the left.

CONTROL OF POSTURE AND MOVEMENT I

8.1 AFFERENT FEEDBACK IN POSITION CONTROL OF THE HUMAN MANDIBLE IN VARIOUS LOAD CONDITIONS. F.Bosman* and C.J.Erkelens* (SPON: A.B.A. Kroese) Dept. of Oral Pathophysiology, Univ. of Utrecht, Sorbonnelaan 16, 3584 CA Utrecht, The Netherlands

Apart from vital functions as chewing, swallowing, speaking, etc. the mandibular motor system is also dealing with maintaining an adequate mandibular position in various positions of the head or during movements of the head. Inherent mechanical properties of jaw muscle and other tissues involved as well as afferent feedback from several receptor groups play a role in mandibular motor control. Due to the complexity of the system special experiments and simulation studies are required to obtain more insight in the relative contribution of both factors. In the present study results from both approaches are compared for force-displacement relations of the human mandible.

In the experiments subjects were resisting a background load on the mandible while maintaining a requested jaw position. After the subjects were asked not to react a new stationary state was reached as result of a sudden change of load. Force, position and surface EMG of elevator and depressor muscles were recorded. The collection of states associated with several load changes makes up a force-displacement curve.

In the computer simulations the group of elevator muscles and the group of depressor muscles were each represented by a muscle model and the mandible by a mass. The muscle models contain a contractile element, a series elastic element, a parallel elastic element and a viscous element. The elastic elements have exponential characteristics. Two types of feedback have been incorporated in this model. The first type showing similar properties as muscle spindles has an excitatory influence on the elevator muscles. The second type has features of periodontal receptors and supplies positive feedback to jaw opening muscles and negative feedback to jaw closing muscles. The basic values of the parameters of the model have been derived from in vivo measured closing movements as a result of external force while feedback from periodontal receptors was excluded by local anaesthesia.

The experimental force displacement curves appeared to depend on the starting conditions (background load and jaw position). The slope of the curves near their starting positions depended on the preload but not on the initial jaw position. Considerable changes of EMG activity in closing and opening muscles were observed after a change in load with latencies between 10 and 40 ms. Moreover the curves for the jaw are not invariant in contrast to torque-angle relations of the arm.

The force displacement curves could be predicted well by the computer simulation. Comparison of the results from both studies revealed that feedback from muscle spindles and periodontal receptors is involved in mandibular motor control.

8.2 CONTROL OF ELEVATOR MUSCLE ACTIVITY DURING CHEWING IN MAN. H.W.van der Glas, L.W.Olthoff*, A.van der Bilt* and F.Bosman*. Lab. of Oral Pathophysiology, Univ. of Utrecht, Sorbonnelaan 16, 3584 CA Utrecht, The Netherlands.

The low level of rhythmic muscle activity for moving the jaw during chewing is probably generated by a central pattern generator (CPG). The additional elevator muscle activity required to overcome the resistance of the food may either be preprogrammed, i.e. intentionally or by a CPG, or may be induced and terminated by peripheral stimuli. In order to investigate the origin of this additional muscle activity, the relationship between events in recordings of the mandibular position and EMG activity was examined.

Silicone-rubber and chewing gum were used as standardized artificial testfoods in 7 subjects. Using bipolar surface electrodes, EMG was recorded from the masseter and anterior temporal muscles on both sides. The mandibular position was recorded with a Selspot system. In full-wave rectified and smoothed EMG, a computer program determined the onset, maximum and offset of the muscle activity. The moment of jaw-closing and opening, the first engagement of the food and the first tooth contact were detected in the jaw position signal and its derivatives (velocity and acceleration). Rank correlations (Kendall) were calculated between variables that made a link between events in the jaw position and the EMG recordings. In order to examine whether events in previous chewing cycles influenced the control of muscle activity in the actual cycles, the rank correlations were calculated between variables in actual as well as subsequent cycles.

The control of elevator muscle activity was based upon information about the height of the food bolus, gained in actual rather than previous chewing cycles. Part of the additional muscle activity in the various cycles preceded the first engagement of the food, suggesting a preprogrammed induction. However, since variables related to the first engagement of the food and the onset of those muscle activities following this engagement co-varied most significantly, these later muscle activities were predominantly peripherally induced by the food engagement as a mechanical stimulus. The first tooth contact following breakage of the food was a main factor in initiating the offset of all muscle activity.

8.3 HUMAN JAW MOVEMENT KINEMATICS IN MASTICATION AND SPEECH. D.J. Ostry and J.R. Flanagan (SPON: F. Wilkinson). McGill University, Montreal H3A 1B1 Canada

A central problem in motor control is the relationship between voluntary movements, such as reaching, grasping and talking, and more primitive motor functions, such as locomotion or mastication. We have addressed this problem in the present paper by examining the movements of the mandible, a single multi-function articulator, which, in humans, supports both mastication and speech. The study focuses on the geometric form of the velocity curve of movements as this has been shown to be invariant under transformation of rate, movement amplitude and inertial load in a variety of different tasks and species. As reported previously, movement amplitudes and durations were found to be greater in mastication than in speech. Nevertheless, detailed similarities were observed in the form of the normalized velocity curves. For jaw closing movements, the normalized curves were similar in form over differences in rate, movement amplitude (speech movements) and the compliance of the bolus (mastication). For opening movements, the curves for mastication and speech were also similar in form. In both, the shape of the curve differed for fast and slow movements. Normalized acceleration and deceleration durations were approximately equal in rapid movements, whereas, for slower movements, deceleration took substantially more time than acceleration. The similarity of the normalized velocity curves points to underlying similarities in aspects of the control of mastication and speech. The biomechanics of the mandible, the role of central function generation, and the possible similarity of neural control regimes are considered in this context.

8.4 STUTTERING: IS IT AN INSTABILITY IN THE COMPLEX SPEECH MOTOR CONTROL SYSTEM? H.B. Nudelman, K.E. Herbrich‡ B.D. Hoyt*and D.B. Rosenfield* Stuttering Cntr. Dept. Neurol., Baylor Col. Med. Houston, Tx 77030.

Speech production is a complex motor control problem. We model the complexity of this motor system by representing it as two nested control loops. The inner loop is the sound production loop and the outer linguistic loop uses this inner loop for the production of phones, words and sentences. We propose that a stuttered event is a momentary instability in this system.

We effectively open the outer loop and quantify the dynamics of the inner loop by using a vocal frequency tracking paradigm that has no linguistic content. Computer generated frequency modulated tones are played for the subject and he is asked to hum and track the frequency modulations. As in other motor tracking systems two types of behavior are observed: i) predictable tracking to periodic inputs, and ii) normal reaction time behaviors to non periodic inputs. Here we will deal only with the predictable data since we feel it is more analogous to speech where the subject knows what he is going to say. Model predictions, using the gain and phase parameters measured from sine wave frequency modulations, are made for square wave frequency modulations. The predictability of the model indicates that the parameters are valid descriptors of the predictable tracking system. Analysis of these parameters shows that stutterers have a larger phase lag at two Hz (frequency modulations near normal running speech) than do fluent speakers.

If the total phase lag equals 180 degrees at a frequency where the gain is greater than or equal to 1, the system will go unstable. This suggests that if the outer loop adds enough phase lag during linguistic processing the total system will go unstable. For instance, a time delay in the outer loop would add phase lag and could drive the system unstable. At two Hz a time delay of 250 ms equals 180 degrees. The data indicate that fluent speakers have on the average 247 ms processing time in the outer loop while stutterers have only 160 ms. This data indicates why the therapies that use forms of slowed speech work. At a frequency of 1 Hz a stutterer now has 500 ms for processing before an instability occurs.

Repeated measures indicate that while a person operates around an average gain and phase these parameters can show large variations. Stutterers tend to have larger variations than do fluent speakers.

8.5 CEREBRAL ACTIVITY ASSOCIATED WITH VOCALIZATION D.H. York and S.C. Dulebohn*, Department of Physiology, School of Medicine, University of Missouri, Columbia, MO 65212

Previous studies, in man have defined specific patterns of cerebral activity which occurs preceding movement of a limb. The present study was undertaken to evaluate whether specific patterns of scalp-recorded cerebral activity could be obtained preceding vocalization.

Subjects were normal volunteers ranging from 22 - 40 years of age. The subject was seated in a semi-reclined position with recordings obtained from the vertex (Cz) referenced to left ear lobe (A1), and a ground placed on the opposite ear lobe (A2). Recordings were obtained with a high gain amplifier, with filter band pass set at 3 - 1000 Hz. The analog signal was sampled at 5000 Hz with data acquisition and analysis performed on an IBM-XT microcomputer. Single trials of EEG recorded 500 msec preceding vocalization and 100 msec following vocalization were averaged after 50 repetitions of a particular word. Multiple trial blocks were combined to form grand averages of several humdred trials. A voice activated trigger established a reference from which cerebral activity was time locked to voice onset.

Consistent patterns of cerebral activity were obtained preceding vocalization of particular words across different subjects. Different words had unique patterns of activity which were specific for a particular utterance. A peak identification algorithm defining number of slope changes in a 10 msec window was used to create histograms of activity. In specific time domains which preceded vocalization, consistent patterns were observed in subjects voicing the same word, but different patterns were seen with different words. A moving window cross correlation analysis demonstrated that these patterns were highly significant ($r = 0.9$) at specific time domains for comparisons of the same word, but not significant when compared across different words or a control of randomly averaged EEG.

This study has demonstrated that consistent scalp recorded cerebral activity patterns can be obtained preceding vocalization of particular words. The patterns are unique for each word and contain specific areas of high temporal correlation.

8.6 FUSIMOTOR SET: MUSCLE SPINDLE SENSITIVITY INCREASES IN NOVEL AND DIFFICULT MOVEMENTS. A.Prochazka, P.Trend*, M.Hulliger* & N.Durmuller*. Depts. of Physiology, Univ. of Alberta, Edmonton, Alta., Canada & St. Thomas's Hospital, London, U.K.; Brain Res. Inst., Zurich, Switzerland.

Chronic recordings from spindle afferents have indicated that CNS control of spindle responsiveness is highly flexible and task-related. In routine tasks such as gait, fusimotor (γ) action was hypothesised to be set to low levels, largely γ_s in type. In novel, difficult or strenuous movements γ_d "wind-up" was implicated (Prochazka et al., Brain Res., 339:136, 1986).

We have now recorded spindle firing in cats performing a range of tasks: stepping at different speeds, walking on beams and ladders of different widths and stabilities, accidental slips and paw shaking. The underlying fusimotor action was inferred in separate experiments: a length servo cyclically replicated the chronically recorded muscle length changes in soleus muscles of anesthetized cats. The responses of spindle endings in these muscles were made to match the chronic spindle firing by concomitant, computer-controlled γ_s and γ_d stimulation. Matches were optimized by iteration.

The results confirmed that fusimotor action is set to negligible or very low levels at rest, and winds up to low, static-dominated levels in slow gait. In fast locomotion, further γ_s wind-up occurs along with some modulated γ_d action. In imposed movements, paw shakes, difficult beam walking and accidental slips, γ_d set can increase greatly, not necessarily in parallel with γ_s set.

The neural substrate of "motor set" (Evarts et al., Neurophysiological Approaches to Higher Brain Functions, N.Y.: Wiley, 1984) may thus be extended to include the fusimotor system and, by implication, other sets of spinal and brainstem neurons. Strong fusimotor wind-up of spindle Ia afferent sensitivity is evidently held in reserve for novel, difficult, or strenuous movements.

8.7 INHIBITION OF SALICYLATE-INDUCED VOMITING IN SQUIRREL MONKEYS BY HEAD FIXATION. C. R. Wilpizeski and L. D. Lowry *. Dept. of Otolaryngology, Jefferson Med. Col. of Thomas Jefferson Univ., Philadelphia, PA 19107.

We found previously that motion-induced vomiting can be inhibited in Bolivian-phenotype squirrel monkeys by firmly fixing the head to a rigid frame during 30-rpm horizontal rotation. It is the opinion of aerospace physiologists that restricting head movement is a means for preventing air and space sickness by reducing sensory input. This investigation was conducted in order to determine whether or not head fixation is effective for inhibiting vomiting of nonmotion origin.

During surgical anesthesia, 10 adult squirrel monkeys were fitted with machine screws attached, head down, to the skull with acrylic cement. After recovery from surgery, each was injected IP with 250 mg/kg body weight of sodium salicylate mixed with sterile water. Dose volumes ranged from 0.75 to 1 ml. Half of the sample was observed while nonrestrained in a transparent plastic test chamber for 2 hr after injection. The other half was restrained by bolting the head to the frame for 1 hr beginning at the time of injection and released for the second hr. After 1 week, the experiment was repeated with reversed restraint conditions. The original mobile subsample received a second injection with head fixed, whereas the subsample with head fixed during the first hr received the repeat injection while nonrestrained. One subject did not vomit during either phase of the experiment and was eliminated from statistical analysis.

Results showed that head fixation significantly increased vomiting latency and significantly decreased emesis frequency. The midpoint of the distributions of vomiting latencies was increased sixfold by head fixation. Some subjects who did not vomit during the 1-hr fixation did so soon after release from the restraining frame. We conclude that head fixation is not specific to preventing or retarding motion-induced vomiting but seems to be a more general phenomenon. Therefore, its effectiveness for inhibiting motion sickness may be more than simply a consequence of reduced sensory input caused by cupular mechanics.

8.8 INDEPENDENT SPECIFICATION OF RESPONSE FEATURES IN A REACTION TIME PARADIGM. M. Favilla*, W.Hening & C.Ghez, Ctr. for Neurobiol & Behav, Columbia Univ and NYS Psych Inst, New York, NY, 10032.

We previously demonstrated that, when aiming rapid isometric responses to a target, subjects can specify amplitude independently of direction (Favilla et al, Neurosci Abstr 1985). This was shown using a novel paradigm in which subjects synchronized their responses to a predictable auditory signal (the last of a series of 4 tones); the required amplitude and direction were signalled by a visual target presented at random intervals (0-400ms) before the last tone. Subjects were to produce single uncorrected force impulses which matched one of six randomized target shifts (3 flexions, 3 extensions). Responses initiated at the shortest S-R intervals were clustered around the middle targets in flexion and extension with about half in the wrong direction. Starting from these two default values, subjects progressively specified the amplitude of responses made both in the correct and the incorrect direction, while the number of wrong direction responses also decreased gradually. The time course of the specification of amplitude was not different from that observed when targets in only one direction were presented. Thus, specification of amplitude did not take longer when direction also had to be specified. These findings conflict with earlier data suggesting that in a reaction time task the processes of specification of different features of motor responses occur serially.

The present study was done to determine if independent specification of responses features could also occur in a reaction time paradigm. In the same subjects (N=5) as our earlier study, we examined the latencies and trajectories of isometric force impulses aimed to unpredictable visual targets under two conditions. In one (Unidirectional condition), subjects were presented with 3 flexion targets, while in the second (Bidirectional condition), subjects were presented with 3 flexion and 3 extension targets. Subjects were urged to respond "as soon as possible" and not to correct responses if either amplitude or direction seemed wrong. In both conditions response amplitudes varied with target size but their range was constricted. In the bidirectional condition, 4 subjects made between 9 and 36% of their responses in the wrong direction. Responses made in the wrong direction by 2 of these subjects showed highly significant specification of amplitude ($p<.01$). When comparing uni- and bidirectional conditions, we found that reaction times were similar and the degree of amplitude specification was the same in 4 subjects . The other subject was the one who did not produce wrong directional responses. This subject did show longer reaction times in the bidirectional condition, but response amplitude was better specified. These results further support the idea that response amplitude and direction are specified by independent neural processing channels.

8.9 **ADAPTIVE VISUAL-MOTOR MODEL FOR RECOGNIZING OBJECT ORIENTATION IN 3-D.** M. Kuperstein, Biology Dept., Wellesley College, Wellesley, Ma., 02181

Studies by Held, Hein and others in the last two decades have shown that, in the kitten, visually guided behavior develops only when changes in visual stimulation are systematically related to self-produced movement. This work extends these studies by hypothesizing that object recognition emerges out of the correlation between object sensation and object manipulation. Within this hypothesis, recognition of object orientation in 3-D occurs when the intended grasping posture of a tilted object in 3-D space is represented and dissociated from all other 3-D orientation.

The general strategy for accomplishing this representation is the **sensory-motor neural circular reaction**. In this reaction, motor activity for the entire range of grasping postures of an object are generated one at a time by some activating source. During each posture the two eyes see the 2-D projection of the 3-D orientation of light contrast made by the grasped object. Visual map activity which is sensitive to contrast orientation, is then correlated with whatever motor map activity was used to grasp the object. The correlation occurs from the changes of synaptic weights between visual inputs and motor outputs. After the correlation is learned, any object that is seen can trigger the visual maps to activate the motor map for the intended grasping posture of that object, apart from other postures. It is the representation of the particular intended grasping posture for an object that becomes the perceptual recognition for that object.

There are three key aspects to the model: 1) A distributive, topographic architecture is used to combine the orientation sensitive visual activity from an object, from both eyes. This motor-target architecture is organized into columns with a global retinal topography. Each column contains representations from all arm muscles. 2) Local computations, that vary across the model's topography, are piece-wise linear. But convergence of all the local computations yields the global, nonlinear representation of 3-D orientation for any object. 3) Learning is achieved by incrementally modifying the distributions of all input weights to the target map over many performance trials. On any trial, only the weights of the active inputs in the trial are changed.

Computer simulations show that the model converges to good representations of object grasping postures. The model is shown to maintain accuracy and stability across many different parameter choices.

8.10 THE EFFECT OF SKIN DESENSITIZATION ON MOTOR UNIT RECRUITMENT AND FIRING RATES. C.J. De Luca, Y. Noda* and I. Matsuzawa*. NeuroMuscular Research Center, Boston University, Boston, MA 02215 USA.

Previous studies from our laboratory showed that skin desensitization increased the amplitude of the H-reflex and modulated the recruitment threshold of motor units. Hence, a study was conducted to investigate the modulating effect of skin afferents on the firing rate of motor units.

The skin over the hand and wrist was desensitized by application of 10% Xylocain. Myoelectric signals were detected from the First Dorsal Interosseus muscle using the selective quadrifilar needle electrode while the subjects generated a isometric force reaching 50% of their maximal voluntary contraction (MVC). The signals were decomposed into their constituent motor unit action potentials using a proven accurate signal Decomposition technique described elsewhere. The experiment was repeated with fixed needle position before, and 15, 30, 45 and 60 minutes after the application of topical anesthesia. The force threshold of progressively recruited motor units and their average firing rates during a plateau of 50% MVC were determined and compared among subsequent contractions.

The results showed that the force threshold of motor units recruited below 20% MVC increased, while their average firing rates (which are among the largest in value) decreased. On the contrary, the force threshold level of motor units recruited above 25% MVC decreased while their average firing rates (which are among the lowest in value) increased. In other words, the dynamic ranges of recruitment thresholds and firing rates became narrower after skin desensitization. Control studies (without application of anesthesia) revealed no significant change of the recruitment threshold or the average firing rates.

The complimentary behavior of the recruitment threshold and average firing rate indicates that the earlier recruited (< 20% MVC) motor units have a diminished net excitation, whereas the latter recruited (> 25% MVC) have an increased net excitation when the skin afferents are desensitized. This interconnected compensatory relationship between recruitment threshold and average firing rate provides one possible explanation for the relatively low firing rate found in higher threshold motor units, which according to the common drive theory receive a lower net excitation.

8.11 COMMON DRIVE BEHAVIOR OF FIRST DORSAL INTEROSSEOUS MOTOR UNITS. Sandra Solar,* D. Stashuk,* C. J. De Luca (SPON: S. Roy). NeuroMuscular Research Center, Boston University, Boston, MA 02215

The common 1-2 Hz fluctuations of mean firing rates of active motor units during isometric contractions has been termed "Common Drive". In previous studies, significant cross correlation values were found to exist between firing rates of motor units within muscles such as the Deltoid, Tibialis Anterior, Extensor Pollicis Longus (EPL), Flexor Pollicis Longus (EPL), Extensor Carpi Ulnaris (ECU), Extensor Carpi Radialis Longus (ECRL) and First Dorsal Interosseous (FDI). Significant cross correlation values were obtained for motor unit pairs selected across the EPL and FPL muscles during either antagonistic or synergistic activation. Furthermore, in studies during synergistic contractions of ECU and ECRL muscles, common fluctuations in mean firing rates between motor units of the two muscles were also observed, but with a significant time shift of the peak cross correlation values. This time shift suggested the existence of a mechanical (proprioceptive) linkage between the muscles. Currently, we are conducting an investigation to determine whether the existence of common drive between muscles is related to a common functionality or to a mechanical linkage.

Myoelectric signals were detected from both FDI muscles of healthy subjects during two sets of experiments. One, functionally linked the subjects FDI muscles by attempting to simultaneously follow identical trapezoidal force trajectories. In the second, the subjects pressed their indices against each other producing a net zero force and mechanically and functionally linking the muscles. The myoelectric signals were recorded by quadrifilar needle electrodes and stored on FM tape. The signals were then digitized and the firing times of their constituent motor unit action potentials were obtained via a proven accurate decomposition algorithm. Mean firing rates of active motor units and their cross-correlations were then estimated.

Preliminary results of cross correlation values (.4 to .9) for motor units within each FDI have shown significant common drive. In addition, no common drive (.2 to .4) has been found between the motor units of right and left FDI's when functionally linked but some common drive (.3 to .6) has been found when they are functionally and mechanically linked. For the latter case the times of occurrence of the peak cross correlation values were found to lie between 0-100 ms. While these results are still preliminary, they seem to suggest that common drive has both a supraspinal as well as a peripheral (proprioceptive) component.

FEEDING AND DRINKING I

9.1 ATTEMPTS TO DEPRESS BRAIN SEROTONIN (5-HT) RELEASE DO NOT ENHANCE FEEDING INDUCED BY INJECTING NOREPINEPHRINE (NE) INTO THE PARAVENTRICULAR NUCLEUS (PVN). E. de Rooy* and D.V. Coscina. (SPON. P. Li). Sect. of Biopsychol., Clarke Institute of Psychiatry, and Depts. of Psychology and Psychiatry, University of Toronto.

Recent work suggests that NE and 5-HT interact on common systems in their control over feeding in the rat. The studies which led to this hypothesis showed that drug treatments which enhance brain 5-HT function block the feeding produced by NE in the PVN to a greater extent than that seen when 5-HT was enhanced alone. If this apparent interaction operates bidirectionally, then injecting NE into the PVN after 5-HT function has been suppressed might produce greater feeding than that seen after either treatment alone. To test that possibility, we measured the 40 minute feeding response of satiated adult male rats with unilateral cannulae aimed at the PVN after each of 4 treatments run in a counterbalanced design: (1) 40 nmoles NE in 0.5 ul injected into the PVN, (2) 250 ug/kg (+)-8-hydroxy-2-(di-n-propylamino)tetralin HBr (8-OH-DPAT) s.c., which is thought to inhibit endogenous 5-HT release by stimulating 5-HT-1A autoreceptors, (3) both treatments, or (4) no active treatment (i.e., isotonic saline; n = 19/condition). NE in the PVN alone or 8-OH-DPAT s.c. alone elicited significant feeding compared to only saline. However, the combination of treatments produced no more feeding than that seen after NE alone. In a second study, the same rats were tested for this PVN-NE feeding response over a 4 week period after half had received an intracisternal injection of the 5-HT neurotoxin, 5,7-dihydroxytryptamine (5,7-DHT; 200 ug in 20 ul 1% ascorbate following i.p. pretreatment with 25 mg/kg desipramine). Compared to vehicle-injected controls, NE produced a tendency toward enhanced feeding 2-3 wks after 5,7-DHT, but this trend was not sustained nor statistically significant. In a third study, satiated normal male rats were tested for their hourly feeding response for 6 consecutive hours after one of 4 treatments: (1) clonidine (30 ug/kg s.c.), (2) 8-OH-DPAT (250 ug/kg s.c.), (3) both treatments, or (4) neither treatment (i.e., isotonic saline; n = 8-9/condition). As previously reported, clonidine elicited reliable feeding compared to saline. However, neither 8-OH-DPAT alone nor in combination with clonidine enhanced feeding over saline. Since clonidine is believed to produce feeding by acting on alpha-2 adrenoceptors in the PVN, these data all imply that it may not be possible to enhance NE-induced feeding by impeding brain endogenous 5-HT release. Alternatively, the broad changes in 5-HT metabolism induced by systemic 8-OH-DPAT or 5,7-DHT may have masked effects of subnormal 5-HT release in the PVN to interact with NE on feeding. Further studies of NE/5-HT manipulations confined to the PVN are needed to address this possibility.

9.2 HYPOTHALAMIC SEROTONIN IN THE CONTROL OF EATING BEHAVIOR. S.F. Leibowitz, G.F. Weiss*, G. Shor-Posner*, U.A. Walsh* and D. Tempel*. The Rockefeller University, New York, N.Y. 10021.

Serotonin (5-HT) has long been known to have an inhibitory effect on food intake. Recent evidence points to central, as well as peripheral, mechanisms in the mediation of this phenomenon. However, essential information is lacking concerning specific brain site(s) involved, as well as specificity and physiological significance of 5-HT's central action. With the use of the brain cannula technique, electrolytic lesions and systemic drug injections, we have obtained evidence in the rat which argues strongly for a potent, behaviorally specific, and physiologically meaningful effect of 5-HT in the hypothalamus.

1) Injection of 5-HT directly into the paraventricular nucleus (PVN) reduces spontaneous, as well as deprivation-induced, feeding. 2) This effect of 5-HT, which is mimicked by PVN injection of compounds which release endogenous 5-HT, is behaviorally specific, as indicated by the finding that 5-HT reduces the size, but not the frequency, of meals taken. 3) Moreover, when animals are permitted to select their food from three simultaneously available macronutrient diets, PVN-injected 5-HT selectively reduces intake of carbohydrate, while sometimes actually enhancing protein intake. 4) This effect of 5-HT on macronutrient intake occurs at doses at least as low as 0.3 nmoles, in contrast to higher doses (> 5.0 nmoles) where the specificity of this effect is lost. 5) While PVN 5-HT reduces spontaneous food intake in both the early and late phases of the dark (active) cycle, it produces a stronger and more selective suppression of carbohydrate ingestion at the onset of the dark. At this time, rats exhibit a natural preference for carbohydrate, and as revealed with the microdialysis technique (B.G. Stanley, this meeting), a peak in PVN content of the 5-HT metabolite 5-HIAA also occurs. 6) Low doses of peripherally injected d-fenfluramine, through release of endogenous 5-HT, produces similar effects to PVN-injected 5-HT. This further supports a role for endogenous 5-HT in control of appetite for specific macronutrients. 7) This serotonergic control appears to be anatomically specific, as indicated by our evidence that electrolytic lesions in the PVN, as opposed to the perifornical lateral hypothalamus, strongly attenuate (by 60-80%) the suppressive effect of d-fenfluramine on feeding.

These results, along with additional findings showing potent effects of PVN electrolytic lesions on carbohydrate and protein ingestion, support the hypothesis that 5-HT innervation to the PVN is critical in coordinating appetite for specific macronutrients, and in mediating the influence of peripherally injected serotonergic drugs on patterns of eating behavior.

9.3 INHIBITION BY 5-HT-2 ANTAGONISTS OF THE ANOREXIC ACTIONS OF PERIPHERALLY ADMINISTERED 5-HYDROXYTRYPTAMINE (5-HT) AND 4-HT IN RATS. K. J. Simansky, B. I. Cohen* and K. Eberle. Dept. of Pharmacol., Med. Coll. of Pennsylvania, Philadelphia, PA 19129

This study examined the structure-activity relationship and the antagonist profile for the anorexic action of peripherally administered serotonin (5-HT) in rats. Male albino rats (350-450 g) were maintained individually with free access to water but with a sweetened milk diet available from 1100-1700 each day. The volume of milk consumed during the first 30 min access to the liquid diet served as the testing period for determining the effects of drugs on feeding. When injected i.p. 6 min before milk was provided, 5-HT (2.5-10 umol/kg) produced a dose-related inhibition of feeding with an ID-50 of 3.8 umol/kg. 4-HT (5, 10, 20, 28 and 40 umol/kg) reduced food intake (by 15-83%) less potently (ID-50=14.8 umol/kg) than 5-HT although the slopes for the anorexic actions of these two hydroxylated tryptamines were not different. By contrast, 7-HT (10-40 umol/kg) had no effect on food intake (e.g., VEH, 19.1 ± 2.4 ml, X ± SE; 40 umol/kg, 18.1 ± 1.6).

The anorexic action of 10 umol/kg 5-HT was antagonized by 60 min pretreatment (i.p.) with 10 umol/kg of xylamidine, methysergide, LY53857 and ketanserin, by 3.4 umol/kg of ritanserin and by 10 umol per kg of pipamperone. For example, meal sizes for the ketanserin experiment were: VEH/VEH, 15.4 ± 2.1 ml; VEH/5-HT, 2.6 ± 0.7 KET/VEH, 14.3 ± 2.3; KET/5-HT, 10.7 ± 1.7. Ketanserin (10 umol/kg) similarly antagonized the anorexic effect of 4-HT (40 umol/kg): VEH/VEH, 18.0 ± 2.7; VEH/4-HT, 1.1 ± 0.6; KET/VEH, 15.9 ± 3.2; KET/4-HT, 9.1 ± 2.6. In a separate experiment, xylamidine (10 umol/kg) reversed the anorexia produced by 4 umol/kg 5-HT and by 20 umol/kg 4-HT: V/V, 18.6 ± 1.4; X/V, 20.3 ± 1.3; V/5-HT, 10.4 ± 1.0; X/5-HT 17.7 ± 1.7; V/4-HT, 9.0 ± 1.3; X/4-HT, 15.3 ± 1.0 ml). The same dose of xylamidine did not, however, reduce the anorexic effect of epinephrine (1 umol/kg): V/E, 5.4 ± 1.4 (-81%); X/E, 4.8 ± 1.3.

Each of the antagonists used inhibit actions of serotonergic drugs at 5-HT-2 receptors. Further analysis revealed that these effects were dose-related and that doses as small as 0.3 umol/kg of xylamidine significantly reversed the action of 5-HT (e.g., VEH/5-HT, 1.3 ± 0.5; XYL/5-HT, 8.9 ± 1.9 ml). By contrast, however, doses as large as 10 umol/kg of the 5-HT-3 antagonist, ICS-205-930, or 20 umol/kg of the 5-HT-1a/1b:Beta receptor blocker, (±) pindolol failed to alter the anorexic action of 5-HT. In concert, these data demonstrate that peripherally acting hydroxylated tryptamines with 5-HT-2 agonist properties (i.e., 4-HT and 5-HT) exert anorexic effects via 5-HT-2-type mechanisms. These data complement results reported elsewhere at this meeting demonstrating that the selective 5-HT-2 agonist dimethoxy-iodophenylaminopropane produces anorexia (see Schechter and Simansky).

9.4 EVIDENCE FOR SEROTONERGIC MODULATION OF SHAM FEEDING IN THE GASTRIC-FISTULATED RAT. J.C. Neill* and S.J. Cooper. Department of Psychology, University of Birmingham, Birmingham B15 2TT, U.K.

Considerable evidence indicates that serotonergic mechanisms are involved in the control of eating responses. In general, drugs which increase serotonergic activity decrease food consumption (Blundell, J.E., Int. J. Obesity, 1: 15, 1977). Sham feeding in the gastric-fistulated rat provides an important model for investigations of factors involved in the maintenance of ingestion. Sham feeding animals exhibit a pronounced satiety deficit. Our present aim is to investigate serotonergic mechanisms in the control of sham feeding, with particular emphasis placed upon the identification of specific serotonin (5-HT) receptor subtype involvement.

Adult, male hooded rats were used (General strain, bred in our laboratory). Each was prepared with a chronic gastric fistula, and trained to consume a 5% sucrose over a 2h test period, according to previously-described procedures (Kirkham, T.C. and Cooper, S.J., Pharmac. Biochem. Behav., 26: 497, 1987). D-fenfluramine (which increases 5-HT activity), over the dose-range 1.0 - 10 mg/kg, i.p., produced a pronounced dose-dependent reduction in sham feeding. The ED50 (dose which produced 50% reduction in intake) was about 1.75 mg/kg. Interestingly, intact rats which had been trained to drink the sucrose solution, were less sensitive to d-fenfluramine's anorectic effect (ED50 > 3.0 mg/kg). The 5-HT receptor agonist, quipazine, also produced a dose-related reduction in sham feeding, and, again, nonfistulated animals were less sensitive. Thus, 3.0 mg/kg quipazine reduced sham feeding by over 40%, while sucrose consumption in nonfistulated animals was reduced by about 10%. Hence, an anorectic effect of 5-HT agonists appears to be enhanced in animals with a satiety deficit.

The selective 5-HT_{1A} receptor agonist, 8-hydroxy-2-(di-n-propylamino) tetralin (8-OH-DPAT) may act at 5-HT cell body autoreceptors when given in small doses, and so decreases serotonergic activity. In support of this hypothesis, we found that 0.1 mg/kg 8-OH-DPAT produced a small increase in sham feeding when injected alone (s.c.). Furthermore, the same dose markedly attenuated the anorectic effect of 3 mg/kg d-fenfluramine in sham feeding rats. These data support the view that 5-HT mechanisms are involved in the control of feeding, and we propose that they may play a part in the maintenance, as distinct from the satiation, of feeding.

(D-fenfluramine was kindly supplied by Institut de Recherches Internationales Servier).

9.5 THE SEROTONIN ANTAGONIST METERGOLINE BLOCKS THE ANORECTIC EFFECT OF CHOLECYSTOKININ. D. Stallone*, S. Nicolaïdis*, J. Gibbs . Laboratoire de Neurobiologie des Régulations, Collège de France, 75231 Paris cedex 05, France.

Serotonin (5HT) and cholecystokinin (CCK) have been separately implicated as factors influencing food intake. Administration of CCK and of drugs such as fenfluramine, which increase the release of 5HT, produce an anorexia characterized by a reduction in meal size and the behavioral responses associated with satiety. Evidence that 5HT and CCK are localized together in APUD cells and have some common physiological effects suggested that the mechanisms of the anorectic action of these two substances may be related. The present study examined the possibility that CCK-induced anorexia depends on serotonergic function.

Testing began after it was demonstrated that metergoline, the 5HT antagonist, significantly attenuated fenfluramine-induced anorexia under our test conditions. The food intake of 4-hour-fasted male rats injected intraperitoneally either with metergoline (1 mg/kg 3 hours before food presentation), with the C-terminal octapeptide of CCK (2, 4 or 8 µg/kg immediately before food presentation), with both metergoline and each dose of CCK-8, or with saline, was measured 30 minutes after refeeding.

CCK-8 alone produced a dose-related suppression of food intake (2 µg/kg, 36.5% decrease ($p \leq 0.05$); 4µ/kg, 63.4% decrease ($p \leq 0.01$); 8µ/kg, 79.7% decrease ($p \leq 0.001$)). When the administration of each dose of CCK-8 was preceded by metergoline injection the anorectic effect of CCK-8 was totally blocked. In addition, injection of metergoline alone produced a 52% increase in food intake ($p \leq 0.01$).

These results indicate that the anorectic action of CCK-8 is dependent upon intact function of serotonergic systems. The facts that metergoline (a) completely blocked the satiety action of every dose of exogenous CCK-8 and (b) increased baseline food intake when administered alone suggest that the increase of baseline food intake by metergoline alone is the result of a metergoline-induced blockade of endogenous CCK. Further studies should clarify the nature of the relationship between 5HT and CCK-8 (whether the serotonergic system is necessary and/or sufficient for the anorectic action of CCK-8) and the site(s) of their interaction.

9.6 5HT AND CA PRECURSOR LEVELS DURING PROTEIN SELECTION. E.L. Gibson*, D.J. Barber* and D.A. Booth. Department of Psychology, University of Birmingham, P.O. Box 363, Birmingham B15 2TT, U.K.

Genuinely protein-specific dietary self-selection requires recognition of both bodily cues to protein need and, at the same time, sensory cues to the protein content of a food (Booth, Appetite, 8: in press, 1987). Pharmacological manipulation of serotoninergic transmission that has been claimed to affect dietary selection has not been shown to play a role in protein selection when replicated on learned protein-specific appetite (Booth et al., Soc. Neurosci. 12: 593, 1986). Nevertheless, the protein need cue might be signalled over neurotransmitter specific pathways or even as changes in 5HT or CA activity induced by plasma amino acid patterns. To explore these possibilities, we compared rats in the protein need state which triggers the protein appetite with rats in which the development of the need had been prevented by protein infusion.

On the day of the experiment, adult male Sprague-Dawley rats were deprived of maintenance chow for the last 5 hours of the dark period and gavaged with a 2.5 ml solution at 2 hr, 30 min and 5 min before test: the solution was either non-nutritive (Sham), 10% maltodextrin (Starch) or 10% casein hydrolysate (Casein), 3 rats per condition. We have previously shown that, after learning, rats select protein-predictive dietary cues in this mildly deprived state when Sham and Starch preloaded on this schedule, but not when Casein preloaded (Baker et al., Nutr. Res., in press; Gibson & Booth, Experientia 42: 1003, 1986). Gut and plasma levels of the large neutral amino acids (LNAAs) were greater following Casein than following Starch (Table 1) or Sham (not shown). The ratio of plasma levels of each LNAA to those of the other five increased for the three branched-chain LNAAs (BCA) valine, leucine and isoleucine and decreased for the three monoamine transmitter precursors tyrosine (TYR), phenylalanine (PHE) and tryptophan (TRP) (Table 1). Similarly, brain levels of the precursor LNAAs decreased while those of the branched-chain LNAAs increased. There were no statistically significant differences between Starch and Sham. The results are consistent with other indications (Gietzen et al., Physiol. Behav. 36: 1071, 1986) of a role for noradrenaline more than 5HT in the learned control of protein consumption by protein need cues in the rat.

9.7 DIURNAL RHYTHM OF MEDIAL HYPOTHALAMIC SEROTONIN METABOLISM IN RELATION TO EATING BEHAVIOR. B.G. Stanley, D.H. Schwartz, L. Hernandez, S.F. Leibowitz and B.G. Hoebel. Dept. of Psychology, Princeton Univ., Princeton, NJ and The Rockefeller Univ., New York, NY.

Evidence suggests that a reciprocal relationship may exist between brain serotonin (5-HT) activity and feeding behavior, with increased medial hypothalamic 5-HT activity suppressing food intake and food ingestion increasing brain 5-HT synthesis. The present experiment addressed these issues by examining diurnal rhythms of 5-HT activity, with repeated measures of changes in extracellular levels of the 5-HT metabolite 5-hydroxyindole acetic acid (5-HIAA), in the medial hypothalamus of freely-feeding and food deprived animals.

The subjects were 11 adult male Sprague-Dawley rats, housed in dialysis test chambers on a 12/12 hr light dark cycle. Microdialysis probes (Hernandez et al. Life Sci., 39, 1986, 2629) were inserted through an indwelling guide cannula into the region of the paraventricular hypothalamus, and samples of dialysate (20 µl/20 min) were collected every 2 hrs for 3 days. 5-HT and 5-HIAA in the samples were measured by HPLC-EC. For the first 2 days the subjects were allowed unrestricted access to food. Results indicate that the quantity of 5-HT in the samples was below the threshold for detection (less than 3 pg). In contrast, 5-HIAA levels averaged 156±41 pg across subjects, and there was a clear diurnal rhythm of this 5-HT metabolite. Specifically, there was a large and reliable increase in the levels of 5-HIAA at the beginning of the nocturnal feeding period (1 hr after lights out), compared to stable levels observed at all other times during the 2-day test period. The mean levels of 5-HIAA increased 45% on day 1 and 75% on day 2 relative to values obtained 1 hr before the beginning of the dark period. This pattern is virtually identical to that we recently reported for medial hypothalamic norepinephrine release (EPA, 58, 1987, 9).

On day 3, we food deprived the subjects for 24 hr and continued to measure 5-HIAA as before. Food deprivation completely abolished the peak of 5-HIAA observed at the beginning of the nocturnal period, without affecting the levels of this metabolite at other times. Subsequent to deprivation, during the light phase, the subjects were fed and 5-HIAA release was measured for 4 hr. Eating behavior following 24 hr of food deprivation had no effect on 5-HIAA release in the medial hypothalamus.

These findings suggest that medial hypothalamic 5-HT activity is specifically altered during the early portion of the nocturnal feeding period and demonstrate that this change is dependent upon the presence of food.

9.8 INGESTION OF SUCROSE INCREASES HYPOTHALAMIC DOPAMINERGIC ACTIVITY IN THE 7 DAY OLD RAT. G.P. Smith, M. Albert*, R.D. Shindledecker*, C. Jerome* and S.H. Ackerman. Dept.of Psychiatry, Eating Disorders Institute and Bourne Lab., NY Hospital-Cornell Medical Center, White Plains, NY 10605.

In the adult rat, sham feeding of 10% and 40% sucrose for 9 minutes increased hypothalamic dopaminergic metabolism (DOPAC/DA), but did not change DOPAC/DA in n. accumbens, olfactory tubercle, frontal cortex, amygdala-pyriform cortex or striatum (Smith et al, Pharmacol. Biochem. Behav. 26:585, 1987). It was not clear in these experiments (1) whether the increase in DOPAC/DA was correlated with the sensory or reinforcing effects of sucrose, and (2) whether the increase in hypothalamic DOPAC/DA depended on prior ingestive experience with sucrose. To attempt to answer these two questions we investigated the neurochemical effect of ingesting sucrose for the first time in 7-8 day old rat pups.

Anterior sublingual cannulas (PE10) were implanted under light ether anesthesia. After 4 hours of food and fluid deprivation, 34 rats were tested individually in a warm, humidified chamber. Rats were infused with water or 10% sucrose for 20 min at a rate of 0.072 ml/min. Volume ingested was inferred from body weight gain. At the end of the intake test, each rat was decapitated and the brain was regionally dissected under microscopic control to obtain hypothalamus, olfactory tubercle, amygdala-piriform cortex and striatum for measurement of monoamines and metabolites by HPLC and electrochemical detection.

Although rats drank equal volumes (ml) of water (0.70 ± .07) and 10% sucrose (0.73 ± .04), hypothalamic DOPAC/DA was larger after sucrose ingestion (0.45 ± .04) than after water ingestion (0.33 ± .03, $p < .05$). Sucrose ingestion did not increase DOPAC/DA in any other brain region and sucrose ingestion had no effect on 5-HT, 5-HIAA or NE in any brain region.

These results demonstrate that the effect of sucrose ingestion on hypothalamic DOPAC/DA is independent of prior experience. The results also demonstrate that the increase of hypothalamic DOPAC/DA is not correlated with ingestive movements because rats ingested equal volumes of sucrose and water. Finally, these data suggest, but do not prove, that the increased hypothalamic dopaminergic activity is associated with the sensory effect of sucrose rather than with its reinforcing effect.

9.9 ALTERATIONS IN NEUROTRANSMITTER METABOLISM BY TOTAL PARENTERAL NUTRITION OF TUMOR-BEARING RATS. W.T. Chance, L. Cao,* J. Nelson, T. Foley-Nelson and J.E. Fischer.* Dept. of Surgery, University of Cincinnati, Cincinnati, OH 45267-0558.

We have observed increases in regional brain concentrations of dopamine (DA) and serotonin (5-HT) metabolites in anorectic tumor-bearing (TB) rats. If these alterations are causes of anorexia, correction of the nutritional imbalance with total parenteral nutrition (TPN) should not affect brain levels of these neurotransmitters. Therefore we assessed neurotransmitter metabolism by HPLC in the nucleus accumbens, hypothalamus, corpus striatum and amygdala of TB (n=6) and control (n=6) rats maintained on rat chow as well as in TB rats (n=4) maintained on TPN (isocaloric and isonitrogenous with amount of chow eaten by control rats). The jugular vein was cannulated 14 days after the induction of methylcholanthrene sarcomas in F-344 rats and TPN was initiated 3 days later. After 14 days of TPN (day 32 post tumor induction), all rats were sacrificed by decapitation, the brains were removed, dissected and frozen in liquid nitrogen prior to biochemical assay. Alterations in precursors (TYR & TRP) and metabolites of DA (DOPAC, 3-MT & HVA) and 5-HT (5-HIAA) for the nucleus accumbens, a representative region, are presented below.

Group	TYR (µg/g)	3-MT (ng/g)	DOPAC (ng/g)	HVA (ng/g)	TRP (µg/g)	5-HIAA (ng/g)
Control	15.9±0.7	151±6	1004±31	390±11	4.1±0.2	586±22
TB-Chow	34.1±3.3*	120±16	1176±58**	420±41	5.9±0.5*	688±35**
TB-TPN	13.4±3.5†	53±21*¶	802±64*†	277±30*¶	7.4±0.3*¶	804±42*¶

*p<0.01, **p<0.05 vs control; †p<0.01, ¶p<0.05 vs TB-Chow.

Thus, TB rats exhibited elevations in the levels of TYR and DOPAC as well as in TRP and 5-HIAA, suggesting increased metabolism of these neurotransmitters. Administration of TPN normalized the catecholamine alterations, while exacerbating the indoleamine changes. These results suggest that both DA and 5-HT metabolism follow precursor availability. The administration of TPN reduced brain TYR, while increasing TRP availability, probably through alterations in transport of these amino acids into the brain. Therefore, increases in DA metabolism may not be of primary importance in the development of anorexia.

9.10 EFFECTS OF PVN CORTICOSTERONE AND NOREPINEPHRINE ADMINISTRATION ON NATURAL FEEDING PATTERNS. D. Tempel*, L. Tomkow* and S.F. Leibowitz (Spon: M. Grumet) Rockefeller Univ. N.Y., N.Y. 10021.

The glucocorticoid corticosterone (CORT) is known to be important in the control of food intake. Evidence indicates that CORT is also necessary for normal α_2-noradrenergic receptor function within the paraventricular nucleus (PVN) and for norepinephrine (NE)-induced feeding to occur. Further, both CORT and NE exhibit circadian rhythms, simultaneously peaking at the start of the nocturnal cycle when natural feeding begins, suggesting that they may interact at this time to influence food intake. In support of this hypothesis, we have observed that rats given pure macronutrient diets exhibit an increased preference for carbohydrate at dark onset. Further, PVN injection of NE and peripheral administration of CORT preferentially stimulate carbohydrate intake.

In light of recent evidence for a dense concentration of glucocorticoid receptors in the PVN, we examined the possibility that CORT regulates feeding, as well as PVN α_2-noradrenergic activity, by direct action upon PVN receptor sites. In these experiments, we studied the effects of direct PVN administration of CORT and NE, in crystalline form, on natural feeding patterns in animals given pure macronutrient diets. These manipulations were made just prior to dark onset, and food intake was recorded for the first hour of the nocturnal cycle.

The reduction of CORT levels after bilateral adrenalectomy (ADX) reduced daily food intake by 28% relative to SHAM-operated rats. During the first hour of the night, ADX reduced feeding by more than 50% ($p<0.05$), due mainly to a strong and selective decline (-75% $p<0.01$) in carbohydrate intake. Fat or protein ingestion was not significantly affected. PVN administration of crystalline CORT (approximately 200µg) in ADX rats produced a significant increase in food intake by specifically enhancing carbohydrate consumption (from 0.9 to 5.7 Kcal, $p<0.001$). Fat and protein intake was unaltered. Thus, PVN CORT completely restored the rats' normal feeding pattern, suggesting that CORT is required for the expression of this pattern at this time.

PVN administration of crystalline NE, in SHAM rats, increased food intake by selectively enhancing ($p<0.05$) carbohydrate ingestion. Consistent with other studies, ADX rats were unresponsive to PVN NE. However, the administration of NE and CORT in combination, in ADX rats, increased food intake by a preferential rise in carbohydrate consumption. This response was similar to that produced in SHAM rats by PVN NE alone, and was also comparable to that seen in ADX rats after the administration of CORT alone. This lack of response additivity suggests that CORT and NE may act through a common mechanism, within the PVN to regulate normal feeding patterns.

9.11 RESPONSES OF DIFFERENT TYPES OF PARAVENTRICULAR NEURONS IN VITRO TO NOREPINEPHRINE (NE) AND OTHER FEEDING-RELEVANT TRANSMITTERS. L.-M. Kow and D.W. Pfaff. The Rockefeller University, New York, NY 10021.

In rats, NE infused into the hypothalamic paraventricular area (PVA) can act through a2-adrenergic receptors to induce feeding behavior (Goldman et al., '85, Eur. J. Pharmacol., 115:11). To investigate the NE action at the neuronal level and to see what type(s) of neurons are responsive, hypothalamic slices were used to record single-unit activity from the PVA.

Of 237 units studied, 28% were silent, 25% fired intermittently or phasically, and the remaining 47% fired continuously. When subjected to bath application of NE (12.5uM) 62% of the 212 units responded with excitation (n=61 units), inhibition (n=53), or biphasic inhibition-excitation (n=18). The excitatory actions of NE were mimicked in 22 out of 23 units by phenylephrine (PhE, an a1 agonist), but not (0/12 units) by clonidine (Clon, an a2 agonist), and were blocked or attenuated by prazosin (an a1 blocker) in 8/8 units. In contrast, the inhibitory actions of NE were mimicked by Clon (18/18 units), but rarely by PhE (1/27 units), and were blocked or attenuated by yohimbin (an a2 blocker) in 13/13 units. B-adrenergic agonist and blocker, isoproterenol and timolol, respectively, had very little effect or inconsistent effects on NE responses. The majority of inhibitory responses (40/53) were observed from continuously-firing units; whereas the majority of excitatory responses (43/61) were shown by other types of units; the correlation is statistically significant (Chi-square test, $p<0.001$, 2-tailed).

In addition to NE, some neurons were further tested with histamine (Hist, 12.5-25uM) and serotonin (5HT, 25uM), which inhibit feeding, and GABA (50uM), which induces feeding, to see whether they act preferentially on NE-inhibited neurons. Hist excited 70% of the 143; and 5HT excited 43% and inhibited 16% of the 74 units tested. None of these responses correlated with any type of NE responses. GABA inhibited 28% and caused excitation, perhaps indirectly, in 9% of the 54 units tested. The inhibitory responses to GABA occurred significantly (Chi-square test, $p<0.02$, 2-tailed) more often in NE-inhibited than in other types of neurons.

Thus, extending from behavioral studies, our results suggest that in the PVA: 1) NE induces feeding by inhibiting continuously-firing neurons; 2) NE-inhibited neurons could mediate feeding-inducing effect of GABA; and 3) the feeding-inhibiting effects of Hist and 5HT and the feeding-inducing effects of NE are mediated through different neuronal populations.

9.12 ESTROGEN-CATECHOLAMINE INTERACTIONS: INDEPENDENT AND DEPENDENT EFFECTS AT ESTROGEN-SENSITIVE BRAIN SITES IN RATS. C. WAYNE SIMPSON *(Spon: C. Nyquist-Battie) Div. of Structural and Systems Biology, Univ. of Missouri-Kansas City, K.C., Mo. 64108.

Alteration of peripheral estrogen levels in rats is well known to influence dopamine (DA) and norepinephrine (NE) levels at anterior hypothalamic locations. Stumpf and his colleagues and others have demonstrated high densities of estrogen sensitive neurons at lateral preoptic (LPO), stria medullaris (SM) and ventromedial hypothalamic (VMH) sites. Catecholamine injections at these same brain sites have been shown to increase short term food intakes. Simpson has shown that high peripheral doses of estradiol benzoate (EB), inhibit the food intake increases seen following DA injections, at a SM site, but not following NE injections at the same site. In the present report additional hypotheses concerning estrogen catecholamine interactions that influence feeding and body weight were investigated. To study the effects of initial body weight on these effects, 3 different groups of rats at significantly different levels of body weight, were injected centrally, with DA and NE at an SM site, with and without concurrent low peripheral doses of EB.

Without estrogen injections, NE and DA elicited significantly increased feeding in 1-2 hours following central injection but there was no increase in 24 hr. body weights in all three weight groups. Peripheral injections of EB did not reduce the short term increases in food intake following NE or DA central injections but did produce significant reductions in body weights in all groups. In a different set of experiments all injections of control material, cholesterol estrogen and NE or DA were delivered at central estrogen-catecholamine sensitive sites specifically in the LPO, SM and VMH. Compared to cholesterol control injections estrogen at doses >5ug elicited significant reductions in body weights and 24 hour food intakes at all three brain sites. In a final series of experiments, EB at estrogen sensitive sites was coupled with NE and DA injections at a SM feeding. NE injections in the SM site elicited 1-2 hour increases in food intakes when EB was placed at three EB sensitive brain sites. DA elicited short term feeding only when EB was placed in the LPO site and DA was injected in the SM site. EB placed in the VMH or SM sites inhibited DA increases in short-term feeding. One set of experiments demonstrated independent effects of EB on body weights and DA or NE on short-term food intakes. In additional experiments however, when EB and the catecholamines are placed at the same site, ie SM dependent interactions are observed in short-term feeding. The combination of results from all experiments suggested complex interactions between estrogen and catecholamines at different brain sites in the control of food intake and body weight.

NEUROENDOCRINE CONTROLS: PITUITARY I

10.1 EVIDENCE FOR TESTICULAR FEEDBACK AT THE LEVEL OF THE ANTERIOR PITUITARY IN HYPOPHYSECTOMIZED, PITUITARY-GRAFTED RATS RECEIVING PULSATILE LHRH. J.E. Levine, C. Gilmore,* R. Simov,* and F.J. Strobl.* Dept. of Neurobiology and Physiology, Northwestern University, Evanston, IL 60201.

The purpose of this study was to examine the extent to which gonadal negative feedback actions are exerted directly at the level of the anterior pituitary (AP) gland. To address this question we developed an in vivo isolated pituitary paradigm to determine whether castration leads to increased gonadotropin secretion under "hypothalamic-clamp" conditions, i.e. during unvarying intermittent LHRH infusions. Since it was found previously that LHRH pulse frequency is increased in short-term castrate rats, we also tested the hypothesis that post-castration increases in LH result from increased LHRH pulse frequency. Hypophysectomized male rats received single AP transplants under the kidney capsule. Animals were fitted with a novel concentric atrial catheter system which allows for intermittent infusions of LHRH (250 ng/5 min/h) and chronic blood sampling. Rats received LHRH infusions for 4-5d before and throughout experimental sessions. On the day of experiments, blood samples were obtained 2h prior to treatment and at every 2h interval for 24h following treatment. Treatments at time 0 were as follows: group 1, sham-surgery; group 2, castration; group 3, LHRH pulse frequency increased to 1 pulse/30 min. Plasma LH levels in all groups were determined by RIA using the NIADDK RIA kit (LH RP-2 standard). In each animal the sella turcica was inspected post-mortem for completeness of hypophysectomy. Viability of pituitary transplants was verified histologically. In sham-operated animals LH levels were 0.3 - 0.7 ng/ml and remained unchanged throughout the 24h post-surgery period. By contrast, LH levels in the castrate animals increased steadily during the 24h following surgery to a level 3- to 5-fold higher than initial values (0.58 $\pm$ .26 ng/ml, pre-castration; 2.00 $\pm$ .48 ng/ml, post-castration). The post-castration increase in LH secretion in these experiments closely resembled that seen previously in pituitary-intact animals in time-course and magnitude. In group 3, a change in LHRH pulse frequency resulted only in transient increases in LH secretion within 4-8h following the frequency shift. Our data demonstrate that most, if not all, of the short-term effects of castration on LH secretion can be accounted for by the withdrawal of gonadal negative feedback at the level of the pituitary gland. Although regulation of the LHRH pulse generator may also operate as a component of an integrated gonadal negative feedback system in male rats, our results support the hypothesis that direct pituitary effects of testosterone are of much greater importance in the acute feedback regulation of LH secretion. Supported by NIH grant HD20677.

10.2 EFFECTS OF PULSATILE GNRH ADMINISTRATION ON α-SUBUNIT AND LHβ GENE EXPRESSION AND ON PULSATILE LH SECRETION DURING LACTATION. Lee, L.-R.*, D. Haisenleder*, J.C. Marshall and M.S. Smith, Dept. of Physiology, Univ. of Pittsburgh, PA 15261 and Dept. of Internal Medicine, Univ. of Michigan, Ann Arbor, MI 48109.

In the rat, suckling of 8 pups results in a suppression of pituitary GnRH receptors (GnRH-R), α-subunit and LHβ gene expression, and pulsatile LH secretion. Twenty-four hr after pup removal from intact rats, GnRH-R have increased 3-4 times, but there are no changes in α-subunit or LHβ mRNA concentrations nor evidence of pulsatile LH secretion. These studies were designed to determine whether administration of pulsatile GnRH could stimulate increases in these parameters. Intact rats suckling 8 pups were implanted with two right atrial catheters on day 8 postpartum and pups were removed on day 9. Blood samples were collected at 10 min intervals for 4 hr at the time of pup removal and 24 hr after pup removal. Pulsatile GnRH (2 ng/pulse every 50 min) was begun at 16 hr after pup removal (GnRH-8 hr) or at the time of pup removal (GnRH-24 hr). After collection of blood samples, pituitaries were removed and GnRH-R was determined or α-subunit and LHβ mRNAs were measured by an RNA dot blot hybridization assay.

There were few detectable LH pulses in saline-infused animals 24 hr after pup removal. The initial GnRH pulses administered at the time of pup removal were generally ineffective in stimulating pulsatile LH secretion. However, by 24 hr after pup removal, significant LH pulses were observed in response to each pulse of GnRH. LH peak heights (10-30 ng/ml) were similar to basal LH pulses observed during diestrus of the estrus cycle. GnRH-R (fmol/pit) and α-subunit and LHβ mRNAs (pg cDNA bound/100 µg pit DNA) were as follows:

GROUP	GnRH-R	α-SUBUNIT	LHB
INTACT + 8	44 ± 8	49 ± 2	5 ± 0.4
INTACT - 8	144 ±12	43 ± 2	5 ± 0.5
INTACT - 8, GNRH-8 hr	--------	44 ± 4	5 ± 0.8
INTACT - 8, GNRH-24 hr	139 ± 5	51 ± 3	5 ± 0.6

These studies demonstrate that restoration of GnRH-R alone is not sufficient to activate LH synthesis. Administration of small pulses of GnRH results in pulsatile LH secretion after upregulation of GnRH-R has occurred. However, induction of pulsatile LH is not accompanied by increased expression of α-subunit and LHβ mRNAs. In contrast, the pituitary of ovx rats has increased content of LH subunit mRNAs at 24 hr after pup removal and releases large amplitude LH pulses in response to the 2 ng dose of GnRH. Thus, in intact rats, the elevated levels of progesterone may inhibit α-subunit and LHβ gene expression (supported by grant HD14643).

10.3 THE EFFECT OF SURGICAL DISCONNECTION OF THE MEDIOBASAL HYPOTHALAMUS (MBH) ON LHRH RELEASE IN VITRO. C.P. Phelps and P.S. Kalra. Dept. of Anatomy, Univ. South Florida, Tampa, Fl and Dept. of Obstetrics and Gynecology, Univ. of Florida, Gainesville, FL.

The reproductive consequences of severing MBH pathways on pituitary luteinizing hormone (LH) release are anovulation and acyclcity in the female rat, whereas changes in basal gonadotropin release in the male are variable. We and others have observed growth of immunoreactive LHRH-containing neurons into scar tissue 1-2 months after anterior hypothalamic lesions. We have now compared basal and secretogogue-evoked LHRH release in vitro from the preoptic area (POA)-MBH of adult male rats at short (10 days) and long (60 days) intervals after frontal cuts (FC). A Halasz-type knife (radius 1.5mm) was used to sever medial LHRH pathways immediately behind the optic chiasm. FC was produced by fifteen 180° rotations of the knife. Additional rats received either sham operations or no surgery. At 10 or 60d after surgery rats were decapitated and the POA-MBH was rapidly removed. Individual POA-MBH fragments were halved longitudinally and perfused continuously for 6 hr at 37°C with a balanced salt solution (pH 7.4) containing 5 mM glucose, 0.1% BSA and 10^{-5} M Bacitracin. After a 60 min preincubation period, fractions (200 µl/10 min) were collected for LHRH determination by RIA. After 100 min of perfusion to estimate basal LHRH secretion rates, 60 mM KCL was added to the medium for 10 min. In a second experiment, POA-MBH of rats bearing FC for 60d and of control and sham operated rats were perfused similarly except that the opiate antagonist naloxone hydrochloride (1 mg/ml) was added to the medium for 30 min during the third hr and 60 mM KCL was added for 10 min during the fifth hour of perfusion. At the end of the incubation each POA-MBH was weighed and assayed for total LHRH content. Although there was considerable variation in individual rats at 10d after FC, the average LHRH release rate (2.9±1.1 pg/10 min) and concentration (40.5±14.4 pg/mg) were reduced when compared to shams (5.4±1.4 pg/10 and 78.8±5.8 pg/mg, respectively). At 60d after FC, the POA-MBH LHRH concentration (29.1±2.6 pg/mg) and basal LHRH release rate (2.6±0.2 pg/10 min) were also significantly reduced as compared to sham operated rats (59.3±7.2 pg/mg, 3.7±0.5 pg/10 min). However, there was no significant difference in LHRH concentration and release rates in short vs. long term FC rats. Although naloxone and KCL stimulated at least a two-fold increase in LHRH output, the response of POA-MBH from 60d and 10d FC rats was significantly lower than that from their respective sham operated rats. Higher release rates were associated with higher individual POA-MBH LHRH concentrations. In summary, severing the anterior neural connections of the MBH not only reduces LHRH content, but also basal and stimulated secretion rates and there was no evidence of functional recovery. Supported by The Whitehall Fnd. Inc. and NIH HD11362.

10.4 NOVEL DECONVOLUTION MECHANICS UNMASK THE NATURE OF SPONTANEOUS LH SECRETORY BURSTS IN VIVO. J.D. Veldhuis and M.L. Johnson. Endocrinology & Biophysics, Depts. of Medicine & Pharmacol., Univ. of Virginia Medical School, Charlottesville, VA 22908.

The exact nature of glandular secretory events is difficult to probe in vivo, since underlying patterns of hormone release are confounded by metabolic clearance (MC). Moreover, MC rates vary among different individuals. Accordingly, to discern the nature of endogenous LH secretory events, we propose a deconvolution model in which circulating hormone concentrations are determined simultaneously by 4 distinct parameters: (i) the location(s); (ii) amplitude(s); and (iii) half-duration(s) of all discrete secretory bursts, which are acted upon by (iv) exponential clearance kinetics. Secretory bursts are modeled as Gaussian distributions of instantaneous molecular secretion rates. The resultant convolution integral that describes the spontaneous fluctuations in plasma hormone concentrations over time can be solved by numerical integration. Moreover, non-linear, least-squares parameter estimation provides mean and bounded probability estimates of endogenous clearance kinetics and underlying secretory impulse amplitudes, durations, and locations. The physiological implications of this model were examined by analyzing spontaneous LH (RIA) pulsatility in 8 men sampled every 5 min for 8 hr. Deconvolution disclosed endogenous LH half-lives (monoexponential) of 87 ± 8.5 min (± SEM), which agreed well with independently determined half-lives of 44-106 min (67% confidence limits) for exogenous LH disappearance in 4 LH-deficient men given 35 mcg human LH by IV bolus injection. Further analysis revealed that underlying LH secretory impulses exhibited half-durations of only 7.8 ± 0.52 min; occurred at a frequency of 6.9 ± 0.55 pulses/8 hr (interpulse intervals of 75 ± 6.3 min); and achieved amplitudes of 0.41 ± 0.05 mIU/min/ml. By deconvolution, the calculated production rate of endogenous LH was 180 ± 14 mIU/min, which accords with that estimated by steady-state LH infusions (228 ± 28 mIU/min). In summary, the present analytical deconvolution model has disclosed discrete Gaussian bursts of LH release that are temporally delimited (half-duration 7.8 min) and occur approximately every 75 min. Moreover, this model correctly estimates endogenous LH production and metabolic clearance rates from measurements of plasma LH concentrations alone. We conclude that rates of endogenous LH production, half-times of native LH clearance, and the nature of spontaneous LH secretory bursts can be unmasked in vivo by this novel deconvolution model without injecting radiolabeled or "cold" hormone.

10.5 **LH SURGE AFTER ESTRADIOL AND PULSATILE GNRH IN HYPOPHYSIAL STALK-TRANSECTED (HST) FEMALE PIGS.** **J. S. Kesner*, M. J. Estienne*, R. R. Kraeling* and G. B. Rampacek*. (SPON: T. G. Reigle). R. B. Russell Agricultural Research Center, USDA-ARS, Athens, GA 30613 and University of Georgia, Athens, GA 30602.**

The objective was to determine sites of action whereby estradiol induces the preovulatory LH surge in pigs. Six domestic pigs (weight = 118 ± 12 kg; mean ± SE) were subjected to HST and ovariectomy (OVX). Pigs received either 1 µg GnRH pulses iv every 45 min from day -5 to 4 and an injection of estradiol benzoate (10 µg EB/kg BW) im on day 0 (TRT 1) or GnRH pulses only on days -5 to 0 and 2 to 4 and EB (TRT 2) or oil vehicle (TRT 3) on day 0. Pigs were reassigned to treatments according to an incomplete latin square design, so that each treatment was administered to four pigs, and so that no individual pig received the same treatment twice. Subsequently, during a third treatment period, all HST gilts received GnRH pulses only from days -5 to 0 and EB on day 0 (TRT 4). Four contemporary OVX pigs, one of which underwent sham-HST, served as positive controls and received saline pulses and EB during each of the three aforementioned treatment periods, which were conducted at 4 week intervals. In stalk-intact pigs, EB inhibited LH release for 48 h, then induced an LH surge that peaked 60 to 84 h after EB. Serum LH in HST pigs increased from undetectable concentrations (<.17 ng/ml) to a plateau at .42 ± .03 ng/ml after 5 days of GnRH stimulation. In TRT 1, LH response to GnRH was inhibited for 12 h after injecting EB, but then serum LH concentrations gradually rose for 36 h to .69 ± .09 ng/ml; surpassing those noted before EB (P<0.05). Interrupting the GnRH pulses immediately after EB (TRT 2), so as to mimic the secretory hiatus of GnRH/LH observed in intact pigs prior to the LH surge, rendered serum LH concentrations undetectable. Resuming GnRH pulses 48 h later stimulated LH concentrations to increase progressively over 4 h to .71 ± .09 ng/ml. When corrected for the compromised capacity of HST pigs to secrete LH, this response was comparable to the preovulatory surge in intact pigs. Without EB treatment, resumption of GnRH stimulation after a 48 h interruption (TRT 3) elicited a resurgence of LH release that was quantitatively similar to that of TRT 2, but peaked much more rapidly; within 1 h. Discontinuing GnRH pulses at the time of EB injection (TRT 4) caused LH concentrations to drop and remain below .17 ng/ml for 96 h. These data indicate that estradiol induces the preovulatory LH surge in pigs by first inhibiting, then restoring GnRH release, while acting at the pituitary to moderate the rate at which the resumed GnRH stimulation accelerates LH release.

10.6 ULTRASTRUCTURAL ANAYLIS OF LHRH NEURONS IN FEMALE RHESUS MACAQUE. J.W. Witkin, M. Ferin* and A.J. Silverman. Depts. Anat. & Cell Biol., Obstet. & Gynecol., Columbia Univ. Coll. P & S, New York, NY 10032.

Adult long-term ovariectomized rhesus macaques were perfused with 4% paraformaldehyde and 0.1% glutaraldehyde through the left cardiac ventricle. A block of tissue encompassing the preoptic area and hypothalamus was postfixed for 2 h and cut at 60 um. Ultrastructural demonstration of LHRH was performed as previously described (Witkin and Silverman, Peptides 6:263,'85). In some cases, the DAB reaction product was silver-intensified to maximize visualization of intracellular sites. Comparisons were made of LHRH neurons in 4 areas: (1) medial preoptic (MPOA); (2) dorsal to the supraoptic nucleus (dSON); (3) the arcuate region (arc); and (4) medial basal hypothalamus (MBH). The distribution of reaction product within individual neurons was not uniform. In some neurons the reaction product was scattered throughout the cytoplasm, but always exclusive of the Golgi apparatus. In others, reaction product was only associated with secretory vesicles. These variations occurred in all regions, suggesting that instead of acting in concert, LHRH neurons are concurrently in various stages of synthesizing, processing and packaging the neuropeptide. Reaction product was never associated with the nucleolus, but in some neurons the nucleus was immunoreactive. This consistency leads us to believe that the nuclear staining, though inexplicable, is not an artifact. In addition to subcellular distribution of reaction product, the synaptic input and amount of glial ensheathment of LHRH soma and dendrites was measured and compared to non-identified neurons. Few synapses onto LHRH neurons were found (none in the MPOA or arc, an average of 0.4 per cell in 5 neurons in the dSON and 0.6 in 5 neurons in the MBH). Hypertrophied glial processes ensheathed an average of 54% of the membrane of LHRH cells in MPOA. Considerably less ensheathment was found in dSON, arc and MBH (an average of 17% of the membrane). There were no synapses onto LHRH dendrites in the MPOA, a few in dSON and arc and most in the MBH. About 1/3 of LHRH dendritic membrane in all regions abutted onto glial processes. Nonidentified neurons and their processes had more synapses than LHRH neurons in all regions and much less glial ensheathment. A most striking finding were a few axodendritic and axosomatic LHRH-LHRH synaptic interactions in the MBH. USPHS NIH AG05366 and HD10665.

10.7 CELLULAR LEVELS OF MESSENGER RNA ENCODING GONADOTROPIN-RELEASING HORMONE (GnRH) ARE ELEVATED AFTER THE LH SURGE ON THE DAY OF PROESTRUS. R. T. Zoeller and W. S. Young, III. Lab. of Cell Biol, NIMH, Bethesda, MD 20892.

Gonadotropin-releasing hormone (GnRH) is synthesized by specific neuronal cells distributed throughout the septum and preoptic area of the rat brain. We have shown previously that levels of mRNA encoding GnRH in cells within the OVLT are influenced by estrogen in a manner suggesting that GnRH synthesis is coupled to GnRH release. Specifically, GnRH mRNA levels are supressed by estrogen under conditions of negative feedback (Zoeller, Seeburg and Young, Endocrine Abstract #32, 1986). If GnRH mRNA levels are coupled to GnRH release, then GnRH mRNA levels should rise after a spontaneous surge release of GnRH to replenish GnRH stores. To test this prediction, we measured GnRH message levels in 4-day cycling rats throughout the day of proestrus. Adult female Sprague-Dawley rats were maintained under temperature and light-controlled conditions; only females exhibiting two consecutive 4-day cycles, as defined by daily vaginal smears, were included in this experiment. Five females each were ether anesthetized and perfused intracardially with 4% formaldehyde at 1000h, 1300h, 1600h, and 1900h on the day of proestrus. Frozen sections (12 µm) were prepared and hybridized according to Young et al. (Neurosci. Lett. 70:198, 1986). Sections were hybridized with an ^{35}S-labelled 48-base oligonucleotide probe complementary to the mRNA region encoding GnRH. Sections and ^{35}S-impregnated brain-paste standards were apposed to emulsion-coated coverslips for 2 weeks; mRNA levels were derived by measurement of light reflectance off silver grains using an image analysis system and normalize as percent 1000h values. GnRH mRNA levels on the day of proestrus were: 100±9.2%, 84±8.6%(ns), 76±7.3%(ns), and 123±13%($p<0.01$) for 1000h, 1300h, 1600h, and 1900h, respectively. Since these animals exhibit an LH surge at approximately 1400-1600h, these results demonstrate that GnRH mRNA levels become elevated after a spontanous surge release of GnRH and suggest that the same signal stimulating GnRH release may stimulate GnRH synthesis in order to replenish GnRH stores.

10.8 CONTROL OF PULSATILE LH RELEASE IN THE OVARIECTOMIZED GUINEA PIG: ROLE OF OPIATERGIC, SEROTONERGIC AND ADRENERGIC SYSTEMS. A.C. Gore*, J.A. Keller-Halbe* and E. Terasawa (SPON: J. Kemnitz). Neurosciences Training Prog. and Wisconsin Reg. Primate Res. Ctr., Univ. of Wis., Madison, WI 53706.

Despite numerous studies in the rat, monkey and human, little information is available on the control mechanism of LHRH release in the guinea pig. In the present experiment involvement of opiatergic, serotonergic and adrenergic neuronal systems in control of pulsatile LH release, presumably by their interaction with the LHRH neurosecretory system, was examined using various agonists and antagonists. Long-term ovariectomized (OVX) female guinea pigs received an indwelling catheter and blood samples were obtained through the catheter at 5 min intervals for a 6 h period. Drugs were injected i.v. after 1.5 h of control samplings. LH release in plasma determined by RIA in OVX guinea pigs was pulsatile, with mean LH levels, interpulse interval and LH pulse amplitude at 951±76 ng/ml, 29.2±1.5 min and 781±127 ng/ml, respectively. In the 1st experiment effects of an opiate agonist (morphine sulfate, 10 mg/kg or fentanyl, 50 µg/kg), opiate antagonist (naloxone, 2 mg/kg) serotonin agonist (quipazine, 15 mg/kg) or serotonin antagonist (methysergide, 15 mg/kg) were tested. Both fentanyl and morphine sulfate suppressed LH release completely, while naloxone significantly enhanced mean LH release 2-3 fold. Although methysergide suppressed LH release, quipazine did not result in any change in LH release. In the 2nd experiment a drug-induced LH suppression was reversed by injection of its corresponding agonist or antagonist 30 min later. The fentanyl-induced LH suppression was reversed by subsequent naloxone administration, and the methysergide-induced LH suppression by quipazine. In the 3rd experiment the interaction of the opiate and serotonin neuronal systems was examined by injecting naloxone 30 min after methysergide, and quipazine 30 min after fentanyl. While naloxone reversed the methysergide-induced LH suppression, quipazine did not overcome the effects of fentanyl. In the 4th experiment the effects of an α_1 antagonist (prazosin, 1 mg/kg), an α_2 agonist (clonidine, 0.1 mg/kg), an α_2 antagonist (rauwolscine, 1 mg/kg) or a β antagonist (propranolol, 2 mg/kg) on LH release in OVX guinea pigs were tested. While both prazosin and rauwolscine suppressed LH release, clonidine did not change LH release. Propranolol also did not affect LH release. Moreover, it was found that, while the rauwolscine-induced LH suppression was not reversed by clonidine, injection of clonidine prior to rauwolscine treatment prevented the rauwolscine-induced LH suppression. These results suggest that 1) the opiatergic system is inhibitory to LHRH release; 2) α-adrenergic, but not β-adrenergic systems, are facilitatory to LHRH release; 3) the serotonergic system is facilitatory, perhaps by inhibiting the opiatergic system. Thus, the opiatergic neuronal system appears to be localized more proximally than the serotonergic system to LHRH neurons. Further experiments investigating interactions between opiatergic and adrenergic systems are in progress. (Supported by NIH Grants RR00167 and HD15433.)

10.9 RAPID RELEASE OF SUBSTANCE P AND LHRH FROM SYNAPTOSOMES PREPARED FROM THE MEDIAL BASAL HYPOTHALAMUS AND SUBSTANTIA NIGRA. M. Selmanoff and C. Shu*. Department of Physiology, University of Maryland, School of Medicine, Baltimore, MD 21201.

In the present study we investigated the Ca^{2+}-dependent, depolarization-induced release of substance P (SP) and LHRH from medial basal hypothalamic (MBH) and substantia nigra (SN) synaptosomes in male rats. SP and LHRH release under basal (5mM K^+) and depolarizing (75mM K^+) conditions was determined over 1-20 sec time intervals using a rapid filtration technique. Synaptosomes were perifused with a physiological saline solution at 30°C containing 0.2mM bacitracin, 5mM KCl, 75mM NaCl, 70mM N-methyl-D-glucamine (a Na^+ substitute), 1mM $MgCl_2$, 10mM glucose, 0.5mM pyruvate, 1mM Na_2HPO_4 and 10mM Hepes-HCl buffer (pH 7.4). Basal efflux was measured in response to a pulse of this 5mM K^+ solution. Depolarization was elicited by adjusting the external KCl concentration to 75mM by iso-osmotic substitution of N-methyl-D-glucamine in the presence of 1mM $CaCl_2$. Release medium was exposed to a 95°C water bath and lyophylized in a vacuum centrifuge. SP and LHRH were quantitated by specific radioimmunoassays sensitive at 1-4pg/tube. Endogenous neuropeptide content was determined in 2N acetic acid extracts of sonicated synaptosomes.

Depolarization of MBH synaptosomes evoked release of SP from 13.0±0.7 (5mM K^+) to 23.0±1.9 (75mM K^+) pg released/10 sec. In contrast, LHRH was not released by depolarization (11.6±0.8 to 12.9 ±1.1) and also did not occur in the presence of 10^{-4} or 10^{-6}M norepinephrine, 10^{-7}M 12-O-tetradecanoylphorbol-13-acetate (TPA), 10^{-5}M forskolin or in female rats.

Significant SP release was seen from both MBH and SN synaptosomes at 20,15,10,5 and only 1 sec of depolarization. The initial rate (1 sec) of SP release was 4.5-fold greater from SN than from MBH synaptosomes [k_{rel}=2.7 (SN) and 0.6 (MBH)]. SP release from SN synaptosomes was 2-3-fold greater at any given time interval compared with release from MBH synaptosomes. We have previously reported that TPA (10^{-7}M) potentiates evoked ^{3}H-dopamine release from striatal and median eminence synaptosomes, however, TPA did not potentiate SP release at this concentration.

Release of LHRH and SP from MBH synaptosomes may occur by different mechanisms. Evoked SP release was more pronounced from SN than from MBH synaptosomes. The release kinetics and/or the readily releasable pools may differ in these two populations of SP nerve terminals. TPA potentiated dopamine but not SP synaptosomal release. This suggests that protein kinase C activation potentiates the intrasynaptosomal stimulus-secretion coupling mechanism in dopaminergic but not SP-containing nerve terminals in these brain regions.

(Supported by NIH grants HD-21351, HD-15955 and RCDA NS-00731).

10.10 GONADOTROPIN RELEASING HORMONE ASSOCIATED PEPTIDE (GAP) AND LUTEINIZING HORMONE RELEASING HORMONE (LHRH) ARE SECRETED AS INTACT PEPTIDES FROM MEDIAN EMINENCE IN RESPONSE TO DIFFERENT SECRETAGOGUES IN VITRO. W. C. Wetsel, M. M. Valenca*, M. D. Culler* and A. Negro-Vilar. Reprod. Neuroendo. Sect., Lab. Reprod. Dev. Tox., NIEHS, NIH, Research Triangle Park, NC 27709.

The sequence for the rat proLHRH has been deduced and found to contain the decapeptide, LHRH, and a 56 amino acid peptide called GAP (PNAS 83:179, 1986). Both LHRH and GAP have been localized in nerve terminals of the median eminence (ME; Nature 316:542, 1985). This location may have functional significance since recent reports have ascribed biological activity to GAP and an N-terminal fragment of GAP (Nature 316:511, 1985; JBC 261:16990, 1986). We have used various agents known to activate different intracellular messenger pathways in LHRH neurons to determine whether GAP is released in vitro from nerve terminals in the ME. In addition, we have used high performance liquid chromatography (HPLC) to characterize all LHRH and GAP release products. Adult, male, Sprague-Dawley rats were decapitated, the ME was dissected, and the tissue fragments were incubated in a Krebs-Ringer bicarbonate glucose buffer. Following a 30 min pre-incubation period, fragments were incubated for additional 30 min periods in the presence of fresh media, either alone or containing prostaglandin E2 (PGE_2), phorbol ester (PDBu), or the depolarizing agent, [K^+]. At the end of the experiment, LHRH and GAP were quantitated by radioimmunoassay. Serial dilutions of a pool of media gave a displacement curve which was parallel to that of the GAP_{1-56} standard. Both GAP and LHRH were secreted into the media under basal conditions. PGE_2 was found to significantly enhance the release of both peptides. PDBu and [K^+] stimulated the highest levels of secretion which were 8- and 4-fold higher than under basal conditions for LHRH and GAP, respectively. In a separate experiment, media that were collected under basal or [K^+]-stimulated conditions were injected separately onto an HPLC apparatus. Peptides were separated according to molecular weight (MW) on a Toyo-Soda G-2000SW column while absorbance was monitored at 280 nm. A single peak of immunoreactive LHRH eluted at approximately 1300 MW, at the same position as synthetic LHRH. Two peaks of GAP immunoreactivity were found. A small peak eluted in the void volume. The predominant peak eluted at 6500 MW, the same position as synthetic GAP_{1-56}. These data indicate that GAP is secreted from median eminence nerve terminals under basal conditions, that GAP is released in response to the same stimuli which stimulate secretion of LHRH, and that the secreted forms of LHRH and GAP appear to be the decapeptide and GAP_{1-56}. These results emphasize the importance of using both in vitro and HPLC methodologies to evaluate the changes which may occur in LHRH prohormone processing and secretion.

10.11 **REPETITIVE TRANSIENT RISES OF CYTOPLASMIC FREE CALCIUM IONS IN A SUB-POPULATION OF LHRH-STIMULATED PITUITARY GONADOTROPES.** D.A. Leong*, D.M. Benedek*, C.E. Lyons*, Jr., G.L. Mandell*, J.A. Sullivan*, M.O. Thorner. Department of Internal Medicine, University of Virginia, Charlottesville, VA 22908.

The precise role of cytosolic calcium ions in the pituitary gonadotrope remains to be established. We have recently combined the new fura-2/AM method for calcium ion measurements using digital imaging microscopy with immunologic techniques that permit quantitation of hormone release from single living cells. This permits the identification of secretory gonadotropes in mixed-cell pituitary preparations (reverse hemolytic plaque assay) together with real time measurements of calcium ions in single cells (fura-2/AM). This approach solves persistent problems associated with (i) mixed-cell populations: secretory gonadotropes in rat pituitary cell preparations comprise just 3-4% of all pituitary cells (ii) population averaging: temporally organised events such as calcium transients can be unambiguously resolved only in single cells. We have previously shown that high doses of LHRH (10.0 nM) rapidly triggers (1-2 sec) calcium mobilization from internal stores in all secretory gonadotropes lasting for 3-5 min. The initial phase of the calcium response is common. However, the calcium profile is strikingly different among individual secretory gonadotropes when stimulation is maintained for a further 45 min at a saturating LHRH dose. Three categories of response are evident: thus calcium levels remain sustained at high levels of calcium (Type I), or plateau to a level above baseline (Type II), or immediately return to baseline (Type III). The second phase of the calcium response is associated with calcium influx through calcium channels, since the response is completely abolished when extracellular calcium is withdrawn. The same repertoire of calcium responses was still obtained in the majority of gonadotropes treated with much lower doses of LHRH (0.001 and 0.01 nM). We report here on a new calcium response profile of repetitive calcium transients triggered in a small sub-population (<10%) of gonadotropes at low (but not high) LHRH doses. Resting levels of calcium ions were stable in this gonadotropes subset prior to stimulation. LHRH activated a striking series of repetitive calcium transients maintained, in some instances, for the entire stimulus period (50 min). There is a common pulse frequency of 2-3 sec (n=7). For each gonadotrope, calcium transients were generated as exact replicas when recordings were analyzed at 100 msec intervals. These findings demonstrate a new level of complexity regulating cytosolic calcium ions levels in the gonadotrope. This phenomenom adds to the accumulating evidence that the mechanism of signal transduction includes information transfer coded in the temporal organization of calcium transients.

10.12 PARTICIPATION OF VOLTAGE-DEPENDENT CALCIUM CHANNELS IN THE REGULATION OF FOLLICLE STIMULATING HORMONE SECRETION IN A PRIMARY PITUITARY CELL CULTURE SYSTEM. G.A.Shangold*, M.Blotner*, E.Y.Lee*, & R.J.Miller, (Spon: R. Dinerstein), Dept. Pharmacol. and Physiol. Sciences and Dept. Obstetrics and Gynecology., Univ. of Chicago, Chicago, Il. 60637.

Calcium channels are clearly important in the control of luteinizing hormone (LH) release by pituitary cells, but to date little information exists concerning their role in the secretion of follicle stimulating hormone (FSH) by these same gonadotroph cells. The present investigation was undertaken to examine the involvement of voltage-sensitive calcium channels (VSCCs) in the stimulation of FSH release by gonadotropin-releasing hormone (GnRH) in primary pituitary cell cultures. Female, 35-day old, S/D rats were sacrificed to obtain pituitaries, from which adenohypophyses were dissected and dispersed in 0.25% trypsin for 20 minutes. After filtration through organza cloth and centrifugation at 225 g for 10 min., cells were plated at 500,000/well in Medium 199 with 10% horse and 2.5% fetal calf serum in 16 mm, 24-well plates. After 2 days, cells were washed 3 times in serum-free media and incubated for 2 hours with test drugs in HEPES buffer. After removal of media aliquots for FSH assay, cells were lysed with 0.2% SDS and protein content deter mined. Cell depolarization with 50 mM K^+ resulted in an increase in basal (5 mM K^+) FSH secretion. GnRH (100 nM) produced a significantly greater release of FSH than did 50 mM K^+. Cd^{++} (100 μM) completely prevented the depolarization-induced increase, and partially blocked the GnRH-mediated increase in FSH secretion. Depolarization-induced FSH stimulation was further enhanced by the dihydropyridine (DHP) VSCC agonist BAY K 8644 (1 μM). The enhancement of FSH secretion caused by 50 mM K^+ with or without BAY K was blocked by the VSCC antagonist nitrendipine (1 μM). Basal (5 mM K^+) secretion was enhanced to a level equal to that brought about by 50 mM K^+ via Na^+ channel activation with 30 μM veratridine. However, neither the K^+- nor GnRH-induced rise in FSH release was inhibited by Na^+ channel blockade with 5 μM tetrodotoxin (TTX). We also examined the effects of the putative regulator of gonadotropin secretion, Neuropeptide Y (NPY), in this cell culture system. As reported for LH secretion (Crowley et al., Endocr. 120:941,1987), NPY (100 nM) had little effect by itself on basal or depolarization-induced FSH release, but did enhance the GnRH-mediated increase in FSH secretion. These results suggest that activation of DHP-sensitive calcium channels can initiate the secretion of FSH from gonadotrophs. VSCCs may also play a role in the stimulation of FSH release by GnRH.

PEPTIDES: BIOSYNTHESIS, METABOLISM AND BIOCHEMICAL CHARACTERIZATION I

11.1 EXPRESSION AND CELL TYPE-SPECIFIC PROCESSING OF RAT PRODYNORPHIN. L. Devi*, J. Douglass* and E. Herbert* (Spon: E. Lewis). Vollum Institute for Advanced Biomedical Research, Oregon Health Sciences University, Portland, Oregon 97201.

The post-translational maturation of a complex precursor polyprotein, prodynorphin, was studied by transformation of a mouse pituitary cell line ($AtT\text{-}20_{D16v}$) and a rat pituitary cell line (GH_4-C1) with a recombinant plasmid encoding rat prodynorphin. This plasmid was constructed by inserting rat preprodynorphin cDNA downstream from the mouse metallothionein promoter and was introduced by co-transformation with the G418-selectable plasmid pKOneo. Stable transformants were isolated and analysed for the presence of the prodynorphin precursor. Chromatography of the cell extract from the stably transformed cell line AtT-20/ZRD19 on Sephadex G-75 revealed the presence of low molecular weight [Leu]enkephalin containing peptides (<2kd) as well as of larger proteins (up to 30kd). Analysis of the low molecular weight peptides on reverse phase HPLC showed the presence of dynorphin A, dynorphin B, ß-neo-endorphin and dynorphin A-(1-8) in addition to authentic [Leu]enkephalin.

In contrast, chromatography of the cell extract from stably transformed cell line GH_4-C1/ZRD13 on Sephadex G-75 revealed the presence of two prominant high molecular weight [Leu]enkephalin containing peaks and a very small low molecular weight peak representing [Leu]enkephalin pentapeptide.

These results suggest that while AtT-20 cells contain enzymes that efficiently process at the "Lys-Arg", Arg-Arg", and single arginine residues of prodynorphin, GH_4-C1 cells do not. The accurate and efficient processing of prodynorphin in AtT-20 cells and not in GH_4-C1 cells suggest that this method of DNA-mediated gene transfer will provide important information regarding post-translational control of mechanisms regulating the expression of neuropeptides and hormones.

11.2 DOPAMINERGIC AND CHOLINERGIC REGULATION OF STRIATAL PROENKEPHALIN mRNA CONTENT. I. Mocchetti, R. Dal Toso, A. Ritter and E. Costa. FIDIA-Georgetown Institute for the Neurosciences, Georgetown University Medical Center, Washington, D.C. 20007

Northern blot analysis for the determination of proenkephalin (PE) mRNA in combination with radioimmunoassay for PE and enkephalin (ENK) showed that striatal dopaminergic terminals exert a tonic inhibition on striatal intrinsic neurons that store ENK. This effect seems to be mediated by dopaminergic receptor of the D-1 type since a prolonged treatment with the D-1 receptor antagonist, SCH 23390, increases ENK synthesis and processing. However, the effect of dopamine on ENK stores may be indirect since dopamine also tonically inhibits cholinergic neurons which, in turn, may regulate the synthesis of ENK in striatal neurons. Such a possibility is suggested by several independent lines of investigations: cholinergic agonists, such as diisopropylfluorophosphate, increases Met-ENK content in striatum while cholinergic antagonists, such as scopolamine, decreases it (Hong et al., Psychopharmacol. 1980). We confirmed this decrease and found it to be associated with a decrease in PE mRNA; furthermore, scopolamine blocks the increase in ENK and PE mRNA striatal content elicited by haloperidol. Primary cultures of striatal neurons were used to study how a signal transduction at synaptic neurotransmitter receptors modulates mRNA content of postsynaptic neurons. A 3 hr treatment with 10 uM of SKF 38393 a specific D-1 agonist, decreases PE mRNA content of these neurons in primary culture supporting the hypothesis that D-1 receptors modulate the PE mRNA content. The culture exposure to carbachol (50 uM) for 12 hr increases PE mRNA content. This effect is already present after 3 hr of exposure. These results suggest that dopaminergic and cholinergic receptors might be either located in enkephalin containing neurons or trans synaptically linked to these cells. Thus, it appears that in striatal cultures the activation of cholinergic or D-1 receptors can affect in opposite direction the content of PE mRNA.

11.3 CHARACTERIZATION AND SECRETION OF PRO-OPIOMELANOCORTIN-CONVERTING ENZYME ACTIVITY BY DISPERSED BOVINE INTERMEDIATE LOBE PITUITARY CELLS. Maria G. Castro* and Y. Peng Loh. Lab. of Neurochemistry & Neuroimmunology, NICHD, NIH, Bethesda, MD 20892

Pro-opiomelanocortin (POMC) is synthesized by the anterior and intermediate lobe (IL) of the pituitary. This prohormone is processed within the secretory vesicles (SV) to yield active hormones by cleavages at paired basic amino acid residues, the most common being Lys-Arg pairs. An enzyme that cleaves this prohormone specifically at the paired basic residues has been characterized and purified from bovine pituitary IL secretory vesicles. This enzyme, named pro-opiomelanocortin converting enzyme (PCE) is a M_r 70,000 glycoprotein (Y.P. Loh et al., Journal of Biological Chemistry, Vol. 260: 12, pp. 7194-7205, 1985), and has a pH optimum of between 4 and 5. One of the criteria for showing that this pro-hormone converting enzyme is physiologically relevant, is to demonstrate that the enzyme is secreted with the POMC derived peptide products in a co-ordinately regulated manner. Hence, the secretion of PCE together with α-MSH from bovine IL dispersed pituitary cells was investigated.

The dispersed bovine IL pituitary cells were incubated in medium with and without 8-Bromo-cyclic-AMP (cAMP: 3×10^{-3}M). The medium was collected and assayed for secretion of PCE and α-MSH. α-MSH was measured by radioimmunoassay and PCE activity was assayed in pH = 4.0 buffer at 37°C using ^{3}[H] phenylalanine labeled mouse POMC or ^{3}[H] arginine-labeled frog POMC as substrates. The processed products formed were identified by immunoprecipitation with ACTH and β-endorphin antisera, and by co-migration with known markers on acid-urea polyacrylamide gels. With cAMP treatment, secretion of PCE activity and α-MSH was 162.4 ± 3.4% and 142 ± 11% respectively, when compared to the controls (without cAMP). The secreted PCE was shown to cleave POMC primarily to 21-23K ACTH, 13K ACTH, 4.5K ACTH, 16K NH_2-terminal glycopeptide (K = 1000 daltons), β-lipotropin and β-endorphin peptides, similar to those synthesized by the mouse and frog IL in situ. This PCE activity was further characterized to have a pH optimum of between 4 and 5 and an inhibitor profile similar to that of the purified bovine IL PCE. These data provide additional support for the presence of PCE in bovine IL secretory vesicles and a role of this enzyme in the processing of POMC "in vivo".

11.4 CHARACTERIZATION OF PEPTIDES DERIVED FROM PRO-OPIOMELANOCORTIN (POMC) IN A NELSON'S SYNDROME PITUITARY TUMOR. C.W. Wilkinson, S.A. Galt*, T.S. Roberts* and S.R. Plymate*. Geriatric Res., Educ. & Clin. Ctr., American Lake VA Med. Ctr., Tacoma, WA 98493; Dept. of Clin. Invest., Madigan Army Med. Ctr., Tacoma, WA 98431; and Univ. of Washington, Seattle, WA 98195.

Several studies have suggested that pituitary adenomas removed from patients with Cushing's disease or Nelson's syndrome may contain greater proportions of more highly-processed forms of POMC-derived peptides than do normal human anterior pituitaries. By means of high-pressure liquid chromatography (HPLC) and radioimmunoassays (RIA) we have characterized specific molecular forms of POMC-derived peptides in tumor tissue from a 46-year old woman diagnosed as having Nelson's syndrome. The patient had been adrenalectomized bilaterally 16 years previously following a diagnosis of Cushing's disease and had been maintained on replacement doses of glucocorticoids. At the time of transsphenoidal surgery, skin pigmentation was excessive, and plasma concentration of immunoreactive ACTH was greater than 1700 pg/ml.

A portion of the tumor (64 mg wet weight) was frozen on solid CO_2 immediately after removal and was extracted by boiling in 1 N acetic acid, sonicating, and centrifuging for 30 min at 13,000 g. The supernatant was applied to ODS-silica cartridges, washed, and eluted with 80% acetonitrile (ACN), 20% aqueous 0.1% trifluoroacetic acid (TFA). The extract was vacuum-dried and resuspended in 0.1% TFA and applied to a 5 micron, C_{18} reverse phase HPLC column. Separations were attained with a gradient from 30% to 40% ACN against water while maintaining a constant TFA concentration of 0.1%. Eluate fractions were collected and assayed for immunoreactive beta-endorphin, gamma-endorphin, alpha-MSH, and ACTH.

Of the low molecular weight immunoreactive beta-endorphin that was extracted, approximately 80% co-eluted with unacetylated human beta-endorphin 1-31; small proportions co-eluted with forms of beta-endorphin 1-27 and 1-26. Virtually all of the gamma-endorphin immunoreactivity co-eluted with unmodified gamma endorphin (beta-endorphin 1-17). Immunoreactive alpha-MSH eluted in three peaks that appear to correspond to native alpha-MSH (32%), the des-acetyl form (18%), and the C-terminally glycine-extended form (50%). Less than 0.1% of the immunoreactive ACTH co-eluted with human ACTH 1-39; the remainder eluted in a broad peak coincident with corticotropin-like intermediate lobe peptide (CLIP).

POMC-derived peptides in this Nelson's syndrome tumor are not characteristic of those in normal human anterior pituitary.

11.5 REGULATION OF CARBOXYPEPTIDASE H BY PRODUCT INHIBITION. Vivian Y.H. Hook and Edmund F. LaGamma. Department of Biochemistry, Uniformed Services University of the Health Sciences, Bethesda, Maryland 20814 and Dept. of Pediatrics and Neurobiology & Behavior, SUNY at Stony Brook, N.Y.

Carboxypeptidase H(CPH) is one of several enzymes required for processing of peptide hormone precursors. In this study, regulation of CPH by its peptide products through a product and feedback inhibition mechanism was investigated. CPH activity in bovine adrenal medulla chromaffin granules and rat adrenal medulla homogenate was inhibited by the peptides (Met)- and (Leu)enkephalin, vasopressin, oxytocin, LHRH, substance P, and TRH, with oxytocin and ACTH 1-14 having the least effect, at concentrations of 2-20 mM. Inhibition by amidated peptide products (vasopressin, oxytocin, LHRH, substance P, and TRH) show that the final products of the precursor processing pathway can regulate CPH. In contrast, bovine serum albumin did not inhibit the enzyme. These levels of peptides are similar to known intragranular peptide concentrations, indicating that product and feedback inhibition of CPH may play a role in the control of neuropeptide synthesis. The kinetics of CPH peptide inhibition was characterized with enkephalin peptides, the most abundant neuroactive peptide products of CPH present in adrenal medulla. CPH in bovine and rat adrenal medulla showed identical kinetics. In addition, soluble and membrane bound forms of CPH from bovine chromaffin granules showed similar kinetics. The approximate K_I values for the proenkephalin-derived peptides (Met)enkephalin, (Leu)-enkephalin,(Met)enkephalin-Arg^6-Gly^7-Leu^8, and (Met)enkephalin-Arg^6Phe^7 were 12.0, 6.5, 7, and 5mM, respectively, with competitive inhibition kinetics. It is of interest that the K_I for (Met)enkephalin was significantly greater than those for the other enkephalin peptides. This may reflect the effects of higher intragranular concentration of (Met)enkephalin compared to (Leu)enkephalin, (Met)enkephalin-Arg^6-Gly^7-Leu^8, and (Met) enkephalin-Arg^6-Phe^7 since one proenkephalin molecule contains 4 copies of (Met)enkephalin and only one copy of each of the other enkephalin peptides. Thus, the products from one multivalent precursor molecule may equivalently inhibit CPH activity. Product inhibition of CPH and perhaps other processing enzymes may serve to limit the maximum peptide concentration within the secretory vesicle. These data support the hypothesis that precursor processing enzymes may play a significant role in the regulation of peptide production in neuroendocrine cells.

11.6 REGULATION OF TRH LEVELS UNDER DIFFERENT PHYSIOLOGICAL CONDITIONS: mRNA LEVELS AND PEPTIDASE ACTIVITIES. L. Covarrubias*[1], R.M. Uribe*, G. Ponce*, J.L. Charli*, and P. Joseph-Bravo* (SPON: A.M. Colome). [1]CINVESTAV (IPN) and Centro de Investigaciones sobre Ingeniería Genética y Biotecnología (UNAM), A.P. 70479, México, D.F. 04510, México.

A clear view of neuronal phenotype establishment not only requires our understanding of those molecular events which occur during development and differentiation within a cell, but also, of the molecular events due to cell interaction and extracellular factor response in the adult animal. On the other hand, homeostasis control involves a precise regulation of the amount of active components in extracellular fluid as well as their biosynthesis in the specific cell producers. Our interest has been focused on the understanding of these important phenomena. Thyrotropin Releasing Hormone (TRH) metabolism is a good study model since our actual knowledge and experimental tools will allow us to attack both cell phenotype and animal homeostasis establishment. As other neuropeptides, it is synthesized from a protein precursor an is degraded in vitro by two solubles (prolylendopeptidase and pyroglutamateamino peptidase I (PGAI)), one membrane bound (PGAII) and one serum enzyme (thyroliberinase).

We studied what might be two limiting stages of metabolism: TRH mRNA levels and TRH degradation. TRH mRNA levels and degrading enzymes' activities were measured under a variety of physiological conditions: hypo- and hyper-thyroidism, circadian cycle and ontogenic development. mRNA was quantified by Northern blot analysis using nick translated rat hypothalamic TRH cDNA kindly donated by R. Goodman (Lechan et al., Science, 231:159, 1986). TRH-mRNA increased 8x from day 5 to 30; during the circadian cycle it fluctuated 2x between the valley and the peak and in hypothyroid rats, a significant increase was also observed.

Degrading enzymes were also affected. Thyroliberinase activity was increased in the hyperthyroid rat. A 3-5 fold increase in PGAII was observed in the adenohypophysis of hyperthyroid rats. This was tissue specific and enzyme specific (no change for PGAI). Opposite changes were seen in the hypothyroid animal. These data suggest biosynthesis and degradation as regulatory events of TRH metabolism. (Supported in part by grants from CONACyT # ICSAXNA 030915 and # ICCBXNA 02144 and Fondo R. Zevada)

11.7 BIOSYNTHESIS OF MATURE THYROTROPIN RELEASING HORMONE BY AtT-20 CELLS TRANSFECTED WITH A CDNA ENCODING PREPROTRH.
Ping Wu*, Kevin A. Sevarino*#, Richard H. Goodman*#, Gail Mandel *# and Ivor M.D. Jackson. Division of Endocrinology, Brown University, Rhode Island Hospital, Providence RI 02902 and #Division of Molecular Medicine, Tufts New England Medical Center, Boston MA 02111.

The structure of rat hypothalamic preproTRH has been deduced by sequencing of preproTRH complementary DNA (cDNA) and consists of a 255 aa sequence containing 5 TRH progenitor sequences , Gln-His-Pro-Gly, demarcated by paired basic aa sequences. To study the post-translational processing and packaging of the precursor for thyrotropin releasing hormone (preproTRH) we have transfected AtT-20 cells with an expression vector containing preproTRH cDNA .

Cotransfection of AtT-20 cells, a mouse pituitary cell line with a neomycin resistance plasmid and an expression vector consisting of the CMV IE promotor (provided by Dr. John J. Kopchick) fused to preproTRH cDNA resulted in several clones of G418-resistant cells containing preproTRH mRNA by Northern blotting. These clones were shown both to contain immunoreactive TRH, (pGlu-His-Pro-NH_2, iTRH) and release iTRH into culture media. Untransfected AtT-20 cells do not contain detectable iTRH or preproTRH mRNA. One of these clones, aKS6.19, was studied further. Cells were extracted with 1M acetic acid/HCl pH 2,boiled and the extract lyophilized for TRH assay using a RIA which only recognizes fully processed TRH. After purification on solid-phase cartridges extracts were also assayed for immunoreactive pCC (ipCC), using an antiserum directed against the sequence Cys-Lys-Arg-Gln-His-Pro-Gly-Lys-Arg-Cys, which recognizes incompletely processed TRH progenitor sequences, and immunoreactive pYT (ipYT), directed against the N-terminal sequence 52-75 preproTRH. The estimated cell contents of iTRH, ipCC and ipYT were 6.88, 1.77 and 2.59 pmol equivalents synthetic standard/mg cell protein respectively. Sephadex G50 chromatography of cell extracts revealed qualitatively similar profiles of ipYT and ipCC to those seen in extracts of rat brain: namely two peaks of ipYT of MW ~3Kd and 7Kd and one of ipCC of ~6Kd. Release of iTRH by aKS6.19 cells was increased by potassium depolarization and by stimulation with dibutyryl cAMP which releases endogenous ACTH from AtT-20 cells (basal TRH release 273.3±5.67 pg/well/hr; 50mM K^+ 492.3±13.68; 5μM Bt_2 cAMP 399.3±26.4. Mean±SEM, n=3). Parallel increases in ipYT release were also observed.

We conclude that a cell line which can post-translationally process endogenous proopiomelanocortin to mature ACTH in secretory granules is also capable of synthesizing mature TRH when transfected with the cDNA for preproTRH. This suggests that the processing mechanisms for post-translational processing of peptide neuromodulators and hormones are not specific for particular peptide precursors. These transfected cell lines provide systems for further studies on the post-translational processing of proTRH.

11.8 HYPOTHYROIDISM INCREASES proTRH mRNA AND IMMUNOREACTIVE proTRH IN THE RAT HYPOTHALAMIC PARAVENTRICULAR NUCLEUS (PVN).
R.M. Lechan, T.P. Segerson#, H. Mobtaker#, G. Burke#, P. Wu#, I.M.D. Jackson, H. Wolfe#, Div. of Endocrinology and Dept. of Pathology, New England Med. Ctr., Boston, MA 02111 & Div. of Endocrinology, Rhode Island Hospital, Providence, R.I. 02902

Recent studies from our laboratories demonstrate that hypothyroidism increases proTRH mRNA in extracts of the PVN, the origin of the TRH-tuberoinfundibular system. To further characterize this response, we have performed semi-quantitative in situ hybridization histochemistry and immunocytochemistry to detect proTRH mRNA and TRH prohormone in hypothyroid rats.

Male, Sprague-Dawley rats were studied after three weeks of hypothyroidism, induced by an initial i.p. injection of propylthiouracil (0.01 mg/g) followed by p.o. methimazole (0.02%) in their drinking water. Hypothyroidism was confirmed by measurement of serum TSH. The brains were fixed by intracardiac perfusion with 4% paraformaldehyde and the region containing the PVN sectioned coronally or horizontally on a vibratome. 20um sections were adhered to glass slides and hybridized with a ^{35}S-labeled proTRH cRNA probe transcribed from the rat proTRH cDNA. The emulsion-coated slides were developed after 5 d of exposure and visualized by darkfield microscopy. The density of silver grains accumulating over each hybridized neuron in the PVN was assessed by computer image analysis, normalized to the mean density per cell over hybridizing neurons in the lateral hypothalamus. Data were expressed as the ratio of individual PVN cell density to mean lateral hypothalamic density versus number of cells. Immunocytochemistry was performed on 50 um free floating sections by the ABC technique using antiserum #351 (1:1000) which recognizes intact or partially processed proTRH.

In control animals, hybridization was seen in the medial and anterior parvocellular divisions of the PVN with a tendency for more intense hybridization in the medial division. The majority of medial parvocellular neurons had ratios of density between 0 and 2 (median: 0.9). In contrast, medial parvocellular neurons in hypothyroid animals showed increased hybridization, with a density ratio range of 0-10 (median: 4.3). Immunocytochemistry showed a marked increase in the accumulation of immunoreactive proTRH in medial but not anterior parvocellular neurons in hypothyroid, but not control animals.

We propose that the simultaneous increase of proTRH mRNA and immunoreactive proTRH in medial parvocellular neurons of the PVN suggest that hypothyroidism induces both transcription and translation of the TRH prohormone. The selective response of medial, but not anterior, parvocellular neurons to hypothyroidism provides further evidence that these cells may be under different regulatory control.

11.9 **PROCESSING OF THE APLYSIA EGG LAYING HORMONE PRECURSOR.**
J.M. Fisher*, R. Newcomb* and R. H. Scheller (SPON: S. Levine). Dept. Biol. Sci., Stanford Univ., Stanford, CA 94305.

The characteristic egg laying behavior of Aplysia californica is thought to be mediated by two clusters of neurosecretory cells called the bag cells. These neurons, which sit on top of the abdominal ganglion, fire preceeding each egg laying episode and release a battery of neuropeptides into the sheath surrounding the ganglion as well as the hemolymph. At least four of these peptides (γ, β, α-BCP and ELH) have distinct biological activities and are produced through proteolytic cleavage of a single 28 kd prohormone. DNA sequence analysis has revealed that the ELH preprohormone contains a signal sequence, eight dibasic putative cleavage sites and numerous single arginine residues. Two system HPLC analysis of crude bag cell homogenates followed by amino acid compositions of the resulting pure peptides has shown that at least seven of the eight dibasic residues, the signal sequence and one single arginine residue are used as proteolytic cleavage sites.

The processing pathway of the ELH precursor is presently under investigation. Intermediates in the processing pathway have been purified by HPLC and are being characterized chemically by amino acid analysis, Edman degradation and tryptic mapping. A series of synthetic peptides from various regions of the precursor have been used to generate antisera. These antibodies are being used for immunoprecipitation studies of the intermediates in the processing pathway as well as for immuno EM investigations of the subcellular localization of the antigens. Pulse chase studies using tritiated amino acids (Phenylalanine, Leucine and Isoleucine) have shown that the amino terminal 2/3 of the precursor is processed more slowly than the carboxyl terminal 1/3 of the molecule; this results in a relatively long lived (apparently 18 kd) intermediate which contains γ, β, and possibly α-BCP as well as several shorter lived, smaller intermediates which all contain ELH. The pathway and kinetics of ELH precursor processing may influence the function of its bioactive peptides in transmission.

11.10 HETEROGENEITY AMONG ACIDIC PEPTIDES ASSOCIATED WITH NEUROSECRETORY VESICLES IN THE BAG CELLS.
S. Arch, M. Mendelson* and M. Deal.* Biological Laboratories, Reed College, Portland, OR 97202.

Use of ^3H-Leu for biosynthetic labeling of bag cell neuropeptides results in the resolution of two major peaks of radiolabel when the contents of a neurosecretory vesicle (NSV) fraction are analyzed by isoelectric focusing. These are the acidic peptide (AP) and the egg-laying hormone (ELH). We have been interested to determine which other peptides are also associated with the NSV fraction. On the basis of the reported nucleotide sequence, we chose to label bag cells with ^3H-Phe since neither the ELH nor the putative AP sequences is illustrated as containing a Phe residue. The IEF profile of Phe-labeled NSV differs in several respects from that obtained with Leu labeling. However, although there is relatively little labeling at the pI 9.3 position occupied by ELH, the pI 4.8 position associated with AP is strongly labeled. To characterize the Phe-labeled acidic species further, we used the pI 4.8 band from IEF as the starting material for SDS-PAGE separation. This selective 2-D approach resolved the Phe-labeled material into two closely spaced peaks of radiolabel at M_r's of 5.6 kD and 4.5 kD. The 5.6 kD peptide is predominant in this case whereas with Leu-labeled material, the 4.5 kD peptide is the major band. If both these peptides are derived from the neuropeptide precursor, the larger is likely to arise from the excision of the α- and γ-BCP's from a common intermediate. We have called this AP-39 to distinguish it from the 27 residue C-terminal AP sequence (AP-27). On the grounds of its level of labeling with the two amino acids, we are led to assume that the 4.5 kD band represents AP-27 and that this peptide contains Phe. Although both AP's are found in an NSV fraction, the presence of membranous contaminants in the fraction preclude the assumption that they are both within the NSV. We, therefore, determined their solubility in response to a range of hyposmolal shocks. The outcome of these experiments disclosed that they show similar solubilities to hyposmolal challenge, thereby indicating that they are enclosed within organelles with the same lability, presumably NSV. The implication from these observations is that the BCP's may be loaded into NSV in an intermediate form and that they are either cosequestered with AP-27 or occupy different NSV's of the same osmotic fragility.

11.11 EXPRESSION OF NEUROPEPTIDE Y mRNA AND PEPTIDE IN MEGAKARYOCYTES: ENHANCED LEVELS IN CERTAIN AUTOIMMUNE MICE. H. Persson*, A. Ericsson*, D. Larhammar, M. Schalling*[1], K.R. McIntyre*[2], J.M. Lundberg*[3], K. Seroogy[1] and T. Hökfelt*[1]. (SPON: B. Green). Depts. Medical Genetics and Immunology[2], Uppsala University, Uppsala, Sweden and Depts. Histology[1] and Pharmacology[3], Karolinska Institute, Stockholm, Sweden

Neuropeptide tyrosine (NPY) is a potent vasoconstrictor agent with a wide distribution in the central and peripheral nervous systems. We demonstrate that high levels of rat NPY mRNA are also found in peripheral blood cells, bone marrow, lung and spleen. Radioimmunoassay revealed high levels of NPY peptide in these tissues. In mice, splenic NPY mRNA and immunoreactive peptide levels differed extensively between strains and were greatly elevated in several strains (NZB, NZBxW and BXSB) that develop a disease resembling human systemic lupus erythematosus. Like the rat, the NZB mouse showed a high content on NPY mRNA in peripheral blood cells and bone marrow. Immunohistochemical staining revealed NPY-like immunoreactivity in large cells morphologically identifiable as megakaryocytes in rat bone marrow and the spleen of the NZB strain. Expression of NPY mRNA in megakaryocytes was confirmed by in situ hybridization. These results demonstrate a synthesis of NPY in megakaryocytes, implying that NPY can be released from platelets and function as a vasoconstrictor during blood vessel damage. In addition, the elevation of splenic NPY in certain autoimmune mouse strains adds to the list of abnormalities associated with these strains.

RETINA I

12.1 RECTIFYING TRANSMISSION AT THE ROD OUTPUT SYNAPSE OF TIGER SALAMANDER RETINA. M. Wilson[1], S. Borges[1], D. Attwell*[2] and S. Wu[3]. [1]Department of Zoology, University of California, Davis, CA 95616, [2]Department of Physiology, University of London, WC1E 6BT, England, [3]Cullen Eye Institute, Baylor College of Medicine, Houston, TX 77030.

Photoreceptors respond to light with a graded hyperpolarization up to 25 mV in amplitude. It has been conventionally assumed that all of this response range is transmitted through the photoreceptor output synapse to second order neurons in the visual system. We have examined the voltage input-output relation of rod to horizontal cell transmission using three different approaches based on simultaneous intracellular recordings from pairs of rods and horizontal cells. All three approaches reveal strong rectification in which only signals coded within 5 mV of the rod dark potential are effectively transmitted to postsynaptic horizontal cells. The gain is high for very small hyperpolarizations (7.2 ± 4.9, mean ± S.D., n = 6), but is much larger for larger rod hyperpolarizations. The whole input-output relation can be approximated by an exponential curve, whose slope decreases e-fold for each 2.1 mV of rod hyperpolarization (2.10 ± 0.44, n = 6). The limitation of signal transmission to the first 5 mV of the rod response is consistent with the reported voltage-dependence of the calcium current in rods (Bader, C.R., Bertrand, D. & Schwartz, E.A., J.Physiol.Lond.,331:253,1982), if it is assumed that calcium influx promotes transmitter release.

What accounts for this apparent paradox that rods have a 25 mV response range, while signals greater than 5 mV in amplitude are clipped ? We propose that the properties of the rod synapse are related to two other poorly related aspects of early visual processing viz. the mixing of signals that occurs by virtue of the strong electrical coupling of adjacent rods, and by virtue of the weak electrical coupling of adjacent rods and cones. We argue that the effect of both kinds of photoreceptor coupling is to offset the limitations imposed by the transmission properties of the rod synapse. We predict that the strengths of both sorts of coupling are quantitatively linked to the relationship between the rod response range and the synapse operating range. Consideration of the strength of coupling for phototreceptors in the salamander retina shows that these predictions are upheld.

12.2 **THE EFFECT OF L-GLUTAMATE ON THE ANOMALOUS RECTIFIER POTASSIUM CONDUCTANCE OF ISOLATED HORIZONTAL CELLS FROM THE WHITE PERCH RETINA.** I. Perlman*, A.G. Knapp and J.E. Dowling. The Biological Laboratories, Harvard University, Cambridge, MA 02138.

Isolated horizontal cells from the white perch retina contain at least three kinds of voltage-dependent potassium channels (E.M. Lasater, J. Neurophysiol. 55, 499, 1986) including the so-called anomalous (or inward) rectifier (AR) channels that open upon hyperpolarization of the membrane. L-glutamate, a putative neurotransmitter between cones and horizontal cells, may inhibit the inward rectifier (A. Kaneko & M. Tachibana, J. Physiol. **388**, 169, 1985). This effect produces a net outward current which opposes current flowing inward through glutamate-gated channels, and thus reduces the apparent glutamate current at hyperpolarized potentials. We have used whole-cell recording techniques to study the effect of L-glutamate on cone horizontal cells isolated from the white perch retina. In every cell studied, the I-V curve recorded in standard Ringer's showed a pronounced inward current at potentials below about -70 mV. This current was identified as I_{AR} based on its voltage-dependence, its variation with changes in external potassium concentration, and its blockade by cesium ions. Pressure-ejection of L-glutamate (100 - 200 µM) evoked an inward current that reversed at about +5 mV and reached a maximum at -60 to -70 mV. At more negative potentials, the inward current decreased and in many cases a net outward current was observed. This effect was due to a reduction in I_{AR}, because in the presence of external Cs^+ application of glutamate elicited an inward current that increased linerly as the holding potential was made more negative. To our surprise, however, pressure ejection of Ringer's alone also appeared to reduce I_{AR}. Moreover, when the recording chamber was perfused rapidly with Ringer's, I_{AR} was again reduced, and the I-V relation for glutamate became similar to that seen in the presence of Cs^+. To explain these observations, we suggest that, in the absence of perfusion, potassium accumulates in an unstirred layer around the cells and enhances I_{AR}. Pressure ejection lowers the concentration of postassium around the cells, thus reducing I_{AR}, and perfusion prevents the local accumulation of potassium. We find no evidence that L-glutamate itself directly affects the anomalous rectifier.

12.3 **PROPERTIES AND DOPAMINE SENSITIVITY OF A VOLTAGE-DEPENDENT SODIUM CONDUCTANCE IN ISOLATED HORIZONTAL CELLS FROM THE WHITE PERCH RETINA.** A.G. Knapp, T. Roe* and J.E. Dowling. The Biological Laboratories, Harvard University, Cambridge, MA 02138.

Isolated horizontal cells from the white perch retina contain a voltage-dependent, TTX-sensitive sodium conductance, I_{Na} (E.M. Lasater, J. Neurophysiol. **55**, 499, 1986). The function of this conductance is unclear, as horizontal cells do not exhibit sodium-dependent action potentials in vivo. It has been suggested that I_{Na} may enable horizontal cells to depolarize rapidly in response to the offset of illumination; sodium influx may also affect the release of GABA from these neurons (S. Yazulla & J. Kleinschmidt, Brain Res. **263**, 63, 1983).

We have used whole-cell voltage clamp techniques to examine additional properties of I_{Na} in cone horizontal cells isolated from the white perch retina. Under conditions that minimize current flow through other ionic conductances, I_{Na} appears as a transient inward current in response to step depolarizations beyond -50 mV, reaches a maximum amplitude near 0 mV and has an extrapolated reversal potential near +40 mV. Both the activation and the inactivation of g_{Na}, the conductance underlying I_{Na}, were found to be strongly voltage-dependent, with half-maximal values at approximately -25 mV and -60 mV, respectively. Double-pulse experiments demonstrated that the time-constant of inactivation was also voltage-dependent. These characteristics are very similar to those of I_{Na} in other types of neurons.

In the intact perch retina, dopamine (DA) is released from interplexiform cells onto cone horizontal cells, where it acts through its intracellular second messenger cAMP to modulate several aspects of neuronal function. We have found that pressure ejection of DA onto isolated cone horizontal cells consistently reduced I_{Na}. In 65% of cells tested, DA reduced I_{Na} by more than 20%, and in some cases it was possible to abolish I_{Na} altogether. The suppression of I_{Na} required relatively high concentrations of DA ($\geq$ 400 μM) and occured more rapidly (maximal effect within 10 sec) and lasted a shorter time (recovery within 90 sec) than those effects of DA known to be mediated by cAMP. Moreover, the reduction in I_{Na} could not be blocked by antagonists of DA, nor could it be mimicked by agents that promote the accumulation of cAMP in horizontal cells. Thus, this action of DA appears to be a nonspecific one, perhaps involving a direct interaction between DA and the sodium channel molecules or adjacent portions of the horizontal cell membrane. Because of the relatively large doses of DA required to inhibit I_{Na}, we doubt that this phenomenon has any physiological significance. It does, however, constitute a potential pitfall in experiments where high concentrations of DA are applied to neural tissue.

12.4 DOPAMINE MIMICS LIGHT-ADAPTATION IN HORIZONTAL CELLS OF THE XENOPUS RETINA. P. Witkovsky, S. Stone, J. Besharse*. Dept. Ophthal., New York Univ. Med. Ctr., NY, NY 10016 and Dept. Anat. & Cell Biol., Emory Univ. Sch. Med. Atlanta GA 30322

The axon-bearing horizontal cell of the Xenopus retina receives direct synaptic inputs from green-sensitive rods and red-sensitive cones. Intracellular recordings from horizontal cells showed that rod- and cone- initiated signals could be distinguished on the bases of waveform, operating range of light intensity and spectral sensitivity. The balance of cone vs. rod input normally is dictated by the daily light/dark cycle. We found, however, that even after prolonged dark-adaptation, addition of 2-10 μM dopamine to the superfusate evoked changes usually associated with light adaptation: rod input was suppressed, cone input became larger and faster. In addition, the horizontal cell depolarized by 9.1 ± 3.8 mV. Dopamine- induced effects took 10-20 min to appear; more than 30 min in dopamine-free Ringer was required to restore the dark-adapted condition. Multiple cycles of dopamine-induced "light-adaptation" followed by dark-adaptation in dopamine-free Ringer could be induced in single horizontal cells. Intracellular recordings from rods demonstrated that rod threshold and V_{max} were not altered by exposure to dopamine.

Dopamine effects on the horizontal cell were imitated by the D_2 agonist LY 171555 at 1 μM. The D_1 agonist SKF 38393 mimicked light-adaptation at 10-20 μM. Its action was blocked by an equimolar concentration of the D_1 antagonist, SCH 23390. Dopamine effects were not blocked either by SCH 23390 or the D_2 antagonist spiroperidol alone, but in combination the two antagonists suppressed completely the light adaptive action of dopamine. The light-evoked responses of horizontal cells were not modified by nor-epinephrine, epinephrine or serotonin (each at 10 μM). These pharmacological data indicate that dopamine works through a combination of D_1 and D_2 dopamine receptors.

Dopamine actions in distal retina that might play a role in the present results are: (1) cone retinomotor movements (Pierce & Besharse), (2) horizontal cell uncoupling (Piccolino et al.), and (3) augmented conductance change induced in the horizontal cell membrane by the putative cone transmitter, glutamate (Knapp & Dowling). The first of these depends on a D_2 receptor and takes 15-30 min to complete. Cone elongation under light-adapted conditions can be elicited by spiroperidol. We found that 5-20 μM spiroperidol slowed the time course and reduced the amplitude of cone-initiated signals. The second and third mechanisms both are mediated by a D_1 receptor. We observed that exposure to dopamine narrowed the receptive field profile of the horizontal cell. Since the length constant $\lambda = (R_m/R_s)^{1/2}$, this result could be expected from either mechanism 2 (increase in R_s) or mechanism 3 (decrease in R_m), or both. The depolarization evoked by dopamine would be expected of mechanism 3 but not of 2.

The available evidence indicates that, in the Xenopus retina, dopamine synthesis and release occur at a greater rate in daytime than at night. Thus, our data suggest that dopamine plays an important role in the daily cycle of light and dark adaptation.

12.5 cAMP AND cGMP DECREASE THE CONDUCTANCE OF ELECTRICAL SYNAPSES BETWEEN HORIZONTAL CELLS OF THE CATFISH RETINA S.H. DeVries* and E.A. Schwartz* (SPON: J. Art) Dept. of Pharm. & Physiol. Sci., The University of Chicago, Chicago IL 60637

Cyclic nucleotides are claimed to regulate the conductance of gap junctions in several tissues. Their effect depends upon the tissue studied. An increase in cAMP may play a role both in the glucagon-induced increase in coupling observed in cultured rat hepatocytes[1] and the dopamine-induced decrease in coupling between teleost retinal horizontal cells.[2] These opposing actions of cAMP suggest an underlying mechanistic diversity. We have investigated the mechanism whereby coupling is regulated in horizontal cells of the teleost. Retinas of the channel catfish (*Ictalurus punctatus*) were dissociated and cultured. Electrical synapses often formed when processes from neighboring cone horizontal cells were closely apposed. Trans-synaptic conductance was measured by controlling the voltage of each cell in a pair with either two switching voltage clamps or two patch pipette voltage clamps. Micropipettes were filled with (in M) KAc, 3; KCl, 1. Patch pipettes contained (in mM) K-aspartate, 65; Na-aspartate, 10; CsCl, 10; HEPES, 10; EGTA, 10; $CaCl_2$, 1; pH 7.0. Synaptic conductances of 10-100 nS were observed with either technique and frequently maintained for more than one hour without significant rundown. Coupling was decreased more than 90% following brief exposures (100 ms) to dopamine (100 μM) or the D1 agonist, fenoldopam (10 μM). Uncoupling occured within 30-60 sec; recoupling required 10-20 min. Neither dopamine nor fenoldopam elicited a membrane current. Applications of IBMX (100 μM) or forskolin (40 μM) transiently reduced coupling by the same amount as dopamine. These experiments indicate that dopamine may uncouple by raising the intracellular concentration of a cyclic nucleotide. Cyclic nucleotides were introduced into one cell of a pair via a third patch pipette. First the conductance between a pair was measured with two pipettes. Then, the membrane occluding the tip of the third pipette was ruptured allowing cAMP to diffuse into the cell. The abrupt introduction of 1-0.1 mM cAMP decreased junctional conductance 50-80% in less than 1 min. Thereafter, a reduced conductance was maintained. Upon withdrawing the third pipette from the cell surface, full coupling resumed in less than 2 min. In similar experiments, 0.1 mM cGMP reversibly reduced junctional conductance 10-40% and 1-0.1 mM 8-Br cAMP irreversibly uncoupled. 5'-AMP (1 mM) had no effect on junctional conductance.

12.6 **TREATMENTS WHICH UNCOUPLE TELEOST RETINAL HORIZONTAL CELLS PROMOTE PHOSPHORYLATION OF A MEMBRANE PROTEIN.** D.G. McMahon, and J.E. Dowling, The Biological Laboratories, Harvard University, Cambridge, MA. 02138.

The neuromodulator dopamine, released from interplexiform cells in the teleost retina, has been shown to have profound effects on the physiology of cone horizontal cells. For example, treatment of white perch (Roccus americana) retinas with dopamine or prolonged darkness reduces the electrical coupling between cone horizontal cells. In isolated pairs of horizontal cells dopamine, and its intracellular second messenger cAMP, uncouple these cells by reducing the junctional conductance, presumably by modifying the gap junctional channels. Since cAMP usually acts through protein phosphorylation we have sought to identify the phosphoprotein targets of this pathway as a first step in understanding the biochemical mechanism by which dopamine and cAMP modulate junctional conductance.

Protein phosphorylation in the perch retina was examined under three conditions which uncouple horizontal cells. Addition of cAMP (1-100μM) to retinal homogenates consistently induced phosphorylation of a protein with an apparent molecular weight of 31Kda on SDS-PAGE. Phosphoproteins of 15Kda, 21Kda, 47Kda, and 70Kda were less consistently observed. Incubation of isolated retinas with dopamine (100μM) resulted in an increase in the phosphorylation of 31Kda and 35Kda proteins. These effects were blocked by the dopamine antagonist haloperidol (100μM). Treatment of retinas with prolonged darkness increased the phosphorylation of the 31Kda protein but decreased that of the 35Kda protein compared with retinas maintained in dim room light.

Two results suggest that the 31Kda protein, which is present in plasma membrane fractions, is of horizontal cell origin. Homogenates enriched for horizontal cells show increased amounts of the 31Kda phosphoprotein compared with homogenates enriched for retinal cells other than horizontal cells. In addition, application of the β-adrenergic agonist isoproterenol (100μM), which increases cAMP levels in the retina but not in horizontal cells, does not phosphorylate the 31Kda protein.

Taken together these results suggest that the 31Kda protein resides in the horizontal cell plasma membrane, and is a target of dopamine's neuromodulatory effects. This protein may be a gap junctional protein, or a protein involved in the regulation of gap junctions. Future experiments will focus on more precise identification of the cellular origin of this protein and its role in modifying electrical coupling.

12.7 IMMUNOHISTOCHEMICAL LOCALIZATION OF CYCLIC AMP IN THE TELEOST RETINA: EFFECTS OF DOPAMINE AND PROLONGED DARKNESS. L.H.Y. Young* and J.E. Dowling. (SPON: A. Adolph) Mass. Eye and Ear Infirmary, Boston, MA 02114 and The Biological Laboratories, Harvard University, Cambridge, MA 02138.

In the fish retina, dopaminergic interplexiform cells serve as centrifugal neurons; they receive input from amacrine cells in the inner plexiform layer and they synapse onto cone horizontal cells in the outer plexiform layer. Horizontal cells are inhibitory interneurons that mediate the antagonistic surround responses of bipolar cells and cone photoreceptors. Many studies have indicated that the lateral inhibitory effects in the outer plexiform layer are modulated by the interplexiform cells and dopamine; however, these studies do not provide any information concerning the mechanisms underlying the effects of dopamine on horizontal cells. In 1981, using enriched horizontal cell fractions prepared from Ficoll sedimentation gradients, Van Buskirk and Dowling provided evidence that dopamine receptors on horizontal cells are linked to adenylate cyclase.

The present study provides information on the immunohistochemical localization of cyclic AMP in the white perch retina. Using a goat anti-cyclic AMP antiserum (gift from Dr. D. O'Brien) with an indirect immunofluorescent staining technique, staining was localized mostly to the outer nuclear layer, proximal inner nuclear layer and ganglion cells in retinas dark-adapted for 30 min. In the distal inner nuclear layer where the cone horizontal cells are located, only faint staining was noted in these short term dark-adapted retinas. Immunofluorescent staining of retinas preincubated for 10 min with 2 mM IBMX followed by a 15 min incubation with 200 uM dopamine showed a marked increase in staining in the distal inner nuclear layer, i.e. in the region of the horizontal cells. Similarly, though to a lesser extent, there was increased staining in this layer following prolonged (> 2 hours) dark adaptation. The staining was blocked by preabsorbing the antiserum with cyclic AMP (Sigma) indicating that the staining was specific to cyclic AMP. These experiments directly localize cyclic AMP to the region of horizontal cells in the fish retina and they provide further evidence that both dopamine and prolonged darkness promote the accumulation of cyclic AMP in the horizontal cells.

12.8 **MODULATION OF CONE INPUTS TO HORIZONTAL CELLS IN THE TIGER SALAMANDER RETINA.** Xiong-Li Yang * and Samuel M. Wu (SPON: W. Strittmatter). Cullen Eye Institute, Baylor College of Medicine, Houston, Texas 77030.

We have investigated the effects of illumination on the synaptic inputs from photoreceptors to horizontal cells (HCs) in the tiger salamander (Ambystoma tigrinum) retina after prolonged dark adaptation (at least 2 hours). Under dark-adapted conditions, HCs receive inputs from both rods and cones. The HC response to 500 nm test flash was predominantly mediated by the rods and that to 700 nm flash was predominantly mediated by the cones. In the presence of dim background illumination, the HC response to 700 nm flash was larger and faster than that recorded under dark-adapted condition. This response enhancement occurred when the background light preceded the test flash by 50 msec and the response amplitude reached its maximum level 2-5 seconds after the onset of the background illumination. The response amplitude in HCs increased with the degree of hyperpolarization in rods. These results suggest that cone signals in HCs are probably suppressed by the rods in darkness, and background illumination reduces this suppression and results in an enhancement of cone signals in the HCs. In addition to the response enhancement resulted from background illumination, HC response to 700 nm flash became larger and faster after the cessation of prolonged light exposure. In contrast to the short-term response enhancement resulted from dim background illumination, this long-term response enhancement in HC required exposure of brighter light for at least 10 minutes to reach its maximum amplitude. It is likely that a cone-mediated mechanism in the tiger salamander retina is responsible for the long-term enhancement of the cone signals in the HCs.

12.9 GREEN-LIGHT MODULATES THE COUPLING BETWEEN NON-UNIVARIANT MONOPHASIC HORIZONTAL CELLS IN CARP (*Cyprinus carpio*) RETINA. M. Kamermans*, B. v. Dijk*, R.C.V.J. Zweypfenning* and H. Spekreijse*. (SPON: European Neuroscience Association) Lab. of Medical Physics, Univ. of Amsterdam, Meibergdreef 15, 1105 AZ Amsterdam-Zuidoost, The Netherlands.

In carp retina, two types of monophasic horizontal cells have been described (Dijk B. van, thesis Univ. of Amsterdam, 1985): the Univariant Monophasic Horizontal Cells (UMHC) and the Non-univariant Monophasic Horizontal Cells (NMHC). UMHCs receive input from red-sensitive cones exclusively, while NMHCs receive input from both red-sensitive and green-sensitive cones. Experiments were designed to reveal the nature of the input to the NMHCs from the green-sensitive cones.

Two types of experiments were used:

A) The dependence of the response amplitude on test spotdiameter was compared to the dependence of the response amplitude on the position of a slit projected in the receptive field.

B) The influence of a steady red and of a steady green background on the responses to red and green test flashes were recorded.

The results found can be explained only by assuming that the resistance of the GAP-junctions between the NMHCs was increased by the green-sensitive cone system. At high intensities of a green background, receptive field profiles will be smaller and feedback more pronounced.

Conclusions: A) The receptive field organization in the horizontal cell layer is not static but changes with the adaptation state.

B) The green-sensitive cone system can modulate the coupling resistance of NMHCs.

12.10 PDA AND BICUCULLINE RELEASE ^{3}H-DOPAMINE IN THE TURTLE RETINA. S.D. Critz and R.E. Marc, Sensory Sciences Ctr., Graduate School Biomedical Sciences, Univ. of Texas, Houston, Texas. 77030.

The circuitry of dopaminergic cells in the retina of the red-eared turtle, Pseudemys scripta elegans, is being studied by observation of the effects of putative neuro-active substances on dopamine release. Eyecups from turtles (lighting regimen: 12 hr. dark/12 hr. light) were removed in dim red light 4 hrs. after light onset, placed in an experimental chamber in darkness, and perfused with turtle bicarbonate buffer (110 mM NaCl, 22 mM $NaHCO_3$, 2.5 mM KCl, 2.0 mM $MgCl_2$, 2.0 mM $CaCl_2$, 5 mM glucose, 0.025 mM pargyline, and 0.010 mM ascorbate) until stable ERG's were observed. The eyecup was incubated in ^{3}H-dopamine (0.2 uM) for 12 mins. and perfusion resumed to washout label not taken up by the cells. After 1-1.5 hrs. putative retinal transmitters, their antagonists, and other bioactive substances were added to the perfusate and effects determined by liquid scintillation counting of collected fractions.

The glutamate antagonist PDA, (2,3-piperidine dicarboxylic acid) has a potent effect on ^{3}H-dopamine release. The concentration used, 4 mM, is reported to block the response of hyperpolarizing bipolar cells to light (Slaughter, M.M. and R.F. Miller, Science, 219:1230-32, 1983) and thus is in the physiological range. Furthermore this dose is required to abolish the "d" wave of the ERG. Other glutamate analogs: APB (20 uM) and kainate (100 uM) had no effect on dopamine release.

The GABA antagonist, bicuculline (100 uM) caused release of dopamine in turtle, similar to results reported in goldfish (O'Conner et al., J. Neurosci., 6:1857-65, 1986). However, this release appears to be calcium-independent.

Other substances tested: acetycholine, carbachol, strychnine, GABA, muscimol, nipecotic acid, and exogenous dopamine, showed no effects on dopamine release.

These findings support a proposed tonic inhibition of dopaminergic cells by GABA (Marshburn, P.B. and P.M. Iuvone, Brain Res., 214:335-47, 1981), and suggest an excitatory input on certain GABA amacrine cells.

12.11 PROLONGED DEPOLARIZING RESPONSES IN TURTLE CONES EVOKED BY STIMULATION OF THE RECEPTIVE FIELD SURROUND.
Wallace B. Thoreson, Jon Gottesman and Dwight A. Burkhardt. Departments of Physiology and Psychology, University of Minnesota, Minneapolis, MN 55455.

Intracellular recordings were made from red- and green-sensitive cone photoreceptors in the retina of the turtle (Psuedymys scripta elegans) , maintained via a recirculating, modified tissue culture medium. Depolarizing influences arising from the surround of the cone's receptive field were isolated and studied in quantitative detail by stimulating the retina with annular flashes in the presence or absence of steady central spots. Two prominent types of responses were observed: 1) a prolonged depolarization which apparently has not been reported heretofore and 2) depolarizing spikes. The spikes, resembling those described by Piccolino and Gerschenfeld [Proc. Roy. Soc. Lond. B 206, 1980], were 200-300 msec in duration and not strictly all-or-none. With increasing annulus intensity, the amplitude of the spike response increased abruptly over a narrow intensity range. At somewhat higher intensities, the spike was followed by, and apparently triggered, a prolonged depolarization of 15-20 mv in amplitude.

In response to either short (0.4 sec) or long (20 sec) flashes, the prolonged depolarization was maintained at a level above the cone's resting membrane potential for some 5-10 sec and then abruptly returned to the level which prevailed prior to the flash. Injection of a brief depolarizing current pulse (0.01 to 0.1 nA) evoked a prolonged depolarization virtually identical to that evoked by light, thus showing that the response is intrinsic to the cone cell. Whether evoked by light or current, the prolonged depolarization markedly attenuates the cone's response to an incremental light flash and also has a remarkably long refractory period of 1-2 min during which neither current nor light can reinstate a full-blown depolarization.

These and additional findings have implications for the role of surround antagonism in photoreceptor mechanisms of light adaptation and color opponency.

12.12 THE ROLE OF HORIZONTAL CELL COUPLING FOR SUPPRESSIVE ROD-CONE INTERACTION.
T. E. Frumkes, N. Denny*, M. Sliwinski*, and T. Eysteinsson. Dept. of Psychology, Queens College of CUNY, Flushing, N. Y. 11367

Diffuse, rod-stimulating background fields markedly enhance cone-mediated responses to spatially focal, rapidly flickering stimuli. We have called this effect suppressive rod-cone interaction (SRCI) and have documented it by means of intracellular recording from cones and many second and third order neurons, and by means of ERG and psychophysical procedures. Last year at these meetings, we reported that SRCI is blocked by pharmacological agents which block photic responses of horizontal cells (HCs). In the present study, we examined the influence of HC electrical coupling on SRCI by applying the analysis of Lamb (1976). In these experiments, we either recorded intracellularly from an amphibian cone or second order neuron, or we used psychophysical procedures in human subjects: we assessed the influence of the size, shape, and retinal position of both stimuli upon the extent of SRCI. We assume that the background field acts by decreasing a tonic rod-inhibitory dark signal which is mediated by horizontal cells (HCs), and the spatial limitations for SRCI reflect the space constant of the electrically coupled HC network. Regardless of species and specific experimental procedures, our analysis suggests that SRCI is determined by a mechanism with a space constant of 400-550 um. In amphibian neurons, this value is often larger than that directly determined with a cone-stimulating slit in a recorded neuron: but this range agrees with that reported for HC axon terminals, the cellular process most likely to feedback onto cones.

12.13 MOLECULAR CHARACTERIZATION OF GENES REQUIRED FOR DROSOPHILA PHOTOTRANSDUCTION.
C. Montell,* C. Zuker* and G. Rubin. Biochemistry Dept., Univerity of California, Berkeley, CA 94720.

The fruitfly, *Drosophila melanogaster*, is an excellent system in which to both study the roles of previously identified photoreceptor cell proteins and to isolate and characterize the roles of genes and proteins important in phototransduction that have not yet been identified in any metazoan system. There are two important advantages of studying phototransduction in the fruitly. 1) Many of the relevant genes have already been genetically identified. 2) DNA sequences can be stably and efficiently introduced into the genome by P-element mediated germline transformation. Therefore, it is possible to identify the DNA sequence encoding a genetically defined locus by complementing the mutant phenotype following introduction of the gene into the genome by germline transformation. We are interested in identifying the DNA sequences encoding these phototransduction genes and characterizing the roles of the coresponding proteins.

Using the above approach, we have identified two genes, *trp* (Montell, C. et al., *Science*, 230:1040, 1985) and *ninaC*, by complementing the mutant phenotypes. Both genes are expressed beginning late in development and encode proteins localized specifically to the photoreceptor cells. The *ninaC* proteins share significant homologies to two types of proteins which define two nonoverlapping domains. One domain shares amino acid homology to protein kinases and the other to all of the globular head region of the myosin heavy chain. The *trp* protein is not homologous to previously sequenced proteins but displays a number of very striking internal repeats. Continuing studies directed at identifying the specific functions of these proteins will be described.

Using a different approach, we have identified two opsin genes, rh3 and rh4, expressed specifically in the R7 ultraviolet sensitive subset of photoreceptor cells (Zuker, C. et al., *J. Neurosci.*, in press; Montell, C. et al., *J. Neurosci.*, in press). Thus, a total of four related Drosophila opsin genes have now been isolated.

13.1 A DIRECT CONNECTION BETWEEN THE BASAL GANGLIA AND THE NUCLEUS BASALIS: A TRACT-TRACING STUDY IN HUMAN POSTMORTEM BRAIN. S.N. Haber. Dept. of Neurobiology and Anatomy, Univ. of Rochester Sch. of Med., Rochester, NY 14642

Previous studies based on tracing techniques and histochemical methods have suggested a direct connection betwen the nucleus accumbens and the nucleus basalis (Haber, Neurosci. Abstr., 10:7, 1984; Grove et al, Brain Res. 367:379, 1986). Recently, using immunohistochemical methods to identify enkephalin-containing striatal efferent fibers projecting to the ventral pallidum and acetylcholinesterase staining to identify neurons of the basal nucleus, the overlap of these systems were studied in the human and nonhuman primate forebrain. The results indicate that the two systems tend, anatomically, to avoid each other, with the exception of a particular subcommissural region in which a precise overlap occurs (Haber, PNAS, 84:1408). The study presented here reports on the use of the tracer molecule, wheat germ agglutinin conjugated horseradish peroxidase (WGA-HRP) in postmortem human basal forebrain to study a direct connection between the basal ganglia and the nucleus basalis.

Blocks of human basal ganglia, approximately 5 mm thick, were removed at autopsy and injected with 0.5-1.0 ul of WGA-HRP, (20% in tris buffer, pH 8.6) using a glass pipette with a 30 um inside diameter tip. Injections were directed into the nucleus accumbens. Blocks were incubated for 24 hr. in calcium-low phosphate buffer, pH 7.2 at 37°C. The tissue was fixed by immersion in 2% paraformaldehyde, 1.25% gluteraldehyde in phosphate buffer and cryoprotected in phosphate buffer with increasing concentrations of sucrose (10%, 20%, 30%). Each block was cut (50um) on a freezing microtome and sections were stained with the TMB method of Mesulam (J. Histochem. Cytochem. 26:106), which were then stabilized with a solution containing 0.05% DAB, 1% colbalt 1% chloride, 1% nickel ammonium sulfate and 0.3% H_2O_2. Several compartments were then counterstained for acetylcholinesterase using the Genser-Jensen and Blackstad method.

Injections into the nucleus accumbens showed fibers leaving the injection site and forming bundles as they traveled into the region of the basal forebrain. Individual fibers could be followed as far as 7 mm. In sections countered stained for acetylcholinesterase, HRP fibers could be seen to traverse individual cholinesterase-positive neurons. These results suggest at the light microscopic level, a direct interaction between the nucleus accumbens and the cholinergic neurons of the basal forebrain may exist in the human forebrain.

Supported by NIH NS22511 and NS01071.

13.2 CELLULAR LOCALIZATION OF CALBINDIN-D_{28K} IN RAT AND MONKEY BASAL GANGLIA. N. Aronin, S. Christakos*, and M. DiFiglia. Univ. Mass. Med. Sch., Worcester, MA 01655, New Jersey Med. Sch., Newark, NJ 07103, and Mass. General Hosp., Boston, MA 02114

Calbindin is a 28,000 M.W. protein found in high concentrations in the mammalian kidney and brain. Regulation of renal calbindin-D_{28K} content is 1,25$(OH)_2$-Vitamin D dependent. Brain and kidney calbindins-D_{28K} are physicochemically identical by peptide mapping and chromatography. Function of calbindin-D_{28K} is unknown. We examined the immunocytochemical localization of calbindin-D_{28K} in the rat and monkey basal ganglia. Anti-calbindin-D_{28K} antiserum was generated in rabbit against purified calbindin from rat kidney. This antiserum crossreacts equally with brain and kidney calbindin-D_{28K}. Brain sections from paraformaldehyde/glutaraldehyde perfused rats(n=7) and monkeys(n=3) were incubated 24-72h with primary antiserum (1:1000-1:1600 dilution), processed with the biotin-avidin method, and treated with diaminobenzidine in H_2O_2. Specific cell labeling was absent with omission of primary antiserum and with primary antiserum preadsorbed with purified calbindin-D_{28K}.

In the neostriatum at the light microscopic level, numerous medium sized cells and their emerging processes were darkly stained. Nuclear staining often appeared darker than cytoplasmic labeling. The caudate neuropil exhibited a dense distribution of immunoreactive processes and punctate elements. Regions of the neostriatum with sparse labeling were also observed. In both species at the ultrastructural level, reaction product was distributed primarily in somata with unindented nuclei and in spiny dendrites. Particularly prominent was the dense immunoreactivity for calbindin-D_{28K} in numerous dendritic spines throughout the neuropil. Axon terminals were also labeled but infrequently. Immunoreactive terminals were filled with round and ovoid vesicles and formed symmetric synapses with unlabeled spines. At the light microscopic level, the globus pallidus exhibited immunoreactive fibers, which in some locations ensheathed unlabeled pallidal dendrites. Large darkly labeled cells were found in the internal and external laminae of the monkey globus pallidus and were continuous with large labeled neurons of the basal nucleus (Meynert). Immunoreactive terminals synapsed with unlabeled pallidal somata and dendrites.

In conclusion, these findings indicate that calbindin-D_{28K} is localized to medium sized spiny neurons in the neostriatum. Its distribution within the basal ganglia is consistent with a striato-pallidal projection of calbindin-D_{28K} containing cells. The prominent immunocytochemical localization of calbindin-D_{28K} immunoreactivity in dendritic spines, which receive the majority of synaptic inputs in the neostriatum, indicates that this protein may play a role in post-synaptic events.

13.3 THE DISTRIBUTION AND STRUCTURE OF LABELED NEURONS AND AXON TERMINALS IN IMMUNOCYTOCHEMICALLY DEFINED STRIATAL, PERICOMMISSURAL AND SUBCOMMISSURAL FOREBRAIN REGIONS IN THE RAT FOLLOWING INJECTIONS OF WGA-HRP IN THE MIDBRAIN VENTRAL TEGMENTAL AREA: LM OF THE TMB PRODUCT AND EM/GOLGI-EM OF ITS DAB-CO++ STABILIZED COUNTERPART. D.S. Zahm. Department of Anatomy and Neurobiology, St. Louis University School of Medicine, St. Louis, MO 63104.

The mesencephalic ventral tegmental area of pentobarbital anesthetized, male S-D rats weighing 225-250g was injected iontophoretically (1-2μA, 7s on - 7s off, 10-20 min) or by pressure (10-15nl, 1%) with HRP conjugated to wheat germ agglutinin (WGA). After 24-48 hours the animals were sacrificed under anesthesia and vibratome sections (50μm) through the forebrain were cut and exposed either to TMB and H_2O_2 in acetate buffer at pH 3.5 (Mesulam, 1978) or to those reactants at pH 5.0 and subsequently to a DAB-Co++-H_2O_2 solution at pH 7.4 (Rye et al., 1984). The former sections were mounted for LM. The latter were further processed for immunocytochemistry (IR) using antisera against substance P (SP) or neurotensin (NT) with DAB as chromagen, or, following osmication, were processed for Golgi according to the method of Freund and Somogyi (1982) or between glass slides as recommended by Izzo et al. (1987), or were embedded for EM without further processing. The distribution of labeled terminals corresponded to published reports (e.g. Beckstead et al., 1979). Retrogradely labeled neurons were most numerous in medial nucleus accumbens, and in a broad subcommissural forebrain area extending from posteromedial parts of the olfactory tubercle through the lateral hypothalamus. The subcommissural group of labeled neurons was centered where ventral pallidum (VP), the lateral division of the bed necleus of stria terminalis (BST) and the lateral preoptic area abut. That tegmentopetal neurons were numerous in each of these structures was confirmed by defining the boundaries of VP using SP-IR and those of the BST with NT-IR in sections containing retrogradely labeled cells or in adjacent sections. Golgi impregnation showed that retrogradely labeled, Gogli-impregnated neurons in the n. accumbens were medium spiny neurons. At this writing double labeled neurons have not been achieved in the subcommissural region, but LM and conventional EM indicate that labeled neurons and proximal dendrites are medium sized (15-20μm), spindle-shaped, and synapse-poor, in contrast to the synapse-rich ventral pallidal neurons, whose territory they invade. To avoid confusing the local collaterals of retrogradely labeled neurons with anterogradely labeled terminals following these injections, the latter, to date, have been studied only in ventromedial caudate-putamen, where labeled neurons were absent. Labeled terminals in this region contacted dendrite shafts with symmetrical specializations. Support: NS-23805 and the American Parkinson Diseáse Association.

13.4 NEUROCHEMICAL COMPARTMENTALIZATION OF THE SUBSTANTIA NIGRA PARS COMPACTA IN THE PRIMATE. J.JIMENEZ-CASTELLANOS* AND A.M.GRAYBIEL. Dept. Brain and Cognitive Sci., Mass.Inst.Tech.,Cambridge, MA 02139

Cross-sections through the squirrel monkey's substantia nigra pars compacta (SNpc) were stained for acetylcholinesterase (AChE) activity, for tyrosine hydroxylase (TH)-like immunoreactivity, for Nissl substance, or for tetramethylbenzidine (TMB) reaction product following injection of WGA-HRP into the caudate nucleus or putamen (with or without accompanying fluoro-gold injections). Both with AChE and with TH histochemistries, discrete compartmentalization of the SNpc was observed. There were striking instances in which the histochemical compartments corresponded to cytoarchitectonic specializations seen in Nissl and TMB-stained sections.

In AChE-stained sections at mid-nigral levels, finger-like zones of low AChE activity appear in the SN in an otherwise AChE positive neuropil. Some zones of heightened AChE staining are also present. The AChE-poor fingers extend ventrally from a horizontal tier which is darkly stained but itself is divided into a lateral pale part and a medial darker part. Patches of lower and higher AChE staining occur within both parts. In TH-immunostained sections, this horizontal tier of the SNpc is sharply divided into a medial half with densely packed TH-positive cells and neuropil, and a lateral half in which TH-positive cell bodies and neuropil are more sparsely distributed. Both the medial and the lateral halves have prominent TH-positive ventral extensions, some but not all corresponding to AChE-poor fingers. The horizontal tier of the SNpc is readily identifiable in Nissl-stained sections. Its medial half forms a discrete band of densely packed neurons broken up into clusters of more darkly and less darkly stained neurons. The lateral half contains more scattered neurons. Ventrally-extending fingers are not as prominent as in the histochemical preparations. Dorsal to the SNpc proper is a tier of pale TH-immunostaining corresponding to the substantia nigra pars mixta (SNpm). The SNpm shows scarcely any staining. Cell group A8, extending caudally from this zone, has stronger AChE activity.

In the retrograde experiments, SNpm was labeled only after a tracer injection in the ventral caudoputamen. In SNpc there were alternating clusters of labeled neurons in the horizontal tier following injections into either caudate nucleus or putamen (cf. Parent et al. '83) and there were instances in which these were aligned with the lighter or darker patches, respectively, of the Nissl preparations. TMB-labeled neurons and axons also appeared in ventrally extending fingers. Cells in the AChE-poor fingers were labeled both after single putamen injections (3 cases) and single caudate nucleus injections (1 case) but no doubly-labeled neurons were found after combined caudate nucleus-putamen injection. Supported by the Seaver Institute, the McKnight Foundation and NSF BNS 8319547.

13.5 HALOPERIDOL-SENSITIVE SIGMA RECEPTORS IN THE SUBSTANTIA NIGRA PARS COMPACTA: AUTORADIOGRAPHIC EVIDENCE FOR SPECIFIC ANATOMICAL LOCALIZATION of [3H] DTG BINDING SITES. A.M. Graybiel, E. Weber, M-J. Besson and K. Karuzis* (SPON: H. Newman-Gage). Dept. Brain and Cog. Sciences, Mass.Inst.Tech., Cambridge, MA 02139

Findings in anterograde tracer experiments suggest that the dopamine-containing cell groups of the cat's midbrain are divided up according to their differential efferent projections to the striosomal and extrastriosomal matrix subdivisions of the striatum (Jimenez-Castellanos and Graybiel '85, '86). The TH-rich densocellular zone of the substantia nigra pars compacta (SNpc) projects strongly to striosomes. Cell group A8 and the cell-sparse zone of the SNpc project more strongly to the extracellular matrix. We report here autoradiographic evidence suggesting that the striosome-projecting densocellular zone of SNpc is the main nigral locus of binding sites labeled with the sigma selective ligand [3H]-1,3 di-o-tolylguanidine ([3H]DTG).

Autoradiographic experiments were carried out on transverse sections cut from unfixed rapidly frozen blocks taken from the cat brainstem under conditions of deep barbiturate anesthesia. [3H]DTG binding was performed at room temperature for 45 min in 2nM [3H]DTG (specific activity 52 Ci/mmol). Non-specific binding was determined by incubation in the presence of a 10^{-5} M haloperidol. Autoradiographic [3H]DTG binding patterns were studied after 1-2 month exposure times and were compared with patterns of TH immunostaining, of AChE staining, and of [3H]SCH23390 and [3H]naloxone binding visible in adjacent or nearly adjacent sections and, for AChE, in some of the same sections stained after autoradiographic exposures were complete.

[3H]DTG binding was generally low in the pars reticulata of the substantia nigra (SNpr), in cell groups A10 and A8 and in the cell-sparse zone of SNpc. By contrast, dense [3H]DTG binding appeared in a restricted caudomedial band of SNpc that corresponded to the TH-rich, AChE poor densocellular zone of SNpc observed in adjacent sections. Binding was nil in control sections incubated in the presence of 10^{-5} M haloperidol. Very different binding patterns were found following incubations with the D1-selective ligand [3H]SCH 23390 and with the opiate receptor-selective ligand [3H]naloxone. In neither case was the densocellular zone of SNpc preferentially labeled.

This anatomical localization of [3H]DTG binding raises the possibility that haloperidol-sensitive sigma receptors might modulate dopamine release in the SNpc and that such effects might be targeted particularly toward the striosomal system. If so, such specificity could be important in understanding the neural basis of sigma-active antipsychotic and psychotomimetic drugs. Supported by the Seaver Institute, the McKnight Foundation and NSF BNS 8319547.

13.6 A CHOLINERGIC PROJECTION FROM THE PEDUNCULOPONTINE TEGMENTAL NUCLEUS TO THE SUBSTANTIA NIGRA IN THE RAT: A LIGHT AND ELECTRON MICROSCOPIC IMMUNOHISTOCHEMICAL STUDY. M.Beninato*, and R.F. Spencer. Dept. of Anatomy, Medical College of Virginia, Richmond, VA 23298-0001.

Putative cholinergic afferents of the rat substantia nigra (SN) were identified by double-labeling with retrograde transport of horseradish peroxidase (HRP) combined with the immunocytochemical localization of choline acetyltransferase (ChAT). The cholinergic projection to the SN originates from neurons located predominantly in the ipsilateral and rostral portions of the pedunculopontine tegmental nucleus (PPN). Other cholinergic neurons that were also retrogradely-labeled with HRP were located in the caudal PPN and lateral dorsal tegmental nucleus (LDTN). A non-cholinergic projection from the PPN was also identified. These findings indicate that the PPN, and to a lesser extent, LDTN are extrinsic sources of acetylcholine to the basal ganglia (cf. N.J. Woolf and L.L. Butcher, Brain Res. Bull., 16:603-637, 1987).

ChAT-immunoreactive axons and synaptic endings were demonstrated in the SN by light and electron microscopy. The distribution of ChAT-immunoreactivity in the was compared to that of acetylcholinesterase (AChE), demonstrated histochemically, and tyrosine hydroxylase (TH) immunoreactivity. Both AChE and TH-immunoreactivity were confined to the pars compacta of the SN (SNc) and SNc dendrites extending into the pars reticulata (SNr). The distribution of ChAT immunoreactivity in the SN as demonstrated by light microscopy revealed a modest network of ChAT-immunoreactive beaded axons in the SNc, as defined by AChE and TH localization, in comparison to a relatively sparse distribution to the SNr. These axonal profiles were most dense in the middle of the rostral-caudal extent of the SNc and appeared to be concentrated in the middle third of the medial-lateral extent. These findings are consistent with those recently described in the ferret (Z. Henderson and S.A. Greenfield, Neurosci. Lett., 73:109-113, 1987). Electron microscopic examination of ChAT-immunoreactive profiles in the SN was confined to the SNc. Unmyelinated small diameter (0.25 μm) ChAT-immunoreactive axons were observed interspersed among numerous other non-immunoreactive axons. ChAT-immunoreactive synaptic endings in juxtaposition to small caliber (0.5 μm) non-immunoreactive dendrites contained numerous spheriodal synaptic vesicles and occasional mitochondria. Synaptic contact zones were characterized by an accumulation of synaptic vesicles along the presynaptic membrane, and a prominent postsynaptic densification producing an asymmetrical pre-/postsynaptic membrane profile typical of excitatory synapses.

These findings provide direct evidence for a cholinergic innervation of the SN, and suggest that this input may have an excitatory effect on neuronal elements in the SNc.

13.7 IMMUNOHISTOCHEMICAL LOCALIZATION OF THE NICOTINIC ACETYLCHOLINE RECEPTOR TO DISTINCT SUBSETS OF MIDBRAIN DOPAMINE NEURONS. A.Y. Deutch, M. Goldstein, J. Holliday*, R.H. Roth and E. Hawrot. Dept. of Pharmacology and Psychiatry, Yale Univ. Sch. of Med., New Haven, CT 06510, and NYU Sch. of Med., New York, NY 10016

Presynaptic regulation of striatal dopamine (DA) release via the nicotinic acetylcholine receptor (NAChR) has been extensively characterized. Implicit in the concept of NAChR presynaptic regulation of DA release from striatal afferents originating in the midbrain is the premise that the NAChR is synthesized within DA neurons of the substantia nigra and axonally transported to the terminal. In situ hybridization histochemistry studies have revealed that the α-3 gene encoding the neuronal α subunit of the putative presynaptic NAChR is present in the ventral tegmental area (VTA) and the substantia nigra, pars compacta (SNpc; Goldman et al., Cell 48:965, 1987). We now report the immunohistochemical localization of the NAChR to distinct subsets of midbrain DA neurons. Monoclonal antibodies (mAb) were generated against purifed Torpedo NAChR. Binding competition studies revealed that one mAb designated 35.74 interacts with the main immunogenic region of the NAChR. Anatomical localization of the NAChR in rat brain was undertaken using this antibody. mAb 35.74 staining was heterogeneously distributed in rat brain and paralleled the reported distribution of (3H)-nicotine binding sites, including the deep layers of the cerebral cortex, anteroventral thalamic nucleus, dentate gyrus, medial habenula and its efferent targets (interpeduncular nucleus and median raphe), and a continuum of cells across the ventral mesencephalon corresponding in location to the A8 (retrorubral field, RRF), A9 (SN), and A10 (VTA) DA cell groups. In some regions, including the ventrolateral medial habenula and the ventral midbrain, intense cytoplasmic staining of neurons and processes was observed. Ventral mesencephalic neurons stained with mAb 35.74 corresponded in morphology to the tyrosine hydroxylase (TH)-positive neurons of the A8-A10 cell groups. 6-hydroxydopamine lesions completely abolished mAb 35.74 staining of SNpc DA neurons. Further immunohistochemical studies revealed that while most of the SNpc DA neurons stained for the NAChR, certain other midbrain DA neurons did not. DA neurons in both the medial aspects of the VTA (the nuc. interfascicularis, rostral linear and central linear nuclei, and dorsal extension of TH-positive neurons to the cerebral aqueduct) and the ventral diffuse portion of the A8 cell group were not stained with mAb 35.74. Thus, the NAChR appears to be synthesized in discrete subsets of midbrain DA neurons. These data suggest that ACh may regulate the functional activity of distinct subsets of midbrain DA neurons via interactions with nicotinic AChR, and may provide clues to the sites where nicotine may exert its behavior rewarding properties. 13.8 SYNAPTOLOGY OF IMMUNOCYTOCHEMICALLY-IDENTIFIED GABAERGIC AND ENKEPHALINERGIC TERMINALS IN MONKEY SUBSTANTIA NIGRA. Gay R. Holstein and Pedro Pasik. Depts. of Neurology and Anatomy, Mount Sinai School of Medicine, CUNY, New York, NY 10029.

Observations of immunocytochemically-identified GABAergic elements in the substantia nigra (SN) from 2 adolescent (1 M. mulatta and 1 M. fascicularis) and one 4-week-old monkey (M. mulatta) were performed on 50 μm vibratome sections which were incubated in a GABA antiserum and processed with the PAP technique. A fourth monkey (M. fascicularis) was studied by a preembedding double label immunocytochemical method where the same procedure as above was combined with an anti-leu enkephalin (ENK) ascites fluid and the avidin-biotin complex technique with avidin-ferritin conjugate as the marker. Similar results were obtained in all subjects treated alike, and no immunostaining was observed in control sections.

Using serial section electron microscopy, a differential distribution of GABAergic inputs to SN cell bodies was apparent. GABAergic boutons occasionally were observed to contact GABA-immunoreactive somata, primarily forming symmetric synapses, whereas such input to GABA-negative cell bodies was rare. A preliminary analysis of the double labeled material revealed that some of the myelinated and unmyelinated GABA-positive fibers were leu-ENK-immunoreactive as well. Boutons which were labeled for both of these substances were also present. These elements contained densely packed vesicles and formed synaptic contacts with dendrites of SN neurons. In addition, some axonal and dendritic profiles showed the GABA immunostain only.

The observations using single label immunocytochemistry, together with our previous report on the pattern of dendritic innervation by GABA-immunoreactive boutons (Neurosci. Lett., 1986) suggest that the GABAergic input to GABA-positive elements in SN is sparse and more uniformly distributed to dendrites and somata. In contrast, GABA-negative elements throughout SN receive a more dense GABAergic input, which is restricted to the dendritic field. The results of the double label procedure indicate that at least a subpopulation of the GABA-positive boutons in SN, namely those profiles with small dark mitochondria and densely packed vesicles, may also contain leu-ENK, and form synapses with neuronal elements in this structure. These boutons resemble the extrinsic afferent terminals which take origin in the neostriatum, pallidum and nucleus accumbens septi.

13.9 NADPH-DIAPHORASE POSITIVE NEURONS IN THE STRIATUM CONTAIN THE MESSENGER RNA (mRNA) FOR SOMATOSTATIN BUT NOT FOR GLUTAMIC ACID DECARBOXYLASE (GAD): AN IN SITU HYBRIDIZATION STUDY.
M.-F. Chesselet and Elaine Robbins* The Medical College of Pennsylvania, 3200 Henry Ave., Philadelphia, PA 19129.

The presence of a high level of NADPH-diaphorase activity characterizes a subset of striatal neurons resistant to a variety of neuronal injuries; in particular, these neurons are spared in local injections of quinolinic acid and in the striatum of patients with Huntington's Disease. Striatal NADPH-diaphorase positive neurons contain somatostatin-like immunoreactivity, suggesting that they are medium aspiny interneurons with an indented nucleus, characteristics described for somatostatin-positive cells. Striatal neurons exhibiting similar density and morphological features as the somatostatinergic neurons have recently been shown to express significantly higher levels of GABA and GAD like immunoreactivities as well as of GAD mRNA than the more numerous GABA-ergic striatal efferent neurons. It is unclear, however, whether somatostatin and GABA coexist in these neurons or whether this subset of striatal GABA-ergic cells form a distinct neuronal population.

In the present study, we sought to confirm that the neuropeptide somatostatin can be synthesized in the NADPH-diaphorase positive neurons of the striatum by demonstrating the presence of the mRNA for preprosomatostatin in these neurons by in situ hybridization cytochemistry. In addition, we have examined whether these neurons also express high levels of GAD mRNA. Frozen sections of rat brain were fixed in paraformaldehyde, stained for NADPH-diaphorase activity, acetylated, dehydrated, and hybridized with ^{35}S-labelled RNA probes transcribed from cDNA coding for preprosomatostatin (R. Goodman, Tuft U.) and GAD (A. Tobin, UCLA). After post-hybridization washes and treatment with RNAse, the sections were dehydrated and processed for autoradiography using Kodak emulsion. An intense labelling was observed with the preprosomatostatin RNA probe in most NADPH-diaphorase positive neurons in the striatum. In contrast, striatal neurons labelled with GAD RNA did not express NADPH-diaphorase activity. The results suggest that NADPH-diaphorase neurons in the striatum produce somatostatin but not GAD, the enzyme necessary for the formation of GABA. In light of the available immunohistochemical data, this suggests that neurons engaged in intense GAD and GABA synthesis constitute a population of medium sized striatal interneurons distinct from previously described peptidergic interneurons. Supported by the Hereditary Disease Foundation, MH and BSN.

13.10 DOPAMINE RECEPTOR-MEDIATED REGULATION OF DOPAMINE TURNOVER IN RAT FETAL SUBSTANTIA NIGRA TRANSPLANTS.
R. Meloni*, N. Hayman* and K. Gale.(SPON: D.Stoff). Dept. of Pharmacology, Georgetown University Schools of Medicine and Dentistry, Washington, D.C. 20007.

Rats receiving solid grafts of fetal substantia nigra placed into a cortical well over one striatum (previously denervated by 6-hydroxydopamine) and their non-transplanted (6-hydroxydopamine lesion and cortical well only) and non-lesioned (cortical well only) controls, were used to assess (by HPLC) levels of dopamine (DA) and its metabolites (DOPAC and HVA) in different regions of the striatum following haloperidol (HAL) (1 mg/kg ip 60 min before sacrifice). The transplant recipient rats, when tested 4 mo after transplantation, showed a 50-100% reduction in turning behavior to both apomorphine and amphetamine, as compared to the pre-transplant baseline, while the lesioned rats without transplant had a slightly elevated turning behavior.

The DA and DOPAC concentrations in the regions of host striata that were well-innervated by the grafts were 8-10 fold higher than those of the non-innervated regions of the same striata, where DA was less than 1% of normal.

Significant (*) effects of HAL on DOPAC/DA and HVA/DA ratios were as follows:

	STRIATUM ON TRANSPLANT SIDE		STRIATUM ON NON-OPERATED SIDE	
	DOPAC/DA	HVA/DA	DOPAC/DA	HVA/DA
SALINE	.54	.18	.26	.05
HALOPERIDOL	.98*	.32*	.61*	.19*
% INCREASE	81%	78%	134%	257%

These data indicate that although DA turnover is higher in the terminals of the grafts than in the non-lesioned striata, it is nevertheless subject to increase in response to DA receptor blockade by HAL. In addition, in HAL-treated rats the **transplant itself** showed a significant (*) increase (by 100%) in both the DOPAC/DA and HVA/DA ratios: from 0.21 to 0.43* and from 0.05 to 0.10* respectively, indicating that DA turnover **intrinsic** to the transplant is also subject to regulation by DA receptors. The proportional increases induced by HAL in metabolite/DA ratios associated with the transplant and its projections were not as great as those observed in the intact striata, indicating either that 1) the impact of DA receptor blockade on transplant DA turnover is less than that on the intact nigrostriatal circuitry, or 2) the apparent rate of accumulation of metabolites may be altered by differences in acid transport in the vicinity of the transplant.

Our data suggest that the transplant is not acting only as a "reservoir" releasing DA at a constant rate, but that feedback control of transplant DA utilization exists. In the event that **host** neurons may partecipate in this feedback regulation, this could allow for a dynamically active transplant, responsive to changes in host neural activity.

13.11 ELECTROPHYSIOLOGICAL EVIDENCE FOR THE FORMATION OF A CORTICOSTRIATAL PATHWAY IN NEOSTRIATAL TISSUE GRAFTS.
C.J. Wilson,P. Emson and C. Feler * Department of Anatomy and Neurobiology, School of Medicine, Univ. of Tennessee, Memphis TN 38163 USA, and Institute of Animal Physiology, Babraham, Cambridge, CB2 4AT, UK.

Extracellular and intracellular recordings were used to study responses recorded from neurons within neostriatal grafts in rats. Grafts were made using cell suspensions from embryos of gestational age between 15 and 18 days. The neostriatum of young adult recipients of the same strain was damaged unilaterally by injection of kainic acid or ibotenic acid to form a lesion approximately 1 mm in diameter. Between 3 and 6 days later an injection of suspended embryonic neostriatal tissue was made stereotaxically into the same position. Recording experiments were performed between 6 weeks and 6 months of surgery. The grafts produced in this way were very reliable in their placement in the neostriatum, making it possible to stereotaxically place recording electrodes into the graft. Stimulating electrodes were placed in the medial agranular field of the frontal cortex, which projects very heavily to the area of neostriatum into which the graft was placed. Animals were anesthetized with urethane and ketamine.

Recordings from the intact neostriatum show a characteristic pattern of initial excitation, inhibition, and rebound excitation following stimulation of the cerebral cortex. Recordings taken from within the graft showed this same pattern of excitation and inhibition. The initial excitatory phase of the response, which has previously been shown to be due to the monosynaptic excitatory effect of corticostriatal afferents, was reliably observed in neurons within the graft, and was normal in amplitude and duration. The inhibitory phase of the response, which is believed to result primarily from the removal of a powerful tonic excitatory synaptic input from the cortex, was also present in the graft.

Intracellular injection of HRP was used to localize neurons from which the recordings were made. Neurons stained in this way were observed to be located within the graft.

These findings indicate that neostriatal tissue grafts can receive an innervation from the cerebral cortex that is comparable to that of the normal neostriatum.

Supported by grant NS 20743, and RCDA NS01078 from NIH, and a collaborative research grant from NATO.

13.12 ONE-YEAR SURVEY OF C.N.S. RECEPTOR ADAPTIVE RESPONSIVENESS IN WISTAR RATS BEARING UNILATERAL NIGRAL 6-OHDA LESIONS.
A. C. Rossi, G. Achilli*, C. Caccia*, M. Carpentieri*, M. A. Cervini*, R. Maj*, L. Pegrassi*and M. Buonamici*
Farmitalia Carlo Erba R.& D., C.N.S. Line, 20014 Nerviano, Italy

The time-course of the modifications of the main neurotransmission systems in male Wistar rats bearing unilateral nigral 6-OHDA lesions (Ungerstedt, U.et al.,Brain Res.,24: 485, 1970) is reported. The more relevant times for this analysis were chosen basing on the evolution of dopamine-agonist-induced rotational behavior (apomorphine: 0.5 mg/kg s.c.). Rotational behavior contralateral to the lesion does consistently appear one month after the lesion, increasing in intensity up to one year. Binding assays were performed with the following ligands: ^{3}H-SCH 23390, ^{3}H-spiperone and ^{3}H-QNB respectively for D-1, D-2 and muscarinic receptors in caudate-putamen (CP); ^{3}H-prazosin for α-1, ^{3}H-yohimbine for α-2 and ^{3}H-dihydroalprenolol for β receptors in sensory-motor cortex (SMC); ^{3}H-serotonin for S-1 receptors in hippocampus (HP). Dopamine (DA) and DOPAC, norepinephrine (NE), serotonin (5-HT) and 5-HIAA were simultaneously determined using reverse-phase HPLC with electrochemical detection. The results are expressed as % variations of the lesioned cerebral side as compared with the intact one. Only B_{max} values are reported no variations in K_D values being evident.

Area (receptors and transmitters)		% of contralateral values (= 100%) 1 month	3 months	12 months
CP	D-1	no change	+ 40	+ 30
	D-2	+ 15	+ 20	+ 15
	muscarinic	no change	no change	no change
	DA	- 97	- 94	- 95
	DOPAC	-100	- 80	- 80
SMC	α-1	+ 40	+ 24	+ 30
	α-2	no change	no change	no change
	β	+ 66	+ 20	-
	NE	- 90	- 80	- 85
HP	S-1	no change	no change	no change
	5-HIAA	no change	no change	no change

Our results indicate that this focal lesion leads to long-lasting and quite complex modifications of the considered cathecolaminergic systems in CP and SMC of the lesioned cerebral side which are consistent with findings reported for human brain tissues from parkinsonian patients (Cash, R., et al.,Brain Res.,322: 269, 1984).

13.13 STRAIN-DEPENDENT DIFFERENTIAL EFFECTS OF MONOAMINE OXIDASE INHIBITION ON DOPAMINERGIC NIGROSTRIATAL FUNCTIONING IN MICE. R. Bose* and C. Pinsky* (SPON: L. Wilson). Department of Pharmacology and Therapeutics, University of Manitoba, 770 Bannatyne Avenue, Winnipeg, Manitoba, Canada R3E 0W3.

Invertebrates lacking active monoamine oxidases (MAO) metabolize biogenic amines by formation of gamma-glutamyl conjugates. These neuronally-inactive conjugates are present also in MAO-containing mammalian neurons. MAO inhibition speculatively could result in an increased degree of gamma-glutamylation of monoamines, thereby diverting glutamyl moieties from biosynthesis of glutathione and rendering the neurons vulnerable to free radical damage. We have examined the acute effects of clorgyline and pargyline, two MAO inhibitors of differential selectivity, in two strains of mice on dopamine-mediated vertical climbing activity (VCA). Also examined were the total glutathione and lipid peroxidation in striatum, cerebral cortex and cerebellum of these mice.

The selective MAO-A inhibitor clorgyline significantly decreased VCA in Swiss-Webster mice ($p \leq 0.01$) while significantly increasing VCA in the Belknap strain ($p \leq 0.05$). The much less selective agent, pargyline, did not alter VCA in Swiss-Webster but decreased VCA numerically in Belknap mice. In rodents, both serotonin and dopamine have been shown to be metabolized by MAO-A. Serotonin, being the preferred substrate for this enzyme, would be better protected and the resulting relative increase in serotoninergic tone would inhibit, by feedback, dopaminergic neurotransmission leading to the reduced VCA seen in Swiss-Webster mice. The Belknap strain, however, appears to differ in showing increased VCA following MAO-A inhibition, possibly due to preferential protection of dopamine or to a lack of serotoninergic inhibitory feedback in the basal ganglia. The reduced lipid peroxidation seen in the striatum of mice treated with MAO inhibitors may be a reflection of reduced H_2O_2 formation consequent on MAO inhibition. Total glutathione content was not significantly altered in the brain regions studied here. Glutamylation or other glutathione conjugate formation therefore does not seem likely as an alternative metabolic pathway for monoamines after acute treatment with MAO inhibitors in these two strains of mice. Further studies with repeated administrations of MAO inhibitors, corresponding to clinically effective regimens, are being carried out.

This study was supported by the United Parkinson Foundation (Chicago), Medical Research Council of Canada and the Centre on Aging of the University of Manitoba.

MONOAMINES AND BEHAVIOR I

14.1 ASPARTAME WITH CARBOHYDRATE FAILS TO AFFECT FOOD INTAKE, APPETITE MOTIVATION, MOOD, LEARNING AND BEHAVIOR IN CHILDREN. S. Saravis*. R. Schachar*. S. Zlotkin*. L. Leiter*, and G.H. Anderson. Hospital for Sick Children and Dept. of Nutritional Sciences, University of Toronto, Toronto, Ontario, Canada.

Aspartame (the methyl ester of phenylalanine and aspartate) is a sweetener in wide use in foods and drinks available to children. The objective of the present study was to test the hypothesis that aspartame combined with carbohydrate will induce neurobehavioral responses in children. A double-blind crossover design was used to examine the effects of a challenge of aspartame ingested with carbohydrate on food intake (energy and macronutrient selection) at lunch time, on subjective feelings of hunger and mood, on performance on a conditional associative learning task, and on selected measures of motor behavior and social interaction.

Ten female and ten male subjects (C.A.: 9.8 +/- 0.8 years) participated in two morning sessions. After an overnight fast, they were given a standardized breakfast at 08:30 and the treatment at 10:30. The treatment consisted of an ice slurry of strawberry Kool-Aid with either the test dose of aspartame (34 mg/kg) or the equivalent sweetness as sodium cyclamate and amino acids as alanine. Both slurries contained polycose to provide each child with 1.75 g/kg of carbohydrate. The dependent variables were measured from 25 to 115 minutes after the slurries were consumed.

No treatment effects were found for any of the dependent measures. Significant time-dependent effects were found for subjective feelings of hunger and for activity level. It is concluded that in comparison with sodium cyclamate, aspartame in doses of 34 mg/kg combined with carbohydrate does not affect short-term energy or macronutrient intake, subjective feelings of hunger or mood, or learning and behavior, in normal 9 and 10 year old children.

This research was supported by the International Life Sciences Institute-Nutrition Foundation, Washington, D.C.

14.2 ELECTROPHYSIOLOGICAL STUDIES OF THE FUNCTIONAL ROLE OF SINGLE, IDENTIFIED SEROTONERGIC NEURONS IN THE LOBSTER VENTRAL NERVE CORD. *P.M. Ma*, B.S. Beltz and E.A. Kravitz,* Dept. Neurobiology, Harvard Medical School, Boston, MA 02115

The injection of certain amines and peptides into the systemic circulation of the lobster has profound modulatory effects on posture and behaviour. Serotonin produces a long-lasting postural change characterized by an over-all flexion of the abdomen, walking legs and claws---a posture reminiscent of the stance taken by dominant lobsters. Several lines of evidence suggest that this results from serotonin promoting the read-out of central motor programs resulting in postural flexion. Direct recording from abdominal postural muscles in intact animals during the "serotonin posture" shows that there is an increase in excitatory junctional potentials (ejps) in flexor muscles and a decrease in ejps in extensor muscles. Recordings from motor nerve roots or from motoneurons in isolated nerve cord preparations superfused with serotonin show that the amine increases the rates of firing of flexor excitatory and extensor inhibitory motoneurons while it decreases the rates of firing of flexor inhibitory and extensor excitatory motoneurons. As a next stage in examining the role of serotonin in postural control in lobsters, immunocytochemical methods were used to search for individual serotonergic cells that might be involved in these circuitries. Within the abdominal and thoracic nerve cord of the lobster, there are several sets of morphologically identifiable serotonergic neurons. One of these sets contains seven pairs of homologous, rostrally projecting neurons, one pair each in each of the six abdominal and the last thoracic ganglia. Among these cells, the pairs in the last thoracic and the first abdominal ganglia are particularly large (roughly 100 um in diameter), and can be identified and impaled reliably for intracellular stimulation and recording. Intracellular recordings show several unique physiological features of these serotonergic cells. Unlike most neuronal somata in the central nervous system of the lobster, large (up to 60 mV), fast action potentials can be recorded from these cells. Most of these cells are active spontaneously, firing action potentials at a steady rate of about 1 Hz. The serotonergic cells receive inputs from at least two major sources: sensory and command inputs. The former are mostly excitatory. The latter are more diverse: flexor command fibres usually excite, while extensor command fibres usually inhibit the serotonergic neurons. In isolated nerve cord preparations, direct intracellular activation of the serotonergic cells has no effect on motor output in recordings from motor nerve roots or from postural muscle fibres. Facilitating interactions are seen, however, with simultaneous activation of the serotonergic cells and flexor command fibres. When the serotonergic cell is activated along with the flexor command, the functional efficacy of the command fibres is enhanced. When the serotonergic cell is inhibited while stimulating the command fibres the ability of the latter to activate motoneurons is reduced. Serotonin may act, therefore, by facilitating transmission between flexor command fibres and their target motoneurons, thereby potentiating the read-out of motor programs resulting in postural flexion. If so, one role of serotonergic neurons may be to act as "gain-setting" elements in postural circuitries. (Supported by MDA and NIH)

14.3 DOPAMINERGIC (D2) MEDIATION OF RAT 22 kHz POSTEJACULATORY ULTRASONIC VOCALIZATION. R. Cagiano*, R.J. Barfield, N.R. White*, E.T. Pleim* & V. Cuomo* (SPON: T.R. McGuire). Dept. of Biol. Sci., Rutgers University, New Brunswick, N.J. 08903 USA and Institute of Pharmacology, University of Bari, 70124 BARI, Italy.

The role of ultrasonic vocalization in the sexual behavior of rats has been studied extensively. There are two types of calls: 1) a 50 kHz mating call emitted by both male and female and 2) a 22 kHz postejaculatory vocalization (PEV) produced only by the male. The 50 kHz calls are associated with sexual arousal in both sexes and are accompanied by an alert, aroused "theta" EEG pattern. The 22 kHz PEV, on the other hand, is associated with the period of sexual refractoriness following ejaculation. During the PEV the rats characteristically display a sleep-like spindling EEG pattern and are behaviorally suppressed.

The neurochemical control of ultrasonic vocalizations is complex and may involve several neurotransmitters. The research reported here was designed to investigate the role of dopamine receptor subtypes in the regulation of ultrasonic vocalization and masculine copulatory behavior. Intact sexually experienced male Long-Evans rats were treated with either saline or selective dopamine D1 (SKF 38393; Smith Kline & French) and dopamine D2 (LY 171555; Eli Lilly) receptor agonists, 15 min before a 30 min mating encounter with sexually receptive ovariectomized female rats injected with estradiol benzoate and progesterone 48 and 4 h before the test session, respectively. A significant decrease in the number of intromissions required for the first ejaculation was found in animals treated with SKF 38393 10 mg/kg/ip and with LY 171555 at doses ranging from 0.01 to 0.5 mg/kg/sc. Rats treated with LY 171555 at the highest dose displayed no postejaculatory vocalization. This phenomenon was found to be dose-dependent because the vocalization reappeared as doses were reduced. Raclopride, a new selective dopamine D2 receptor antagonist (0.5 mg/kg/sc), given 30 min before the test session, antagonized the suppressive effects of LY 171555 on postejaculatory vocalization whereas SCH 23390 (a dopamine D1 receptor antagonist; Schering), at the dose of 0.01 mg/kg/i.p., did not. Finally, raclopride given alone at the same dose drastically suppressed all behavioral activity. Results to date suggest that the dopamine D2 receptor plays an important role in the regulation of the 22 kHz postejaculatory vocalization, and that it has little or no involvement with other aspects of masculine copulatory behavior or 50 kHz mating calls.

14.4 INVOLVEMENT OF THE AMYGDALA IN STIMULUS-REWARD ASSOCIATION : INTERACTION WITH THE VENTRAL STRIATUM. M.Cador*, B.J. Everitt*+ and T.W.Robbins*. Depts. of Experimental Psychology and +Anatomy , University of Cambridge, Cambridge, England. (Spon: C. Dourish)

The nucleus accumbens as part of the ventral striatal complex, has a pivotal neuroanatomical position between the limbic system and the basal ganglia which has led to the proposal that it is an "interface between motivation and action".The dopamine (DA) agonist d-amphetamine (AMPH) injected into the nucleus accumbens enhances the control over behaviour exerted by conditioned reinforcers (CR). This effect is blocked by DA depletion from the ventral striatum effected by intra-accumbens 6-hydroxydopamine (Taylor & Robbins, Psychopharm., 90,390,1986). The ventral striatum receives projections from the basolateral nucleus of the amygdala, an area which has been implicated in stimulus-reward association. In the present study, we examine the involvement of the amygdala in the potentiation of responding for conditioned reinforcers following intra-accumbens AMPH injections.Thirsty rats were trained to associate a light (CR) with water and then implanted with permanent guide cannulae aimed at the nucleus accumbens. Half of these rats received excitotoxic lesion of the amygdala (AMY) by infusions of N-methyl-d-aspartate (0.12 M in 0.3 ul phosphate buffer) into the basolateral region whereas the other half received control infusions of the vehicle. In the test phase, water was no longer presented but responding on one of two novel levers produced the light (CR lever), whereas responding on the other lever (NCR lever) had no effect. The two groups received four counterbalanced intra-accumbens infusions of AMPH (3,10,30 ug/1ul) or vehicle over four test days. Intra-accumbens AMPH infusions dose-dependently increased responding on the CR lever but had no significant effect on responding on the NCR lever. Compared with controls, the AMY group exhibited a significant, selective reduction in responding on the CR lever, with no change on the NCR lever, irrespective of drug or control treatment. Control experiments showed that the AMY group were not hypodipsic and exhibited similar levels of locomotor activity compared to the vehicle group.The hyperactivity response following either i.p. or intra-accumbens AMPH was also unchanged. These results indicate a role for the amygdala in mediating the effects of stimulus-reward associations on behaviour, via DA-dependent mechanisms of the ventral striatum.

14.5 DIFFERENTIAL EFFECTS ON SPONTANEOUS MOTOR BEHAVIOR, FEEDING, AND ORAL STEREOTYPY FOLLOWING AMPHETAMINE MICROINJECTION INTO ANATOMICALLY DEFINED SUBREGIONS OF RAT STRIATUM. A.E. Kelley and A. Gauthier* Department of Psychology, Harvard University, Cambridge, MA 02138

The neurotransmitter dopamine (DA) has been implicated in a wide range of motor and motivational behaviors. Many of these behaviors are thought to be mediated by the striatum (including nucleus accumbens and caudate-putamen), the major projection target of mid-brain DA neurons. Although cytoarchitectually consistent throughout, lesion and anatomical studies of the striatum's afferent connections have suggested functional heterogeneity. However, there have been few studies of discrete DA stimulation of striatal subregions. This study analyzed the behavioral effects of amphetamine injections into striatal sites chosen on the basis of differential afferent fiber systems. These sites were the nucleus accumbens, which receives its primary input from hippocampus,the ventrolateral striatum, which is heavily innervated by amygdala and perirhinal cortex, and dorsolateral striatum, which is afferented by sensori-motor cortex. Three groups of rats were implanted with cannulae aimed at these sites. They were maintained with food and water ad libitum throughout the experiment. On test days, rats received either saline, 0.1µg, 1.0µg, or 5.0µg in 0.5 µl every two days. Rats were returned to the home cage immediately after infusion, where their behavior was recorded over a 40 min. period by observation and an automated event recorder. The session was also videotaped. Behaviors measured were locomotion (center crossings), rearing (frequency and duration), feeding and drinking (duration,bouts and intake). Two further categories were analyzed from videotape following the experiment: stereotyped biting and oral behavior (combined scores of feeding and biting). When injected into nucleus accumbens, amphetamine produced a dose-dependent increase in locomotion and rearing, and a decrease in average duration of rears (total duration/frequency). There were no effects on feeding or drinking. In contrast, amphetamine injected into ventrolateral striatum enhanced feeding, and at higher doses an intense, stereotyped biting of the forepaws was observed. Combined scores of oral behavior were dose-dependently increased by amphetamine in this site. Locomotor and rearing scores were decreased in the first part of the session, indicated by significant dose x time interactions. Amphetamine injected into dorsolateral striatum produced no measurable effects on the behaviors recorded. These findings provide evidence for differential behavioral effects of amphetamine within subareas of "limbic-afferented" striatum, which are in addition distinguishable from effects within "non-limbic" striatum. A specific ventrolateral site may be linked to the motor circuitry underlying feeding and oral behavior.

14.6 **NEUROCHEMICAL CONSEQUENCES OF CONDITIONED CIRCLING IN LOCALIZED REGIONS OF THE STRIATUM.** C. Szostak*, A. Jakubovic, A.G. Phillips and H.C. Fibiger. Div. Neurol. Sci., Dept. Psychiatry, Univ. British Columbia, Vancouver, B.C. Canada V6T 1W5.

High rates of circling established and maintained by operant procedures have been associated with increased dopamine (DA) utilization within the striatum (STR) (J. Neurosci. 6, 1986). The observation that conditioned circling is associated with bilateral increases in DA utilization is in contrast with the hypothesis that circling is dependent upon a hemispheric imbalance in striatal DA activity. Given that the STR is not a homogenous structure in terms of its neuroanatomical connections, neurochemistry or behavioral functions, the detection of behaviorally-induced neurochemical asymmetries may be facilitated by fine-grained dissections of the STR. Accordingly, the effects of conditioned circling on concentrations of DA and its metabolites in 10 discrete sub-regions of the STR were determined.

Spraque-Dawley rats were trained to circle in their preferred direction for water according to a Fixed Ratio 2 schedule of reinforcement. The neurochemical consequences of conditioned circling were determined upon attainment of stable levels of responding. The STR was sectioned into 3 consecutive, 1 mm thick coronal slices. The first 2 slices were both dissected into 4 quadrants (dorsolateral, dorsomedial, ventrolateral, ventromedial) while the tail of the STR (3rd slice) was divided into dorsomedial and ventrolateral subregions. DA metabolism, as determined by metabolite concentrations and metabolite to DA ratios, was enhanced bilaterally within the anterior dorsolateral and dorsomedial STR, relative to non-circling, water-deprived control rats. No other neurochemical effects were detected.

The present results confirm that conditioned circling is associated with a bilateral augmentation in DA utilization. No evidence of behaviorally-induced neurochemical asymmetries was obtained even though rats were trained to circle in their preferred direction, a procedure which should enhance the likelihood of detecting asymmetrical effects. The present results are consistent with the suggestion by Joyce, Davis and van Hartesveldt (Eur. J. Pharmacol. 72, 1981) that the dorsal STR critically underlies rotational behavior.

14.7 HYPERRESPONSIVITY OF LOCUS COERULEUS IS ASSOCIATED WITH STRESS-INDUCED BEHAVIORAL DEPRESSION. J.M. Weiss, P.E. Simson, J.A. Knight, & C.D. Kilts. Dept. of Psychiatry, Duke University Medical Center, Durham, NC 27710.

Depression of active behavior occurs in rats after they have been exposed to highly stressful, uncontrollable events. Evidence from various sources indicates that this behavioral effect is mediated by a large fall in the concentration of norepinephrine (NE) in the locus coeruleus (LC) region of the brain, resulting in decreased availability of NE for release in that brain region and, consequently, an understimulation of alpha-2 receptors that normally respond to this transmitter. Since LC alpha-2 receptors inhibit firing of LC cells, reduced stimulation of these receptors should disinhibit LC cells. Therefore, firing (depolarization) of LC cells should be elevated after animals have been exposed to stressful conditions that depress active behavior.

A recent observation increases our ability to assess the influence of alpha-2 receptors on LC activity. Simson and Weiss (J. Neurosci., in press) found that LC cells considerably increase their firing to excitatory stimuli when alpha-2 receptors are blocked; in fact, the response of LC cells to excitatory stimuli is a much more sensitive index of alpha-2 receptor blockade in the LC than is a change in baseline firing rate. Therefore, responsivity of LC cells to stimulation should be particularly indicative of whether a "functional alpha-2 blockade" is present in the LC after exposure to stressful conditions that depress active behavior.

As in previous experiments, animals exposed to uncontrollable shock (N=11) showed less active behavior in a 15 min. swim test given 1.5 hours after shock. Using an Activity Score [AS] computed by subtracting seconds of floating from seconds of struggling, shocked animals showed less activity (mean AS = -306.4 ± 67.0) than did animals given no shock (N=7; mean AS= -91.2 ± 24.9; $p<.01$) Immediately after the swim test, animals were anesthetized with chloral hydrate and LC activity recorded. Baseline LC activity was elevated in shocked animals (mean firing rate 2.0 ± 0.4 per sec) in comparison to unshocked animals (1.2 ± 0.1), although this difference did not reach statistical significance ($t=1.7$, $df=16$). However, responsivity to paw compression (PC), an excitatory stimulus to the LC, was markedly, and significantly, elevated in shocked animals. In response to PC, average firing rate was 7.4 ± 0.7 per second in shocked animals and 4.4 ± 0.5 in animals given no shock ($p<.001$).

The results described above indicate that LC cells of stressed animals showing depression of active behavior are hyperresponsive to an excitatory input. That increased activity of the LC is involved in stress-induced behavioral depression was also supported by correlational findings. For the individual animals in this study, we correlated (a) the average increase in response of LC cells from baseline produced by PC and (b) Activity Score in the swim test. The correlation was $r=-.70$ ($p<.001$).

In summary, responsivity of LC units to excitatory stimulation was found to be elevated in stress-induced behavioral depression, and the degree of LC responsivity observed in individual animals correlated with the magnitude of depression seen in these animals.

14.8 PHENYLALANINE AND SPONTANEOUS BEHAVIOR IN THE RAT: ANALYSIS USING COMPUTER PATTERN RECOGNITION. P.J. Mullenix, M.S. Tassinari* and W.J. Kernan*. Toxicology Dept., Forsyth Dental Center, Boston, MA 02115 and Veterinary Diagnostic Lab., Iowa State University, Ames, IA 50011.

The effects of phenylalanine on the spontaneous motor behavior of the rodent have not been clearly defined. Increased, decreased and unaffected locomotor activity have all been reported (Thurmond et al., Pharmacol. Biochem. Behav. 12:525-532, 1980; Snodgrass, J. Pharm. Pharmacol. 26:931-936, 1974; Gibson et al., Psychopharmacology 76:118-121, 1982). The extent to which differences in behavioral methodology contribute to this confusion is unknown. Therefore, a new computer pattern recognition system (Kernan et al., Pharmacol. Biochem. Behav. 27:in press, 1987), which automatically classifies behavioral acts and determines the structure of motor output, was used to analyze the acute effects of phenylalanine in rats.

Fifteen male Sprague-Dawley rats (250-300g) were dosed orally with 281 mg/kg L-phenylalanine (PHE) suspended in a vehicle comprised of .5% w/v methylcellulose, .1% v/v polysorbate and distilled water. An additional fifteen male rats received the vehicle only. Both treated and control rats were fasted overnight prior to gavage. One hour subsequent to treatment, a control and an experimental rat were placed simultaneously on opposite sides of a divided, Plexiglas, novel environment which they explored for 15 minutes. All tests were conducted during the animals' diurnal period between 9:00 A.M. and 12:00 Noon. Movements were monitored from horizontal and vertical views using two video cameras. Behavior sampling rate was at 1 frame per second, and the frames were transfered to computers for analysis in real time. The behaviors recorded and the parameters quantified were more extensive than previously possible with other techniques. The frequency, duration and distribution in time of 16 different motor acts, as well as the velocity of movement, horizontal and vertical movements, circling and time spent in any sub-area of the test chamber, were determined for each rat. Immediately following the behavioral test, blood samples were obtained by cardiac puncture, and plasma PHE concentration was determined using HPLC.

The concentration of PHE in the plasma of control rats was 117.3 ± 9.8 µmol/l (SE, N=6), and PHE concentration in the plasma of treated animals was 246.4 ± 37.9 µmol/l (SE, N=6). Despite the relatively high concentration of PHE in the plasma of the treated rats, no significant signs of abnormal spontaneous behavior could be related to PHE treatment. Among the parameters tested, no pattern or trend characteristic of hyperactivity, an overt sign of CNS stimulation, was observed.

14.9 LATERAL DIFFERENCES IN MONOAMINE CONTENT OF DISCRETE BRAIN NUCLEI IN AMPHETAMINE-SENSITIZED RATS. J.M. Rivet*, G.J. LaHoste*°, P. Mormède* and M. Le Moal INSERM U-259, rue Camille Saint Saëns 33077 Bordeaux Cedex, France;°Dept. Psychobiol., Irvine University, Irvine, CA, USA.

Recent studies suggest that the preferred direction of rotation shown by rats following peripheral administration of amphetamine is due to an endogenous asymmetry of striatal dopamine (DA). This has been confirmed in female but not male rats. In addition, sensitization to amphetamine has been shown to result in enhanced release of DA following amphetamine challenge. In order to pursue these phenomena further, we measured monoamines and their metabolites in discrete brain nuclei in amphetamine-sensitized male and female rats which has been categorized as left- or right-turning (LT or RT). d-Amphetamine sulfate was administered (1.2 mg/kg in males; 0.85 mg/kg in females) three times at 10-day intervals and rotation was observed. Four to six weeks following the last injection, rats were placed in a novel environment for 15 minutes and decapitated. Brains were quickly removed and frozen at -80°C. Punches of discrete nuclei from the left and right hemispheres were taken from cryostat sections. Monoamine levels were measured by HPLC-EC.

Neurochemical differences were found in the lateral striatum of male rats according to their behavioral lateralization, DA and 5HT being higher in left turners. No such difference was found in females or in the medial striatum. Furthermore transmitter levels were equally distributed in both sides of these brain regions so that there was no neurochemical correlates of behavioral asymmetry. This is in contrast to what has been previously reported for female rats when amphetamine was administered prior to sacrifice.

Hypothalamic areas were also investigated for neurochemical asymmetries. The arcuate nucleus of both male and female rats showed a striking asymmetry in DA distribution, the left side having the highest DA concentration. However, the DOPAC/DA ratio, an index of DA turnover was the same in both sides. The paraventricular nucleus of male rats showed a difference in indole distribution, 5HT and 5HIAA levels being higher in the right side. However there was no relationship between neurochemical and behavioral lateralization. Little is known about functional significance of such differences.

14.10 CSF NOREPINEPHRINE AND MHPG, BUT NOT CSF HVA, IS UNDER STATE DEPENDENT CONTROL IN SCHIZOPHRENIA. D.P. van Kammen, W.B. van Kammen*, J. Peters*, M. Linnoila*, J. Yao*, and N. Nugent*. VA Medical Center, Highland Drive, Pittsburgh, PA 15206

In spite of the considerable evidence of dopaminergic involvement in schizophrenia, disturbances in the noradrenergic system have repeatedly and consistently been reported. In this study we examined our previous findings of increased CSF NE in schizophrenic patients. We have reported relationships between psychosis and CSF NE and MHPG, that could not always be replicated. In this study we controlled for changes in clinical state by comparing CSF monoamines in drugfree patients who were stable with those that relapsed. After we obtained informed consent, we studied 29 schizophrenic patients (DSM III) (age 20-50 yrs.) who were chronically treated with haloperidol (20 mg/day), received an LP according to standard procedures. After placebo replacement 14 patients relapsed and 15 did not in an 8 week placebo replacement trial. At the time of meeting relapse criteria patients received a second LP. Psychosis ratings (Bunney-Hamburg scale) of the day before and the hours of sleep of the night before the LP's were recorded. CSF NE, MHPG, HVA and 5HIAA were measured with HPLC.

RESULTS: Haloperidol treated patients, who would relapse later, had higher CSF NE levels (0.742±0.33 vs. 0.425±0.27 pg/ml, $p<.01$), but CSF HVA, MHPG and 5HIAA, sleep and psychosis ratings were identical compared to those patients who would not relapse after haloperidol withdrawal. After haloperidol withdrawal CSF NE, (0.875±.478 vs. 0.419±.26 $p<.007$), CSF MHPG (47.5±16.8 vs. 34.8±9.1, $p<.03$), psychosis (10.3±1.7 vs. 4.2±1.7, $p<.0001$) were significantly higher in the patients who relapsed than in the patients who did not. Relapsing patients slept considerably less the night before the LP (5.0±2.2 vs. 7.3±0.6 hours, $p<.003$). Similarly, correlations between these variables among the relapsers showed CSF NE to intercorrelate highly with sleep, and psychosis (r's.from -.55 and -.59 to .52 and .74). The relationship between CSF NE and MHPG were identical in both groups ($r=.50$, $p<.05$).

DISCUSSION: Our data indicate that increased NE is already present in haloperidol treated schizphrenic patients who will relapse after haloperidol withdrawal and that NE activity is further increased around the time of relapse. This increase in NE may contribute to psychotic worsening rather than be the result of the stress of psychosis exacerbation. Longitudinal sleep and behavioral, and weekly plasma data will be presented at the meeting as well.

14.11 DOPAMINE AND NOREPINEPHRINE ALTER SENSORY PHYSIOLOGY IN SCHIZOPHRENIA AND MANIA BY DIFFERENT MECHANISMS. L. Adler, G. Gerhardt, R. Franks*, N. Baker*, H. Nagamoto*, C. Drebing* and R. Freedman. Depts. of Psychiatry and Pharmacology, Univ. Colo. Hlth. Sci. Ctr., Denver, CO 80262.

Hyperactivity to sensory stimulation is a prominent characteristic of both schizophrenia and mania. Neurophysiological recordings show a common deficit in an inhibitory gating mechanism which regulates sensitivity to repeated auditory stimuli. Dopamine and norepinephrine are hypothesized to have major roles in these illnesses, but how they might cause aberrant sensory processing has not yet been elucidated. In this study, gating of auditory evoked potentials (as measured by the P50 auditory evoked potential conditioning-testing paradigm) during treatment of both illnesses was correlated with plasma dopamine and norepinephrine metabolites. Schizophrenics were found to have a fixed deficit in inhibitory auditory sensory gating, which is a familial trait unchanged by medication. During acute illness, they have an additional transient hypersensitivity to stimuli, manifested as smaller evoked potential waves, which is mediated by dopamine. Plasma HVA in treated schizophrenics decreased significaantly from baseline (18.9 $\pm$ 4.7 to 13.1 $\pm$ 3.2 ng/ml s.d., $p < 0.01$, by paired t-test). Manics have only the deficit in inhibitory gating, which is transient and mediated by norepinephrine. Plasma MHPG in manics decreased from 5.6 $\pm$ 1.3 to 3.4 $\pm$ 0.05 ng/ml s.d.($p < 0.01$ by paired t-test) with a corresponding improvement in auditory sensory gating. Thus, the common neurophysiological deficit in the two psychoses arises from different biochemical abnormalities, which may explain similarities in acute symptoms and differences in lifetime course.

14.12 EVIDENCE THAT BETA-ADRENERGIC ACTIVITY INHIBITS RATHER THAN FACILITATES LORDOSIS BEHAVIOR IN THE FEMALE RAT. S.D. Mendelson and B.B. Gorzalka. Dept. of Psychology, Univ. of British Columbia, Vancouver, B.C. V6T 1Y7, Canada.

Observations of inhibition of lordosis behavior following central (Foreman and Moss, Pharmacol. Biochem. Behav., 9:235, 1978) and peripheral (Fernandez-Guasti et al., Pharmacol. Biochem. Behav. 22:279, 1985) administration of racemic propranolol have led to the hypothesis that activation of central beta-adrenergic receptors facilitates lordosis behavior in female rats. In the present study both (-) propranolol (9 mg/kg) and (+) propranolol (9 mg/kg) were found to inhibit lordosis when administered peripherally to ovariectomized rats that had received estrogen and progesterone. Of the two optical isomers of propranolol, only the (-) form is known to be active at beta-adrenergic receptors, whereas both (-) and (+) isomers produce stabilization of neural membranes (Fitzgerald, Clin. Pharmacol. Ther. , 10:292, 1969). These data suggest that the stabilization of neural membranes rather than beta-adrenergic blockade was responsible for the lordosis-inhibiting effects of propranolol. Consistent with this possibility are our findings that the centrally active beta-adrenergic antagonist metoprolol (Cowen et al., Br. J. Pharmacol. , 76:265, 1982) (0-75 mg/kg) had no effect on lordosis behavior, whereas the membrane stabilizing drug lidocaine (30 mg/kg) inhibited lordosis responding. Peripheral administration of the centrally active beta-adrenergic agonist salbutamol (6-20 mg/kg) was found to inhibit lordosis, and this effect was reversed by the co-administration of metoprolol (20 mg/kg). These data suggest that stimulation of central beta-adrenergic receptors may inhibit rather than facilitate lordosis.

GENE STRUCTURE AND FUNCTION I

15.1 cDNA CLONING OF A SEROTONIN 5-HT_{1C} RECEPTOR USING ELECTROPHYSIOLOGICAL ASSAYS OF mRNA INJECTED XENOPUS OOCYTES

H. Lubbert*, B.J. Hoffman+, T.P. Snutch*, T. van Dyke**#, A.J. Levine**#, P.R. Hartig+, H.A. Lester, and N. Davidson* (Spon: Z. Annau). Divs. of Biology and Chemistry, Caltech, Pasadena, CA 91125, +Depts. of Biology and Env. Health Sci., Johns Hopkins University, Baltimore MD 21205, #Dept. of Mol. Biology, Princeton University, Princeton, NJ 08544.

We have designed a strategy for the cloning of neurotransmitter receptor and ion channel cDNAs which is based on electrophysiological assays of mRNA injected Xenopus oocytes. This procedure circumvents the purification of these membrane proteins which is hindered by their low abundance and their hydrophobic nature. It involves methods for RNA fractionation by high resolution gel electrophoresis, directional cDNA cloning in a single-stranded vector, and screening of the cDNA library by voltage-clamp measurements of currents induced by serotonin in mRNA injected oocytes.

We used this approach to isolate a serotonin receptor cDNA clone from mouse choroid plexus papilloma. The clone was identified by hybrid depletion and hybrid selection procedures. The receptor expressed in oocytes injected with hybrid selected RNA is fully functional, indicating that it is composed of a single subunit encoded by a 5 kb RNA. The pharmacology of the hybrid selected receptor confirms that we have successfully cloned a 5-HT_{1C} receptor cDNA.

15.2 ANALYSES OF CLONED SEROTONIN 5-HT_{1C} RECEPTOR cDNAs

B.J. Hoffman, H. Lubbert*+, H. Nguyen*+, P.R. Hartig, H.A. Lester+, and N. Davidson*+. Depts. of Biology and Env. Health Sci., Johns Hopkins University, Baltimore, MD 21205 and +Divs. of Biology and Chemistry, Caltech, Pasadena, CA 91125.

Serotonin (5-HT) induces conductances in Xenopus oocytes injected with rat brain mRNA. Although there are at least six subtypes of serotonin binding sites in the mammalian central and peripheral nervous systems, we have shown that only the 5-HT_{1C} receptor is functionally expressed in mRNA injected oocytes. This receptor opens an endogenous Ca dependent Cl channel in the oocyte membrane via inositol trisphosphate (IP_3) release. We have shown that 5-HT_{1C} receptors mediate an increase in phosphoinositide turnover in intact rodent and pig choroid plexi. The richest source of 5-HT_{1C} binding sites is the choroid plexus while other regions of the brain, for instance, hippocampus, cortex and striatum, express lower densities of these receptors. Using serotonin-induced currents in mRNA injected oocytes as a bioassay, we have isolated a cDNA clone for the serotonin 5-HT_{1C} receptor.

We will present preliminary sequence data for a 5-HT_{1C} receptor and compare computer analyses of our data to other receptors and transmembrane proteins. Using Northern blot analysis, we have determined the abundance and size distribution of serotonin 5-HT_{1C} receptor mRNA in various brain regions and in several peripheral tissues which receive serotonergic innervation. Since these receptors are present in all mammalian species examined, we have analyzed the homology between 5-HT_{1C} receptor genes in rat, mouse, pig and human by Southern blotting.

15.3 **MUTATIONAL ANALYSIS OF A CYCLIC AMP-RESPONSIVE ENHANCER ELEMENT IN THE HUMAN VIP GENE.** J.S. Fink, M. Verhave*, T. Tsukada*, G. Mandel* and R.H. Goodman*. Division of Molecular Medicine, New England Medical Center, Boston, MA 02111 and Dept. of Neurology, Massachusetts General Hospital, Boston, MA 02114.

Transcription of the human VIP (hVIP) gene is regulated by cyclic AMP (cAMP). We have previously identified a 17 base pair (bp) region within the 5'-flanking sequences of the hVIP gene that is important for transcriptional regulation by cAMP. These sequences are capable of conferring cAMP-responsiveness to a heterologous viral promotor. In this study we sought to determine (1) if the VIP cAMP regulatory element (CRE) has characteristics of an "enhancer", i.e. the ability to confer cAMP-regulation to a heterologous promotor in an orientation and distance-independent manner, and (2) the critical nucleotides necessary for activity of the VIP CRE.

Fusion genes containing portions of the 5'-flanking region of the hVIP gene linked to the Rous sarcoma virus (RSV) promotor and the chloramphenicol acetyltransferase (CAT) reporter gene were introduced into PC12 or C6 glioma cells and tested for responsiveness to forskolin, an activator of adenylate cyclase. The VIP CRE conferred cAMP regulation when introduced in either orientation, or when placed 300 bp upstream from the RSV promotor or 3' to the CAT coding sequences. S1 nuclease mapping demonstrated that the VIP CRE faithfully regulated transcription from the heterologous RSV promotor. Using synthetic oligonucleotides containing base changes within the VIP CRE we determined that mutation in the 3' or 5' ends of the VIP CRE resulted in a 40-75% loss of cAMP responsiveness. Mutation of bases in a middle region of the VIP CRE (nucleotides -78 to -80 from the VIP transcription initiation site) preserved cAMP responsiveness.

We conclude: (1) the hVIP CRE is a regulatable enhancer, such as is present in the interferon, phosphoenolpyruvate carboxykinase, proenkephalin and c-fos genes, and (2) sequences contained within the VIP CRE form 2 functional domains which are necessary for full activity.

15.4 TRANSCRIPTIONAL CONTROL OF THE RAT CORTICOTROPIN RELEASING HORMONE GENE. A.F. Seasholtz*, R.C. Thompson*, E. Herbert*, and J.O. Douglass* (SPON: R. Nishi). Vollum Institute for Advanced Biomedical Research, Oregon Health Sciences University, Portland, OR 97201.

The rat corticotropin releasing hormone (CRH) gene has been isolated and characterized by DNA sequence analysis (Thompson, R.C., Seasholtz, A.F., and Herbert, E., Mol. Endo., 1:363,. 1987). RNA blot analysis demonstrates the expression of the CRH gene in numerous regions of the rat brain as well as the spinal cord, adrenal gland, pituitary, and testis. The rat CRH gene exhibits a structural organization similar to that of the human gene (Shibahara, S. et al., EMBO 2:775, 1983), having two exons separated by an intervening sequence. Analysis of the nucleotide sequence homology between the human and rat CRH genes reveals several highly conserved regions (greater than 90% homology) including the CRH peptide-encoding sequence and the 5' flanking sequence. Studies with a variety of other genes have shown that DNA sequences 5' to the mRNA cap site often contain transcriptional control sequences including enhancer (or silencer) elements, tissue-specific elements, or DNA elements responsible for regulation by cAMP, phorbol esters, or glucocorticoids. The 335 bp of DNA immediately 5' to the putative mRNA cap sites for the human and rat CRH genes show 94% homology, suggesting that this region may contain regulatory elements which have been conserved through evolution. In order to test for transcriptional control elements, 1.4 kb of 5' flanking DNA from the rat CRH gene has been fused to the coding sequence of the E. coli chloramphenicol acetyltransferase (CAT) gene to create the plasmid CRHCAT. In this fusion gene construct, the amount of CAT enzyme activity reflects the amount of protein produced under the control of the linked CRH regulatory region. The CRHCAT plasmid DNA has been transfected into a variety of cell lines including PC-12 (rat pheochromocytoma), AtT-20 (mouse anterior pituitary), and CV-1 (monkey kidney) cells. We have been able to demonstrate regulation of CAT gene expression by cAMP analogues and glucocorticoids, suggesting the presence of these regulatory elements in the 5' flanking sequence of the rat CRH gene. The exact locations of these transcriptional control elements are being determined using deletion analysis.

15.5 REGULATION OF EXPRESSION OF A NEURON SPECIFIC GENE: NEUROPEPTIDE Y

Janet M. Allen, Joseph B. Martin and Gerhard Heinrich
Department of Neurology and Medicine
Mass General Hospital and Howard Hughes Medical Institute
Boston, MA 02114

Neuropeptide Y (NPY) is a 36 amino acid amidated peptide that is produced exclusively by neural tissue. It is present in abundance in mammalian brain and in a subset of sympathetic neurons. The peptide meets some of the criteria required for neurotransmitter status. It is a potent vasoconstrictor peripherally and has been implicated in the central control of blood pressure, circadian rhythms and feeding behavior.

The PC 12 clonal cell line has been used extensively as a model of neuronal differentiation. Nerve growth factor (NGF) induces these cells to undergo changes to neuronal morphology. We have used this cell line to investigate the molecular mechanisms involved in the regulation of expression of the NPY gene. In particular the effect of NGF on the levels of NPY has been determined by Northern blot hybridization analysis. Low levels of NPY mRNA were identified in resting naive PC 12 cells which was indistinguisable from NPY mRNA extracted from rat brain. Levels were induced five fold by the addition of NGF to the medium at a dose of 30ng/ml, whereas lower doses had no effect. The effect of NGF on NPY mRNA was rapid in onset and reversible, preceeding the NGF induced changes in morphology by several days. A smaller twofold rise in NPY mRNA was observed in cells treated with epidermal growth factor but no effect was found following treatment with fibroblast growth factor, bradykinin or dexamethasone. These results indicate that NPY gene expression is regulated in PC 12 cells at the level of NPY mRNA.

To identify the cis and trans factors that regulate NPY gene expression, the NPY gene was cloned from a rat genomic library. Structural analysis revealed 4 exons and 3 introns residing in a 15kb fragment of rat genomic DNA. The organisation is very similar to that of pancreatic polypeptide gene and identical with the human gene, such that exons encode functional domains in the mRNA and NPY precursor. The promoter regions of human and rat NPY are highly homologous suggesting important cis elements are present that meidate cell-specific and transcriptional regulation.

15.6 NERVE GROWTH FACTOR GENE EXPRESSION: REGULATION OF TRANSCRIPTION AND mRNA STABILITY. M.Zheng*, P.D.Rennert* and G.Heinrich. Lab for Mol. Endo., Howard Hughes Med. Inst., Dep. Med., Mass. Gen. Hosp., Boston, MA 02114

Nerve growth factor (NGF) is essential for the survival of specific neurons. During development and adulthood NGF production by neuronal targets is limited to minute amounts under basal conditions but can be rapidly and substantially modulated by injury and hormones. Inasmuch as NGF production is limited by cellular levels of NGF mRNA we are focusing on the molecular mechanisms that regulate NGF gene transcription and NGF mRNA stability, the two crucial determinants of NGF mRNA levels and NGF production.

To structurally and functionally identify the cis elements that regulate NGF gene transcription, we cloned and analyzed the promoter and 5' flanking regions of mouse and rat NGF genes, and fused these regions to a reporter gene encoding human growth hormone. Comparison of the nucleotide sequences of rat and mouse NGF genes revealed >90% homology in exon 1 and the promoter region, but <70% further upstream, suggesting that important regulatory elements are close to the promoter. Transcriptional initiation sites were mapped by S1-nuclease protection and reverse transcription. Deletion analysis, gel delay, and footprinting experiments are being carried out to characterize the cis and trans factors that act on the NGF gene.

To determine NGF mRNA stability, transcription was inhibited with actinomycin D in L929 fibroblasts, and slices of mouse salivary gland and rat heart, and NGF mRNA decay measured by Northern blot hybridization. NGF mRNA was unstable in L929 cells and heart (T1/2 > 1h), but stable in SMG (T1/2 > 12h). Dexamethasone rapidly reduced NGF mRNA levels in L929 cells, but had no effect on T1/2. Puromycin had no effect on T1/2 in L929 cells or SMG. The short T1/2 of NGF mRNA in target tissues may account in part for the low tissue levels of NGF. To identify the region(s) of NGF mRNA that determine stability, segments of NGF mRNA were spliced into the stable human growth hormone mRNA. Analysis of the stability of the chimeric mRNAs by transient expression of the chimeric genes in L929 cells will delineate the region(s) of NGF mRNA involved in regulation of its stability.

15.7 **CLONING AND SEQUENCE ANALYSIS OF cDNA FOR RAT CARBOXYPEPTIDASE E (ENKEPHALIN CONVERTASE).** L.D.Fricker Department of Molecular Pharmacology, Albert Einstein College of Medicine, Bronx NY 10461

Many peptide hormones and neurotransmitters are produced from larger precursors which contain pairs of basic amino acids surrounding the bioactive peptides, and the sequential action of trypsin-like and carboxypeptidase B-like enzymes would liberate the peptides. Carboxypeptidase E (CPE, also designated enkephalin convertase, carboxypeptidase H, and EC 3.4.17.10) is thought to be the carboxypeptidase B-like enzyme involved in the production of many different peptide hormones and neurotransmitters. Two enzymatically active forms of CPE, a soluble and a membrane-bound form, are present in peptidergic secretory granules. The two forms have similar enzymatic and physical properties, as well as an identical N-terminal amino acid sequence. Recently, a cDNA clone encoding CPE has been isolated from a bovine pituitary cDNA library (Fricker,L.D., et al, Nature 323:461, 1986). This cDNA clone was not full length, and no information regarding the precursor structure of the enzyme was provided from the nucleotide sequence. In order to obtain a full length clone, the bovine cDNA was used to screen rat brain cDNA libraries. A clone which appears to code for the complete CPE protein was isolated and sequenced. This initial translation product contains an additional 42 amino acids on the N-terminus of the active forms of CPE. Of this N-terminal peptide, the first 25 amino acids resemble a signal peptide, and there are several potential signal peptide cleavage sites in positions 17-25. The remainder of this N-terminal peptide contains several charged amino acids, and does not fit with the predicted structure of signal peptides. Furthermore, there are five adjacent arginines immediately preceding the N-terminus of the active forms of CPE. This suggests that a trypsin-like endopeptidase is involved in the production of enzymatically active CPE.

The predicted amino acid sequence for rat CPE is 94% homologous with bovine CPE. As with bovine CPE, the rat CPE sequence contains several pairs of basic amino acids. One of these pairs is 20 amino acids from the C-terminus of the initial translation product, and this region is completely homologous with the bovine sequence. The predicted secondary structure of this C-terminal region is an amphipathic α-helix, which may interact with the lipid bilayer. This could contribute to the binding of the enzyme to the membranes. Since the soluble form of CPE is 3000 Da smaller than the membrane-bound form, cleavage of this C-terminal peptide at the pair of basic amino acids near the C-terminus would be consistent with the difference in molecular weight of the two forms. Biochemical studies that address this possibility will be presented.

15.8 THE COMPLETE NUCLEOTIDE SEQUENCE AND STRUCTURE OF THE GENE ENCODING BOVINE ADRENAL PHENYLETHANOLAMINE N-METHYLTRANSFERASE D.K. Batter, S.R. D'Mello*, L.M. Turzai*, H.B. Hughes*, A.E. Gioio*, and B.B. Kaplan Molecular Neurobiology Program, Department of Psychiatry, University of Pittsburgh School of Medicine, Pittsburgh, PA 15213

Phenylethanolamine N-methyltransferase (PNMT) is the terminal enzyme of the catecholamine biosynthetic pathway, catalyzing the conversion of norepinephrine to epinephrine. Importantly, the expression of the PNMT gene, in part, defines the adrenergic cell phenotype. To determine the molecular genetic mechanisms controlling selection of the catecholamine phenotype, we have initiated studies on the regulation of adrenal PNMT gene expression. In this communication, we report the complete structure and nucleotide sequence of the gene for bovine adrenal PNMT.

A cloned PNMT cDNA probe was used to screen a Charon 28 bovine genomic library. After screening approximately 1.0 x 10^6 pfu, one recombinant phage (λP1) was identified which included the entire PNMT gene within 17 kilobases of genomic DNA. A restriction endonuclease map of λP1 was constructed and exon-containing fragments identified by Southern blot analysis. These fragments were sub-cloned into M13 vectors, and sequenced by the Sanger dideoxy method. Analysis of these fragments, and several more further upstream, indicates that the bovine PNMT gene is 1594 base pairs (bp) in length, consisting of three exons interrupted by two introns. The transcription initiation site was identified by conventional primer extension analysis and a recently published method using T4 DNA polymerase (Hu & Davidson Gene 42:21-29, 1986). Results of both these experiments indicate that transcription is initiated at a 'C' residue, located 12 bp upstream from the ATG translation start site. The 3' untranslated region is 88 bp in length and contains the expected polyadenylation signal (AATAAA). A putative promoter sequence (TATA box) is located 25 bp upstream from the transcription initiation site. Genomic Southern blot analysis indicates that the PNMT gene is probably present in a single copy per haploid genome. Additionally, computer comparison of the nucleotide sequence data with consensus sequences of known regulatory elements revealed possible binding sites for glucocorticoid receptors, and for the Sp1 regulatory protein. Interestingly, whereas the location of putative Sp1 binding sites are restricted to the 5' flanking region of the gene, those for the binding of glucocorticoid receptors appear both in 5' and 3' flanking regions and within the third exon of the PNMT gene. The functional significance of these putative regulatory sequences, with respect to PNMT gene expression, remains to be elucidated. Comparison of the sequence of the bovine PNMT exons to cDNA sequences encoding several biogenic amine-synthesizing enzymes revealed no significant regions of homology.

15.9 BC1 RNA IS ENCODED BY A UNIQUE GENE WHICH IS EXPRESSED HETEROGENEOUSLY IN THE RAT NERVOUS SYSTEM. H. Tiedge*, R. T. Fremeau, A. H. Ahn*, C. Slater*, D. I. Lugo, J. Pintar, J. L. Roberts, and J. Brosius*, Columbia University College of Physicians and Surgeons, 722 W 168th St., New York, NY 10032.

BC1 is a small non-messenger RNA that is subject to developmental and tissue-specific gene expression. This cytoplasmic RNA was initially identified by Sutcliffe and coworkers (PNAS U.S.A. 79: 4942, 1982) based on its ability to hybridize to the 75 nucleotide repetitive ID element. cDNA sequence analysis demonstrated that BC1 RNA is homogeneous and is transcribed from only one gene (DeChiara, T. M., and Brosius, J., PNAS U.S.A. 84: 2624, 1987). BC1 RNA is comprised of three domains: (1) the 5' ID element which includes an internal RNA polymerase III promoter, (2) a central A-rich region, and (3) a 3' unique sequence.

To begin to understand the possible functions of BC1 RNA in the nervous system, we examined its cellular localization in rat brain and selected peripheral tissues by hybridization *in situ*.. The unique part of the molecule was used as a probe. Within the brain, BC1 RNA is expressed heterogeneously. High levels of expression were found in the thalamus, the hypothalamus, the zonal layer of the superior colliculus, the dorsal cortex of the inferior colliculus, the dorsal and medial central gray, the dorsal tegmentum, and the amygdaloid complex. Intermediate levels were detected in certain layers of the neocortex and the hippocampus. Low levels were detectable in the cerebellum and the striatum. Only background labelling was observed overlying the corpus callosum, the anterior commissure, and the choroid plexus. Brain stem levels were generally low except for the area postrema, the nucleus tractus solitarius, and the spinal trigeminal nucleus. In the spinal cord BC1 RNA was found exclusively in the central gray matter. BC1 RNA has also been found to be expressed in peripheral nervous tissues such as the dorsal root ganglia, the superior cervical ganglia, the retina, and the anterior lobe of the pituitary. No specific labelling was observed in liver, kidney, and spleen, or in any section hybridized with a sense-strand probe.

During embryogenesis, BC1 RNA was detectable at a low level as early as day e11.5, mainly in the developing spinal cord. By day e16, significant amounts of BC1 RNA were detectable in a distinct area of the myelencephalon. By postnatal day 8, the pattern of BC1 expression in the brain was very similar to that found in adult.

Investigations of the molecular mechanisms underlying the temporal and spatial regulation of the BC1 gene will be presented.

15.10 MOLECULAR CLONING OF A cDNA ENCODING RABBIT MYELIN P_2 PROTEIN V. Narayanan*, E. Barbosa*, R. Reed* and G. Tennekoon*. Depts. of Neurology and Molecular Biology and Genetics, Johns Hopkins Univ. Sch. of Med., Baltimore, MD 21205. (SPON: R. Johnson)

Myelin basic protein P_2 causes experimental allergic neuritis (EAN). Although it was initially thought to reside exclusively in the PNS, immunocytochemical studies have shown its presence also in the rabbit CNS. Amino acid sequence of P_2 has shown that P_2 is homologous with other fatty acid binding proteins, with the closest homology being to adipocyte fatty acid binding protein. Although the adipocyte fatty acid binding protein was cloned (Bernlohr 1984), we were unable to use this cloned cDNA (pAL 422) for investigation of expression of myelin P_2, so we proceeded to clone myelin P_2 protein.

Total RNA was isolated from the sciatic nerves of 9 to 10-day-old New Zealand white rabbits followed by selection of polyA$^+$ RNA. In vitro translation of polyA$^+$ RNA using the rabbit reticulocyte system followed by immunoprecipitation with rabbit anti-bovine P_2 antibody gave a single band of M.W. 14,800. The polyA$^+$ RNA was then used to construct cDNA as described by Gubler and Hoffmann, and the library construct in the bacteriophage gt10. From 1 ng of DNA 10^6 recombinants were obtained. An oligonucleotide mixture was synthesized based on the amino acid sequence of rabbit myelin P_2 protein from positions 14 to 22 (N-Glu-Asn-Phe-Asp-Asp-Tyr-Met-Lys-Ala-OH). After purification by HPLC, the oligonucleotides were end-labeled with (^{32}P) -ATP and used to screen the library. From about 15,000 clones, 6 positive clones were identified after plaque purification and re-screening. Cross-hybridization with the probes suggested that all six clones belonged to the same family. One of the phage clones containing a 1.2 kb insert was subcloned into Bluescript vector - pSN 2.9B. Sanger dideoxy sequencing revealed a single open reading frame corresponding to the published P_2 amino acid sequence. RNA blots using the nick translated pSN2.9B recognized a 2 kb mRNA in rabbit sciatic nerve and spinal cord. However, no signal was detected on RNA blots containing total RNA from liver and heart. These tissues are known to contain other fatty acid binding proteins.

The developmental profile of P_2 mRNA levels in sciatic nerves and CNS as well as the full length nucleotide sequence will be presented.

15.11 MUTATION IN THE GENE FOR MYELIN PROTEOLIPID PROTEIN (PLP) AND DM-20 IN THE DYSMYELINATING *JIMPY* MOUSE. K.-A. Nave, C. Lai*, F.E. Bloom, and R.J. Milner. Research Institute of Scripps Clinic, and Depts. of Neuroscience and Biology, University of California, San Diego, La Jolla, California 92037.

Proteolipids (PLP and DM-20) are the major integral membrane proteins of CNS myelin and are implicated in the formation and maturation of the myelin sheath. We show that the DM-20 protein of myelin derives from an alternatively spliced PLP gene transcript and differs by the internal deletion of 35 amino acids from the 276 residue PLP sequence. DM-20 specific mRNA splicing results from the selection of an alternative 5' splice site located 105 base pairs within the third exon of the PLP gene.

The mutant mouse *jimpy*, which has a developmental defect in the formation of CNS myelin, lacks immunoreactive PLP but has demonstratable expression of PLP mRNA on Northern blot analysis. We have characterized PLP cDNAs obtained from 20 day old *jimpy* mouse brain mRNA and found a deletion of 74 nucleotides in the protein coding region. Additionally, this deletion causes a frameshift of translation and predicts that *jimpy* -PLP has a truncated and altered C-terminus, which is unlikely to be functionally inserted into the myelin membrane. DM-20 mRNA in *jimpy* shows the same deletion, which further demonstrates that both proteins are derived from the same X-linked gene.

Genomic Southern blotting experiments and sequence analysis of the *jimpy* PLP gene, however, show that the 74 nucleotide sequence is not deleted in the mutant gene but corresponds to a separate exon. We suggest that a mutation affecting a consensus splice site of the PLP gene and leading to the loss of the fifth coding exon from both PLP and DM-20 mRNA is the primary defect of the *jimpy* mutant.

Supported in part by grants from NIH (NS 21815), NIAAA (AA 06420) and McNeil Pharmaceuticals.

15.12 EXPRESSION OF A HOMEOBOX GENE IN THE CNS OF NORMAL AND TRANSGENIC MICE. J Zakany*, M. Patel*, C. M. Nguyen-Huu* (SPON: C. Noback) Depts. of Urology and Microbiology, College of Physicians and Surgeons, Columbia University, New York, NY, 10032.

Several mouse homeobox containing genes are expressed in specific regions of the developing central nervous system. We have isolated a murine homeobox containing gene localized on chromosome 6 designated Hox-1.3. The longest open reading frame in the cDNA sequence predicts a protein of 269 aminoacid residues with the homeobox located very close to the carboxyl terminus. The sequence of the genomic DNA shows the presence oftwo exons separated by an 0.95 kb intron positioned 20 bp upstream of the homeobox. RN-ase protection experiments indicate that the 5 end of the Hox-1.3 transcript is located at 0.25 kb upstream of the first ATG initiation codon. In the adult, Hox-1.3 transcripts are detected at high levels in the spinal cord and at lower levels in other tissues such as brain, testis, liver and kidney. In the midgestational embryo, the gene is mainly expressed in the lower myelencephalon and the cervical spinal cord.

In order to identify cis-acting regulatory sequences of the Hox-1.3 gene we have generated several lines of transgenic mice containing putative Hox-1.3 promoter/regulatory sequences fused to indicator sequences. The first fusion gene (Hox-1.3-hGh) contains about 3 kb 5 flanking sequences, the first exon, the intron and part of the second exon of Hox-1.3 fused in frame to human growth hormone gene sequences. The second fusion gene (Hox-1.3-lacZ) contains the complete Hox-1.3 gene with the structural gene for E. coli -galactosidase iserted immediately downstream of the initiation codon. The indicator sequences have been arranged to ensure their transcription into a hybrid message and translation into a hybrid Hox-1.3-hGH protein or a functional -galactosidase protein. Thus the expression of the transgenes can be analyzed at the molecular as well as histochemical levels. The results of the comparative analyses of the expression of the transgenes and the endogenous Hox-1.3 gene in the central nervous system will be presented.

15.13 **Interspecies Comparison of the Promoter Region of the Putative Drosophila Sodium Channel.** C. Smith* and L. Salkoff (SPON: L. Salkoff). Dept. Anat. & Neurobio., Washington Univ. Sch. Med., St. Louis, MO 63110.

Unlike the vertebrates, the expression of the voltage-sensitive sodium channel in the invertebrates, such as Drosophila, is limited to neural tissue. Thus, the promoter of the Drosophila sodium channel gene must contain elements that direct its expression uniquely to neurons. We are seeking to identify those promoter elements that specifically address the expression of the voltage-gated sodium channel gene to neurons. The deduced amino acid sequence of a Drosophila melanogaster ion channel, with high homology to the vertebrate sodium channel, has been determined, (Salkoff et al, Soc. Neuro. Sci. Abst., this issue). This deduced sequence encompasses all four homology units, containing all the intramembrane elements assumed to be essential for correct channel function. This includes 24 putative membrane spanning units (6 per homology unit) and 24 presumed gating charges having the same location as the gating charges of the vertebrate sodium channel.

The genomic DNA sequence for these regions as well as the promoter region 5' to the coding regions has been determined. We are conducting an interspecies comparative study of the promoter region of this possible sodium channel gene. Sequences located 5' to the transcriptional start site may be involved with controlling the expression of the gene so that it is expressed in the appropriate tissue type (neuron but not muscle), at the proper time in development and in the correct amount. We are using a second species, D. virilis, in this study to take advantage of the fact that Drosophila DNA drifts at approximately 1% per 1,000,000 years. D. virilis is about 50,000,000 years distant from melanogaster. Consequently, there is a high probability that any highly conserved regions in the promoter sequences of these two species will be of functional significance. This supposition is supported by the findings of Scholnick et al (Science 234:998-1002 (1986)) in their study of the melanogaster dopa decarboxylase promoter. A portion of this work compares the promoter regions of melanogaster and virilis. Many of the conserved sequences were shown to be essential for tissue specific expression and for controlling the level of expression in different tissues.

Our sequence data of the virilis promoter show several areas of very highly conserved DNA; in some instances the homology to the melanogaster sequence exceeds 90%. To begin our analysis of the significance of these conserved regions, we will link the virilis promoter to beta-galactosidase and, after p-element transformation of wild type Drosophila with this construct, we will study beta-galactosidase expression in response to specific alterations made to the conserved sequences in the promoter.

16.1 SEROTONIN FACILITATES A NON-CHOLINERGIC SYNAPSE IN THE BUCCAL MASS OF APLYSIA. D.P. Lotshaw and P.E. Lloyd, Dept. of Pharmacological and Physiological Sciences, Univ. of Chicago, Chicago, IL 60637.

Sensitization of defensive reflex behaviors in the marine mollusk Aplysia has been attributed to heterosynaptic facilitation of central sensory neuron to motor neuron synapses. Serotonin (5-HT) can mimic heterosynaptic facilitation at these synapses and 5-HT released from the metacerebral cell (MCC) has also been found to mediate arousal of feeding behavior by potentiating cholinergic buccal muscle contractions (Weiss et al., J. Neurophysiol. 41:181-203). In the present study 5-HT or MCC stimulation was found to facilitate a non-cholinergic neuro-muscular synapse in the buccal mass, demonstrating the existence of peripheral serotonergic heterosynaptic facilitation.

The motor neuron employed was one of the large ventral neurons of the symmetrically paired buccal ganglia. The neuron was located on the rostral border of the ventral cluster between the identified neurons B15 and B8 and was readily characterized by the absence of inhibitory synaptic input from the identified buccal neurons B4 and B5. The motor neuron innervated the most rostral I3 muscle bundles of the buccal mass. The I3 muscle consists of several parallel bundles which encircle and close the jaws upon contraction. Bursts of action potentials at frequencies greater than 15 Hz are required to induce muscle contractions. Contractions were not affected by the cholinergic antagonist hexamethonium. Motor neuron induced muscle contractions exhibited long lasting potentiation and the interval between motor neuron spike bursts was generally in excess of two minutes. Stimulation of the MCC or brief perfusion of 1μM 5-HT over the I3 muscle transiently increased isotonic contractions between 100% and 200% over controls.

Muscle post-synaptic potentials (PSP) were recorded intracellularly in response to brief bursts of motor neuron spikes evoked at 20 to 25 Hz because the PSP exhibited pronounced facilitation whereas single spike PSPs were not detectable. Perfusion of the muscle with 1 μM 5-HT or MCC stimulation induced multiple effects on the muscle membrane and synaptic transmission: the muscle fiber membrane potential usually hyperpolarized by a few mV, the muscle fiber input resistance decreased, the magnitude of the PSP increased, and the relaxation rate of the PSP increased. A post-synaptic site of action may partially explain these serotonergic effects. If the muscle membrane hyperpolarization may be attributed to an increased ion conductance, possibly K^+, the corresponding decreased input resistance would be expected to increase the relaxation rate of the PSP by decreasing the membrane time constant. The magnitude of the muscle fiber hyperpolarization was insufficient to account for the increased PSP amplitude, which was observed to increase by 50% to 100% over controls in response to 1 μM 5-HT or MCC stimulation. It remains to be determined whether the 5-HT induced increase in the PSP reflects an increase in transmitter release or an increase in the sensitivity of the post-synaptic membrane to the transmitter. (Supported by NIH NS23569 and Whitehall Foundation grants).

16.2 **STRUCTURE AND BIOLOGICAL ACTIVITY OF MYOMODULIN, A NOVEL NEUROPEPTIDE PRESENT IN AN IDENTIFIED CHOLINERGIC BUCCAL MOTONEURON OF *APLYSIA*.** **K.R. Weiss, E.C. Cropper, R. Tenenbaum* and I Kupfermann. Cntr. Neurobiol. & Behav., N.Y. State Psychiat. Inst., and Columbia Univ., N.Y., N.Y. 10032**

The accessory radula closer muscle (ARC) has provided a useful model for the study of motor control, specifically modulatory processes involved in the expression of food induced behavioral arousal. Food-arousal is a behavioral state that is expressed in part via modulation of the properties of muscle contractions. ARC contractions are known to be modulated by several substances, including a peptide factor, termed myomodulin, which is present in cholinergic ARC motoneuron B16. To help define the complement of potential modulatory peptides in the muscle we used HPLC to fractionate extracts of ARC muscle, and then tested the various fractions for bioactivity on the muscle. These studies have shown that the ARC contains numerous bioactive substances that either enhance or depress ARC contractions, and we have purified and sequenced a number of these substances. Inhibitory peaks include some unidentified substances as well as FMRFa and a novel peptide termed buccalin (Cropper et al., these abstracts). Two of the potentiating substances consist of SCP_A and SCP_B. Gas phase sequencing of a third potentiating substance established a putative sequence for a novel peptide. It was found that only the amidated replica had chromatographic and biological properties identical to that of the native peptide present in the muscle. The structure of this peptide is Pro-Met-Ser-Met-Leu-Arg-Leu-amide. In additional experiments utilizing 3 stages of HPLC, we found that this peptide precisely coelutes with the ^{35}S labeled peptidic factor myomodulin extracted from B16 neurons. We therefore conclude that the newly sequenced peptide is identical to the previously unsequenced factor-myomodulin, and that this peptide is present in the cholinergic motoneuron B16.

In conclusion, sequencing the SCPs and myomodulin from the ARC muscle and the localization of these peptides to the cholinergic motoneurons for the ARC muscle, coupled with our knowledge of the modulatory role of the serotonergic innervation of this muscle creates an exciting opportunity to study the role of multineuronal convergent modulation in a behavioral context.

16.3 **BUCCALIN: A NOVEL MODULATORY NEUROPEPTIDE COLOCALIZED TO THE SCP-CONTAINING CHOLINERGIC MOTONEURON B15 OF *APLYSIA*.** **E.C. Cropper, R. Tenenbaum*, I. Kupfermann, and K.R. Weiss. Cntr. Neurobiol. & Behav., N.Y. State Psychiat. Inst., and Columbia Univ., N.Y.,N.Y. 10032**

Recently we demonstrated that the cholinergic motor neuron B15 contains the two neuropeptides, SCP_A and SCP_B. These neuropeptides, when exogenously applied, potentiate motor neuron evoked contractions of the ARC, the muscle innervated by B15. B15s labeled with 35-S methionine, and fractionated using RP-HPLC, are however, characterized by a peak of radioactivity in addition to those which coelute with synthetic SCP_A or SCP_B. To determine whether B15 synthesizes a novel neuropeptide the non-SCP peak of radioactivity was added to material extracted from ARC muscles, and the peak was purified using four stages of sequential RP-HPLC, followed by gas phase sequence analysis. A peptide with the proposed structure for the B15 peptide was then commercially synthesized, and its chromatographic properties compared to those of the non-SCP peak of B15 radioactivity. From these experiments we determined that B15 does indeed contain a novel neuropeptide, buccalin, and that its structure is: Gly-Met-Asp-Ser-Leu-Ala-Phe-Ser-Gly-Gly-Leu-amide. To test its bioactivity buccalin was applied to ARC neuromuscular preparations. In contrast to the SCPs, buccalin decreased the size of motor neuron elicited contractions of the ARC. Also unlike the action of the SCPs, the change of contraction size was not associated with a change of relaxation rate, suggesting that buccalin is acting primarily presynaptically. Consistent with this idea we found that buccalin decreased ARC EJPs, but had no effect on the size of muscle contractions produced by direct application of ACh to the ARC.

In summary, we have purified and sequenced buccalin, a novel neuropepide; colocalized it with SCP_A and SCP_B to the cholinergic motor neuron B15, and demonstrated that when exogenously applied to the ARC it decreases ARC contraction size without affecting rate of relaxation. We have thus characterized an experimentally advantageous system for the behaviorally relevant study of peptide cotransmission.

16.4 TRANSPORT OF NEUROPEPTIDES FROM CENTRAL GANGLIA TO MUSCLES INVOLVED IN FEEDING IN *APLYSIA*. Philip E. Lloyd, Dept Pharm Physiol Sci, Univ Chicago, Chicago IL 60637

A number of neuropeptides with modulatory actions on feeding (buccal) muscles have recently been identified and sequenced. These peptides include FMRFamide (Fa), the two small cardioactive peptides (SCPs), myomodulin (Mm; Cropper et al., PNAS In Press), and bucculin (Bn; Cropper et al., these abstracts). These peptides modulate the efficacy of synaptic transmission between motor neurons and buccal muscle. Complements of these peptides are also found in motor neurons along with conventional transmitters. If these peptides are modulatory transmitters, it should be possible to demonstrate that they are transported from their sites of synthesis in the neuronal cell bodies to their presumed release sites in buccal muscle. To determine if such transport occurred, buccal or cerebral ganglia were incubated with ^{35}S-methionine in a small sub-chamber. Intact nerves ran through a vaseline barrier into a second larger sub-chamber containing the buccal mass. The outer chamber contained 100μM cold methionine to inhibit incorporation of leaked labelled methionine. After a 24 h label period, both chamber were chased with saline +1mM methionine for 24 or 48 h. At the end of these periods, individual muscles or muscle groups were dissected, extracted in the presence of cold peptides, and run on RP-HPLC (counter-ion: TFA) and aliquots of the samples counted. Remaining aliquots of peaks were run on a different RP-HPLC system (counter-ion: HFBA) to support tentative peptide identifications. The results can be summarized as follows: i) All 5 peptides were transported from buccal ganglia to buccal muscles; ii) In overall quantities of transport, the peptides were ranked Mm ≥SCPs >Fa >>Bn; iii) Different complements of the peptides were reproducibly transported to different muscles e.g. peptides transported to the ARC muscle were ranked Mm ~SCPs ~Bn >>>Fa; iv) Mm was the predominant peptide transported via the radula nerves; v) No measureable peptide transport from the cerebral ganglia to buccal muscle was observed. However, Mm was the predominant peptide transported from the cerebral to the buccal ganglia suggesting that this peptide may have important central actions. These results indicate that these peptides are all likely to be transmitters and that peptide complements should vary from muscle to muscle. (supported by NIH NS23569 and the Whitehall Foundation)

16.5 **PURIFICATION AND SEQUENCING OF TWO NEUROPEPTIDES CONTAINED IN NEURON R15 OF *APLYSIA*.** I. Kupfermann, H. Bayley*, P.E. LLoyd, R. Tenenbaum*, L. Buck*, E.C. Cropper, and K.R. Weiss. (SPON: L.D. Mitchell) Cntr. Neurobiol. & Behav., N.Y. State Psychiat. Inst., and Columbia Univ., N.Y.,N.Y. 10032

A peptidic factor contained in the neuron R15 increases the water content of *Aplysia* suggesting that peptides released from the cell regulate water balance (Kupfermann & Weiss, 1976). We now report the purification and sequence analysis of two R15 peptides, one of which mimics the bioactivity of the peptidic factor.

Peptides were extracted from 820 dissected cells and separated by two steps of reverse-phase HPLC. The purification yielded a single bioactive peptide (R15 α1) which was analyzed for amino acid content and subjected to sequence analysis, suggesting the structure:

Asp-Val-Ser-Asp-Gly-Ser-Ala-Glu-Arg-Arg-Pro-Tyr-Thr-Arg-

Met-Gly-Ser-Gly-Gly-Leu-Lys-Leu-His-Cys-Gln-Val-His-Pro-

Ala-Asn-Cys-Pro-Gly-Gly-Leu-Met-Val-Thr.

The peptide failed to react with iodoacetate indicating that the two cysteines are connected by a disulfide bridge. To confirm the assigned structure the peptide was synthesized, with a disulfide bridge. The chromatographic properties and bioactivity of the synthetic material were identical to those of the native peptide. Interestingly, the peptide contains the sequence Arg-Arg, a potential site for proteolytic processing.

Several other HPLC peaks were inactive in the bioassay for water uptake. The sequence of one of these peptides (R15 β) is:

Ser-Asp-Leu-Leu-Gly-Ala-Leu-Leu-Ser-Arg-Asn-Ser-Pro-

Ser-Ser-Tyr-Gly-Leu-Pro-Ser-Arg-Asp-Met-Ser-Thr-Ala-Tyr.

Both peptide sequences are encoded within a single, recently sequenced, cDNA (Buck et al.).

16.6 PRIMARY STRUCTURE OF Aplysia ATRIAL GLAND AND BAG CELL PEPTIDES. G.T. Nagle, S.D. Painter, J.E. Blankenship and A. Kurosky* Marine Biomedical Institute and *Department of Human Biological Chemistry and Genetics, University of Texas Medical Branch, Galveston,TX 77550.

The role of the neuroendocrine bag cells in the initiation of egg laying has been intensively investigated in the marine mollusc Aplysia californica. In vivo and in vitro electrophysiological studies of A. brasiliana bag cells, however, have contributed significantly to our knowledge of the bag-cell system. We therefore purified and chemically characterized the egg-laying hormone (ELH) from the bag cells of A. brasiliana. Amino acid compositional and sequence analyses demonstrated that it is a 36-residue peptide whose sequence is identical to that of A. californica ELH. This is consistent with earlier observations that suggested extensive sequence homologies between the two peptides: (1) bag-cell extracts from either species induce egg laying when injected into the other species; and (2) A. brasiliana genomic DNA hybridizes with an A. californica ELH cDNA probe.

While the bag cell egg-laying hormones of A. brasiliana and A. californica are chemically identical, they differ from three ELH-related peptides expressed in the A. californica atrial gland, an exocrine organ secreting into the oviduct (Nagle et al., J. Biol. Chem. 261:7853, 1986; Rothman et al., J. Biol. Chem. 261:1616, 1986). Unlike bag cell ELH, each of the three atrial gland peptides (A-ELH, [Ala^{27}]A-ELH, and [Gln^{23},Ala^{27}]A-ELH) is disulfide-bonded to an identical 18-residue acidic peptide (A-AP). A small proportion (20%) of the atrial gland peptide complexes are further cleaved in vivo.

In addition to the ELH-related sequences, we have isolated and chemically characterized several other peptide products of ELH-family genes expressed in the atrial gland. These include peptide A, A-AP and a 13-residue peptide whose amino acid composition matches a sequence predicted from genetic analyses of an A gene cDNA clone. We have also isolated peptide B and a 13-residue peptide whose amino acid composition matches a sequence predicted from genetic analyses of a genomic B clone. The two 13-residue peptides define the precise site of signal sequence cleavage in the peptide A and B precursors. Supported by NSF BNS85-17575, NIH 22079, & NIH 11255.

16.7 FRESHLY DEPOSITED EGG CORDONS AND ATRIAL GLAND FACTORS INDUCE COPULATORY BEHAVIOR IN APLYSIA. S.D. Painter, A.R. Gustavson*[1],V.K. Kalman, G.T. Nagle and J.E. Blankenship. The Marine Biomedical Institute, University of Texas Medical Branch, Galveston,TX 77550 and [1]Dept. of Psychology, University of Southern California, Los Angeles,CA 90089.

Egg-laying activity in the marine mollusc Aplysia appears to be regulated by a small family of genes, each of which encodes a polyprotein precursor containing a peptide sequence homologous to egg-laying hormone (ELH). The ELH-family genes are expressed in an organ-specific manner within the animal. Thus, for example, the ELH gene is expressed in the neuroendocrine bag cells of the abdominal ganglion. The peptide products of this gene induce egg release from the ovotestis and have well-defined effects on both neuronal and behavioral activity. In contrast, at least three other genes of the ELH family are expressed in the atrial gland, an exocrine organ secreting into the oviduct of Aplysia. The peptide products of the atrial gland genes have no known physiological function. Our experiments were designed to test the hypothesis that the atrial gland gene products might serve a pheromonal role and coordinate reproductive activity among (rather than within) individuals. Our studies show that there is a shorter latency to copulation when an Aplysia is paired with an animal that is actively laying eggs than when it is paired with a sexually mature but non-laying animal. Moreover, the effect of egg deposition on latency to copulation can be mimicked by the addition of either acidic or neutral extracts of the atrial gland to the bathing medium. In contrast, addition of extracts of other regions of the reproductive tract, including the oviduct, do not influence the latency to copulation. These results suggest that atrial gland products, secreted onto the egg cordon as it passes through the oviduct, may play a pheromonal role and influence reproductive behavior among individuals. Experiments are in progress to determine whether or not the active factor(s) are products of the ELH-family genes expressed in this organ. Supported by NIH Grants NS-22079 and NS-11255, and by NSF Grant BNS 85-17575.

16.8 SYNTHETIC NEUROPEPTIDE EGG-LAYING HORMONE (ELH) OF APLYSIA CALIFORNICA INDUCES NORMAL EGG-LAYING: STRUCTURE-ACTIVITY STUDIES. F. Strumwasser, D. L. Schiller* and S.B.H. Kent*. Marine Biological Laboratory, Woods Hole, MA 02543 and Division of Biology, California Institute of Technology, Pasadena, CA 91125.

ELH in Aplysia is synthesized by the bag cell neurons of the abdominal ganglion and controls egg-laying (EL) and associated behaviors. ELH contains 36 amino-acid residues and has an amidated carboxy-terminal lysine (Chiu et al., '79). The primary structure of the preprohormone for ELH has been deduced from a cDNA clone. The prohormone has 271 amino-acid residues and ten putative cleavage sites (Scheller et al., '83). There is good evidence that a number of peptides, besides ELH, are released during a synaptically initiated electrical discharge of the bag cells. ELH and an acidic peptide (pI 4.8) are released (Stuart et al., '80) as well as two forms of α-bag cell peptide (Sigvardt et al., '86). Other as yet unidentified peptides are also released during the bag cell discharge. These findings raise the possibility that the integrated behavior of EL is due to the action of several peptides rather than ELH alone, although purified ELH induces EL. Our studies were directed at addressing whether synthetic ELH is sufficient to induce normal EL and to determine what portion of the peptide is necessary for EL. ELH and its fragments were synthesized by either manual or automatic stepwise solid phase peptide synthesis on a benzhydrylamine-resin and purified by reverse-phase HPLC on a Vydac C4 column. Purity, as judged by analytical HPLC, was 92-98%. Synthetic ELH 1-36 amide induced normal EL when injected at doses of 70-200 ug in 7/7 animals. Locomotion was inhibited, eggs were extruded in the egg string, the string was properly attached to the substrate and wound, and the weight of egg string produced and the latency to onset of EL were normal. Thus we conclude that ELH is sufficient to induce all the presently known components of EL. Although purified ELH is reported to induce EL at approximately 2.5 nanomoles (11 ug), we used approximately 10 to 100 times this quantity when testing fragments. Removal of either the amino-terminal or carboxy-terminal 7 amino-acid residues resulted in a peptide unable to elicit EL. Thus ELH 8-36 amide (1500 ug), ELH 14-36 amide (1250 ug) and ELH 1-29 amide (1500 ug) did not induce EL. This implies that both relatively intact amino- and carboxy-termini are essential for EL. This fact is particularly interesting in that there is specific charge conservation in the position of residues 6, 8, 12, 17, 21, 22, 24, 28, 30, 32 and 36 when the sequences of A. californica and A. parvula (Nambu and Scheller, '86) are compared. Specific charge conservation is also present in the ELH of the fresh water snail Lymnaea stagnalis except at residues 21, 28 and 36 (Ebberink et al., '85). Subtle changes such as ELH 1-35 amide (200 ug) allow normal EL in A. c. (Supported by NS21046 to F.S. and NSF DMB85-00298 to S.B.H.K.)

16.9 STRUCTURE AND FUNCTION OF A NOVEL NEUROPEPTIDE (CALFLUXIN) GENERATED FROM THE EGG-LAYING HORMONE PRECURSOR OF *LYMNAEA*. R.H.M. Ebberink*, W.J.A.G. Dictus* and J. Joosse* (SPON: European Neuroscience Association). Department of Biology, Vrije Universiteit, Amsterdam, The Netherlands, NL-1007 MC.

Recent studies on the role of Ca^{2+} as an intracellular messenger in the regulation of the secretion process in a female accessory sex gland (albumen gland) of the freshwater snail *Lymnaea stagnalis* have shown that the glandular cells contain in a particular stage of the egg-laying process a relative high concentration of intracellular Ca^{2+}. Subsequent in vitro studies indicated that the increase in intracellular Ca^{2+} concentration is induced by a neuropeptide (calfluxin). This peptide could be extracted from the cerebral commissure, the neurohaemal area of the caudo dorsal cells, which regulate the complex processes of egg-laying and the associated behavior.

Calfluxin has been purified and the structure elucidated (Arg-Val-Asp-Ser-Ala-Asp-Glu-Ser-Asn-Asp-Asp-Gly-Phe-Asp). The chromatographical and biological behavior of the synthetic peptide is identical to that of the native peptide. Calfluxin appears to be one of the peptides generated from the egg-laying hormone precursor of *Lymnaea*. Beside calfluxine at this moment five other peptides of the precursor are of interest: the ovulation hormone (egg-laying hormone), three ß-CDCPs (pentapeptides) and α-CDCP (nonapeptide). Calfluxine is situated between the ß-CDCPs and α-CDCP region of the precursor.

Comparison of the egg-laying hormone precursors of *Lymnaea* and *Aplysia* show significant homology in the egg-laying hormone regions (50%), the aCDCP/aBCP region (70%) and the ß-CDCP/ß-,χ-BCP regions (80-100%). The region converting the ß-CDCP with α-CDCP (the calfluxin region) is much shorter than the counterpart of the ELH precursor. However, the amino acid sequences 4-7 and 8-12 of calfluxin are located uninterrupted on the counterpart of the *Aplysia* precursor.

Signal-respons coupling was studied with calfluxin, and these studies indicate that mobilization of intracellular Ca^{2+} is mediated via the protein kinase C stimulated activation of the Na^+/H^+-exchange, thus leading to an increase of the internal pH. IP_3 may have a role in the mobilization of Ca^{2+} from internal sources, whereas the influx of extracellular Ca^{2+} is mediated by protein kinase C independent Ca^{2+}-channels.

16.10 ACTIVATION OF THE BAG CELLS BY ELH/BCP-IMMUNOREACTIVE NEURONS IN THE RIGHT PLEURAL GANGLION OF APLYSIA CALIFORNICA. R.O. Brown and E. Mayeri. Div. of Neuroscience, Dept. of Physiology, University of California, San Francisco, CA 94143-0444.

The bag cells are 800 neuroendocrine cells in the abdominal ganglion of Aplysia which control egg-laying. They fire in episodic discharges to release multiple neuropeptides, including egg-laying hormone (ELH) and alpha-bag cell peptide (α-BCP), derived from a common precursor. Immunoreactive ELH and α-BCP have also been co-localized to small clusters of 12-24 neurons in the cerebral ganglion and 4-16 neurons in the pleural ganglion. The electrophysiological properties and functions of these head ganglia ELH/BCP cells, and their relationship to the bag cells, have not previously been described.

We identified a cluster of white cells in the right pleural ganglion which resemble the bag cells morphologically and physiologically. Intracellular recordings were made from 18 of these cells in 12 preparations. In 2 preparations they were injected with Lucifer Yellow, and subsequent immunocytochemical processing with α-BCP antiserum confirmed they were ELH/BCP cells.

Intracellular electrical stimulation of ELH/BCP cells in isolated right pleural ganglia caused depolarizing afterpotentials and synchronous afterdischarges (N=4 out of 4 preparations). This indicates that the pleural ELH/BCP cells, like bag cells, posess an intrinsic positive feedback mechanism to produce regenerative discharges.

In combined right pleural plus abdominal ganglia preparations with the right pleuroabdominal connectives intact, activation of pleural ELH/BCP cells by intracellular stimulation caused depolarizations and afterdischarges in the abdominal ganglion bag cells (5/5). Direct stimulation of bag cell discharges in the abdominal ganglion caused depolarizations (2/3) but not discharges (0/3) in the pleural ELH/BCP cells. These results indicate a bidirectional, but asymmetrical, functional connection between the pleural ELH/BCP cells and the bag cells.

α-BCP, and the structurally related ß-BCP and γ-BCP, have autoexcitatory effects on the bag cells, and are candidate neurotransmitters for the spread of activation between pleural ELH/BCP cells and the bag cells.

The ELH/BCP cells in the pleural ganglion are the first identified cells found to activate the bag cells. They, and by extension the cerebral ELH/BCP cells, may comprise a descending neuronal pathway which normally triggers bag cell discharges. In addition to activating the bag cells, neuropeptides released by these ELH/BCP cells might also act directly on neurons in the head ganglia to mediate aspects of egg-laying behavior.

16.11 **INACTIVATION OF ALPHA-BAG CELL PEPTIDE IN THE ABDOMINAL GANGLION OF APLYSIA.** B.S. Rothman, G.A. Phares* and T.A. Groves*. Dept. of Biology, San Francisco State University, San Francisco, CA 94132.

We are using the isolated abdominal ganglion of Aplysia to study in detail the inactivation of a single peptide neurotransmitter, alpha-bag cell peptide (α-BCP[1-9]). α-BCP and a group of 6-9 other peptides are synthesized and released by the bag cells, two clusters of 400 homogeneous neuroendocrine cells located in the rostral margin of the ganglion. α-BCP mediates bag cell-induced inhibition of left upper quadrant (LUQ) neurons L2, L3, L4 and L6.

Sigvardt et al. (J. Neurosci. 6: 803) showed that after electrical stimulation of the bag cells, recovery from perfusate of LUQ inhibitory activity depended on a battery of protease inhibitors, and recovery of α BCP[1-9] and its derivative, α-BCP[1-8], strictly depended on the presence of diprotin A, a dipeptidyl-aminopeptidase inhibitor. These findings suggested that both α-BCP[1-9] and α-BCP[1-8] were inactivated by a membrane-bound peptidase located within the extracellular space of the ganglion. Furthermore, since α-BCP[1-8] was also recovered, and this peptide is 30-fold more active than α-BCP[1-9] on LUQ neurons, it seemed likely that α-BCP[1-9] underwent both activation and inactivation by separate peptidases.

To further test these hypotheses, we mimicked release of α-BCP without the concomitant release of the other bag cell peptides by arterially perfusing synthetic α-BCP[1-9] into the ganglion. Specifically, an isolated abdominal ganglion was mounted in a low dead-volume sealed chamber, and continuously perfused with an artificial sea water solution containing α-BCP plus 40 µg/ml of protein carriers. The perfusate was collected on ice and analyzed by a reverse phase-HPLC system that can resolve all α-BCP fragments tested. When α-BCP[1-9] was perfused at concentrations of 1-10 µM, 40% to 80% of intact α-BCP was recovered, and two fragments, α-BCP[3-9] and α-BCP[1-8], were generated respectively at about 10% and 5% the levels of α-BCP[1-9]. These products were identified by comigration with chemically synthesized standards on HPLC under isocratic conditions. Diprotin A inhibited generation of α-BCP[3-9] in a dose dependent manner, with an IC50 of 2 µM, but had little effect on the generation of α-BCP[1-8]. Arterial perfusion of α-BCP[1-8], under conditions identical to those above, generated α-BCP[3-8] and α-BCP[1-7], fragments analogous to those derived from perfusion of α-BCP[1-9].

These results provide additional evidence that α-BCP[1-9] is both activated and inactivated by membrane-bound peptidases. Combined with the findings of Sigvardt et al., the results suggest that inactivation is the dominant process. These processes may provide a means by which α-BCP[1-9] can produce short-lasting but intense actions limited to the abdominal ganglion.

16.12 THE BAG CELL PEPTIDES ALPHA-BCP AND ELH MODULATE THE EXCITABILITY OF TARGET NEURONS IN THE ABDOMINAL GANGLION OF *APLYSIA* BY CHANGING Ca^{2+}- AND K^+-CURRENTS. Rene F. Jansen* and Earl Mayeri. Department of Physiology, University of California, San Francisco, CA 94143.

The neuropeptides egg-laying hormone (ELH) and alpha-bag cell peptide (alpha-BCP) are putative neurotransmitters derived from a common precursor protein, and are released by the bag cells in the abdominal ganglion of *Aplysia californica*. ELH is the neurotransmitter that mediates the long-lasting excitation of the left lower quadrant (LUQ) neurons, and alpha-BCP mediates inhibition of the left upper quadrant (LUQ) neurons. We here report further on the voltage clamp analysis of the ionic mechanisms of long term regulation of neuronal excitability by ELH and alpha-BCP.

Pressure application of alpha-BCP onto surgically isolated LUQ neurons causes a hyperpolarization which interrupts ongoing pacemaker activity in these neurons. The slow inward current that underlies pacemaker activity is partly blocked by Ca^{2+}-channel blockers and partly by TTX. Experiments indicate that alpha-BCP closes the slowly inactivating Ca^{2+}-channel. In Ba/TEA/4AP-containing seawater, the alpha-BCP evoked current has a U-shaped I-V characteristic that peaks at about 10 mV. It is blocked by adding the Ca-channel blockers Co^{2+}, Cd^{2+} or Ni^{2+} to the medium, and is unaffected by removing external Na^+ or adding TTX. Alpha-BCP additionally causes an increase in K^+-conductance. This K^+-current is blocked completely by external Rb^+ (5 mM), and partially by external Cs^+ (10 mM).

ELH induces hours-long repetitive firing in LLQ neurons without substantially changing the resting membrane potential. The currents evoked by ELH in these neurons include: i) a hyperpolarizing, inwardly rectifying K^+-current that is blocked by Rb^+ (5 mM) and Cs^+ (10 mM), and which has a chord-conductance that shifts with the external $[K^+]$, ii) a small, steady depolarizing current and iii) a depolarizing current activated at membrane potentials above -40 mV.

The second current is Na^+-dependent, present at all membrane potentials tested, and is the only current that remains after prolonged exposure (typically 1hr.) to 0 mM Ca^{2+}/ 10 mM Ni^{2+}-containing medium. The third current is apparently unaffected by adding Ni^{2+} (10 mM) to Ca^{2+}-containing medium (10-15 min.), and is not blocked by 0 mM Na^+ or 100 mM TEA/ 0 mM Na^+; we are currently investigating the nature of this current. The ionic mechanism of action of ELH on the LLQ neurons is apparently different from that of ELH on the buccal motorneuron B_{16} described by Kirk and Scheller (Proc.Natl.Acad.Sci. 83:3017).

We conclude that alpha-BCP and ELH are neurotransmitters that use multiple and apparently distinct ionic mechanisms to modulate the excitability of their respective target neurons.

Supported by NIH grants NS16490 and NS16033.

16.13 **MODULATION OF IONIC CURRENTS IN THE IDENTIFIED MOTORNEURON B15 OF APLYSIA BY 5-HT, SCPb, AND FMRFamide.** Ronald Taussig* and Richard H. Scheller, Dept of Biol. Sci. Stanford Univ., Stanford, Ca 94305

The accessory radular closure muscle in Aplysia is inervated by two identified buccal ganglion motorneurons, B15 and B16. Previous studies have demonstrated that several neurotransmitters have direct affects on the electrical activities of these neurons. Egg-laying hormone and the biogenic amine serotonin (5-HT) both excite B16, while small cardioactive peptide b (SCPb) and 5-HT depolarize B15. Both motorneurons are inhibited by the amidated tetrapeptide Phe-Met-Arg-Phe-amide (FMRFamide). Using the two electrode voltage clamp technique, we have identified ionic currents in B15 which are modulated by 5-HT, SCPb, and FMRFamide.

5-HT, SCPb, and FMRFamide were bath applied to an axotomized B15 under voltage clamp. In normal saline containing 20 mM Cobalt, both 5-HT (50 uM) and SCPb (10 uM) induced or enhanced a voltage dependent slow inward current. Replacement of sodium with N-Methyl D-Glucamine abolished this response but uncovered two additional currents which were affected by application of either 5-HT or SCPb. Both of these currents were sensitive to varying extracellular potassium concentrations.

Bath application of FMRFamide (5 uM) to B15 modulate currents in opposite directions to those of the excitatory transmitters 5-HT or SCPb. FMRFamide reduced the voltage dependent slow inward carried by sodium, while simultaneusly increasing a current resembling the S-current.

AUDITORY SYSTEM I

17.1 CYTOCHALASIN D SUPPRESSES SOUND EVOKED POTENTIALS IN THE GUINEA PIG COCHLEA. S.E. Barron, R.P. Bobbin, P.S. Guth, and C.H. Norris, (Dept. of Pharmacology, Tulane Medical School and Dept. of Otorhinolaryngology LSU Medical School, New Orleans, LA 70112)

Although actin has been localized in hair cells, evidence for its role in intact cochlear preparations is lacking. The present study was undertaken to test the hypothesis that actin is involved in cochlear function (e.g. the active process) by observing the effects of a potent inhibitor of actin polymerization, cytochalasin D, on evoked cochlear potentials. Perilymphatic spaces of guinea pig cochlea were perfused with Ringer solutions containing either cytochalasin D (10^{-8} to 10^{-5} M) or DMSO (0.00005% to 0.05%) at a rate of 2.5 µl/min for 10 min (Bledsoe et al., Hear. Res. 4:109, 1981). Immediately after each period of perfusion, the compound potential (CAP), N_1 latency, cochlear microphonics (CM), and summating potential (SP) evoked by 10 kHz tone bursts of varying intensity were recorded from an electrode in the basal turn. Cytochalasin D suppressed CAP, N_1 latency and SP in a dose-dependent fashion but had only slight effects on CM. DMSO had no effect. These results provide pharmacological evidence that actin is involved in cochlear function. . . possibly the active mechanical process of the organ of Corti. (Supported by Grants from NSF, NINCDS, the Southern Hearing and Speech Foundation, Kresge Foundation and the LA. Lions Eye Fnd.)

17.2 THE ORIGIN OF PHASE LOCKING IN THE AUDITORY RESPONSE IN THE PIGEON. K.G. Hill*, Jianwu Mo* and G. Stange*. SPON: (Eldon E. Ball). Research School of Biological Sciences, Australian National University, GPO Box 475, Canberra City, ACT 2601, Australia.

Recordings were obtained of spike potentials in single fibres in the VIIIth nerve of the pigeon (Columba livia) in order to study properties of phase locking to a sinusoidal stimulus waveform. In response to closed-field, monaural sound presentation, tuning and intensity functions of spike responses were determined. From measures of spike time to 4 µs accuracy, period histograms were constructed and characterized in terms of vector strength and phase angle of response. Intensity functions also were determined for vector strength and phase angle of response for individual fibres at several frequencies.

Typically, response-frequency profiles showed a single peak, denoting fibre characteristic frequency (CF), bordered at adjacent higher and lower frequencies by areas of suppression of background firing rate. With increasing sound pressure level (SPL) the response peak widened and suppression bands shifted to higher and lower frequencies. Spike rate intensity functions at CF showed monotonic increase, whereas at adjacent lower and higher frequencies, spike rate initially declined then increased with increasing SPL. Vector strength intensity functions monotonically increased at both CF and at adjacent frequencies, starting below excitatory rate threshold or at suppression thresholds, independent of increasing or decreasing spike rate.

At low SPL up to about 50dB, intensity functions for phase angle of response to different frequencies were rather flat. The phase angle of response to frequency below CF, however, was greater than that at CF, indicating relative phase lag, whereas, phase angle for frequency above CF was less than that at CF, indicating relative phase lead. Phase angles of response in a single fibre to three frequencies, at, above and below CF, closely match measurements of group delay in the basilar membrane (BM) velocity response (Gummer, A.W., Smolders, J. and Klinke, R. Hearing Research, in press.

The independance of vector strength intensity functions from spike rate functions imply that phase locking of spikes does not depend on transsynaptic excitation of afferent fibres in accord with hair cell receptor potentials. Close correspondence between phase angle of spike response and group delay of BM mechanical response at CF suggests that the factor responsible for phase locking has a frequency-dependent locus on the BM. It is suggested that this factor is the cochlear microphonic potential.

17.3 THE EFFECTS OF NOISE ON PHASE-LOCKED DISCHARGES OF AMPHIBIAN AUDITORY NERVE FIBERS. P.M. Narins. Dept. of Biology, Univ. of California at Los Angeles, Los Angeles, CA 90024.

Amphibian auditory nerve fibers fire in a phase-locked fashion in response to sinusoidal stimuli of frequencies up to 1.2 kHz at 22°C. For many species of frogs this range includes not only sounds of biological significance (predators, prey, etc.) but communication signal frequencies as well. In this study the degree of phase-locking was quantified for 65 single units in the Puerto Rican coqui, Eleutherodactylus coqui, both in response to tones presented alone, and in the presence of continuous, broadband masking noise of various levels. Detailed studies of the low-frequency, suppressible fibers and the mid-frequency, non-suppressible fibers from the amphibian papilla (a.p.) and high frequency, non-suppressible fibers from the basilar papilla (b.p.) revealed that fibers from all three populations exhibit clear phase-locked responses to pure tones. B.p. units only phase-lock to test frequencies (TFs) below the fiber's characteristic frequency (CF). The phase-vs.-intensity functions for all fibers are complex; they show level-independence near threshold intensities, follow no consistent pattern at middle intensities (10-40 dB>CF-threshold), but at higher intensities another pattern emerges. For TFs>CF, increasing intensity results in an increased phase lead relative to CF, and for TFs<CF raising intensity results in an increased phase lag relative to CF. This pattern is most easily seen for a.p. fibers.

Wideband noise presented at increasing levels progressively reduced the phase-locking of auditory nerve fibers to tones. Specifically, the vector strength (VS, a quantitative measure of phase-locking) falls off with increasing levels of masking noise. The noise level required to produce a fixed reduction in VS was clearly related to the fibers CF-threshold. However, on the average, TFs<CF showed a steeper rate of VS falloff with masking noise level than do TFs>CF. Moreover, TFs<CF showed either phase-independence or a slight phase lag with increased masking noise level whereas those TFs>CF exhibited a pronounced phase lead in the presence of masking noise. These effects were observed for all a.p. fibers tested, suggesting that the underlying mechanisms do not necessarily involve two-tone suppression.

(Supported by NIH/NINCDS grant no. NS19725).

17.4 DERIVED AUDITORY POTENTIALS IN THE ALLIGATOR LIZARD (Gerrhonotus multicarinatus). T.A. Jones and T.N. Decker*, Depts. of Oral Biology, UNMC and Special Education and Communication Disorders, UNL Lincoln, NE 68583.

In birds and mammals, a vibration of the basilar membrane travels from the base to the apex of the cochlea at a velocity which decreases as a function of distance. The time of its arrival at any particular position will depend on the traveling wave velocities encountered and the distance traversed during travel. Through the use of a high-pass subtractive masking paradigm (Teas et al., 1962 . Don and Eggermont 1978) derived potentials can be recorded that temporally relate the latency of neural activation as a function of place of stimulation on the membrane. Typically in the mammal the relationship shows that as progressively more apical portions of the basilar membrane are masked, the remaining far-field components evoked by the click are shifted later in time. The progressive latency shift is thought to be indicative of the traveling wave on the basilar membrane. This hypothesis has not been explicitly tested in an ear that does not have a traveling wave phenomenon. The auditory system of the alligator lizard (Gerrhonotus multicarinatus) has been shown to have a relatively wide frequency response and neurons show relatively sharp tuning curves between 100 and 5KHz. Yet the ear does not employ smoothly graded mechanical tuning in the periphery to accomplish frequency analysis (Weiss et al., 1978). Therefore, it does not have a continuous preeminent cochlear traveling wave. In the present study derived far-field auditory responses were recorded in the alligator lizard using broad band stimuli (acoustic clicks) and maskers (high pass cutoffs: half octave steps, 250-8000Hz, slopes: -96dB/octave). Clicks were presented at a repetition rate of 10/sec. Auditory responses were obtained using subcutaneous electrodes (vertex-G1, ipsilateral neck=G2, contralateral neck = ground). Electrical signals were led to an amplifier (10,000X; LF=100; HF=10,000) and in turn to a computer and digitized. Threshold was determined and 20dBSL clicks used to elicite responses thereafter. The level of unfiltered wide-band noise sufficient to mask far-field responses was determined. Without changing intensity levels, far-field responses to 20 dBSL clicks were recorded in the presence of high-pass-filtered noise. Maskers were presented in descending order according to frequency cutoff (8000 Hz to 250 Hz). The narrow-band contributions to auditory responses were generated by successively substracting the response waveforms obtained in the presence of noise at each half-octave cutoff. Peak-to-peak amplitudes and latencies of the response onset were measured.

Tonotopic groups making substantial amplitude contributions to the far-field response included those between 500 and 8000 Hz. The progressive shifts in onset latency normally associated with these tonotopic groups in mammals were essentially absent in lizard derived responses from 1000-8000Hz. These findings support the hypothesis that the latency shifts normally associated with tonotopic groups in mammals do reflect the temporal behavior of a traveling wave.

17.5 EFFECT OF TEMPERATURE ON THE TUNING OF ORTHOPTERAN HAIR CELLS. B.P. Oldfield* (SPON: J.D. Pettigrew). Neuroscience Laboratory, Dept. of Physiology and Pharmacology, Univ. of Qld., St. Lucia, 4067, Qld. Australia.

Despite recent evidence of intrinsic electrical tuning in some vertebrate hair cells (reviewed in 1) such mechanisms are not thought to be responsible for the tuning of hair cells, such as those of mammals with characteristic sound frequencies greater than 1 kHz (2). Orthopteran hair cells, however, are tuned to sound frequencies greater than 1 kHz without the assistance of peripheral mechanical filters (3,4,5). The nature of the intrinsic tuning mechanism in these auditory receptors is yet to be identified. A primary tool in discriminating between intrinsic and extrinsic tuning mechanisms has been the quantification of the effect of temperature on the tuning of hair cells (6,7). This tool has been applied to the hair cells of the locust *Valanga irregularis* (Orthoptera, Acrididae) where I show that the tuning mechanism is even more temperature-dependent than that of vertebrate hair cells known to be intrinsically-tuned.

The auditory organs of locusts contain up to 70 auditory receptors and are tuned to sound frequencies between 1 and 18 kHz. By isolating the auditory organ and recording from receptors with glass microelectrodes I have shown that the characteristic sound frequency of individual hair cells undergoes a reversible increase for temperature increases between 1 and 7°C. The average change in characteristic frequency (n=16) was 0.14 octaves/°C, which corresponds to a thermal Q_{10} of 2.7. This value exceeds that expected from temperature-dependent changes in the mechanical properties of a simple mechanical resonator. The extreme temperature-dependence of the tuning properties thus supports other evidence that these hair cells are tuned intrinsically, and not by virtue of the mechanical properties of peripheral filters. This finding confirms that auditory receptors can be tuned to sound frequencies in excess of 1 kHz as a result of intrinsic, possibly electromechanical, properties.

17.6 COCHLEAR PERFUSION TO STUDY NEUROCHEMICAL MECHANISMS AT A MULTITRANSMITTER SYNAPSE. D.W. Hoffman, K.L. Jones* and A.E. Stinnett* (SPON: E.J. Walsh). Neurochemistry Lab, SIU Sch. of Med., Springfield, IL 62708

We are using the chinchilla cochlea as a model system to study neurochemical interactions of co-localized transmitters. The cochlea is innervated by brainstem neurons which terminate under both inner and outer hair cells. Those which innervate eighth nerve dendrites under inner hair cells have been shown to contain enkephalins (Fex and Altschuler, PNAS 78:1255, 1981) dynorphins (Hoffman et al., Hearing Res., 17:47, 1985) and acetylcholine (ACh) (Norris and Guth, Acta Otolaryngol., 77:318, 1974). We use this preparation as an in situ perfusion chamber to study neurochemical interactions of these co-localized transmitters.

The auditory bulla is approached ventrolaterally to avoid disruption of the ossicular chain and tympanic membrane. The bulla is opened, and a hole is drilled into the scala tympani of the cochlea near the base, using a fine pick and root canal file. Glass capillary tubing drawn out to a fine tip is cemented into the hole with cyanoacrylate ester. PE-10 tubing connects the pipette to a microliter syringe driven by a syringe pump, which can provide flow rates of as low as 1 microliter/min. A second (efflux) pipette is placed near the first, but in the scala vestibuli, to provide complete perfusion of the perilymphatic space. We use this preparation to study neurotransmitter release, and transmitter interactions in this natural perfusion chamber.

Met- and leu-enkephalin, dynorphin B and ACh are all released by high potassium or veratridine. Peptides are measured by HPLC-RIA, and ACh by radioenzymatic assay. These results expand the data on the neurotransmitter/neuromodulator role of these neuropeptides in the inner ear, and confirm the earlier identification of ACh in inner ear perfusates by bioassay. We are now seeking to determine the effects of neuropeptides and ACh and each other's release processes.

17.7 ISOLATION OF NEUROACTIVE SUBSTANCES FROM HAIR CELL EXTRACTS. W. F. Sewell and E. A. Mroz *. Eaton-Peabody Laboratory, Massachusetts Eye and Ear Infirmary, Departments of Otolaryngology and Physiology, and the Program in Neuroscience, Harvard Medical School, Boston, MA. 02114.

Hair cells, the sensory cells of the inner ear, release a yet-unidentified neurotransmitter to excite primary afferent neurons. Because this neurotransmitter does not appear to be one of the known neurotransmitter candidates, our strategy for its identification is to extract and purify substances from hair cell tissue that can excite afferent fibers innervating hair cells.

We have previously reported (Assoc. Res. Otolaryngol. Abstr. 9: 114, 1986) that aqueous extracts of goldfish (*Carassius auratus*) inner ears excite afferent fibers innervating the hair cells of the lateral line organ of *Xenopus laevis*. Gel-filtration chromatography (Sephadex G-10) of such extracts yields two peaks of excitatory activity, one eluting with low-molecular-weight substances (ca. 200) and one eluting with high-molecular-weight substances (> 700). Both peaks are well separated from glutamate and aspartate.

We now report that further purification of the high-molecular-weight peak by gel-filtration chromatography (Sephadex G-25) suggests that it is due to a substance with a molecular weight of about 4000. We have identified calcitonin gene-related peptide (molecular weight of 3800) as a candidate to be the high-molecular-weight active substance, based upon similarities in molecular weights, tissue distributions, and biological activities.

We also report that the low-molecular-weight peak can be resolved into two excitatory components by further purification with cation-exchange chromatography. Each component elutes with a peak of ninhydrin-positive material. The chromatographic behaviors of these components suggest that they are due to zwitterions. The values of pH at which the components elute suggest that one zwitterion has a titratable anionic group with a pK of 2.3 and that the other has a titratable anionic group with a pK of 2.8.

17.8 SOUND-EVOKED EFFERENT EFFECTS ON THE DISCHARGE PROPERTIES OF SINGLE AUDITORY-NERVE FIBERS. E.H. Warren, III* [1,3] and M.C. Liberman* [1,2,3] (SPON: N.Y.S. Kiang). [1] Program in Neuroscience, and [2] Department of Otolaryngology, Harvard Medical School; and [3] Eaton-Peabody Laboratory, Massachusetts Eye and Ear Infirmary, Boston, MA 02114.

The mammalian cochlea is supplied with an efferent innervation that originates in the region of the superior olivary complex (Rasmussen, *J. Comp. Neurol.*, 84:141, 1946). The recent observation that these efferent neurons respond to sound, even in barbiturate-anesthetized animals (Liberman and Brown, *Hearing Res.*, 24:17, 1986), suggests that this efferent activity may affect the response properties of auditory-nerve (afferent) fibers as described in many different preparations. Since roughly 1/3 of the efferent neurons projecting to each cochlea respond best to contralateral acoustic stimulation (Liberman and Brown, *ibid.*,), one test for influences of sound-evoked efferent activity on auditory-nerve discharge is to compare the response properties of single afferent fibers with and without contralateral stimuli (Buño, *Exp. Neurol.*, 59:62, 1978).

We find that the sound-driven response of single auditory-nerve fibers in barbiturate-anesthetized cats can be suppressed by contralateral tones at levels as low as 30 dB SPL. Contributions of middle ear muscles are eliminated by cutting their tendons on both sides prior to recording from single units. Ipsilateral stimuli are tone bursts at the characteristic frequency of the afferent fiber, roughly 10 dB above threshold. Discharge rates to this probe tone with and without contralateral tones of different frequencies and levels are compared. The suppression is strongest 1) when the contralateral stimulus is continuous (rather than bursted), 2) when the contralateral tone is near the unit's CF, and 3) among units with CF near 1.5 kHz. All of these characteristics are predictable based on existing knowledge of the properties of olivocochlear efferent neurons.

Contralateral acoustic stimulation is similar to electrical stimulation of the efferent bundle (e.g. Wiederhold and Kiang, *J. Acoust. Soc. Am.*, 48:950, 1970) in many respects. Both show relatively slow onset of suppression (200 msec to maximal effect). For both conditions, the effect on the ipsilateral rate-level function at CF for units with high (> 18 sec $^{-1}$) spontaneous rates (SRs) can reasonably be described as a simple *translation* of the function along the sound-level axis toward higher tone levels, whereas the effects on low-SR units often include a reduction in the saturated discharge rate, as well.

The strongest evidence that contralateral suppresion is mediated by the olivocochlear efferents is that the effect disappears immediately after sectioning the efferent bundle within the inferior vestibular nerve. In all our experiments the completeness of the cuts is confirmed histologically.

The finding that contralateral-sound stimulation can influence cochlear activity suggests a rapid method for assessing the overall physiological state of the olivocochlear efferent system in an animal. Comparisons of gross cochlear potentials with and without a preceding contralateral stimulus can conceivably provide an index of efferent activity which might prove helpful in studies of auditory system function.

17.9 TWO-TONE SUPPRESSION IN INNER HAIR CELL RESPONSE PATTERNS. M.A. Cheatham* and P. Dallos. Auditory Physiology Lab. Northwestern University, Evanston IL 60201.

In an attempt to understand the processing of complex stimuli by the peripheral auditory system, we have measured ac receptor potentials (RP) from individual inner hair cells (IHC) in the guinea pig organ of Corti. The purpose of the experiment was to characterize a phenomenon known as two-tone suppression (2TS) in which the addition of a second sinusoid to a single tone input decreases the response to the latter. Although many experiments have documented the magnitude changes which result from interactions between the two inputs, phase changes have received little attention. Since phase behavior is important to the understanding of underlying mechanisms, we have studied 2TS to ask whether the magnitude and phase changes resulting from the introduction of a suppressor differ from those to be expected by simply reducing stimulus level.

Data obtained from the third turn where characteristic frequencies (CF) range between 800 and 1000 Hz indicate that RPs for single tone stimuli are level dependent. For example, when frequency response functions are obtained to define response areas at several levels, frequency selectivity is enhanced as input level decreases. This occurs because of a strong compressive nonlinearity at CF, which results in the steepening of high and low frequency slopes as stimulus level is decreased. This behavior is reflected in the accompanying phase shifts which go through a lead/lag transition at CF which moves to a slightly higher frequency as input is reduced. Thus, by comparing the magnitude and phase changes occurring during suppression with predictions made on the basis of the well-documented nature of level-dependent responses to single-tone stimuli, it should be possible to determine whether 2TS operates by simply attenuating input to the cell.

To ascertain the magnitude and phase changes resulting from the presence of a high frequency suppressor (1500 Hz), frequency response functions were measured for IHCs. Results indicate that the effects are not predicted by a simple attenuation model. Although the suppressor causes a decrease in the magnitude of the ac RP, the largest deviations are measured at the CF of the cell causing the frequency response functions to become broader. The CF also moves to a lower frequency and the phase goes through a lag/lead transition exactly opposite to the results expected by simply decreasing input to the cell. Consequently, a simple attenuation model does not adequately describe basic features of 2TS in the apex of the cochlea for high-side suppressors.

17.10 CHANGES IN CAT EAR CANAL ACOUSTIC DISTORTION-PRODUCT SIGNALS PREDICT NEURAL-RESPONSE THRESHOLD INCREASES AFTER OVEREXPOSURE. M.L. Wiederhold, J.W. Davis*, C.E. Sheridan* and G.A. Schulmeier*. Div. of Otorhinolaryngology, Univ. of Texas Health Science Center, and Audie L. Murphy Memorial Veterans' Hospital, San Antonio, TX 78284.

Previous studies have shown that when two tones were presented simultaneously, distortion-product signals can be observed in responses of auditory-nerve fibers, the cochlear microphonic and in the sound field in the external ear canal. These indicators of nonlinear cochlear mechanics are vulnerable to a number of physiological insults, including noise exposure. With primary-tone stimuli at frequencies f_1 and f_2, a prominent distortion-product (DP) signal at $2f_1 - f_2$ can readily be detected in the sound pressure measured in the cat ear canal. Using a fast-Fourier-transform spectrum analyzer, f_1 levels (L_1) needed to generate DPs at -10 dB SPL ranged from approximately 40 to 70 dB SPL. For all animals in which DPs were seen with low primary-tone levels, there was a sharp dip in the growth function near L_1 = 70 dB SPL, with rapid growth above this dip. Below the dip, the DP level is maximized when L_2 is 10 dB below L_1. Using primary frequencies of 4.0 and 5.2 kHz, the low-level portion of the DP growth function is reduced more (in dB) by acoustic overstimulation than is the portion above the dip. Several measures of change in the DP growth function have been correlated with short-term increases in N_1 threshold (TTS) caused by exposure to either 4 kHz tones or 500 Hz octave bands of noise, over a range of levels and durations. Either reduction of DP level at a fixed level of primary tones (vertical measure) or increase in primary-tone level needed to produce a criterion DP level (horizontal measure) is highly correlated with neural threshold increases. Changes in DP are minimal after exposures which caused neural threshold increases less than 20 dB, but increase 1 to 2 dB for each dB of N_1 threshold increase, beyond 20 dB. Nomarski light-microscopic examination of plastic-embedded surface preparations of the exposed cochleas revealed little disruption of hair-cell stereocilia which could be correlated with either exposure or threshold shift. Prominent vacuolization was seen in afferent-fiber dendrites beneath inner hair cells. The extent of vacuolization along the basilar membrane is related to the amount and frequency range of threshold increases.

17.11 THE DEPENDENCE OF SPONTANEOUS ACTIVITY OF LATERAL LINE AFFERENTS ON CALCIUM, MAGNESIUM, AND COBALT. S.L. Guth* and D.G. Drescher (SPON: J. Benjamins). Lab. of Bio-otology, Wayne State Univ. Sch. of Med., Detroit, MI 48201.

The afferent neurons of the mechanoreceptive lateral line (and other acousticolateralis organs) have a significant level of activity in the absence of mechanical stimulation. The source of this spontaneous activity has been attributed to the vesicular release of afferent neurotransmitter from the mechanosensory hair cells onto primary afferent dendrites (Flock and Russell, J. Physiol. 257:45, 1976). Such release of neurotransmitter is believed to be a calcium-dependent process which can be perturbed by altering the composition of the solution bathing the synaptic side of skin containing lateral line organs. Concentration-effect curves were determined for the action of Ca^{++}, Mg^{++}, and Co^{++} (0.1 - 8 mM) on lateral line organs of post-metamorphic Xenopus laevis. Spontaneous activity was inversely proportional to the concentration of each divalent cation in the absence of others. High concentrations of divalent cations were capable of suppressing spontaneous activity completely. For any given concentration of divalent cation, spontaneous activity was higher in the presence of Mg^{++} than either Ca^{++} or Co^{++}. Remarkably, the concentration-effect curves for Ca^{++} and the calcium channel blocker, Co^{++}, were very similar. It is difficult to reconcile these results with the hypothesis that spontaneous activity depends entirely upon voltage dependent calcium current and alternative hypotheses are suggested (Drescher and Drescher, Life Sci. 40:1371, 1987).

17.12 SYNAPTIC MORPHOLOGY AND VESICLE MORPHOMETRY OF HAIR CELLS IN THE TELEOST SACCULAR MACULA. M.J. Drescher*, D.G. Drescher, J.S. Hatfield* and C.M. Seitz*. Lab. of Bio-otology, Wayne State Univ. Sch. of Med., and Dept. of Pathology, Harper Hospital, Detroit, MI 48201.

The hair cells of the teleost saccular macula are of a single type, thought to be similar to vestibular type II hair cells of higher vertebrates. Saccular maculae of the rainbow trout, fixed in 1% glutaraldehyde, 4% formalin, 0.1 M sodium phosphate, pH 7.2, and postfixed in osmium tetroxide, have been examined by electron microscopy and analyzed with Bioquant II (R and M Biometrics).

Numerous clear vesicles were observed in hair cells, particularly below the level of the nucleus. Electron-dense synaptic bodies, similar to those described for the goldfish by Hama and Saito (J. Neurocytol. 6:361, 1977), were present at presynaptic sites and in the infranuclear cytoplasm at a distance from the plasma membrane ("heterotopic" bodies). The synaptic bodies were surrounded by halos of clear vesicles which appeared to be connected to the bodies by thin, radiating filaments. Synaptic bodies occurred singly and in clusters of 6-15 or more, reminiscent of the "ribbon fields" of pinealocytes (Vollrath, L., Z. Zellforsch. 145:171, 1973).

Morphometric analysis yielded diameters from perimeters for three populations of vesicles. Vesicles encircling synaptic bodies in hair cells had diameters of 47.5 ± 0.6 nm, vesicles in hair cells unassociated with synaptic bodies had diameters of 47.3 ± 0.5 nm, while vesicles in presumptive efferent endings on hair cells had diameters of 55.4 ± 0.5 nm (mean ± SEM). Presumptive efferent vesicles were significantly larger than hair cell vesicles (for both populations; $p < 0.001$), while no significant difference in diameter was determined between the two vesicle populations within the hair cells. Similar differences between efferent and hair cell vesicles were observed for glutaraldehyde and osmium tetroxide-based fixatives. Roundness factors ($4\pi Area/Perimeter^2$) were approximately 0.9 for all three populations of vesicles. In summary, the hair cell synaptic vesicles appear to be smaller than the presumptive efferent synaptic vesicles.

INTERHEMISPHERIC RELATIONS

18.1 AN INVESTIGATION INTO THE EFFECTS OF LEFT AND RIGHT HEMISPHERE REMOVAL ON RELEASE CALLING IN FROGS. R.H. Bauer, C.A. McCandlish* and V.D. Douglas*. Dept. Psych. Mid. Tenn. St. Univ., Murfreesboro, TN 37132.

Over 100 years ago Broca demonstrated that the left hemisphere plays a major role in articulation of speech. Since this initial observation, a wide variety of evidence has supported the finding that language is lateralized in the left hemisphere. Attempts to demonstrate hemispheric dominance in animals were for the most part unsuccessful, and for a time hemispheric dominance was thought to be a major distinction between the human and animal brain. However, Nottebohm (Science, 167:95, 1970) clearly demonstrated that singing in male canaries is lateralized to the left hemisphere. Thus, lateralization is not a major difference between the human and animal brain but, at least for vocalization, lateralization occurs early in evolution. The major purpose of the present study is to examine the possibility that vocalization of a species farther down the evolutionary scale is also lateralized to the left hemisphere. Frogs and toads are the earliest species to exhibit true vocal cords and vocalization is produced by neural control from higher brain areas. Furthermore, calling behavior is known to alter the behavior of other members of the species in socially significant ways. For example, when a male mounts another male or a nongravid female the mounted frog emits a sharp, rapid call until they are released, hence the name release call.

Adult male frogs (Rana pipiens) approximately 8 cm long were housed in two compartment cages with water on one side. Release calling was produced by lightly holding the frog behind the front legs, caudally along the thorax. Baseline release calling was recorded during two 30 sec periods, 5 days a week for 10 weeks. Four groups of six frogs each were formed by matching frogs on the number of croaks in the baseline. These groups were as follows: (a) right telencephalic ablations, (b) left telencephalic ablations, (c) sham operations, and (d) nonoperates. The telencephalon from the olfactory bulb to the dorsal groove was removed by aspiration. Testing resumed 7 days after treatment for 6 weeks postoperatively.

Release calling was not significantly altered by left or right hemispheric ablations, indicating that this behavior is not lateralized in either hemisphere. The mating call, as distinguished from the release call, increases during the breeding season and appears to be involved in territoriality and attraction of females. Calling of this type can be induced by hormone injections. We are currently investigating the effects of hormone injections on the mating call by frogs with left and right hemispheric ablations.

18.2 **SEXUAL DIMORPHISM OF LATERALIZATION IN MICE SELECTIVELY BRED FOR DEGREE OF FUNCTIONAL ASYMMETRY: INTERACTION OF SEX, HANDEDNESS AND GENOTYPE**
Robert L. Collins.
Jackson Laboratory, Bar Harbor, ME 04609.

Sex differences in the degree of lateralization, but not in its direction, were reported in C57BL/6J inbred mice tested for handedness (Collins, Science, 187:181-184, 1975). In 'unbiased worlds' female mice were more strongly lateralized than males. To demonstrate that differences in degree of lateralization were heritable according to an autosomal pattern, a selective breeding program was initiated. A genetically heterogeneous, 8-way cross, foundation population was formed and 11 generations of bidirectional selection was practiced for extremes of lateralization. This produced two lines of mice that differed markedly in strength of handedness (Collins, in S. D. Glick (Ed.), Cerebral Lateralization in Nonhuman Species, Academic Press, 41-70,1985). Following a period of random within line mating, selection was reimpressed during S28-S30 generations.

The degree of lateralization according to handedness direction, sex, and line was examined in mice for S7 through S10 ($n = 1749$) and S28-S30 ($n = 1123$). Laterality by Sex by Handedness interactions were found in both data sets ($p = 0.003$ and 0.07). In the strongly lateralized HI line, sinistral females were more lateralized than sinistral males (1.52 vs 1.31 logit transformed PPE score, unweighted means), whereas the pattern was nonsignificantly reversed for dextral mice (1.32 vs 1.35). In the weakly lateralized LO line, sinistral males were more lateralized than sinistral females (0.71 vs 0.64), and dextral females were more lateralized than dextral males (0.66 vs 0.56). The laterality by sex pattern of the HI line was reversed in the LO line. Thus, in lines selected for extremes of lateralization, sex differences in degree of asymmetry interact with the direction of laterality and genotype or evolutionary history.

This selective breeding program, based originally on a sex difference observed in inbred mice, may have altered normal sexual characteristics of the lines. HI line females seem somewhat 'masculinized'. For example, they are aggressive fighters and show greater absolute asymmetries of orbitofrontol cortex and hippocampus. LO males appear somewhat 'de-masculinized'--they are hypogonadal with lowered circulating testosterone level. This suggests that developmental effects of gonadal steroids may play a role in affecting differences in degree of asymmetry as well as sexually dimorphic forms of hemispheric lateralization distinguishing the lines.

18.3 NEOCORTICAL SYMMETRY AND ASYMMETRY IN THE RAT: DIFFERENT PATTERNS OF CALLOSAL CONNECTIONS. G.D. Rosen, A.M. Galaburda, and G.F. Sherman. Neuroanatomical Dyslexia Lab, Beth Israel Hospital and Harvard Medical School, Boston, MA 02215.

Histological analysis of area 17 in the rat has revealed that volume asymmetries of this area reflect side differences in neuronal numbers. Furthermore, brains with symmetrical visual cortices have a greater bilateral number of neurons in this area than brains with asymmetrical visual cortices; asymmetrical visual areas, moreover, show a relative reduction in neuronal numbers on one side, rather than an increase on the other side. We have suggested that asymmetry may reflect the unilateral enhancement of ontogenetic cell loss in the cortex, and symmetry the interference with this process (Galaburda *et al.*, *Neuropsychologia*, 1987, in press). The purpose of this study was to determine whether the suggested preservation of neurons in symmetrical brains is accompanied by preservation of callosal patterns that antedate developmental cortical cell death.

Eight 90 day-old Wistar rats received midsagittal callosal sections. After one week's survival, animals were sacrificed and brains removed, fixed, embedded, sectioned at 30 μm and stained using the Fink-Heimer method for degenerating axon terminals. Adjacent sections were stained for Nissl substance with cresyl violet. Somatosensory area 2 was parceled on the Nissl sections; the Fink-Heimer sections were digitized under darkfield illumination on a Gould FD-5000 interfaced with a VAX 11/750 minicomputer; the Nissl sections and digitized images were overlayed and the architectonic borders on the former transferred onto the latter. The volume of each architectonic area and its mean total density of terminations were quantified. Qualitative assessment involved determination of the degree of columnar and laminar distribution of the terminal boutons.

The mean total density of axonal terminals in area 2 was inversely proportional to the degree of asymmetry of this area. Visual examination suggested that this was so because the brains with more symmetrical area 2's had fewer projection-weak regions. Further analysis revealed that the pattern of callosal projections in brains with asymmetrical sensorimotor/somatosensory areas was significantly more restricted to discrete regions than that in brains with symmetrical areas ($t = 12.65$, $df = 6$, $p < 0.001$). In the rodent at birth the pattern of callosal projections is relatively diffuse throughout the cortex, and subsequently establishes an appearance of discrete areas of projection by withdrawal of axons. This pruning process appears to occur to a lesser extent in brains with symmetrical areas than in those with established asymmetry. (Supported by NIH grant HD 19819 and a grant from the Hood Foundation).

18.4 MORPHOLOGICAL STUDY OF HEMISPHERIC ASYMMETRIES IN NORMAL AND ACALLOSAL MICE. S.L.Schmidt*,E.M.A.Caparelli-Daquer*,E.Volchan*(SPON:L.R.G.Brito). department of Neurobiology,Institute of Biophysics C.C.F9, U.F.R.J.; Inst. of Biology,U.E.R.J. , Rio de Janeiro , Brazil

It has been suggested that the normal development of the corpus callosum (C.C.) is responsible for the establishment of brain asymmetries.Cerebral asymmetries have been described in several species.In particular,right-left anatomical differences have been reported in male rodents. As the C.C. fails to develop in many mice of the BALB/cCF strain we decided to look for morphological asymmetries in the brain of these abnormal animals, reasoning that their occurence would disproof the determinant participation of the C.C. Forty - six adult males of the BALB/cCF strain were intracardially perfused under ether anesthesia with saline (0.9% NaCl) followed by a 4% solution of formaldehyde. After several weeks postfixation , the brains were removed from the skull and photographed from above. The dorsal area of each hemisphere was measured from the photographic prints, with the aid of a computer. The cerebral hemispheres were split apart by cutting the brain through the midsagittal plane and weighed on a digital balance. The left hemispheres were embedded in paraffin and cut into 10 μm parasagittal sections. These sections were stained with cresyl-violet and charted with a camera lucida.The midsagittal area of the C.C. was measured from these chart (n=46) in order to descriminate normal from abnormal animals. The C.C. was considered normal if its area exceeded 0.64mm² (n=24) and abnormal if its area was below 0.44mm² (n=13). In normal animals the mean difference between left and right dorsal areas demonstrated a significant absolute asymmetry the left hemisphere being consistently greater than the right hemisphere. The same was true for weight,the left hemisphere being heavier than the right hemisphere. In mice with callosal deffects, however there was no significant mean difference between dorsal areas as well as between weights of the hemispheres.Our results suggest that the C.C. does play a role in the development of morphological asymmetries. We do not know if these anatomical differences are related with functional asymmetries. The indication that the C.C. is implied in the establishment of laterality is supported by neuropsychological studies of human patients with callosal agenesis,but interpretation of these results is still controversial.Furthermore the use of anatomical measures for assessing asymmetry and establishing structure - function correlation, should be approached with caution, since recent studies have showed that they cannot predict reliably the occurrence of functional asymmetry in particular cortical areas.

18.5 RELATIVE CONTRIBUTION OF THE CORPUS CALLOSUM TO THE BILATERAL RECEPTIVE FIELD OF CELLS IN S-11. J.P. Guillemot, D. Petit* and F. Leporé. Dept of kinanthropologie and Psychologie, UQAM and Univ. de Montréal, C.P. 6128, Succ A, H3C 3J7.

The corpus callosum contributes to the interhemispheric transfer of somatosensory information. Since the somatosensory pathways are essentially crossed, many studies have postulated that the corpus callosum may be responsible for the presence of bilateral receptive fields (RFs) in cortical area S-11. On the other hand, subcortical structures as well as commissures other than the corpus callosum, may also contribute to the bilateral nature of these cells. In order to assess the relative contribution of the corpus callosum, this study compared corpus callosum-sectioned cats to normal cats. The location and RF properties of cells with bilateral RFs were compared. Single cell recordings in anesthetized and paralyzed cats were carried out with glass micropipettes and responses were amplified by conventional methods. Stimuli used to elicit responses within RF were: light touch, pressure, air puffs and passive movements of the limbs.

Results showed that the corpus callosum makes an important contribution to bilateral activation of cells in S-11, since less than half the number of cells with bilateral RF is found in corpus callosum-sectioned cats as compared to normal cats. The decrease in proportion of bilateral RF is found for all body regions with the exception of the face. However, the substantial proportion of bilateral RFs remaining in callosotomized cats indicate that this structure is not the only contributor to bilateral activation of cells in S-11. The relative importance of the callosal contribution to bilateral RFs to different body regions is also assessed and discussed with respect to the roles normally attributed to the corpus callosum.

18.6 **ASSYMETRIC HAND PREFERENCE IN FOUR SPECIES OF CAPTIVE APES** J. E. Heestand*. (SPON: J.S. Lockard). Univ. of Wash., Seattle, WA. 98195.

Interest in the evolution of neural lateralization in Man has led investigators to employ the comparative method to examine asymmetry in other primates, both on a neurologic and behavioral level. One theory maintains that the origin of language was gestural in nature and was preceded by hand preferences developed through the performance of bimanual tasks requiring asymmetrical use (Hewes, G., Cur. Anthro., 14:5-24, 1973). It has been suggested that the development of hand preferences was fostered by asymmetrical orienting during foraging (Sanford et al., Brain Beh. Evol., 25:217-224, 1985) when one limb performs a strength and the other a dexterous function. This leads to a prediction that the degree of preference should be related to the extent to which strength is an integral part of the foraging pattern.

Studies on monkeys have typically made extensive use of lesions or commissurotomy and few studies, using either monkeys or apes, have focused on observations of naturally occurring behavior in social groups. In the present study 70 apes representing four species [Gorilla gorilla, Pongo pygmaeus, Pan troglodytes and Symphalangus syndactylus] were observed in social groups in semi-natural captive environments at six zoos. Using the focal animal sampling technique the behavior in which the animal was engaged, the limb being used and the nature of the limb usage were recorded for a total of 12 hours. Direct-testing for eating involving fine manipulation was conducted with 11 animals.

Results revealed that there were significant species-typical hand/limb preferences (walk/run category) for orangutans ($p=.04$), siamangs ($p=.05$), chimpanzees ($p=.001$) and gorillas ($p=.01$). In addition, the bias for each species was in the same direction, namely a right preference that was significant ($p<.05$). Also, hand preferences were obtained for a significant number of the individuals under direct-testing although no preference was evident during free feeding.

Unlike human populations, non-human primate populations have not demonstrated the presence of a genetic component to handedness since, from population to population, consistent left-right proportions have not been found. This inconsistency has led many investigators to state that hand preferences in monkeys is a learned trait with no specific underlying neurologic correlate. Notably, in the present study, the four species of apes evinced the same hand/limb preference for a single behavioral category. These findings indicate that a limb preference is important in locomotion. As such, the findings of the present study suggest the presence of a neurologic correlate in apes.

18.7 THE HUMAN CORPUS CALLOSUM: AN MRI STUDY VARYING SEX, HANDEDNESS AND AGE. RM Harris, JW Sundsten* and RA Fischer-Wright*. University of Washington, Seattle, WA 98195.

Several recent studies have investigated variations in the cross-sectional area of the human corpus callosum or of its parts, especially the splenium, with respect to gender or handedness. Although initial studies using autopsied brains showed significantly larger values in females over males and left-handers over right-handers, later studies using magnetic resonance imaging (MRI) have failed to confirm these differences. In order to evaluate the effects of both gender and handedness simultaneously, as well as age, we have undertaken an MRI study of 24 normal human volunteers. These included equal numbers (12 each) of males and females, left and right-handers, and ages less than or greater than 30. Midsagittal spin-echo images 5 mm thick were obtained and the region of the corpus callosum magnified by a factor of 3. Cross-sectional areas were digitized for the entire corpus callosum (average value 6.34 $\pm$ .99 cm^2) and its posterior fifth, the splenium (1.83 $\pm$ .31 cm^2), as well as the maximal splenial width in the dorsal-ventral direction (1.62 $\pm$ .23 cm). An analysis of variance for the factors gender, handedness and age showed no statistically significant variations for any of the three callosal variables ($p > .16$ for all cases). For each variable, however, the average value for females was larger than that for males, for left-handers larger than for right handers, and for older subjects larger than for younger subjects. In an attempt to correct for differences in brain size, each variable was divided by the cross-sectional area of the cerebral cortex, obtained from the mid-sagittal scan. An analysis of variance for these ratios again showed no significant differences, with the exception of the splenial width divided by the cortical area, in which females were larger than males (0.020 $\pm$ .003 vs. 0.017 $\pm$ .002) at the $p = 0.02$ level.

The most obvious feature of these data was the large natural variations in callosal measurements within groups. For example, the total callosal area varied between 4.36 and 9.45 cm^2. Although the average values for the callosal measurements were somewhat larger for females and for left-handers, the large variability makes it unlikely that these are significant differences.

18.8 SIMPLE REACTION TIMES TO LATERALIZED LIGHT FLASHES IN NORMAL SUBJECTS, FOUR COMMISSUROTOMIZED PATIENTS, AND A CALLOSAL AGENESIS BOY: VARIETIES OF INTERHEMISPHERIC COMMUNICATION ROUTES. J. M. Clarke* and E. Zaidel* (SPON: D. Zaidel). Dept. of Psychology, Univ. California, Los Angeles, Los Angeles, CA 90024-1563.

In 1912, Poffenberger (Archives of Psychology, 23:1, 1912) first demonstrated that simple reaction times to lateralized light flashes are a few milliseconds longer when the responding hand and the visual hemifield in which the light flash appears are on opposite sides (crossed condition) than when they are on the same side (uncrossed condition). The crossed-uncrossed difference (CUD) appears to be a measure of interhemispheric transmission time across the corpus callosum in normal individuals.

Using a computerized tachistoscope, we had subjects respond to 10 blocks of 80 trials. To assess whether visual information was being transferred, two different light intensities were used. Intensity and visual field of presentation varied randomly within blocks of trials, while response hand alternated after each block. For 20 undergraduates the mean CUD was 2.1 ms (SD=3.7), which was invariant over light intensity despite a significant main effect of light intensity on overall reaction times. The absence of an effect of light intensity on the CUD suggests that motor rather than visual information was transferred.

Sergent and Myers (Perception & Psychophysics, 37:571, 1985) found notably larger mean CUDs (30 & 50 ms) in two commissurotomized subjects. However, the two light intensities they used were not sufficiently differentiated to affect overall reaction times. Therefore, it was not clear whether the CUDs represented visual transfer across the superior colliculus, subcallosal transfer of a motor code, or ipsilateral motor control.

In the present study, the overall CUDs from four completely commissurotomized subjects varied from 34 to 61 ms, and the intensity manipulation had significant effects on reaction times. The CUDs remained invariant over the two intensities for patients L.B. and A.A., suggesting a motor route. The CUD was inversely affected by light intensity for patient N.G., probably representing transfer of visual information across the superior colliculus. Surprisingly, the CUD for patient R.Y. was significantly larger for brighter flashes. However, R.Y. exhibited an unusual inability to respond to many of the light flashes that appeared in the right visual hemifield when he was using his left, but not right, hand. An idiosyncratic route of noncallosal transfer may be responsible for this latter result.

An eight-year old boy (M.M.) with callosal agenesis had an overall CUD of 20 ms, which is comparable to CUDs observed in similar patients (eg. Milner, A. D., et al., Neuropsychologia, 23:323, 1985). However, contrary to previous findings, the CUD for M.M. was unaffected by different light intensities, despite a main effect of intensity, suggesting a nonvisual route.

18.9 USE OF THE INTRACAROTID SODIUM AMYTAL PROCEDURE TO PREDICT SIDE AND SITE OF FOCAL LESION. Peter J. Snyder, Robert A. Novelly*, and Maria D. Lifrak*. Dept. of Psychology and Neuroscience Program, Michigan State Univ., E. Lansing, MI 48824-1117

Although the intracarotid sodium amytal procedure (ISA) was developed to determine hemispheric dominance for speech in humans (Wada, 1949), the procedure was later expanded by Branch, Milner & Rasmussen (1964) in order to discern patency of memory in the hemisphere contralateral to the side of proposed surgery. Their extended procedure was designed to evaluate the risk of inadvertent production of an amnestic syndrome following unilateral temporal lobectomy.

We propose that standardized administration and quantification of ISA memory assessment in each hemisphere may lead to the further development of this procedure for independent diagnosis of side and site of focal epileptogenic lesions. Our data suggest that patients with epileptogenic lesions of the left (L) versus right (R) temporal lobes, and frontal versus temporal lobes can be differentiated with this procedure.

Of 70 epilepsy surgery patients seen at the Yale - West Haven, CT., VAMC Epilepsy Center, 67 met criteria for a single focal epileptogenic lesion (determined by a combination of scalp EEG, CT scan, and/or chronic depth EEG). Site and side of lesions were: Temporal - R=26 / L=25; Frontal - R=10 / L=6. A standardized and quantifiable ISA memory procedure, developed by the 2nd author, was administered to all subjects. No differences were found between the four groups with regard to amount of sodium amytal administered, age of onset of the discharging lesion, or Wechsler IQ indices.

A 2x4 factorial ANOVA, with hemisphere assessed and side/site of lesion as the 2 factors, was conducted on the memory data. A significant 2-way interaction effect was obtained, $F(3,126)=21.576$, $p<.001$. A posteriori analysis (Newman-Keuls, $p<.001$) showed significantly lower memory values for the lesioned hemisphere of both R and L temporal lobe patients compared to the non-lesioned hemispheres of these two groups. In contrast, no significant differences were observed between memory values for the lesioned vs. non-lesioned hemisphere of either R or L frontal lobe patients.

Despite individual exceptions, a pattern of memory preservation emerges that could extend the use of the ISA beyond its classical applications, mentioned above. Since it is often difficult to discriminate frontal vs. temporal seizure foci via standard diagnostic techniques, an adjunct and independent methodology, such as the ISA memory procedure, could be of considerable practical value.

18.10 ASYMMETRIES IN NEGLECT AND PATTERN OF RECOVERY FOLLOWING LEFT VS. RIGHT MEDIAL PRECENTRAL PREFRONTAL CORTEX LESIONS IN RATS. J.M. VARGO*, J.V. CORWIN*, V. KING* AND R.L. REEP (SPON: J. McLean) Dept. of Psychology, Univ. of New Orleans, New Orleans, LA 70148 and Depts. of Physio. Sci. and Neurosci., Univ. of Florida, Gainesville, FL 32610.

Human brain organization is characterized by lateralization of function. An increasing number of studies are now documenting lateralization of nonhuman brain organization. Previous research has indicated that behavioral asymmetries are produced by unilateral destruction of medial precentral prefrontal cortex (MPP) in rats (J.V. Corwin et al., 1986, Soc. Neurosci. Abst., 12:1537). The present parametric study is a further examination of the patterns of behavioral asymmetries and recovery of function from multi-modal neglect produced by unilateral destruction of MPP.

The subjects were 42 male Long-Evans hooded rats: 12 received unilateral lesions of the left MPP (L-MPP), 18 received unilateral lesions of the right MPP (R-MPP), and 12 were controls. Nine of the controls had an equal amount of cortex removed unilaterally at a location just lateral to MPP, the remaining 3 subject's received skull removal only. Total neglect scores were calculated using "blind" ratings of the degree of orientation to the presentation of visual, somatosensory and auditory stimuli to each side of the body. Testing was conducted 3 times a week for a minimum of 3 weeks or until recovery (2 consecutive test days with the ratio of neglect side/non-neglect side ≥ 0.60).

There were no significant differences between the lesion extents of any of the surgical groups. Significant differences were found in each paired comparison between L-MPP operates, R-MPP operates and pooled controls for total neglect scores and for scores within each modality during weeks one (all p's<0.01) and two (all p's<0.05), with the exception of R-MPP and control somatosensory scores during week two. L-MPP operates demonstrated significantly more severe neglect than R-MPP operates during week one ($p<0.05$). The L-MPP group showed consistent contralateral neglect. In contrast, 12 of the 18 R-MPP operates showed consistent ipsilateral neglect, and the remaining six exhibited ipsilateral or contralateral neglect one day and opposite-sided neglect on subsequent test days. These animals "switched" neglect sides from one to three times before recovery. In contrast to our previous findings, no R-MPP animals exhibited exclusively contralateral neglect. There was no significant difference in the rate of recovery between the L-MPP and R-MPP operates.

These results are in accord with both anatomical (Van Eden et al. (1984) Dev. Brain Res., 12:146-153) and neurochemical (Slopsema et al. (1982) Brain Res., 250:197-200) findings indicating asymmetries in the MPP of rats.

18.11 THE ISSUE OF BRAIN WEIGHT AND NEW MEASURES OF SEXUAL DIMORPHISM IN STUDIES OF THE HUMAN BRAIN. T. Adesanya*, D. J. Woodward & M-C de Lacoste (SPON: R. J. Kosinski). *Dept. Cell Biology and Anatomy., UTHSCD, Dallas, Texas 75235.*

The advent of **Nuclear Magnetic Resonance Imaging** techniques has made it possible for investigators to obtain gross brain measurements *in vivo* and attempt to correlate those with neuropsychological profiles [e.g., sex, handedness, lateralization of function] and/or psychiatric history [e.g., schizophrenia]. However, one of the determinants of gross measurements is overall brain size and, hence, unless one is assured that there is no variation in brain weight in a particular sample, it must considered as one of the variables in the data analysis. Since complete series for each brain of MRI images are usually difficult and expensive to obtain, investigators have had to depend on select linear measurements or single-section surface areas to estimate sample variation in brain size. This study was undertaken to isolate a set of gross brain measurements that could readily be identified on mid-sagittal MRI scans and used to accurately predict brain weight. A second aim was to determine if a subset of these measurements [exclusive of callosal area] could function to study sex differences in the brain in normal populations or hormonally aberrant groups.

Whole brain [N=80] perfused in situ with embalming fluid and stored in 10% buffered formalin were acquired from the UTHSCD Willed Body Program. Brain weights were recorded at different time periods but those utilized in this study were obtained immediately prior to the compilation of an extensive battery of gross measurements. Mid-sagittal sections were photographed and these were used to obtain surface areas of the entire section and of select regions [e.g., cuneus] using the laboratory CARP software. Our sample size was statistically age- and sex-matched and evinced the expected sex difference in brain weight[$p = .003$]. As anticipated a number of measures were statistically correlated with brain weight although none had a Pearson r of greater than .70. Multiple regression techniques further isolated six of these variables [including total surface area, inferior-superior frontal dimensions, etc. but not anterior to posterior distance] as the most useful for predicting brain weight [Multiple R=.9238]. However, not one of the selected variables reflected the observed sex difference in brain weight. In other words, measures that could be used to reliably estimate brain weight were nearly identical between the sexes. Yet, ANOVA techniques demonstrate a consistent sex and brain effect on the size/area of a number of brain measurements. In practical terms, this means that in examining the relationship between sex and the size of individual brain structures, one must obtain an accurate measurement of brain weight to control for the influence of that variable. Perhaps, better estimates of brain weight can be acquired from a number of serial MRI sections or from skull measurements.

We were able to isolate a subset of variables that appear to be consistently statistically sexually dimorphic These include distances between the callosal sulcus and the superior aspect of the brain and between the rostrum and splenium and, respectively, the frontal and occipital poles. Additionally, we observed that the calloso- marginal sulcus is more likely to bifurcate or radiate in the female right hemisphere. Finally, although we did confirm Papez observation of sex differences in the direction and degree of asymmetry in the cuneus, these differences were not statistically significant in this sample.

18.12 SEX DIFFERENCES IN THE HUMAN MASSA INTERMEDIA. Laura S. Allen* and Roger A. Gorski (SPON: A. Adinolfi). Dept. of Anatomy and Lab. of Neuroendocrinology, UCLA School of Medicine, Los Angeles, CA 90024.

Several neuroanatomical sex differences have been identified in birds and mammals which could underlie functional sex differences in reproductive behavior and physiology. However, relatively little is known about sexual dimorphism in the human brain. Sexually dimorphic cell groups in the preoptic-anterior hypothalamus (Swaab, D.F. and Fliers, E., Science, 228:1112, 1985; Allen L.S. et al., Endocrinology Suppl., 118:633, 1986) are larger in men and, at the midsagittal plane of the brain, several structures may be larger in women. The massa intermedia is more often present in females than in males (Morel, F., Acta Anatomica, 4:203, 1948), and the cross-sectional area of the anterior commissure (Allen, L.S. and Gorski, R.A., Anat. Rec., 214:3A, 1986) and the corpus callosum (DeLaCoste-Utamsing, C. and Holloway, R.L., Science, 216:1431, 1982) are greater in women than in men. We examined the possibility that the mid-sagittal cross-sectional area of the massa intermedia (MI) in post-mortem human tissue is also sexually dimorphic. The region of the brain containing the thalamus was sectioned midsagitally. Therefore, the MI, if present, protruded from the thalamic wall of the third ventricle. The midsagittal surface of each MI was placed against a glass, with an adjacent ruler taped at the same plane, and photographed. The image was projected onto white paper at a magnification of 12X, and the border of the MI was traced. The area of each tracing was determined using a bioquant hipad digitizer. Our results are based on analysis of the brains of 48 females which ranged in age from 1 to 87 years (X=63±21), and 36 males from 1 to 81 years (X=54±22). The massa intermedia was present in the brains of 40 (83%) of the females and in 26 (72%) of the males. The area of the MI in females, which ranged from 0 to 1.279 cm^2 (X=.354±.341) averaged 68% larger than the area of the MI in males, which ranged from 0 to .814 cm^2 (X=.211±.183) (p=.026). The more frequent presence of the MI in females does not account for this sex difference since in these 40 individuals the MI is 45% larger (X=.42±.330) than in the 26 males with an MI (X=.292±.150). These differences are present despite the fact that the male brains were an average of 14% larger in weight than the female brains. Since the role of gonadal hormones on the sexually dimorphic structures in the human brain cannot be determined by experimental manipulation of humans, as has been demonstrated in other animals, it is possible that radiological techniques such as magnetic resonance imaging in humans with abnormal hormone exposure, may further elucidate the role of sex hormones in influencing the structure of the human brain as well.

18.13 ANALYSIS OF THE MAGNETIC ALPHA RHYTHM IN SIGNAL SPACE. R.J. Ilmoniemi and S.J. Williamson. Neuromagnetism Laboratory, Depts. of Physics and Psychology, New York University, 4 Washington Place, New York, NY 10003.

We have investigated the magnetic field produced by spontaneous alpha activity using two seven-channel SQUID gradiometers positioned bilaterally over the occipital head of normal subjects. This provides 14 simultaneous, independent measures, which are sufficient to determine a wide variety of possible source configurations. Nevertheless, we have analyzed the data in a more general sense by exploiting the advantages of a 14-dimensional signal space. The analysis is therefore independent of any specific models of the source configuration.

Each of the several trials in a session consisted of eighteen 16-second epochs of data collection, with a two-second separation between epochs. Subjects were instructed to keep eyes closed except for three 18-second periods in each trial, during which the characteristic suppression of alpha activity could be observed when the subject looked at a visual pattern. In some trials, hemifield visual presentation was applied. To facilitate the handling of the large amounts of data collected in this study, an automatic detection scheme for alpha spindles was developed. Each detected spindle was characterized by its duration, frequency, time of occurrence, and by the rms-amplitudes in the 14 signal channels; these characteristics formed the basis for subsequent analysis. Since there may be multiple simultaneous sources distributed over large areas of cortex, we look at the behavior of the field pattern from spindle to spindle or within spindles, thus avoiding uncertain assumptions about the sources.

The measured field values are conveniently represented as coordinates of a vector in the 14-dimensional signal space. Using methods of cluster analysis, we observed that there are intervals of time when the signal vector is confined to a small region of signal space, implying that these spindles are produced by nearly identical source configurations. At other times, possibly contingent on the experimental situation, locations of spindles in signal space appear to bear little relation to their predecessors. We will show how representing each spindle on a two-dimensional surface allows us to observe dependencies of various characteristics of the spindles on source configuration. Similarly, this representation reveals dependencies of the source configuration on experimental conditions.

In order to infer regions of activity that give rise to the observed spindles, we represent the source of each spindle by an equivalent current dipole and show relationships between source position in the occipital-parietal regions and characteristics of the spindle.

18.14 COMPARISON OF RIGHT- VS. LEFT-HAND SOMATOSENSORY ACTIVATION: A POSITRON EMISSION TOMOGRAPHIC STUDY. F. Yoshii*, M.D. Ginsberg, R.E. Kelley, J.Y. Chang, W. Barker, G. Ingenito, A.M. Apicella, R. Duara, and T.E. Boothe. Cerebral Vascular Disease Research Center, Department of Neurology, University of Miami School of Medicine, Miami, FL; and Section of Positron Emission Tomography, Department of Radiology, Mount Sinai Medical Center, Miami Beach, FL.

The left brain and right brain are differently organized. Speech is a left-hemisphere function and visuospatial function is related to the right hemisphere. Anatomical hemispheric asymmetries, such as a larger left than right planum temporale and a longer and lower left than right sylvian fissure are well known. However, functional differences of the somatosensory cortices of the two hemispheres have not been studied. We compared the activation capacity of the right and left somatosensory cortices in normal right-handed volunteers using positron emission tomography (PET) and the double-injection kinetic model of 18-F)fluoro-deoxyglucose (Chang et al, J Nucl Med, 1987). This model allowed us to use each subject as his own control; thus, cerebral metabolic rate for glucose (CMRglc) could be assessed in two behavioral states -- rest and activation.

Ten subjects were males and 6 were females. Somatosensory activation was performed by palpation and sorting of mah-jongg tiles with one hand (Ginsberg et al, Neurology, in press). In 8 subjects (mean age ± SD: 50.8 ± 21.0 y/o) who used the right hand for activation, CMRglc in the left (contralateral) somatosensory cortex (SSC) increased 16.2 ± 6.1% during the activation task, while the CMRglc increase in the right (ipsilateral) SSC was 3.8 ± 4.8%. In 8 subjects (40.0 ± 20.1 y/o) who used the left hand for activation, the CMRglc increase in the right (contralateral) SSC was 12.1 ± 2.9% and that in the left (ipsilateral) SSC was 5.4 ± 2.3%. In both groups, activation of the contralateral SSC was significantly higher than that of the ipsilateral SSC (for the left hand, $P < 0.05$; for the right hand, $P < 0.01$). Thus, contralateral SSC stimulation did not differ significantly between the left- and right-hand groups. However, when an index of interhemispheral activation asymmetry was computed by dividing the CMRglc increase in the ipsilateral by that of the contralateral SSC, the index in subjects using the right hand was 0.23 ± 0.22, while in subjects using the left hand it was 0.45 ± 0.20. Our findings suggest that, in right-handed individuals, right- and left-hand somatosensory stimulation gives rise to equal degrees of contralateral SSC activation, while the tendency toward ipsilateral/contralateral symmetry of activation is greater when the left hand is stimulated. 18.15 BRAIN WEIGHT AND CORPUS CALLOSUM SIZE IN MICE SELECTED FOR HIGH AND LOW DEGREES OF PAW PREFERENCE. B. Cassells, R.L. Collins, and D. Wahlsten. Dept. of Psychology, Univ. of Waterloo, Waterloo, ON Canada, and Jackson Laboratory, Bar Harbor, ME 04609.

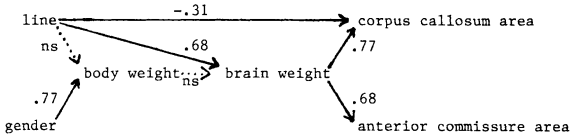
Mice (n=109) from the 29th generation of lines selected for high and low degrees of paw preference were tested for direction and degree of paw preference at 6 to 10 weeks. At 10 to 14 weeks, they were perfused intracardially with 0.9% saline followed by 10% buffered formalin and their brains removed. The myelin staining intensity of the genu of the corpus callosum and morphometric indices of all major myelinated forebrain commissures were assessed from 25μ frozen midsagittal sections stained with Sudan Black B. All measures were adjusted to a perfusion age of 90 days. A stepwise discriminant analysis followed by a path analysis based on multiple regression revealed that the data were consistent with the following causal model:



Positive coefficients indicated high > low and male > female or positive covariation of measures. The nonsignificant (ns, $p > .01$) effects remaining in the diagram were included for theoretical reasons. Gender significantly influenced body weight only. The brains of the high line mice were relatively larger (by 45 mg or 11%). No significant effects on anterior commissure area independent of brain weight were evident. However, the callosal areas of the low line mice were larger (by .092 mm^2 or 12%) relative to their brain weights. Because the lines did not differ on myelin staining intensity of the genu, selection for high degree of paw preference may have produced an increase in relative brain size that surpassed the increase in the number of callosal axons linking the two cerebral cortices and, perhaps, greater hemispheric independence and functional specialization. However, in the total sample, relative brain weight (but not relative callosal area) was significantly related (positively) to degree of paw preference. This suggests that relative brain weight (but not degree of interhemispheric connectivity) is an important influence on degree of functional lateralization. No differences between lines or genders in percentage of area in or shape of the posterior fifth of the corpus callosum or in the absolute or relative areas of the hippocampal or dorsal fornical commissures were evident.

18.16 EEG COHERENCE AND INTELLIGENCE IN CHILDREN. R.S. Hernandez, A.T. Arenander and R.W. Boyer*. Dept. of Physiol., and Dept. of Psych., Maharishi Int'l Univ., Fairfield, IA 52556.

EEG coherence (COH) is considered to be an estimate of the stability of the phase relationship between any two scalp recorded signals within a given frequency band. COH is thought to reflect the amount and strength of cortical connectivity, and thus, high COH is considered to represent a state of low functional neural differentiation. During periods of high COH neurons may be functionally more coupled corresponding to periods of lower, perhaps less independent, information processing. Current research has indicated apparent paradoxical conclusions regarding the relationship between standardized IQ scores and measures of COH during eyes-closed (EC) conditions: a robust inverse correlation in children, and a positive correlation in adults. The purpose of the present study was to examine the correlation across a range of cerebral function; from low to high levels of excitation. A sequence of different task conditions were employed to modify brain state in order to create a dynamic range of activation.

EEG was recorded from 48 right handed normal children aged 10 to 16 years during the following sequence of conditions: rest/EC, rest/eyes-open (EO), mental arithmetic/EC, word generation/EC, Transcendental Meditation (TM) practice/EC, rest/EO, rest/EC. TM was included because this mental procedure is reported to produce substantially de-excited brain states, and high COH. Raw EEG from 16 scalp locations was digitized at 120 Hz, and 25 artifact-free seconds of data were analyzed using complex demodulation, giving phase and power spectrum information across standard EEG frequency bands. COH, the ratio of the square of the cross spectrum to the product of the autospectrum, was computed for all combinations of lead pairs. The Weschler Intelligence Scale for Children-Revised (WISC-R) test was also administered.

Preliminary polynomial regression analyses, using full scale IQ as the dependent variable, indicate an inverse correlation between IQ and COH in frontal derivations in alpha and theta frequencies across all conditions, with rest/EC, rest/EO and mental arithmetic sigificant at the $p > .005$ level.

18.17 VISUAL SEARCH IN HYPOTHETICALLY PSYCHOSIS-PRONE COLLEGE STUDENTS. J. W. Jutai* (SPON: R.E. Walley). Dept. of Psychology, Univ. of Alberta, Edmonton, Canada T6G 2E9.

This research examined the possibility that a lateralized cerebral hemispheric abnormality is present in individuals at risk for the development of psychotic disorder, and that this abnormality is the same as that hypothesized to underlie cognitive dysfunction in schizophrenia. It has been suggested that the primary, initial disturbance in schizophrenia occurs in the right cerebral hemisphere and results in damage to a cortical network involved in attention. A key aspect of attention particularly sensitive to right-hemisphere damage is its distribution within extrapersonal space. Eight hundred college students were screened using psychometric measures of psychiatric vulnerability. Experimental subjects (n=51) were those with extreme high scores on at least one of four psychosis-proneness scales developed by Chapman and colleagues at the University of Wisconsin. Other research has shown that many of these individuals show cognitive deficits similar to those of adult diagnosed schizophrenics. Control subjects (n=21) scored with 0.5 S.D. of the mean on all scales. Subjects were tested using letter/shape cancellation tasks designed by behavioral neurologists to detect abnormalities in the spatial distribution of attention. If the prepsychotic period in the development of psychotic disorder is associated with dysfunction of right hemisphere mechanisms of attentional control, it was expected that experimental subjects would show evidence of deviant visual search on the cancellation tasks. This hypothesis was supported by the data. More than 50% of experimental subjects employed an erratic search strategy typically observed in right-brain damaged patients, compared with less than 20% of controls. Also presented will be the results of further analyses which examined search strategy as a function of type of prepsychotic indicator. Discussion will place the findings in the context of the existing body of research which has demonstrated 'schizophrenic-like' information-processing abnormalities in hypothetically psychosis-prone young adults.

18.18 ANALYSIS OF SPECIALIZED COGNITIVE FUNCTIONS IN DEAF AND HEARING SIGNERS. D. MCKEE* AND H.W. GORDON. Department of Special Education, California State University, Northridge, CA 91330.

This study analyzed the performance of deaf adults on specialized cognitive functions which are associated with the left and right hemispheres, and explored the relationship between the cognitive profile and a number of variables: etiology, age of onset and degree of hearing loss, and age of sign language acquisition. Two sequential tests in the Cognitive Laterality Battery (CLB), developed by Gordon (1986), were modified so that deaf subjects could process the sequential stimuli by the visual modality instead of the auditory. There was significant correlation betwen the original auditory and modified visual tests ($r=.62$, $p<.001$), although the scores on the modified tests were higher than the scores on the original tests. Using the norms for the hearing tests would overestimate a subject's performance. The other tests on the CLB were adapted directly using videotaped instructions in Sign and 35mm slide projector for presentation. Nevertheless, deaf subjects performed below the norms on these modified sequential tests. For the deaf sample as a whole, cognitive function was below average for the verbal and sequential skills associated with the left hemisphere ($p<.001$) and above average on the visuospatial skills associated with the right hemisphere ($p<.05$). In other words, the cognitive profile of the deaf sample significantly favored processing associated with the right hemisphere by one-half standard deviation.

When the variables related to deafness, i.e., age of sign language acquisition, were examined in terms of cognitive functioning among deaf subjects, there were no significant differences among groups categorized by language acquisition. The results were inconclusive as to whether sign language acquisition affects cognitive functioning, partly due to insufficient information on fluency skills and codes of sign language. Hence, further investigations were recommended in this area. Hearing subjects whose parents were deaf and who used American Sign Language exclusively at home, performed nearly normally in comparison to the norms but performed significantly better than deaf subjects of deaf parents on left hemisphere function ($t=2.77$), $p<.05$). Use of Sign as a first language was ruled out as a factor in cognitive functioning. It is concluded that lack of auditory experience may have an influence on the cerebral development and organization of certain higher cognitive functions such as temporal processing and visuospatial skills.

18.PO **HAND PREFERENCE AND SEX DIFFERENCES IN THE ISTHMUS OF THE CORPUS CALLOSUM.** S. F. Witelson. Department of Psychiatry, McMaster University, Hamilton, Ontario, Canada, L8N 3Z5.

The size and morphology of the midsagittal section of the corpus callosum in individuals varying in hand preference and sex were further evaluated by subdividing the callosum into seven divisions, roughly representing functionally different cortical regions. Geometric divisions along the maximal anteroposterior axis of the callosum were used to divide the callosum into the genu, rostrum, splenium and four trunk regions. Area measures of these subdivisions were made on brains obtained from 56 consecutive autopsies from adults who underwent neuropsychological testing prior to death. The total sample analyzed was 51, with five cases excluded due to incomplete data. This sample includes the 42 cases reported previously (Witelson, Science, 229:665,1985; Neurology & Neurobiology, 17:117, 1986) to show hand differences in total area but no hand or sex differences in the splenium.

Hand preference was now found to vary with size of the callosum, particularly in the region of the isthmus, the posterior part of the trunk, which houses the callosal fibers connecting the right and left parietotemporal cortical regions. Hand preference was dichotomously classified into consistent-right-handers (n = 33) and non consistent-right-handers (including all mixed and left handers, n = 18). The non consistent-right-handers had a larger overall callosal area, mainly due to larger anterior and mid regions, with no difference in the splenium. The most marked difference occurred in the isthmus ($\bar{X}$ scores = 72.4 vs 61.5 mm^2, $F = 6.9$, $p = .01$). Moreover, there was a significant interaction between hand preference and sex ($F = 10.1$, $p = .003$), which indicated that the difference between the hand groups was more marked in males than females.

Sex differences were also found in callosal size and morphology. Absolute area of the total callosum was statistically larger in males than females. The splenial area was almost significantly larger in men ($\bar{X}$ scores = 186.8 vs 173.6 mm^2, $F = 3.0$, $p = .09$), comparable to the results of most previous reports (reviewed in Witelson & Kigar, Wenner-Gren Int. Symp. Series, 47: 466, 1987). In contrast, in the isthmus, females had a significantly larger absolute area than males, among right handers ($\bar{X}$ scores = 64.4 vs 54.0 mm^2, $t = 2.29$, $p = .03$). Analyses controlling for sex difference in brain size and total callosal size highlighted the sex differences in callosal anatomy. The variation in size of the callosum, in particular the region serving the parietotemporal cortex, and its correlation with hand preference and sex will be discussed in terms of differences in patterns of hemisphere specialization and cognition between right and left handers, and males and females.

BIOLOGICAL RHYTHMS I

19.1 **THE EFFECTS OF HYPERGRAVITY ON THE CIRCADIAN RHYTHM OF CONIDIATION IN *NEUROSPORA CRASSA*.** H.N. Krum*[1], C.A. Fuller[2], F.M. Sulzman*[3] and J.S. Ferraro[1] (SPON: E. Barca). [1]Dept. of Biol. Sci., SUNY-Binghamton, Binghamton, NY, 13901; [2]Dept. of Animal Physiol., UC-Davis, Davis, CA 95616; [3]Div. of Life Sci., NASA, Washington, DC 20546.

To determine whether the circadian rhythm of conidiation in *Neurospora crassa* is endogenously derived or is driven by some geophysical time cue, an experiment was conducted on space shuttle flight STS-9, where inoculated race tubes were exposed to the microgravity environment of space. The results demonstrated that the rhythm can persist in space. However, there were several minor alterations noted; an increase in the period of the oscillation and the variability of the growth rate and a diminished rhythm amplitude, which eventually damped out in 25% of the flight tubes. On day seven of the flight, the tubes were exposed to light while their growth fronts were marked. It appears that some aspect of this marking process reinstated a robust rhythm in all the tubes which continued throughout the remainder of the flight.

We have hypothesized that the damping found prior to the marking procedure on STS-9 may have been a result of the hypergravity pulse of launch and not due to the microgravity of the orbital lab; furthermore, that the marking procedure, by exposing the samples to light, had reinstated rhythmicity. To test this hypothesis, we conducted an investigations into the effects of acute and chronic exposure to hypergravity. The acute studies consisted of a 10 minute 3G exposure (similar to launch). A chronic (7 day) 3G exposure was used in order to determine if there were any long term effects of hypergravity. Both BND and CSP strains of *Neurospora* were used. The onset of both the acute and chronic exposures to the 3G force was evenly distributed through-out the circadian cycle; i.e. packages filled with inoculated race tubes were placed on the centrifuge at circadian time (CT) 3, 9, 15, & 21. Two groups of the acute exposure group were exposed to light shortly after being removed from the centrifuge to determine whether the effects of the 3G force could be reversed through the use of a light pulse as had been suggested.

While chronic exposure of *Neurospora* to a 3G force had no damping effect, an acute exposure to hypergravity causes significant damping of the circadian rhythm of conidiation. Furthermore, a brief light pulse given 36 hours after the acute exposure eliminates any effect of the acute 3G exposure on damping. BND was more susceptible to the hypergravity perturbation than CSP. The average free-running period increases with chronic hypergravity similar to what was seen during spaceflight. Moreover, the period of each individual cycle continues to increase throughout the exposure period. It is not known whether this increase in cycle length possesses a threshold, since the period continued to increase for the entire length of the experiment. These results suggest that most, if not all, of the aberrant effects observed on STS-9 spaceflight can be explained by the hypergravity encountered during launch and not due to the lack of geophysical zeitgebers in space. Supported by NASA Grant NAG236 (JSF).

19.2 DEVELOPMENT OF CIRCADIAN RHYTHMS IN THE *LIMULUS* VISUAL SYSTEM. R. B. Barlow, Jr. Institute for Sensory Research, Syracuse University, Syracuse, NY 13244.

Circadian rhythms characterize the *Limulus* visual system. They are generated by a circadian clock which transmits efferent optic nerve activity from the brain at night to all major visual organs. The clock's input to the lateral eye produces pronounced circadian changes in retinal anatomy, physiology and metabolism that adapt the eye for diurnal changes in ambient illumination. (Barlow, R. B., Jr., J. Neurosci., 3:856, 1983).

How do the circadian rhythms develop? Is the clock programmed genetically or environmentally? To answer these questions, we fertilized eggs and raised them in the laboratory under three conditions: cyclic lighting (LD), constant light (LL), and constant dark (DD). Most eggs hatched after one month. After about 6 months, the animals reached the third juvenile stage (4 to 5 mm across the carapace). At this stage, the lateral eyes were large enough to produce stable electroretinographic responses (ERGs) when the animals were placed in darkness. Changes in the ERG amplitude were used as indicators of circadian rhythms in retinal sensitivity.

All LD 12:12 animals exhibited circadian rhythms in retinal sensitivity, but LL animals did not. DD animals had degenerate eyes and did not yield recordable ERGs. Animals raised on non-24 hr light cycles of LD 15.5:15.5 and LD 8.5:8.5 exhibited either a damped circadian rhythm in retinal sensitivity or no rhythm at all.

Circadian rhythms could be generated in most LL animals by exposure to multiple LD 12:12 cycles. In some animals, sustained circadian rhythms could be triggered by just a single light pulse of 6 hr or less in duration.

In sum, both genetic and environmental factors influence the development of circadian rhythms in the *Limulus* visual system. The genes set the length of the period to approximately 24 hr. Environmental lighting triggers the rhythm, perhaps by synchronizing the activity of multiple oscillators.

19.3 A CIRCADIAN RHYTHM RECORDED IN VITRO FROM THE OPTIC LOBE OF THE COCKROACH. Terry L. Page, Department of General Biology, Vanderbilt University, Nashville, TN 37235.

The timing signal that regulates the circadian rhythm of locomotor activity in the cockroach Leucophaea maderae originates in the optic lobes of the protocerebrum. Results from previous studies have shown that the pacemaking system is composed of two mutually coupled oscillators, one located in each optic lobe. One remaining issue is whether or not the optic lobe can independently generate a circadian oscillation in the absence of neural or hormonal communication with the rest of the animal.

To answer this question optic lobes were removed from male cockroaches and maintained in either Mark's M-20 medium (J. Insect Physiol. 18:847, 1972) or the "5+4" medium of Chen and Levi-Montalchini (PNAS 66:32, 1970). Results were similar for both media. Spontaneous multiunit activity was recorded from the cut end of the optic tract with a suction electrode which was also held the optic lobe at the surface of the medium. Action potentials were electronically counted and printed to paper tape every hour. The tissue was maintained in constant dim light at constant temperature (23 $\pm$ 0.2°C).

In these conditions optic lobes exhibited spontaneous neural activity for up to 10 days, with usual survival times of 3-5 days. Multiunit activity was recorded from a total of 26 lobes for 3 or more days. Activity was judged to exhibit a circadian rhythm if plots of activity vs. time subjectively appeared periodic and if times of peak activity Days 1 and 2 and Days 2 and 3 were approximately 24 h apart (dissection on Day 0). Based on these criteria, activity in 6 of 11 optic lobes maintained in 5+4 medium and 7 of 15 optic lobes in M-20 medium was rhythmic. Analysis of freerunning period and phase with respect to the prior light cycle was also based on the time of the maximum hourly activity in each cycle. The average value of the period of the rhythms was 23.8 $\pm$ 1.90 h (N=13). Peak activity generally occurred during the early subjective day. For optic lobes of animals that had been maintained in a light cycle (LD 12:12) with lights-on at 08:00, average peak time was 12.0 $\pm$ 2.19 h on Day 2 and 11.8 $\pm$ 3.56 h on Day 3 (N=6). For optic lobes from animals from a light cycle with lights-on at 22:00 time of peak activity was 21.8 $\pm$ 3.77 on Day 2 and 23.2 $\pm$ 3.89 h for Day 3 (N=5).

These data indicate that the isolated optic lobe is able to generate a circadian oscillation in the frequency of action potentials in the optic tract, and that the phase of the rhythm is dependent on the prior lighting conditions. Supported by NIH Grant No. GM30030.

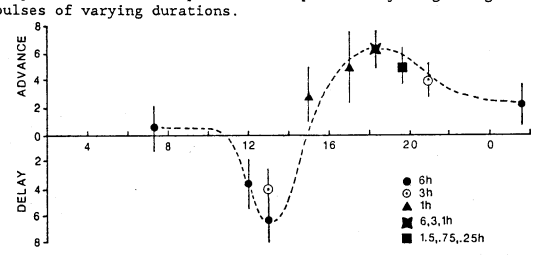
19.4 CIRCADIAN RHYTHMICITY OF BEHAVIORAL RESPONSES TO LIGHT IN THE CRAYFISH. F. Fernández de Miguel* and H. Aréchiga, Depto. de Fisiología, Biofísica y Neurociencias, CINVESTAV, México, D. F.

Light is known to affect crustacean behavior in a variety of ways, ranging from attraction induced by low levels of illumination, to avoidance reactions under strong light pulses. Little is known however, about the physiological mechanisms involved in these behaviors. In the present work, we analyse the effects of light intensity on locomotor behavior, as a function of the 24-hour cycle, and provide some information on possible neurophysiological mechanisms involved.

The experiments were conducted in adult crayfishes Procambarus clarki, of either sex and in intermolt. Locomotor activity was recorded from freely moving animals, placed in actographic two-compartment chambers, similar to those used by Aréchiga and Atkinson (Mar. Biol. 32: 63, 1975). Light intensity was externally controlled in the chambers and the position and rate of movement of individual animals was detected by means of a multichannel interface. Recordings of electrical activity from retinal elements and visual neurons were conventionally made. Two types of locomotor responses were detected: a) light attraction, as defined by displacement of the animals from a dark compartment to the illuminated one and b) light avoidance, when the movement was in the opposite direction. In either case, the time alloted as latency of the response was shorter than the average interval between spontaneous changes of compartment in darkness. Light attraction was induced in dark-adapted animals at day-time at 0.8 + 0.1 lux, whereas at night, the threshold value was 0.3 $\pm$ 0.2 lux. Above that level of intensity, the average latency of the response remained constant. The threshold for avoidance reaction was 15 lux at day-time and 9 lux at night. In animals kept during several days under recording, the changes in responsiveness to light closely parallelled the circadian rhythm of locomotor activity, which displayed a periodicity of τ=22.3 + 0.8 hs. in D:D and 24.52 + 0.8 hs in L:L, with two peaks of activity at subjective night. Light responsiveness showed the shortest latency at that time of day. The light intensity values for the switch from one behavior to the other also vary along the 24-hour cycle. The threshold for the avoidance reaction corresponds to the necessary intensity to promote the dispersion of proximal shielding pigments within retinal photoreceptors. The whole range of both the attraction and avoidance reactions falls within the dynamic range of the V-log I curve of electroretinogram and the F-log I curve of the light responses in sustaining fibers in the optic peduncle, suggesting that this neural pathway may subserve the light-input of both reactions.

19.5 PHASE-RESPONSE CURVE OF THE ISOLATED PINEAL GLAND OF *ANOLIS* M.Max*, S.Wisner*M.Menaker, Dept Biol, U of Va, Ch'lle, Va 22901

The isolated pineal of the iguanid lizard, *Anolis carolinensis* has been shown to display the three main properties of a circadian clock/system: It is rhythmic in constant conditions (freeruns), it synchronizes to a light:dark cycle (entrainment), and its period of oscillation is only slightly dependent on ambient temperature (temperature compensation)(Menaker and Wisner 83). Here we report that it possess another classic property of circadian systems, phasic response to single light pulses. Isolated glands superfused for four days in the dark are exposed to single light pulses delivered at specific times during the second day of culture. Alloquiots of superfusate from individual glands are collected every 90 minutes throughout the four days of culture, and assayed by RIA for melatonin. Phase shifts are determined by comparing the time of the fourth peak of light pulsed glands with controls that have received no light pulse. We find that glands shift their peak of melatonin secretion to an earlier time (advance) in response to a light pulse given late in the subjective night (CT 15-22), to a later time (delay) in response to light pulses early in their subjective night (CT 12-14), and do not shift in response to light pulses given during their subjective day. Single light pulses of durations from 15min. to 6hr given during the late subjective night (CT 18-19) produce equivalent 6hr. phase advances. A light pulse of 6hr. given early in the subjective night (CT 13) produces a 6hr. delay while a 3hr. light pulse given at the same circadian time results in a delay of only 3hr. While it is clear that the duration of the light pulse is not important in determining the magnitude of the advancing phase shift, we are less sure that this is true for delaying light pulses. Further experiments employing short duration light pulses around CT 13 will answer this question. The phase-response curve shown below is a composite of the mean phase shifts produced by single light pulses of varying durations.



19.6 OSCILLATION OF CYCLIC AMP AND MELATONIN RELEASE IN CHICK PINEAL CULTURES. S. S. Nikaido and J. S. Takahashi. Dept. of Neurobiology and Physiology, Northwestern Univ., Evanston, IL 60201.

Dissociated chick pineal cells express a circadian oscillation of serotonin N-acetyltransferase (NAT) activity and of melatonin release in vitro. The cell cultures are photosensitive and the melatonin oscillation can be entrained by light cycles in culture. Previous studies have suggested that cAMP may be involved in the regulation of NAT in the chick pineal.

To determine whether cAMP levels oscillate, dispersed chick pineals were grown on Cytodex 3 beads for 2 days and then were transferred to a flow-through culture system (about 2 pineal equivalents per culture). Both melatonin and cAMP were measured by radioimmunoassay from the same samples collected every two hours over a period of 6 days. Chick pineal cultures expressed an oscillation of cAMP efflux on a LD 12:12 light cycle. The cAMP oscillation was in phase with the rhythm of melatonin release. The level of cAMP efflux oscillated with trough values around 0.3 pmol/hr during the day and peak values of 0.6-0.8 pmol/hr during the night. Corresponding melatonin release levels were 20 pmol/hr during the day and 200-400 pmol/hr during the night. In the presence of 0.25 mM isobutylmethylxanthine (IBMX), a phosphodiesterase inhibitor, the levels of cAMP efflux increased about 10-fold with trough values of 1-2 pmol/hr and peak values of 2-8 pmol/hr while melatonin release oscillated between 50 pmol/hr and 400-800 pmol/hr.

We have also found a day-night oscillation in cAMP content in chick pineal cell cultures. Dispersed chick pineal cells were plated at 1.25 x 10^5 cells per well and cultured for 36 hrs before the first sample was taken. Under these conditions, the day value for cAMP content was 6.89 $\pm$ 1.32 fmol/well (mean $\pm$ S.E.; n=8) and the night value for cAMP content was 22.5 $\pm$ 2.44 fmol/well. The cAMP content was correlated with cAMP efflux during the previous 6-hr interval (day: 7.69 $\pm$ 1.20 fmol/well; night: 34.8 $\pm$ 2.6 fmol/well). With a 15-min pretreatment with IBMX, day content value increased to 11.3 $\pm$ 2.34 fmol/well and night content value increased to 45.7 $\pm$ 1.35 fmol/well.

In order to investigate the mechanisms controlling the oscillation of cAMP, we have initiated a series of experiments studying the role of G-proteins. Pertussis toxin treatment of static cultures during the light phase of a LD 12:12 cycle resulted in a dose-dependent elevation of melatonin release during the day. Whereas, pertussis toxin treatment during the dark phase did not elevate melatonin release. These results indicate a differential effect of pertussis toxin with time of day and suggest a possible role for pertussis-toxin sensitive processes in the regulation of the melatonin rhythm. (Supported by NIMH grant MH39592, Searle Scholars Award 85-H-107 and NSF PYI award DCB-8451642)

19.7 EFFECTS OF PERTUSSIS TOXIN ON LIGHT-INDUCED REDUCTION IN MELATONIN RELEASE AND PHASE-SHIFTING RESPONSE OF CIRCADIAN OSCILLATOR IN CHICK PINEAL CELLS. L.M. Robertson and J.S. Takahashi. Neurobiology & Physiology, Northwestern University, Evanston, IL 60201.

Chick pineal cells express a circadian oscillation of melatonin release. Light regulates the melatonin rhythm by the process of entrainment (which involves control of phase and period) and acute exposure to light causes a reduction in melatonin release. The mechanisms underlying phototransduction in the avian pineal gland are poorly understood. In retinal photoreceptors, the G-protein, transducin, is neccessary for phototransduction: ADP-ribosylation of transducin by pertussis toxin (PT) blocks the effect of light. We explored the effects of PT on both the acute and phase-shifting effects of light in cultured chick pineal cells. Cells were plated on 48-well dishes in medium-199 with serum and were maintained on LD 12:12. Beginning at circadian time (CT) 14 or 17 (lights off at CT12) of the 5th night in culture, cells were exposed to 0, 100, or 300ng/ml of PT. Medium was changed at CT20 with the same doses of PT. One-half of each group was exposed to 3 hr of light (125 lux) beginning at CT20. Control cultures were maintained in darkness. Medium was sampled at the end of the 3-hr and assayed for melatonin by RIA. Exposure to light caused a reduction in melatonin release relative to dark controls. Treatment with 100 or 300ng/ml PT from CT14-23 completely blocked the light-induced reduction in melatonin. A partial block was also observed with 100 or 300ng/ml PT from CT17-23. We used a flow-through culture system to determine whether PT treatment also blocked the phase-shifting effects of light. Chick pineal cells were cultured and light-induced phase shifts measured as previously described (Robertson and Takahashi, Soc. Neurosci. Abst. 12:221, 1986). Previous experiments showed that a 3-hr 125 lux light pulse caused a submaximal phase shift of the melatonin rhythm relative to dark controls. Cultures exposed to a 3-hr light pulse (125 lux) beginning at CT20 were advanced 4.95 $\pm$ 0.37 hr ($\bar{X} \pm$ SEM) relative to dark controls. PT (100ng/ml) treatment for 9 hr (CT14-23) had no effect on the phase of the rhythm in constant darkness. Cultures treated with PT (100ng/ml) for 9 hr (CT14-23) and exposed to a 3-hr light pulse (CT20-23) were phase advanced 5.05 $\pm$ 0.39 hr relative to dark controls. Therefore, PT did not block the light-induced phase shift. However, analysis of melatonin release during the light pulse revealed that PT blocked the light-induced acute reduction in melatonin release in the same experiment. In summary, treatment with pertussis toxin can block the acute reduction of melatonin without blocking the phase-shifting effect of light. These results suggest a differential effect of pertussis toxin on the acute and entraining effects of light. (Supported by NIMH grant MH39592, Searle Scholars award 85-H-107 and NSF PYI award DCB-8451642 to JST and NIMH award F31 MH09465 to LMR).

19.8 FURTHER CHARACTERIZATION AND REGIONAL DISTRIBUTION OF 2-[^{125}I]-IODOMELATONIN BINDING SITES IN HAMSTER BRAIN MEMBRANES. M.J. Duncan, J.S.Takahashi and M.L. Dubocovich, Dept. Pharmacol., Northwestern Univ. Med. School, Chicago, IL 60611 and Dept. Neurobiol. and Physiol., Northwestern Univ., Evanston, IL 60201.

We have previously characterized a high affinity 2-[^{125}I]-iodomelatonin binding site in membrane preparations from Syrian hamster whole brains (Duncan, M.J. et al., Eur. J. Pharmacol. 132:333, 1986). The present studies determined the subcellular and regional localization of 2-[^{125}I]-iodomelatonin binding sites and the potencies of various compounds that act at monoaminergic sites to compete for 2-[^{125}I]-iodomelatonin binding in hamster brain membranes. Membranes from hamster whole brains were prepared in ice-cold assay buffer (50 mM Tris-HCl, pH=7.7 at 25°C). Assays containing membranes (150-250 ug protein), 2-[^{125}I]-iodomelatonin (85-125 pM) and various drugs were incubated at 0°C for 1 h. Binding was terminated by filtration. Specific binding, defined as the difference between binding in the absence and presence of 10 uM 6-Cl-melatonin, was 65-75% of total binding. When specific binding (fmol/mg prot) of 2-[^{125}I]-iodomelatonin (85 pM) was measured in three membrane fractions (N=3), the highest amount of binding was found in the P_2 fraction (1.29 $\pm$ 0.23) as compared to the P_1 fraction (0.37 $\pm$ 0.03) or the total washed membrane fraction (P_1 + P_2). 2-[^{125}I]-iodomelatonin binding sites (fmol/mg prot) were found to be unevenly distributed in eight brain regions (N=3) examined: hypothalamus (6.20 $\pm$ 0.24), brainstem (5.87 $\pm$ 0.36), retina (5.24 $\pm$ 1.43), striatum (4.25 $\pm$ 0.89), olfactory bulbs (3.44 $\pm$ 0.08), cerebral cortex (2.96 $\pm$ 0.38), cerebellum (2.74 $\pm$ 0.41) and pituitary (1.88 $\pm$ 0.11). The affinity (K_i) of 6-Cl-melatonin for the 2-[^{125}I]-iodomelatonin binding site was 15.8 $\pm$ 2.3 nM (N=6). Compounds known to act at serotonin, dopamine and alpha receptor sites were markedly less potent than 6-Cl-melatonin in competing for 2-[^{125}I]-iodomelatonin binding [(IC_{50}, nM) ketanserine (600), bufotenine (1,590), fluphenazine (1,800), spiperone (2,000), serotonin (4,000), propranolol (5,000), yohimbine (>70,000); methysergide, cinanserine, cyproheptidine, phentolamine, dopamine, norepinephrine and epinephrine were inactive at concentrations up to 100,000 nM]. These results suggest that 2-[^{125}I]-iodomelatonin does not bind to monoaminergic receptor sites and in conjunction with our previous report indicate that 2-[^{125}I]-iodomelatonin can be used to selectively label melatonin binding sites in the brain. Furthermore, the presence of a high level of 2-[^{125}I]-iodomelatonin binding in the hypothalamus is consistent with previous studies suggesting that this region is a target site for the photoperiodic effects of melatonin.

19.9 **TEMPORAL ORGANIZATION OF CRITICAL PROTEIN SYNTHESIS IN THE BIOLOGICAL CLOCK IN THE APLYSIA EYE.** S. J. Yeung* and A. Eskin (SPON: G. F. Gwilliam). Biol. Dept., University of Houston, Houston, Tx 77004.

Protein synthesis seems to be a general requirement for circadian timing. We have attempted to define when proteins important for timing are synthesized in the Aplysia eye.

Rothman and Strumwasser (1976), Jacklet (1977) and Lotshaw and Jacklet (1986) generated phase-response curves (PRC) for relatively long pulses (6hr) of anisomycin and puromycin. Although recovery of protein synthesis after a pulse of anisomycin was reported to be rapid in cultured cells, Lotshaw and Jacklet and we found that recovery was slow (2.5hr to recover to 40% of control and more than 8hr to fully recover) in Aplysia eyes. Therefore, it is difficult to infer accurately when protein synthesis is important from the anisomycin PRC's. Thus, a protein synthesis inhibitor whose effect reverses quickly needs to be identified.

We studied recovery from inhibition of protein synthesis after 2hr pulses of emetine ($2X10^{-5}$M) and O-methylthreonine (4mM). Both emetine and O-methylthreonine seemed to reverse no faster than anisomycin. Cycloheximide (CHX) reversed faster than the others. CHX 10mM (1hr) produced 89$\pm$4% (N = 4) inhibition of ^{3}H-leucine incorporation and within 3 hr after the pulse, the recovery was 85$\pm$22% (N = 4).

We obtained a PRC using 1hr pulses of CHX (10mM). The magnitudes of the phase shifts were small (largest phase shift: -1.2$\pm$0.6hr, N = 7). CHX produces no phase shift from CT11 to CT21. There may be a small advance phase shift at about CT09. Delay phase shifts occur from CT18 to CT09. Can the CHX PRC be explained by different kinetics of recovery at different phases? Slow recovery (longer duration of inhibition) at certain phases may produce phase shifts whereas fast recovery at other phases may not produce phase shifts. No difference in the recovery time was observed when recovery from inhibition by CHX was measured at two phases (a phase when CHX produces no phase shift and a phase when CHX delays the circadian rhythm). Synthesis of proteins important for the timing mechanism seems to occur during late subjective night and most of the subjective day (i.e. from CT18 to CT09). We are searching for proteins synthesized only during that time period and comparing them with proteins whose synthesis is modified by phase-shifting treatments of light and serotonin.

Supported by NSF BNS8216756 and NIMH MH41979.

19.10 PHASIC DISCHARGE OF NEURONS IN THE RAT SUPRACHIASMATIC NUCLEUS. J. D. Miller and C. A. Fuller. Department of Animal Physiology, University of California, Davis, CA 95616.

This study reports data from a subpopulation of single suprachiasmatic nucleus (SCN) units recorded in ongoing electrophysiological investigations of SCN neurons and their afferent inputs. Male albino rats (Wistar, $\bar{x}$ = 263 $\pm$ 23 g) were anesthetized with urethane and catheterized in the femoral vein. Standard electrophysiological techniques were used to record the activity of single units in the SCN and adjacent areas (e.g., medial preoptic and retrochiasmatic areas). A fiber optics light source was used to apply photic stimuli directly to the eye (85 Lux). In approximately 19% of fast green labelled placements in the SCN and immediately adjacent optic chiasm (OC), but not in adjoining peri-SCN regions, we observed phasic discharge (bursting) with a period of approximately 3 min (n = 11, $\bar{x}$ = 199 $\pm$ 28 sec). The action potential waveforms were either biphasic (n = 5) or triphasic (n = 6), with an average duration of 3.0 $\pm$ 0.3 msec. These parameters differ considerably from the characteristics of chiasmatic fibers (monophasic waveforms with durations typically $\leq$1 msec). Interspike interval (ISI) histograms were generated for these cells for sequential periods of rapid (active state) and slow (inactive state) discharge. These cells periodically decreased their firing rates from a relatively active state ($\overline{ISI}$ = 87.3 $\pm$ 31 msec) to an inactive state ($\overline{ISI}$ = 233 $\pm$ 68 msec) by 147% (t for related measures = 4.4, df = 10, p <0.01). This population was also examined for burst activity in the msec range. Burst length averaged 3 to 4 spikes/burst in the active or inactive states. Decremental bursting was not observed. The mean percent change in bursts/total spikes increased by 18.6 $\pm$ 7.1% (t = 2.6, n = 11, p <0.05) from the active state (mean % bursting = 15.7 $\pm$ 6.1%) to the relatively inactive state (mean % bursting = 34.3 $\pm$ 6%). No parametric differences were observed between placements in the SCN proper and placements in the OC. Only VIP and GRP immunoreactive neurons have been observed in the dorsal OC. Through the period augmenting effects of strong coupling mechanisms as proposed in some mathematical models, a relatively small number of SCN neurons could be sufficient to generate circadian periodicity. It is possible that bursting neurons such as the ones described, with ultradian periodicity approximating that of many well-known biochemical reactions, may be the ultimate substrate of the circadian clock of the SCN.

This research was supported by NIMH Grant 7RO1-MH41477-01.

19.11 ELECTRICAL AND METABOLIC ACTIVITY OF THE SUPRACHIASMATIC NUCLEUS (SCN) OF THE GOLDEN HAMSTER IN HYPOTHALAMIC SLICES. S. Shibata* and R.Y. Moore (SPON: A.Rosen). Depts. of Neurology and Neurobiology, SUNY-Stony Brook, Stony Brook, NY 11794 and Dept. of Pharmacology, Kyushu University, Fukuoka 812, Japan

The evidence for the SCN as a circadian pacemaker in the mammalian brain includes observations of circadian rhythms in glucose metabolism in vivo (Schwartz et al, 1980) and in vitro (Newman and Hospod, 1986) and electrical activity in vivo (Inouye and Kawamura, 1979) and in vitro (Shibata et al, 1982). These observations have been obtained primarily from studies on the rat but, in contrast, the hamster is the species most often chosen for behavioral investigation of the functional properties of the circadian system. In this context, the present study was undertaken to determine whether a circadian rhythm in SCN metabolism and single unit activity can be shown in hamster hypothalamic slices in vitro.

Adult male golden hamsters weighing 120-150 g maintained in a normal or reversed light-dark cycle were used. After decapitation, the brain was quickly removed and coronal hypothalamic slices (400 μm), including the SCN and the anterior hypothalamus (AHA), were prepared using a tissue chopper. Preparations were pre-incubated for one hour and transferred either to a recording chamber for electrophysiology or an incubation chamber for analysis of glucose metabolism using the 14C-2-deoxyglucose technique. Neuronal activity was recorded extracellularly through glass electrodes. Incubations with isotope were carried out for 20 min and then removed from the chamber and rinsed for 30 min. These slices were cryostat-sectioned at 20 μm, and the sections exposed against X-ray film for 2 weeks. The autoradiographs are then analyzed by densitometry and a simple estimate of local glucose utilization (LGU, μ mole glucose/100g tissue/min) was obtained.

Single unit activity is highest at circadian time (CT) 4-6 (CT00.00 is the time of lights on) with a mean firing rate of 8.6±1.0 imp./sec (Mean ± S.E.). It is lowest at CT16-18, 2.3±0.4. Although we compared the neuron activity between ventrolateral and dorsomedial SCN, no difference was observed in the firing rates between these areas. Autoradiographs of SCN and AHA were obtained from slices during subjective day (CT0600) and subjective night (CT1800). The SCN appears as a pair of densely labeled areas above the optic chiasm during subjective day but are lightly labeled or not evident during subjective night. The LGU of SCN is approximately three times higher during subjective day than subjective night whereas the LGU of AHA is nearly identical at these time points.

Since apparent circadian rhythms are demonstrated in SCN single unit activity as well as in SCN 2-DG utilization, we conclude that the brain slice method is useful for analysis of circadian function in the hamster SCN. Supported by NS-16304.

19.12 **EFFECTS OF IONIC MANIPULATION ON THE CIRCADIAN RHYTHM OF NEURONAL FIRING RATE IN THE SUPRACHIASMATIC BRAIN SLICE.** Martha U. Gillette. Department of Physiology & Biophysics and Neural & Behavioral Biology Program, University of Illinois, Urbana, IL 61801.

Understanding of the circadian pacemaking properties of the mammalian suprachiasmatic nuclei (SCN) has been enhanced by study of their physiology in vitro. Circadian rhythms of neuronal firing rate and vasopressin secretion can be measured in rat SCN maintained in culture demonstrating that a circadian oscillator is endogenous to this tissue. As a prelude to examining cellular mechanisms which underlie nighttime entrainment, we have examined the effect of in vitro depolarizing pulses of K^+ on the subsequent cycle of firing rate in SCN neurons.

Hypothalamic slices (500 μ thick) containing the SCN were prepared from Long-Evans rats at a phase-neutral time (CT 10-11), and maintained in a brain slice chamber perfused with HEPES-buffered Earle's Balanced Salt Solution. In order to determine the sensitivity of the oscillator to depolarization, three 10 min pulses of 50 mM KCl, separated by 10 min periods with normal media (KCl= 5.4 mM) were applied to the tissue. This stimulation regime has been shown to relieve general depressive effects on neuronal excitability of long-term K^+ exposure (Hartter & Ramirez, Endocr. 107: 375, 1980). High K^+ medium was maintained isosmotic by adjusting the NaCl content and was preheated and oxygenated for >5 min before use.

50 mM K^+ pulses applied during CT 17-19 had no effect upon the viability of the slices, nor upon the ability of SCN neurons to generate their circadian rhythm in firing rate (n=6). The peak of this oscillation occurred at CT 1.53±0.82 in K^+ treated slices. This represents a mean phase advance of 6.7 hr from the unperturbed time of peak in vitro at CT 7.87±0.36.

These investigations demonstrate that this regime of depolarizing K+ pulses is a potent phase-shifting treatment to the isolated oscillator. We are now in a position to test the ability of other medium replacements to permit or antagonize depolarization-induced phase changes. Further, these data support the notion that dissection-induced K+ release may have contributed to the phase-shifting effects of slice preparation during the animal's night (Gillette, Br. Res. 379:176, 1986). Supported by PHS Grant NS22155.

19.13 PROGRESSIVE AND DIFFERENTIAL DEGENERATION OF CIRCADIAN RHYTHMS IN AGING FEMALE RATS. B. Tate-Ostroff. Department of Anatomy and Cellular Biology, Harvard Medical School, and Department of Psychiatry, McLean Hospital, Belmont, MA 02178.

The virgin, aging female rat experiences a loss of normal estrous cyclicity and the onset of persistent vaginal estrus (PVE) at approximately 8 months of age. PVE appears similar to that induced by disruptions of normal circadian rhythmicity, for instance by lesions of the suprachiasmatic nuclei or by exposure to constant bright light. It has been suggested that PVE in aging females is the result of age-related alterations in the circadian system. However, we have examined the circadian rhythms of gross motor activity and body temperature in rats undergoing the transition to PVE and found no alterations in circadian rhythms in animals exposed to normal lighting schedules (Tate-Ostroff and Bridges, 1986). Our initial studies were performed in animals exposed to a regular lighting schedule (LD14:10) and it is possible that rhythmicity was induced by this alternating environmental cue instead of being endogenously generated. We therefore extended our studies to PVE females free running in costant conditions. Middle-aged female rats (N=5, 7-9 months of age) that had entered PVE within the month preceding data collection and young females (N=3, 3 months of age) showing normal estrous cycles, were transferred from LD14:10 to dim, constant light of less than 4 lux (LL). Body temperature and gross motor activity data were simultaneously collected from each animal via implanted telemeters (Mini-mitters). Daily vaginal smears were also taken from each animal. Both PVE, middle-aged females and normally cycling, young females showed free running circadian rhythms. We conclude that PVE is probably the result of age-related alterations in the reproductive system and not a secondary effect of age-related alterations in the circadian system.

Since other laboratories have reported abnormal circadian rhythms in PVE rats, some PVE animals were monitored for months after the onset of PVE. These animals did eventually showed abnormal rhythms, with abnormalities in activity rhythms being displayed before abnormalities in body temperature. The sequence of loss of normal activity rhythms before the loss of normal body temperature rhythms may be a consequence of the strenght of coupling between these rhythms and the primary oscillator.

19.14 INFLUENCE OF AGE AND ACTIVITY RESTRICTION ON SLEEP-WAKE AND DRINKING RHYTHMS IN THE MOUSE. D. M. Edgar, T. S. Kilduff and W. C. Dement. Sleep Research Center, Stanford University School of Medicine, Stanford, CA 94305.

Previous studies in this laboratory have implicated activity as an important determinant of sleep and wakefulness consolidation in the mouse. Activity restriction, imposed by locking an otherwise freely rotating running wheel, decreases consolidation of wakefulness during the subjective day and dampens the amplitude of the circadian sleep-wake cycle. These altered sleep-wake patterns are remarkably similar to that observed in aged animals. In the present study, we investigated the generality of activity restriction effects by simultaneously monitoring drinking patterns and arousal states. We have also compared the effects of activity restriction in young (< 6 mos.) and older (18-22 mos.) mice.

Young and old male Mus musculus (C57/BL/6Nnia) were surgically prepared with chronic implants which permitted EEG and EMG recording. Animals were individually housed in filter-top cages, each equipped with a swivel commutator and running wheel. Ambient temperature was maintained at 24-25°C, lighting was LD 12:12, and both food and water were available ad libitum. Drinking and sleep-wake stages (awake, slow wave, and paradoxical sleep) were monitored in 10 sec epochs using a recently developed microcomputer based sleep scoring system. Parity between human and computer based sleep-wake determinations was validated in excess of 97%. Mice were monitored 20-30 d with freely rotating running wheels, for 16-24 d with wheels locked, and then for an 14 d of free wheel running opportunity.

With running wheels unlocked, young mice exhibited robust circadian rhythms in sleep-wakefulness and drinking which were entrained to the light-dark cycle. Older mice exhibited circadian rhythms lower in amplitude and less stable in waveform. When running wheels were locked, all animals exhibited an initial diminution of circadian amplitude of the sleep-wakefulness and drinking rhythms. Partial restoration of sleep-wake rhythm amplitudes and total restoration of the drinking rhythm was observed 6-10 days after wheel locking was initiated. After wheel availability was reestablished, sleep-wake rhythm amplitudes were completely restored. Total sleep time per day did not differ appreciably between old and young animals while wheels were locked (about 750 min/24 hrs). However, the patterns of wakefulness observed in the older animals during the wheel lock period showed noticeably greater wake fragmentation. These observations support the notion that activity plays an important role in sleep consolidation, but may have less influence on the drinking rhythm. In addition, activity may be of particular importance for the consolidation of sleep-wake rhythms in older animals (Supported by NRSA AG05397 to DME, AG06490, and MH05804 to WCD).

19.15 CIRCADIAN EFFECTS AND AVOIDANCE LEARNING IN GENETICALLY DEFINED MICE. D. F. Peeler, Department of Neurosurgery, University of Mississippi Medical Center, Jackson, MS 39216

Circadian rhythms characterize a variety of behaviors and have been reported to be at least in part a function of genetic influences. The genetically defined mouse strains C57BL/6 and BALB/c have been shown to exhibit variation in several activity measures as a function of both strain and time of day. Genetic but not circadian influences have been reported for these strains on another behavioral measure - shuttle box avoidance. It consistently has been reported that C57BL/6 mice are inferior to BALB/c in rate and degree of acquisition. Recent attempts to replicate earlier findings from this and other laboratories of superior performance in a shuttle box task by BALB/c have given mixed results. Examination of the data revealed that C57BL/6 and BALB/c adult male mice which were trained to avoid shock by crossing a hurdle in a shuttle box at times primarily late (after about 15:00 hours) or earlier (before about 11:00 hours) in the working day produced the typical pattern of avoidance response acquisition (i.e., BALB/c acquire the response more readily and to a greater proficiency than C57BL/6). (Animals are maintained on a 12 hr. light/dark cycle, with light on from 6:00 to 18:00.) However, if training is conducted at an intermediate time (between about 13:00 and 15:00), this relationship between strains is changed: the C57BL/6 exhibit a considerable, statistically significant improvement in both rate and final level of acquisition. They achieve essentially the level of the BALB/c tested at earlier or later times. BALB/c at the 13:00 to 15:00 period show a non-significant trend toward performance decrement. The seven RI strains derived from these progenitor strains give mixed results: those RI strains having poorest performance at the earlier or later times tend to improve, while those having good acquisition tend to remain in this category. Thus, the distribution of scores for avoidance performance is in part dependent upon the time of day (or position in the light/dark cycle) at which testing is conducted.

C57BL/6 mice have been reported to have a trough of tyrosine hydroxylase activity at about this (intermediate) point in the light/dark cycle, while they and the BALB/c show out of phase levels of tryptophan hydroxylase, serotonin and its metabolites in selected brain sites at this time. Also, this change in performance occurs at approximately the same time of day that BALB/c and some of the RI strains (but not C57BL/6 and the other RI strains) exhibit an increase in emotionality (measured as defecation during initial exposure to activity testing), and show a reduction of investigatory but not locomotor activity.

Thus, several behavioral and neurophysiological variables exhibit comparable, in phase circadian cyclicity. The implication is that some of these characteristics may be manifestations of genetic determinants at the same or linked loci.

19.16 SENSORIMOTOR BIASING OF SYNCHRONIZATION TIMING. H. Kim, D. Hary, and G.P. Moore*. School of Engineering, University of Southern California, Los Angeles, CA 90089-1451.

In studies of temporal tracking behavior, subjects were asked to synchronize the sound produced by tapping a Morse key with the sound from a loudspeaker driven by a periodic metronome source (interval 700 ms). The sound produced by the Morse key was a click delivered through a second loudspeaker. The Morse key itself was silent in operation. The tap-triggered sound was subject to selected delays, ranging from 0 to 60 ms. When the delay was set to 0 ms, all subjects led the metronome (mean 21 ms, 6 ms s.d.), confirming numerous earlier studies (Hary and Moore, Human Neurobiology, 4:73, 1985). As the delay time between tap and the tap-evoked sound increased, subjects would have to tap earlier in the metronome cycle in order to maintain the same relative synchrony. 6 of 14 subjects did this. The remaining 8 subjects, although also tapping earlier in the cycle, all achieved near-synchrony (an average of 0 ms, 4 ms s.d.) when the delay between tap and sound was made large enough, some achieving synchrony when the delay was as small as 30 ms. We hypothesize that these latter subjects, by dissociating the proprioceptive/motor components of their response from the auditory product of the response were able to attend to the audio error and correct it to a value not significantly different from zero. The inability of the other subjects to achieve synchrony is a matter of continuing investigation.

(Supported by NIH Grants RR-01861 and BRSG S07RR07012-19. Mr. Kim was a participant in the Summer Science Training Program at USC).

19.17 CORTICAL COMPONENTS OF THE EEG REVEALED BY REAL-TIME OPTICAL IMAGING OF NEURONAL ACTIVITY IN CAT CORTEX. A. Arieli*, R.D. Frostig, E.E. Lieke, R. Hildesheim*, and A. Grinvald. The Weizmann Institute of Science, IBM Thomas J. Watson Res. Ctr., and Laboratory of Neurobiology, The Rockefeller University.

Optical imaging of fast cortical activity *in vivo* provides information about electrical activity of neuronal assemblies with millisecond time resolution, and a few hundred microns spatial resolution. Since the optical signals are restricted to their site of origin within the upper cortical layers, comparisons between electrically recorded EEG waves and spatio-temporal optical maps provides a new approach for analysing the origin of individual EEG components, event related potentials, and interactions among distant neuronal assemblies.

The exposed cat visual cortex was stained for 90-120 min prior to optical imaging. We used a 12×12 diode array and found that the styryl dye RH-795 provides relatively large signals in the cat cortex. To investigate the cortical components of the EEG, two types of experiments were performed. In the first one, spontaneous epileptiform activity was induced in the cortex by topical application of bicucculine. In the amplitude domain the activity was relatively uniform. However the foci of activity and propagation of the epileptic waves was determined by analysis of the millisecond temporal domain (similar to rat experiments by Orbach et al. 1985, London et al. 1986). The spatio-temporal patterns of repetitive epileptic bursts were mapped for 30 seconds continuously, and such measurements repeated up to 10 times (the fractional change in fluorescence was 0.3%). A comparison with surface recording of the EEG indicated that only negative waves with a distinct time course originated from the upper layers of the stained cortex. Therefore, optical imaging can determine the cortical origin of components of the EEG waves.

In the second experiment, normal spontaneous activity of stained cortex was optically monitored. Although the optical signals were much smaller in this experiment, they were resolved without averaging when large sleep spindles occurred. The spatial distribution of the optical signals which correlated in time with the largest sleep spindles was nonuniform: large optical signals were observed at different sites. In addition the particular nonuniform patterns varied from one spindle to the next. These observations suggest that optical imaging can reveal the spatial and temporal organization of interacting neuronal assemblies.

An alternative way to analyse the data would be to calculate the cross correlation between all possible pairs from 128 sites. The results of such an analysis, which is likely to increase the sensitivity and spatial resolution, will be discussed.

We thank Dr. L.B. Cohen for computer programs. Supported by NIH grant NS-14716, a Fellowship from the Feinberg Graduate School and by IBM.

19.18 ENDOGENOUS POSTICTAL ANTICONVULSANT SYSTEMS THAT CONTROL SEIZURES IN GERBILS AND HAMSTERS. Paul L. Prather* and W. B. Iturrian, Pharmacology, Univ. of Georgia, Athens, GA. 30602.

In epileptics, a postictal phase prevents seizure recurrence for several days. In rodents, paired electroshock shows a two phased postictal period consisting of a brief period of hyperexcitability in which a second tonic extensor seizure can be elicited, followed by a prolonged period of depression and anticonvulsant effects. The spontaneous seizures of the gerbil model of epilepsy do not appear to occur randomly but rather show a periodicity across days. Each individual possesses its own rhythm suggesting that seizure diathesis involves an oscillator of brain excitability modified by postictal mechanisms. The neurological basis for a long term oscillator or postictal protection is not known but endogenous anticonvulsant chemical(s) are attractive possibilities since they can be modified by genetic, behavioral, and pharmacological methods. We suggest that several different endogenous systems are activated by seizure and that they act in cascade-like sequence. Furthermore, deficits in different parts of the cascade contribute to the hereditary spontaneous seizure of gerbils and hamsters.

Our inbred, genetically epileptic, black gerbils have brief explosive tonic-clonic seizures elicited by handling but become refractory with optimal anticonvulsant effects occurring biphasically at 15 min and at 2 to 3 days. In contrast, our genetically epileptic sz hamster (derived from Bio 86.93) have BDZ deficits. Therefore, their seizures are bouts of increasing severity becoming tonic by 30 minutes and persist for 3 hours without an apparent postictal protective phase. Although sound does not precipitate seizure in either species, it can either increase or decrease brain excitability depending upon the temporal relationship between sound and seizure testing. Brief (sec) sound (100dbA) blocks gerbils' postictal effect occurring at 15 min but then protects both gerbils and hamsters from seizure for many days. Indomethacin (10 mg/kg) also blocks the 15 min postictal event. Although the sz hamster outgrows spontaneous seizures, deficits in postictal inhibition persist since paired electroshock elicits a 2nd tonic extensor seizure without any depression phase. Morphine sulfate (10 mg/kg) reduces the incidence of 2nd seizure by 39% without significantly altering the initial seizure. This protective effect was reversed by the opiate antagonist naloxone. In hamsters without the sz trait, naloxone (4 mg/kg) blocks the postictal anticonvulsant effect of paired electroshock and incidence of 2nd tonic extensor seizure increased to 88%. Indomethacin is anticonvulsant for sz hamsters but blocks postictal effects in controls. Numerous endogenous chemicals are released following a seizure (or auditory stimulation) that regulate brain excitability but short term and long term effects may differ dramatically.

20.1 REPRODUCTIVE OUTPUT OF PAIRED MALE RATS AS A FUNCTION OF SOCIAL DOMINANCE. J.A. Witcher*, W.R. Bachman*, and N.T. Adler, Dept. Psychology, Univ. Pennsylvania, Philadelphia PA, 19104.

Dominant rats sire more offspring in a competitive mating situation than submissive rats. To investigate the mechanisms of these effects a number of reproductively relevant variables were investigated. These variables included mating behavior during the first ejaculatory series, number of sperm ejaculated and transported, and copulatory plug within female reproductive tract after the first ejaculatory series.

Virgin Long-Evans and Sprague-Dawley male rats (90 days) were initially housed, alone in hanging metal cages (43X25X18cm; 14L:10D lights on 0600). An estrous female was introduced into each male's cage and remained until the male ejaculated. Twenty min after ejaculation sperm within the female reproductive tract were counted and copulatory plug assessed. This was repeated four times with each male with no less than 3 days between mating sessions. Each male was given 4 mating sessions.

Pairs of males were established by introducing a Sprague-Dawley male from one cage into the home cage of a Long-Evans male of matched weight or vice versa. Following observation of agonistic behavior, dominant and submissive status was assigned to each male. After one week of the male's co-habitation estrous females were introduced one at a time to each pair of males until each member of the pair had attained an ejaculation. Sperm counts were performed 20 min after ejaculation. This was repeated for each pair until each male had mated with five females, with no pair being tested within less than 3 days of a previous mating session.

Therefore, data from 4 mating sessions in a non-competitive mating situation and 5 mating sessions in a competitive mating situation were obtained. In the non-competitive situation no differences existed between rats that were to be dominant, as opposed to submissive, with respect to mating efficiency, sperm output, or copulatory plugs. However, after the first competitive mating, sperm recovery in females mated with dominant males was slightly elevated when compared to the four non-competitive matings; while sperm recovery from females mated with submissive males dropped by more than 50%. Over the next 4 competitive matings the submissive animals' sperm output gradually rose to non-competitive mating levels while, the dominant males' sperm output was maintained at non-competitive mating levels. In addition, submissive males' copulatory efficiency and copulatory plug weight was reduced when compared to that of dominant males. Copulatory efficiency and plug weight did not display recovery over the mating sessions, unlike sperm output which did recover.

Pairing of adult male rats results in a dominance relationship. Dominance appears to confer a reproductive advantage via both acute and chronic mechanisms. The acute mechanism is reflected in a transient lowering of sperm output by a submissive male while a more chronic mechanism is manifest in behavior and copulatory plug characteristics.

20.2 RETENTION OF SEXUAL BEHAVIOR AFTER CASTRATION : ENVIRONMENTAL INFLUENCES. B. E. F. Wee, K. L. Sinchak*, and L. G. Clemens. Department of Zoology and Neuroscience Program, Michigan State University, East Lansing, MI 48824.

The extent to which sexual behaviors are retained after castration varies among different strains of mice, as well as among individuals of the same genotype (Wee et al., Neurosci. Abstr. 1985). Two groups of castrated B6D2F1 mice were distinguished on the basis of their behavioral response to castration. The males designated as the "continuers" (C) retained the ejaculatory reflex for 25 weeks after surgery; the "noncontinuers" (NC) did not retain this reflex. These two groups of castrates did not differ in their levels of plasma testosterone or nuclear estrogen receptors in the medial preoptic area (Clemens et al., submitted). These results ruled out the possibility that C had higher levels of non-gonadal androgens or estrogens than NC.

An alternative hypothesis is that the behavioral differences between C and NC are due to environmental factors. The present study examined the role of the amount of behavioral testing after castration and the testing environment in the retention of masculine sexual behaviors after castration by B6D2F1 (F1) mice. EXPERIMENT 1 Male F1 mice received six weekly sex behavior tests in 10 gallon aquaria converted to testing arenas, followed by either sham operation or castration. Weekly testing resumed one week later for half of the animals (the continuously tested (CT) group); the other animals (the delay tested (DT) group) received six additional weekly tests only after a 12 week delay.

Approximately 40% of all the castrates continued to display the ejaculatory reflex 18 weeks after surgery. No significant differences were observed between the CT and DT castrates for any of the behavioral latencies or for the percent of tests with ejaculation. Further, the percent of males designated as C varied between the two groups of castrates: 9 out of 48 (19%) CT versus 17 out of 45 (38%) DT. Sham operated CT and DT males continued to show high levels of copulatory behavior throughout the experiment. These results indicate that continuous behavioral testing after castration is not necessary for the retention of sexual behaviors. EXPERIMENT 2 The animals from Expt. 1 received an additional four behavior tests in either the test arenas or the animal's home cage. The percent of tests with behaviors was not significantly different between home and arena tests for the sham operated males or the continuers for any of the behaviors. In contrast, among NC (castrates that stopped showing sex behavior when tested in the arena), those tested in the home cage had significantly more tests with sex behavior (MWU, $p < .01$) than the arena-tested mice. These results suggest that among arena-tested castrates, NC are more sensitive than C to possible inhibitory influences from the test arenas.

Thus, the retention of copulatory behaviors by some, but not all, F1 castrates appears to be related, at least in part, to environmental factors.

20.3 **BEHAVIORAL AND PHYSIOLOGICAL EFFECTS OF DIHYDROTESTOSTERONE AND TESTOSTERONE IN CASTRATE RATS MATCHED FOR CIRCULATING LEVELS OF ANDROGENS.** K. J. Streator*, P. K. Westfahl* and J. A. Czaja. Miami University, Oxford, Ohio 45056

It has been suggested that, compared to its parent compound testosterone (T), the relative ineffectiviness of dihydrotestosterone (DHT) on male rat sexual behavior may relate to differences in bioavailability of these androgens. If this is so, then administration of larger doses of DHT should be sufficient in themselves to increase levels of male rat sexual behavior. A dose-response study was run to assess this possibility. Male Long-Evans rats were castrated and then injected for 34 days with either oil vehicle or dihydrotestosterone propionate (DHTP, either 316 µg, 1000 µg, or 3160 µg). For comparison, additional groups of rats were treated with testosterone propionate (TP, either 3.16 µg, 10 µg, 31.6 µg, 100 µg, or 316 µg). At the end of this treatment schedule, animals were tested for mating behavior and then killed for autopsy.

Compared to injections of oil alone, the DHTP treatments maintained significantly higher levels of sexual behavior (Log[1/latency to ejaculation], $F[3,45]=9.870$, $p<.001$), accessory tissue weights (Log[mg seminal vesicle weight], $F[3,45]=847.637$, $p<.001$), and circulating androgens (Log[pg/ml DHT], $F[3,45]=74.832$, $p<.001$), and did so in a dose-dependent manner. At the same dose level (316 µg), TP injections were more effective than DHTP injections in maintaining seminal vesicle weights ($t[23]=2.497$, $p<.05$) and sexual behavior ($t[23]=3.894$, $p<.001$). However, radioimmunoassay of serum for T and DHT revealed that the TP injections induced significantly higher circulating levels of androgens than did the DHTP injections (Log[pg/ml], $t[23]=2.921$, $p<.01$). Data were therefore reanalyzed for 19 pairs of animals matched for levels of circulating androgens. Matched this way, given levels of circulating DHT were found to be significantly more effective than the same levels of circulating T in maintaining peripheral organ weights ($t[18]=6.860$, $p<.01$), although DHT was still less effective than T in maintaining mating behavior (Log [1/latency to ejaculation], $t[18]=3.518$, $p<.01$).

The same dose of DHTP and TP did not result in comparable circulating levels of these hormones, a difference in bioavailability which was reflected in the effects of these treatments on peripheral target tissues. It is possible that similar factors may produce even greater differences in bioavailability of these hormones to the brain, differences which would at least partially account for the reduced effectiveness of peripheral DHTP treatments on sexual behavior of male rats.

20.4 TESTOSTERONE REINSTATES THE LATERALIZED HYPERACTIVITY SECONDARY TO CORTICAL LESIONS IN CASTRATED MALE RATS. S.E. Starkstein*, T.H. Moran, J.A. Bowersox*, L. Shnayder*, R.G. Robinson (SPON: P.R. McHugh). Dept. of Psychiatry, Johns Hopkins Univ., Balt., MD 21205.

In adult male rats, focal suction lesion of the right frontal cortex (FC) produce hyperactivity, while similar lesions of the left hemisphere fail to produce this behavioral change. This lateralized phenomenon is gender-related, as female rats do not develop hyperactivity after a right FC suction lesion, and age-related, as prepuberal male rats do not develop hyperactivity after similar lesions (Soc Neurosci Abst, 12:841, 1986). Sexual maturation also plays an important role as prepuberally-castrated adult male rats do not develop hyperactivity after receiving a right suction FC lesion. In the present experiment, we examined the role of steroid hormones in the production of this lateralized behavior. Male rats were castrated prior to puberty and placed in running wheel cages. Following when puberty would normally occur, rats were divided into the following groups: FC suction lesion with testosterone implant, FS suction lesion with sham implant, sham lesion with testosterone implant and sham lesion with sham implant. Lesion or sham procedures were performed on the right or left hemispheres. Testosterone implants were made to mimic normal circulating testosterone levels. Post-operative activity was monitored for 30 days. Overall, testosterone increased activity levels. Rats with right FC suction lesions and testosterone implants showed a significantly higher degree of hyperactivity ($F(1,23)= 5.23$, $p<.05$). For the left hemisphere group there were no differences in activity between rats with a FC suction lesion and testosterone implants and rats with sham lesions and testosterone implants. These results demonstrated that: 1) testosterone reinstates the hyperactivity phenomena in prepuberally castrated adult male rats after a FC suction lesion. 2) this is a lateralized phenomena, as only rats with right hemisphere lesions showed this response, and 3) this is also a gender-related phenomena, as female ovariectomized rats with a right FC suction lesion and testosterone implants do not develop hyperactivity (Soc Neurosci Abst 12: 841, 1986). This study suggests that lateralized hyperactivity is the consequence of a specific interaction between steroid hormones and brain structures.

20.5 LOCAL SITE OF ACTION FOR TESTOSTERONE'S ANABOLIC EFFECT ON RAT BULBOCAVERNOSUS. M.N. Rand and S.M. Breedlove, Psychology Department, U.C. Berkeley, Berkeley, CA 94720.

Testosterone has an anabolic effect on muscle, and lack of testosterone decreases the size of many muscles, including the bulbocavernosus (BC) and levator ani (LA) of rats. It is not known whether testosterone exerts this influence directly upon muscle cells or whether it acts elsewhere, e.g. via motoneurons. We attempted to determine the general site of testosterone action in adult male rat BC muscles and their motoneurons comprising the spinal nucleus of the bulbocavernosus (SNB).

Adult male rats 60-90 days of age were castrated and implanted with two capsules, one containing testosterone (Sigma) and the other anti-androgen (SCH16423, Schering Corp.). These capsules had a single small diffusible Silastic surface (approx. 2 mm^2) and were sutured one on each side of the BC so that the diffusible surface faced the muscle. After 30 days the animals were sacrificed and the BC, spinal cord, and seminal vesicles were dissected out. The muscles were trimmed, cut in half medially and then weighed without knowledge of their steroid treatment. Muscle half weights were compared using a repeated measures t-test.

Muscle halves receiving local testosterone treatment were found to be significantly heavier than those receiving local anti-androgen treatment ($n = 11$, $p < 0.01$).

The difference in BC half weights cannot be due to central effects of testosterone and anti-androgen since the laterality of steroid treatment could not have been retained at the distance of the SNB cell bodies which innervate the BC. Testosterone must therefore act at or near the muscle for its anabolic effect.

Rat BC muscles and SNB motoneurons are sexually dimorphic and mediate sexual function in males. Rat SNB dendritic length is also increased by administration of testosterone in adulthood (Kurz et al., Science 232:395, 1986). We are currently measuring SNB motoneuron dendrites filled with cholera-toxin HRP conjugate to see if there is a unilateral effect on dendritic length in the adult male rat SNB with the peripheral, lateralized administration of testosterone to the BC. In any case, the direct anabolic effect of androgen on the BC muscles themselves may play an important role in male copulatory behavior.

20.6 SPINAL BLOCK REVEALS ROLES FOR BRAIN AND SPINAL CORD IN MEDIATION OF MALE RAT SEXUAL REFLEXES. B. D. Sachs and D. Bitran*. Dept. of Psychology, U-20, Univ. of Connecticut, Storrs, CT 06268.

The potential for penile erection varies as a function of antecedent copulation. As measured by erection latency in ex copula tests, the erectile potential of rats increases after 1-3 ejaculations and is depressed after 6 or more ejaculations. The contributions of spinal and brain sites in mediating these changes are unknown. Surgical transection of the thoracic spinal cord reduces erection latency and increases the number of penile reflexes during ex copula tests. We explored these phenomena further with a reversible "functional" spinal transection.

Tetracaine (TET; 1.4 mg/5 ul saline) or the vehicle alone (SAL) was infused into the intrathecal space of adult male rats via catheters terminating at the T9-T10 spinal segments. In penile reflex tests immediately after infusion, TET males had much shorter latencies than SAL males to the first penile body erection ($\bar{X}$ = 1.5 min vs 11.1 min, $p < .0001$) and to first glans erection ($\bar{X}$ = 3.0 min vs 11.0 min, $p < .0005$). However, the number of responses displayed by the two groups of males was similar. Thus, TET treatment mimicked the accelerative but not the "productive" effects of surgical transection, partially supporting previous conclusions of supraspinal inhibitory influences on penile erection.

The anatomical specificity of the effect of TET in the spinal cord was explored in another study by delivery of TET or SAL to the L5-L6 spinal segments known to regulate penile reflexes ex copula. The proportion of TET males responding in this condition (2/9) was lower than when TET was delivered to the thoracic cord (10/13; $p < .025$). Hence, the effect of TET in the spinal cord is site-specific.

In a third experiment, males copulated to sexual exhaustion (6-12 ejaculations) prior to infusion with TET or SAL directed at T9-T10. None of the 5 males in each group displayed penile reflexes in subsequent tests. From these data we infer (1) that the presumed release from supraspinal inhibition effected by intrathecal TET could not override the depressive effects of repeated ejaculations on penile reflex potential, and (2) that these depressive effects are largely endogenous to the lumbosacral cord.

These experiments establish for the first time that the spinal cord mediates some changes in reflex potential consequent to ejaculation, and support the view that the brain and the spinal cord interact in modulating the effects of copulation on penile reflex potential.

20.7 EFFECTS OF INTRATHECAL TESTOSTERONE ADMINISTRATION ON PENILE REFLEXES IN RATS. R. P. Horodnic*, B. D. Sachs and R. E. Leipheimer* (SPON: R. L. Gilliland). Dept. of Biol. Sci., Youngstown State Univ., Youngstown, OH 44555.

Actions of the perineal muscles are known to regulate specific components of penile reflexes in rats. Studies have demonstrated that these reflexes are dependent on androgens. However, the specific effects of testosterone (T) on the spinal motor nuclei in regulating penile responses remain unclear. Hart (Physiol. Behav. 3:735-738, 1968) reported an increase in penile reflexes following spinal implantation of (T) into the cauda equina of the spinal cord in castrated, spinally transected rats, suggesting a direct action of (T) on spinal neurons mediating penile responses. In order to test this hypothesis in spinally intact animals, male rats known to respond in ex copula tests were implanted with cannulae in the subarachnoid space terminating in the L5-L6 spinal segments. Four weeks after castration penile responses declined and the rats were injected with 250 ug testosterone benzoate (TB) sc to increase their baseline penile reflex activity and tests were done 3 and 6 days later. Latency to first glans response decreased 3 days after sc injection ($P < .001$). The mean number of glans responses increased during this same interval ($P < .01$). By 6 days after sc injection penile responses began to decline: Latency increased ($P < .05$); and mean responses decreased ($P < .05$). Because penile responses had declined, rats received intrathecal (IT) injections of 10 ng TB on day 7, and were tested on day 10. Latency decreased on day 10 ($P < .02$), and mean responses increased to levels comparable to those seen after sc injection of 250 ug TB. By day 13 (6 days after IT injection), penile responses again declined: Latency increased ($P < .05$); and mean responses declined ($P < .05$). To test whether the effects of IT injection of TB were due to systemic absorption, the rats were injected sc with 10 ng TB. Penile reflex tests conducted 3 days after sc injection of 10 ng showed that mean responses were less than those seen 3 days after IT injection ($P < .05$).

Therefore, these results suggest that the facilitatory effects of IT injection of TB are due to actions on the spinal neurons which regulate penile reflexes and not to systemic effects.

20.8 GABAERGIC MEDIATION OF SEXUAL REFLEXES IN LUMBOSACRAL SPINAL CORD IN MALE RATS. D. Bitran*, S. A. Miller*, D. B. McQuade*, R. E. Leipheimer*#, and B. D. Sachs (SPON: M. Wilson). Dept of Psychology, University of Connecticut, Storrs, CT 06268 and #Dept of Biology, Youngstown State University, Youngstown, OH 44555

Systemic administration of baclofen (BAC), a $GABA_B$ receptor agonist, was previously reported (Leipheimer & Sachs, Soc Neurosci Abst, 1986) to inhibit ex copula penile reflexes but not to affect copulatory behavior. In contrast, treatment with $GABA_A$ agonists did not affect penile responses either in or ex copula. The spinal cord is a likely site of action for the observed effects of BAC on penile reflexes, since GABAergic terminals and receptors have been located in the cord, including the L5-L6 spinal segments that contain the motoneurons innervating penile muscles.

In the first experiment, intrathecal injection of 0.8 ug BAC aimed at the L5-L6 spinal cord decreased the proportion of animals displaying penile reflexes (0/8 BAC vs 5/8 saline, $p < .02$). A smaller dose of BAC (0.2 ug) decreased the number of erections ($\bar{X}$ = 5.8 vs 22.0, $p < .03$) and number of reflex clusters ($\bar{X}$ = 3.0 vs 6.6, $p < .02$) relative to saline controls. An intermediate dose of 0.4 ug BAC had intermediate inhibitory effects. None of these doses prevented rats from copulating to ejaculation.

A potentiation of penile reflexes occurs after 1 to 4 ejaculations as reflected by a shorter latency to the first reflex. Apparently copulation acts to reduce a source of tonic inhibition. In a second study, we found that antecedent ejaculation eliminated the inhibitory effects of low doses of intrathecal BAC (0.2 and 0.4 ug) but not a high dose (0.8 ug). Thus, copulation prior to ex copula tests for penile reflexes shifted to the right the dose-response curve of BAC. The anatomical specificity of this inhibition was then tested by intrathecal injection with 0.8 ug BAC directed at the T9-T10 spinal segments. In contrast to the effects of lumbosacral injection, BAC onto the thoracic cord did not affect any measure of penile reflexes following an ejaculation.

The role of spinal $GABA_A$ receptors on penile reflexes was assessed by intrathecal injection of THIP (0.5, 1, 2 ug) onto the lumbosacral spinal cord. Hints of facilitative effects at 1 ug proved to be unreliable, and a weak inhibitory effect was observed at 2 ug. Specifically, a decrease in the number of erections ($\bar{X}$ = 5.8 vs 14.3, $p < .05$) and erections per cluster ($\bar{X}$ = 1.4 vs 2.8, $p < .05$) were observed.

In summary, the data indicate that stimulation of $GABA_B$ receptors in the lumbosacral spinal cord inhibits penile reflexes in a context-sensitive and dose-related fashion. We can not rule out a potential role for $GABA_A$ receptors, but it appears that spinal inhibition of penile reflexes by GABA is mediated to a greater extent by $GABA_B$ receptors.

20.9 EVIDENCE FOR OXYTOCIN INNERVATION OF PERINEAL MOTOR NEURONS IN RATS. E. P. Monaghan and S. M. Breedlove. Psychology Dept., U. C. Berkeley, Berkeley, CA 94720.

Swanson and McKellar (J. Comp. Neurol., 188: 87-106, 1979) found oxytocin (OT) innervation throughout the spinal cord of rats. OT injections i.c.v. elicit penile erections in male rats (Melis, et al., Soc. Neurosci. Abstr. 12:223, '86) and plasma concentrations of OT are elevated after ejaculation (Stoneham, et al., J. Endocrinol. 107:97 '85). In rats, the bulbocavernosus (BC) muscles are involved in producing erections and in copulatory behavior. We decided to take a detailed look at OT innervation at the level of the spinal cord containing motor neurons which innervate the BC muscles, namely the spinal nucleus of the bulbocavernosus (SNB).

Adult male rats received six hourly intra-gastric infusions of tap water prior to being sacrificed and perfused with 0.9% saline and 4% paraformaldehyde. The hydration procedure enhances the OT immunoreactivity in the spinal cord (Swanson & McKeller, 1979). The area of the spinal cord between L5 and L6 was cut into 50 µm sections. Labelled fibers were localized using rabbit anti-OT (Immuno Nuclear Group, Stillwater Minn.) as the primary antibody in ABC immunohistochemistry using diaminobenzidine as a chromogen.

Immunoreactive fibers were found between lumbar levels 5 and 6, including the region of the SNB. The paraventricular nucleus (PVN) has been implicated as a possible afferent to the SNB (Monaghan & Breedlove, Soc. Neurosci. Abstr. 12:1219, '86); these findings that OT-like fibers are present in the area of the SNB support the possibility that the PVN provides input to the perineal motoneurons. Such OT innervation of perineal motoneurons may play a significant role in male reproductive behavior.

20.10 APOMORPHINE AND HALOPERIDOL, BUT NOT DOMPERIDONE, AFFECT PENILE REFLEXES IN RATS. E. A. Pehek*, R. C. Eaton*, T. J. Bazzett* and E. M. Hull (SPON: C. J. Smith). State University of NY at Buffalo, NY 14260.

Other investigators have shown that dopamine (DA) agonists have a biphasic effect on penile erection in rats, with low to moderate doses facilitating, and high doses inhibiting, erection. These studies did not distinguish between erection and seminal emission. One aim of the present studies was to examine the effects of apomorphine (APO), a DA agonist, and haloperidol (HAL), a DA antagonist, on penile reflexes and seminal emission in the supine rat. A second aim was to determine whether the effects on penile responses were mediated by actions on the central nervous system (CNS). This question was investigated by comparing the actions of HAL and domperidone (DOM), a DA antagonist that does not cross the blood-brain barrier. Penile reflexes were evoked via retraction of the penile sheath, and usually occurred within ten minutes following retraction.

A moderate dose of APO (100 ug/kg) decreased reflex latency whereas a higher dose (500 ug/kg) decreased the total number of reflexes. Both doses increased the incidence of seminal emission. HAL (300 ug/kg) reduced the number of reflexes and increased reflex latency. APO administration antagonized the effects of HAL on reflex latency and reflex number. HAL antagonized both the facilitative effect of 100 ug/kg APO on seminal emission and the inhibitory effect of 500 ug/kg APO on reflex number. DOM produced no effects on its own, and did not block any of the actions of APO.

These results demonstrate that APO has a biphasic effect on penile reflexes, with a moderate dose facilitating, and a higher dose impairing, penile reflex potential. APO facilitated seminal emission at both doses, suggesting that separate populations of dopamine receptors may regulate penile reflexes and seminal emission. These effects appear to be pharmacologically specific to the DA receptor, since HAL and APO have antagonistic actions. Furthermore, since DOM administration did not affect penile responses, the present results suggest that the effects of dopaminergic agents on penile responses are mediated by actions on the CNS.

20.11 MICROINJECTION OF CIS-FLUPENTHIXOL, A DOPAMINE ANTAGONIST, INTO THE MEDIAL PREOPTIC AREA IMPAIRS SEXUAL BEHAVIOR OF MALE RATS. E. M. Hull, E. A. Pehek*, R. K. Warner*, T. J. Bazzett*, D. Bitran*, L. C. Band*, and R. C. Eaton*. Dept. of Psychology, SUNY at Buffalo, Amherst, NY 14260.

We have previously shown that microinjection of the dopamine (DA) agonist apomorphine (APO) into the medial preoptic area (MPOA) of male rats facilitated several measures of sexual behavior. If DA receptors in the MPOA are important for the control of male sex behavior, then blocking DA receptors with cis-flupenthixol (FLU) should impair copulation. Furthermore, concurrently administered FLU should block the facilitative effects of APO.

In Experiment 1 male rats received 0, .2, 2, or 10 µg FLU, microinjected into the MPOA 5 min before each of four weekly tests with a receptive female. These doses of FLU did not significantly affect copulation.

In Experiment 2 doses of 0, 20, or 40 µg FLU were injected into the MPOA. Both 20 and 40 µg dramatically reduced ejaculation frequency. Fewer males mounted, intromitted, and ejaculated after FLU. Furthermore, among those animals that did copulate following FLU, ejaculation frequency was reduced, and copulation was slowed. Thus, higher doses of FLU dramatically impaired copulation.

Experiment 3 tested the ability of FLU to block the facilitative effects of APO. FLU (10 µg, ineffective alone in Experiment 1), APO (.5 µg, previously shown to facilitate copulation), the combination of the two, or vehicle were microinjected in counterbalanced order. APO injected alone increased ejaculation frequency, as before. FLU completely blocked this facilitation, but had no effect of its own on this measure. However, FLU injected alone slowed the rate of copulation. Neither drug produced major changes in activity or nonsexual motivation in home cage tests in the absence of a female.

These experiments support our hypothesis that DA receptors in the MPOA are important for the facilitation of sexual behavior of male rats.

20.12 **EFFECTS OF CASTRATION, STEROID REPLACEMENT AND COPULATORY EXPERIENCE ON SEXUAL AROUSAL AND MESOLIMBIC DOPAMINE** J. B. Mitchell and J. Stewart, Center for Studies in Behavioral Neurobiology, Psychology Department, Concordia University, 1455 de Maisonneuve Blvd. W., Montreal, Quebec, Canada, H3G 1M8.

A number of studies have implicated dopamine (DA) in the control of male sexual behavior (e.g. Malmnas, J. Endocrin 73:187, 1977; Baum and Starr, Pharm, Biochem & Behav, 13:57, 1980; McIntosh and Barfield, Behav Brain Res, 12:267, 1984). Alderson and Baum (Brain Res, 218:189, 1981) have reported that concentrations of DA and its metabolites are decreased 30 days post-castration. However, they have also reported a failure to replicate this finding (Baum, Melamed, and Globus, Brain Res Bull, 16:145, 1986). The present studies were undertaken to investigate the effect of castration on the concentrations of DA and the DA metabolites dihydroxyphenylacetic acid (DOPAC) and homovanillic acid (HVA) in the mesolimbic and nigrostriatal DA systems using the brain microdissection technique of Palkovits (Palkovits and Brownstein, 1983) and HPLC with electrochemical detection. Behavioral tests for sexual arousal and copulation were undertaken to determine if changes in DA content could be related to deficits in sexual behavior. Measures of sexual arousal included precopulatory behavior as well as the latency to initiate mounting (Grant and McIntosh, Behav, 21:246, 1963; Heimer and Larsson, Brain Res, 3:248, 1966; Stewart and Kaczender-Henrik, Hormones and Behav, 2:255, 1971).

DA and DOPAC concentrations in the nucleus accumbens, but not the caudate putamen, decreased by as much as 30 % after castration, falling to their lowest levels 4 weeks after gonadectomy. Castrated animals also displayed significantly less precopulatory behavior. Both the decrease in mesolimbic DA and the deficits in sexual behavior were prevented by post-castration androgen administration. Neither castration nor steroid administration affected the concentrations of norepinephrine, serotonin, or the serotonin metabolite 5-hydroxyindoleacetic acid (5-HIAA) in any brain area assayed. In males allowed post-castration copulatory experiences the castration-induced deficit in sexual arousal was attenuated; once copulation had been initiated the two groups of castrates did not differ significantly.

These findings indicate that androgens are important for the maintenance of sexual arousal and the initiation of copulation, but that sexual experience can partially compensate for the absence of androgens. Furthermore, the biochemical data suggest that the mesolimbic DA system is affected by androgens and that it may be involved in mediating sexual arousal.

20.13 EFFECTS OF AN OPIATE ANTAGONIST MICROINJECTED INTO THE MPOA ON MALE COPULATORY BEHAVIOR. Linda C. Band* and Elaine M. Hull (SPON: R. McIsaac). Psychology Department, SUNY at Buffalo, NY 14260.

We have previously reported that a hydrophilic form of the opiate antagonist naloxone microinjected into the medial preoptic area (MPOA) of male rats facilitated copulatory rate in poor copulators. Morphine microinjected into the same site produced a delayed cessation of copulation.

In subsequent studies, naloxone microinjected into the MPOA of average copulators produced a dose-related impairment of copulatory rate: .1 ug produced no effects; .5 ug reduced intromission rate and intromission ratio; 1 ug decreased ejaculation frequency, slowed intromission rate, and tended to lengthen ejaculation latency and the postejaculatory interval; 10 ug reduced intromission rate and frequency. Maximal effects on copulatory rate were seen approximately 15 minutes after injection.

Apparently contradictory data both within and between laboratories, concerning the effects of opiate receptor blockade on copulation, may be resolved by noting baseline performance, hormonal state, drug dosage, and site of injection.

20.14 COPULATORY AVOIDANCE IN MALE RATS: ALTERATIONS IN SERUM LEVELS OF TESTOSTERONE AND LUTEINIZING HORMONE. G. J. Lawrence, S. W. Kiefer, & C. W. Metzler*, Dept. of Psychology, Kansas State University, Manhattan, KS 66506.

Male rats demonstrate conditioned avoidance to mating behavior when illness is paired with copulatory encounters with estrous females that have been sprayed with a novel almond odor; only a weak avoidance is noted when male rats are conditioned without the almond odor (Lawrence & Kiefer, Behav. Neuro., 1987, 101). Levels of serum testosterone and luteinizing hormone (LH) were measured in two experiments in the present study to determine what changes occur in the hormone levels (a) in untrained male rats following ejaculation and (b) in conditioned males that display copulatory avoidance behavior.

Following each encounter with an estrous female, experimental male rats were made ill with lithium chloride (LiCl) by intubation immediately following ejaculation or at the termination of a 20-min session. One-half of the experimental males (Odor-Sex/Ill group) were trained with estrous females that had been sprayed with a 2% almond solution; the remaining experimental males (Sex/Ill group) were trained with estrous females without the almond odor. Controls were included for the effects of almond odor, illness, test environment, and ether anesthesia. Blood samples were collected by cardiac puncture within 90 s after the induction of light ether anesthesia, immediately following the copulatory encounters. In Experiment 1, control males were yoked to experimental males, and blood was collected at baseline, after first ejaculation, and after the second consecutive trial in which experimental males failed to ejaculate. In Experiment 2, blood was collected at baseline, and after Trials 4 and 8.

Serum levels of both hormones showed significant surges following ejaculation. However, in the males that exhibited avoidance to copulatory behavior, serum levels of both hormones were significantly decreased from baseline values. Results indicated that male rats conditioned to avoid copulatory behavior exhibited significant decreases in serum levels of testosterone and LH, reductions which were correlated with the behavioral changes.

20.15 **TEMPORAL ASPECTS OF THE NUCLEAR UPTAKE OF ^{3}H-TESTOSTERONE AND ITS METABOLITES IN THE BRAIN OF THE MALE RAT.** **R.W. Bonsall*, H.D. Rees and R.P. Michael. Department of Psychiatry, Emory University School of Medicine, Georgia Mental Health Institute, 1256 Briarcliff Rd, Atlanta, Georgia 30306.**

In male mammals, testosterone (T) is secreted by the gonads in an episodic manner in response to stimulation by gonadotropins. To investigate the significance of episodic secretion for the nuclear uptake of T and its metabolites in target organs, including the brain, 24 adult male rats (250-330 g) were adrenalectomized and castrated. Three days later each rat was injected with ^{3}H-T (1 μCi/g body weight) as a bolus via the jugular vein. Four rats were killed at each of the following intervals after injection: 30, 60, 90, 120, 180 and 240 min. Brains were rapidly removed and dissected to obtain the following blocks: hypothalamus and preoptic area (HYP/POA), amygdala (AMG), parietal cortex (PCX), and cerebellar cortex (CBL). Samples from each animal were analyzed separately (168 samples). Brain blocks, as well as pituitary gland, seminal vesicles (SV) and prostate (PRO) were homogenized and centrifuged to obtain purified nuclear fractions. Ether extracts of the nuclei were chromatographed on reverse-phase, high performance columns and fractions representing estradiol (E), T and dihydrotestosterone (DHT) were analyzed for radioactivity. In the brain, ^{3}H-E was detected in HYP/POA and AMG, but not in PCX or CBL, and levels declined from a maximum at 60 min (HYP/POA: 5,780 ± 630 dpm/mg DNA, mean ± SEM; AMG: 8,997 ± 1,088 dpm/mg DNA) to a minimum at 240 min (HYP/POA: 691 ± 691 dpm/mg DNA; AMG: 3,618 ± 474 dpm/mg DNA). Unchanged ^{3}H-T was present in the brain cell nuclei of HYP/POA and AMG, but not of PCX or CBL and declined from a maximum at 30 min (HYP/POA: 2,962 ± 304 dpm/mg DNA; AMG: 2,722 ± 465 dpm/mg DNA) to undetectable levels at 90 min. ^{3}H-DHT was present only as a minor metabolite of ^{3}H-T in nuclei from HYP/POA and AMG of some males. In pituitary gland, unchanged ^{3}H-T was the major form of radioactivity; maximum levels occurred at 30 min (13,689 ± 2,385 dpm/mg DNA) and concentrations declined rapidly thereafter. In genital tract structures, ^{3}H-DHT was the major form of radioactivity and was highest at 90 min after the injection (SV: 918,560 ± 122,618 dpm/mg DNA; PRO: 944,698 ± 257,446 dpm/mg DNA) while ^{3}H-T concentrations, in contrast, were highest at 30 min (SV: 64,046 ± 3,244 dpm/mg DNA; PRO: 52,824 ± 3,862 dpm/mg DNA) and declined with a half-life of about 30 min. Thus, in brain, pituitary gland and genital tract, the nuclear uptake of ^{3}H-T was much shorter-lived than that of its metabolites. However, T is more effective in restoring the sexual activity of castrates than either its estrogenic or androgenic metabolites, and the present results suggest that the unique temporal aspects of the nuclear uptake of unchanged T may be significant for the behavioral actions of this potent hormone.

This work was supported by USPHS grant number MH 19506, the Emory University Research Fund and the Georgia Department of Human Resources.

20.16 MEASUREMENT OF CYTOSOLIC AND CELL NUCLEAR ANDROGEN RECEPTORS IN MICRODISSECTED RAT BRAIN NUCLEI. C.E. Roselli, R.J. Handa*, and J.A. Resko*. Department of Physiology, Oregon Health Sciences University, Portland, OR 97201 and Oregon Regional Primate Center, Beaverton, OR 97006

Androgens are important regulators of neuroendocrine function and reproductive behavior in male rats. The binding of androgens to specific high affinity receptor sites in brain tissue is postulated as an initial event in the mechanism of central androgenic action. In vivo autoradiography has established that androgen receptors (ARs) are distributed heterogeneously throughout the hypothalamus and amygdala. However, it is important to establish not only the location, but also the concentration of ARs in the central nervous system so that an accurate representation of the functional capacity of this system can be obtained under various physiological conditions. As an initial part of this effort, we have measured the concentration of both cytosolic (ARc) and nuclear androgen receptors (ARn) in microdissected brain samples from intact male Sprague-Dawley rats. Twelve individual nuclei were bilaterally removed from 300-μm frozen sections and pooled from 6 rats for each determination. The content of AR was measured with single point in vitro assays that used saturating concentrations of ^{3}H-dihydrotestosterone (S.A. 141 Ci/mmol) and either the 105,000 x g cytosol or a nuclear extract. Nuclei were purified by centrifugation through 2.15 M sucrose at 50,000 x g. Androgen receptor was then extracted from the purified nuclei with 0.8 M KCl. We found that ARc and ARn were distributed similarly throughout the hypothalamus and amygdala. The highest levels of both were measured in the ventromedial nucleus of the hypothalamus (ARc = 16.8 ± 4.2 [SEM] fmol/mg protein; ARn = 235.6 ± 23 fmol/mg DNA). High levels of receptor were also detected in the medial amygdala (ARc = 8.6 ± 1.5 fmol/mg protein; ARn = 153 ± 21 fmol/mg DNA); periventricular preoptic area (ARc = 7.2 fmol/mg protein; ARn = 145 ± 6.9 fmol/ mg DNA); and arcuate nucleus - median eminence (ARc = 6.6 ± 1.2 fmol/mg protein; ARn = 138 ± 18 fmol/mg DNA). Low but detectable ARc levels were measured in the lateral preoptic area (1.7 ± .2 fmol/mg protein) and cortical amygdala (2.0 ± 0.3 fmol/mg protein), however, we did not consistently measure ARn in either of these nuclei. Our results provide a quantitative profile of AR concentrations in specific hypothalamic and limbic nuclei of the rat brain. These data show that in intact males the distributions of ARc and ARn are similar.

20.17 **NUCLEAR UPTAKE OF ^{3}H-TESTOSTERONE AND ITS METABOLITES IN THE BRAIN AND PITUITARY GLAND OF MALE CYNOMOLGUS MONKEYS: A COMBINED AUTORADIOGRAPHIC AND CHROMATOGRAPHIC STUDY.** **H.D. Rees, R.W. Bonsall* and R.P. Michael. Department of Psychiatry, Emory University School of Medicine, and Georgia Mental Health Institute, 1256 Briarcliff Road, Atlanta, GA 30306.**

Administration of testosterone to castrated male macaques restores sexual behavior and retards the frequency of luteinizing hormone pulses. To investigate how these effects may be mediated, autoradiography was used to map target cells and high performance liquid chromatography (HPLC) was used to measure radioactive metabolites in the brain after the administration of ^{3}H-testosterone to male cynomolgus monkeys. Two adult males (5.2 and 5.3 kg) castrated 3 days earlier were injected i.v. with 3 mCi [1,2,6,7-^{3}H]testosterone (92 Ci/mmol) and killed after 30 min. The left halves of the brains were frozen, and 4-micron sections were thaw-mounted on emulsion-coated slides and processed for autoradiography. A cell was considered labeled if its nucleus had a silver grain density at least twice that of adjacent tissue. In the brain, all labeled cells appeared to be neurons. The highest percentages of labeled neurons were found in the ventromedial nucleus (n.) (mean 34%), anterior hypothalamic area (27%), accessory basal amygdaloid n. (26%), medial preoptic n. (23%), bed n. of stria terminalis (21%), and cortical amygdaloid n. (21%). Fewer neurons were labeled in the arcuate n. (18%), lateral septal n. (16%), medial amygdaloid n. (14%), and paraventricular n. (9%). In the pituitary gland, labeling was found in only about 0.5% of pars distalis cells. Samples of 14 brain regions were dissected from the right halves of these same brains and homogenized. Purified cell nuclei were prepared and ether extracts were analyzed by reverse-phase HPLC on Spherisorb 5-ODS columns using 50% aqueous acetonitrile. Unchanged ^{3}H-testosterone was present in nuclear fractions from all brain areas. ^{3}H-Estradiol was a major metabolite in nuclei from three areas: hypothalamus (38%), preoptic area (47%), and amygdala (55%). The proportion of the total extracted radioactivity represented by ^{3}H-dihydrotestosterone was highest in the mammillary body area (27%) and thalamus (9%) and did not exceed 6% in any other brain region. In the pituitary gland, 96% of the extracted nuclear radioactivity was in the form of ^{3}H-testosterone and 2.6% was in the form of ^{3}H-estradiol. These results in male cynomolgus monkeys are in agreement with those in male rhesus monkeys. The autoradiographic data indicate that target neurons for testosterone are located primarily in circumscribed regions of the hypothalamus, preoptic area and amygdala. The biochemical data suggest that in these brain areas the actions of testosterone depend on unchanged testosterone or on estradiol formed locally by aromatization, rather than on dihydrotestosterone. These results may help explain behavioral data showing that testosterone is much more effective than dihydrotestosterone in restoring the sexual behavior of castrated males (Michael, R.P. et al., 1986, Physiol. Behav., 36: 349-355).

20.18 A QUANTITATIVE GOLGI ANALYSIS OF THE NEURONS IN THE MEDIAL NUCLEUS OF THE AMYGDALA IN MALE GOLDEN HAMSTERS: CASTRATION ALTERS DENDRITIC LENGTH. D.Gomez*, S.Newman. Dept.of Anatomy & Cell Biology, University of Michigan, Ann Arbor, MI. 48109.

The medial nucleus of the amygdala (M) is an important area for controlling mating behavior in the male Golden Hamster (Mesocricetus auratus). M receives chemosensory input from both olfactory and vomeronasal systems which are essential for this behavior and it projects directly to other mating control centers of the brain. Neurons in M also actively accumulate androgens. We are investigating the detailed structural organization of these neurons to determine how these inputs are integrated to guide mating behavior. We hypothesize that an important role of androgens in this system is to maintain the dendritic length and arborization of these neurons.

The normal morphology of the neurons in M have been studied in adult male hamsters using a Ramón-Moliner modification of the Golgi technique. The neurons throughout M are primarily of two types. Type I cells are few in number, have either a pyramidal or multipolar shaped perikarya (long axis = 20-24 µm), and have at least three primary dendrites which radiate and branch sparingly. Type II cells are more numerous and generally have smaller cell bodies (long axis = 9-21 µm) which are spherical, ovoid or fusiform in shape. One to three primary dendrites extend out from the long axis of the cell body and branch sparingly.

The caudodorsal region of M is an area in which neurons actively accumulate androgens and are primarily Type II cells. Measurements on the length of all the dendritic processes per neuron in this specific region of M were made using a Tektonics digitizing pad on tissue from 4 long-term castrated animals (4-6 months) and 5 intact animals. Thirty-six neurons from each group were analyzed and the sum of the lengths of all dendritic processes per neuron (DL) was calculated. The average DL was 495 µm for the neurons from the intact group and 355 µm for the castrated group. This indicates a 28% decrease in DL after castration in this brain area ($P < .05$). The level of dendritic branching per neuron was also determined and the percentage of neurons having each level of branches are listed in the table below.

ORDER	1st	2nd	3rd	4th	5th
GROUP					
Intact (neurons=36)	100%	89%	58%	22%	6%
Castrated (neurons=36)	100%	83%	31%	6%	0%

Fewer neurons from the castrated group have third order branches and beyond than those in the intact group.($P < .05$). This suggests that androgens may be involved in maintaining the dendritic length and the distal dendritic processes of the neurons in this area. (Supported by NIH,NS #20629 to SWN).

20.19 STEROID MODULATION OF MONOAMINE LEVELS AND TURNOVER IN THE VOCAL CONTROL SYSTEM AND HYPOTHALAMUS OF THE MALE ZEBRA FINCH. S.R.Barclay, A.Gardner and C.F.Harding. Biopsychology Program, Hunter College, C.U.N.Y., New York, N.Y. 10021.

In many vertebrate species, testosterone plays a critical role in the activation of male sexual behavior. Singing behavior in passerine birds serves multiple reproductive functions including attracting females (courtship behaviors) and helping to repel other males from the vicinity (territorial behaviors). Courtship behaviors, including singing are abolished by castration and can be restored by testosterone administration. Behavioral and biochemical studies indicate that most of male courtship behavior requires the combined action of estrogens and androgens. These steroids are concentrated in specific vocal control nuclei and induce changes in neural functioning which activate behavior. A growing body of evidence suggests that one mechanism by which steroids exert their effects is through modulation of neural transmission. Considerable evidence from mammalian species indicates that steroid effects in modulating male sexual behavior are mediated by steroid-induced changes in catecholaminergic (CA) neurotransmission.

The purpose of this study was to measure the effects of behaviorally effective steroids on CA levels and turnover in steroid-sensitive brain areas (vocal control nuclei: RA, HVc, ICo, MAN, Area X and hypothalamic nuclei: POA, PVM) in zebra finches. Three weeks after castration, the males used in this experiment were implanted with Silastic capsules containing either androstenedione (AE) or cholesterol and placed in an individual cage with a female for one week. To allow for calculation of CA turnover rates the birds were divided into two subgroups: one received an injection of α-methyl-para-tyrosine (αMPT), the other a control injection of saline. The appropriate dosage and time course of MPT treatment was empirically determined in a preliminary study. Brain nuclei were microdissected from 180µ frozen sections using the Palkovits punch technique and expelled into sodium acetate buffer containing an internal standard. The concentrations of CA and serotonin were determined by electrochemical detection in an HPLC system.

Steroid treatment significantly affected norepinephrine turnover rates in two hypothalamic nuclei and three vocal control nuclei (Area X, HVc and RA). Less systematic effects were seen in other neurotransmitters examined. Dopamine levels and turnover were affected in POA, MAN and RA. Serotonergic function was affected in HVc and POA. Research is currently in progress to determine if the effects of AE treatment are due to one class of metabolites (androgenic or estrogenic) or if these effects on monoaminergic turnover result from the interaction of androgens and estrogens. (Supported by grant HD-15191 and MH-00591 to CFH)

20.20 ANDROGEN ELEVATED BUT CORTICOSTERONE UNAFFECTED BY ACUTE AND CHRONIC SOCIAL STRESS IN LIZARDS

N. Greenberg and D. Crews*
Departments of Zoology, University of Tennessee, Knoxville and * University of Texas, Austin

Previous work has demonstrated that socially subordinate male lizards, Anolis carolinensis, have elevated circulating levels of corticosterone if intact but not if castrated (Greenberg et al. 1983). In a subsequent study, evidence was provided that chronically elevated corticosterone is a key factor in an anomolous adrenal catecholamine (epinephrine) response to sexually receptive females. The present work was undertaken to further characterize the relationship between aggressive and reproductive behavior, social dominance, plasma androgen, and corticosterone.

After agonistic encounters between territorially competitive male lizards, winners show a striking elevation in total plasma androgen while androgen levels in losers are unaffected. Subsequent cohabitation with the loser leads to a more modest but nevertheless significant elevation in androgen at one week, post-encounter. Androgen levels in losers, however, are unaffected. Winners recover pre-encounter levels of courtship behavior by one-week post-encounter but losers remain relatively depressed in reproductive activity. Plasma corticosterone levels are not affected either immediately or at one week post-encounter. This finding, inconsistent with the earlier study, may reflect the differences between the time scale (in the earlier study, animals cohabited for several weeks before blood sampling) or activity levels (in the earlier study subjects were not exposed to receptive females).

20.21 ACTIVITY, APPETITE, AND WEIGHT GAIN IN THE ADRENALECTOMIZED MALE ZUCKER RAT. Thomas W. Castonguay, Lori Ann Roth*, and Judith S. Stern*. Food Intake Laboratory and Nutrition Department, University of California - Davis Davis CA 95616

Many of the anomalies associated with genetic obesity are attenuated (if not reversed) subsequent to adrenalectomy (ADX). ADX promotes decreased levels of activity (revolutions in running wheels) in Sprague-Dawley rats. Conversely, restricted access to food can promote increases in activity. The present study was conducted to observe the effects of ADX on running wheel behavior of obese and lean Zucker rats. Obese and lean males were housed in Wahmann running wheels or standard, rack-mounted stainless steel cages. At surgery, rats were assigned to active or sedentary groups and monitored for 4 weeks. Body weight and food and water intake were determined daily. All ADX rats had ad libitum access to .9% NaCl. In addition to these groups, obese sham operated active animals were pair fed to obese ADX active rats. On Day 1, obese rats weighed more than did their lean littermates (343.9 ± 11.2 g vs 266.6 ± 6.3 g). No other differences were noted. By Day 28, the body weights of active obese and lean groups did not differ from sedentary controls. ADX failed to promote differences between active and sedentary groups of either genotype. On Day 1, obese sham operated sedentary and active rats ate more per day than any of the other rats. ADX rats of both genotypes ate less/day than did their sham operated controls. Obese ADX active and sedentary groups ate less than did the lean sham operated sedentary group. By Day 28, differences between surgical conditions, activity conditions, and genotypes were not observed. On Day 1, lean ADX active and sedentary groups drank more than did sham operated controls. By Day 28, all ADX groups were drinking more fluid/day than did their sham operated controls. Activity failed to influence daily fluid intake. Finally, on Day 1, lean sham operated rats ran more than either ADX or sham operated obese groups, but not more than the lean ADX group. By Day 28, there were no differences between lean ADX and sham operated groups. Obese sham operated rats that were pair fed to ADX obese rats ran more than the obese sham operated controls as well as more than the obese ADX ad libitum fed group. The decrease in intake following ADX in the obese fails to promote the increase in activity that follows caloric restriction. Unlike many of the other anomalies associated with genetic obesity, the hypoactivity of the obese rat is not easily or quickly reversed following ADX. (Supported in part by NIH grants DK18899 and AM35747)

20.22 CHRONIC CORTICOSTERONE ADMINISTRATION INCREASES ESCAPE BEHAVIOR IN RATS. M. Egawa*, E.A. Stone and B.M. McEwen, (SPON: D. J. Micco) Dept. Psychiatry, New York Univ. Sch. Med., New York, NY 10016 and Lab. Neuroendocrinology, The Rockefeller Univ., New York, NY 10021.

In the course of previous biochemical studies of the effects of chronic corticosterone treatment in rats we made the unexpected behavioral observation that the treated animals showed a pronounced tendency to escape while be held. Behavioral changes that occur with chronic corticosterone treatment are of potential clinical interest because of their possible relevance to the affective and psychotic changes produced by this hormone in humans. Since this tendency to escape had not to our knowlegde been reported previously we undertook the following systematic study of it.

Rats were given corticosterone dissolved in ethanol in their drinking water (200 µg/ml, final ethanol conc. 1.2%). Controls received water with ethanol only. Daily tests were conducted for escape behavior (pulling away or backing-up while being held by the tail on a horizontal cage top for 30 sec.) and spontaneous motor activity (rearing and ambulation during 3 min in a behavioral test chamber). Dose response studies were carried out using 25-200 µg corticosterone administered for 3 days. For studies of habituation to stress rats were subjected to restraint (2 hrs/day for 4 days). Plasma corticosterone (trunk blood) levels were measured by RIA.

It was found that corticosterone markedly stimulated tail-pulling behavior during the escape test. The effect was evident beginning on day 2 and peaked on days 3 and 4 of treatment (percent of controls: day 3, 406 ± 78, $p < .01$ and day 4, 562 ± 90, $p < .005$). The hormone produced the effect in a dose dependent manner. Some spontaneous tail-pulling behavior was also evident in nontreated rats. Repeated stress for 4 days produced a reduction in the spontaneous behavior (56.3 ± 8%, $p < .05$) due to habituation. This reduction was markedly enhanced by prior adrenalectomy (83 ± 7%, $p < .005$). In contrast to its effect on escape behavior, corticosterone reduced motor activity. The latter effect however was observed only in repeated behavioral tests and not in the single test used in the dose response study.

From the above results, it is evident that elevated corticosterone level caused by exogenous hormone administration produces a dramatic rise in escape behavior in rats. Furthermore, the effect of adrenalectomy on spontaneous escape behavior in stressed rats suggests that increased release of endogenous corticosterone may serve to maintain levels of this behavior during adaptation to stress. Since exaggerated escape behavior can be a manifestation of psychotic disturbance this behavioral effect in rats may be related to the abnormal changes in CNS function produced in humans by the latter hormone. (Supported in part by grant MH22768).

20.23 SALIVARY CORTISOL ANALYSIS - FURTHER EVIDENCE AS TO ITS CLINICAL UTILITY IN THE DST, D. M. Martin, C. E. Turner*, D. H. Sherman*, M. A. Grimes*, Psychiatric Diagnostic Laboratories of America, Inc., South Plainfield, NJ 07080

The Dexamethasone Suppression Test (DST) is the most widely applied laboratory determination used as a state marker for endogenous depression and objective predictor of treatment response. The test is used both in outpatient and inpatient settings and requires at least two post dexamethasone blood draws for cortisol analysis. These draws require a skilled phlebotomist to collect the sample and a centrifuge to prepare the sample for refrigerated storage until analysis.

Salivary cortisol parallels the circadian rhythms observed in serum and responds to stimulation by ACTH or suppression to dexamethasone. Our group investigated its use as an alternative to the standard blood collection technique.

Seventy (70) inpatients with a preliminary diagnosis of major affective disorders were asked to participate in the study. If the DST was determined to be clinically indicated, the patients were asked to provide approximately 2-3 mls of saliva in a plastic centrifuge tube prior to venipuncture for cortisol analysis. Serum cortisol was determined by a standard radioimmunoassay technique and salivary concentrations were determined by a modification of the same technique.

Using the criteria of nonsuppression in serum of 5 ug/dl and 90 ng/dl in saliva, 61 of the 70 patients had similar findings in saliva and in serum. These data suggest that salivary cortisol determinations can be used in the DST without the loss of sensitivity or specificity. Compared to venipuncture, the collection of saliva is more convenient, painless and suitable for both inpatient and outpatient applications. This noninvasive approach requires no skilled personnel, equipment or preparation, and the sample is stable at room temperature for several days.

21.1 TOPOGRAPHIC ORGANIZATION IN THE SPINAL PROJECTION TO THE LATERAL RETICULAR NUCLEUS IN THE RAT.
N. Rajakumar*, A.W. Hrycyshyn* and B.A. Flumerfelt. (SPON: K. Elisevich). Department of Anatomy, The University of Western Ontario, London, Canada. N6A 5C1.

The organization of the afferent projections from the spinal cord to the lateral reticular nucleus (LRN) in the rat was studied using anterogradely transported lectin conjugated horseradish peroxidase (WGA-HRP). The tracer was placed at various levels of the spinal cord. A hemicordectomy was done just caudal to the placement of the WGA-HRP to ensure that no tracer was taken up by fibres of passage originating at lower levels. Sections through the LRN were examined microscopically under bright-field and polarized light after treatment with tetramethyl benzidine (Mesulam, 1978).

The results revealed that the cervical spinal cord projects mainly to the magnocellular portion of the caudal two-thirds of the contralateral LRN with only a sparse projection to the ipsilateral nucleus. The lumbar spinal cord projects mainly to the ventrolateral portion of the middle third of the LRN, with a sparse projection to the subtrigeminal portion and to the rostral third of the magnocellular LRN. Following placement of the tracer in the thoracic spinal cord, moderate labelling was seen in the intermediate zone between the cervical and lumbar projection areas within the LRN.

The above data indicate that the spinal projection to the LRN is topographically organized in the rat. The topographic pattern within the LRN shifts from caudo-medial to rosto-lateral with descending levels of the spinal cord. These results are consistent with the view that the neck and forelimb spinal projection terminates within the forelimb area of the LRN, while the hindlimb spinal input terminates within the hindlimb area of the LRN. Thus the pattern of connectivity within the LRN and that of its connectivity to the cerebellum is consistent with the hypothesis that the LRN plays an important role in coordinating motor activity.

21.2 IMMUNOHISTOCHEMICAL LABELING OF MONOAMINERGIC TERMINALS IN PHRENIC NUCLEUS OF THE RAT. W.-Z. Zhan*, H.H. Ellenberger and J.L. Feldman. Systems Neurobiology Lab., Kinesiology Department, UCLA, Los Angeles, CA 90024-1568.

The termination patterns of monoaminergic axons in the phrenic nucleus were studied in Wistar rats. The phrenic nerve was dipped in biotinylated horseradish peroxidase (Bi-HRP) to retrogradely label phrenic motoneurons. After a 48 hr. survival time the animals were sacrificed and perfused; the cervical spinal cord was then sliced into 20-30 μm sections. The transported Bi-HRP was visualized using an avidin-biotin reaction (ABC kit, Vector Labs) with a heavy metal enhanced, black diaminobenzidine (DAB) reaction product. Then the tissue was incubated with antisera against dopamine β-hydroxylase (DBH), phenylethanolamine-N-methyltransferase (PNMT) and serotonin to identify the terminations of monoaminergic neurons. From the C3 to C5 spinal cord, DBH-positive terminals with varicosities formed a dense network, with presumptive synaptic contacts on dendrites and somas of phrenic motoneurons. There were fewer PNMT-positive terminal arborizations in the cervical spinal cord compared to thoracic spinal cord; PNMT terminals were not seen in the vicinity of phrenic motoneurons. Numerous serotonin containing axons and terminals contacting phrenic motoneurons were also labeled. These monoaminergic inputs may not be respiratory specific, however, since we also observed similar termination patterns in other adjacent (non-respiratory muscle) motoneuron pools. The supraspinal origins of the serotonin and norepinephrine projections to the phrenic nucleus are not from the dorsal or ventral respiratory groups (Ellenberger et al., this volume), but were not otherwise determined. The results suggest that phrenic motoneuronal activity can be influenced by monosynaptic supraspinal inputs from norepinephrine and serotonin containing neurons. This input appears to be shared by other spinal motoneurons rather than a respiratory specific influence limited to phrenic motoneurons. Supported by NIH Grants NS 24742, HL 37941 and HL 07363.

21.3 ASCENDING AND DESCENDING PROJECTIONS TO MEDULLARY RETICULAR SITES WHICH ACTIVATE EPAXIAL MUSCLES IN THE RAT. A. Robbins, S. Schwartz-Giblin and D.W. Pfaff. Lab of Neurobiology and Behavior, Rockefeller University, New York, N.Y. 10021.

The epaxial muscles, lateral and medial longissimus (LL and ML), are active during lordosis, the sexual posture of the female rat characterized by dorsiflexion of the back and elevation of the tailbase. Stimulation of the medullary reticular formation (MRF) can activate these muscles (Femano et al., Am. J. Physiol., R389:246, 1984). Since electrical stimulation of other lordosis-relevant brain sites and peripheral nerves can facilitate MRF-induced muscle activity, this experiment aimed to precisely determine which brain and spinal cord neurons project to effective sites in the MRF using electrophysiological and neuroanatomical techniques.

In anesthetized female rats, the MRF was explored with electrical stimulation using currents less than 50uA, and EMG activity was recorded from ipsilateral LL and ML muscles. When an effective site was found, the retrograde fluorescent tracer, fluoro-gold, was applied to the site in a cannula prepared as follows: a 15% polyacrylamide gel was drawn into a 32g cannula and the cannula tip was soaked in a 20% fluoro-gold solution. The gel allows for slower release and a more confined deposition site (Fahrbach et al., J. Comp. Neurol., 225:605, 1984). The cannula was inserted into a guide cannula attached to the stimulating electrode, to a depth equal to the tip of the stimulating electrode. The cannula containing fluoro-gold remained in the brain 10-13 hrs and the animals survived for 4 days.

Effective stimulation sites and corresponding fluoro-gold deposition sites were located in the dorsal n. gigantocellularis. Labeled cells with descending projections were seen in contralateral n. gigantocellularis, parvocellular reticular n., medial and lateral vestibular n., midbrain central gray, n. lateral lemniscus, tegmentum, lateral hypothalamus, amygdala, paraventricular n., anterior hypothalamic area, and the bed n. stria terminalis. Of interest was the paucity of labeled cells in the ventromedial n., a crucial hypothalamic area for lordosis behavior. Labeled cells with ascending projections were observed in the cervical and lumbar spinal cord, primarily in lamina V, VIII and X. The number of cells observed in the lumbar cord was much smaller than in the cervical cord.

Experiments are being conducted to determine if the afferent projections to ineffective MRF sites differ from the pattern observed to effective sites. Preliminary evidence indicates that, in paired comparisons, there is a tendency toward a larger number of projections from contralateral MRF, midbrain central gray and cervical spinal cord to effective MRF sites than to ineffective MRF sites.

21.4 ORIGINS OF BRAINSTEM AFFERENTS AND BULBOSPINAI PATHWAYS IN THE PARROT. D.M.S. Webster and J.D. Steeves. Dept. of Zoology, University of British Columbia (UBC), Vancouver, B.C., V6T 2A9.

The purpose of this study was to correlate, in dexterous prehensile and non-prehensile birds, the origins of descending brainstem-spinal pathways, as well as the afferent projections from rostral brain to brainstem.

True blue (TB) dye (5%), or wheat germ agglutinin-horseradish peroxidase (WGA-HRP) (2%), was injected (5 uL) bilaterally into the high lumbar spinal cord in 4 Sulphur-crested cockatoos, and 1 Eastern rosella parrot. Examination showed that the distribution of retrogradely labelled neurons within the medullary and pontine reticlar formation, raphe nuclei, red nucleus, descending and lateral vestibular nuclei, lateral and periventricular hypothalamic nuclei, was essentially the same as previously described for the duck and goose (Webster and Steeves, 1986. Soc. Neurosci. Abs. **12**:882).

In parrot, duck and goose, TB was also used to determine the source of afferent projections to the medullary reticular formation and other brainstem areas known to play a role in the initiation of locomotion (Steeves et al., 1987. Brain Res. **401**:205). Following unilateral injection of TB (0.1 uL) into the nucleus reticularis gigantocellularis (Rgc), labelled cells were found in the vestibular nuclei, cerebellar nuclei, inferior olive, contralateral reticular formation, nucleus intercollicularis, interstitial and hypothalamic nuclei. A few labelled cells were also found in the wulst and the paleostriatum primitivum, but only following larger injections of TB (1.0 uL) into the Rgc.

Similar results were found in all avian species (Sulphur-crested cockatoo, Eastern rosella, Pekin duck, and Canada goose). Therefore, we conclude that there were little or no differences in 1) the afferent projections onto brainstem reticular formation neurons, or 2) descending bulbospinal projections in either prehensile and non-prehensile birds that might underlie the observed pedal dexterity of parrots .

Supported by NSERC of Canada.

21.5 PROJECTIONS OF THE LOCUS COERULEUS TO BRAINSTEM NUCLEI: AN ANTEROGRADE TRANSPORT STUDY IN THE RAT. R. Grzanna and J.-M. Fritschy* (SPON: A. Georgopoulos). Department of Neuroscience, Johns Hopkins University School of Medicine, Baltimore, MD 21205.

It is a widely held notion that locus coeruleus (LC) efferents have a widespread and diffuse distribution throughout the central nervous system. We have recently reported that in the spinal cord LC axons are distributed preferentially in the dorsal horn with only a sparse input to the ventral horn. In the present set of experiments, we studied the distribution of LC axons in the brainstem. The anterograde tracer phaseolus vulgaris leukoagglutinin (PHA-L) was iontophoresed unilaterally into the LC. After a two week survival period rats were perfused and brainstem sections were processed for PHA-L immunocytochemistry using the avidin-biotin peroxidase complex method. To determine definitively whether PHA-L labeled fibers were noradrenergic (NA) axons, we processed a separate series of sections for double immunohistochemical staining using antibodies to PHA-L and antibodies to dopamine-beta-hydroxylase.

Numerous PHA-L labeled LC axons were observed in the spinal cord, the cerebellum and the inferior colliculus. An unexpected finding of our experiments was the low density of PHA-L labeled axons in the hindbrain compared to that seen in either the spinal cord or the cerebellum. Extensive regions of the brainstem were almost devoid of PHA-L labeled LC axons including regions known for their dense NA innervation such as the nucleus of the solitary tract, dorsal motor nucleus of the vagus and the raphe nuclei. The highest density of PHA-labeled LC axons was observed in the cochlear nuclei and throughout the rostro-caudal extent of the sensory trigeminal nucleus bilaterally. Very few PHA-L labeled LC axons were observed in the motor nucleus of V and in somatic motor nuclei of cranial nerves. In contrast to the very low density of PHA-L labeled fibers in these nuclei, the motor nucleus of the facial nerve contained a moderate number of LC axons. Analysis of PHA-L LC axons revealed a broad spectrum of morphologically different types of fibers varying in their diameter and the shape and spacing of their varicosities. The entire range of fiber types was represented in the trigeminal complex.

The results of the present study reveal a distinct regional distribution of LC axons in the brainstem and provide further evidence against the hypothesis that the LC exerts a global influence on brainstem functions. The absence of LC axons in extensive regions including motor nuclei of cranial nerves suggests a highly restricted influence of the LC in the brainstem. Based upon the observation of numerous LC axons in the trigeminal nuclear complex, we propose that the LC influences primarily the processing of sensory inputs. (Support: MH 41977 and NS 16654).

21.6 CORTICAL AND CEREBELLAR PROJECTIONS IN THE NUCLEUS OF DARKSCHEWITSCH (ND) IN THE CAT. J.G. Rutherford, D.G. Gwyn and A. Zuk-Harper*. Dept. of Anatomy, Dalhousie University, Halifax, N.S., Canada B3H 4H7.

The ND is a small midbrain nucleus traditionally classified as an accessory oculomotor nucleus. However, this cell group is known to be the source of a substantial projection to the inferior olive (IO) in the cat (J. Comp. Neurol., 212:278, 1982). In this study, anterograde terminal and retrograde neuronal labeling in the ND following horseradish peroxidase (HRP) injections into the cerebral cortex, and anterograde labeling in the ND following HRP injections into the deep cerebellar nuclei (dCN), is described and discussed.

Injections of from 0.36 to 2.00 µl of wheat germ agglutinin-HRP (WGA-HRP) were placed unilaterally in the cerebral cortex anterior and posterior to the cruciate sulcus in each of 9 male and female cats. In a further 4 animals, from 0.12 to 0.38 µl of WGA-HRP was injected unilaterally into the dCN, using stereotaxic coordinates for guidance. Following survival times ranging from 1 to 4 days, cats were sacrificed, and 40 µm frozen sections were cut in the transverse plane through the injection sites, and in the transverse or horizontal planes through the midbrain and caudal diencephalon. Sections were reacted for HRP activity using tetramethyl benzidine as the chromogen.

Cortical injections of WGA-HRP produced anterograde labeling of varying density throughout the ND, from its caudal pole rostrally to the level at which the fasciculus retroflexus passes laterally adjacent to the periaqueductal gray (PAG). The labeling sharply defined the boundaries of the ND, and was predominantly, but not exclusively ipsilateral to the injection sites. Retrogradely labeled somata were found in the PAG adjacent to the ND, and in the ND itself, where the distribution of anterograde labeling overlapped the position of the cortically projecting neurons. Retrogradely labeled cells increased in number at more rostral levels of the ND. Following cerebellar injections, anterograde labeling was noted in the ND contralateral to the injection sites, and again extended throughout the rostro-caudal length of the ND. Thus the cerebellar input to this region overlapped the anterograde and retrograde labeling resulting from cortical injections of WGA-HRP.

Convergence, and potentially integration, of cortical and cerebellar input in the ND, a nucleus projecting substantially to the IO, suggests that this cell group is a functional adjunct to the red nucleus, rather than an accessory oculomotor nucleus. Additionally, the ND may be involved in relaying combined cerebellar and cortically derived information to the cerebral cortex. Supported by the MRC of Canada.

21.7 DESCENDING PROJECTIONS FROM THE PERIAQUEDUCTAL GREY (PAG) AND SURROUNDING TEGMENTUM, Petra Smulders (1) and Gert Holstege (2) Dept. Anat. Erasmus University Rotterdam The Netherlands (1) and Dept. Anat. Univ. California San Fransisco CA 94143 (2) (SPON:Daunton)

The PAG is one of the largest structures in the central nervous system, but its function is not well understood. It is known that the PAG maintains reciprocal connections with many limbic areas in the di- and telencephalon and that it sends fibers to the nucleus raphe magnus and adjoining tegmental field. However, the descending pathways have never been described in great detail. Therefore, in 32 cases injections of 0,5 µL containing 50 µCi ^{3}H-leucine were made in various parts of the PAG and surrounding areas. In almost all cases a basic descending projection system was observed, in which a large stream of labeled fibers passed from the injection site ventrolaterally into the lateral mesencephalic tegmentum. In this area the fibers turned caudally to descend through the lateral tegmentum of caudal mesencephalon and pons. At the level of the caudal pons the fiber stream shifted ventromedially and descended further through the ventral part of the medial tegmentum of caudal pons and medulla. Many labeled fibers terminated in the areas through which they descended and in the area of the nucleus raphe magnus. However, this study also revealed some other projections, such as:

1: The basic pattern of descending fibers was also found in cases with injections in areas lateral and ventral to the PAG.
2: When the lateral and ventrolateral PAG was injected, a very specific distribution was observed to the nucleus retro-ambiguus.
3: In the cases with injections in the ventrolateral PAG labeled fibers were also distributed to the nucleus raphe pallidus.
4: In many of the cases some labeled fibers were observed in the solitary and dorsal vagal nuclei, but none to the motor trigeminal, facial and hypoglossal nuclei or to the dorsal group of the nucleus ambiguus.
5: In the cases with injections in the lateral PAG and laterally adjoining tegmentum, labeled fibers were found descending in all funiculi of the spinal cord untill mid-thoracic levels. From the ventral funiculi labeled fibers were distributed to laminae VIII and adjoining VII and to lamina X. From the dorsolateral funiculus a few labeled fibers were distributed to the upper thoracic intermediolateral (sympathetic) cell column. HRP injections in the spinal cord corroborated these autoradiographic findings.
6: In many cases some labeled fibers were distributed to the lateral tegmental field of caudal pons and medulla. These projections were best seen at caudal medullary levels. If the injection sites extended into the dorsal raphe nuclei, the projections to the caudal pontine and medullary lateral tegmental field were much stronger and labeled fibers were also found in the lateral facial subnuclei.
Supported by a grant of NASA/Ames Research Center to G.H.

21.8 SIZE DIFFERENCES IN CELLS OF ORIGIN OF FTG DESCENDING PATHWAYS IN THE CAT. A. Mitani, K. Ito, Y. Mitani and R.W. McCarley. Lab. Neuroscience, Dept. Psychiatry, Harvard Medical School, Brockton/West Roxbury VAMC, Brockton, MA 02401

Numerous physiological studies in the cat implicate neurons of the pontobulbar gigantocellular tegmental field (FTG) in control of events related to the sleep-waking cycle and motor activity. However it is not known if there is a morphological differentiation of FTG neurons corresponding to projections with different functional roles. This study sought to determine the relationship between morphological features of FTG neurons and their descending fiber trajectories. We first injected WGA-HRP and anterogradely labeled descending fibers (N=14 animals). We then injected HRP into the ventral (N=3) or lateral funiculus (N=7) of cervical spinal cord or into bulbar reticular formation (N=4) where the anterogradely labeled fibers had been found and determined the distribution and sizes of the retrogradely HRP-labeled neuronal somata.

Predominantly large to giant-sized neurons gave rise to reticulospinal projections that descended in the medial longitudinal fasiculus (MLF) and in ventral funiculus (VF): (1) Neurons in the pontine FTG (average soma diameter = 43.4 um) and rostral bulbar FTG (41.3 um) gave rise to reticulospinal fibers descending in the ipsilateral MLF and VF and distributed in laminae V-X with an ipsilateral predominance. These were primarily large diameter fibers; (2) Neurons (46.9 um) in the bulbar FTG gave rise to reticulospinal fibers descending in the contralateral MLF and VF. These were mainly large diameter fibers.

The projection patterns of smaller neurons were different in that: (3) Predominantly medium-sized neurons (29.5 um) in the pontine FTG gave rise to reticuloreticular fibers that descended directly to and distributed in the bilateral bulbar reticular formation. These were small diameter fibers; (4) Predominantly medium-sized neurons (28.9 um) in the bulbar FTG gave rise to reticulospinal fibers descending in the ipsilateral reticular formation and lateral funiculus. These were small diameter fibers. The differences in size distribution of cells of origin between these latter two groups and the MLF-VF fibers were highly statistically significant ($p's < .001$, Kolmogoroff-Smirnoff test). These findings confirm and enrich the data of our intracellular HPR studies of pontine FTG neurons and suggest neuronal size is an important organizing feature for reticular formation.

21.9 OPERANT CONDITIONING OF PRIMATE SPINAL REFLEXES: BEHAVIOR OF THE UNCONDITIONED LEG. J.G. Calaitges* and J.R. Wolpaw (SPON: E.W. Wolpaw). Wadsworth Labs, NYS Dept Hlth, Albany, NY 12201; and Depts Neurol & Anat, Albany Med Coll, Albany, NY 12208.

Operant conditioning of the wholly spinal and largely monosynaptic H-reflex (J Neurophysiol 57:443-459, 1987) may prove to be a powerful experimental model for the study of primate memory substrates. Evidence suggests that conditioning causes a persistent alteration in the lumbosacral spinal cord, a potentially accessible memory substrate. In the present study, we conditioned the H-reflex in one leg and simultaneously monitored the H-reflex in the other, unconditioned, leg.

Five monkeys (Macaca nemestrina) with triceps surae EMG electrodes and a posterior tibial nerve cuff in each leg learned to maintain stable background EMG bilaterally. At random times, bilateral nerve cuff stimuli just above M response threshold elicited the H-reflexes. In control mode, reward always followed. In HR↑ or HR↓ mode, it followed only if the H-reflex in one leg (the conditioned leg) was above (HR↑, 3 animals) or below (HR↓, 2 animals) criterion. Monkeys worked 3000-6000 trials/day over 4-6 months. Background EMG and M response were stable throughout. Under the control mode, H reflexes in both legs were stable.

Under the HR↑ or HR↓ mode, the conditioned leg's H-reflex changed in the expected direction over weeks and months in all 5 monkeys. In contrast, under the HR↑ mode, the unconditioned leg's H-reflex fell slightly in one monkey, rose slightly in one, and rose as much as the conditioned leg's in the third. Under the HR↓ mode, the unconditioned leg's H-reflex rose slightly in both animals.

The results indicate that operantly conditioned change in the H-reflex is relatively specific to the conditioned leg. The unconditioned leg usually shows little or no change in the conditioned direction. This finding suggests that conditioned H-reflex change is a result of asymmetrical activity in descending pathways. Furthermore, and most important, it supports current efforts to delineate the persistent spinal alterations by comparing the conditioned and unconditioned sides of the cord (Wolpaw & Lee, this vol).

21.10 **NEURAL RESPONSES TO ACOUSTIC STARTLE-ELICITING STIMULI IN THE PONTINE RETICULAR FORMATION OF THE CAT: RELATIONSHIP WITH NECK EMG STARTLE RESPONSE.** S. S. Suzuki, M.-F. Wu* and J. M. Siegel. Neurobiology Research, V. A. Medical Center, Sepulveda, CA 91343, and Department of Psychiatry, UCLA School of Medicine, Los Angeles, CA 90024.

The pontine reticular formation (PRF) has been implicated in the instigation of the acoustic startle reflex (ASR), by lesion, electrical stimulation, and anatomical tracing studies. However, except for a previous report from this lab, unit recording from this area in relation to ASR has not been reported. In the present study, single unit responses in the PRF to startle-eliciting stimuli (S), along with neck EMG responses, were studied in unrestrained, behaving cats under a variety of stimulus conditions.

A total of 105 cells, which showed a response to eliciting stimuli between 90 and 120 dB, were examined. Most of these cells had thresholds over 90 dB, and were found in nucleus reticularis pontis caudalis, and rostral nucleus reticularis gigantocellularis, between P3 and P7. The majority (71%) of the auditory-responsive cells had latencies less than 20 msec: 39% 3-7 msec, 32% 8-19 msec. The spinal projections of 41 responsive and 38 non-responsive cells were antidromically determined by electrical stimulation of the cervical (C2) and lumbar (L1) spinal cord. Reticulospinal (RS) cells were significantly more likely than non-RS cells to respond to auditory stimuli (65% vs 35%). 59% (24 of 41) of the responsive cells had spinal projections, with .5-1.5 msec latency to C2 stimulation. Adding an average of 7 msec response latency to eliciting stimulus, the total time required for these cells to execute a response is within the range of neck EMG response (6-10 msec latency, 5-15 msec duration), consistent with a direct role of these neurons in startle elicitation. Behaviorally, most of these cells were related to head and facial movements, and received convergent inputs from deep superior colliculus, midbrain tegmentum, motor cortex, vestibular nucleus, neck muscles, and spinal cord.

The magnitude of the mammalian ASR can be suppressed by a prestimulus (P), a phenomena which has been termed "reflex inhibition". We found that discharges to S of the eleven PRF cells tested were also inhibited by the prestimulus (30%-90% inhibition, with 80 dB P, 110-120 dB S, and 80-100 msec ISI). The amount of inhibition on the units examined was comparable to that of EMG responses measured simultaneously. Manipulation of the intensity of the eliciting stimulus showed that the responses of PRF reticulospinal neurons paralleled the EMG startle response.

These results support the hypothesis that PRF is directly involved in startle elicitation, and that the modulatory process exerted by the prestimulus is occurring at or before PRF RS neurons.

(Supported by the V. A. and USPHS grant NS14610.)

21.11 **MODULATION BY PRESTIMULUS AND BACKGROUND NOISE OF MULTIPLE-UNIT ACTIVITIES IN THE INFERIOR COLLICULUS OF THE RAT: RELATIONSHIP WITH THE ACOUSTIC PINNA REFLEX.** M.-F. Wu* (SPON: D. McGinty). Department of Psychology, University of Rochester, Rochester, NY 14627.

The inferior colliculus (IC) has been implicated in prestimulus inhibition of the acoustic startle reflex in the rat. The present study correlated multiple-unit activities of the IC neurons with the simultaneously measured acoustic pinna EMG response, which has been suggested to be a component of the startle response, in spinally transected rats.

The pinna reflex followed the whole-body startle in all aspects of the effects examined: prestimulus frequency, prestimulus intensity, inter-stimulus interval, and the frequency of noise and noise-offset. High trial by trial correlations between the amplitude of the EMG response and that of the whole-body startle, measured with an accelerometer, were found, suggesting that the acoustic pinna reflex is part of the startle response and that similar modulatory mechanisms must be involved for both measures.

Significant correlations, either negative or positive, between neural discharges to the prestimulus and EMG startle amplitude were found in about 50% of the unit-clusters examined, supporting the notion that the IC is involved in prestimulus modulation. These units were found in all divisions of the IC. The sign of correlation, however, depended on the best frequency (BF) of the unit: mid- (5-15 KHz) and high-frequency (>15 KHz) units showed negative while low-frequency (<5 KHz) units showed positive correlations.

About 50% of the IC unit-clusters showed discharge suppression by prestimuli. Most of these inhibited-units were found in the dorsal cortex and the dorsal and rostral portion of the external cortex, and tended to have an on or pauser type response pattern. However, only those with a BF in the midrange showed a pattern of prestimulus effect parallel to that of the pinna EMG. Most units were affected by the background noise, either inhibition or facilitation, depending on the frequency of the noise and the BF of the unit, with no clear response type or anatomical specificity. Only the effects of the midrange units paralleled that of the EMG. Together with correlational analyses between spike and EMG startle responses, the results suggest that the startle mechanism must be mediated by neurons in the lower auditory system having midrange BF's and a phasic response pattern, and that there is a modulatory process occurring in the afferent limb of the reflex circuit which may be responsible for part of the effects produced by prestimuli and background noise. A partial functional and anatomical segregation within the IC regarding those neurons mediating reflex modification and those related to reflex elicitation was suggested.

21.12 2-DEOXYGLUCOSE STUDY OF THE PLANTAR CUSHION REFLEX IN THE CAT: THREE-DIMENSIONAL RECONSTRUCTIONS. D.P. Crockett*, W.K. Smith, E. Proshansky*, J.S. Kauer, W.B. Stewart, D.J. Woodward, D.S. Schlusselberg and M.D. Egger. Dept. of Anatomy, UMDNJ-R.W. Johnson Med. Sch., Piscataway, NJ 08854 and Dept. of Anatomy & Cell Biol., Univ. of Texas Hth. Sci. Ctr., Dallas, TX 75235.

As part of our interest in functional neuroanatomy, we report on three-dimensional reconstructions of spinal cord activity associated with a simple, highly stereotyped behavior as revealed by ^{14}C-2-Deoxyglucose (2-DG) serial autoradiographs. Our model behavior is the plantar cushion (PC) reflex, which is a downward flexion of the toes in response to moderate stimulation of the PC in cats.

Four chronically (4-11 days) spinalized cats were injected (i.v.) with 2-DG (100 μCi/Kg). The PC on one side was stimulated transdermally through needle electrodes (0.5 ms/pulse; 3 Hz; 45 min). At the termination of stimulation, the animals were deeply anesthetized and the spinal cords were quickly removed. Transverse, 32 μm-thick sections were cut on a cryostat. In general, six neighboring sections were saved for autoradiography and the next six discarded. Approximately 40 autoradiographs from each cat were chosen (≈16 mm A-P) for computer analysis and 3-D reconstruction using CARP (Computer Assisted Reconstruction Package) on a Data General MV-8000 II computer equipped with an Ikonas (Adage 3000) color raster graphics system. The images were digitized directly from the X-ray films. Minor artifacts were eliminated by a "bubble removal" routine. The images were "stretched" to correct for the geometrical anisometry of the digitization process. The data were normalized using the dorsal column white matter as a standard for background or minimal 2-DG activity.

Several strategies of analysis were employed: Three-dimensional volume images were color-coded to represent different levels of functional activity. On the reconstructed volumes, virtual sections were made in the horizontal, sagittal and transverse planes in order to view regions of 2-DG activity. Activity in various regions within the grey and white matter was quantified to reveal differences between ipsi- and contralateral regions within a section, as well as possible variations between sections.

The three-dimensional reconstructions confirmed the existence of stimulation-elicited heightened 2-DG activity dorsomedially in the lumbar dorsal horn of unanesthetized spinal cords.

21.13 THREE DIMENSIONAL AND MORPHOMETRIC STUDIES USING A COMPUTERIZED SPINAL INJURY DEVICE. B.T. STOKES, M.S. BEATTIE, J.C. BRESNAHAN, S.K. SOMERSON, P.A. WALTERS and M.S. ROSS, Depts. Physiol., Surgery and Anatomy, Ohio State University, Columbus, OH 43210

Previous reports have emphasized the behavioral and physiological sequelae of injuries produced with a feedback controlled injury device (Somerson and Stokes, 1987, Exp. Neurol. in press). Here a detailed reconstruction of lesions was performed on the spinal cords of three previously defined groups of spinal cord injured rats. Displacement (time and magnitude) of the spinal cord was controlled using biomechanical feedback during the injury process; the displacement amplitude was kept constant (1.54 +/- .02 mm) while the time of compression was varied between the groups. The three levels of injury were designated as light, intermediate, and heavy; impact durations were 14, 19, and 24 msec., respectively. Laminectomies were performed at midthoracic cord (T-9 or T-10) and the vertebral column was rigidly fixed during injury by using vertebral clamps rostral and caudal to the exposed cord. Such paradigms have been shown in previous reports to result in predictable courses of partial behavioral recovery using several indices of locomotor mobility, postural compensation, and fine motor control.

Morphological results reinforced the behavioral and biomechanical data. Morphometric analysis using a Zeiss Videoplan system revealed that lesion length and to a lesser extent lesion volume (based on biconical frustum analysis) were correlated with biomechanical measures of the impact. An automated MINC-11/23 system was also used to produce three dimensional reconstructions of the lesions to test the assumption of the biconical nature of the lesion volume and see if the behaviorally identical heavy and intermediate groups had geometrically different lesions. As previously reported, the light injury group showed anatomical sparing at the lesion epicenter (66.2%); this evolved into an ovoid shaped lesion in the rostral and caudal neuropil. Intermediate and heavy impacts, however, produced lesions over much greater distances with a displacement of lesion sites toward the dorsal columns in adjacent rostral and caudal sections. Geometric analysis therefore suggests that although after a certain point, biomechanical parameters may lose their sensitivity as behavioral predictors (i.e. once the neuropil and fiber tracts are destroyed at the lesion epicenter), they continue to be useful as predictors of lesion geometry. Such analysis may be of some import to those therapeutic attempts (drugs or spinal transplants) which could potentially alter secondary necrosis after spinal injury. (Supported by USPHS-10165)

21.14 FAILURE TO DEMONSTRATE AXONAL SPROUTING AFTER SUBTOTAL SPINAL CORD LESIONS IN RATS. J.W. Little, R.M. Harris, R.C. Sohlberg*. Seattle V.A.M.C. and Univ. of Washington, Seattle, WA, 98108

Significant recovery of motor function is common following subtotal spinal cord lesions in experimental animals and human patients. Axonal sprouting or growth of new terminals by spared descending pathways is one postulated mechanism to explain this motor recovery. This study attempts to demonstrate sprouting by spared descending pathways in rats undergoing subtotal spinal cord section, utilizing anterograde labeling with horseradish peroxidase (HRP).

Adult female rats underwent partial section of the spinal cord in the mid-thoracic region, sparing either the left lateral and/or ventral funiculi. After four weeks of motor recovery in which considerable return of hindleg postural and locomotor abilities was observed, an injection of 30% HRP, using a glass micropipette and iontophoresis, was made into the left side of the lumbosacral enlargement. Anterograde labeling of commissural fibers and terminals in these rats was compared with similar labeling in non-lesioned controls. In all cases the injections themselves were confined to the left half of the cord, but anterogradely labeled fibers were seen crossing to the right side of the cord.

At high magnification, numerous labeled terminals could be seen along axons, both as en passant boutons and at the ends of short collateral branches. No significant differences could be found in the location or extent of crossing fibers or boutons between the lesioned rats and the control rats. No abnormal terminal morphology was observed in the lesioned rats which might indicate sprouting. The average number of terminals per unit length of individual axons was not increased in lesioned rats over controls. We have thus found no evidence for sprouting of commissural axons four weeks after a subtotal spinal cord lesion. This may be due to technical problems in demonstrating sprouting, or may indicate that axonal sprouting does not play a major role in motor recovery.

21.15 EFFECT OF 4-AMINOPYRIDINE ON ACTION POTENTIAL CONDUCTION IN MYELINATED AXONS OF CHRONICALLY INJURED SPINAL CORD A. R. Blight, Departments of Neurosurgery and Physiology & Biophysics, NYU Medical Center, New York, NY 10016.

Severe mechanical trauma to the spinal cord results in rapid local destruction of most axons, followed by a slower demyelination of many of the surviving axons. Partial remyelination occurs in succeeding weeks, but leaves many axons thinly and irregularly myelinated at the lesion site. This is reflected in deficits of action potential conduction, including conduction block at physiological temperature (Blight, *Neuroscience*, 10: 1471, 1983).

The K^+ channel blocker 4-aminopyridine (4-AP) may be useful in treatment of demyelinating conditions (reviewed by Stefoski et al., *Ann. Neurol.*. 21: 71, 1987). The drug was therefore tested in an *in vitro* preparation of injured spinal cord, prior to *in vivo* tests on conduction in descending pathways (see Gruner et al., this meeting). The recording techniques and injury model have been described in detail (Blight, 1983; Blight & DeCrescito, Neuroscience 19: 321, 1986). In this study, the spinal cords of 12 adult female cats were injured, under pentobarbital anesthesia, by an 8 g weight dropped 20 cm onto the exposed dura at T9, with the vertebral body mechanically stabilized. Animals were maintained with specialized care for 4-11 months post injury, then the thoracic spinal cord was isolated *in vitro*. Microelectrode recordings were made from single myelinated axons that conducted across the chronic lesion site, in ventral and lateral tracts.

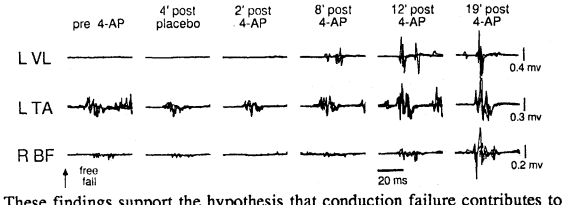
The majority of tested axons (68%) in spinal cords from chronically paralyzed animals were blocked at temperatures below 36°C, compared with only 19% in those animals that showed some recovery of postural and locomotory function. Of 8 axons in which it was possible to demonstrate a conduction block, briefly apply 0.5 mM 4-AP, wait for up to 10 minutes and test the temperature of conduction block again, 2 showed substantial improvement in safety factor, with conduction block raised from 29 and 30°C to >37°C. (Following exposure to 4-AP, the absolute refractory period at 37°C was 4 ms in one of these axons.) Two other fibers showed modest increases in blocking temperature of only 2-3°C, sufficient to produce conduction at 37°C in one axon, but not the other. Four other fibers showed no change in the temperature of conduction block with exposure to 4-AP. Another striking effect of the drug was an increase in spontaneous activity of axons in the white matter, which are usually silent in the isolated preparation. 4-AP produced spontaneous bursting in 64% of axons that failed to conduct across the lesion, and in 35% of those that did conduct at 25°C in chronically paralyzed animals. 18 axons conducting through the lesion in recovering animals were exposed to 4-AP, but none of these became spontaneously active.

It was concluded that 4-AP may be useful in the treatment of chronic spinal cord injuries, both because it improves safety factor in a proportion of axons and because it increases excitability in others, which may compensate to some extent for loss of information in parallel channels. Nonetheless it appears that much of the conduction loss in the chronic lesion is not reversed, even by quite high levels of 4-AP, and further investigation of the physiological and structural basis of those conduction deficits is required. (Supported by contract TC 85-02 from the American Paralysis Association and by grant NS21122 from NIH/NINCDS).

21.16 RECOVERY OF MOTOR FUNCTION IN CHRONIC EXPERIMENTAL SPINAL CORD INJURY ENHANCED BY 4-AMINOPYRIDINE. J.A. Gruner, A.R. Blight, M. Petruziello*. Depts. of Neurosurgery and Physiology & Biophysics, NYU Medical Ctr., NY, NY 10016.

In order to investigate factors underlying recovery of function after chronic spinal cord injury, we have developed a technique for assessing motor function in animal models of spinal cord injury, based on hindlimb EMG free-fall responses (FFR) (Gruner et al., *CNS Trauma* 1: 139, 1984). Standardized contusion injury of cat spinal cord (Blight & DeCrescito, *Neuroscience*, 19: 321, 1986) produces chronic loss of 90-95% of white matter at the injury site, resulting in near complete paraplegia and severe attenuation of FFR. These chronic deficits may result at least partly from demyelination of the lesion site (Blight, *Neuroscience*, 10: 1471, 1983). Recently, 4-aminopyridine (4-AP) has been reported to improve function and axonal conduction in human and experimental demyelinating lesions. We therefore examined the effect of this drug on injured spinal cord.

Seven adult female SPF cats were injured using the weight drop technique. Under pentobarbital anesthesia, the T9 spinal cord was exposed, and an 8 or 10 gm weight dropped 20 cm onto the dura, with the vertebral body rigidly supported. The sterile incision was closed and the animals allowed to recover. They were maintained with specialized care and were tested 3-7 months later, together with 4 uninjured cats. The animals were sedated with 25 mg/kg ketamine i.m. and placed in a harness for the controlled drop. Free-fall lasted 200 ms; the harness was then decelerated by rubber tubing. EMG's were recorded from vastus lateralis (VL), tibialis anterior (TA), biceps femoris (BF), and medial gastrocnemius (MG) bilaterally. Four sets of 8 drops were obtained at the start of testing and at 5', 10', and 15' after i.v. injection of 1 mg/kg 4-AP; in some animals drops were also obtained after placebo injections. The figure shows an example of the effect of 4-AP on FFR in one injured cat. The mean peak-peak FFR amplitude in injured cats increased from 28 to 138 μV over 15 min. from 4-AP injection ($p<0.006$, paired t-test). In the normal cats, there was an apparent increase from 1.86 to 2.89 mV (NS).



These findings support the hypothesis that conduction failure contributes to functional deficits. 4-AP may also act through enhanced synaptic transmission in the lumbar cord; we have noted that FFR in injured cats are sometimes facilitated by limb manipulation or peripheral electrical stimulation.. (Supported by contract from the American Paralysis Association and NIH grants NS21122 & NS10164).

21.17 A NEW PHARMACOLOGIC APPROACH TO SPINAL CORD INJURY: STUDY USING A DYNAMIC INJURY MODEL IN RATS.
S. Tsuyoshi Ohnishi, James K. Barr* and Chika Katagi*. Membrane Research Institute, University City Science Center, Phila, PA 19104.

It is accepted that traumatic spinal cord necrosis takes place in two steps, i.e., primary injury accompanied by an immediate loss of action potential and rapid ion movements (calcium influx and potassium efflux), and secondary injury which, in several hours, leads to cell necrosis. Thus, the rationale for therapy should be to intervene in these steps. We have been studying irreversible membrane damage of sickle red blood cells(1,2), and found close similarity between the mechanism of spinal cord necrosis and that of sickle cell membrane damage. Namely, (a) reactions seem to be initiated by calcium influx, (b) entering calcium ions activate movement of monovalent cations, and (c) this movement causes water transport, leading ultimately to cell necrosis. We found that two types of drugs can prevent damage of sickle cell membranes (2,3), i.e., (i) inhibitors of the calcium-activated potassium efflux (e.g., quinine), and (ii) drugs which interact with calmodulin (such as chlorpromazine; CPZ). Therefore, we hypothesized that these drugs may have a beneficial effect in spinal cord injury. Using Sprague-Dawley rats (200-250 g) and a dynamic weight-drop (10 g x 5 cm) technique(3), we tested the effect of drugs (one bolus addition; i.p. 30 minutes prior to injury). Motor recovery was estimated using the modified Tarlov score(3). Four weeks after injury, the Tarlov score was 2.2±0.5 (n=10) in non-treated group, but the score improved to 4.4±0.7 (n=5) in a quinine-administered group (20 mg/kg body weight) and to 4.0±0.5 (n=5) in a CPZ-administered group (20 mg/kg) Difference between non-treated and drug-treated groups was significant ($P<0.01$). Other potassium channel inhibitors also demonstrated a beneficial effect. Measurement of water content as well as assay of Ca, Na and K contents by atomic absorption method(4) demonstrated that these drugs inhibited movement of water and cations. Morphometric study also confirmed the beneficial effects of these drugs. References: (1) Ohnishi et al.(1986) Biochim. Biophys. Acta 886:119. PHARMACOLOGY OF SYNAPTIC TRANSMISSION I

22.1 MONOSYNAPTIC CONNECTIONS BETWEEN CEREBELLAR GRANULE AND PURKINJE CELLS IN DISSOCIATED CELL CULTURE.
T. Hirano* and S. Hagiwara. Dept. of Physiology, Jerry Lewis Neuromuscular Research Center and Ahmanson Laboratory of the Brain Research Institute, School of Medicine, UCLA, Los Angeles, CA 90024.

Synaptic properties between neurons in the mammalian central nervous system can be most thoroughly investigated in dissociated cell cultures, because of good visibility and accessibility. Previous work (Hirano et al., PNAS 83:4957, 1986) has established synaptic formation between identified cerebellar granule and Purkinje cells in dissociated cell culture. Using these identified cells, we are attempting to characterize the transmitter and the receptor on the postsynaptic membrane. It has been suggested that the transmitter is glutamate, and the recent work by Kano and Kato (Nature 325:276, 1987) suggests that the postsynaptic receptor channel is a quisqualate (QUIS) receptor as opposed to a kainate or N-methyl-D-aspartate (NMDA) receptor.

Neurons were dissociated from cerebella of rat prenatal embryos about 18 days of gestation (for Purkinje cells) and from cerebella of 6-8 day old rats (for granule cells). The dissociated cells were mixed and cultured for 4 weeks before experiments. Simultaneous whole cell clamp recordings were performed on the presynaptic granule and the postsynaptic Purkinje cell somata at room temperature (20-22°C). Monosynaptic connections between two cells were identified by a short (2.5-6.5 msec) and constant latency of excitatory postsynaptic current (epsc). In several pairs of cells the granule cell was filled with lucifer yellow and the Purkinje cell with propidium iodide, and their morphological contact was observed under fluorescent light. Kynurenate, an excitatory amino acid antagonist, abolished the monosynaptic epsc at 1 mM without affecting the presynaptic action potential. DL-2-amino-5-phosphonovaleric acid (APV), a specific antagonist for NMDA receptors, had no effect on the monosynaptic epsc at 0.5 mM in the normal external solution containing 1 mM Mg. Kynurenate inhibited both externally applied glutamate and aspartate induced inward current in Purkinje cells, and APV inhibited the aspartate response while having little effect on the glutamate response. The above results indicate that glutamate is more likely to be the transmitter than aspartate and that a non-NMDA receptor is working on the postsynaptic membrane. Finally we examined the effect of QUIS on a Purkinje cell. QUIS decreased the amplitude of the epsc and increased steady inward current in a dose dependent manner, and the amount of decrease of the amplitude of the epsc by QUIS paralleled the amplitude of QUIS induced inward current. This result is consistent with the presence of QUIS receptors on the postsynaptic membrane, and suggests that QUIS binds to the postsynaptic receptors and reduces the number of receptors available for released transmitter.

22.2 LITHIUM BLOCKS PI MEDIATED TRANSMITTER ACTION IN RAT BRAIN: ELECTROPHYSIOLOGICAL STUDIES IN THE HIPPOCAMPAL SLICE.
J.M. Baraban, P.F. Worley, W. Heller, S.H. Snyder. Department of Neuroscience, Johns Hopkins University School of Medicine, Baltimore, MD 21205.

Since lithium blocks the re-cycling of inositol phosphate, it has been hypothesized that this effect on the PI system may contribute to its therapeutic action in affective illness. In previous studies using a smooth muscle preparation, we have demonstrated that therapeutic concentrations of lithium alter transmitter induced contractile responses thought to be mediated by the PI system (Menkes et al., PNAS 83:5727, 1986). Using the hippocampal slice preparation, we have recently demonstrated that muscarinic agonists block the inhibitory actions of adenosine by stimulating protein kinase C, via the PI cycle (Worley et al., PNAS, in press). Accordingly, to examine whether lithium affects PI mediated transmitter responses in brain, we have investigated its effects on muscarinic blockade of adenosine.

Field potentials elicited by stimulation of Schaffer collaterals were recorded from the CA1 pyramidal cell layer. As lithium might be expected to affect the PI system after prolonged stimulation, we first assessed the ability of carbachol (50 μM), which was used to drive the PI system, to block adenosine over the course of a one hour incubation. In these preliminary experiments, we found that in about two-thirds of slices tested, carbachol's blockade of adenosine remained intact for one hour, while in the remainder we observed variable degrees of rundown of carbachol's action. To reduce variability in assessing the effects of LiCl on this response, we studied slices in which carbachol's block of adenosine was preserved following a 1 hr incubation. At this point, carbachol was washed off and slices were then treated with either control saline, LiCl (1 or 2 mM) or RbCl (2 mM) for 1 hr and then re-exposed to carbachol. These concentrations of LiCl or RbCl did not alter baseline synaptic responses or adenosine's ability to completely inhibit the population spike. However, in the LiCl treated slices, carbachol's ability to block adenosine fatigues within 15 minutes, whereas in control or RbCl treated slices, it does not. Interestingly, phorbol 12,13-diacetate (1-2 μM), an activator of PKC, still blocks adenosine when carbachol is ineffective, suggesting that fatigue produced by lithium is proximal to activation of PKC and may reflect its action on the PI cycle.

22.3 EFFECTS OF L-VESAMICOL (L-AH5183) ON NEUROMUSCULAR TRANSMISSION R.F.Halliwell*, C.Prior* and I.G.Marshall* (SPON: N.N.Durant) Dept. of Physiol. & Pharmacol., Univ. Strathclyde, Glasgow G1 1XW, Scotland, UK.

Vesamicol (AH5183, 2-(4-phenylpiperidino) cyclohexanol) produces a frequency-dependent block of neuromuscular transmission (Marshall,I.G., Brit.J.Pharmacol., 38: 503, 1970) and an inhibition of the uptake of acetylcholine by isolated synaptic vesicles (Anderson et al., Molec.Pharmacol., 24: 48, 1983). Vesamicol possesses one assymetric center in the C ring, and the L-isomer has been shown to be the active form in isolated vesicles (Bahr,B.A. & Parsons,S.M., P.N.A.S., 83: 2267, 1986). In this study, we have examined the effects of the two isomers of vesamicol on neuromuscular transmission in the isolated contracting rat hemidiaphragm, and the effects of L-vesamicol on miniature endplate potentials (MEPPs) in isolated mouse diaphragm and end-plate currents (EPCs and MEPCs) in snake costocutaneous nerve-muscle preparations.

In the rat hemidiaphragm L-vesamicol was 20 times more potent at reducing twitches elicited at 1Hz than was D-vesamicol. This finding agrees well with results obtained from isolated synaptic vesicles. In contrast, the two isomers were equieffective in producing twitch augmentation in the hemidiaphragm prior to the neuromuscular block. L-vesamicol was examined in more detail on the hemidiaphragm and found to exhibit similar blocking characteristics to those of racemic vesamicol, i.e. a frequency-dependent block not reversed by anticholinesterases or by choline. However, the block produced by L-vesamicol (5 x 10^{-6}M) was partially relieved by 3,4-diaminopyridine (10^{-4}M).

In the stimulated mouse hemidiaphragm preparation (5Hz for 20 min) L-vesamicol (10^{-5}M) reduced the amplitude of MEPPs. In the presence of L-vesamicol there was a wider spread of MEPP amplitudes than in the absence of the drug, with the appearance of apparently normal-sized MEPPs amongst the small MEPPs. In some preparations it was possible to increase the occurence of these normal-sized MEPPs by the addition of lanthanum (2 x 10^{-4}M). In the voltage-clamped snake muscle L-vesamicol (2.5 x 10^{-6}M) produced a marked increase in MEPC frequency and a reduction in EPC amplitude after rapid nerve stimulation. No changes were observed in the rate of decay of EPCs or MEPCs indicating a lack of effect of vesamicol on endplate ion channels. The reversing effect of aminopyridines and the ability to release normal-sized quanta in the presence of vesamicol block may indicate that it is possible to release a store of transmitter not normally released after block by vesamicol.

22.4 Selective Inhibition of Protein Kinase C mimic the actions of Acetylcholine in "in vivo" hippocampus. N.Agopyan & K.Krnjevic, Departments of Anaesthesia Research and Physiology,McGill University, Montreal, Quebec,H3G 1Y6 Canada.

Tumor-promoting phorbol esters mimic diacylglycerol (Nishizuka,Y 1984,Science,225:1365) by activating protein kinase C. The muscarinic action of ACh in hippocampus is postulated to accelerate the turnover of inositol phospholipids and recently it was reported that phorbol esters mimic some of the actions of muscarinic agonists, such as blocking the slow afterhyperpolarization (Malenka et al.,1986,J. Neurosc.,6:475). This led us to investigate the effects of selective activation and inhibition of protein kinase C on synaptic transmission in the hippocampus in situ.

All experiments were carried out on Sprague Dawley rats anaesthetized with urethane and maintained in a stereotaxic head frame. Extracellular field potentials, induced by fimbrial stimulation (0.6 Hz), were recorded simultaneously in the CA1 stratum pyramidale and stratum radiatum with the central barrels of 5-and 3-barrelled pipettes separated by a vertical inter tip distance of 200-250 um. Peripheral barrels were used for iontophoretic application of phorbol 12-13-diacetate (PDAc:7.43 mM;14-56 nA), 1-2 methylpiperazine dihydrochloride (H-7: 8 mM; 14-56 nA), acetylcholine chloride (ACh 500 mM; 28-56 nA) and NaCl (3M,56-140 nA).

Applications of PDAc in stratum pyramidale increased the amplitude of the somatic population spike and decreased its latency; but unlike ACh (Rovira et al.,1983,Neuroscience,8:97) it never induced multiple spikes. Application of PDAc in the apical (stratum radiatum) dendritic layer increased the amplitude of the negative field and decreased its latency, which in turn caused an increase in the somatic population spike amplitude and a decrease in its latency. If the stimulation intensity was below threshold for evoking a population spike, PDAc application at either somatic or dendritic level induced the appearance of a population spike, which gradually increased in amplitude and decreased in latency.

On the other hand, H-7 which is the most potent and selective protein kinase C inhibitor (Kawamoto S.& Hidaka, H.,1984, Biochem. Biophys.125, 258) when applied in stratum pyramidale increased the amplitude and the number of population spikes induced by fimbrial stimulation. Application of H-7 in dendritic layer increased the amplitude and the duration of the negative field. H-7 also induced the appearance of a population spike at a stimulation intensity which was below threshold for inducing the population spike. The effects induced by H-7 were reversed by PDAc. PDAc and H-7 induced their effects approximately 20-40 s after the start of application. Unlike ACh they had a longer lasting action. Recovery was usually observed 10-15 min after the termination of injection.

These observations provide evidence that ACh may act via inhibition of protein kinase C rather than activation.

22.5 **INFLUENCE OF CYTOCHALASIN B ON SPONTANEOUS AND DRIVEN ACTIVITY IN RAT SOMATIC SENSORY CORTEX.** H.-M. F. Hwang, S.M. Lee* and F.F. Ebner, Center for Neural Science, Brown University, Providence, R.I. 02912.

Extrinsic inputs to the cerebral cortex terminate mainly on dendritic spines of cortical neurons. Dendritic spines contain a high percentage of the actin found in cortex (Matus, *et al.*, P.N.A.S., 1982). Our experiments tested the hypothesis that transient depolymerization of actin would produce reversible decreases in synaptic efficacy at axospinous synapses. The test consisted of ventricular or local injection of the actin polymerization blocking agent, cytochalasin B (CB), while recording the spontaneous activity and responses to whisker movement in PMBSF SI neurons. Since CB requires DMSO to go into solution, experimental and control injections were made simultaneously in the two hemispheres; the effect of vehicle alone in the left hemisphere was compared to the effect of injecting vehicle plus CB in the right hemisphere for 10-12 hours after injection.

Glass micropipettes, 1.2 mm O.D. for recording and 2.0 mm O.D. for injection were assembled so that the tips were separated by 1.5 mm. Two pairs were placed symmetrically in the part of the barrelfield representing usually the D5 whisker in 5 adult Long-Evans rats under urethane anesthesia. The depth was fixed so that the injection was into layer IV and the recording was from layer V neurons. 4 ul of Ringers solution with 1% DMSO was injected into the left hemisphere and 4 ul this vehicle plus 10^{-4} M CB into the right hemisphere.

A predictable sequence of changes in spontaneous activity and stimulus evoked neuronal discharges occured following injection of CB, that were never observed with the vehicle alone. Normal cell activity followed both injections for approximately 30 min before the CB side started to show a slowly progressing diminution in spontaneous bursting of layer V pyramidal cells. Near total absence of spontaneous activity lasted for less than 1 hour on the CB side, during which time no stimulus-evoked action potentials could be elicited by whisker movement. Eventually in all animals an altered type of spontaneous activity returned on the CB side. The alteration took the form of: 1) a decrease in the number of spikes per burst (without altered interspike interval), 2) an increased interburst interval, 3) an increase in epileptiform activity and spindling, 4) a decrease in the amplitude of spontaneous spikes and 5) a decrease in the number and amplitude of spikes per stimulus-evoked response. These alterations persisted for at least 8 hours before the responses showed a trend toward a return to normal. We are investigating whether complete recovery occurs at very long survival times and the possible mechanisms that may be responsible for the changes in synaptic properties induced by CB. (supported by ONR grant #NOOO-14-811-K-0041)

22.6 GONADAL STEROID EFFECTS ON ATP-STIMULATED SODIUM TRANSPORT IN PIG BRAIN SYNAPTOSOMES. C. Rollin*, A. Arieff*, C. Fraser*, J. Kucharczyk, D. Norman* and P. Sarnacki*. Departments of Medicine and Radiology, University of California, San Francisco, CA 94143.

The principal female gonadal hormones, estrogen and progesterone, have been shown to elicit rapid changes in brain cell membrane permeability and conductance, leading to modifications of membrane functions. The subcellular basis for some of these changes was investigated in synaptosomes isolated from different regions of the brain of prepubertal micropigs. Synaptosomes are resealed vesicles from nerve endings isolated by homogenization and differential centrifugation on a discontinuous Ficoll gradient, and are morphologically intact and metabolically active. ATP stimulated sodium uptake was measured in inverted vesicles in the presence and absence of steroid hormones. Either estradiol-17B or progesterone was added to the incubation media at concentrations of 0.01-100 ng/ml and 1-1000 ng/ml, respectively. Sodium uptake was then measured at 5 minutes. All concentrations of estradiol resulted in a significant ($p < 0.001$) decrease in sodium uptake with the maximum inhibitory effect exerted at a physiological concentration of 100 pg/ml. The average sodium uptake decreased from 6.3 ± 0.3 to 5.4 ± 0.3 nmoles/mg synaptosomal proteins. Similarly, progesterone at all concentrations inhibited sodium uptake with the maximum inhibitory effect observed at 1000 ng/ml. All areas of the brain (cerebral and cerebellar cortex, pons, basal ganglia, septum) showed significant ($p < 0.001$) progesterone-induced reduction in sodium uptake (6.6 ± 0.3 to 4.7 ± 0.5 nmoles/mg protein). Previous studies have demonstrated an inhibitory interaction between progesterone and Na-K-ATPase in cardiac muscle cells and erythrocytes. Sex differences have also been observed in Na-K-ATPase activity in human erythrocytes. The results of the present study suggest that both estrogen and progesterone also significantly inhibit ATP stimulated sodium uptake in pig brain synaptosomes.

22.7 IS VASOACTIVE INTESTINAL POLYPEPTIDE (VIP) THE VASODILATOR TRANSMITTER IN CEREBRAL ARTERIES? T.J-F. Lee, Y. Shirasaki*, S.D. Shillcutt*, and S. Sarwinski*, Department of Pharmacology, Southern Illinois University School of Medicine, Springfield, IL 62708.

Dense VIP-like immunoreactive fibers have been shown to be present in pial vessels from several species. Ultrastructural immunocytochemical studies demonstrate that the VIP-like immunoreactivity is present in the neuronal granular vesicles of the nonsympathetic nerves. Release of the immunoreactive VIP upon excitation of these nonsympathetic nerves has been demonstrated in cat pial vessels. Furthermore, VIP induces vasodilation, which is independent of endothelial cells, and antibodies against VIP block the transmural nerve stimulation (TNS)-induced vasodilation. These results suggest that VIP is the potential vasodilator transmitter in cerebral blood vessels, although the direct evidence for demonstrating the vasodilator responses to the endogenously released VIP has not been presented. Therefore, the present study was designed to further investigate the potential role of VIP as the cerebral vasodilator transmitter. The results from in vitro tissue bath study indicate that in cat cerebral arteries VIP receptor antagonists such as (N-Ac-Tyr^1,D-Phe^2)-GRF$_{(1-29)}$-NH$_2$ and (D-P-chloro-Phe^6, Leu^{17}) VIP, blocked the exogenous VIP-induced relaxation but did not affect the TNS-induced relaxation. Hemoglobin and methylene blue, which are known to inhibit the cyclic GMP synthesis, blocked the TNS-induced vasodilation, suggesting that the TNS-induced relaxation is mediated by cyclic GMP system. Exogenously applied VIP, however, enhanced cyclic AMP levels but did not affect those of cyclic GMP. These results are inconsistent with the hypothesis that VIP is directly involved in the TNS-induced vasodilation in cerebral arteries. (Supported by NIH HL 27763 and AHA/IHA 83-1040.)

22.8 LINDANE BUT NOT DELTAMETHRIN BLOCKS A COMPONENT OF GABA-ACTIVATED CHLORIDE CHANNELS. N. Ogata*, S.M. Vogel* and T. Narahashi (SPON: J. Frey). Department of Pharmacology, Northwestern University Medical School, Chicago, IL 60611.

The pyrethroid insecticide, deltamethrin, has been shown to inhibit the binding of a radioligand for the picrotoxinin-recognition site in rat brain synaptic membranes (Lawrence, L.J. and J.E. Casida, Science, 221:1399, 1983), suggesting a possible interaction between pyrethroids and the $GABA_A$ receptor-ionophore complex. In addition, another class of insecticides, lindane (the gamma isomer of hexachlorocyclohexane), produces CNS hyperexcitability similar to that caused by known GABA antagonists in mammals. We, therefore, examined direct interactions between these insecticides and the GABA-activated ionic channels, using cultured neurons of the newborn rat dorsal root ganglia (DRG). The membrane of the DRG cell was voltage-clamped using the whole cell patch clamp technique. GABA (10^{-5}M) produced an inward current of about 0.5 nA which comprised an initial peak and sustained components. The initial peak component decayed rapidly, whereas the sustained component persisted throughout the superfusion of GABA. An increase in GABA concentration after the decay of the initial component or repeated application of a single concentration of GABA within short intervals produced only the sustained component. Therefore, the initial peak and sustained components appeared to reflect desensitizing and non-desensitizing components, respectively. Both components had the same reversal potential of about -50 mV when internal and external concentrations of Cl^- were 20 mM and 130 mM, respectively. The reversal potential was shifted in a manner predicted by the Nernst potential for Cl^- when external Cl^- concentrations were altered. Co^{2+} (2 mM) and tetrodotoxin (2 x 10^{-6}M) had no effect on the GABA-induced inward current. Both desensitizing and non-desensitizing components were readily blocked by bicuculline (10^{-6}M), indicating that the inward current induced by GABA was $GABA_A$ receptor-mediated. Lindane (10^{-5}M), which had no effect on any of the voltage-gated sodium, potassium, or calcium channels, readily suppressed the initial peak component of the GABA-induced Cl^- current, without affecting the sustained component. On the contrary, deltamethrin, which markedly modified the sodium channel kinetics, had no effect on the GABA-induced Cl^- current. These results indicate that the action of lindane, but not of deltamethrin, appears to involve interaction with the $GABA_A$ receptor-ionophore complex. Our results that the initial peak component was preferentially blocked by lindane might indicate that there are two types of $GABA_A$ receptor-Cl^- channel complexes in rat DRG cells.

22.9 ETHANOL HAS NO EFFECT ON GABA-INDUCED MEMBRANE CURRENT IN CELLS CULTURED FROM DISSOCIATED EMBRYONIC RAT HIPPOCAMPUS S.Huck, R.Gratzl+ and F.Grießmayer+, Dept.of Neuropharmacology, University of Vienna, A-1090 Vienna, Austria.

Recent studies indicate that ethanol stimulates GABA-mediated $^{36}Cl^-$ transport in rat brain synaptosomes (Suzdak et al., PNAS 83, 4071, 1986). The ethanol-mediated $^{36}Cl^-$ influx is selectively blocked by the imidabenzodiazepine Ro 15-4513 (Suzdak et al., Science 234, 1243, 1986).

Electrophysiological data of ethanol effects on the GABA system are, however, conflicting. We therefore investigated the GABA-ethanol interrelationship by means of the patch clamp technique in cultured hippocampal cells.

The hippocampal tissue of 18 day old embryos was dissociated and maintained in culture by conventional procedures. Recordings were performed within 2 to 7 days after plating. Patch pipettes were filled with (mM): CsCl (104), TEA-Cl (16), $CaCl_2$ (0.19), EGTA (4), glucose (8), HEPES (8), pH 7.3. The bathing solution was NaCl (120), KCl (3), $CaCl_2$ (2), $MgCl_2$ (2), glucose (20), HEPES (10), pH 7.3. Substances were applied close to the cells by means of a 5-barrel needle device, capped by a glass capillary with a tip diameter between 100 and 150µ. The fluid, ejected by hydrostatic pressure, was stopped or allowed to flow by pneumatic pressure-controlled cylinders developed in our laboratory.

The application of GABA induced dose-dependant, rapidly inactivating inward currents in cells clamped at negative holdings potentials. In the presence of 100µM pentobarbital, GABA responses were markedly enhanced. Pharmacologically relevant concentrations of ethanol, ranging from 10 to 100mM, neither induced changes in membrane conductance when the substance was given alone, nor did they potentiate or inhibit the effect of 5µm GABA when applied in combination.

At the present, we do not know why ethanol stimulates the influx of $^{36}Cl^-$ in synaptosomes and potentiates the action of GABA-ergic substances in this preparation, whereas it is devoid of such effects when investigated in cultured hippocampal cells with electrophysiological techniques.

22.10 SODIUM VALPROATE DECREASES EXCITATORY SYNAPTIC POTENTIATION IN THE IN VITRO HIPPOCAMPUS. W.H. Griffith and L. Taylor*. Department of Medical Pharmacology and Toxicology, Texas A&M University, College Station, Texas 77843

Evidence is available to suggest a significant involvement of excitatory synaptic transmission in the generation and spread of epileptiform activity in the hippocampus. One mechanism responsible for short term synaptic enhancement is post-tetanic potentiation (PTP); and under certain conditions, potentiation within a network of cells will result in an epileptiform event or paroxysmal depolarizing shift (PDS). We studied the effects of the anticonvulsant sodium valproate (NaVP) on, first, the magnitude and time course of PTP and, second, the ability of NaVP to inhibit PDS generation. We report that NaVP (30-200 µM) decreases the magnitude but not the time course of PTP of the dendritic CA1 field excitatory postsynaptic potential (EPSP); and 100 µM NaVP reduces PDS generation in CA3 pyramidal cells.

Transverse slices of hippocampus from adult rats (175-200 gms) were cut using a McIlwain tissue chopper and transferred to a holding chamber where they were maintained for 1-2 hours before use. NaVP was first dissolved in distilled water and then diluted to a final concentration in the physiological solution. Extracellularly recorded field EPSPs were recorded from the apical dendrites of CA1 pyramidal cells following Schaffer-collateral stimulation. Intracellularly recorded EPSPs and excitatory postsynaptic currents (EPSCs) were recorded in CA3 pyramidal cells following mossy fiber stimulation. Reproducible episodes of PTP could be recorded in the same preparation using a conditioning paradigm of 100 Hz stimulation for 1 sec. Every slice served as its own control and results were analyzed using a two-tailed paired T test. Under control conditions, PTP of the dendritic EPSP exhibited increases of 200-250% of control and declined with a time constant of decay 50-100 ms (N=31). NaVP at concentrations of 30-200 µM significantly ($P<0.05$) decreased the amplitude of PTP but did not change its time course (N=8 at each concentration).

A second series of experiments studied EPSCs of the mossy fiber to CA3 synapse. In disinhibited slices (addition of 10-20 µM picrotoxinin), enhancement of excitatory synaptic responses can lead to the network-evoked PDS. Under voltage clamp recording conditions, the underlying synaptic current can be studied at different potentials and the synaptic conductance quantified. NaVP (100 µM) depressed the generation of the PDS (N=5) and reduced the synaptic conductance during the network event. One anticonvulsant action of NaVP may be to reduce excitatory synaptic potentiation resulting in a reduction in the ability of nerve networks to generate epileptiform episodes (Supported by NIH grant NS22456).

22.11 DIFFERENTIAL EFFECTS OF FOUR-AMINOPYRIDINE ON SYNAPTIC TRANSMISSION IN BULLFROG SPINAL CORD IN VITRO . N.C. Tkacs* and R.D. Wurster . Department of Physiology, Loyola University Medical Center, Maywood, IL 60153.

The potassium channel blocking drug, 4-aminopyridine (4-AP), is thought to potentiate synaptic transmission by prolonging the action potential at synaptic terminals, thus facilitating calcium entry. We have studied the effects of this compound on ventral root responses (VRRs) to lateral column (LC) and dorsal root (DR) stimulation in the isolated bullfrog hemicord.

Spinal cords were removed from four bullfrogs by standard methods. After hemisection, the caudal hemicord is placed in the superfusion chamber and eighth or ninth dorsal and ventral roots are led into adjacent mineral oil pools for stimulation and recording. Tungsten wire electrodes are advanced into the lateral funiculus to stimulate descending motor pathways. The cord is continually superfused with oxygenated bicarbonate-phosphate buffered Ringer's solution. Temperature is maintained at 12 C.

The stimulation protocol for the two experimental preparations and time- and stimulation-matched controls was as follows: Period I - 50 minutes, stimulation every two minutes, alternating LC and DR supramaximal stimuli; Period II - 50 minutes, stimulation every two minutes in the presence or absence of 5 uM 4-AP; Period III - 60 minutes, stimulation every two minutes, then less frequently for 3 to 5 hours.

4-AP appeared to affect only the DR-VRR. During Period III the average DR-VRR in the 4-AP group was 75% larger than control. In contrast, the LC-VRR during the same period was 1.5% smaller in the 4-AP group compared to control. Data from the remaining three hours of washout show a similar augmentation of the DR-VRR in the 4-AP group of 94% over controls, while the LC-VRR was 16% smaller in the 4-AP group.

One possible explanation for this difference is that the pool of motoneurons is closer to being maximally excited by the LC stimulus, which always produces a 3- to 5-fold greater response than DR stimulation. Alternatively, the 4-AP effect on DR vs LC VRRs may reflect some difference in modulation of the two synaptic inputs, which also differ in bouton location and interneuron involvement. Further studies will be required to characterize the effective dose range of 4-AP, and the effect of altering stimulation patterns on 4-AP potentiation.

22.12 **4-AMINOPYRIDINE INDUCED RHYTHMIC SPONTANEOUS DISCHARGE IN THE ISOLATED SUPERIOR CERVICAL GANGLION OF THE RAT.** ***Karim A. Alkadhi.*** Department of Pharmacology, College of Pharmacy, University of Houston, Houston, TX 77004.

It is known that 4-aminopyridine can induce marked spontaneous discharge in mammalian ganglia (Goto and Watanabe, Japan. J. Pharmacol. 32: 607, 1982). The discharge varies in amplitude and frequency from ganglion to ganglion. In about 70% of the preparations I have observed that 4-aminopyridine induced rhythmic spontaneous bursts of discharge. Superior cervical ganglia isolated from rats were desheathed and placed in oxygenated Locke's solution (1.1. mM Ca^{2+}, pH 7.4) in a constant temperature (31±1°C) chamber. Potentials were recorded by a capillary suction electrode from the postganglionic (internal carotid) nerve. Addition of 50 μM 4-aminopyridine caused spontaneous discharge to appear within 5 min. The discharge increased in frequency and amplitude with time and usually stabilized in about 30 min. The rhythmic bursts may appear initially (within 5-10 min) and later become fused as the frequency of discharge increases. In some experiments the rhythmic bursts persisted throughout. The rhythmic bursts may appear suddenly after full development of the discharge in which case the potentials in a burst are usually much larger (2-3 times) in amplitude than regular discharge. The bursts occurred regularly every 1.43±0.01 s. Each burst is typically composed of 4-5 potentials, the first of which is usually the largest in amplitude (102.6±2.2, 63.6±4.4, 72.2±3.5, 69.7±1.8, μV, potentials 1 through 4 respectively). The potentials within a burst occur at regular intervals of 0.12±0.001 s. The discharge and bursts were completely blocked by hexamethonium (500 μM) indicating involvement of acetylcholine receptors. Preliminary experiments suggest that rhythmic discharge may be independent of the 4-aminopyridine concentration.

22.13 INHIBITION OF CENTRAL NEUROTRANSMITTER RELEASE BY ω-CONOTOXIN GVIA, A PEPTIDE MODULATOR OF THE N-TYPE VOLTAGE-SENSITIVE CALCIUM CHANNEL. D.J. Dooley[1], A. Lupp*[2], G. Hertting*[2] and H. Osswald*[1]. [1]Gödecke Research Institute, D-7800 Freiburg, F.R.G. and [2]Institute of Pharmacology, University of Freiburg, D-7800 Freiburg, F.R.G.

ω-Conotoxin GVIA (ω-CT), a 27 amino acid peptide (Olivera et al., Science, 230:1338, 1985), binds to the neuronal N-type voltage-sensitive calcium channel (N-VSCC) (Cruz et al., Biochemistry, 26:820, 1987), and, thereby, reduces the depolarization-induced calcium influx required for vesicular release of neurotransmitter (Hirning et al., Neurosci. Abstr., 12:28, 1986; Reynolds et al., Proc. Natl. Acad. Sci. USA, 83:8804, 1986; Rivier et al., J. Biol. Chem., 262:1194, 1987). In the present study, we indirectly investigated the generality of this phenomenon across different neurotransmitter systems by measuring stimulation-evoked neurotransmitter release from slices prepared from discrete regions of the rabbit central nervous system.

Electrical stimulation (2 min; rectangular pulses of 2 msec, 3 Hz, 5 V/cm, and 24 mA) of superfused slices containing [^{3}H]-dopamine, [^{3}H]-noradrenaline, [^{3}H]-5-hydroxytryptamine, or [^{3}H]-acetylcholine produced tritium overflows which were decreased by 40-50 % by 5 nM ω-CT (30-min tissue exposure time). Additional experiments using 5 nM ω-CT and hippocampal slices labeled with [^{3}H]-noradrenaline indicated the following: (1) the time dependence of ω-CT-induced inhibition, (2) the competitive antagonism between buffer calcium concentration and ω-CT, (3) the lack of effect of stimulation frequency (15 min; 0.4 Hz) on ω-CT-induced inhibition, (4) the ineffectiveness of the L-type VSCC modulators (+)- and (-)-202-791 (1 μM) either in the presence or absence of ω-CT, (5) the additive effect of the N-VSCC antagonist cadmium (40 μM) and ω-CT, (6) the antagonism between the protein kinase C activator 4-β-phorbol-12,13-dibutyrate (0.1 μM) and ω-CT, and (7) the antagonism between the potassium channel antagonist 4-aminopyridine (10 μM) and ω-CT. In all cases, the employed substances did not alter basal tritium outflow.

ω-CT appears to be a useful and potent pharmacologic tool in studying the involvement of the N-VSCC in synaptic function. The comparable ω-CT-induced attenuation of stimulation-evoked release of the classical neurotransmitters (viz., dopamine, noradrenaline, 5-hydroxytryptamine, and acetylcholine) suggests that the molecular nature of the N-VSCC is similar or identical across central neurotransmitter systems. Moreover, pharmacologic modulation of the N-VSCC conceivably alters both intraneuronal and multisynaptic events.

22.14 EFFECTS OF GABA ON CA3 PYRAMIDAL CELL DENDRITES IN THE MATURE RABBIT HIPPOCAMPUS. D. Janigro and P.A. Schwartzkroin, Dept. of Neurological Surgery, Univ. of Washington, RI-20, Seattle, WA 98195

It is generally agreed that gamma-aminobutyric acid (GABA) acts as an inhibitory neurotransmitter in various regions in the CNS. Its inhibitory effects are thought to be mediated through at least two different receptor subtypes. The GABA-A receptor is sensitive to blockade by micromolar concentrations of the convulsant agent bicuculline, and is associated with chloride channel. The GABA-B receptor is not sensitive to bicuculline and is thought to mediate an increase in K^+ conductance. GABA effects in the CA1 region of the hippocampus have been shown to depend on the site of application; somatic application generally leads to cell hyperpolarization, whereas application of GABA in the dendritic region depolarizes the cells. We now report the results of investigations on the effects of GABA applied on CA3 pyramidal cell dendrites.

Slices from mature (30-35 days postnatal) rabbits were examined in vitro using standard electrophysiological techniques. GABA was either pressure ejected (1 mM) or iontophoretically applied (1 M, pH 4) onto the distal portion of basal or apical dendrites. The predominant response of the pyramidal cells tested with dendritic GABA application was a 5-20 mV hyperpolarization, although depolarizing responses were obtained in 25% of the 18 cells tested. Both hyperpolarizing and depolarizing responses were associated with a decrease in cell input resistance. Bicuculline methiodide (BMI, 40 uM, bath application) abolished the early component of the afferent-induced IPSP in the CA3 region and led to afterdischarge activity following both orthodromic and antidromic stimulation. The hyperpolarizing response to dendritic GABA application was either unaffected or increased by this BMI treatment, whereas the depolarizing response was abolished (within 30), unmasking an underlying hyperpolarization. Perfusion of the tissue with medium containing 0.5 mM $CaCl_2$ and 8.0 mM $MgSO_4$ did not affect the response to GABA, suggesting that GABA was having a direct post-synaptic effect. Intracellular infusion of Cl^- into CA3 pyramidal cells (KCl-filled pipettes) did not alter the hyperpolarization produced by dendritic GABA application.

Our data show that the predominant response of CA3 pyramidal cells to dendritic GABA application is a hyperpolarization. This response contrasts with the widespread depolarization produced by dendritic GABA application in the CA1 region. We suggest that the CA3 hyperpolarizing response is mediated through a GABA-B receptor since it is insensitive to BMI and appears to be unaffected by altering the intracellular Cl^- concentration. In contrast, the depolarization following dendritic GABA application is sensitive to BMI, and is likely to be mediated via a GABA-A receptor subtype. In some cells, the GABA-A mediated depolarization may mask an underlying GABA-B mediated hyperplarization.

22.15 ANOXIA IN HIPPOCAMPAL SLICES: COMPARISON OF FIELD POTENTIAL RECORDINGS FROM SUBMERGED AND SUPERFUSED PREPARATIONS.
M. B. MacIver, Department of Anesthesia, Stanford University School of Medicine, Stanford, CA 94305-5117.

Synaptically evoked field potentials recorded from submerged hippocampal slices exhibit considerably smaller amplitudes (approx. 2 mV) compared with responses from either superfused (gas/liquid interface) or *in vivo* preparations (10 to 30 mV). A possible explanation for this decreased amplitude is the enhanced "grounding" produced using the submerged preparation. Transmembrane current fluxes which underlie extracellularly recorded field potentials could be shunted more readily to bath ground when slices are completely surrounded by the conductive medium (artificial cerebral spinal fluid; ACSF). Alternatively, it is possible that the viability of neurons is compromised using submerged preparations and reduced field potential amplitudes could reflect a smaller number of cells contributing to synaptically evoked responses. The present study examined which of these two possible factors contribute most to reduced extracellular voltage responses by comparing field potential amplitudes recorded before and after hippocampal slices were submerged. Particular care was taken to ensure that stimulating and recording sites were maintained as slices were gradually covered by ACSF solution (5 - 10 min). The temperature of the solution was continually monitored and maintained at 35°C in the recording chamber. Response amplitudes and the size of stimulus artifacts did not change (< 10%) for the first hour after slices were completely submerged; however, a gradual decrement in amplitudes were observed over the following 2 to 3 hours. This reduction in amplitude resulted in field potentials of 0.5 to 5.0 mV and was sometimes accompanied by the appearance of two or more population spikes, suggesting that depression of postsynaptic excitability did not contribute to the observed depression of response amplitudes. When slices were returned to the superfused condition, response amplitudes did not recover, or showed only marginal improvement. The decrement in field potential amplitudes was markedly enhanced by decreasing the pO_2 in the recording chamber. Thus, the smaller field potential responses from submerged preparations appear to result from neuronal depression, secondary to a lack of oxygen, rather than from differences in the electrical characteristics between superfused and submerged preparations.

Supported by NIH grant NS13108 to Joan J. Kendig.

22.16 OXIDATIVE DAMAGE IN GUINEA PIG HIPPOCAMPAL SLICE.
T. C. Pellmar and K. L. Neel*. Physiology Department, Armed Forces Radiobiology Research Institute, Bethesda, MD 20814-5145.

Previous studies have shown that free radicals, generated by radiation and through the Fenton reaction, produce both synaptic and postsynaptic damage in the hippocampal brain slice (Pellmar, Brain Res. 364:377-381, 1986; Pellmar and Tolliver, in Brain Slices, Karger, Basel, 1987). The possible mechanisms underlying free radical damage include lipid peroxidation and oxidative attack. To evaluate the contribution of oxidation to the observed damage, chloramine T, a specific oxidant of methionine and cysteine residues of proteins, was studied.

Hippocampal slices were prepared from euthanized male Hartley guinea pigs. Stimulation of *stratum radiatum* (0.2 Hz, 0.02-0.5 mA, 200 μs) with stainless steel electrodes evoked a population spike (pop spike) recorded in *stratum pyramidale* of CA1 and a dendritic response (pop PSP) and afferent volley (AV) recorded in the *stratum radiatum* of CA1. From these orthodromically evoked potentials, three input-output (I/O) curves were generated before and after application of chloramine T. Pop spike vs AV demonstrated the net effect of the oxidant, pop PSP vs AV revealed synaptic mechanisms, and pop spike vs pop PSP showed postsynaptic actions. A dose response curve for chloramine T was generated: the pop spike was evoked at half maximal amplitude in control solution and the decrease produced by chloramine T was evaluated. Only one dose was applied to each slice.

Chloramine T (25-500 μM) produced a dose-dependent decrease in the orthodromic response (ED_{50} ≃150 μM). A dose of at least 50 μM was required to produce an effect. The actions of chloramine T were usually reversible with wash. The I/O curves revealed that both the pop spike and the pop PSP were significantly reduced. However, the ability of the pop PSP to produce a pop spike was not impaired by chloramine T. Chloramine T was specific for synaptic damage (100 μM, $n = 8$, $p < 0.05$; 250 μM, $n = 7$, $p < 0.05$). These studies suggest that oxidation reactions can account for the synaptic component of the damage produced by free radicals but may not underlie all the effects. This is consistent with the mechanisms suggested by the radiation experiments. Studies with another oxidizing agent are in progress to further test this conclusion.

PHARMACOLOGY OF SYNAPTIC TRANSMISSION II

23.1 PRESYNAPTIC ROLE OF INOSITOL 1,4,5-TRISPHOSPHATE AND DIACYLGLYCEROL IN BRADYKININ-INDUCED ACETYLCHOLINE RELEASE AT NG108-15 NEUROBLASTOMA HYBRID-MYOTUBE SYNAPSES.
Haruhiro Higashida. Laboratory of Biochemical Genetics, NHLBI, NIH, MD 20892 U.S.A. and Department of Pharmacology, Cancer Research Institute, Kanazawa University, Kanazawa 920, Japan

Bradykinin (BK) causes rapid conversion of phosphatidylinositol 4,5-bisphosphate to inositol 1,4,5-trisphosphate ($InsP_3$) and diacylglycerol (DAG) in NG108-15 neuroblastoma x glioma hybrid cells. Diffusional BK application onto NG108-15 cells facilitates acetylcholine release from the hybrid cells: miniature end-plate potential (m.e.p.p.) frequency in a cultured rat muscle cell which had been synaptically connected to the NG108-15 cells were increased by BK application (Yano et al., J. Biol. Chem. 259, 10201, 1984). Simultaneous electrophysiological recordings from a synapse pair of hybrid and muscle cells revealed that the frequency of m.e.p.p.s. was increased during both membrane hyperpolarization and depolarization of the hybrid cell in response to iontophoretic application (+30 nA for 1-5 s) of BK (0.1 mM in 0.1 mM HCl in pipettes). The early BK-induced facilitation of ACh release during the hyperpolarization of the hybrid cells was mimicked by intracellular injections (10-50 nC) of Ca^{2+} (0.5 M in pipettes) or $InsP_3$ (0.25 mM in pipettes). The mean m.e.p.p. frequency increased by 6.9, 3.9 and 3.7 fold in BK, Ca^{2+} and $InsP_3$ application, respectively, from the control values (0.3-4 events/s).

Within 3-5 min after perfusion with 1-2 μM phorboldibutyrate (PDBu), the frequency of m.e.p.p.s. started to increase, and reached a plateau after 8 min with a mean increase of 3.0 fold during a depolarization of the hybrid cells which is due to the inhibition of the M-current (Higashida & Brown, Nature, 323, 333, 1986). Facilitation by BK application or injection of $InsP_3$ was observed even in hybrid cells which had been treated with PDBu or 4 mM Ba^{2+}, an M-current inactivator, or 30 μM H-7, an inhibitor of protein kinase C. The results suggest that these two intermediate substances ($InsP_3$ and DAG) mediate BK-induced presynaptic facilitation: ACh release is inducible by $InsP_3$-dependent release of Ca^{2+} from intracellular storage sites and protein phosphorylation by DAG-activated protein kinase C.

23.2 TYPICAL AND ATYPICAL ANTIPSYCHOTICS: DIFFERENTIAL ACTIONS AT DOPAMINE (DA) RECEPTOR SUBTYPES.
A.I. Salama, M.J. Czupryna*, M.A. Pacheco*, and C.F. Saller. Department of Pharmacology, Stuart Pharmaceuticals, A Division of ICI Americas Inc., Wilmington, DE 19897.

The actions of typical (e.g., chlorpromazine, fluphenazine, haloperidol) and atypical (i.e., clozapine and fluperlapine) antipsychotic drugs at D-1 and D-2 DA receptors in rat striatum were examined. The affinities of these compounds at D-1 DA receptors, which are positively coupled to adenylate cyclase, were measured using ^{3}H-SCH 23390 binding, and their affinities at D-2 receptors, which are negatively linked to adenylate cyclase in rat striatum, were measured using ^{3}H-spiperone binding. The stimulation of adenylate cyclase by the D-1 agonist SKF 38393 and the K^+-evoked release of ^{3}H-acetylcholine (Ach) from striatal tissue slices were measured as functional indices of activity at D-1 and D-2 receptors, respectively (Saller and Salama, J. Pharmacol. Exp. Ther. 236:714, 1986).

In vitro, the typical antipsychotics possessed considerably greater affinities for D-2 binding sites than for D-1 sites. The affinities of clozapine and fluperlapine at D-1 sites relative to D-2 sites were much greater than those of the typical antipsychotics. In this regard, the in vitro D-1/D-2 affinity ratio of D-butaclamol was similar to clozapine and fluperlapine, but in ex vivo binding studies, it resembled the typicals.

A high positive correlation was found between the abilities of all of the compounds that were examined to inhibit SKF 38393-stimulated adenylate cyclase activity and their affinities at ^{3}H-SCH 23390-labeled sites. This observation somewhat contrasts with the report that clozapine and fluperlapine appeared to possess greater potency at blocking DA-stimulated adenylate cyclase activity than at displacing ^{3}H-SCH 23390 binding relative to the typical antipsychotics (Andersen and Braerstrup, J. Neurochem. 47:1822, 1986). However, DA is a mixed agonist that also stimulates D-2 receptors which inhibit adenylate cyclase activity, and this might partially explain this discrepancy.

Clozapine and fluperlapine also differed from the typicals in their effects on the K^+-evoked release of ^{3}H-Ach. The typicals all enhanced the K^+-evoked release of ^{3}H-Ach, presumably by blocking D-2 receptors, whereas clozapine and fluperlapine tended to lower ^{3}H-Ach release. The observations with clozapine and fluperlapine, which block D-1 and D-2 receptors, are reminiscent of our previous findings that D-1 blockade with SCH 23390 can attenuate the enhancement of ^{3}H-Ach release by haloperidol (Saller and Salama, ibid.). Thus, differences in the effects of typical and atypical antipsychotics may be at least partially attributable to their differential actions at D-1 and D-2 receptors.

23.3 SYNERGISTIC ACTIONS OF NE AND PROTEIN KINASE C: ELECTROPHYSIOLOGICAL STUDIES IN THE DENTATE GYRUS. P.F. Worley and J.M. Baraban, Department of Neuroscience, Johns Hopkins University School of Medicine, Baltimore, MD 21205.

Both norepinephrine (NE) and protein kinase C (PKC) have been implicated in long-term potentiation (LTP) of synaptic responses in the dentate gyrus elicited by stimulation of the perforant pathway. To assess the interactions between these two modulators of synaptic activity, we have examined the acute effects of phorbol esters, activators of PKC, and NE on synaptic responses in the dentate. In a previous study, we demonstrated that a prominent action of phorbol esters is their ability to block adenosine's inhibitory effects on synaptic transmission (Worley et al., PNAS, in press). In the present study, we have found that in the dentate gyrus, NE (1-10 μM) greatly potentiates the ability of phorbol 12,13-dibutyrate (PDA) to block adenosine. NE's effect is mimicked by the application of forskolin (10 μM), an activator of adenylate cyclase. Neither 50 μM forskolin nor 100 μM NE alone alter adenosine's inhibitory action. These findings suggest that PKC and adenylate cyclase systems act synergistically to modulate synaptic responses in the dentate. Others have demonstrated the selective involvement of NE in LTP in the dentate but not in the CA1 region of the hippocampus. We have also found that NE and forskolin do not potentiate PKC's block of adenosine in CA1. Thus, the interactions between cyclase and PKC systems appear to be particularly important in modulating synaptic responses in the dentate and may reflect the extremely high levels of G_s-cyclase complex in granule cells detected by [^{3}H]forskolin autoradiography (Worley, PNAS 83:4053, 1986).

23.4 ALPHA-ADRENOCEPTOR MODULATION OF TRANSMITTER RELEASE AT MAMMALIAN MOTOR NERVE TERMINALS.
H. Chen* and W.F. Dryden, Department of Pharmacology, University of Alberta, Edmonton, Alberta, Canada, T6G 2H7.

Miyamoto and Breckenridge (J. Gen. Physiol. 63: 609-624, 1974) showed that both epinephrine and norepinephrine could increase MEPP frequency in rat phrenic nerve neuromuscular junction, and attributed this to an action on presynaptic adrenoceptors which increased nerve terminal cyclic-AMP level. This contrasted with an earlier report (Kuba, J. Physiol., 211: 551-570, 1970) in which the effects of the catecholamines on EPC were blocked by phentolamine but not by pronethalol. Other experiments, using reversal of tubocurarine blockade, indicated indirectly that the presynaptic effect of norepinephrine and epinephrine were mediated by alpha-adrenoceptors (Bowman and Nott, Pharmacol. Res., 21: 27-72, 1969; Malta et al., Br. J. Pharmacol., 65: 249-256, 1979). The present work was undertaken to compare the effects of specific agonists and antagonists of adrenoceptor subclasses on spontaneous and accelerated transmitter release at the mouse phrenic nerve terminals.

Mouse hemidiaphragm preparations with residual phrenic nerve stump were pinned on a Sylgard base and perfused at room temperature with Bretag's solution (Life Sci., 8: 319-329, 1969). Using conventional intracellular microelectrodes MEPP frequency was recorded for periods up to 30 min from the same muscle endplate under control conditions, and during perfusion of agonist drug. Similar experiments were performed in which $[K]_0$ was increased to 15 mM with a corresponding reduction in $[Na]_0$. Resting MEPP frequency was not affected by epinephrine (10 μM), norepinephrine (1-10 μM) or phenylephrine (1-10 μM). Exposures >15 min to isoproterenol (0.1-10 μM), dobutamine (1-10 μM) or salbutamol (0.1-10 μM) depressed spontaneous M.E.P.P. frequency in a concentration dependent manner that was unaffected by propranolol (10 μM). Accelerated release, using 15 mM $[K]_0$ was increased by epinephrine (1-10 μM), norepinephrine (0.1-10 μM) and phenylephrine (1-10 μM). This effect was not sustained >15 min and was blocked by prazosin (1-10 μM) but not by yohimbine or nadolol. Isoproterenol (1-100 μM) had no effect. Catecholamine induced increases in transmitter release at the motor nerve terminal are mediated through alpha-1 adrenoceptors. No evidence for the presence of other adrenoceptor subclasses was found. The effect is only seen under conditions of accelerated release, in contrast to cyclic-AMP mediated effects, which are also seen in resting MEPP frequency.

23.5 ETHANOL POTENTIATES PRIMARY AFFERENT DEPOLARIZATION IN FROG SPINAL CORD. M.O. Poulter* and A.L.Padjen, (SPON.B.Harvey) Department of Pharmacology and Therapeutics, McGill Univ., Montreal, Quebec, H3G 1Y6

The effect of ethanol on primary afferent depolarization (PAD, a GABA-mediated synaptic potential) was studied using intracellular recording from large myelinated primary afferent axons penetrated at the dorsal root (DR) entry zone. In agreement with the previous results obtained from whole population recording (sucrose gap technique) DR-PAD was increased in amplitude and decreased in duration (+25% $p<<.001$ and 25% $p<.02$ n=8 by paired t-test, respectively). The decrease in effective resistance (R_e) accompanying PAD (cf. Padjen & Hashiguchi, 1983; obtained by "current-clamp" technique) was further decreased by ETOH (60% with 100 mM), without any change in estimated reversal potential. In the presence of tetrodotoxin (0.25 μM, used to block indirect responses), ETOH did not reproducibly potentiate GABA (1 - 2 mM) mediated change in membrane resistance unlike responses on dorsal root ganglia (GABA 10 - 50 μM) which were regularly increased (cf. Padjen et al. 1987). ETOH increased R_e (+25% n=5 $p<.03$ by paired t-test) and usually depolarized the primary afferents (1-2 mV; reversed on washout). In view of the possiblilty that ETOH increases intracellular Ca^{2+} ($[Ca^{2+}]_i$; cf. Carlen et al. 1985) we examined the effects of caffeine (5 mM) (which raises $[Ca^{2+}]_i$). The results were qualitatively similar to those of ETOH: an increase in the R_e (+38% n=3 $p<.01$ by paired t-test) and a small depolarization (3-4 mV).

Our results suggest that ETOH: 1. increases PAD by, at least in part, potentiating GABA-mediated chloride conductance; contribution of presynaptic effects could not be excluded. 2) The increase in R_e is caused by the blockade of a resting conductance, possibly gK_s (slow K conductance of Dubois, 1983) which is active at resting membrane potential (result of an increase in $[Ca^{2+}]_i$?).

Supported by the AMBRF and the MRC of Canada.

23.6 CHOLINERGIC TRANSMISSION IN PANCREATIC GANGLIA OF THE CAT.
J. A. Love* and J. H. Szurszewski. Department of Physiology and Biophysics, Mayo Clinic, Rochester, MN 55905.

The intrapancreatic neural mechanisms involved in the control of pancreatic secretion are unknown. To better understand the neural control of pancreatic function as well as the neurophysiology of parasympathetic ganglia, we examined synaptic transmission in intrapancreatic ganglia of the cat. Cats were anesthetized with ketamine and pentobarbital and the neck of the pancreas removed. Pancreatic ganglia with their attached nerve trunks were dissected free from the parenchyma and pinned to the floor of a tissue bath. Ganglia were perfused with oxygenated Krebs solution warmed to 35-37°C. Intracellular recordings were made using 3M KCl-filled glass microelectrodes and nerve trunks were stimulated with bipolar steel electrodes. Cholinergic agonists dissolved in Krebs solution were applied to the ganglia by pressure ejection from a pipette positioned close to the recording electrode. Cholinergic antagonists were applied by superfusion. In all cells tested nerve stimulation evoked fast excitatory postsynaptic potentials (EPSPs) which were abolished by hexamethonium. Slow EPSPs were observed in most cells following repetitive nerve stimulation at frequencies as low as 1 Hz. Frequently, slow EPSPs were resistant to cholinergic blockade with hexamethonium and atropine. Exogenous acetylcholine (ACh) evoked 3 types of responses. Most frequently a fast initial depolarization was followed by a slowly developing, long-lasting depolarization. The fast ACH depolarization was accompanied by a decrease in input resistance, enhanced by hyperpolarization, diminished and then abolished by depolarization to -20 to -10 mV, and abolished by hexamethonium. The slow ACh depolarization was accompanied by an increase in input resistance and excitability, enhanced by depolarization, diminished and abolished but not reversed by hyperpolarization to -60 to -70 mV, and abolished by atropine. In some cells a rapid hyperpolarization with a decrease in input resistance was observed between the fast depolarization and the slow depolarization. This potential decreased with hyperpolarization and appeared to be enhanced by an increased amplitude of the preceding fast depolarization. Other cells responded to acetylcholine with only a fast depolarization. The nicotinic agonist DMPP mimicked the fast ACh potential while muscarine mimicked the slow ACh potential. Thus, pancreatic ganglia exhibit both fast nicotinic and slow muscarinic cholinergic potentials which allow for the integration of central and possibly peripheral input to the pancreas. The ACh potentials resemble those observed in sympathetic ganglia. (Supported by DK 17632 and HLO 7111.)

23.7 THE RELATIONSHIP OF AGONIST PROPERTIES TO THE ACTIVATION KINETICS OF THE NICOTINIC ACETYLCHOLINE RECEPTOR. R.L. Papke, G.L. Millhauser, Z. Lieberman* and R.E. Oswald. Department of Pharmacology, Cornell University, Ithaca, N.Y. 14853 USA.

A series of five systematically varying derivatives of acetylcholine (ACh) were used to study the activation kinetics of nicotinic acetylcholine receptors (nAChRs) from BC_3H-1 cells. The goal of the study was to relate the structural characteristics of the agonist to the microscopic kinetics of agonist binding and channel activation as deduced from the opening and closing of single AChR channels recorded in the cell attached configuration. The derivatives were substituted on the acetyl moiety with either H, F, Br, Cl or CH_3. All five derivatives were potent agonists which gave rise to single channel events having conductances of 50 pS. In all cases, the open channel lifetimes (and burst durations) were double exponentially distributed with the shorter time constant varying between 0.2 and 0.35 ms and the longer time constant varying between 8 and 19 ms, depending upon the agonist (PrCh>ClACh>ACh>BrACh> FACh). At 100 nM, at least four exponentials were present in the closed time distribution for all five agonists. Because of the variation of the shortest time constant with the nature of the agonist but not the concentration of agonist, it was assumed to represent dwells in the A_2R state (see scheme below). By examining only the bursts of openings represented by the longer exponential of the open time and burst duration histograms, the scheme shown below can adequately explain the observed data. Based on the above data, estimates were made of the opening (β) and closing (α) rates of the channel and the dissociation (k_-) rate of agonist binding. In conjunction with estimates of the number of AChRs per patch (170 ± 50) and the number of bursts per second, the association rate (k_+) was measured, assuming no cooperativity in binding (*i.e.*, $k_+=k_1=2k_2$ and $k_-=2k_{-1}=k_{-2}$). The association and dissociation rates for the agonists were highly correlated with the bond length at the substituted position (rates decreased with increasing bond length); and the opening and closing rates were correlated with the ionic character of the bond (opening rates decreased and closing rates increased with increasing ionicity of the bond). This suggests that the energy barrier for binding is increased by increasing the bond length (BrACh>ClACh>PrACh>FACh>ACh), and the doubly liganded open state is destabilized by the ionic character of the substituent bond.

$$A + R \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} A + AR \underset{k_{-2}}{\overset{k_2}{\rightleftharpoons}} A_2R \underset{\alpha}{\overset{\beta}{\rightleftharpoons}} A_2R^*$$

A = ACh, **R** = AChR, **AR** = singly liganded AChR, $\mathbf{A_2R}$ = doubly liganded AChR (closed channel), $\mathbf{A_2R^*}$ = doubly liganded AChR (channel open).

23.8 EFFECTS OF SOMAN ON TRANSMISSION THROUGH BULLFROG SYMPATHETIC GANGLIA. T.J. Heppner* and J.F. Fiekers. Dept. Anat. and Neurobiol., Univ. of Vermont Coll. Med., Burlington, VT 05405.

The concentration-dependent effects of the acetylcholinesterase inhibitor soman were examined on transmission through the isolated bullfrog sympathetic chain. Suction electrodes were used to (1) stimulate the sympathetic chain anterior to the 8th ganglion and (2) record the compound action potential (CAP) from the 9th and 10th spinal nerves. The CAP was recorded in normal saline and at concentrations of soman ranging from 0.01-10 uM. Soman at concentrations < 10 uM had no detectable effects on the CAP evoked with 0.1 Hz supramaximal stimulation. In 10 uM soman, there was a minimal decrease in the CAP amplitude while the duration showed a slight increase after 10 min of continuous stimulation at 0.1 Hz.

The concentration-dependent effects of soman (0.1-10 uM) on the CAP were also examined using train stimulation (maximum stimulating rate = 1 train/5 minutes) at frequencies of 10,20 and 30 Hz (2 second duration). The response to train stimulation was analyzed by comparing the amplitude of the initial spikes in the train with the mean amplitude of the last three spikes. The percent decrease in amplitude in normal saline at 20 and 30 Hz train stimulation was 11% and 19.5%, respectively. In the presence of 10 uM soman, the percent rundown was increased to 18.2% and 51.5% at train frequencies of 20 and 30 Hz, respectively. Spike amplitudes were not significantly changed in soman concentrations < 10 uM.

Intracellular responses were also obtained from the 9th and 10th ganglia during single and train stimulation before and after the addition of soman. The amplitude and duration of the synaptically induced depolarization following a spike were increased 300% and 240%, respectively, 3 minutes after soman addition (1.0 uM). At 10 Hz train stimulation in normal saline, intracellular recordings often showed no sustained depolarization. However, train stimulation in the presence of 0.1 uM soman induced a sustained depolarization that continued for several minutes after stimulation was stopped. Trains of 30 Hz increased the amplitude of the sustained depolarization approximately 20 mV.

Additional studies with soman have shown that (1) antidromic spikes are not changed (1.0 uM) and (2) cells voltage clamped at -50 showed a prolonged decay phase of the EPSC in 1.0 uM soman. The above results are consistent with a localized effect of soman on ganglionic transmission. This work supported in part by the US Army Medical Research and Development Command, Contract No. DAMD17-86-C-6031.

23.9 HALOTHANE BLOCKS LONG-TERM POTENTIATION BUT NOT PAIRED-PULSE POTENTIATION IN HIPPOCAMPUS. J. J. Kendig and M. B. MacIver, Department of Anesthesia, Stanford University School of Medicine, Stanford CA 94305-5117

Previous studies from this laboratory have shown that the halogenated ether anesthetic, methoxyflurane, blocks paired-pulse potentiation (PP), but not long-term potentiation (LTP) of synaptic transmission in hippocampal slices (Tauck and Kendig, 1985, Soc. Neuroscience Abs., vol. 11, p. 780). This is in contrast to the effects of dissociative anesthetics (e.g. ketamine and PCP) which effectively block LTP via depression of responses mediated by NMDA excitatory amino acid receptors. These results suggest that the structurally different volatile and intravenous anesthetics may alter the integrative properties of hippocampal synaptic transmission in a differential manner, involving distinct, structurally selective, membrane sites of action for each agent. The present study examined whether volatile agents differ among themselves in this respect by examining the effects of a halogenated alkane anesthetic (halothane) on PP and LTP for synaptically evoked responses from Schaffer-collateral inputs to hippocampal CA1 neurons. Clinical concentrations of halothane (0.5 to 1.0 vol %) produced a reversible depression of evoked field potentials (50 to 20% of control); however, PP and LTP were not blocked. Higher concentrations (>1.2 vol %) produced further depression (<10% of control) of field potential amplitudes and blocked LTP, but PP potentiation was not altered. The effects of all concentrations studied (up to 2.0 vol %) were readily reversible. The block of LTP and lack of effect on PP potentiation produced by halothane contrasts with the effects of methoxyflurane. The differential effects of these two volatile anesthetics suggest that their mechanisms of action may be fundamentally different at the synaptic level and/or their membrane sites of action differ. Furthermore, these results provide additional support for the concept that the mechanisms underlying PP and LTP in hippocampal synaptic responses are separable.

23.10 THE EFFECT OF PHENCYCLIDINE ON THE PHYSICAL STATE OF MODEL MEMBRANES. A FLUORESCENCE AND ELECTRON SPIN RESONANCE STUDY. M.M. Sarasua*, W.O. Boggan, K.A. Koehler*, S.L. Masters*. Department of Psychiatry and Behavioral Sciences, Medical University of South Carolina, Charleston, SC 29425 and Departments of Biochemistry and Surgery, Case Western Reserve University School of Medicine, Cleveland, OH 44109.

To characterize the membrane depth-dependent effects of the drug Phencyclidine (PCP) in dipalmitoylphosphatidylcholine: dipalmitoylphosphatidylglycerol (8:2) sonicated bilayer vesicles, a series of substituted (9-anthroyloxyl) stearic acid fluorescence and doxyl stearic acid spin resonance probes are employed. The PCP concentration-dependence of the response of probes located at C-2, 3, 9 and 12 reveal marked regio-specific differences in the effects of PCP on the fluorescence polarization values for four fluorescence probes. These differences are manifest in the PCP concentration-dependencies of fluorescence polarization both above and below the phospholipid phase transition temperature, T_m, and in the width of the phase transition, ΔT. The 5-doxylstearic acid probe was utilized for determination of S, the order parameter, of the probe as a function of PCP concentration. The biphasic behavior of PCP in negatively charged PC/PG membranes are interpreted in terms of selective interactions of PCP with different regions or phases of the phospholipid bilayer.

23.11 KETAMINE INCREASES DISCHARGE RATE BUT REDUCES SENSORY RESPONSES OF SINGLE CORTICAL NEURONS RECORDED IN BEHAVING RATS I.M. Patel*, and J.K. Chapin, (Spon: G.C. Salmoiraghi), Hahnemann University, Philadelphia, PA 19102.

The dissociative general anesthetic ketamine is widely used in the clinic and in research, and it is functionally related to the drug of abuse phencyclidine, yet its effects on neural circuits are poorly understood. The aim of this study was to define the effect of subanesthetic doses (5-10 mg/Kg body weight) of ketamine on discharge rates and sensory responses of single neurons recorded in the somatosensory (SI) cortex of awake, behaving rats. Units were recorded either with drivable microelectrodes or with floating microwires. In the latter, up to eight single units could be simultaneously recorded for time periods up to 21 days. The behavioral paradigm generally involved running the animals on a treadmill which was switched on and off in a regular cycle. In some animals it was also possible to directly test drug induced changes in neuronal sensory responsiveness by stimulating through electrodes chronically implanted in the forepaw.

The initial behavioral effects of these subanesthetic doses involved: 1- a 10-20 minute induction phase characterized by confusion and marked hyperactivity, and 2- a subsequent 20-40 minute period before recovery in which the drug effects clearly remained, but the animals were able to perform correctly in the treadmill paradigm.

Neurophysiologically, it was found that these doses of ketamine increased the discharge rates of single somatosensory cortical neurons from 100-300%. These increases were greatest during the initial induction period, but continued for the full 40-50 minute duration of the drug effect. During resting as well as treadmill running, these increases were far greater than could be accounted for by concomitant increases in motor activity. Paradoxically, the same ketamine doses strongly suppressed the short latency sensory responses of these neurons, whether the stimulation was delivered through electrodes implanted in the paw, or was the result of the natural stimulation of skin receptors which occurs at the start of treadmill movement. Nevertheless, some cells exhibited an increase in long latency (200 msec) responses to the same sensory stimuli. It is possible that this increase in cortical activity, combined with the suppression of sensory input, may produce some of the disorienting behavioral effects of this drug. Supported by AA-06965, AA-00089, and BNS-8519579 to JKC.

23.12 PATCH CLAMP RECORDING FROM CORPUS STRIATUM NEURONS OF ADULT RATS. Jonathan E. Freedman and Forrest F. Weight. Electrophysiology Section, Lab. of Physiologic and Pharmacologic Studies, National Institute on Alcohol Abuse and Alcoholism, Rockville, MD 20852.

Fully differentiated neurons from the corpus striatum (caudate and putamen) of adult rats were acutely dissociated by a modification of the PIPES-trypsin method of Kay and Wong (*J. Neurosci. Methods* **16**: 227). This method rapidly and consistently yielded intact cell soma with truncated neurites and clean membrane surfaces suitable for recording with patch electrodes. Patch recording from mammalian CNS was thus possible without resort to embryonic tissue.

In whole-cell recordings, patch pipettes contained (in mM): KCl, 140; $CaCl_2$, 1; $MgCl_2$, 2; EGTA 11; HEPES, 10 (pH 7.4, 320 mosm). The extracellular bath contained: NaCl, 150; KCl, 5; $CaCl_2$, 2.5; $MgCl_2$, 1; *d*-glucose, 10; HEPES, 10 (pH 7.4, adjusted with sucrose to 340 mosm).

Current clamp recording indicated that the cells had resting membrane potentials of -50 to -80 mV and apparent input resistances of 300 - 500 MΩ. Cells fired action potentials of 90 mV spike amplitude, and the firing rate increased with depolarization. This indicated that the cells remained electrically excitable, with high input resistance presumably resulting from shortened neurites and GΩ seal recording conditions. In whole-cell voltage clamp, step depolarization from -90 mV elicited fast inward and delayed outward currents. Total inward current had a threshold around -60 mV and an amplitude of at least 3 nA at -50 mV. Total outward current had a threshold around -45 mV and an amplitude of 1 - 4 nA at +30 mV.

Single channel recording was performed in the cell-attached configuration. Whereas few spontaneous channel openings were observed when the pipette contained a solution similar to the extracellular bath, several distinct types of channels were expressed when the electrode contained the high KCl patch pipette solution described above.

The striatum is a major postsynaptic target of dopaminergic neurons in mammalian brain. We hope to utilize this preparation to study the effects of dopamine at the single channel level, so as to better understand the actions of this neurotransmitter as well as the actions of neuroleptic drugs.

23.13 INHIBITION BY DOPAMINE OF BASAL INOSITOL PHOSPHATE FORMATION IN RAT STRIATAL SLICES. Pizzi,M.*, Da Prada,M.*, Spano, P.F., and Haefely W.E*(SPON: M.Motta). Inst. Pharm. Exp. Ther. School of Medicine Brescia Univ., Italy. Dept.Pharm. Res. Hoffmann - La Roche , Basle Switzerland.

Dopamine (DA) has been shown to act in the nervous system through the stimulation of specific receptors, designated as D-1 and D-2 , which stimulate and inhibit adenylate cyclase respectively.
However many of cerebral dopamine functions seem to be uncoupled to any modification of cyclic AMP neuronal content. For other neurotransmitter such as Ach, NE, 5-HT ,it has been demonstrated that receptor activation could stimulate polyphosphoinositide (PPI) breackdown with the formation of diacylglicerol inositol monophosphate (InsP), inositol bisphosphate ($InsP_2$) and inositol trisphosphate ($InsP_3$). The aim of our study was to identify whether DA too might affect the PPI turnover.
Rat striatal slices ,after a 20 min preincubation in a Krebs-Ringer buffer (KRb) at 37° C under an atmosphere of O_2/CO_2, were labelled wuth myo-(3H)inositol (1.35 uM) for 2 hours. Labelled slices were rinsed and than incubated in a KRb in the presence of 10 mM Li^+, 5 uM scopolamine (muscarinic antagonist), 5 uM kynurenic acid (glutamate antagonist) and test drugs (final volume 500 ul). The reaction was stopped after 20 min by 2min boiling , and by adding 750 ul $HClO_4$ 0.4 N. Inositol polyphosphates were separeted by ion exchange chromatography. DA dose-dependently decreased the level of $InsP_3$ and $InsP_2$ with an IC_{50} of about 180 nM. DA effect has been shown to be time-dependent. It reached its maximal value at 20 min incubation (over 50 % decrease). Dopamine effect was more potently reproduced by the D-2 selective agonists RU 24213 (IC_{50} nM), quinpirole (IC_{50} 10 nM) and lisuride (IC_{50} 10 nM). On the contrary fenoldopam which selectively stimulates the D-1 receptor , did not affect the inositol phosphate content even at hight concentrations (up to 1uM). Norpropylapomorphine (NPA), effect tested at 1 uM concentration was prevented by the D-2 receptor antagonist domperidone and by haloperidol (both 5 uM), but not by the D-1 antagonist SCH 23390 (100 nM). In summary our results indicate that DA affects the PPI turnover in brain as revealed by the decrease of inositol polyphosphate content. This phenomenon is linked to the activation of a D-2 type receptor , and is probably independent of any modification of endgenous Ach/glutamate release.

23.14 EFFECTS OF CHRONIC ADMINISTRATION OF ANTIDEPRESSANTS ON 5-HYDROXY TRYPTAMINE UPTAKE AND PAROXETINE BINDING. Y. Minatogawa*, Y. Watanabe*, A. Moriya*, T. Higuchi, Y. Igarashi*, T. Yamauchi* and M. Mikuni°. Dept. of Psychiatry, Saitama Medical School, Moroyama, Saitama, 350-04 Japan, °Div. of Mental Disorder Research, Natl. Institute of Neuroscience, Natl. Center of Neurology and Psychiatry, Kodaira, Tokyo, 187 Japan.

It is well known that acute administration of antidepressant(AD) inhibits the uptake of 5-hydroxytryptamine(5-HT) at presynaptic membranes. However, there were few reports on the chronic effects of AD on 5-HT uptake sites. Recently, high affinity[^{3}H]paroxetine binding sites have been demonstrated in mammarian brain and these binding sites are considered to be associated with 5-HT uptake transporter complex. However, there is no report on the chronic effect of AD on [^{3}H]paroxetine binding sites.

To investigate the effects of chronic AD administration on 5-HT uptake sites and [^{3}H]paroxetine binding sites, following experiments were carried out. Rats were administered (i.p.) either chlorimipramin (CMI, 10mg/kg), desmethylimipramin (DMI, 10mg/kg) or mianserin (MIA, 5mg/kg) for 2 weeks. For kinetic studies, cerebral cortex was homogenized with 100 vol. of Krebs-Ringer bicarbonate (KRB,pH 7.4) and after centrifugation, the pellet was resuspended with 50 vol. of KRB. The suspension was incubated with 5-HT ($1x10^{-8}$ ~$4x10^{-7}$M) containing[^{3}H]5-HT($1x10^{-8}$M) for 2 min at 37°C. The data obtained were analyzed by Lineweaver-Burk method. For uptake inhibition studies, the crude membrane suspension was incubated with CMI ($1x10^{-4}$~$1x10^{-10}$M) and[^{3}H]5HT ($5x10^{-8}$M). The data obtained were analyzed by conventional graphical techniques. Specific 5-HT uptake was defined as the difference between the uptake value obtained at 37°C and that at 0°C. Paroxetine binding studies were performed by incubating the crude membrane (4 mg/tube) with[^{3}H] paroxetine ($0.2x10^{-9}$~$5x10^{-9}$M) for 60 min at 25°C in Tris-HCl buffer-solution (pH 7.4) containing 120 mM NaCl and 5 mM KCl. Specific binding was defined as the difference between the binding in the presence and absence of fluoxetine ($1x10^{-5}$M).

In kinetic study of 5-HT uptake, the Km and Vmax values of control rats were 0.15μM, 4.98pmole/mg protein·min, respectively. No changes were observed on the Km values following CMI, DMI or MIA chronic administration. Only chronic MIA administration induced slight decrease of the Vmax value and increase of the Ki value. Scatchard analysis of[^{3}H]paroxetine binding revealed a Kd of 41.4 pM and the Bmax of 32.0 pmoles/g tissue, and no obvious changes were observed in chronic AD administration.

These data suggest that chronic AD administration except MIA may induce no adaptive change in 5-HT uptake transporter complex.

24.1 ALTERATIONS OF THE CENTRAL ADRENERGIC SYSTEM IN CHRONIC MPTP-INDUCED MONKEY PARKINSONISM. R. Miyoshi, S. Kito, M. Shimizu*, and Y. Yamamura. Third Department of Internal Medicine, Hiroshima University School of Medicine, Hiroshima 734, Japan.

In 1983, Langston described 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP) intoxicated human parkinsonism, and it was discovered that MPTP was selectively toxic to the dopamine neurons of the substantia nigra. Recent studies have shown that not only the nigro-striatal dopamine but also locus coeruleus noradrenaline neuronal systems are susceptible. In the present paper, the authors examined alterations of the central adrenergic system in chronic MPTP-induced monkey parkinsonism. Adult Japanese monkeys were used in this experiment. MPTP was administrated intravenously to monkeys in doses of 0.16 to 0.27 mg/kg body weight/shot repeatedly. Animals were feeded for 6 to 18 months. After deep anesthesia, brains were rapidly removed and dissected into hemispheres. One hemisphere was used for conventional neuropathological observations and the other one for receptor binding assay of adrenergic receptors. The frontal, parietal, temporal and occipital cortices and cerebellum were dissected and P_2 fractions were prepared. For observation of α_1 and α_2 adrenoceptors, ^{3}H-WB 4101 and ^{3}H-clonidine were used as radioactive ligand, respectively. In the substantia nigra of all MPTP-induced monkey parkinsonism, nerve cells were remarkably reduced and those surviving were atrophic as previously reported. In addition, loss of nerve cells and gliosis were considerably observed in the locus coeruleus, though not so severely affected as in the substantia nigra. There were no notable changes in other brain areas. In the brain of these parkinsonian monkeys, ^{3}H-clonidine binding sites were significantly decreased in the temporal and parietal cortices and also had a tendency to decrease in other cortex areas. As for ^{3}H-WB 4101 binding sites, they were reduced as half as normal controls in the temporal and parietal cortices and tended to decrease in other areas. Saturation experiments revealed that the decrease of both ^{3}H-clonidine and ^{3}H-WB 4101 binidng sites was due to a reduction of maximal receptor number. Above-mentioned results strongly suggest that the adrenergic neuron system is damaged in addition to the dopaminergic one in the brain of MPTP-induced monkey parkinsonism.

24.2 DA RECEPTOR BINDING IN MPTP TREATED MONKEYS: CORRELATION WITH NEUROCHEMISTRY AND BEHAVIOR . K.A. Steece, M.W. Tayrien*, T.J. Collier, R. Loy, R.H. Roth[1], D.E. Redmond,Jr.[2], & J.R. Sladek, Jr.. Dept. of Neurobiol. & Anat., Univ. of Rochester School of Medicine, Rochester, NY, and Depts. of Pharmacology[1] and Psychiatry[2], Yale Univ. School of Medicine, New Haven, CT.

The degeneration of the nigrostriatal DA system associated with Parkinson's disease reveals a complex regulation of D2 DA receptors. Intially there is an apparent compensatory increase in the number of receptors. In contrast, the more disabled patients who no longer respond to levo-dopa therapy have a low number of striatal D2 receptors. Both an increase (Joyce *et al.*, 1986, Brain Res 382:360) and a decrease (Hantraye *et al.*, 1986, Life Sci 39:1375) in D2 receptor number have been reported in MPTP-induced parkinsonian monkeys.

Morphological and neurochemical studies in our laboratories with MPTP treated monkeys have confirmed the destruction of nigrostriatal neurons by this neurotoxin. These data have been correlated with the behavioral status of individual monkeys. It was thus of interest to examine D2 receptor status in monkeys with various degrees of experimental parkinsonism.

Ongoing experiments in our laboratories make analysis of receptor changes in 4% paraformaldehyde perfused tissue imperative. Therefore, it was neccessary to determine whether striatal D2 receptors were still viable using this fixation protocol. Biochemical experiments were performed to determine binding characteristics of sulpiride displacement of 3H-spiperone to slide mounted striatal tissue sections in 0.1% (control) and 4% paraformaldehyde perfused rats. Equilibration time was 60 minutes in control tissue and 120 minutes in 4% tissue. This may be attributable to a delay in penetration rate of the ligand into the tissue related to an increase in cross-linking associated with the stronger degree of fixation in the 4% animals. A maximum ratio of specific to non-specific binding (3:2) was obtained for both preparations with two 15 minute washes in cold buffer. Scatchard analysis revealed no difference in affinity between 0.1% (K_D=80$\pm$12pM($\pm$SEM)) and 4% (K_D=73$\pm$11pM) fixed tissue. These data indicate a slight decrease in receptor density from 0.1% (B_{MAX}= 50$\pm$1 fmol/mg tissue) to 4% (B_{MAX}=38$\pm$5) fixation. These initial studies in perfused rat brain indicate our ability to assess changes in a population of receptors that satisfy many of the criteria which have been described for D2 receptor populations in other more extensively characterized systems.

Binding studies in 3 control African green monkeys indicate D2 receptors in this system also survive the 4% fixation protocol. Preliminary results in 2 MPTP treated monkeys revealed a marked decrease in specific D2 receptor binding in these severely parkinsonian monkeys compared to intact animals. Autoradiography is currently being examined in several MPTP treated monkeys to investigate whether various receptor changes might be regionally specific as well as correlated to the degree of experimental parkinsonism. This modification of the approach for receptor binding analysis as performed in concert with ongoing behavioral, neurochemical and immunohistochemical analyses will permit application of this technique to transplant recipients to better correlate improvements seen following fetal nerve cell grafts in parkinsonian monkeys.

24.3 BIOTRANSFORMATION OF MPTP GENERATES SUPEROXIDE RADICAL IN VITRO. Z.L. Rossetti*, A. Sotgiu, D.E. Sharp, M. Hadjiconstantinou and N.H. Neff. Department of Pharmacology, The Ohio State University, College of Medicine, Columbus, OH 43210.

The chemical mechanism(s) for the destruction of neurons by MPTP is still unknown. It has been suggested that during the biotransformation of MPTP cytotoxic intermediates are formed. Recently, the formation of oxygen free radical intermediates has been detected from the enzymatic reduction of the oxidation product of MPTP, 1-methyl-4-phenyl-pyridinium ion (MPP^+). We report now that incubation of MPTP with a mouse brain mitochondrial preparation results in oxygen-dependent formation of free radicals, which can be trapped and observed by electron spin resonance (ESR). The spin adducts with 1,1-dimethylpyrrolidine-N-oxide (DMPO) of hydroxyl radical and of an unidentified carbon-based radical were observed. Radical formation could be suppressed by superoxide dismutase (SOD), indicating the production of superoxide radical. Pretreatment of animals with deprenyl, a monoamine oxidase (MAO) inhibitor, before the preparation of mitochondria or the inclusion of deprenyl in a mitochondrial preparation from control animals inhibited the appearance of the ESR signal, suggesting that free radical generation is MAO dependent. In the absence of mitochondria, an ESR spectrum was obtained when 1-methyl-4-phenyl-2,3-dihydropyridinium perchlorate ($MPTP^+$, the intermediate metabolite of MPTP) and MPP^+ were incubated together, but not when they were incubated independently. We conclude from these observation that MPP^+ causes the isomerization of $MPDP^+$ to 1,2 or 1,4 isomers which are oxidized to MPP^+ with the formation of superoxide. ^{13}C NMR studies of the reaction mixtures support this explanation.It is possible that generation of free radicals contributes to MPTP toxicity in vivo.

24.4 SYNTHESIS AND BIOLOGICAL ACTIVITY OF METHYL SUBSTITUTED ANALOGS OF THE NEUROTOXIN MPTP AND ITS METABOLITES $MPDP^+$ AND MPP^+ E. A. Johnson, A. Trevor, and N. Castagnoli Jr. (SPON: J. Lavail) Division of Toxicology, University of California, San Francisco, CA 94143-0446

MPTP (1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine) has recently been shown to cause selective destruction of the substantia nigra of humans and non human primates, resulting in a Parkinsonian syndrome which is clinically indistinguishable from idiopathic Parkinsons disease. The neurotoxic effects of MPTP are dependent upon its bioactivation by monoamine oxidase (MAO) to produce the two electron oxidation product $MPDP^+$. This unstable metabolite is rapidly further oxidized to the stable pyridinium species MPP^+. The neurotoxicity of MPTP is currently ascribed to the action of one or both of these metabolites. The possibility that idiopathic Parkinsons disease might result from exposure to an environmental toxin similar to MPTP has been suggested. Such a toxin may also require activation by MAO. Elucidation of the structure activity relationship of substituted tetrahydropyridines as substrates of MAO is an important step in the process of elimination of potential candidate neurotoxins. Therefore, we undertook the synthesis and biological evaluation of methyl substituted analogs of the tetrahydropyridine and its two metabolites. Compound **1**, 1,2-dimethyl-4-phenyl-1,2,3,6-tetrahydropyridine, and the corresponding 1,2-dimethyl-4-phenylpyrdinium iodide (**2**) were obtained via disproportionation of 1,2-dimethyl-4-phenyl-1,2-dihydropyridine. Compound **3**, 1,6-dimethyl-4-phenyl-1,2,3,6-tetrahydropyridine was obtained via a Grignard reaction of MeMgBr on 1-methyl-6-cyano-4-phenyl-1,2,3,6-tetrahydropyridine. The methyl substituted $MPDP^+$ analog, **4**, (1,2-dimethyl-4-phenyl-2,3-dihydropyridinium perchlorate), was obtained via a Grignard reaction of MeMgBr on MPP+. The interactions of compounds **1** and **3** with MAO and their striatal dopamine depleting properties in the mouse have been examined. The oxidation of **1** and **3** proceeded extremely slowly. Compound **1**, however, competitively inhibited the MAO B catalysed oxidation of MPTP (Ki .378 mM) suggesting that it does have access to the active site of the enzyme. IV administration of **1** to C57 black mice caused only 8.4% depletion of straital dopamine compared to an 81% depletion with MPTP. On the other hand, the pyridinium compound **2**, a potential metabolite of **1** and **3**, was as effective as MPP^+ in inhibiting mitochondrial respiration and even more toxic than MPP^+ to freshly prepared hepatocytes. It appears, therefore, that although the structural requirements of MPTP type MAO substrates may be severe, the corresponding requirements for molecules displaying toxic properties related to the metabolite MPP+ may be less restricive.

24.5 TOXICITY OF COMPOUNDS RELATED TO MPP+ FOR DOPAMINERGIC NEURONS IN CULTURE. P.P. Michel*, J. Sanchez-Ramos*, B. Pressman*, S. Efange* and F. Hefti (SPON:J.D. Potter). Dept. of Neurology, University of Miami, Miami FL 33101.

MPTP is a selective neurotoxin for dopaminergic neurons. Several reports indicate that the selectivity of the action of MPTP is due to the uptake of its metabolite, MPP+, into the dopaminergic neurons. After uptake, MPP+ is believed to inhibit mitochondrial energy metabolism resulting in cell death. We therefore hypothesized that other compounds satisfying these two criteria (selective uptake and mitochondrial toxicity) are selective toxins for dopaminergic neurons. We previously reported that MPP+ selectively destroys dopaminergic neurons in cultures of dissociated cells from the rat ventral mesencephalon. This culture system was used to test for the effects of potential toxins.

Cultures were prepared from rat embryos (E15) as described earlier (Sanchez-Ramos et al., Neurosci. Lett. 72:215,1986). They were grown for 7 days and then exposed to test compounds for 24 h. Thereafter, they were analyzed for selective and non-selective toxicity. Selective toxicity for dopaminergic neurons was assessed by staining the cultures for tyrosine hydroxylase (TH) and counting the number of positively stained neurons. Non-specific toxicity was assessed by counting cells visible in phase contrast microscopy.

We tested different guanidine derivatives which are ionized cations at physiological pH. The alkylguanidines (C=4,5,7 or 8), previously described as electron transport inhibitors, induced a non-specific degeneration of all the cultured cells. The effective concentration 50 (EC50) decreased with increasing length of the alkyl side chain and ranged from 45.8 to 1.9 uM. Under the same conditions, MPP+ selectively destroyed TH-positive cells with an EC50 of 0.3 uM. Benzyl guanidine and guanethidine produced only non-specific toxic effects ressembling those of alkylguanidines. The EC50 of benzyl guanidine was 20.9 uM. Guanethidine which destroys peripheral catecholaminergic neurons in vivo, was least effective (EC50 64.3uM). Compounds under investigation include homo-MPP+, isoquinolinium, and triazines.

Since human Parkinson's disease is associated with a selective degeneration of dopaminergic neurons, these studies might lead to the identification of novel compounds possibly involved in the its pathogenesis.

24.6 **IN VITRO EFFECT OF CYPERQUAT (MPP^+), PARAQUAT AND DIQUAT ON ^{45}Ca TRANSPORT IN MITOCHONDRIA FROM RAT STRIATUM AND LIVER.**

J.H. Thakar, M.N. Hassan and J.D. Grimes. (Spons. W. Hendelman). Parkinson Disease Laboratory, Ottawa Civic Hospital, Ottawa, Ontario, Canada. K1Y 4E9.

1-methyl-4-phenyl-1,2,3,6 tetrahydropyridine (MPTP) is a neurotoxic compound, which produces parkinsonism in man and several animal species. MPTP is metabolized to MPP^+ by the mitochondrial enzyme monoamine oxidase. Studies from our laboratory (Abstracts Society for Neuroscience #350.4, 1985 and #28.7, 1986) and those from other groups have shown that MPTP per se does not affect energy production in mitochondria. However, MPP^+ inhibits the NAD^+-linked substrate oxidation in mitochondria from various sources. Since calcium plays an important role in the release of neurotransmitters and since mitochindria have a cardinal role in the regulation of intracellular calcium we have evaluated the effects of MPP^+ and two structurally related herbicides paraquat and diquat on calcium transport in mitochondria from rat striatum and liver.

Mitochondria were isolated at 0-4°C, from neostriatum (pooled from at least four animals) and liver of adult male Sprague-Dawley rats. The homogenizing medium consisted of 0.23M mannitol, 0.07M sucrose, 0.1mM EDTA and bovine serum albumin at pH 7.4. The homogenates were centrifuged at 2,000g for 10 min to remove debris. The supernatants were centrifuged at 10,000g for 10 min to obtain mitochondrial pellets. Calcium transport was studied by incubating the organelles in the presence of 0.1mM $^{45}CaCl_2$, 0.23M mannitol, 0.07M sucrose, 5mM K_2HPO_4. Tris-HCl pH 7.4, plus pyruvate (5mM) - malate (1mM) as substrate at 30°C, in the presence or absence of 5mM $MgCl_2$ + 30μM ADP. The organelles were preincubated with MPP^+ (0.5mM), paraquat (5mM) and diquat (5mM) for 3 min. The uptake was started by adding ^{45}Ca and stopped by filtering the mixture through GF/B glass microfiber filters.

In the absence of Mg.ADP, mitochondria from striatum exhibited a linear uptake of Ca over 10 min and this was inhibited by MPP^+, paraquat and diquat. Liver organelles under this condition showed a small and non-linear accumulation of ^{45}Ca. Addition of Mg.ADP markedly increased Ca accumulation in striatal and liver preparations. In striatal preparations, in the presence of Mg.ADP, the inhibition of Ca uptake by MPP^+, paraquat and diquat was attenuated. In liver mitochondria diquat exhibited a marked inhibition of Ca uptake, whereas cyperquat and paraquat showed only marginal inhibition. These findings indicate that cyperquat and related compounds can perturb mitochondrial transport.

This study was supported by the PSI Foundation of Ontario and the Parkinson's Disease Society of Ottawa-Carleton.

24.7 MPTP INDUCES DEGENERATION IN NUCLEUS SAGULUM, THALAMUS, DORSAL RAPHE, AND OF NON-CORTICAL PROJECTING DOPAMINERGIC BRAINSTEM NEURONS. R.C. Switzer and S.K. Campbell*, University of Tennessee, Depts. Pathology and Medical Biology, Knoxville, TN 37920

For an MPTP-treated animal to be a valid model of Parkinson's disease in humans, the populations of neurons induced to degenerate by MPTP in an animal must be congruent with those observed to be affected in Parkinsonism. To detect and characterize the population of degenerating neurons in MPTP-treated C57B6 mice, we applied the degeneration-sensitive cupric-silver stain of de Olmos. Previously (Neurosci. Abst. 1985), we had shown that within 48-72 hours after MPTP was administered, degeneration of neurons occurred in the substantia nigra (SN) and ventral tegmental area (VTA) in cell groups A8,9, and 10. In addition to these populations, we have also found degenerating neurons in the brainstem within the nucleus sagulum, in the rostral dorsal raphe nucleus, and in the lateral part of the medial thalamic nucleus (the region embraced by the interal medullary lamina of the thalamus). These three areas have far fewer neurons affected than in SN and VTA. The nucleus sagulum is a little known cell group situated laterally near the surface of the brainstem just caudal to the lateral lemniscus and dorsal to the middle cerebellar peduncle. A first impression is that these neurons are not part of the catecholamine population but part of the distribution of the noradrenergic A7 cell group which, as found in the rat, seems to overlap the location of the nucleus sagulum. A localization of dopamine beta hydroxylase in the C57 mouse is necessary to resolve this issue. The few but nevertheless distinct degenerating thalamic neurons do not appear to be part of any catecholaminergic cell groups. The raphe neurons affected are restricted to the rostral limits of this system at a coronal level that includes the oculomotor nucleus.

Although the number of degenerating neurons revealed by the cupric-silver stain is quite spectacular, it is clear that not all of the neurons are affected. Since the areas to which the components of the cell groups A8, 9, and 10 project are well established, we can infer which subsets of neurons are not affected by examining the areas to which the axons project for degenerating synaptic terminals. The striatum, nucleus accumbens, and ventral striatum exhibit dense terminal degeneration while we found lesser densities of terminals in the habenula. None of the cortical areas that receive dopamine input displayed any degeneration. This feature could be an important clue in determining why only some of the dopamine neurons in the CNS are affected by MPTP.

24.8 FLUOXETINE PRETREATMENT ATTENUATES THE MPTP-INDUCED DECREASE IN DIHYDROXYPHENYLACETIC ACID (DOPAC). W.J Brooks* and G.C. Wagner. Psychology Dept., Rutgers Univ. New Brunswick, NJ 08903

In order for 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP) to exert neurotoxic effects on dopaminergic neurons, it must first be metabolized to 1-methyl-4-phenylpyridinium ion (MPP^+) by monoamine oxidase 'B' (MAO-B). Since MAO-B is located in serotonergic neurons and astrocytes, the conversion of MPTP to MPP+ must take place outside the dopaminergic neuron. It was previously demonstrated that pretreatment with a serotonin transport inhibitor, fluoxetine, protected dopaminergic neurons against the toxic action of MPTP. In addition to its action as a neurotoxin, MPTP has also been shown to acutely inhibit monoamine oxidase, thereby causing a decrease in the concentration of DOPAC in the striatum. The following study was conducted in order to determine if fluoxetine pretreatment would attenuate the MPTP-induced decrease in DOPAC.

Adult male Swiss-Webster mice were fluoxetine (10 mg/kg, IP) 16-h prior to MPTP (10 mg/kg, IP) or with an equal volume of saline 16-h prior to the MPTP. Control mice received fluoxetine 16-h prior to a second injection of saline or two injections of saline. All mice were sacrificed 2 h after the second injection, brains removed, striatum dissected and assayed for dopamine, DOPAC and serotonin by HPLC.

It was observed that control mice (saline/saline) had 13.04 ug dopamine/g tissue (± .87), 1.99 ug DOPAC/g tissue (± .15) and 0.77 ug serotonin/g tissue (± .16). Fluoxetine alone produced no significant change in any of these values when administered 18 h prior to sacrifice. MPTP alone caused no significant change in dopamine (11.16 ug/g ± .74) or serotonin (0.71 ± .05) levels but produced a significant decrease in DOPAC (0.87 ± .10) levels. Fluoxetine, administered as a pretreatment to MPTP, produced no significant change in the concentration of dopamine (12.36 ug/g ± .62) or serontonin (1.06 ug/g ± .18) but significantly reversed the MPTP-induced decrease in DOPAC (1.31 ug/g ± .08).

These data indicate that the decrease in the concentration of DOPAC caused by MPTP is occurring outside the dopaminergic neuron as a result of the inhibition of monoamine oxidase in serotonergic neurons or astrocytes.

24.9 AGE-DEPENDENT EFFECTS OF MPTP: CORRELATION WITH MAO-B ACTIVITY. S.L. Walsh, S. Auerbach and G.C. Wagner. Depts. of Psychology and Biology, Rutgers University, New Brunswick, NJ 08903.

Systemic administration of MPTP, a potent neurotoxin, results in selective destruction of the dopaminergic neurons in humans, subhuman primates and rodents. It has been demonstrated that this toxin induces a permanent parkinsonian-like syndrome in humans and subhuman primates. These toxic actions are, in part, dependent upon MPTP's conversion to MPP^+ by monoamine oxidase B (MAO-B), and the subsequent uptake of MPP^+ by the dopaminergic uptake pump. Pretreatment with the MAO inhibitors, pargyline and deprenyl protect against the toxic effects of MPTP in vivo. Since MAO activity increases significantly as aging occurs in humans, subhuman primates and rodents, there may be an enhanced sensitivity to the toxic effects of MPTP in developing animals. In addition, it would be predicted that this increased sensitivity to MPTP would correlate with the increasing MAO activity.

Swiss-Webster male mice aged 1, 2, 4, 8, and 16 weeks and 1 year of age were treated with four injections (subcutaneous) of 12.5 mg/kg of MPTP hydrochloride with two hours between each injection. For each age group, one group of controls were treated with saline vehicle under the same injection regimen, and a second group of controls were untreated and sacrificed at the age of treatment for the first two groups. One week after treatment, the mice were sacrificed, brains dissected and divided into right and left halves. For all three groups, the right brain halves were assayed for monamine oxidase B activity using a colorimetric assay with benzylamine as the substrate. The left halves were assayed for dopamine and serotonin content utilizing high performance liquid chromatography.

It was observed that there was a significant age-dependent increase in MAO-B activity. There was also a significant age-dependent effect of MPTP toxicity on dopamine levels, with the youngest age points showing no depletions and the one year-old mice suffering a 68% depletion of whole brain dopamine. No significant effect was observed on serotonin levels. The age-dependent increase in MAO-B activity was highly correlated with the extent of the lesion incurred at various age points. It was also observed that MPTP administration resulted in a significant increase in MAO-B activity in comparison to controls one week after treatment, with the youngest age groups exhibiting a greater increase in activity than older animals.

24.10 THE AGE-RELATED ENHANCEMENT OF MPTP TOXICICITY: TOXICOKINETIC VERSUS TOXICODYNAMIC FACTORS. I. Irwin*, G.A. Ricaurte*, L.E. DeLanney, J.W. Langston. (SPON: J.W. Tetrud) Inst. Med. Res., San Jose, CA; Stanford Univ. Sch. of Med., Stanford, CA.

Recent observations indicating that the neurotoxic effects of MPTP (1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine) increase with age suggest that this neurotoxin may provide a useful tool for the study of the relationship between aging and Parkinson's disease (Lewin, 1985; Langston, 1987). To clarify the relative contribution of toxicokinetic factors (changes in biodisposition of MPTP or its putative toxic metabolite MPP+) vs toxicodynamic factors (changes in the sensitivity of neurons with age) several experiments were done. The first of these was designed to determine (1) if MPP+ is further converted to other metabolites in the CNS and (2) if the elimination of MPP+ from the CNS changes with age. To circumvent questions relating to the alterations in the peripheral biodisposition of MPTP and MPP+ with age, MPP+ was given directly into the central nervous system (CNS) via the intracerebroventricular (ICV) route. C57Bl/6 mice of two different ages (6 wk vs 8 mos old) were compared in all experiments. ^{3}H-labelled MPP+ (20 μg) was administered ICV to mice from each age group (n=30/group). Five animals from each group were killed 2, 4, and 8 hrs later, their brains removed, and the total radioactivity measured using liquid scintillation counting. By comparing these results with concentrations determined by GC/MS, virtually all of the radioactivity could be accounted for as MPP+. Thus, it appears that MPP+ is not further metabolized in brain. MPP+ was eliminated from the brain in a time-dependent manner in both young and older animals, but no significant differences were detected between the two age groups (MPP+ values [μg/g] for young vs old were: 2 hr - 5.6 ± 0.5 vs 5.5 ± 0.9; 4 hr - 3.5 ± 0.3 vs 3.4 ± 0.4; 8 hr - 1.5 ± 0.3 vs 1.2 ± 0.1).

Since no differences in the CNS biotransformation or elimination of MPP+ between the two groups were found, we could now directly assess the relative sensitivity of the two age groups to the DA-depleting effects of MPP+ by administering it directly to the brain via the IVC route. MPP+ (10 or 20 ug) was administered to each group (n=5/dosage group). Animals were killed after 5 days and striatal DA measured. DA depletions (μg/g) were equivalent in old vs young (Control - 11.3 ± 0.2 vs 11.1 ± 0.4; 10 μg - 11.4 ± 0.5 vs 10.5 ± 0.51; 20 μg - 7.3 ± 1.7 vs 8.1 ± 2.1). Hence, there appears to be no difference in sensitivity between the two age groups studied in regard to the DA-depleting effects of MPP+. These results suggest that toxicokinetic factors may underly the age-related increase in the striatal dopamine-depleting effects of MPTP.

24.11 THE EFFECT OF DIETHYLDITHIOCARBAMATE (DDC) ON THE BIODISPOSITION OF MPTP: AN EXPLANATION FOR ENHANCED NEUROTOXICITY. E. Y. Wu*, I. Irwin*, L. S., Forno, L. E. DeLanney, A. Trevor*, J. W. Langston. Univ. Calif., San Francisco, CA; Inst. Med. Res., San Jose, CA; Vet. Adm. Med. Ctr., Palo Alto, CA.

DDC has been reported to exacerbate the dopamine-depleting effects of MPTP in mice (Corsini et al, 1985). We have confirmed these observations in 6 to 8 wk old C57Bl/6 mice. Two animals given 400 mg/kg of DDC 1/2 hr prior to a 30 mg/kg IP dose of MPTP and studied 10 days later showed severe neuronal cell loss in the substantia nigra (SN), accompanied by glial-microglial reactions. Lower doses of MPTP (10 or 20 mg/kg) in combination with DDC produced definite but less severe cell loss. In contrast, when mice were given MPTP alone (30 mg/kg/dose IP) (even when repeated on a daily basis for up to 10 days) or DDC alone (400 mg/kg), no SN cell loss was seen. Histologically, these changes are quite similar to those seen in primates after MPTP administration.

To determine the mechanism underlying the DDC-induced exacerbation of MPTP-induced neurotoxicity, groups of animals (n=15/group) were given either MPTP (30 mg/kg) alone, DDC (400 mg/kg) alone, or DDC (400 mg/kg) 1/2 hour prior to MPTP (30 mg/kg). Mice were killed after 0.5, 1.0 and 2.0 hr, and striatum (STR), ventral mesencephalon (VME), and frontal cortex (FC) analyzed for MPTP and MPP+ using GC/MS. MPTP (detected only at 30 min) was much higher in mice given DDC + MPTP vs MPTP alone (STR - 4.7 ± 0.6 vs. 1.9 ± 0.2; VME - 1.4 ± 0.1 vs. 4.3 ± 0.7 vs. 1.4 ± 0.1; FC - 5.5 ± 0.6 vs 1.6 ± 0.3 μg/g). Pre-administered DDC also increased MPP+ concentrations in these regions (STR - 11.3 ± 0.2 vs 10.6 ± 0.7; VME - 9.1 ± 1.1 vs 6.6 ± 0.4; FC - 12.7 ± 1.0 vs 7.9 ± 0.5 μg/g). The molecular mechanisms underlying this effect were further investigated in vitro. In a partially-purified MAO B preparation, DDC enhanced the biotransformation of MPTP in a concentration-dependent manner. Bovine liver MAO B (6-8 mU) incubated with 3.3 mM MPTP produced MPDP+ at a rate of 38.7 ± 4.0 nmole/30 min. The addition of DDC (100 or 500 μM) significantly increased this rate to 52.6 ± 5.7, and 58 ± 3.3 nmole/30 minutes respectively. DDC (12.5, 25, 100, or 500 μM) also enhanced MPP+ production (19.9, 24.6, 33.6, 53.5% respectively) in mouse brain homogenates incubated with MPTP (100 μM).

These results suggest that DDC enhances MPTP-induced neurotoxicity by increasing brain concentrations of MPP+. Factors contributing to this increase appear to include greater delivery of MPTP to the central nervous system, increased MAO-mediated biotransformation of MPTP to MPP+, and possibly reduced elimination of MPP+ from the brain.

24.12 EFFECTS OF THE COMBINED TREATMENT OF DIETHYLDITHIOCARBAMATE AND MPTP ON BEHAVIOR IN THE RODENT. D.M. Yurek, A.Y. Deutch[1], R.H. Roth[1], and J.R. Sladek, Jr. Dept. of Neurobiology and Anatomy, Univ. of Rochester Medical School, Rochester, NY 14642 and [1]Dept. of Pharmacology, Yale Univ. School of Medicine, New Haven, CT 06510.

The dopamine-depleting effects of the neurotoxin 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP) are enhanced when administered in combination with diethyldithiocarbamate (DDC) in mice (Corsini *et al.*, *Eur. J. Pharmacol.*, 119:127-128). This study examined the behavioral correlates associated with this treatment. Male C57 BL mice were pretreated with 400 mg/kg (i.p.) of DDC one-half hour prior to the administration of either vehicle, 15.0, 22.5, 26.5, or 30.0 mg/kg (i.p.) of MPTP. The same treatment was repeated twelve hours later. Initially, weight loss was observed for the two highest doses of MPTP-treated mice and maximal weight loss occurred at 3 and 5 days after the treatment. Mice with >15% weight loss displayed dorsal spinal flexion and were hyper-responsive to tactile stimuli. However, 14 days following MPTP treatment we observed that body weights returned to pre-MPTP levels for all doses, although postural abnormalities were still evident.

The effects of the combined treatment of DDC and MPTP on diurnal spontaneous locomotor activity varied. Locomotor activity was assessed by monitoring the number of infrared light beam interruptions/hour that occurred during either the 'light' or 'dark' phase of the animal's diurnal cycle. Pre-MPTP activity monitoring determined that dark phase activity was 15-fold greater than light phase activity. At 3 and 5 days post-MPTP, dark phase activity was found to be significantly lower than pre-MPTP dark activity for the two highest MPTP doses. Conversely, during this same post-MPTP period, light phase activity was found to be greater than pre-MPTP light phase activity for the same MPTP doses. These data suggest that the combined treatment of DDC and MPTP (1) attenuates locomotor activity associated with the active phase of the diurnal cycle and (2) activates mice during the inactive phase of their diurnal cycle.

One week after the MPTP administration these same mice were treated with either vehicle, 0.2, or 2.0 mg/kg (i.p.) apomorphine. The low dose of apomorphine (0.2) enhanced locomotor activity for animals treated with two highest doses of MPTP. Mice treated with the two highest doses of MPTP and administered 2.0 mg/kg (i.p.) apomorphine exhibited enhanced stereotypic behavior. These data most likely reflect post synaptic receptor supersensitization.

Behavioral correlates for MPTP-induced dopamine depletion exist 1 week following MPTP treatment. However, the recovery of feeding behavior, as expressed by body weight changes, which occurred after the first week is indicative of compensatory changes in dopamine function. Furthermore, the hyper-responsivity associated with mice treated with the two highest doses of MPTP may indicate that lateral caudate innervation may have been spared, thus we may be observing the behavioral effects associated with an incomplete dopaminergic lesion.

These data will also be discussed in relation to changes in striatal dopamine content and nigral tyrosine hydroxylase levels. This research was supported by T32 MH 18260 (DMY) and AG 00847 (JRS).

24.13 EFFECTS OF DIETHYLDITHIOCARBAMIC ACID ON THE DISTRIBUTION AND TOXICITY OF 1-METHYL-4-PHENYLPYRIDINIUM IN C57/BL MICE. D.B. Miller, J.F. Reinhard[1] and J.P. O'Callaghan. U.S. EPA, RTP, NC 27711 and [1]The Wellcome Research Laboratories, Burroughs Wellcome Co., RTP, NC 27709

Diethyldithiocarbamic acid (DDC) potentiates the toxicity of the dopaminergic neurotoxicant 1-methyl-4-phenyl-1 2,3,6-tetrahydropyridine (MPTP) based on increased lethality, enhanced catecholamine depletions and elevated glial fibrillary acidic protein (GFAP) levels in striatum and hippocampus as well as more pronounced motor dysfunction (Miller et al. Toxicologist 7:154, 1986). Because DDC and related dithiocarbamates can cause a redistribution of quartenary compounds (O'Callaghan and Miller, Br. Research 370:354, 1986) it may effect this increase in toxicity by a redistribution of 1-methyl-4-phenylpyridinium (MPP^+) the toxic metabolite of MPTP or it may increase the toxicity of MPP^+ itself. Here we characterize the effects in the C57/Bl mouse of DDC on the distribution and toxicity of MPP^+. Tritiated MPP^+ was used to determine the distribution of MPP^+ in brain, heart and liver following DDC. Brain and heart catecholamine levels were determined by liquid chromatograph and electrochemical detection. RIA of the astrocyte-localized protein GFAP was used to assess possible CNS injury following DDC/MPP^+.

Mice were given (n=6) s.c. sal or DDC (400 mg/kg) followed 0.5 hr later by an i.p. injection of tritiated MPP^+ and unlabeled MPP^+ at a dosage of 5.0 mg/kg. At 0.25, 0.5, 1.0 or 4 hrs after dosing mice were anesthetized with pentobarbital, perfused with 0.9% sal, and brain, heart and liver were removed. Tissues were dissolved and radioactivity determined by liquid scintillation spectrometry. Other groups (n=5/gp) received s.c. sal or DDC (400 mg/kg) followed 0.5 hr later by i.p. MPP^+ (5.0 or 10.0 mg/kg) daily for 4 days. Two days after the last injection brain and heart were removed for biochemical assay. DDC did not affect the distribution of MPP^+. DDC did increase, however, the general toxicity of MPP^+ as indicated by 70% mortality in the DDC/10.0 mg/kg MPP^+ group after the first injection. No decreases in dopamine or elevations in GFAP were observed in striatum after either MPP^+ or DDC/MPP^+ However, slight elevations in GFAP were seen in hippocampus in the DDC/MPP^+ group and indicate the combination may result in damage to this brain area.

24.14 RELATIVE EFFICACY OF BETA-CARBOLINE ANALOGS OF MPP+ AS INHIBITORS OF STRIATAL DOPAMINE UPTAKE. M. A. Collins, G. E. Drucker*, E. J. Neafsey and K. Raikoff.*
Departments of Biochemistry and Anatomy, Loyola Univ. Sch. of Medicine, Maywood, IL 60153.

N-Methyl-phenylpyridinium ion (MPP+) is the oxidized active form of the synthetic dopaminergic neurotoxin, MPTP. It is of interest that N-methylated beta-carbolines (BCs), which can form in peripheral and nerve tissues via carbonyl condensations of indoleamines (tryptamine, serotonin, etc.) followed by enzymic oxidation/methylation, structurally resemble MPP+. We have proposed (Collins, Neafsey, Neurosci. Lett. 1985) that the nigrostriatal dopaminergic loss underlying Parkinson's disease could be due to "MPP+-like" alkaloidal BCs which arise in vivo. Since avid uptake of MPP+ into dopamine cells appears to be a prerequisite for its neurotoxicity, it was reasoned that a potential endogenous toxin also would exhibit the same requirement. Thus, we have synthesized or obtained BCs and 3,4-dihydro-beta-carbolines (DHBCs) of various families, both N-methylated and normethylated, and have initiated a comparative study of their ability to inhibit 3H-dopamine uptake by rat striatal synaptosomes. By analogy with MPP+, inhibition of dopamine uptake is assumed to be due to competitive uptake of BCs and DHBCs into dopamine terminals. To date, certain structure-activity relationships have emerged. Overall, DHBCs are nearly equipotent with BCs as dopamine uptake inhibitors. The most effective alkaloidal derivatives are the 7-oxygenated (methoxy, hydroxy) BCs and DHBCs, with IC50's in the range of 4-12 uM, whereas the 6-methoxylated analogs are 15- to 25-fold less potent. N-methylation to form a quaternary nitrogen (beta-carbolinium ion) generally appears to increase potency, with the exception of the 7-hydroxy-substituted compounds. This might reflect the ability of the hydroxyl to delocalize the quaternary positive charge into the indole ring. Although an order of magnitude less potent that MPP+ in terms of assumed uptake, selected BCs (or DHBCs) apparently would be accumulated to a significant extent by dopaminergic cells over an prolonged period of time. Whether such BCs can induce neurotoxicity in those cells remains to be investigated in cultures and in vivo models. Supported by NS 23891 and the LUMC Dean's Fund.

24.15 COMBINED TREATMENT WITH ETHANOL OR ACETALDEHYDE AND MPTP: A MODEL OF SELECTIVE DESTRUCTION OF SUBSTANTIA NIGRA DA NEURONS IN YOUNG MATURE MICE. A. Zuddas, S. Schinelli, U. Bonucelli, G.U. Corsini, I.J. Kopin, NINCDS, National Institutes of Health, Bethesda, MD.

In humans and monkeys MPTP induces parkinsonism due to selective destruction of nigra striatal DA neurons. Long lasting neurochemical changes, but not cell loss, have been reported in brain of young mature mice treated with high doses of MPTP. We have recently reported that ethanol (ETOH), acetaldehyde (ACE) as well as diethyldithiocarbamate (an inhibitor of super oxide dismutase and aldehyde dehydrogenase) potentiate MPTP toxicity in mice, (Corsini, et al., Life Sci. 40:827, 1987) and causing an extensive destruction of DA neurons in substantia nigra pars compacta (SNc) (Zuddas, et al., Neurology 37 Suppl 1:333, 1987). To determine whether such enhancement of neurotoxicity was specific, we studied the effects of these combined treatments on mice of different ages, by measuring the content of DA, NE and 5HT in different brain areas. We also studied the recovery of striatal DA 5 weeks after the treatments. In addition, the striatal DA was evaluated in aged rats treated with ethanol and MPTP. Male C57 black mice, 5 and 8 weeks old were treated with ACE (250 mg/kg, i.p.) 10 min before, 10 and 30 min after MPTP (30 mg/kg, i.p.). Five week old mice were sacrificed seven days after the treatments; 8 week old animals were sacrificed either seven or 35 days after the injections. ACE treatment of 5 week old mice did not enhance DA depletion seen 7 days after MPTP treatment (50% depletion vs 43% depletion by MPTP alone). In 8 week old mice, however, ACE given with MPTP decreased striatal DA by 93% compared with 51% depletion when given alone. One month later, striatal DA content recovered to 64% of controls in the older mice treated with MPTP alone, whereas in ACE-MPTP treated animals, no significant recovery occurred. In the ACE-MPTP treated mice changes in DA levels were observed only in the striatum. DA content in hypothalamus, olfactory bulb and frontal cortex was unmodified in comparison to controls. Contents of NE and 5HT in hypothalamus, cerebral cortex, olfactory bulb and striatum were not affected by any of the treatments. In addition, marked loss of tyrosine hydroxylase immunoreactivity was observed in SNc but not in ventral tegmental area nor in locus coeruleus. The same biochemical and histological findings were observed in 8 week old mice treated twice with combined ETOH (1 g/kg, i.p.) and MPTP (30 mg/kg, i.p.). On the other hand, this treatment was not effective in the rat. One year old Sprague Dawley rats treated 5 days with ETOH (1 g/kg,i.p.) and MPTP (30 mg/kg, i.p.) or with MPTP alone showed no change in striatal DA content. Out data show that enhancement of MPTP neurotoxicity by acetaldehyde is specific for nigra striatal DA pathway without significant recovery by 5 weeks. Rats and very young mice are not sensitive to this enhancement. This result suggests that in 8 week old mice, ETOH or ACE and MPTP treatment is a more useful model of parkinsonism than MPTP treatment alone.

24.16 INTERACTION OF BRAIN-DERIVED MITOGENS AND ETHANOL ON ASTROCYTIC CELL KINETICS. D. L. Davies and T. Jang, Dept. of Anatomy, Univ. of Arkansas for Medical Sciences, Little Rock, AR 72205-7199.

Injury of the brain stimulates the presence of tissue mitogens which may contribute to reactive gliosis (Nieto-Sampedro, M., et al., Brain Res. 343:320, 1985), and similar mitogens have been implicated in developmental proliferative growth of the brain (Guilian, D., et al., J. Cell Biol. 102:803, 1986). Moreover, ethanol-intoxication is a frequent predisposing factor for traumatic injury in adults and prenatal ethanol exposure may result in cerebral hypocellularity. The present study was undertaken to assess the astrocytic response to tissue mitogens and the vulnerability of this response to ethanol toxicity.

An extract of brain was used as a source of mitogens. The extract was prepared by homogenation of adult rat brains in phosphate buffered saline (1:2 ratio) followed by centrifugation at 10,000G for 30 min; the supernatant was sterilized by filtration. Astrocytic cell cultures were used as an assay system.

Primary cultures were prepared from the cerebra of rats between 1 and 3 days postnatal age. The medium was DMEM fortified with 10% FBS. Confluent cultures were shaken vigorously for 5 sec to remove process bearing cells; the remaining adherent cells were trypsinized and subcultivated into 35 mm culture dishes.

On culture day 6, eight experimental groups were designated. Half of the cultures received brain extract (150 mg protein/ml nutrient medium); ethanol was administered at 4 dose levels: 0.0 g%, 0.1 g%, 0.2 g%, or 0.5 g% (i.e. 0.0, 21.7, 43.4, or 108.5 mM). Cultures were incubated in closed vapor chambers designed to maintain consistent ethanol concentrations with 5% CO_2 at 37° C. The total number of cells in these cultures was determined on culture days 8, 10 and 12. For analysis of cell-cycle parameters cultures were stained with propidium iodide (Burns, E. R. et al., Cytometry 4:150, 1983) and the DNA content of individual cells was assessed by flow cytometry (Ortho Cytofluorograft IIS). The astrocytic identity of the cultures was verified by immunolocalization of GFA (the antibody was a gift from Dr. D. Dahl). The ethanol concentration of the medium was measured enzymatically.

Ethanol content of the medium after 72 hr of incubation was at least 94% of the initial concentrations. Brain extract slightly increased total cell number, however, statistically significant differences were not achieved with this dosage of the extract. The flow cytometric data indicated that treatment with brain extract marginally increased the number of cells in the S and G_2/M phases of the cell-cycle. Constant exposure to 0.5 g% ethanol for 6 days suppressed total cell number relative to untreated controls. Thusfar, ethanol-related changes in the cell-cycle have not been detected. Supported by USPHS Grant #AA07145.

24.17 STEREOLOGICAL STUDY OF THE RAT HIPPOCAMPAL MOSSY FIBER-CA3 SYNAPSES AFTER LONG-TERM ALCOHOL CONSUMPTION AND WITHDRAWAL.M.M. Paula-Barbosa, M.A.Tavares*, M.M.Pacheco*, M.C.Pinho* and A.Cadete-Leite*
Dept. of Anatomy, Oporto School of Medicine,Oporto 4200,Portugal.

Neuronal loss was found to occur in the adult rat hippocampal formation (HF) after 5 months of chronic alcohol consumption (CAC) (Walker,D.W., Science, 209:711,1980). As we observed that in the cerebellar cortex alcohol induced changes were progressive, we thought it would be of interest to study, using recently described stereological techniques, the effects of CAC in the HF after longer periods of treatment and withdrawal.Attention was paid to the synaptic system between granule cell mossy fibers and CA3 pyramids (MF-CA3) due to its relevant role within the HF trisynaptic circuitry.

This study was undertaken in 5 groups of 6 rats:alcohol treated with an 20% aqueous ethanol solution for 6 and 18 months starting at 2-month age, respective age-matched pair-fed controls and in an alcohol-treated group for 12 months, rehabilitated ad libitum for 6 months (recovery group). The disector method (Sterio,D.C., J. Microsc., 134: 127,1984) was applied for the determination of numerical densities (Nv) of neurons and synapses. For the neurons, serial semithin sections from 3 different blocks per animal were used (6 disectors per block). For the synapses, serial ultrathin sections from 3 blocks per animal were used (10 disectors per block).

After 6 and 18 months of CAC the Nvs of granule cells and CA3 pyramids were significantly reduced. No significant differences were found in the number of synapses between MF-CA3 after 6 months of experiment, conversely to what happens after 18 months of CAC where MF-CA3 synapses were significantly reduced. The fraction of MF endings plasmalemma occupied by active zones was significantly increased in alcohol-fed groups. In the recovery group a significant reduction of neurons was found when compared both with the 18 months alcohol-fed and control groups. The Nv of MF-CA3 synapses was significantly reduced when compared with the 18-month control group; no significant differences were found when compared with the alcohol-treated group. The fraction of MF endings plasmalemma occupied by active zones was significantly increased when compared with controls; no significant differences were found when comparison was made with alcohol-treated group.

We conclude that: 1) the HF is remarkably sensitive to CAC ; 2) there are signs of synaptic remodelling in alcohol-treated and recovery groups and 3) alcohol withdrawal doesn't reverse the alcohol induced degenerative changes.

SENSORY SYSTEMS: SOMATOSENSORY

25.1 RESPONSIVENESS OF SURVIVING SOMATIC SENSORY CORTEX FOLLOWING LESIONS OF SI OR SII IN ADULT AND INFANT CATS AND PRIMATES. H. Burton, K. Sathian*, K. Alloway, S. Warren and M. Carlson.
Depts. Anatomy-Neurobiology and Psychiatry, Washington Univ. Sch. Med., St. Louis, MO 63110

Lesions of either the first (SI) or second (SII) somatosensory cortical area impair the capacity of adult macaques to discriminate textured surfaces, whereas infant macaques recover this capacity if either SI or SII is spared (Burton et al., '87). An important issue is whether the lesions interrupt "serial" or "parallel" interactions between SI and SII. Thalamocortical connections may be crucial to this problem as the extent of dual projections to SI and SII from VPL may change with age or species. We are studying these issues by recording neuronal activity in SI or SII after lesions of the other area made at various ages in 3 species: cats, galagos and macaques.

Following removal of SI bilaterally and SII unilaterally at 3 days or 4 weeks of age in cats, we found that at maturity the remaining SII mapped normally with cutaneous stimuli. Local anesthetization of SI with lidocaine in adult cats (Burton & Robinson, Somato Res. 4:215-236,1987) or lesions of SI in adult galago also failed to alter SII responsiveness.

We have also made SI and SII lesions in the hand and digit areas of juvenile and infant macaques. Multi-unit recordings, to date, from the SI hand area show no changes in responsiveness or topographic organization after lesions of SII. Recordings have also been obtained from SII following an 8 month old SI lesion made in a juvenile. In this case responses to somatic stimuli could be recorded in the depths of the lateral sulcus. In contrast to the normal SII, most of the responses were not evoked by low threshold cutaneous stimuli and well-defined receptive fields were not found. Effective stimuli consisted of slow stroking, squeezes, or crude joint manipulations. Von Frey filament forces of >300mg, and frequently of >1000mg, were needed to activate neurons. Some pockets of low threshold (<300mg) responses were found amidst the higher threshold activity. Despite the generally increased difficulty in evoking responses, the expected radial to ulnar digit sequence was recorded along the parietal operculum. Recordings in SII obtained from outside the hand and digit area responded to low threshold stimuli. No selective enlargement of these representations have been noted. Results from SII in animals with infant SI lesions will be reported subsequently. (Funds from NS15070, NS07071, MH14677)

25.2 POTENTIAL ROLE OF THALAMOCORTICAL CONNECTIONS IN RECOVERY OF TACTILE FUNCTION FOLLOWING SOMATIC SENSORY CORTEX LESIONS INFANT PRIMATES. M. Carlson, D.D.M.O'Leary & H. Burton.
Depts. Psychiatry, Neurosurgery, Anatomy & Neurobiology, and McDonnell Center for Studies of Higher Brain Function, Washington University School of Medicine, St. Louis, MO. 63110.

Electrophysiological studies of tactile input to primary (SI) and secondary (SII) somatic sensory cortices have allowed comparison of the organization and function of SI and SII hand areas in the Old World anthropoid, Macaca, and prosimian, Galago. Our recent behavioral studies of infant Macaca have shown that, although SI and SII are necessary for normal tactile discrimination in the adult, that either SI or SII alone can mediate texture discrimination in the infant.

We have found texture discrimination capacity of the normal adult Galago to be less than that of adult Macaca, possibly due to the smaller and less complex SI hand area in Galago. Removal of SI or SII in adult Galago reduced tactile performance below normal levels. Ongoing studies of infant Galago show that, as in infant Macaca, tactile function recovers following either SI or SII removals.

We have proposed that the recovery of tactile function in the infant primate may depend upon an exuberant pattern of thalamocortical projections from the ventroposterior (VP) nucleus in the infant. Such projections might be stabilized by removal of either SI or SII and, thereby, serve as a basis for the equipotentiality of function seen in SI and SII in infant primates. To examine this issue in normal animals, we have injected the retrogradely transported fluorescent dyes, Fast Blue and Diamidino Yellow, into SI and SII, respectively. Dye injections into adult Galago confirm our earlier findings using HRP of separate projections to SI and SII from VP. Similar dye injections in infant Galago reveal a less segregated pattern in VP, and double-labeled cells are more common. Injections in SI- or SII-lesioned infants and adults are planned to search for maintained projections in the infant-lesioned animal.

25.3 GABA, NEUROPEPTIDE AND ChAT EXPRESSION IN NEURONS OF THE FETAL MONKEY SENSORY-MOTOR CORTEX. G.W. Huntley*, S.H.C. Hendry, E.G. Jones, L.M. Chalupa and H.B. Killackey (SPON: M.A. Kirby). Depts. of Anatomy and Neurobiology and Psychobiology, University of California, Irvine, CA 92717 and Dept. of Psychology, University of California, Davis, CA 95616.

Immunocytochemical methods were used to examine the morphology and distribution of GABAergic, peptidergic and cholinergic neurons in the sensory-motor cortex of monkeys (Macaca mulatta) during the latter third of gestation (E110, 121, 135 and 150). Areal and laminar boundaries were determined by specific patterns of histochemical staining for cytochrome oxidase and acetylcholinesterase and by staining with thionin. In each of the fetuses, GABA-immunoreactive neurons are found through the thickness of the cortex and in the underlying white matter but were concentrated in two bands that included developing layers I-III and layer VI and the subjacent white matter. All GABA neurons are non-pyramidal cells. Co-localization experiments demonstrate that sub-populations of the GABA neurons are immunoreactive for cholecystokinin octapeptide (CCK), substance P (SP), somatostatin (SRIF) and neuropeptide (NPY) from the earliest ages examined. CCK somata occupy layers II and III; the cells give rise to processes that descend and form a dense plexus in layers V and VI. SP somata are concentrated in a thin band corresponding to layer V; they give rise to processes that ascend and form a dense plexus in layers I and II. The SP somata are particularly dense in the first somatic sensory area (SI) and less dense in the precentral motor area (area 4). Both SRIF and NPY somata are densely packed in layer VI and the subcortical white matter; their processes make up a broad plexus in layer V and a thin plexus in layer I. The layer I plexus is absent from area 3 of SI. At the four ages examined, none of the GABA or neuropeptide neurons is retrogradely labeled by injections of Fast Blue, Nuclear Yellow or rhodamine latex beads in the contralateral sensory-motor cortex. The described patterns are seen for each of the fetuses, although the numbers of neuropeptide immunoreactive neurons and the intensity of their staining declines in the older fetuses. Non-pyramidal neurons immunoreactive for choline acetyltransferase (ChAT) are also present in the sensory-motor cortex of fetal monkeys. A low density of ChAT-positive somata are diffusely scattered in layers V and VI and more densely packed in the subcortical white matter; their processes ascend to the middle layers of the cortex. The immunostaining patterns in fetal monkeys are unlike those seen in adult monkeys in the density of somata that are stained in the white matter (GABA, NPY and SRIF), in the restricted laminar distribution of somata and processes (GABA, CCK and SP), in the morphology of neurons (SP) and in the existence intrinsic ChAT-immunoreactive neurons.

Supported by Grants EY 06432, NS 21377 and RR 00169 from the National Institutes of Health.

25.4 **DOUBLE LABELLED NEURONS IN PRIMARY SOMATOSENSORY CORTEX (AREA 3B) OF THE FETAL RHESUS MONKEY.** L.M. Chalupa and H.P. Killackey, Dept. of Psychology and Calif. Primate Research Center, Univ. of California, Davis, 95616 and Dept. of Psychobiology, Univ. of California, Irvine, CA 92717.

In a previous study, we provided evidence that callosal projection neurons in the postcentral gyrus of the rhesus monkey undergo a marked change in areal distribution between embryonic days (E) 119 and 133. Initially, callosal projection neurons are evenly and continuously distributed throughout the postcentral gyrus although located in the appropriate cortical layers. At E133 and later, their areal distribution is not continuous, the density of callosal projection neurons varying both within and across cytoarchitectonic areas (Killackey & Chalupa, J. Comp. Neurol. 244:331, 1986). In the present study, we investigated the possibility that some callosal projection neurons may have multiple projections during the period of widespread distribution.

The cerebral cortices of four fetal rhesus monkeys (2 at E110, and 2 at E135) were injected with a combination of fluorescent tracers. Multiple injections of fast blue were made throughout the postcentral gyrus of one hemisphere and more restricted injections of rhodamine labelled microspheres were made into the posterior portion of the crown of the postcentral gyrus of the other hemisphere. The fetuses were sacrificed at E138 or later, after the discontinuous distribution of callosal projections is established. The brains were removed, sectioned and examined for the distribution of labelled cells with fluorescent microscopy.

In the animals injected at the younger age (E110), when callosal neurons were widespread, a continuous pattern of fast blue labelled neurons could still be detected in the postcentral gyrus. Further, in area 3b pockets of neurons which were labelled with fast blue were also labelled with rhodamine microspheres. As expected in the animals injected at the older age (E135), the overall distribution of fast blue neurons was discontinuous. In area 3b, individual neurons were labelled with either fast blue or rhodamine microspheres, but there were very few, if any, double labelled cells. These results indicate that the discontinuous distribution of callosal projection neurons is achieved in the primate cortex by mechanisms involving process elimination.

[Supported by NIH grants RR 00169 and NS 17234.]

25.5 NEONATAL THALAMIC LESIONS ALTER THE PATTERN OF CALLOSAL CONNECTIONS IN THE PARIETAL CORTEX OF THE RAT. K.A. Koralek and H.P. Killackey. Dept. of Psychobiology, Univ. of California, Irvine, CA 92717.

In neonatal rats, callosal projection neurons are widely and uniformly distributed across the parietal cortex. During early postnatal development, many neurons eliminate their callosal processes, and a well-defined pattern of callosal projections emerges (Ivy and Killackey, J. Neurosci., '82). We have recently shown that neonatal damage to the somatosensory periphery alters the tangential distribution of callosal cells and terminations in the parietal cortex (Koralek and Killackey, Soc. Neurosci. Abs., '86). These data suggest that the input from the thalamus shapes the distribution of callosal cells and terminations. In this study we directly test this hypothesis.

We removed the thalamus of rats on the day of birth, a time prior to the growth of thalamocortical axons into the somatosensory cortex. Large unilateral thalamic lesions were made by aspiration from a posterior approach in neonatal Long-Evans rats. At one month of age, multiple injections of horseradish peroxidase were placed into the cortex contralateral to the lesion, so as to be evenly distributed throughout parietal cortex. After a 24-36 hour survival period, the animals were perfused and the hemisphere ipsilateral to the lesion was flattened and sectioned tangentially. The thalamus was sectioned in the coronal plane. Both series of sections were processed with tetramethyl benzidine. Normal rats of the same age were used as control subjects.

Animals subjected to thalamic lesions at birth present a severely altered pattern of callosal connections. Aberrant patches of labelled cells and terminations are interspersed with zones containing little or no label. In all cases examined so far, the tangential distributions of callosal projection neurons and of terminations are the same. Features which characterize the normal adult callosal pattern cannot be recognized within the aberrant patchwork.

We conclude that input from the thalamus plays a crucial role in shaping the normal pattern of callosal connections during development of parietal cortex.

25.6 NEONATAL DEAFFERENTATION-PRODUCED METABOLIC REORGANIZATION IN SI BARREL CORTEX OF RAT: A COMBINED (14C)-2 DEOXYGLUCOSE (2DG) AND CYTOCHROME OXIDASE (CO) STUDY. R.L. Craik, C.L. Hand and P.J. Hand. Physical Therapy, Beaver College, Glenside, PA; Anim. Biol., Sch. of Vet. Med., and Dept. of Neurol., Sch. of Med., Univ. of PA, Phila., PA 19104.

The metabolic (functional) reorganization of rat SI cortex following neonatal vibrissa follicle deafferentation which spared #3 vibrissa of row C (SC3) consisted of an enlarged and diffuse pattern of SC3-activated metabolic labeling in contralateral SI compared to that associated with activation of the control C3 vibrissa (CC3; Sheu and Hand, 1982). The current study combines use of the 2DG and CO techniques to quantify (1) areal extent, (2) density, and (3) localization of SC3 metabolic labeling in laminae IIIb-IV of SI cortex of Sprague-Dawley rats (n=8) 90 days postneonatal vibrissa follicle deafferentation (postnatal day 2 or 3; PND 0=birthdate).

Quantitative areal analysis of C3-related metabolic activity in serial tangential sections through lam. IIIb-IV revealed the mean areal extent of labeling on the SC3 side was 1.7mm^2 compared to .32mm^2 on the CC3 side, representing a 5.3-fold increase on the SC3 side. Regarding density of metabolic labeling related to activated SC3 and CC3 barrels, quantitative densitometric analysis indicated an average increase of 9.4% for SC3 barrel compared to CC3 (p=.01). The 2DG labeling associated with CC3 activation was localized to the CO-labeled CC3 barrel and its surrounding septum. In contrast, 2DG labeling associated with SC3 activation was enlarged, diffuse, and extended over CO-labeled rows B, C, and D, with densest metabolic labeling confined to row C and its septa. Compared to the control side, boundaries of the CO-labeled barrels on the SC3 side were not as well-defined. Extent of the alteration of CO-labeled barrels on the SC3 side was variable in nature, ranging from ill-defined to totally disrupted barrels.

In conclusion, CO-labeled SI barrels were altered variably by neonatal vibrissa deafferentation, with some exhibiting severe disruption while others were reasonably distinct. The 2DG pattern of labeling associated with SC3 activation, however, was consistently diffuse and extended well beyond the CO-labeled SC3 barrel limits. If CO-labeled activity in SI barrel cortex is primarily in dendritic mitochondria of barrel neurons (Wong-Riley and Welt, 1980), then our results of a less-disrupted CO-pattern of labeling compared to the 2DG pattern suggest that factors such as reorganization of thalamocortical and local corticocortical circuitry may be operating in addition to some reorientation of barrel neuron dendrites to produce the enlarged and diffuse SC3-activated 2DG labeling. (Supported by NIH grant NS-22283-01A2)

25.7 THE DEVELOPMENT OF THE VIBRISSAE RELATED NEOCORTICAL AFFERENTS TO SOMATOSENSORY CORTEX OF THE RAT. Karl. F. Jensen, Neurotoxicology Division, Health Effects Research Laboratory, United States Environmental Protection Agency, Research Triangle Park, NC 27711

The clustered pattern of terminal arbors of thalamocortical axons projecting to the vibrissae region of the rat somatosensory cortex mimics the pattern of whiskers on the face of the rat. Furthermore, the immunohistochemical labeling pattern of an antibody to p38, an intrinsic protein of small synaptic vesicles (Jahn et al., 1985, PNAS 82:4137-4141), corresponds to the vibrissae related pattern of thalamocortical afferents in the developing somatosensory cortex (Jensen et al. 1986, Soc. Neurosci. Abstr. 12:1051). To further characterize the development of the vibrissae related neocortical map the pattern of p38 immunoreactivity was compared to the vibrissae related pattern of cytochrome oxidase activity.

Long-Evans rat pups were sacrificed at various times between birth and 21 days of age by perfusion with 4% paraformaldehyde under barbiturate anaesthesia. Tangential sections of flattened neocortex were incubated with a monoclonal antibody to p38 and processed for either indirect flourescein or PAP immunohistochemstry. Adjacent sections were processed to demonstrate the vibrissae related pattern of cytochrome oxidase activity.

While both p38 immunoreactivity and cytochrome oxidase activity demonstrate the vibrissae related pattern, two significant differences were observed in the development. First, patterned p38 immunoreactivity is apparent on pnd-2 prior to the appearance of patterned cytochrome oxidase activity on pnd-3. Second, while the vibrissae related pattern of cytochrome oxidase activity persists into adulthood, p38 immunoreactivity becomes uniformly distributed throughout the vibrissae region from pnd-12 to pnd-14. These results suggest that while p38 and cytochrome oxidase are not colocalized throughout development, the vibrissae related pattern of cytochrome oxidase is intimately linked to the ingrowth of neocortical afferents during early postnatal development.

25.8 THE EFFECTS OF SENSORY DEPRIVATION ON GLUTAMIC ACID DECARBOXYLASE IMMUNOREACTIVITY IN THE RAT SmI BARREL CORTEX. N.D. Akhtar* and P.W. Land. Dept. of Neurobiology, Anatomy and Cell Science, Univ. of Pittsburgh Sch. of Med., Pittsburgh, PA 15261

The somatosensory cortex (SmI) of adult rats contains neuronal aggregates, called barrels, each of which is functionally linked to the corresponding vibrissa (the "columnar" vibrissa or whisker) on the contralateral face. Electrophysiological studies (Simons and Land, Nature 326:694-697, 1987) indicate that tactile deprivation by chronic whisker trimming from birth results in abnormalities in responses of barrel neurons to stimulation of the regrown whiskers. These abnormalities include enlarged receptive fields, reduced selectivity for whisker deflection at particular angles, increased responsiveness and altered patterns of stimulus evoked discharges compared with cells in normal barrels. Such changes suggest diminished effectiveness of intracortical inhibition in neonatally deprived barrels.

Immunocytochemical methods were used to examine the distribution of glutamic acid decarboxylase (GAD) in SmI of rats that had one or more rows of whiskers chronically trimmed for 2 months beginning at birth or during adulthood. Whisker trimming begun in adulthood results in a marked but reversible decrease in GAD staining in barrels corresponding to the trimmed whiskers. This presumably reflects down- and up-regulation of GAD synthesis following changes in sensory input. By contrast, GAD staining in SmI of animals trimmed from birth is similar to that in normal animals. Deprived and non-deprived barrels contain equivalent numbers of GAD+ neurons and a dense accumulation of GAD+ terminals. The trimmed vibrissae of some neonatally deprived animals were allowed to grow to normal lengths for 6-8 weeks, after which time those whiskers were again trimmed for 2 months. The second trimming, in adulthood, had no effect on GAD staining in the corresponding barrels.

Our results indicate that GAD neurons and terminals in SmI barrels develop without normal stimulation of the corresponding whiskers. However, GAD regulation in neonatally deprived barrels becomes refractory to subsequent changes in vibrissal input, whereas maintenance of GAD levels in normal barrels is critically dependent on stimulation of the columnar whisker. The finding that sensory input from neonatally trimmed vibrissae has little or no influence on the metabolism of GAD containing cells is surprising, given the unusually vigorous response of many deprived neurons to whisker deflection. One possibility is that GAD cells in neonatally deprived barrels become dominated by non-columnar inputs. This would be compatible with recent electrophysiological data and would further point to abnormalities in intracortical inhibitory mechanisms following tactile deprivation early in life. Supported by NIH grant NS 23047.

25.9 DENDRITIC OVERPRODUCTION AND ORIENTED DENDRITIC LOSS IN THE DEVELOPMENT OF NEURONS IN THE POSTEROMEDIAL BARREL SUBFIELD OF MOUSE SOMATOSENSORY CORTEX. W. T. Greenough, F.-L. F. Chang, I. R. Niesman, and E. P. Loeb. Depts. Psychol. and Anat. Sci., and Neur. & Behav. Biol. Prog., Univ. Illinois, Champaign, IL 61820.

Axonal proliferation and loss, in the generation of patterned arrays in the CNS, are well established developmental phenomena. Dendritic overproduction and regression has been reported, and in some cases there is evidence for its modulation by neuronal activity. However, the notion that initial dendritic outgrowth may in some cases be relatively nonsystematic and that pattern is subsequently imposed through selective dendrite elimination has not been widely demonstrated. The highly ordered dendritic arrangement of the vibrissae-associated somatosensory cortical barrel system, in which dendrites of cells in barrel walls are oriented towards the hollow, provides a unique opportunity to study oriented dendritic field development in cerebral cortex. We studied a total of 143 Golgi-stained (methylene blue counterstained) spiny stellate neurons in the walls and hollows of cortical barrels of mice at postnatal ages 10, 15, 20, 25, and 30 days. Only cells in approximately the inner 1/3 of the cell-dense barrel wall were examined. Projection tracings of the dendritic fields of these cells were made with the aid of a camera lucida, and the relative location of the barrel hollow was recorded. Dendritic length was quantified in terms of the number of intersections between dendrites and a series of concentric rings at 10 micron intervals around the soma. For quantification of growth oriented towards or away from the hollow, the rings were separated into quadrants, and only intersections in the quadrant centered towards the hollow and the quadrant opposite, away from the hollow, were included. The overall growth of dendritic fields was progressive across these ages, dendritic length increasing with increasing age. The number of primary branches decreased with increasing age, while the remaining branches proliferated. However, the pattern of growth was different for branches extending towards the hollow or away from it: for branches growing towards the hollow, dendritic growth increased smoothly across the ages examined; for branches growing away from the hollow, dendritic length decreased with increasing age. While primary branches decreased across age both on the side of the soma towards the hollow and on the side opposite the hollow, the decrease was substantially greater on the side away from the hollow. These data indicate that oriented dendritic fields in this system arise, at least in part, through elimination of branches that have grown in the improper direction. —Supported by ONR and NIMH.

25.10 INVARIANCE IN THE OVERALL PATCHY ORGANIZATION OF TACTILE PROJECTIONS TO CEREBELLAR CORTEX FOLLOWING PERIPHERAL NERVE LESIONS MADE EARLY IN CEREBELLAR DEVELOPMENT. J. B. Schlottman* and J. M. Bower. Div. of Biology 216-76, Caltech, Pasadena, CA 91125.

The organization of mossy fiber tactile projections to the granule cell layer of the cerebellar hemispheres results in a patchy somatotopic map representing selective parts of the body surface (Shambes et al., B.B.E. 15: 94, 1978). The patches are defined by sharp boundaries between projections from different body regions (Woolston et al., Brain Res. 209: 255, 1981). Comparisons of these maps between individuals of one species (rat) or even between closely related species (rat-mouse) reveal a remarkably invariant pattern of patches in any one cerebellar folium. For example, the map in crus IIa of the rat or mouse is characterized by a large ipsilateral upper lip patch surrounded by smaller patches representing other peri-oral surfaces (e.g., lower lip, lower incisor, upper incisor). This invariance suggests that the general organization of this patchy pattern may be somewhat inflexibly specified during development. This suggestion is in keeping with our recent Purkinje cell lineage experiments showing, in chimeric mice, that cells are grouped in lineage domains comparable in size and distribution to the physiologically defined patches (K. Herrup & J. Bower, Soc. Neurosci. Abstr. 12: 769, 1986).

To investigate further the establishment of this patchy organization during development, we have disrupted the normal patterns of innervation by lesioning specific peripheral nerves at a time before cerebellar connections are fully established. Specifically, we severed (under anesthesia) trigeminal nerve branches innervating the upper lip of 9-day-old rats. After these rats reached adulthood, we mapped the area of crus IIa usually containing a large representation of the now denervated upper lip. The resulting maps reveal that the overall patchy organization was virtually unchanged, i.e, there remained a very large central patch similar in shape and dimension to the one normally receiving upper lip projections. This large patch was now completely occupied by projections from two small areas bordering the upper lip, namely the corner of the mouth and an area directly below the nose. The outlying small patches representing other body surfaces in these animals were in all respects normal. These results are consistent with the view that the boundaries between patches in the tactile projection to cerebellar granule cell layer may be established inflexibly during development, for example by Purkinje cell lineage.

25.11 TRANSGANGLIONIC HRP TRANSPORT FROM PREVIOUSLY LESIONED AND UNLESIONED FELINE TEETH. M.A. Henry[1], L.E. Westrum[2], Lonnie R. Johnson[3]* and R.C. Canfield[4]. Facial Pain Center[2], Univ. of Florida, Gainesville, FL 32610, Depts. of Neurosurg.[2] and Rest. Dent.[4], Univ. of Wash., Seattle, WA 98195 and Dept. of Surg. Dent.[3], Univ. of Colo., Denver, CO 80262

Previous studies have established that transganglionic degeneration occurs following peripheral dental lesions. The present study investigates the differences and/or similarities in HRP transport following pulpal injections in previously lesioned and unlesioned teeth within the same subject. Immature feline subjects, 5-7 weeks of age, were used in the study. Coronal pulpal tissue was removed (pulpotomy) from the ipsilateral maxillary and mandiblular cuspid. One week to 10 days later, 1 µl of a 40% HRP solution was injected into each of the previously lesioned, ipsilateral cuspids and into the contralateral (unlesioned) maxillary and mandibular cuspids. The HRP injection procedure was repeated on the second day and the subjects transcardially perfused with mixed aldehydes on the third day. The trigeminal ganglia, brain stem and cervical spinal cord to the C_3 level were removed, sectioned and processed for HRP light microscopy by the TMB method of Mesulam. Examination revealed approximately the same number of labeled cells within the ipsilateral (lesioned side) and contralateral (unlesioned side) ganglia. Examination of the cervical spinal cord revealed sparse terminal labeling within the substantia gelantinosa layer of the dorsal horn from C_1 - C_3. Within caudal pars caudalis (PC), terminal and fiber labeling increased noticeably on both sides of the brain stem. A difference was detected in the relative density of labeled elements within mid PC, with the unlesioned side containing more label. This difference was maintained rostrally through to mid pars interpolaris (PI). Within mid PI and continuing rostrally through pars oralis, the densest label appeared, but there were no apparent differences in the relative density of label when one side was compared to the other. Even though small volumes of HRP solution were passively injected into the preparation, HRP still appeared to leak out the apex and label periodontal ligament receptors as a few labeled mesencephalic nucleus cell bodies were identified on both sides.

In conclusion, this study demonstrates less HRP label within the periobex region of the spinal trigeminal nucleus on the side that was previously lesioned. This is the same area where synaptic terminals and small axons undergoing electron-dense degeneration have been described following dental lesions. Other regions of the trigeminal brain stem nuclear complex appear unaffected. Supported by NIH grants DE04942 and NS20482.

25.12 **ONTOGENY OF CARBOHYDRATE DIFFERENTIATION ANTIGENS IN CHICK DORSAL ROOT GANGLIA AND SPINAL CORD** S. A. Scott, J. Dodd† and T. M. Jessell††. Dept. of Neurobiology and Behavior, SUNY at Stony Brook, Stony Brook, NY 11794, †Dept. of Physiology and Cell Biophysics and ††Howard Hughes Medical Institute, Columbia University College of Physicians and Surgeons, NY, NY 10032.

Dorsal root ganglia (DRG) contain a diversity of sensory neurons, which make specific connections in the periphery and CNS. Little is known about the development and early connectivity patterns of these functional subsets of DRG neurons. To investigate these problems it would be useful to have markers for various classes of sensory neurons that project to different targets. To this end we are examining the ontogeny and specificity of expression of carbohydrate differentiation antigens [Dodd *et al.* (1984); Dodd & Jessell (1985); Dodd (1986)] in chick DRG and spinal cord.

Cryostat sections of lumbosacral spinal cord and DRG of embryos from St18 (3d) through hatchlings have been labeled with monoclonal antibodies AC4, anti-SSEA-1 or 1B2/1B7, which recognize different lactoseries glycoconjugates. To identify the targets of immunoreactive cells, sensory neurons projecting in selected cutaneous or muscle nerves have been retrogradely labeled with fluorescent tracers. The AC4 antigen first appears in chick neural tissue between St22 (3½d) and St26 (5d). By St27 (5½d) the dorsal half of the spinal cord and a few ventrolateral DRG neurons stain intensely. The dorsal expression of this antigen in the cord is transient; by St32 (7½d) AC4 immunoreactivity forms a uniform meshwork throughout the gray matter, but is essentially absent from cell bodies. In hatchlings the AC4 antigen also weakly delineates dorsal horn laminae 1-3. The number of AC4-positive sensory neurons increases during development, with approximately 30-40% of sensory neurons being labeled throughout DRG in hatchlings. SSEA-1-reactive neurons appear in DRG on a roughly similar time course, but this antigen is not expressed transiently in dorsal cord. In contrast, the 1B2/1B7 antigen appears relatively late in embryonic development. Weakly labeled sensory neurons can first be detected in embryos near hatching; however, labeling is virtually absent from the spinal cord at all stages studied. Preliminary observations of retrogradely labeled DRG suggest that AC4- and SSEA-1-positive sensory neurons project to targets in both skin and muscle in hatchlings. Further studies are underway to determine whether these subpopulations of neurons also project to diverse targets in younger embryos.

25.13 **DEVELOPMENT OF THE MUSCLE AFFERENT-MOTONEURON PATHWAY IN THE CHICK EMBRYO: PHYSIOLOGY.** M. T. Lee and M. J. O'Donovan. Dept. Physiol. & Biophys., U. of Iowa, Iowa City, IA 52242.

We have examined the development and properties of synaptic connections between muscle afferents and motoneurons in the spinal cord of the chick embryo *in vitro*. Responses to muscle nerve stimulation were recorded intracellularly in hindlimb motoneurons and extracellularly in ventral roots (VRs) and muscle nerves.

In relatively mature embryos (stages 38-39), muscle afferent activation produces depolarizing synaptic potentials in the motoneurons. The earliest of these potentials can be elicited with low-intensity stimulation and appears 4-5 msec after the arrival of the afferent volley in the cord. With more intense stimulation, this early PSP merges with later depolarizations of variable amplitude and duration, including those produced by the central pattern generator for locomotion. The early PSP persists in the presence of 200 µ*M* 2-amino-5-phosphonovaleric acid (APV), a specific antagonist of NMDA receptors, but is greatly reduced in amplitude by 1.25 m*M* kynurenic acid, a general antagonist of excitatory amino acids. Both of these agents completely block the later depolarizations. The excitatory nature of the early PSP is indicated by its ability to fire motoneurons and by its persistence in saline containing 100 µ*M* picrotoxin and 10 µ*M* strychnine, blockers of IPSPs mediated by GABA and glycine, respectively. Solutions that inhibit chemical synaptic transmission (zero-Ca + 2m*M* Mn) eliminate both the early PSP and later depolarizations. Taken together, these observations suggest that the early PSP is the monosynaptic EPSP produced by Ia muscle afferents.

We have used VR recordings to monitor the development of connectivity between muscle afferents and motoneurons. The monosynaptic EPSP is detectable in the VRs by stages 31-32 (8-9 days), when afferents begin to grow into the vicinity of motoneuron dendrites. Longer-latency depolarizations can be elicited by stimulation of muscle afferents at least 1-2 days earlier, by stage 28. The pharmacological distinction between the monosynaptic EPSP and later depolarizations exists at all stages where both inputs are present. Even at the earliest period in the formation of sensory-motor synapses, we have found no evidence for electrical transmission in this pathway. The first monosynaptic connections between muscle afferents and motoneurons develop at a time when both are decreasing in number through cell death, raising the possibility that cell death may be involved in the generation of sensory-motor specificity.

In order to characterize the patterns of sensory-motor specificity in this system, we have developed a procedure for recording motoneuron synaptic potentials in identified muscle nerves. In the presence of APV, picrotoxin, and strychnine, the afferent-evoked, monosynaptic EPSP can be isolated and is detectable in muscle nerves. Moreover, the various nerves can be distinguished on the basis of their responses to stimulation of different muscle afferents. This procedure offers the opportunity to determine the connectivity patterns of large populations of afferents and motoneurons in a manner that is rapid and sensitive.

25.14 ANATOMICAL STUDIES OF AFFERENT PROJECTIONS TO MOTONEURONS IN THE LUMBOSACRAL CORD OF THE CHICK EMBRYO. M.J. Koebbe* and M.J. O'Donovan (SPON: Gary Dutton) Dept. of Physiology and Biophysics, University of Iowa, Iowa City, IA 52242.

We have examined the development of sensory projections to lumbosacral motoneurons in the chick spinal cord between stage 28 and stage 40. The spinal projection of sensory axons was visualized by anterograde labelling with horseradish peroxidase (HRP). Contralateral motoneurons in the same segments were retrogradely labelled with HRP. HRP was injected into the dorsal root ganglia (DRG) and ventral roots (VR) of 1-3 lumbosacral segments in each embryo using an in vitro preparation of the spinal cord. Transport of HRP was allowed to proceed for 5-9 hours. The spinal cords were processed for the HRP reaction product using either tetramethyl benzidine (TMB) or diaminobenzidine chloride (DAB). Spinal cords processed with DAB were paraffin embedded and sectioned at 10 µM. Best demonstration of HRP in sensory axons and motoneurons was attained with 40 µM frozen sections using a concentration of 0.005% TMB in an ammonium-molybdate buffer at pH 6.0.

Sensory axons first penetrated the dorsal gray matter at stage 29. Prior to this stage labelling was confined to a dorsolateral band of the white matter. By stage 32 afferent fibers had reached the vicinity of motoneuron dendrites which extended into the dorsal third of the spinal cord. The sensory projection increased in density and projected more ventrally with further development so that by stage 36 sensory axons had reached motoneuron somata, corresponding to an average growth rate of approximately 100 µM/day. By stage 39 sensory fibers were widely distributed throughout the spinal gray matter and distinct terminal fields were evident in the dorsal horn and in the lateral motor column. These results indicate that afferent fibers first reach motoneuron dendrites between stages 31 and 32. This time corresponds to the earliest stage that monosynaptic connections between muscle afferents and motoneurons can be detected physiologically (Lee and O'Donovan, this meeting) and indicates that the first sensory-motor connections are axo-dendritic and are located in the dorsal 1/3 of the spinal cord. Supported by NIH NS22559.

26.1 NEONATAL COCHLEAR LESIONS: INFLUENCE UPON 2-DEOXYGLUCOSE UPTAKE BY CENTRAL AUDITORY STRUCTURES IN ADULTHOOD. A.F. Ryan* and N.K. Woolf. Division of Otolaryngology, UCSD School of Medicine and VA Medical Center, La Jolla, CA 92093.

The destruction of all or part of the cochlea deprives a portion of the central auditory system of afferent innervation. In the adult, this deafferentation results in a permanent loss of inputs to the central neurons, and substantial bilateral asymmetry in evoked 2-deoxyglucose (2-DG) uptake by many auditory nuclei. The present study was designed to evaluate the degree to which developmental plasticity might allow the functional re-innervation of central auditory neurons following neonatal damage to the cochlea.

Neonatal mongolian gerbils had one cochlea surgically ablated at either 0, 2, 6, or 10 days after birth (DAB). After survival to young adulthood (45-60 DAB), the animals were injected with 16.7 uCi of 14C-2-deoxyglucose and placed in a sound-attenuated chamber. They were stimulated bilaterally at 85 dB SPL with either wide band noise or a 3.0 kHz pure tone for one hour, after which their brains were processed for autoradiography. Uptake of 2-DG into brain structures was assessed by densitometry. The results obtained in neonatal animals were compared to those observed in gerbils which received cochlear ablations as adults.

Responses of the cochlear nucleus and inferior colliculus innervated by the intact ear of all subjects were similar to those seen in gerbils with two normal cochleas.

In all successful lesions, 2-DG uptake in the cochlear nucleus on the side of the ablated cochlea was extremely low, consistent with complete deafferentation. The volume of this cochlear nucleus was severely reduced in neonatally ablated subjects, and especially in those lesioned at 0-6 DAB.

In the inferior colliculus associated with the lesioned cochlea of all subjects, regardless of age, 2-DG uptake was markedly lower than in the colliculus innervated by the intact cochlea. In animals stimulated with the 3.0 kHz tone, the inferior colliculus innervated by the intact cochlea showed a restricted band of elevated 2-DG uptake in the appropriate tonotopic location. In contrast, the opposite inferior colliculus showed a band of reduced 2-DG uptake at the same tonotopic location, consistent with inhibitory input from the intact cochlea. This response is is similar to that seen in a normal animal stimulated monaurally.

These results are inconsistent with extensive functional reorganization of the innervation to the inferior colliculus following neonatal cochlear ablation.

Supported by grant NS14945 from the NIH/NINCDS, by the Research Service of the VA, and by the Duaei Hearing Research Fund.

26.2 DENDRITIC ARCHITECTURE IN THE LATERAL SUPERIOR OLIVARY NUCLEUS OF ADULT AND DEVELOPING FERRET. Craig K. Henkel, Mary Wells and Judy K. Brunso-Bechtold. Dept. of Anatomy, Bowman Gray School of Medicine, Wake Forest University, Winston-Salem, NC 27103

In order for the developing auditory system to assemble neural circuits for sound localization, central neurons with binaural afferents must form appropriate connections. Presumably this development will be reflected in the maturation of dendritic processes. In this study the normal dendritic architecture of neurons in the lateral superior olivary nucleus (LSO) was studied in the ferret. A modification of the Golgi-Kopsch technique was used and observations are reported from adult material and a postnatal series including ages P0, P4, P6, P7, P8, P12, P24, P21, P22, P24, and P56. In the adult the most commonly observed neurons in LSO distributed dendrites in one of two patterns, fusiform or multipolar. Fusiform cells had two to three thick, smooth, primary dendrites that were obviously oriented across the tonotopic axis of the nucleus. These primary dendrites exhibited very little branching proximally whereas distally they were characterized by a profusion of thin tendrils. The tendrils extended up to 35 µm from the ends of the parent processes. The second pattern was that of multipolar cells with as many as five primary dendrites radiating from the soma and with no apparent orientation to the tonotopic axis. The dendrites of multipolar cells were thinner than those of fusiform cells and exhibited three to four orders of branching. Long, delicate dendritic extensions were frequently observed, but elaboration of tendrils at the ends of these dendrites was uncommon. By the end of the first postnatal week cells with clearly oriented dendrites were observed. More frequently the cells were multipolar and resembled the stellate cells in mature animals. Through postnatal day 24 numerous dendritic appendages and thin filamentous processes with bulbous swellings persisted on all regions of the dendrites and somata. By postnatal day 56 the dendrites and surface of the somata were smooth or exhibited only occasional dendritic spines. The formation of tendrils was not observed to be initiated until the fourth postnatal week. In conclusion, in the ferret at least two cell types were observed in LSO. Other experiments will be required to determine whether or not both types are principal cells with axons projecting to the inferior colliculus. The separate time courses for dendritic orientation and initiation and proliferation of tendril outgrowth suggest that these features of dendritic maturation are correlated with different events and will be explored further.

Supported by NIH grant NS 23092.

26.3 ULTRASTRUCTURE OF THE DEVELOPING MEDIAL SUPERIOR OLIVE IN THE FERRET. Judy K. Brunso-Bechtold, Constance Linville, and Craig K. Henkel. Department of Anatomy, Bowman Gray School of Medicine of Wake Forest University, Winston-Salem, NC 27103

Because of the importance of the medial superior olive (MSO) in mammalian binaural interaction, we have undertaken a detailed study of the development of that nucleus. As the ear canals in the ferret do not open until one postnatal month, the ferret is an excellent model in which to study MSO development. Ferrets were sacrificed on postnatal days (P) 0, 2, 4, 8, 16, 20, and 34 as well as at maturity. All animals were perfused with a fixative of 2% glutaraldehyde/2% paraformaldehyde in .15M cacodylate buffer and the brain was stored overnight in fixative. The brainstem was then sectioned at 200 µm in the coronal plane. The tissue was blocked using a lightfield/darkfield dissecting microscope, postfixed in 2% osmium with 1.5% potassium ferricyanide, dehydrated, and embedded in araldite. Thin sections were mounted on formvar-coated slot grids and viewed with a Zeiss 10-CA electron microscope. On P0 the neurons are extremely immature in appearance with relatively scant cytoplasm and no appendages. There are few synaptic terminals present and those that can be seen are small with rounded vesicles and are most commonly found in the neuropil. Glia can be distinguished at this stage, but there are few of the glial processes which are prevalent at later ages. At P2, P4 and P8, appendages and synapses are present more frequently, although they are still quite sparse. Glial processes are becoming more apparent and often lie adjacent to the somata. At P8, the somata contain more cytoplasm and are more mature in appearance. By P16 and P20 synaptic terminals containing flattened vesicles are common. Terminals are prevalent on the cell body and are considerably larger than at earlier ages although there do not appear to be as many contacts as in the adult. In addition, the terminals are beginning to be encapsulated by glial processes. Numerous appendages are present on the somata and proximal dendrites and myelin figures can be seen in the neuropil. By P34 the nucleus appears quite mature. The synaptic terminals are often large, containing either flattened or rounded vesicles, are found around the somata and proximal dendrites of the oriented cells, and are heavily encapsulated by glial processes. Thus, features of the mature synaptology are beginning to develop in the two weeks preceding opening of the ear canal. Supported by NIH grant NS 23092.

26.4 RAPID CHANGES IN GERBIL ANTEROVENTRAL COCHLEAR NUCLEUS CELL SIZE FOLLOWING TETRODOTOXIN BLOCKADE OF EIGHTH NERVE ACTIVITY. T.R. Pasic* and E.W Rubel. Depts. of Otolaryngology and Physiology/Biophysics, Univ. of Washington Sch. of Medicine. Seattle, WA 98195.

Large spherical cells of the mammalian anteroventral cochlear nucleus (AVCN) receive direct excitatory input from eighth nerve axons. Cochlear ablation has revealed transsynaptic regulation of large spherical cells by eighth nerve axons in neonates of several vertebrate species, including the gerbil. Such changes may be due to loss of eighth nerve electrical activity or loss of activity-independent trophic factors. We have developed a method to chronically, yet reversibly, block eighth nerve electrical activity without violating the integrity of the inner ear. Tetrodotoxin (TTX) was embedded in an ethylene-vinyl acetate copolymer resin (Elvax). A small piece of Elvax containing 250, 500 or 750 ng of TTX was then placed on the round window membrane, allowing the TTX to diffuse into the inner ear. The onset, duration and magnitude of the auditory threshold shift was measured by auditory brain stem response. For all doses, the sound-evoked response was abolished within ten minutes of placement of TTX on the round window membrane. Neural blockade lasted 24 to 46 hours. Implants of Elvax without TTX did not produce a significant threshold shift. TTX, which blocks voltage-gated sodium channels, did not abolish the potassium-dependent cochlear microphonic response.

The regulatory role of afferent electrical activity on gerbil AVCN large spherical cells was examined by measuring their cross-sectional area after one of three manipulations: unilateral eighth nerve action potential blockade with TTX in Elvax, unilateral surgical cochlear ablation or unilateral sham operation (Elvax without TTX). Cell size decreases 21% ipsilateral to TTX placement ($p < 0.01$), 25% ipsilateral to cochlear ablation ($p < 0.01$) and increases 2% ipsilateral to sham operation ($p > 0.50$) by 48 hours after the manipulation. These findings confirm previous work in the avian auditory system (Born, D.E. and E.W Rubel, J. Neurosci., submitted) and support the hypothesis that electrical activity is a major factor in transneuronal regulation. Support was provided by PHS grants T32-NS07246 and R01-NS24518.

26.5 THE ROLE OF MONAURAL AND BINAURAL INPUTS IN THE DEVELOPMENT OF THE AUDITORY SPACE MAP IN THE FERRET SUPERIOR COLLICULUS

A.J. King*, M.E. Hutchings* and D.R. Moore, University Laboratory of Physiology, Parks Road, Oxford OX1 3PT, England.

(SPON: European Neuroscience Association)

The superior colliculus (SC) contains topographically aligned maps of auditory and visual space. Both binaural and monaural cues contribute to the generation of the auditory receptive fields. Thus, acute, unilateral ear occlusion or cochlear destruction result in a loss of spatial tuning to white-noise stimuli more than 20 dB above threshold, but have no effect on the sensitivity of SC cells to sound location for near threshold intensities. We have previously demonstrated that the neural mechanisms by which these cells achieve their spatial selectivity can be adjusted by early acoustic experience. Raising ferrets with one ear occluded from before the onset of hearing until adulthood leads to essentially normal spatial receptive fields and map of auditory space in the SC ipsilateral to the occlusion for all sound levels tested (Hutchings, King & Moore, 1986, J. Physiol. 381, 49P). In order to assess the role of the monaural input from the intact, contralateral ear in the maturation of the auditory space map, we have examined the responses of SC cells in adult ferrets subjected to unilateral cochlear ablation at 21 days of age.

Recordings were made in an anechoic room from paralysed, anaesthetized animals when they were 4-5 months old. Within 15 dB of threshold, all cells (n = 28) examined exhibited sharply tuned receptive fields with clearly defined best positions in both azimuth and elevation. The best positions of these units varied in azimuth from the anterior to the posterior field along the rostro-caudal axis of the SC and were, in general, closely aligned with the centres of the visual receptive fields of cells recorded in the overlying superficial layers. However, at higher sound levels, no topography was evident since nearly all cells either gave omnidirectional responses or were sharply tuned to a restricted region of space behind the animal, irrespective of their location within the SC.

The presence of threshold spatial tuning in neonatally cochlear ablated ferrets indicates that this is a response to monaural cues. However, this mechanism appears to be insufficient to maintain tuning at higher sound levels, which is consistent with the effects of acute cochlear destruction. These results therefore suggest that the normal representation of auditory space observed in animals with one ear chronically occluded results from a change in the binaural cues to which the cells respond.

26.6 DEVELOPMENT OF CROSSED AND UNCROSSED PROJECTIONS FROM THE COCHLEAR NUCLEUS TO THE INFERIOR COLLICULUS IN THE FERRET.

D.R. Moore, N.E. Kowalchuk*, University Laboratory of Physiology, Parks Road, Oxford OX1 3PT, U.K.

In a series of studies we have demonstrated plasticity in the number of neurons in each cochlear nucleus (CN) projecting directly to the inferior colliculus (IC) of the ferret. Normally, the ratio of uncrossed to crossed neurons in the adult CN-IC projection is I:C=1:45. Neonatal, unilateral hearing loss (conductive and/or sensorineural) results in a significant change in this ratio, principally if not exclusively because of an increase in the number of ipsilaterally projecting CN neurons. To investigate some possible mechanisms underlying this plasticity we have studied the number and laterality of neurons comprising the CN-IC projection in normal, neonatal ferrets.

Ferrets were produced from timed matings and pregnancies. At ages ranging from postnatal day (P) 9 to P80 multiple injections of 10% WGA-HRP (200-300nl) were made into the left IC. Animals were perfused 48hrs. later and the brains were reacted using TMB histochemistry. For every third, 40μm frontal section the position of retrogradely labelled neurons in each CN was drawn on a camera lucida. Counts were made for each division of the CN, as defined by the neutral red counterstain, and corrected for missing sections.

In the youngest ferrets (P9) it was not possible to perform reliable quantitative analysis. Nevertheless, there appeared to be more labelled CN neurons ipsilateral to the injected IC than in adults. In older animals (P18, P26) quantitative analysis showed a significant ($p < 0.01$) increase in both the number of ipsilaterally labelled CN neurons and the ratio (P18: I:C=1:33, P26: I:C=1:29) of ipsi- to contralateral labelling, relative to adults. These increases were similar in magnitude to those observed following neonatal cochlear lesions (I:C=31). At older ages (P39, P57, P77) the ratio (I:C) did not differ significantly from the adult ratio. No age-related changes in the contralateral projection were observed.

These results show that, in common with the retinotectal system, there is an initial exuberance in the number and/or terminal arborization of ipsilaterally-projecting CN neurons in the auditory brainstem.

26.7 VISUAL DEPRIVATION DEGRADES THE AUDITORY MAP OF SPACE IN THE OPTIC TECTUM OF DEVELOPING BARN OWLS.

E. I. Knudsen, Department of Neurobiology, Stanford University School of Medicine, Stanford, CA 94305.

In barn owls reared under normal conditions, auditory neurons in the optic tectum are sharply tuned for sound source location and are systematically organized according to their spatial tuning to form a map of space. In addition, these neurons respond to visual stimuli and the visual and auditory maps of space in the tectum are in register.

Auditory spatial tuning derives from the central processing of localization cues such as frequency-dependent, interaural differences in timing and intensity of sound; the auditory space-map results from a systematic variation in the tuning of neurons for these cues. Does the development of this "computational" map depend upon vision? In part, it does.

Two barn owls were raised with both eyelids sutured shut. When full grown, the eyelids were opened and the owls were prepared for tectal recording. Auditory-visual units in the optic tectum were tested for location of auditory and visual receptive fields and sharpness of auditory spatial tuning. The data show that the auditory spatial tuning of single units was normal in sharpness (based on size of the spatial region from which the unit responds with greater than 50% of maximum response) and that spatial tuning varied approximately normally across the tectum. Thus, vision is not necessary for the development of a basic auditory map of space.

However, the alignment of auditory spatial fields with visual receptive fields of units was abnormally poor. Whereas, visual receptive field locations progressed systematically across the tectum, auditory spatial tuning changed relatively erratically. The data support the hypothesis that visually-guided experience during early life is responsible for the precision of the auditory map of space observed in the tectum of normal adults.

26.8 RAPID PROLIFERATION OF GLIAL PROCESSES FOLLOWING DEAFFERENTATION OF N. MAGNOCELLULARIS IN NEONATAL CHICKENS.

E.W Rubel and G.H. MacDonald* (SPON: R.W. Rodieck.) Depts. of Otolaryngology and Physiology/Biophysics, Univ. of Washington Sch. of Medicine. Seattle, WA 98195.

The brain stem auditory system of neonatal chickens has proven to be a useful preparation in which to study afferent regulation of neuronal elements in the central nervous system. Previous studies have shown rapid changes in cell size, protein systhesis and metabolic properties in n. magnocellularis (NM) neurons following removal of the cochlea. Neuronal changes are evident within 1 hour of cochlea removal and well defined within 6 hours. Recent experiments indicate that an important regulatory signal underlying these transneuronal events is the activity of 8th nerve afferents to NM.

We have begun to examine changes in non-neuronal elements that may be regulated by neuronal activity. Changes in glial fibrillary acidic protein (GFAP) immunoreactivity were studied in astrocytes of NM following unilateral removal of the cochlea. The cochlea was removed in neonatal chickens (5-14 days posthatch) in such a way as to spare eighth nerve ganglion cells. Following survival times ranging from 1-24 hours, the chicks were anesthetized and perfused with a fixative containing paraformaldehyde, lysine and sodium meta-periodate. Serial sections through NM were cut on a vibratome or from paraffin embedded tissue and reacted with a rabbit antiserum against bovine GFAP (Dako, Inc.) at concentrations of 1:400 or 1:800. Control sections were incubated in nonimmune purified rabbit IgG.

GFAP staining in NM ipsilateral to the cochlea removal was compared to that observed in the contralateral, normally innervated, NM in the same tissue section. One hour following cochlea removal there was no obvious difference in staining for GFAP on the two sides of the brain. However, in every subject sacrificed 3 hours after cochlea removal there was an increase in the intensity of the reaction product, the number of immunoreative processes and the length of immunoreactive processes in NM on the side of the brain ipsilateral to the cochlea removal. This initial change is first seen primarily at the periphery of the nucleus but is evident throughout NM by 6 hours after cochlea removal. After 12 hours the glia reaction is marked by intensely immunoreactive cell bodies and processes in patches throughout NM and bordering the nucleus. Degenerating terminals are not yet apparent. These results suggest that elimination of neuronal activity can activate glial expression of GFAP and elongation of astrocytic processes well before actual degeneration of axons or synaptic terminals. Supported by NINCDS grant #NS24522.

26.9 SYNAPSES IN EARLY NEUROGENESIS OF THE TANGENTIAL VESTIBULAR NUCLEUS OF THE CHICK EMBRYO. R. Petralia and K.D. Peusner. George Washington Univ. Sch. of Med., Washington, D.C. 20037.

The chick tangential nucleus (TN), in the lateral vestibular complex of the medulla, is composed essentially of two neuron types, principal (PC) and elongate cells (EC). Migration and differentiation of PC occur mainly between 6 and 13 days in the embryo (Golgi method; Peusner and Morest, 1977). The major input to the embryonic PC is the spoon endings (SE), formed by colossal vestibular fibers; small vestibular fibers also form terminals on the PC. Colossal fibers form synapses on PC around 8 days, with spoon ending formation between 10 and 13 days. In the absence of the vestibular nerve, the PC migrate and differentiate normally from 5-8 days, but thereafter degenerate and die by 13 days. Thus, completion of differentiation and survival may depend in part on spoon synapses. However, what influences cell migration and the outgrowth of axons and dendrites from 5-8 days is unknown and is the issue of the present ultrastructural investigation.

At the earliest age studied (5-6 days), the TN can be identified in light microscope, toluidine-blue stained sections, where fewer cells appear at progressively anterior levels of the TN, suggestive of a developmental gradient. The precursors of PC, the primitive epithelial cells (PEC), enter the TN from a medial-to-lateral direction, while at an earlier age the precursors of the EC proceed from a dorsal-to-ventral direction. At 5 days, the presumptive TN contains 3 types of processes identified by ultrastructure: vestibular fibers, external processes of PEC, and longitudinal fibers (presumptive dorsal spinocerebellar fibers). Between 5-6 days, the longitudinal fibers or their short branches form synapses on the lateral processes of the mediolateral PEC. At 6-6.5 days, the longitudinal fibers form synapses on the lateral processes of the postmigratory PC, while at 6.5-7 days the longitudinal fibers form synapses on the somata of the PC. These synapses are immature with few, round synaptic vesicles apposed to asymmetric membrane densities.

In conclusion, although the TN is an interstitial nucleus of the vestibular nerve, the very first synapses are formed by non-vestibular inputs. Conceivably migration and early differentiation of PC between 5-8 days may depend on contact by these first synapses. Moreover, these first synapses may influence axon outgrowth and connection to cervical spinal cord (Gross and Oppenheim, 1985; Cox and Peusner, 1987). Supported by NIH grant R01 NS18108.

26.10 RESPONSE OF THE RAT FETUS TO OLFACTORY STIMULATION PRESENTED IN UTERO. W.P. Smotherman. Laboratory for Psychobiological Research, Departments of Psychology and Zoology, Oregon State University, Corvallis, OR 97331.

Techniques for manipulating and directly observing the rat fetus in utero are providing information about mammalian behavioral development before birth [Smotherman & Robinson, Animal Behavior 34: 1859-1873, 1986]. Late in gestation rat fetuses are responsive to changes in their intrauterine environment and exhibit behavioral responsiveness to chemosensory stimulation [Smotherman & Robinson, Behavioral Neuroscience, in press].

Nineteen and 20-day-old rat fetuses exhibit a pattern of behavioral activation following intraoral infusion of a solution containing a novel olfactory stimulus. Fetuses that receive a 20 ul pulse of a lemon solution through an intraoral cannulae show a spike in behavioral activity coincident with the moment of infusion. The importance of olfaction in mediating this response is underscored by the virtually identical pattern of behavioral activation exhibited by fetuses that receive an intraoral infusion of citral -- a tasteless lemon odor. This conclusion is further supported by the results of experiments involving surgical transection of the olfactory bulbs. Following olfactory bulb transection, 19 and 20-day-old fetuses exhibit no change in spontaneous activity or in response to tactile stimulation, but fail to show behavioral activation in response to lemon or citral infusion. The effect of olfactory bulb transection is greater on day 19 than on day 20 of gestation suggesting that the behavioral responsiveness may be mediated by multiple sensory modalities in the older fetus.

26.11 OLFACTORY DENERVATION IN THE NEWBORN (BUT NOT ADULT) RATS REDUCES THE NUMBER OF MITRAL AND TUFTED CELLS AND OF GLOMERULI IN THE OLFFACTORY BULB. E. Meisami and S. Emamian. Dept. of Physiology & Biophysics, University of Illinois, Urbana, IL 61801.

Newborn male albino rats were denervated unilaterally by cutting the olfactory nerve in front and underneath the olfactory bulb (OB). At 30-days the operated and control OBs were removed, fixed, sectioned frontally and serially at 10um, and Nissl(thionin) stained. Similar procedures were carried out in normal 30-day rats and in rats operated at 30-days and examined at 60-days. All bulbs were subjected to morphometric and numerical histoarchitectural analysis. The results showed that in the normal rat: 1) no significant difference existed between the left and right OBs of normal rats; 2) mean number of glomeruli (based on counts of spherical or elipsoid periglomerular cell-assemblies) was about 3100 per OB, and mean glomerular diameter 71 um; mean values for total number of mitral and tufted cells were about 63000 and 130,000 per OB, respectively.

In the operated 30 day-old rats: 1) the denervated bulbs were markedly smaller(30%). 2) of the OB layers, only the olfactory nerve layer was completely absent, indicating lack of regeneration of the olfactory nerve; other OB layers (glomerular, external and internal plexiform and the internal granular) were, however, markedly (30-40%) reduced in thickness; glomerular layer appeared particularly disorganized; 3) While the total numbers of glomeruli, mitral and tufted cells in the control OBs of the operated animals did not differ significantly from those in the normal animals, these numbers were markedly reduced in the denervated OBs: glomerular diameter, 34%; glomerular number, 25%; mitral cell number, 31%; tufted cell number 64%. Comparison of distribution profiles of these bulbar elements in the control and operated bulbs revealed that the reductions occured along the entire OB length. OBs operated at 30-days and examined at 60-days were smaller and had slightly reduced numbers of the bulbar elements but the differences were not statistically significant. The results indicate that during the postnatal development (sukling period) the proliferating and growing fibers of the olfactory neurons exert profound transneuronal effects on the development and structural organization of the olfactory bulb.

26.12 PROLIFERATION PATTERNS DURING POSTNATAL DEVELOPMENT IN THE OLFACTORY BULB OF NORMAL AND UNILATERALLY DEPRIVED RATS. L.L. Frazier and P.C. Brunjes. Dept. of Psychol, Univ. of Virginia, Charlottesville, VA. 22903.

Unilateral external naris closure on postnatal Day 1 results in a 25% reduction in the volume of the olfactory bulb 30 days later (Brain.Res.Rev,11, 1). The small size of deprived bulbs has been shown to be due at least in part to dramatic decreases in cellular densities and numbers of the latest arising-relay (external tufted cells) and interneuronal (granule cells) cell populations and the latter groups' associated glia (Soc.Neurosci.Abst.,12, 125). Changes in cell number may result from alterations in cell proliferation, cell death, or both. Several lines of evidence suggest a key role for cell death, including observations that granule cell number in adult rats appears to be regulated by cell death (J.Comp.Neurol.,239, 117), and the finding that unilateral deprivation has little effect on laminar volume, cell density or number in the proliferative zone of the bulb, the subependymal layer (SUB). Nevertheless, evidence of a consistent developmental lag in the number of granule to relay cells has been reported, suggesting changes in proliferation rates should not be excluded. The current study assessed proliferation patterns in both normal and deprived bulbs. Occluded and sham-operated rat pups were injected with 3H-thymidine on postnatal Days 2, 5, 10, 20, or 30. Bulbs were removed 24 hr later, embedded in JB4, sectioned horizontally, and processed for autoradiography. Sections representing the middle of the SUB were selected and counts of the number of labelled vs. unlabelled cells made at 25, 50 and 75 % of the layer's rostral-caudal extent. A gradient of proliferation was found with higher numbers of labelled cells at 50 and 75% of the layer's extent at Days 2 and 5, and more at 75% at Day 10. Decreased numbers of labelled cells were found by Day 20, and only in the caudal SUB. The findings suggest a rostral to caudal proliferation pattern in early life. No differences in numbers or patterns of labelled cells were encountered between normal and deprived subjects at Days 2, 5 or 10, indicating the procedure does not affect early cellular proliferation. Supported by the ONR, Whitehall Foundation and NIH (NS23154)

26.13 ROLE OF HOST PLANT AND SENSORY ENVIRONMENT IN MATURATION OF OLFACTORY RECEPTOR SYSTEM OF THE BOLL WEEVIL, ANTHONOMUS GRANDIS. J. C. Dickens* and E. E. Moorman* (SPON: D. Stork.) USDA-ARS Boll Weevil Research Unit, Mississippi State, MS 39762.

We investigated maturation of olfactory receptors in boll weevils fed either their host plant, cotton, or an artificial diet from time of emergence. We recorded summated olfactory receptor potentials (electroantennograms=EAGs) from different age groups of weevils in response to serial dilutions of a non-specific host plant odorant (1-hexanol, a component of "green" odor), a specific host plant odor (beta-bisabolol, a sesquiterpene reported only from the host plant and its close relatives), and the specific aggregation pheromone of the weevil (grandlure, a mixture of four specific insect-produced odorants). In order to facilitate comparisons among dosage response curves, the following nonlinear model was used

$$V = \frac{Vmax}{1 + e^{-k * Lrate}}$$

where V is the response variable, Vmax is the maximum receptor potential and Lrate is the dosage of the odorant. No differences were found in either Vmax or k for insects of the same age and sex fed on their natural host plant containing both 1-hexanol and beta-bisabolol or the artificial diet which was devoid of these odorants. Vmax increased from day of emergence through day 4 of adulthood in both groups. While k tended to increase through day 6, these differences in k were not significant. Overall k values were different for each chemical and thus were indicative of separate receptor populations. If Vmax is considered a measure of acceptors responsive to each odorant, then the number of responding acceptors increases from emergence through day 4 regardless of diet or concomitant sensory environment. Since k is measure of the dynamics of acceptor response and remains fairly constant, changes in responses (V) elicited by a particular odorant must be due to changes in the size of the population of responding acceptors rather than dynamics of individual acceptors. Similar to the boll weevil, studies of the olfactory receptor system of the workerbee indicated maturation to take place on day 4 (Masson, C. M. and Arnold, G. A., J. Insect Physiol. 30:7, 1984). However, considerable plasticity was noted in the olfactory receptor system of the workerbee since EAGs elicited by a particular odorant varied according to whether individuals were reared in isolation or groups. Maturation of the olfactory receptor system of the boll weevil appears to be more predetermined, at least with regard to diet and concomitant sensory environment. These results correlate well with ecology and behavior of both the boll weevil and the workerbee.

26.14 POSTNATAL DEVELOPMENT OF THE ROSTRAL SOLITARY NUCLEUS IN THE ALBINO RAT: ANALYSIS OF PLANAR DENDRITIC LENGTH, MITOCHONDRIAL ENZYME ACTIVITY, AND GABA-LIKE IMMUNOREACTIVITY. P.S. Lasiter and D.L. Kachele*. Dept. of Psychol., Florida Atlantic University, Boca Raton, FL 33431.

Taste responses develop in lower-order central gustatory relays during a prolonged period of rats' postnatal life. We have previously reported that planar dendritic growth and activity of the mitochondrial-linked enzymes cytochrome oxidase (CO) and succinic acid dehydrogenase (SDH) is well-correlated with the development of taste responsivity in the second-order central gustatory relay located in the medial parabrachial nucleus (Lasiter, P.S. et al., Abst. Assoc. Chem. Soc., 9:85, 1987). The present studies examined development of neurons in the first-order central gustatory relay located in the rostral pole of the nucleus of the solitary tract (NST). Three distinct methodologies were employed; Golgi impregnations, histochemistry for CO and SDH, and staining for GABA-like immunoreactivity (GABA-LI). The rostral NST contains neurons with five distinct somatic morphologies. These neurons can be classified as small (F1) or large (F2) fusiform types, with mean aspect ratios (AR; minimum central cross-sectional diameter/maximum central cross-sectional diameter) of 0.274 and 0.372, respectively, small (M1) or large (M2) multipolar types with mean ARs of 0.459 and 0.461, respectively, and an oviform type (Ov) with a mean AR of 0.875. Morphometric analyses performed according to somatic type indicated that mean lengths of first- and second-order dendrites do not reliably increase between 11 days and 65 days. Mean first-order dendritic lengths were 34.56 μm for F1 types, 62.96 μm for F2 types, 31.98 μm for M1 types, 46.64 μm for M2 types, and 46.44 μm for Ov types. Histochemical studies indicated that activity of CO and SDH increases in the rostral NST from 10 days to 20 days, and that CO and SDH activity is asymptotic after approximately 25 days. GABA-LI immunoreactivity was confined to F1 and M1 neuron types in the rostral gustatory-responsive portion of the NST. Somatic GABA-LI of F1 and M1 neurons increased from 10 days to 20 days, and reached adult-like levels after approximately 22-25 days. These results indicate that the development of taste responsivity in the rostral NST during the first five weeks of life is probably not related to extensive radial dendritic growth. However, ontogeny of gustatory responsivity in the NST may be related to the maturation of peripheral receptor/fiber systems that provide input to NST neurons or maturation of neurochemical systems that promote synaptic transmission in the NST.

26.15 **THE PRENATAL "SENSITIVE PERIOD" OF ENVIRONMENTAL INFLUENCES ON THE DEVELOPING GUSTATORY SYSTEM.** **D.L. Hill and P.R. Przekop*. Dept. Psychology, University of Virginia, Charlottesville, VA 22903.**

The development of taste in rat is a postnatal phenomenon in which sodium, initially a poor stimulus, becomes very effective. Development appears to involve the addition of an amiloride-sensitive sodium component to the receptor membrane which is absent in the immature rat. Since the largest developmental changes occur to salt stimuli, especially NaCl, the development of salt taste responses might be especially susceptible to environmental influences. Indeed, responses from the chorda tympani nerve to sodium salts are lower in rats fed a low-sodium (0.03%) diet beginning at 3 days gestation compared to controls. However, responses to non-sodium stimuli are unaffected. In adult rats, sodium deprivation has no effect upon multifiber chorda tympani responses. Therefore, a specific time period exists in which the taste system can be altered functionally by modifications in the diet. The present study examines this time period by instituting sodium deprivation during different periods of both pre- and postnatal development and comparing multifiber chorda tympani responses among deprivation groups. Concentration series (0.05-0.5M) of NaCl, NH_4Cl, KCl, and sodium acetate were flowed over the anterior tongue. The tongue was also stimulated with NaCl after lingual application of the epithelial sodium transport blocker, amiloride hydrochloride. Results suggest that the degree of response attenuation to sodium salts (NaCl & sodium acetate) is determined by the **prenatal** age at which sodium deprivation is imposed upon the animal. There appears to exist a continuum with given endpoints corresponding to periods of development when deprivation has a maximal effect through no effect. Importantly, these endpoints correspond to 8 days gestation (maximal effect) and 15 days gestation (no effect); deprivation imposed at 10 to 11 days gestation has an intermediate effect. Therefore, deprivation is not an all or none phenomenon in altering sodium responses. Moreover, the taste system remains plastic for a relatively short period of early development, with the degree of plasticity changing during this period. In summary, we have demonstrated there exists a "sensitive period" in which environmental factors have a permanent influence on the developing gustatory system. This period apparently occurs before the appearance of peripheral gustatory structures. Although these effects are reversible at the peripheral level, they may not be reversible in the central nervous system.

Supported by NIH Grant #NS24741.

27.1 TOLERANCE TO HALOPERIDOL-INDUCED "ANOREXIA" IS NOT CONTINGENT ON BEHAVIORAL EXPERIENCE. D. L. Wolgin and G. B. Thompson*. Dept. of Psychology, Florida Atlantic Univ., Boca Raton, FL 33431.

Two experiments were performed to determine whether tolerance to the "anorexigenic" effect of haloperidol is contingent on access to food in the drugged state. In the first experiment, groups of rats were given the drug (2.5 or 5 mg/kg) either before (Group Pre) or after (Group Post) a 30-min milk drinking session for 54 days. A control group (Group Sal) was given injections of saline. To control for cumulative deprivation during this phase of the experiment, the intakes of Group Post and Group Sal were yoked to that of Group Pre. On the test day (Day 55), all of the groups were given haloperidol prior to milk to assess the level of tolerance. During the chronic phase, rats receiving the drug prior to milk (Group Pre) recovered to only 45% (2.5 mg/kg) and 25% (5 mg/kg) of baseline levels of milk intake. On the test day, these rats showed less tolerance than rats given chronic injections of the drug after feeding (Group Post).

In the second experiment, dose-response curves were determined both before and after rats received chronic injections of either haloperidol (2.5 mg/kg) or saline for 14 days. During the chronic phase, haloperidol-treated rats were injected with the drug either before or after access to milk, as above. On the initial dose-response determination, haloperidol decreased milk intake at all dose levels (1.25, 2.5, and 5 mg/kg). Following chronic injections of the drug, there was a shift in the dose-response curves upward and to the right in both Group Pre and Group Post, but not in Group Sal. Comparisons of the ED50's before and after chronic exposure to the drug revealed a four-fold shift in both drugged groups (Group Pre = 3.97; Group Post = 4.66). These results suggest that tolerance to the "anorexigenic" effect of haloperidol is not contingent on access to food in the drugged state.

27.2 LONG-TERM EFFECTS OF MELPERONE ON ORAL MOVEMENTS IN RATS. P. Johansson*, L.M. Gunne*, and U. Bondesson*. (SPON:G. Ellison) Psychiatric Research Center, Ulleråker Hospital, S-750 17 Uppsala, Sweden.

Chronic administration of a variety of antipsychotic drugs, including haloperidol, fluphenazine, chlorpromazine, and thioridazine, has been found to elicit an increased rate of vacuous chewing movements (VCM) in rats (Gunne et al., Pharmacol. Biochem. & Behav. 25:897, 1986). On the other hand, the atypical neuroleptic, clozapine, has not been found to cause this effect over a wide dose range (Johansson et al., Psychopharmacol. Bull. 22:1017, 1986). This potential model for tardive dyskinesia (TD) has been applied to test a variety of antipsychotic drugs for their TD-inducing propensity.

Melperone is an effective antipsychotic drug (Bjerkenstedt et al., Arch. Psychiatr. Nervenkr. 226:157, 1978), with many characteristics similar to clozapine. There are few reports of TD connected with this drug.

In the present experiment rats were chronically given doses of melperone (25, 60, and 125 ug/ml) or haloperidol (2.0 and 5.0 ug/ml) in their drinking water for a period of 16 months. VCM rates were measured monthly. All groups had low starting levels of VCMs with no significant differences between groups. After three months the haloperidol groups started to show significant increases in VCMs compared to controls. This effect continued for the rest of the 16 months experiment. The melperone-treated groups did not differ from the controls. These doses of melperone do not appear to cause increased VCMs in this model of TD.

27.3 NEUROLEPTIC-INDUCED ORAL DYSKINESIAS: METHODOLOGICAL ISSUES. A.D. Levy, R.E. See, E.D. Levin & G. Ellison. Dept. Psychology, UCLA, Los Angeles, CA 90024.

Animal models of neuroleptic-induced dyskinesias have been controversial; alterations in oral activity in laboratory animals have been described as a model of tardive dyskinesia (TD) or acute dystonia. Some researchers have observed early onset enhancement of oral movements resembling dystonia, others have observed a latent syndrome more characteristic of TD, while some have not observed alterations in oral activity.

In 3 separate experiments, rats were chronically administered haloperidol (HAL) in a variety of ways (chronic injections given twice weekly, subcutaneous implants, and chronic decanoate injections) and examined for oral movements in two testing environments -- in an open cage, and in a Plexiglas tube to facilitate observation of the oral region. In the open cage, oral activity was enhanced during neuroleptic exposure and subsided rapidly following drug withdrawal. In the tube, oral activity was low during drug treatments, and elevated upon drug withdrawal. The final study was designed to explain these trends. Rats were examined in each testing apparatus on each of 4 days of the chronic HAL injection cycle. Immediately following HAL injections oral activity was elevated and motor activity nearly eliminated in the observation cages, while oral movements in the tube were not altered. On subsequent days, motor activity scores began to rise, and oral movements returned to control levels.

The data suggest that the method of data collection has a substantial impact on interpretations. The negative correlation between oral and motor activity scores in the observations cages suggests that an artifact related to motor activity influences oral activity scores. Active rats show few oral movements in the cages, while most oral activity is observed when rats are otherwise immobile. The data have implications for TD research. Open cage environments may detect early onset neuroleptic-induced oral activity, while the tube may be better suited for observing latent neuroleptic-induced alterations in oral movements. Clearly animal models of TD and dystonia must be reevaluated to account for the differences obtained in each testing environment.

27.4 BEHAVIORAL AND RECEPTOR CHANGES IN RATS FOLLOWING CHRONIC TREATMENT WITH HALOPERIDOL DECANOATE AND FLUPHENAZINE DECANOATE. R.E. See, J. Williams, & G. Ellison Dept. of Psychology, UCLA, Los Angeles, CA, 90024.

We have previously found that chronic neuroleptic administration in rats can produce a syndrome of late-onset increases in oral activity, particularly of small amplitude oral movements as recorded by a computerized movement detection circuit. In the present study, rats were treated for 10 months with either haloperidol decanoate, fluphenazine decanoate, or vehicle. Extensive behavioral observation utilizing this computerized system as well as a human observer showed the development of a complex syndrome of oral activity changes in the drug-treated animals, which persisted upon withdrawal.

In order to examine some of the possible changes in receptor populations that may underlie these behavioral changes, autoradiographic analysis was conducted on the brains of these neuroleptic-treated rats. Rats were killed by decapitation 50 days after drug withdrawal and the brains removed and stored at -80 C. Twenty micron coronal sections were thaw mounted onto subbed microscope slides. Both D1 and D2 receptors were localized as well as GABA receptors. For D1 binding, serial sections were incubated in Tris-HCl buffer (50 mM, pH 7.4) containing [^{3}H]SCH 23390 (77.7 Ci/mmole) at a concentration of 1.0 nM. Adjacent sections were incubated in buffer that included unlabeled SCH 23390 (1 uM) for nonspecific binding. For D2 binding, sections were incubated in buffer containing [^{3}H]spiperone (21.0 Ci/mmole) at a concentration of 1.4 nM, along with mianserin (1 uM), a 5-HT inhibitor. Nonspecific binding was represented by the addition of sulpiride (10 uM). For examining GABA receptors, sections were incubated in a Tris-citrate buffer (0.31 M, pH 7.1) containing [^{3}H]muscimol (39.4 Ci/mmole) at a concentration of 10 nM. GABA (0.2 mM) was used for nonspecific binding. Specific binding of each [^{3}H] ligand was as follows: [^{3}H]SCH 23390, 90-95%; [^{3}H]spiperone, 50%; and [^{3}H]muscimol, 75-80%.

Slide-mounted tissue sections were apposed to LKB Ultrofilm in X-ray cassettes for 3 to 6 weeks. Films were developed and then examined using an IBAS 1+2 image analyzer connected to a video camera. Differences in regional binding between groups will be discussed as well as correlations with behavioral changes found in the drug-treated animals.

27.5 CHRONIC NALTREXONE ALTERS MORPHINE-INDUCED DOPAMINE SYNTHESIS IN MESOLIMBIC AND NIGROSTRIATAL SYSTEMS. M. T. Bardo, J. L. Neisewander and R. B. Ennis*. Department of Psychology, University of Kentucky, Lexington, KY 40506.

Adult male rats were implanted with a slow-release pellet of naltrexone or they were given sham surgery. Ten days later, the naltrexone pellet was removed or a second sham surgery was performed. At one of various different intervals during or after pellet implantation, dopamine (DA) synthesis was assessed in the mesolimbic and nigrostriatal systems. Each animal was administered interperitoneally 100 mg/kg M-hydroxybenzylhydrate dihydrochloride, an inhibitor of the enzyme dihydroxyphenylalanine (DOPA) decarboxylase. Thirty min after injection, each animal was sacrificed by rapid decapitation and the olfactory tubercle, nucleus accumbens, anterior striatum and midbrain A9/A10 region were dissected for analysis of DOPA levels, an index of tyrosine hydroxylase activity. In order to assess the effect of morphine, in some experiments animals received either morphine (15 mg/kg, s.c.) or saline 30 min prior to M-hydroxybenzylhydrate.

The results indicated no significant change in DA synthesis either 1 or 10 days after the start of pellet implantation. As expected however, morphine increased DA synthesis in both the mesolimbic and nigrostriatal systems in sham control animals. More important, one day after naltrexone pellet removal, when mu-type opiate receptors are increased, there was an increased response to the DA-stimulating effect of morphine in olfactory tubercle. At 3 and 10 days after cessation of naltrexone exposure however, a decreased response to morphine was evident in olfactory tubercle, nucleus accumbens, striatum and A9/A10 region. The onset of subsensitivity to morphine occurred earlier in the nigrostriatal system than in the mesolimbic system. Thus, chronic naltrexone treatment induces a biphasic change in DA systems, with a period of supersensitivity followed by a rebound period of subsensitivity to opiates.

27.6 **EFFECT OF NEONATAL ADMINISTRATION OF MONOSODIUM GLUTAMATE ON THE YAWNING BEHAVIOUR OF THE RAT.**

E. Dogerx, J. Valenciax and B. Holmgrenx (SPON: M.R. Budelli) Dept. de Ciencias Fisiológicas, *Instituto de Ciencias. Univ. Autònoma de Puebla. Apartado Postal 406 Puebla, Mèxico.*

Systemic administration of L-Monosodium Glutamate (MSG) to neonatal rodents produces lesions in the retinae, the circumventricular organs (e.g. the subfornical organ, area postrema) and several hypothalamic nuclei, resulting in a number of behavioural, metabolic and endocrinological abnormalities. The MSG treatment produces a loss of 80-90 % of the cell bodies of dopaminergic neurons whitin the arcuate nucleus and also of the pro-opiomelanocortin system, with an alteration of intra-hypothalamic neurotransmitter levels. The present study was carried out to investigate the effect of these lesions on the regulation of yawning behaviour. 27 male Sprague-Dawley rats were injected intraperitonelly with a solution of MSG (55.5 %) or equivolumetric doses of 13% NaCl (osmotic control) in an ascending dose schedule from 2.0 to 4.0 g/Kg on postnatal days 1-5. Histological analysis demonstrates a loss of neuronal bodies in the arcuate; and a diminution of 30 % of the hypophysis weigth ($p < 0.005$ Student t test). The behavioural observations were performed between 16-17 hrs. when the rats reached 30 and 60 days old. Yawns and penile erections were monitored and clocked by two observers, under standard conditions. Early postnatal administration of MSG resulted in a decrease of 50 % in spontaneus yawning frequency ($p < 0.005$ Mann-Whitney U test) and 36 % of apomorphine induced yawning (0.05 mg/Kg) ($p < 0.01$ Mann-Whitney U test) in 60 days old rats, but not at 30 days. The results suggest that direct damage of hypothalamic dopaminergic and pro-opiomelanocortin neurons, or its indirect effects on hypophyseal function (secretion of ACTH and MSH), may produce the above described significant decrease of yawning frequency.

27.7 NEUROLEPTIC MALIGNENT SYNDROME IS ASSOCIATED WITH LOW LEVELS OF SERUM IRON. Patricia I. Rosebush*, (SPON: Michael F. Mazurek). Dept. of Psychiatry, Univ. of Toronto and Harvard Medical School.

Neuroleptic malignant syndrome (NMS) is a clinically-defined disorder characterized by fever, rigidity, and obtundation. Serum levels of creatine phosphokinase (CPK) are elevated in virtually all cases. While the aetiology of NMS is unknown, its pathogenesis is believed to involve an increased blockade of dopaminergic transmission.

We have studied 23 consecutive cases of NMS in 19 individual patients (4 patients developed NMS on 2 separate occasions). 21 of the 23 episodes (18 of 19 patients) were associated with subnormal levels of serum iron, with values falling 70% or more below the lower limit of normal in 7 patients. In each case for which data are available the serum iron returned to normal levels upon resolution of the NMS. Where multiple data points were available, there was a strong negative correlation between levels of serum iron and concentrations of serum CPK. There was no correlation between serum iron and body temperature.

These results raise the question whether the decrease of serum iron levels might play a role in the pathophysiology of NMS. Iron is known to be important for dopamine receptor function, low iron resulting in decreased dopamine receptor binding through a loss of dopamine receptors, while the affinity of the receptor remains unchanged. It is especially interesting in this regard that iron deficient patients are known to suffer from akathesia, a movement disorder generally believed to arise from dopaminergic blockade in the nigrostriatal pathway.

27.8 PLASMA PROLACTIN RESPONSE TO COCAINE AFTER HALOPERIDOL PRETREATMENT. D. B. Lozovsky, M.A. Sherer*, K.M. Kumor* and J.H. Jaffe*. Addiction Research Center, NIDA, Baltimore, MD 21224.

Cocaine inhibits neuronal uptake of norepinephrine, dopamine and serotonin (Carmichael, F.J. and Israel, Y., J. Pharmac. Exp. Ther. 186:253,1973; Ross, S.B. and Renui, A.L., Eur. J. Pharm. 2:181,1967; Snyder, S.H. and Coyle, J.T., J. Pharmac. Exp. Ther. 165:78, 1969; Ross, S.B. and Renuci, A.L., Eur. J. Pharm. 7:270,1969). Since these transmitters regulate neurohormones differently, neuroendocrine changes induced by cocaine might vary depending on the time course and dose responsiveness to cocaine and the levels of activity of the neurotransmitter systems involved. This variability might be responsible for the controversial results reported on the effects of cocaine on plasma prolactin (PRL) levels in drug abusers (Dakis, C.A. and Gold, M.S., Neurosci. & Behav. Rev. 9:469,1985, Gawin, F.H. and Kleber, H.D., Brit. J. Psychiat.147: 569,1985). The purpose of this study was to investigate whether cocaine can affect PRL secretion via non-dopaminergic mechanisms. Accordingly, we measured plasma PRL after cocaine administration to subjects pretreated with the dopamine receptor blocker, haloperidol. The subjects were five inpatient male cocaine users, aged 22 to 34 yrs. Four conditions (placebo/placebo, placebo/cocaine, haloperidol/placebo, and haloperidol/cocaine) were studied in a double-blind randomized design. Haloperidol (8 mg, IM) or placebo were given 20 min prior to cocaine (40 mg, IV) or placebo. Blood samples were taken 10 min before and 10 min after administration of haloperidol or placebo and 15,30, 45,60,90,120 and 180 min after administration of cocaine or placebo. Plasma PRL was measured by a double-antibody RIA. While there was a trend toward a slight decrease in plasma PRL after the placebo/cocaine as compared to the placebo/placebo condition, haloperidol induced the expected sustained rise in PRL. Infusion of cocaine after haloperidol resulted in additional increases in plasma PRL which were significant at 45 min time point (37% higher than after haloperidol/placebo). Similar trend was also noted for the 30 and 60 min time points. This PRL-elevating effect of cocaine in subjects with blocked dopamine receptors might result from the drug-induced inhibition of serotonin uptake.

27.9 COCAINE EFFECTS ON PLASMA VASOPRESSIN, CORTICOSTERONE, AND PROLACTIN IN THE RAT: TIME COURSE FOLLOWING ACUTE INJECTION. E.H. Ellinwood, Jr., J.K. Nishita, C.M. Kuhn, J.C. Ritchie, and L. Bero*. Dept. of Psychiatry and Pharmacology, Duke Univ. Med. Cntr., Durham, NC 27710.

The possibility that endogenous release of arginine vasopressin (AVP) in the brain interacts with drugs of abuse as epiphenomena has provided a potential basis for clinical utility. For example, in rats AVP can markedly alter the development and maintenance of tolerance to the physiological and behavioral effects of repeated exposure to ethanol. However, plasma AVP levels in rats are not merely reduced by ethanol, but follow a biphasic time course (elevated 5 minutes after i.p. injection and inhibited 30-60 minutes after injection). In the present study we examined the short-term time course of AVP release and that of two stress-related hormones, corticosterone (CORT) and prolactin (PRL), following the acute injection of cocaine.

Pairs of male Sprague-Dawley rats (250-310 g) were randomly injected i.p. with one of three doses of cocaine (10, 20, or 40 mg/kg) or saline. All rats were tested during hours 2-4 at the beginning of the colony light phase (12:12 LD-cycle). A separate control group received no injection. Rats were decapitated at 5, 10, and 20 minutes following the injection. Trunk blood was collected in chilled heparin-coated tubes and the whole brains were rapidly extracted and frozen on dry ice. The entire sacrifice and specimen collection procedure was completed within 2-3 minutes. Plasma AVP, CORT, and PRL were assayed by RIA along with osmolality (by freezing point depression) and electrolytes, sodium and potassium (NOVA 11 Analyzer).

Plasma AVP levels were not affected by the 10 mg/kg dose of cocaine and no significant change in AVP was found for any of the dosages at 5 minutes after their injection. Ten minutes after the 20 mg/kg cocaine injection, AVP levels were significantly elevated (10.5 $\pm$ 1.7 pg/ml) compared to saline-injected controls (6.1 $\pm$ 0.7 pg/ml; $p<.05$). This effect was no longer apparent at 20 minutes after injection. The 40 mg/kg cocaine injection produced similar but attenuated increases in AVP levels at 10 and 20 minutes after injection.

CORT levels were elevated by the cocaine injections and were not significantly different across the three time points. PRL, osmolality, and electrolyte levels were not affected by any of the cocaine regimens. Assays of specific brain tissue areas remain to be completed.

Rapidly changing AVP levels in response to acute cocaine injection may interact with some of the effects of cocaine.

27.10 EFFECTS OF CHRONIC COCAINE ON REGIONAL BRAIN METABOLISM, DOPAMINE AND OPIATE RECEPTOR BINDING. R. P. Hammer, Jr., D. Yoshishige* and S. A. Jacobson*. Dept. of Anatomy & Reprod. Biol., Univ. Hawaii School of Medicine, Honolulu, HI 96822.

Chronic exposure to cocaine is thought to affect dopamine systems in brain reward centers which produce reinforcing behavior. We used a combined autoradiographic deoxyglucose (DG)/receptor binding technique to study the influence of cocaine on brain metabolism and neurochemical systems. Osmotic minipumps which infused either 1 mg/kg/day or 10 mg/kg/day cocaine HCl, or saline were subcutaneously implanted into adult male Sprague-Dawley rats. After 2 weeks, animals were given 0.5 mCi/kg [^{3}H]2DG intravenously. Forty-five min later, brains were removed, frozen, and sectioned into adjacent series for 2DG autoradiography and receptor binding. 2DG series were immediately exposed to ^{3}H-sensitive film in X-ray cassettes. Receptor binding series were preincubated in buffer at 0°C (6 X 2 min) to remove ^{3}H label, and incubated in either 2.5 nM [^{3}H]naloxone in 50 mM Tris HCl (pH 7.4) and 100 mM NaCl at 0°C for 1 hr to label mu opiate receptors or 10 nM [^{3}H]sulpiride in 50 mM Tris HCl (pH 7.4) and 120 mM NaCl at 22°C for 1 hr to label D_2 receptors. After rinsing and drying, sections were exposed to ^{3}H-sensitive film. Regional autoradiographic densitometry was performed using a Quantitative Densitometry System. Optical density values were converted to absolute values using calibrated tissue standards. The 10 mg/kg/day dose caused significant ($p<0.05$) decrease of 2DG uptake in nucleus accumbens (NAc), substantia nigra pars compacta (SNc) and reticulata (SNr), but no change in striatum, globus pallidus, or locus ceruleus. Sulpiride binding was not affected by either dose in the NAc, SNr, or in any portion of the striatum. Dose-dependent alteration of naloxone binding, however, was observed. Opiate receptor density significantly ($p<0.05$) decreased in the basolateral nucleus of the amygdala, SNc, and dorsal raphe nuclei, and increased in the lateral hypothalamus, medial geniculate, and inferior colliculus compared to the same regions in saline-treated brains. Additional trends for altered binding were noted in the NAc, central nucleus of the amygdala, and ventral tegmental area. No other brain region of the 90 analyzed showed significant effects. While dopamine reuptake is known to be affected by cocaine, D_2 receptor binding was unaffected in this paradigm. Chronic cocaine exposure altered metabolism in several dopamine-related brain reward regions. Moreover, opiate binding was specifically affected in reward centers and not in other regions (with the exception of several auditory-related regions). These data suggest that the reinforcing action of cocaine may be mediated by opiate systems in brain reward centers, which are altered by chronic cocaine exposure. (Supported by USPHS Awards HD19951, DA04081 and NS01161 to R.P.H.)

27.11 PERSISTENT EFFECTS OF COCAINE ON RAT BRAIN TYROSINE HYDROXYLASE. Charles A. Harrington[1], Peter B. Silverman[1], Z.-Q. Zhu*[2]. [1]Department of Psychiatry, Mental Sciences Institute, University of Texas Health Science Center-Houston. [2]Department of Neurosurgery, Baylor College of Medicine-Houston.

A number of neurochemical and behavioral changes are associated with the acute administration of the central nervous system stimulant, cocaine. Cocaine increases striatal dopamine concentration after a single administration but animals given repeated administrations exhibited decreased levels of dopamine in the striatum. Levels of HVA are increased. In addition, animals treated multiple times with cocaine exhibit supersensitive motor activity response to subsequent cocaine challenges.

The activity of tyrosine hydroxylase (TH) has been found to be increased in animals given acute and chronic doses of cocaine. To further clarify the effect of cocaine on TH, we investigated TH with immunocytochemical methods in rat cortex and hippocampus at various times after subcutaneous administration of cocaine. In addition, the concentration of norepinephrine and dopamine were measured in cortex and hippocampus. Total biopterin co-factor levels were also quantified in hippocampus of animals at time periods in which increased TH was observed.

Male Sprague-Dawley rats were administered 100 mg/kg cocaine hydrochloride or vehicle subcutaneously of each of three successive days. One, three and seven days after the last dose of cocaine animals were sacrificed by decapitation. Tissue was processed by $HClO_4$ extraction for neurotransmitter measurement, by acid I_2 oxidation for total pterin analysis, or by glutaldehyde fixation for immunocytochemical analysis. Neurotransmitter and pterin levels were comparable between vehicle or cocaine treated animals at 1, 3 and 7 days after treatment. However TH levels were substantially increased, as demonstrated immunocytochemically, 7 days after cocaine treatment (although not at 1, or 3 days post treatment). We conclude that chronic or intermittent high frequency cocaine use may cause long term changes in the level of key enzymes, such as TH, in catecholamine metabolism in the central nervous system.

27.12 BENZOYLTROPINE AND TROPACOCAINE: EPIDEMIOLOGICAL AND BIOCHEMICAL EVIDENCE FOR CHOLINERGIC ACTIVITY IN THESE COCAINE-IMPURITIES. E.M. Meyer, A.J. Ruttenber*, L. Hearn*, J. Judkins*, M.-T. T. Nguyen*, R. Miller*, and C.L. Devane* (SPON: S.P. Baker). Univ. of Florida Schools of Medicine and Pharmacy, Gainesville, FL, Center for Disease Control, Atlanta, GA, and Office of the Medical Examiner for Dade County, FL.

Epidemiological evidence implicates the alkaloids benzoyltropine and tropacocaine in at least some of the toxic effects occassionally associated with street cocaine preparations. In 9 samples of street preparations obtained from Dec. 1983 through Nov. 1986, 7 contained tropacocaine (0.07-2.7 mg/g cocaine) and 2 others contained benzoyltropine (52 and 175 mg/g cocaine). At least 4 of the former and 1 of the latter group reported symptoms of atropine-toxicity, either central or peripheral.

We therefore investigated the possible actions of these two compounds on several cholinergic systems. Preliminary studies suggest that both compounds inhibit high affinity choline transport and coupled acetylcholine synthesis. ACh synthesis coupled to high affinity choline uptake was inhibited maximally by 85% and 92% by tropacocaine and benzoyltropine, respectively, at 100 uM concentrations. However, both drugs inhibited synthesis over 50% at 3-10 uM concentrations. Total choline uptake by these rat cerebral cortical synaptosomes was similarly inhibited. Interestingly, both compounds significantly inhibited the release of newly synthesized ACh from rat cerebral cortical synaptosomes. At 100 uM, these release-inhibition effects were not further enhanced by adding the muscarinic agonist oxotremorine. These results suggest that both compounds may be active at presynaptic M2 muscarinic receptors in this tissue; however, the alternative hypothesis of sodium channel inactivation is also being investigated.

In order to study the pharmacokinetic properties of these drugs, we also developed an HPLC separation procedure using a 5 micron trimethylsilane column with acetonitrile:phosphate buffer (20:80) containing triethylamine. This procedure separates benzoyltropine and tropacocaine from cocaine, nor-cocaine, and benzoyleecgonine, and allows us to correlate the disposition of the drugs with their behavioral and cardiovascular actions.

27.13 AUDITORY EVOKED POTENTIALS STUDIES OF THE CEREBRAL CORTEX, AMYGDALA, AND NUCLEUS ACCUMBENS DURING AMPHETAMINE ALTERED STATES. C.C. Turbes and G.T. Schneider*. Dept. of Anatomy, Creighton University Sch. of Med. Omaha, NE 68178.

These studies are made on cats and are concerned with changes in auditory evoked potentials related to the action of (d) and (l) amphetamine. Recordings in the cerebral cortex, nucleus accumbens and certain amygdala nuclei. The analog data is stored on FM tape for processing with a minicomputer. The data is processed in the time and frequency domains. Autospectral, coherence spectral and cross correlation estimates are performed on pre, during and post-amphetamine recordings. Comparisons are made with the pre and post-amphetamine recordings. Comparisons are made with the pre and post background electrical activity.

Changes in the analog and processed data show changes that relate to the action of d and l isomers and are different from each other. There are changes that relate to the amphetamine dosage level, the number of repeated doses and the region of the brain. The physical parameters of the stimuli are very important and must be controlled. There are changes in the analog and processed data that relate to the action of amphetamine.

These are evident in latency, amplitude, duration of the P and N peaks of the evoked potentials. There are changes in the frequencies and power of the auotspectral data as well as coherence spectra that relate to the actions of amphetamine. Time domain data shows changes in the cross correlation plots that relates to changes in the interaction between the brain regions studied. Comparisons studies are made with the cross correlation data and the coherence spectral data.

27.14 EFFECT OF A LOW DOSE REGIMEN OF 3,4,METHYLENEDIOXYMETHAMPHETAMINE UPON REGIONAL BRAIN NEUROTRANSMITTERS. R.E. Maloney*, M.D. Schechter, and B.K. Yamamoto. Dept. of Pharmacology, Northeastern Ohio Univs. Coll. of Medicine, Rootstown, Ohio 44272.

Previous studies have shown that the Schedule I drug MDMA ("Ecstasy", "ADAM") decreases 5HT content, synthesis and metabolism. These experiments have employed acute or subchronic dosing regimens using doses ranging from 5-30 mg/kg. To assess the effect of lower doses upon 5HT and other neurotransmitter systems, MDMA was administered to rats according to a pseudo-random dosing paradigm formally used to train rats to discriminate its stimulus properties (Schechter, Pharm. Biochem. and Behav. 26, 1987). Male Sprague Dawley rats were injected i.p. with 1.5 mg/kg ±MDMA 2-3 times /week for 6 weeks. Saline was administered on non-drug days. Control rats received daily injections of saline. Subsequently, all rats were sacrificed and the caudate, nucleus accumbens, hippocampus, hypothalamus, lateral septum, amygdala and prefrontal cortex were punch-dissected and assayed for norepinephrine, dopamine, serotonin and their metabolites by HPLC with electrochemical detection. Caudate, hypothalamus, amygdala and lateral septum all exhibited increases in 5HT and/or 5HIAA. These ranged from a 37% increase in amygdala 5HIAA to a 112% and 119% increase in caudate and amygdala 5HT, respectively. Hippocampus 5HIAA was decreased but 5HT was unchanged. Norepinephrine levels were not altered in any of the areas examined. Dopamine content was increased in caudate (32%), amygdala (80%), and lateral septum (58%). No changes were seen in DOPAC in any of these areas. No neurotransmitter changes were seen in nucleus accumbens and prefrontal cortex. Body weight increases did not differ between control- and MDMA-treated animals over the course of the experiment. In conclusion, a low dose of MDMA administered on an intermittent schedule for 6 weeks produced selective increases in regional neurotransmitter content. The most consistent and dramatic changes were upon the serotonergic system with the dopaminergic system affected to a lesser extent.

Funded by grant no. RO1 DA 04181.

27.15 BIPHASIC BEHAVIORAL AND NEUROCHEMICAL EFFECTS FOLLOWING N-ETHYL-METHYLENEDIOXYAMPHETAMINE (MDE) ADMINISTRATION J.W. BOJA, B.K. YAMAMOTO AND M.D. SCHECHTER. Department of Pharmacology, Northeastern Ohio Univ. College of Medicine, Rootstown, Ohio 44272

The psychoactive drug methylenedioxymethamphetamine (MDMA) has the ability to release both dopamine (DA) and serotonin (5-HT) [Schmidt, et al., Biochem. Pharmcol. 36:747-755, 1987] in the rat brain and its N-ethyl analog MDE also releases DA [Boja, et al., Soc. Neurosci. Abstr., 12:608, 1986]. In order to determine the behavioral effects of MDE, male rats trained to discriminate 0.8 mg/kg amphetamine (AMPH) from 1.4 mg/kg norfenfluramine (NF), using a two-lever operant discrimination task, were administered 2.0 mg/kg MDE and tested at 20 min intervals for 180 min. NF-like responding was prevalent at 20 and 40 min following MDE administration, whereas AMPH-like responding was prevalent at 100-160 min. Vehicle-like responding was seen at 180 min post-MDE administration.

In order to investigate the neurochemical effects of MDE in awake behaving animals, naive male rats were chronically implanted with stearate-modified carbon paste electrodes in the caudate nucleus and allowed to recover 72 hrs prior to testing. In vivo voltammetric recordings, using linear sweep scans from -0.2 to +0.4V and semidifferential signal processing, were made at five min intervals. Peak DA current was measured at +0.15V. MDE (15mg/kg) was injected after a stable baseline was established. Data are expressed as percent of the baseline electrochemical signal (± SEM).

MIN	DA	MIN	DA
0	100.0 (1.1)	100	123.0 (6.9)
20	87.9 (7.4)	120	113.8 (10.9)
40	98.5 (3.0)	140	109.9 (15.7)
60	117.0 (4.9)	160	108.9 (5.5)
80	125.2 (7.4)*	180	97.3 (12.9)

*Significantly different from baseline, $p<0.05$.

These results indicate that MDE initially inhibits DA efflux and precludes AMPH-like discrimination, thus resulting in NF-like responding. After 60 min following MDE administration, DA efflux increases and is maximal by 80 min. At this time AMPH-like discrimination parallels DA efflux which occurs between 60-160 min following MDE administration.

Funded by grant no. RO1 DA04181.

27.16 THE ACUTE EFFECTS OF 3,4,METHYLENEDIOXYMETHAMPHETAMINE ON TRANSMITTER CONTENT IN LIMBIC BRAIN AREAS. L.J. Spanos and B.K. Yamamoto. Department of Pharmacology, Northeastern Ohio Universities College of Medicine, Rootstown, Ohio 44272.

3,4-Methylenedioxymethamphetamine ±(MDMA), an amphetamine analog, has recently been classified as a Schedule I drug due to its abuse potential. Previous studies have shown that at high doses, MDMA is neurotoxic to serotonergic neurons. However, the drug has been reported to have therapeutic value because it enhances communication and sensory awareness. This suggests a limbic component to its mechanism of action. To test this hypothesis, four limbic brain regions were examined to determine the possible differential effect on neurotransmitter metabolism in response to this drug. Male Sprague-Dawley rats were injected i.p. with 2.5, 5 and 10 mg/kg of ±MDMA. Control rats were injected with saline vehicle. All animals were sacrificed at two different time points (60 and 120 minutes). The nucleus accumbens, amygdala, lateral septum, and medial prefrontal cortex were punch-dissected and assayed for norepinephrine, dopamine, serotonin and their metabolites using HPLC with electrochemical detection. No changes were observed at the lowest dose in any of the brain areas examined. At the 5 and 10 mg/kg dose however, consistent and significant decreases (27-82%) in serotonin occurred in all regions. Nucleus accumbens and lateral septum 5HIAA content also decreased by approximately 25% while medial prefrontal cortex showed a 62% increase in this metabolite at both time points. Dopamine content increased by 35% in nucleus accumbens while DOPAC decreased by the same amount. DOPAC also was decreased by 50% in amygdala but was not altered in any other brain region. No other alterations in neurotransmitter metabolism were observed. In conclusion, the acute administration of ±MDMA produced selective and dramatic decreases in the serotonin content of limbic brain regions while transient and subtle changes were observed in dopamine and norepinephrine.

Funded by grant RO1 DA 04181 (M.D. Schechter, P.I.).

27.17 STUDIES ON THE ROUTE OF ADMINISTRATION AND DURATION OF EFFECT OF (±)METHYLENEDIOXYMETHAMPHETAMINE (MDMA) IN RATS. K.T. Finnegan*, G.A. Ricaurte*, S.J. Peroutka, I. Irwin* and J.W. Langston. Inst. for Med. Res., San Jose, CA 95128; Dept. of Neurology, Stanford Univ. Sch. of Med., Stanford, CA 94305.

Recreational use of MDMA has become increasingly widespread. Research in experimental animals has raised concern that this drug may be neurotoxic. Specifically, subcutaneous administration of MDMA has been found to produce a long-lasting depletion of serotonergic nerve terminal markers in rats and monkeys. However, the relevance of these findings to humans, who typically self-administer the drug orally, is unclear. Another unanswered question relates to whether or not serotonin (5HT) levels recover with time after MDMA administration. In this study, both of these issues were addressed.

Groups of rats (n=4) were administered MDMA orally (PO) (7.5, 15.0, 30.0 mg/kg) twice daily for 4 days. Two weeks after drug administration, rats were killed, the hippocampi dissected free, and the concentration of 5HT determined. To probe for possible recovery of 5HT with time, groups of rats (n=4) were injected subcutaneously (SC) with 20 mg/kg MDMA twice daily for 4 days. Individual groups of rats were then killed 2, 7, 10, 13 and 20 weeks after drug administration for the determination of hippocampal 5HT.

Orally administered MDMA produced a long-lasting, dose-related depletion of 5HT in the hippocampus (control 0.37 ± 0.04; 7.5 mg/kg 0.18 ± 0.01; 15 mg/kg 0.15 ± 0.01; 30 mg/kg 0.09 ± 0.01). These results are comparable to those previously reported after SC administration of MDMA. Preliminary results from our laboratory indicate that the PO and SC routes may indeed produce similar effects. For example, 15 mg/kg of MDMA given SC produced a 62.5% depletion of 5HT; this same dose given PO produced a 59% depletion.

In the second experiment, 5HT determinations at various times after MDMA treatment revealed partial recovery. Two weeks after MDMA treatment, hippocampal 5HT was reduced by 64% (control 0.41 ± 0.01; experimental 0.15 ± 0.02). However, 5HT concentrations had recovered to 62% of control values by 20 weeks (control 0.372 ± 0.01; experimental 0.23 ± 0.017).

These results suggest that orally administered MDMA may be no less toxic than when the drug is administered parenterally. Further, these findings indicate that there is partial recovery of 5HT levels with time. This recovery may reflect regenerative sprouting of 5HT nerve fibers. Whether actual functional reinnervation occurs, however, remains to be determined.

27.18 CEREBROSPINAL FLUID MONOAMINE METABOLITES IN CHRONIC HUMAN USERS OF 3,4 - METHYLENEDIOXYMETHAMPHETAMINE (MDMA; ECSTASY). S. J. Peroutka and K. F. Faull. Departments of Neurology, Pharmacology, Psychiatry and Behavioral Sciences, Stanford University School of Medicine, Stanford, CA 94305.

3,4-Methylenedioxymethamphetamine (MDMA; Ecstasy) is a novel psychoactive agent which is used recreationally in the United States. Recently, this compound has been shown to destroy serotonergic nerve terminals in rats. The present study attempted to determine if cerebrospinal fluid metabolites of serotonin, dopamine, and/or norepinephrine were altered in chronic human users of MDMA. The initial analysis involved four people who averaged 20-25 doses of approximately 150 mg MDMA over a six-month time period. The subjects remained free of psychotropic medications for at least two weeks prior to a lumbar puncture. The lumbar puncture was performed between 7:00 and 9:00 a.m. The patients fasted since the evening prior to the study. 15 cc of cerebrospinal fluid was collected, 4 cc of which was placed in an ascorbate containing test tube and immediately frozen on dry ice. 5-hydroxyindoleacetic acid (5-HIAA), 3-methoxy-4-hydroxyphenylethylene glycol (MHPG), 3,4-dihydroxyphenylacetic acid (DOPAC) and homovanillic acid (HVA) were measured by gas chromatography/mass spectrometry. Control values were obtained from neurological and psychiatric patients who had no known history of psychoactive drug abuse. In three of the four patients, all cerebrospinal fluid metabolites were within normal limits. In the fourth subject, the MHPG level was within normal limits. However, the levels of 5-HIAA, DOPAC, HVA were reduced to approximately 25 to 40% of control values in this single patient. This individual denied any long-term clinical effects from psychotropic drug use except for possible alterations in sleep patterns. The subject had taken a total of approximately 4 to 5 grams of MDMA in addition to numerous other psychoactive medications including d-LSD, psilocybin, mescaline, cocaine and marijuana. The implications of these findings for both the clinical and recreational use of drugs such as MDMA will be discussed.

27.19 EFFECTS OF MPTP ON CENTRAL DOPAMINERGIC SYSTEMS IN A LIZARD E. Font* (1), R.C. Switzer (2), N. Greenberg (1) and E.F. O'Connor (3) (SPON: J. LUBAR). (1) Life Sciences Grad. Prog. in Ethology, Univ. of Tennessee, Knoxville TN 37996. (2) Memorial Res. Ctr., Univ. of Tennessee, Knoxville TN 37920. (3) Dept. of Psychology, Univ. of Tennessee, Knoxville, TN 37996.

Systemic administration of MPTP causes destruction of dopaminergic neurons in the substantia nigra of humans, primates, dogs, cats and mice, mimicking idiopathic Parkinson's disease. With few exceptions, the neurotoxicity of MPTP in non-mammalian species remains unexplored. The present study was undertaken to investigate the neurotoxic effects of MPTP in the lizard, Anolis carolinensis (Sauria, Iguanidae).

Twenty-six male A. carolinensis were injected i.p. with MPTP in doses ranging from 4 to 100 mg/kg, producing a variety of behavioral abnormalities. These included pronounced color changes and nuchal crest erection, indicative of an acute stress response, as well as hypokinesia. Seven of the lizards receiving doses over 57 mg/kg showed clonic jerks and severe postural rigidity, and died within 48 hrs of injection. The remaining lizards recovered after a variable period of time. Following a survival time of 3 to 13 days they were sacrificed using sodium pentobarbital. The brains of all 26 animals were removed and prepared for histological examination using a modification of the cupric-silver technique. This technique has been shown by one of us (RCS) to distinctly reveal the neuropathological changes following MPTP administration in mice. In the lizards, axons in different stages of degeneration, corresponding to the different survival times, were observed ascending in the lateral forebrain bundle to a terminal station in the striatum. This appears to be homologous to the dopaminergic nigrostriatal projection of mammals. Degenerating cell bodies were observed in the substantia nigra and ventral tegmental area in animals that were sacrificed at 5 days.

Research now under progress will clarify the neurotoxic effects of MPTP in this animal model using histofluorescence and chromatographic analysis.

27.20 REGULATION OF DOPAMINE RECEPTOR SENSITIVITY: EFFECTS OF 1-METHYL-4-PHENYLPYRIDINIUM (MPP^+) ON PRIMING. B.E. Mileson*, M.H. Lewis, R.B Mailman. Curriculum in Toxicology, Depts. of Psychiatry and Pharmacology, Biol. Sci. Res. Ctr., Univ. of North Carolina Sch. of Med., Chapel Hill, NC 27514.

Male Sprague Dawley rats were anesthetized with ether, and received 80 ug of MPP^+ (intracisternally, IC) in 20 ul of vehicle. One to two weeks following IC injection, MPP^+ and vehicle treated control rats were challenged with apomorphine (0.3 mg/kg, sc). Apomorphine-induced behaviors were quantified using a computer supported observational method by observers unaware of animal treatments. MPP^+ treated animals displayed significantly more licking and gnawing in response to apomorphine ($p < 0.05$) than vehicle treated controls. While this observation could be explained by MPP^+-induced dopamine receptor supersensitivity, it could also be due to a "priming" effect of MPP^+. ["Priming" is the observation that initial exposure to a drug results in enhanced response to subsequent doses of that drug, a phenomenon seen with several classes of compounds, including dopamine receptor ligands. Thus, behavioral stereotypies induced by apomorphine (0.3 mg/kg, sc) are significantly less intense in drug naive rats than in rats pretreated two weeks earlier with this dose of apomorphine.] To test these alternate hypotheses, a second apomorphine challenge was performed four weeks later. In this second challenge, the MPP^+-treated animals showed no increases in licking or gnawing from the first challenge. Conversely, the control rats displayed an increased response to apomorphine challenge, as expected from the "priming" effect of the previous dose. There was no difference between MPP^+ and control rats in this second challenge. After a minimum of five days to permit elimination of apomorphine, the rats were decapitated, and striatal dopamine, DOPAC and HVA concentrations measured. No differences were seen between control and lesioned rats, clearly confirming that permanent generalized decreases in striatal dopamine concentrations did not elicit behavioral supersensitivity to apomorphine. In a separate study, dopamine and its metabolites were measured immediately after IC injection of MPP^+. After four hr (but not 1 hr), striatal DA and DOPAC concentrations were profoundly elevated. These data are consistent with the hypothesis that MPP^+ (administered IC) causes priming of the dopaminergic system, possibly due to transient increases in striatal DA triggered by MPP^+ insult.

27 PO BROMOCRIPTINE INTERACTS WITH DESIPRAMINE IN COCAINE WITHDRAWAL. R.H. Loiselle, A.J. Giannini, M.S. King*, L.R. DiMarzio*, C.A. Armbrecht*. Northeast Ohio Med. Coll., P.O. Box 2169, Youngstown, OH 44504.

Thirty-six cocaine abusers were withdrawn from cocaine over a 90-day period. Twelve received placebo (group P), 12 received bromocriptine 2.5 mg. q.i.d. plus placebo (B-P), and 12 received bromocriptine 2.5 mg. q.i.d. plus desipramine 200 mg. q.d. (B-D). Both B-D and B-P were significantly more effective in controlling withdrawal symptoms than P. ($p<.001$ for both) throughout the duration of the study. After 30 days ($p<.05$) 60 days ($p<.05$) and 90 days ($p<.02$) B-D was more effective than B-P in controlling withdrawal symptoms. This study supports both the dopamine-depletion and dopamine-receptor supersensitivity models in cocaine withdrawal.

27PO COMPARISON OF BROMOCRIPTINE AND AMANTADINE IN THE TREATMENT OF ACUTE COCAINE WITHDRAWAL. A.J. Giannini, R.H. Loiselle, B.A. Sullivan* and M.C. Giannini*. Northeast Ohio Coll. Med., P.O. Box 2169, Youngstown, OH 44505.

Thirty age-matched white males in the 20's and thirties who had abused cocaine daily for at least six months agreed to be detoxified. One-third of this group were given either amantadine (A), bromocriptine (B), or placebo (P). Both amantadine and bromocriptine are central dopamine agonists. Amantadine was given at a dosage of 100 mg. q.6 hrs., bromocriptine 2.5 mg. q.6 hrs., and placebo cap 1 q.6 hrs. The response was measured daily for 10 days. By the end of day 2, both the A and B groups showed significant improvement over placebo ($p<.01$ for both groups). This improvement continued over the study, though by the end of the seventh day the difference between A and B groups and P group were only ($p<.05$). Throughout the study there were no significant differences between A and B groups. Since both amantadine and bromocriptine are dopamine agonists, this study supports the dopamine-depletion hypothesis of cocaine abuse and withdrawal.

CHRONIC DRUGS AND NEUROTOXICITY II

28.1 EFFECT OF EXERCISE ON BENZODIAZEPINE TOLERANCE ASSESSED WITH AN OPERANT BEHAVIOURAL TASK IN RATS. A.J. Goudie and S. Kaney*. Dept of Psychology, University of Liverpool, P.O. Box 147, Liverpool L69 3BX, U.K.

McMaster and Carney (1986) reported that chronic exercise produces tolerance to behavioural actions of muscarinic antagonists (Pharmacol. Biochem. & Behav. 24: 865). We report here that tolerance to the sedative (rate-supressant) action of the short-acting benzodiazepine midazolam is facilitated by previous (remote) exercise in a running wheel.

Rats responded for food on a Fixed Ratio 15 schedule (15 min sessions). After training, subjects were run in 4 weekly cycles in which midazolam tolerance was assessed on consecutive Fridays, i.e. all subjects received midazolam before these operant sessions. On Mondays, subjects in 4 groups (n=8) were treated according to a 2 x 2 factorial design:-

Group	Treatment	Exercise Condition
1	Midazolam	Forced exercise
2	Midazolam	No exercise
3	Saline	Forced exercise
4	Saline	No exercise

On Tuesdays through Thursdays all subjects responded (without any drug treatment) in operant sessions. The rate-suppressant actions of midazolam on Fridays were determined by expressing response rates as percentages of mean response rates on the preceding Wednesday and Thursday. Midazolam was administered at 1 mg/kg (s.c.). Forced exercise involved placing subjects for 80 mins in a wheel rotating at a constant speed of 6 r.p.m. The duration of exercise was chosen to cover the total duration of time for which midazolam is behaviourally active in rats at 1 mg/kg.

The response levels (%) obtained on consecutive Fridays were analysed with a 2 x 2 repeated measures ANOVA. There was a significant effect of repeated tolerance test days ($p<0.001$); i.e. tolerance developed rapidly to the rate-suppressant action of midazolam. There was a significant main effect of exercise ($p<0.05$), animals that received exercise on Mondays showed more tolerance than those that received no exercise. There was no exercise x treatment interaction ($F<1$); i.e. the facilitatory effect of exercise on tolerance was seen in animals that were exercised under drug and under saline. The effect of type of treatment administered on Mondays approached, but did not reach, significance ($F=3.99$, df=1, 28). These data show that exercise remote from drug treatment facilitates tolerance by a mechanism which is at present unknown, but which may involve stress effects (cf. Peris and Cunningham, Alcohol Drug Res. 7: 187, 1987).

28.2 **COMPARISON OF BICUCULLINE, FLURAZEPAM AND PICROTOXIN SEIZURE THRESHOLDS IN DIAZEPAM DEPENDENT-WITHDRAWN AND BARBITAL DEPENDENT-WITHDRAWN RATS.** W.M. Bourn and C.E. Reigel (SPON: J.W. Dailey). Sch. of Pharmacy, NE Louisiana Univ., Monroe, LA 71209 and Dept. of Basic Sci., Univ. of Illinois Col. of Med. at Peoria, Peoria, IL 61656.

Barbiturates and benzodiazepines (BZs) are capable of producing physical dependence in humans following sufficient chronic high dosage administration. Abrupt withdrawal of these agents in physically dependent individuals results in the CNS depressant withdrawal syndrome. This syndrome is characterized by excessive CNS excitation, typified by grand-mal type convulsions in severe instances. Agents in one class are capable of cross-substituting for agents of the other class and maintaining a physical dependence. Upon withdrawal of the second agent, symptoms of the CNS withdrawal syndrome appear.

BZs and barbiturates are generally considered to cross-substitute in animal models of physical dependence. However, we have previously reported incomplete cross-substitution from barbital to diazepam (DZ) physical dependence in the rat (Fed. Proc. 41: 1542, 1982). Using susceptibility to sound-induced seizures as the withdrawal measure (characteristic of barbiturate withdrawal), DZ did maintain the barbital physical dependence. However, upon withdrawal of DZ, susceptibility to sound-induced seizures was not present. These results suggested that barbiturate and BZ physical dependence are similar, but not identical in rats. Analogous to this, barbiturates and BZs both augment GABAergic activity, but do so through different receptors. BZ binding to BZ receptors enhances GABA binding whereas barbiturate binding to the barbiturate receptor prolongs the opening of the GABA/chloride ionophore initiated by GABA receptor activation.

It is possible that enhanced net GABAergic activity initiated at different receptors within the GABA/BZ/chloride ionophore receptor complex could maintain a physical dependence when a BZ is cross-substituted for a barbiturate. Adaptive changes due to chronic receptor occupation could dissipate following cross-substitution to an agent acting at another receptor within the GABA/BZ/chloride ionophore complex. This could account for the lost of sound-induced seizure susceptibility upon DZ withdrawal discribed above. To test this hypothesis, IV seizure thresholds were determined for convulsant agents that bind to the GABA receptor (bicuculline), BZ receptor (flurazepam) and barbiturate receptor (picrotoxin) in barbital and DZ dependent-withdrawn rats and non-dependent vehicle controls. Barbital withdrawn and DZ withdrawn rats exhibited lower flurazepam (FLZ) and picrotoxin seizure thresholds than controls. FLZ seizure threshold was lowered more in DZ withdrawn rats than in barbital withdrawn rats. Picrotoxin seizure threshold was lowered more in barbital withdrawn rats than in DZ withdrawn rats. Bicuculline seizure threshold was lowered only in barbital withdrawn rats.

28.3 PICROTOXIN EFFECTS ON FENVALERATE-INDUCED LOCOMOTOR ACTIVITY. K.M. Tolson, W.M. Bourn, and F.O. Risinger. School of Pharmacy, Northeast Louisiana University, Monroe, LA 71209-0470.

The neurotoxicity of fenvalerate (FNV), a synthetic pyrethroid of the Type II class, seems to be associated with the mammalian GABAergic system. In vitro studies (Lawrence & Casida, Science, 221:1399, 1983 and Crofton et al., The Toxicologist, 6:197, 1986) have linked FNV and other Type II pyrethroids with the TBPS/picrotoxinin binding site(s). The present study examined the relationship between FNV and the GABA receptor-ionophore complex with locomotor activity as the dependent variable.

The time course of FNV toxicity was determined for both male and female Sprague-Dawley rats. Animals were dosed orally with FNV (100 mg/kg) or corn oil vehicle. Time to onset and activity levels were measured in an electronic activity monitoring system. Two activity levels were monitored continuously for four hours after dosing--head/limb movement and whole body movement. Onset of the toxicity syndrome, characterized by an increase in activity, was achieved within the first hour of testing in female rats ($p<0.01$). In male rats the onset did not occur until the second hour of testing ($p<0.01$). After the initial onset, activity levels remained high ($p<0.01$) as both sexes progressed into the toxicity syndrome of FNV.

If picrotoxin (PTX) and FNV share a common binding site, one would expect pretreatment with a subconvulsive dose (2 mg/kg) of PTX to alter the binding and subsequent toxicity syndrome of FNV. PTX was administered ip to female rats thirty minutes prior to FNV exposure (100 mg/kg). PTX alone produced a decrease in activity ($p<0.01$) within the first hour of testing. Rats receiving PTX prior to FNV also exhibited a decrease in activity ($p<0.01$) within the first hour, but by the fourth hour there was an increase in activity ($p<0.01$) associated with the onset of the FNV toxicity syndrome. Thus, pretreatment with PTX was found to delay the time to onset by three hours in female rats. These findings provide further (behavioral) evidence that links Type II pyrethroids with the picrotoxinin domain within the GABA receptor-ionophore complex.

28.4 FOOD AVERSION TO DEOXYNIVALENOL (VOMITOXIN) IN RATS AND THE ROLE OF THE AREA POSTREMA. K.-P. Ossenkopp, W. A. Rapley*, and M. Hirst. Depts. Psychology and Pharmacology & Toxicology, University of Western Ontario, London, Ontario, Canada, N6A 5C2.

The presence of vomitoxin in livestock feed is associated with food rejection and reduced weight gain. The present experiments used a rat model to investigate the nature and possible underlying mechanisms of the vomitoxin-induced food rejection response. In Experiment 1 male albino rats (Sprague Dawley) were maintained in an isolated operant conditioning chamber and obtained food pellets by pressing a lever on a continuous reinforcement (CRF) schedule. After a training period with normal Noyes pellets, the rats were presented with pellets containing various levels of vomitoxin (3, 6, or 12 ppm). Number of lever presses, number of pellets consumed, weight gain and water intake were monitored and compared to control rats over a 10 day period. Increasing levels of vomitoxin produced significant decrements in body weight gain and rapid dose-related rejections of the food pellets. In Experiment 2 male albino rats were given thermal cautery lesions of the area postrema (AP), a circumventricular organ known to be a chemoreceptor for blood-borne toxins, or sham lesions. Following a 10 day recovery period the rats were again maintained in the isolated operant conditioning chambers in the same manner as in the first experiment. When the rats were presented with food pellets containing 48 ppm of deoxynivalenol both the AP lesioned and sham lesioned rats exhibited significant decrements in weight gain. The sham lesioned animals exhibited high levels of pellet rejection whereas the AP lesioned rats showed much lower levels of rejection ($p < .01$). However, number of pellets consumed did not differ between the two groups. Thus, the AP seems to be necessary for high levels of food aversion displayed in response to food pellets containing the vomitoxin. However, integrity of the AP does not seem to be important for reductions in body weight gain in response to vomitoxin contaminated food.

28.5 ANTAGONISTIC EFFECT OF ZINC ON MORPHINE-INDUCED ANALGESIA, TOLERANCE AND NALOXONE-PRECIPITATED WITHDRAWAL SYNDROME IN RATS. M. Baraldi. Dept. of Pharmaceutical Sciences, Section of Pharmacology and Pharmacognosy, Modena University,41100 Modena, Italy.

There are several evidence suggesting that endogenous opioids and zinc may interact to regulate neuronal functions in brain areas where they are co-localized. Zinc has been shown to inhibit in vitro opioid binding by reducing in a dose related fashion both the affinity and the number of binding sites. This effect could be related to the high affinity of zinc for the SH- groups present in opioid receptors, since thiol-reducing agents can restore the binding properties of opioid receptors altered by the exposure to the oxidative effect of the metal. Furthermore it is noteworthy that the Enkephalin-degrading enzymes are zinc-metal enzymes and that thiorphan inhibits the enkephalinase activity presumably by binding zinc which resides in the active sites of the enzyme. These data prompted us to test the behavioral and biochemical effects induced in normal rats and in morphine-tolerant rats by the supplementation of pharmacological doses of zinc which we demonstrated to increase the release of ACTH from anterior pituitary and to induce hyperalgesia. Pellets of morphine (75 mg) or placebo were implanted subcutaneously to rats which received at the same time a subcutaneous depot injection of ZnO2 (110 mg/Kg) or the vehicle alone. Here we report that the administration of zinc reduced the analgesic effect of morphine and the Naloxone-precipitated withdrawal syndrome. Interestingly the treatment with morphine alone induced a reduction of zinc in plasma and in brain tissue and a decreased presence of ACTH in plasma, that is exatly the opposite effect induced by the supplementation of zinc alone. A further indication of the antagonistic effect of zinc and morphine is represented by the ability of morphine to prevent the oxidative effect of zinc on opioid receptors. These observations could be of value in order to test the effect of zinc supplementation in opiate addiction.

28.6 EFFECT OF CHRONIC LEAD INTOXICATION ON DOPAMINE METABOLISM AND TRANSMISSION IN THE RAT NEOSTRIATUM. D. Martínez-Fong*, M. E. Gutiérrez* and J. Aceves* (SPON. J. Alanís). Dept. of Physiol. Biophys. and Neurosci. Centro de Investigación y de Estudios Avanzados del IPN. 07000, México, D. F.

Rats intoxicated with low lead levels show hyperactivity and stereotyped behavior. Increase in dopamine (DA) metabolism and transmission in neostriatum and nucleus accumbens septi elicits this same behavior. Then, increase in DA metabolism and neurotransmission would be expected in these brain areas of lead intoxicated animals. Here we have studied this possibility. We studied the effect of lead intoxication on the activity of some enzymes involved in DA metabolism; the effect on DA transmission was judged observing modifications in rotational behavior induced by amphetamine in animals with 6-hydroxydopamine lesion. Female rats were exposed to 1400 ppm of Pb acetate via drinking water two months before and during pregnancy, and also during lactation until 21 days postpartum. At this time, the same Pb solution was given to male offsprings until their sacrifice at 3 months of age. Animals of the same age were used as controls. In Pb-intoxicated animals, the quinonoide dihydrobiopterin reductase (QDBR) activity and the levels of tetrahydrobiopterin (BH4) increased 33 and 40% respectively, but cyclohydrolase activity remained normal, suggesting that the increase in TH4 (tyrosine hydroxylase cofactor) was due to increase in QDBR activity. Tyrosine hydroxylase activity, as judged by the increase in DOPAC (measured voltametrically in vivo) after the blockade of the DA presynaptic autoreceptors with haloperidol, was also found increased in intoxicated animals. Paradoxically, rotational behavior (turns/min) was significantly reduced in intoxicated animals. Pb concentrations were significantly increased in striatal tissues and blood. The results suggest that Pb intoxication increases, as expected, DA metabolism in neostriatum. Pb intoxicated animals also showed the paradoxical response to amphetamine, which is a common feature of plumbism in mammals.

28.7 ACUTE LEAD EXPOSURE REDUCES GLUCOSE UTILIZATION IN THE RAT BRAIN. John M. Bertoni and Pamela M. Sprenkle *, Department of Neurology, Jefferson Medical College, Philadelphia, PA 19107

The 2-deoxyglucose autoradiographic method was used to assess the effects of acute lead exposure on regional brain glucose metabolism in the rat. Eight male Long-Evans hooded rats weighing between 317 and 364g were cannulated for access to the femoral artery and vein, then given an IV bolus of lead acetate (50mg PbAc/kg or 27mg Pb/kg) or saline and observed for at least 7 hours prior to the start of the 2-deoxyglucose experiment. Under controlled conditions of light and sound, the rats were injected with 14C-2-deoxyglucose, then sacrificed after 45 min. The brains were frozen in cooled isopentane at -40 ° C and 20 u sections were made. Every third slice was dried on glass slides and apposed to Kodak SB5 X-ray film for 5 days. Local cerebral metabolic rates for glucose (lCMRglu) were measured by densitometry with a computerized image analyzer. Four other rats were similarly given lead but without 2-deoxyglucose, and blood samples were taken at -1, 15, and 30 min and at 1, 2, and 6 hours, with corresponding mean (± SE) lead levels in the blood of 1.8 ± 1.4, 156 ± 14.6, 182 ± 20.4, 155 ± 17.4, 134 ± 12.5 and 36 ± 2.3 ppm. Whole brain lead was 0.45 ± 0.22 and 1.20 ± 0.15 ppm in the control and lead-treated groups, respectively ($\bar{p}<0.025$). The greatest reductions in lCMRglu occurred in the following structures: medial geniculate bodies (15.6 ± 2.5%), anterior commissure (11.8 ± 6.2%), and auditory cortex (10.4 ± 4.1%). The auditory centers are known to be among the most metabolically active in the mammalian brain. These data support the hypothesis that brain areas with the highest glucose metabolism, highest Na,K-ATPase activity and greatest synaptic densities are most vulnerable to the effects of lead.

Supported in part by grant ES031841 from the National Institute of Environmental Health Sciences, the Gustavus and Louise Pfeiffer Foundation of Santa Monica, CA, and Jefferson Medical College institutional funds.

28.8 HEMODYNAMIC EFFECTS OF MERCURY CHLORIDE IN INTACT AND IN ISOLATED PERFUSED RABBIT HEARTS. H.M. Rhee and B.H. Choi. Department of Pharmacology, Oral Roberts University School of Medicine, Tulsa, OK 74137 and Department of Pathology, University of California Irvine, Irvine, CA 92717.

Although it is well known that both organic and inorganic mercurial compounds are capable of producing severe toxic damage to the central nervous system the precise mechanisms of cellular damage in the brain are poorly understood. Since inorganic mercurial compounds do not readily cross the blood-brain-barrier and are also known to cause acute cardiovascular effects in intact animals the pathogenesis of neurotoxic damage in inorganic mercury intoxication may be different from that of organic mercury in that the CNS damage may be greatly influenced by direct action of these compounds to peripheral organs. In order to characterize the acute effect of mercuric chloride New Zealand white rabbit (1.5-2.5 kg) were anesthetized (pentobarbital 30 mg/kg) and instrumented as reported previously (J Pharmacol Exp Ther 234: 534, 1985). At the same time the left renal sympathetic nerve activity was monitored during the injection of mercury to test whether or not mercury alters nerve activity which might produce hemodynamic alteration secondarily. In intact anesthetized rabbits an intravenous injection with small doses of mercuric chloride (100 µg/kg or less) did not produce significant changes in systemic blood pressure, heart rate or renal nerve activity. Large doses (500 µg/kg or more), on the other hand, depressed these parameters significantly. For example, a fast bolus injection of mercuric chloride (2 mg/kg) produced a state of shock with transient increase in the nerve activity. Since this cardiovascular action of mercuric chloride suggested a direct action of mercury to the heart, the action of mercuric chloride was tested in isolated perfused rabbit hearts. The isolated hearts were retrogradely perfused with Krebs-Henseleit solution as reported previously (Oxygen Transport to Tissue, Lubbers et al (eds), Vol V, Plenum Press 1984, p. 389) with different concentrations of mercury at 37°C. One mg% of mercuric chloride solution reduced the contractile force by 30% in 10 sec and the first derivative of intraventricular pressure (dP/dt) was also reduced proportionately. These results suggest that hemodynamic action of mercuric chloride was indeed due to its primary action on the heart and that these effects must be taken into account when analyzing the vulnerability and damaging effects of mercurial compounds to the central nervous system.

(supported in part by USPHS grant ES 02928)

28.9 EFFECTS OF INHALED p-XYLENE ON LEARNING AND MEMORY IN RATS. P.J. Bushnell. Neurotoxicology Division, US EPA, Res. Tri. Park, NC 27711.

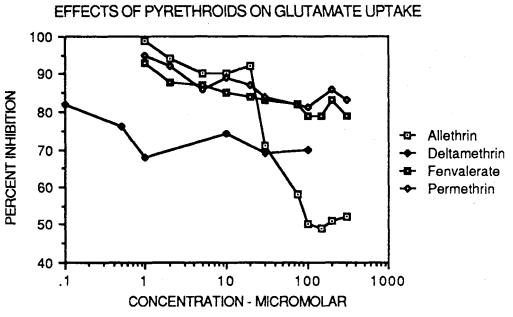
p-Xylene is a prevalent solvent and chemical precursor used in both industry and household products. While the population at risk for exposure is thus quite large, little is known about its neurobehavioral effects. Young adult male Long-Evans rats inhaled p-xylene at concentrations of 0 to 1600 ppm, 4 hr per day for 1 to 5 days, and were evaluated immediately following exposure on several learning and memory tasks. Autoshaping was carried out across 5 successive days with p-xylene exposure in the morning followed by testing in the afternoon. For this test, the retraction of a single lever on a variable-time 50" schedule predicted delivery of a food pellet. When the force required to depress the lever was <0.10 N, acquisition of the barpress response was faster in animals having inhaled 1600 ppm p-xylene than in air-exposed controls. When the force was increased to 0.20 N, however, p-xylene exposed rats acquired the response no faster than controls. Learning was also assessed in the 8-arm radial maze (8-ARM) by baiting a different set of 4 arms daily and measuring decline in number of errors (entries into unbaited arms) required to obtain the rewards across 10 trials/day. Rats having inhaled 1600 ppm p-xylene made more errors in this repeated acquisition paradigm. To asses working memory, rats were trained in an operant chamber on a discrete-trial conditional delayed response paradigm. These rats received pellets for pressing one of two levers in the choice phase of a trial if that lever had been presented alone in the prior sample phase of that trial. On half the trials, a cue light indicated the correct response, thus providing a discrimination control condition within the task. Performance on both uncued (memory) and cued (discrimination) trials was unaffected by prior inhalation of 1600 ppm p-xylene. It thus appears that acute p-xylene inhalation at 1600 ppm (16 times the TLV) does not affect memory in rats. The increase in rate of barpress acquisition may be explained on the basis of decreased motor control induced by p-xylene. The increase in errors in the repeated acquisition test may reflect impaired ability to process spatial information after p-xylene exposure.

28.10 EFFECTS OF CHRONIC EXPOSURE TO TRICRESYL PHOSPHATE IN F344 RATS AND B6C3F$_1$ MICE: BEHAVIORAL AND BIOCHEMICAL CORRELATES. R. Irwin*, G. B. Freeman, R. Trejo*, M. Hejtmancik* and A. Peters* (SPON: S. Tjioe). Battelle, Columbus, OH and National Toxicology Program, RTP, NC.

Subchronic exposure to tricresyl phosphate (TCP) (0-13000 ppm TCP in rats; 0-4200 ppm in mice), an organophosphate of known neurotoxicity, decreases forelimb grip strength in male rats and both forelimb and hindlimb grip strength in male and female mice. It was suggested that a TCP-induced depression of body weight accounted for the observed grip strength impairment in rats, but not in mice (Haggerty et al., The Toxicologist, 6: 218, 1986). In an ongoing chronic dosed feed study (2 years), F344 rats are exposed to 0, 75, 150, 300 or 600 ppm, while B6C3F$_1$ mice receive 0, 60, 125, or 250 ppm. After 13 weeks of dosing, forelimb gripstrength was unaffected by TCP in both mice and rats. Hindlimb grip strength decreased in male rats (300 and 600 ppm), but not in female rats. In mice, decrements in hinglimb grip strength were observed in males (250 ppm) and females (125, 250 ppm). TCP had no effect on food consumption in either species. In addition, all dose groups of both sexes exhibited group mean body weight values that were similar to those of respective controls. As a biochemical index of potential toxicity, serum cholinesterase levels showed a dose-dependent reduction in both rats and mice. In rats, serum cholinesterase declined significantly relative to control in the 300 (-18%) and 600 (-27%) ppm male dose groups and the 150 (-23%), 300 (-35%) and 600 (-49%) ppm female dose groups. Serum cholinesterase values in all dose groups of mice were significantly lower than control [males: 60 ppm (-31%), 125 (-53%), 250 (-72%); females: 60 ppm (-28%), 125 (-56%), 250 (-77%)]. These results suggest that grip strength is sufficiently sensitive to detect sex and species differences in the behaviorally neurotoxic effects of TCP.

28.11 EFFECTS OF PYRETHROID INSECTICIDES ON THE ACTIVE UPTAKE OF GLUTAMATE INTO RAT BRAIN SYNAPTOSOMES. A. S. Bloom and A. T. Accardi. Dept. of Pharmacology and Toxicology, Med. Col. of Wisconsin, Milwaukee, WI 53226.

The Na^+-dependent binding site for glutamate in brain membranes is thought to be associated with the high affinity uptake of that putative neurotransmitter into neurons. We have previously demonstrated that pyrethroid insecticides inhibit the Na^+-dependent binding of glutamate to rat brain membranes (Neurosci. Abs., 11 :632, 1985). We have now investigated the effects of several pyrethroids on glutamate uptake. The uptake of ^3H-glutamate was measured in a crude mitochondrial preparation of rat forebrain at 37° C. Pyrethroids were added using DMSO as the vehicle. Allethrin (ALL), permethrin (PER), deltamethrin (DEL) and fenvalerate (FEN) were examined. All of the pyrethroids



tested inhibited the uptake of glutamate. ALL had the most effect, inhibiting 50% at a concentration of 100μM. DEL was the most potent, producing significant inhibition at concentrations as low as 0.1 μM. However the maximum inhibition observed with DEL was only 30%. PER and FEN were less active. Kinetic studies indicated that the inhibition was noncompetative in nature. The above data demonstrate that the pyrethroid insecticides can inhibit the high affinity glutamate uptake system. It is possible that this action is due in part to an effect on glutamate binding to the carrier in this system. (Supported by USPHS grant ES 03102).

28.12 SODIUM BENZOATE INCREASES FREE TRYPTOPHAN (TRP) IN BLOOD AND SEROTONIN (5-HT) FLUX IN CORTEX OF HYPERAMMONEMIC SPF MICE. M.L. Batshaw, S.L. Hyman, J.C. Coyle, and I. Qureshi (spon. James C. Harris). Depts. Peds., Psych. and Kennedy Inst. Johns Hopkins Meds Inst., Balto. and Hopital Ste. Justine, Montreal

Sodium benzoate has proven effective treatment of hyperammonemia in children with inborn errors of urea synthesis. It provides an alternative pathway for waste nitrogen excretion as hippurate. Normal dose is 1.75 mmol/kg/d. Toxicity associated with high dosage benzoate (>4 mmol/kg/d) simulates ammonia toxicity with anorexia and lethargy. The mechanism of these behavioral abnormalities is unclear but may involve altered serotonin metabolism. We have previously shown that hyperammonemia leads to increased serotonin flux in cortex of rats who received infusions of urease (Pediat Res 20:1310-15,1986). We now report that benzoate also increases cortical serotonin flux. We injected i.p. 1 or 5 mmol/kg of sodium benzoate or sodium acetate (control) in congenitally hyperammonemic Spf/y and in normoammonemic CD-1 mice with sacrifice 1 hr. later (n=10 each group). Plasma benzoate levels were similar in both animals (mean) 35 uM and 6362 uM for 1 and 5 mmol/kg injections respectively. These are comparable to levels found in children receiving similar dosage. Benzoate also accumulated in cortex, 29 pmol/mg tissue and 2239 pmol/mg respectively. Compared to CD-1 mice, Spf mice (all conditions) had higher cortical levels of HIAA ($p<.001$), 5-HT and Trp ($p<.005$). Benzoate treatment resulted in a significant increase in HIAA, $p<.001$, and 5-HT, $p<.05$ in CD-1 mice and an increase in HIAA, $p<.001$ in Spf mice. There was no treatment effect on cortical levels of norepinephrine, GABA or amino acids. Benzoate treatment resulted in an increase in free serum Trp levels in CD-1, $p<.001$, and Spf mice, $p<.09$. Sodium acetate had no effect on free Trp or cortical serotonin flux. The effect of benzoate on free Trp and on serotonin flux was most evident with the 5 mmol/kg dose. These results suggest that the effect of hyperammonemia and benzoate may be synergistic in increasing serotonin flux. The mechanism of the benzoate induced changes appears to involve competition of benzoate with Trp for albumin binding sites in blood. This study indicates that benzoate toxicity may be linked to altered serotonin metabolism and that the treatment margin of safety is rather narrow.

ACTION POTENTIALS AND ION CHANNELS I

29.1 **MORE THAN ONE RNA SPECIES IS INVOLVED IN CONTROLLING INACTIVATION OF RAT BRAIN Na CHANNELS EXPRESSED IN XENOPUS OOCYTES.** D.S. Krafte*, T.P. Snutch*, J.P. Leonard, N. Davidson*, & H.A. Lester. Divs. of Biology and Chemistry, Caltech, Pasadena, CA 91125.

We have injected RNA from the brains of 18 day old rats into Xenopus oocytes in order to study the properties of voltage-dependent Na channels from this tissue. Oocytes were injected either with unfractionated poly(A+) (RNA_u) or poly(A+) RNA that was size fractionated over a sucrose gradient. We identified a fraction (RNA_α) that contained the 9 kb mRNA encoding the α subunit of the Na channel both by Northern blot analysis and by electrophysiological recording. Currents elicited by this fraction exhibited a 3 fold or greater slowing of the macroscopic inactivation rate as compared to currents following injection of RNA_u. In addition, the steady-state voltage dependence of inactivation was shifted in the depolarizing direction (V1/2 = -45 mV for RNA_u vs. -34 mV for RNA_α). To eliminate the possibility that these effects were an artifact of our manipulations we pooled all the fractions from the gradient and injected the pooled RNA into oocytes. Macroscopic inactivation of Na currents elicited by pooled RNA was indistinguishable from that following injection of RNA_u. The mechanism behind the slowing of the inactivation kinetics was investigated at the single channel level using both cell-attached and excised outside-out patches. In both cases a greater tendency for the channels to reopen appears to underlie the macroscopic observations. This gating behavior is illustrated in the current traces below in response to a voltage step from -100 mV to -20 mV in a cell-attached patch (left-RNA_u, right-RNA_α, calibration bars = 2 pA and 4 ms). The single channel conductance was approximately 13 pS for channels induced by both RNA_u and RNA_α injections. Supported by NS-11756 and by fellowships from NIH and AHA.

29.2 TTX-sensitive Na channels expressed in Xenopus oocytes injected with rabbit heart RNA. Fedora Sutton*, Kiyonori Yoshii*, Norman Davidson* and Henry A. Lester. Division of Biology 156-29, Caltech Pasadena CA 91125.

We are characterizing the types of sodium channels expressed in cardiac tissue. RNA was isolated from atrium, ventricle, or whole rabbit or rat heart (ages 8 to 25 d). Based on Northern blot analysis with the neuronal specific probe pSCG-10, there was no detectable contamination with neuronal RNA. Two hundred ng of RNA was injected into oocytes in 50 nl of water. After 2 d incubation at 20°C, voltage-dependent Na currents (100-500 nA peak) were observed with a standard two-electrode voltage-clamp circuit. With either ventricular or atrial RNA, these currents were blocked by TTX; the dose response relation suggests that at least 90% of the channels were blocked by the binding of a single TTX molecule with a dissociation constant of 8 ± 2 nm. This affinity equals that for blockade of the 5-10 fold larger Na currents induced by rat or rabbit brain RNA. This sensitivity to TTX contrasts with the dissociation constant of at least 1 μM observed with voltage-clamp analysis of ventricular muscle. Perhaps TTX insensitivity requires a post-translational modification that oocytes cannot perform. Supported by HL-35782 and by NIH fellowship to F.S.

29.3 **Evidence for alpha-2,8-linked polysialic acid in the glycopeptide of the voltage-sensitive Na channel from *E. electricus*.**

William M. James & William S. Agnew, Department of Physiology, Yale University, 333 Cedar St, New Haven, CT 06510

All of the known homologous voltage-sensitive Na channels from vertebrates are glycoproteins. The protein from eel electroplax is formed of a single peptide of 208 kDa, which when normally glycosylated runs on SDS-gels as a diffuse band of ~290 kDa. Compositional analysis indicates 29% of the glycopeptide is carbohydrate, enriched in sialic acid and N-acetylhexosamines (Miller, Agnew & Levinson, 1983, Biochem.22,462). We have investigated susceptibility of the carbohydrate to exo and endoglycosidases and here report the effects of treatment with two neuraminidases. Denatured glycopeptide was prepared with by our previously reported DEAE ion-exchange and Sepharose gel filtration protocols. Electrophoretic subfractions were prepared as well resolved substrate by preparative SDS-gel electrophoresis.

When treated with the exoneuraminidase from *C. perfringens* (37 C, 0.8 U/ml, 3 h), SDS-PAGE showed the average apparent size on 5.5% gels was decreased from 290 kDa to 220 kDa. This was prevented by the inhibitor 2-deoxy-3-dehydro-N-acetylneuraminic acid. A second enzyme tested was endo-N-acetylneuraminidaase (Endo-N) from K1F bacteriophage induced *E.coli* (Hallenbeck, et al, 1987, J.Biol.Chem.,262,3553). Endo-N is specific for long unbranched polysialic acid homopolymers of minimal chain length 5; cleavage leaves the proximal 4 sialic acids unhydrolyzed. Treatment with this enzyme under similar conditions produced a similar increment in electrophoretic mobility, indicating apparent loss of of 70 kDa (25%). Thus, a sizeable fraction of the sialic acid appears to be linked in unbranched homopolymers of polysialic acid. It can be estimated that removal of all ~113 sialic acid residues would cause minor losses of both mass (12%) and charge (<2% of SDS-denatured peptide). Thus the sialic acid-bearing moiety may form an extended structure that contributes to a large hydrodynamic resulting in substantial retardation on acrylamide gels.

To our knowledge the electroplax Na channel is only the second protein from excitable tissues reported to exhibit polysialic acid, the other being the embryonic neural cell adhesion molecules (NCAM) involved in cell-cell interactions during development. Experiments are in progress with native glycopeptide to test whether the polysialylation plays a role in channel function.

29.4 IMMUNOCYTOCHEMICAL LOCALIZATION OF SODIUM CHANNELS IN HIGH FREQUENCY PACEMAKING NEURONS OF ELECTRIC FISH. L. Maler, M. Ellisman, and S.R. Levinson. Dept. of Anatomy, University of Ottawa, Ottawa, Ont. K1H 8M5, Dept. of Neuroscience, UCSD, La Jolla, CA 92093, and Dept. of Physiology, University of Colorado, Denver CO 80262.

The electrical behaviour of neurons is dependent on voltage sensitive ion channels; although the differential distribution of ion channels over the somatic, dendritic, and axonal membranes contributes to the integrative properties of the neuron it has not been possible to directly visualize this distribution. Sodium channels are located on unmyelinated axons and are densely clustered at axonal nodes and the initial segment. Recently an antibody has been developed against the sodium channels isolated from the electric organ of Electrophorus electricus, a gymnotiform fish. It was also verified that this antibody produced reliable localization of sodium channels on electrocytes and at nodes of Ranvier of the eel (Ellisman & Levinson, 1982). We have used immunocytochemistry to study the distribution of sodium channels on functionally defined neuronal populations of another gymnotiform fish, Apteronotus leptorhynchus. This species has an electric organ discharge (EOD) which ranges from 600-1000Hz. The EOD frequency is set by a medullary pacemaker nucleus which contains pacemaker cells with intrinsic axons and relay cells whose axons innervate spinal electromotor neurons. The pacemaker nucleus is rich in saxitoxin binding sites and the pacemaker potential is a TTX sensitive sodium current (Reed, Stys & Maler, unpubl. obs.). A subset of the electrosensory afferent system discharges in a phase-locked one-to-one fashion to the EOD (i.e. 600-1000Hz) - the phase coder or T system. Phase coders project to a specific population of neurons in the medulla (spherical cells) and these in turn project to adendritic giant cells in the midbrain (Carr et al., 1986); both spherical and giant cells maintain a one to one phase-locked discharge to the EOD. In the pacemaker nucleus sodium channels are located in the plasmalemma at nodes and the initial segment of pacemaker and relay cells. The somatic plasmalemma of both pacemaker and relay cells is densely labelled by the sodium channel antibody and this labelling extends onto the proximal dendrites of the relay cells. The plasmalemma of the large club endings generated by pacemaker cells are also strongly immunoreactive for the sodium channel protein. In contrast, the spherical and giant cells which fire at the same rate as the pacemaker cells, do not have sodium channel immunoreactivity associated with their plasmalemma; nodes of Ranvier on the axons of these cells are labelled by the sodium channel antibody. These results demonstrate that a high density of somatic sodium channels is important for cells which generate the pacemaker discharge, but not for cells which merely passively follow the discharge.

29.5 EFFECTS OF NEURAMINIDASE TREATMENT OF BATRACHOTOXIN-MODIFIED EEL PURIFIED SODIUM CHANNELS IN PLANAR LIPID BILAYERS. E. Recio-Pinto, W.B. Thornhill, D.S. Duch, S.R. Levinson, and B.W. Urban*. Depts. Anesthesiology and Physiology. Cornell U. Med. Coll., New York, N.Y. 10021. Dept of Physiology, Univ of Colorado, School of Medicine, Denver, CO 80262.

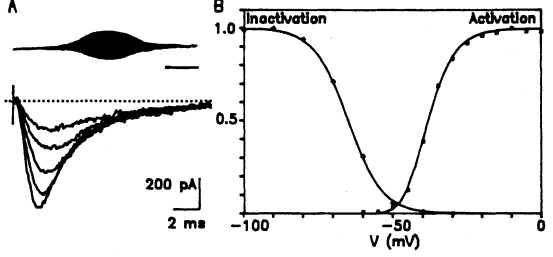
Treatment with neuraminidase, which removes sialic acids, resulted in a decrease in the apparent molecular weight of the purified eel sodium channel from 290 to 210 kDa as detected on polyacrylamide SDS gels. Neuraminidase treated (5 hrs) and untreated purified, reconstituted sodium channels were fused with neutral planar bilayers in the presence of batrachotoxin as previously described (Recio-Pinto, E., Duch, D.S., Levinson, S.R. and Urban, B.W., 1987; J. Gen. Physiol., in press). In symmetrical 0.1 M NaCl the mid-point potential of the steady state activation curve was lower in the neuraminidase treated (-46 mV) than in untreated (-76 mV) channels. Neuraminidase treated channels frequently showed subconductance-like states (two major peaks around 16 pS and 8 pS), which was the predominant one in untreated channels. Some neuraminidase treated channels also showed a non-linear current-voltage relationship. In other experiments untreated reconstituted sodium channels were first fused with planar bilayers and then treated with neuraminidase (symmetrical 0.1 M NaCl). Neuraminidase treatment produced a shift in the mid-point potential to more depolarized potentials of about 20 mV. In addition, neuraminidase treatment increased the frequency of subconductance-like states. We conclude that removal of sialic acids with neuraminidase accounts for these changes in channel behavior, by either decreasing the negative charges in the extracellular surface of the channel and/or allowing conformational changes of the channel.

29.6 **VOLTAGE-CLAMP ANALYSIS OF Na^+ CURRENTS IN ISOLATED NEURONS FROM THE GUINEA PIG CNS**

Alan R. Kay * & Robert K.S. Wong. (SPON : K.-W. Yau) Dept. Neurology, Columbia University CPS, New York, NY 10032.

Macroscopic Na^+ currents were measured in the whole-cell mode of patch-clamping, from neurons isolated (method of Kay & Wong, J. Neurosci Methods, 16, 227,'86) from the hippocampus, neocortex and thalamus of mature guinea pig brain. K^+ currents were blocked by external TEA, Cs & 4AP, and internally by Tris. Ca^{2+} currents were blocked by 200 μM Cd^{2+}.The Na^+ current could be controlled throughout its range of activation when the external Na^+ was reduced to 30 mM (see fig. A ; hippocampal CA1 neuron (scale 10 μm) depicted above current traces; reponses to steps to -42, -40, -38, -36 & -34 from -90 mV). Adequate voltage-clamp was also ensured by the electrotonic compactness of the cells (length of processes $< 0.1\lambda$), low access resistance of electrodes (2 -5 MΩ), and small capacitance of the cells (2 -15 pF). In some instances unclamped Na^+ currents were observed together with controlled Na^+ currents; such recordings were always associated with the presence of fine branches.

The steady-state activation and inactivation curves (see Fig. B; hippocampal CA1 neuron) of the Na^+ current overlapped to a small extent, consistent with the small 'window-current' observed. Moreover, in none of the areas from which Na^+ currents were recorded, was a separate persistent Na^+ current evident. We attempted, without success, to record this putative current in the presence of a number of different Ca^{2+} blockers (La^{3+} Co^{2+} Mn^{2+} & Ni^{2+}), as Cd^{2+} has been reported to block the persistent Na^+ in cardiac Purkinje fibres (Carmeliet, 1987). In addition to the fast inactivation of the Na^+ current which occurs with time constants in the range 2 - 20 ms, a slow phase of recovery from inactivation (half-time 30 s) was observed. Complete recovery from this phase of inactivation doubled the Na conductance available for activation. (Supported by NIH grant NS 24682 & the Klingenstein Foundation).



29.7 SOMA-DENDRITIC LOCALIZATION OF Na^+ CHANNELS IN PYRAMIDAL NEURONS ACUTELY ISOLATED FROM RAT NEOCORTEX. J.R. Huguenard, O.P. Hamill*, and D.A. Prince. Dept. of Neurology, Stanford Univ. Sch. of Med., Stanford, CA 94305.

Although the electroexcitability of dendrites has been studied directly in cerebellar Purkinje cells and hippocampal pyramidal neurons, much less is known about the properties of dendritic membranes in mammalian neocortical neurons. We have directly measured Na^+ current in dendritic membranes of pyramidal neurons from rat sensorimotor cortex, using the acute cell isolation procedure of Kay and Wong (J. Neurosci. Meth. 16: 227, 1986).

Isolated pyramidal neurons were easily identified on morphological criteria. We applied the patch clamp technique to such neurons from P3-P8 animals under conditions which isolated Na^+ currents. Two techniques were used to localize the current to dendritic vs. somatic membrane areas. The first involved differential perfusion of a cell during whole cell voltage clamping so that only a portion of the membrane was exposed to a Na^+-containing solution, whereas the rest of the neuron was bathed in 0 Na (choline substitution). Under these conditions we found that the amplitude of the Na^+ current (normalized to membrane area) was approximately equal over apical dendritic and somatic membranes (ca. 40 pS/μ^2). A second technique involved direct measurement of single channel currents with cell-attached patches from different membrane sites. At least one somatic site and 1-3 sites on the primary apical dendrite up to 100μ from the soma were sampled sequentially in each cell. This technique provided results similar to those of the differential perfusion experiments. The density of Na^+ channels per equivalent patch was uniform throughout the dendro-somatic membrane area. Furthermore, the kinetic properties of the channels were consistent with the idea of a uniform population distributed through the entire membrane. We conclude that there is a relatively uniform distribution of Na^+ channels over the somatic and primary apical dendritic membranes of cortical pyramidal neurons at these ages and that the regenerative Na^+ currents in the major dendritic processes are equivalent to those of the soma.

Supported by NIH grants NS 06477 and NS 12151.

29.8 DIAZEPAM (VALIUM) ACTIONS ON MOUSE AND GUINEA PIG AURICULAR MUSCLE. E. Gijón*, M.C. Márquez-Orozco*, A. Márquez-Orozco* and X. García*.(SPON: B. Ortega-Corona). Department of Physiology and Department of Embryology. School of Medicine. National Autonomous University of México. México, D.F. 04510. MEXICO.

It has been described that benzodiazepines reduce the action potential duration and cause a negative inotropic effect on heart muscle from dog, cat, guinea-pig and rabbit, and this has been explained as a calcium current diminution (Akutagawa, K., Makino, M. and Ishii, K., Japan. J. Pharmacol., 33:845-850, 1983). Bones from mouse treated with diazepam, fix greater quantities of calcium (Márquez-Orozco, M.C., Márquez-Orozco, A., Alvarez, G. and Sámano-Bishop, A., Bol. Soc. Mex. Cienc. Fisiol. 7(1): 10-15, 1984). Our studies on mouse auricular muscle showed that diazepam increases the action potential duration in a reversible form and causes positive inotropic effect (García, X., Márquez-Orozco,M.C., Márquez-Orozco, A. and Gijón, E., Res. C. Nacl. Farmac. and Reg. Reu. latinoam. Assoc. Pharmacol. 10: 101, 1986. Further studies on diazepam action on electrical and mechanical activity of left auricular muscle from CD-1 stump mouse and Hartley guinea-pig, mounted horizontally in a constant temperature bath (34º C) perfused with Krebs solution, Ca2+ 1.25 mM, bubbled with a mixture of 98% O2 and 2% CO2. Diazepam ampules (Valium 10) Roche, were used, with a final bath concentration of 1.75X10-4 M. It was found in preparations electrically driven, from mouse and guinea-pig, that diazepam induces an increase in action potential duration measured at 20% repolarization, an increase in amplitude and duration of reverse potential, a decrease in the rate of spike depolarization, and modifies the conduction velocity of the action potential. It produces in preparatios with spontaneous activity, positive chronotropic and inotropic effects, and inotropic effect in electrically driven preparations. The change in action potential duration on mouse preparations, is higher than on guinea-pig preparations, c.a. X3. These findings support that diazepam action may be due to an increase in the inward calcium current and a reduction in the inward sodium current.

29.9 PYRETHROID INSECTICIDES AND DDT MODIFY ALKALOID-DEPENDENT ACTIVATION OF THE VOLTAGE-SENSITIVE SODIUM CHANNEL. J. R. Bloomquist and D. M. Soderlund. Department of Entomology, New York State Agricultural Experiment Station, Cornell University, Geneva, New York 14456.

The actions of pyrethroid insecticides and DDT on alkaloid-dependent activation of the voltage-sensitive sodium channel were studied using measurements of ^{22}Na uptake into mouse brain synaptosomes. Deltamethrin and DDT at near-saturating concentrations enhanced maximal sodium uptake (E_{max}) stimulated by high concentrations of veratridine with little effect on potency measured as half-maximal uptake ($K_{0.5}$). Cismethrin, however, increased the potency of veratridine-dependent uptake 3-fold with no increase in E_{max}. All three insecticides also enhanced sodium uptake in the presence of 1 µm batrachotoxin. With DDT (100 µm), the $K_{0.5}$ for batrachotoxin activation was shifted to 2-fold lower concentrations with no change in E_{max}. In contrast, deltamethrin, cismethrin, and DDT inhibited activation of the sodium channel by aconitine. Cismethrin (10 µm) was a noncompetitive inhibitor of aconitine-dependent uptake, decreasing E_{max} 34% without affecting the potency of aconitine. The inhibition of aconitine-dependent uptake by 100 µm cismethrin was expressed in the presence of 1 µm sea anemone toxin II, where E_{max} was decreased 60%.

The inhibition of aconitine-dependent sodium uptake by these insecticides suggests a possible overlap or negative allosteric coupling between the binding sites for insecticides and aconitine that differs from the enhancement of uptake observed with these compounds and either veratridine or batrachotoxin. Thus, the actions of DDT and pyrethroids on the voltage-sensitive sodium channel reveal unique characteristics of the action of aconitine that are not shared by veratridine and batrachotoxin. This work was supported by NIH Grant ES02160. We thank Dr. John Daly for supplying a sample of batrachotoxin.

29.10 YOHIMBINE'S EFFECT ON THE BINDING OF BATRACHOTOXININ TO MOUSE BRAIN SODIUM CHANNELS. I. Zimanyi*, A. Lajtha, E.S. Vizi, and M.E.A. Reith. Center for Neurochemistry, N.S. Kline Institute, Ward's Island, New York, NY 10035, and Institute of Exp. Med. Hung. Acad. Sci., Budapest POB 67, H-1450, Hungary,

Local anesthetics, such as procaine and lidocaine inhibit the binding of [^{3}H]BTX-B to sodium channels of rat or mouse brain, involving a specific receptor, and although their inhibitory effect appears to be competitive, the mechanism is best described by the allosteric model for heterotropic cooperative interactions (Reith M.E.A. et al., J. Biol. Chem., 261:7300, 1986).

Although yohimbine is best known as an alpha$_2$-adrenoceptor antagonist, it also has a meaningful local anesthetic activity. Previous electrophysiological and biochemical studies indicate that yohimbine binds to the gating molecules of sodium channels and modifies their opening and closing rates. Revenko et al. (Neuroscience, 7:1377, 1982) suggested that yohimbine and local anesthetics share a common receptor in sodium channels.

In the present study [^{3}H]BTX-B binding to mouse brain cortex was used as a tool to investigate the interactions of yohimbine and other local anesthetics with the gating mechanism of voltage-dependent sodium channels.

Yohimbine inhibited the [^{3}H]BTX-B binding with an IC_{50} of 9.6 uM. The Hill coefficient was 1.07 $\pm$ 0.04 (n=4), suggesting that yohimbine interacts with single class of binding sites. Saturation analysis with 5-200 nM of BTX-B in the absence and presence of 10 uM yohimbine indicated a K_d of 27 nM and 61 nM, and a B_{max} of 3.5 and 4.2 pmol/mg of protein, respectively, in agreement with yohimbine beeing a competitive inhibitor of BTX-B binding.

Kinetic studies of the dissociation rate of the BTX-receptor complex indicated that yohimbine, unlike that procaine or lidocaine had no effect on the rate of aconitine-induced dissociation of [^{3}H]BTX-B. The values of the k_{-1} in the absence and in the presence of 10 uM yohimbine were 0.0061 and 0.0066 min^{-1}, respectively. Therefore the mechanism by which yohimbine inhibits BTX-B binding is different from that for local anesthetics. The latter drugs shift the sodium channel to an inactive form from which BTX-B dissociates with a high rate. The data taken together strengthen the idea that yohimbine competes with BTX for the BTX receptor sites themselves, while other local anesthetics act through their own binding sites. The effect of yohimbine shown here suggests that local anesthetic action of compounds can be achieved by mechanism other than those involving receptors in the channel distinct from the BTX site. Supported by NIDA grant DA 03025, and by a grant for Cocaine Research from N.Y. State.

29.11 IN VIVO ANTICONVULSANT ACTIVITY AND IN VITRO BLOCKADE OF REPETITIVE ACTION POTENTIALS BY TWO PUTATIVE ANTICONVULSANTS, RALITOLINE (CI-946) AND CI-953. C.P. Taylor, D.M. Rock, M.J. McLean, and R.L Macdonald. Dept. Pharmacol., Warner-Lambert/ Parke-Davis Pharmaceutical Research, Ann Arbor, MI 48105 and Dept. Neurol., Univ. Michigan Sch. Med., Ann Arbor, MI 48109.

Although anticonvulsants have been used for the clinical treatment of partial seizures for many years, there is a need for new agents with better efficacy and fewer side effects. Ralitoline ((Z)-N-(2-chloro-6-methylphenyl)-2-(3-methyl-4-oxo-2-thiazolidineylidene)acetamide) and CI-953 (N-(2-chloro-6-methylphenyl)-N'-4-pyridinyl urea, monohydrochloride) have related chemical structures that are different from those of known anticonvulsants. Both compounds were tested by the Antiepileptic Drug Discovery Program of NINCDS. Ralitoline and CI-953 prevented tonic extensor seizures from maximal electroshock in mice with ED_{50} values of 15 mg/kg and 12 mg/kg PO respectively. Ataxia was the first dose-related side effect in mice, with ED_{50} values of 205 mg/kg and 240 mg/kg respectively. Thus both compounds are expected to prevent tonic-clonic seizures. Neither compound completely protected mice from clonic seizures in mice produced by the convulsants pentylenetetrazol, bicuculline or picrotoxin and so neither compound is expected to prevent absence seizures.

Rats were kindled with electrical stimuli from chronically-implanted electrodes in the dorsal hippocampus until generalized (stage 5) seizures were reliably obtained (methods of Vartanian and Taylor, Neurosci. Abstr. 10:406,1984). After administration of ralitoline or CI-953, the electrical current necessary to produce a focal afterdischarge was increased in a dose-related manner, at doses that did not cause ataxia. Thus both compounds would be expected to prevent partial seizures.

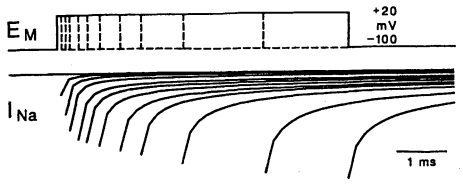
Spinal cord neurons were cultured from neonatal mice and drugs were added to the bathing physiological solution (McLean and Macdonald, J. Pharmacol. Exp. Ther. 227:779,1983). Intracellular recordings in vitro showed that ralitoline (0.1 to 1.0 µg/ml) or CI-953 (0.2 to 3 µg/ml) blocked sustained repetitive action potentials elicited by depolarizing current steps (450 msec) but did not block the initial spike of the train. Spontaneous action potentials (caused by spontaneous synaptic activity) were decreased with higher drug concentrations (3 µg/ml of ralitoline, 10 µg/ml of CI-953). Postsynaptic GABA and glutamate iontophoretic responses were not altered at 30 µg/ml (ralitoline) or 20 µg/ml (CI-953).

These results indicate that both experimental drugs may act specifically on voltage-sensitive sodium channels (Catterall, Trends Pharmacol. Sci. 8:57, 1987).

29.12 MODIFICATION OF SODIUM CHANNELS IN THE RESTING STATE BY FENFLUTHRIN M. Nishio* and T. Narahashi. Dept. of Pharmacol., Northwestern Univ. Med. Sch., Chicago, IL 60611.

The pyrethroid insecticides are known to modify the gating kinetics of sodium channels. However, it has been a matter of controversy whether pyrethroids modify the sodium channel in the open state or in the resting state. Experiments were performed with squid giant axons using fenfluthrin, a new fast-acting pyrethroid. It is a type I pyrethroid devoid of a cyano group at the α position. Sodium channel currents were recorded with internally perfused squid giant axons under voltage clamp conditions. The external solution contained (mM): 110 NaCl, 345 TMA-Cl, 50 CaCl and 5 HEPES with the final pH adjusted to 8.0. The internal solution contained (mM): 250 Cs-glutamte, 20 NaF, 400 sucrose and 30 Na-phosphate with the final pH adjusted to 7.3.

The internal application of fenfluthrin inhibited the falling phase of the sodium current during the depolarizing pulse and prolonged the sodium tail current associated with step repolarization. If the pyrethroid modified the channel in its open state, the rate at which the channel arrived at the modified open state, which is represented by the time course of the development of tail current amplitude, would be dose-dependent. The membrane was depolarized to +20 mV (the sodium equilibrium potential) for various durations and the tail currents associated with repolarization to -100 mV were recorded. The time course of the development of tail current amplitude was expressed by two exponential functions. Each of the fast and slow time constants remained unchanged at various concentrations of fenfluthrin (1-30 µM), indicating that the rate of arrival of channels in the modified open state is independent of dose. The decay of tail current, which represents the closing kinetics of modified channels, was dual exponential. In the concentration range tested, the time constants of both fast and slow components were independent of dose. These results suggest that fenfluthrin modifies the sodium channel in its resting state. Supported by NIH grant NS14143.



29.13 KINETICS OF BLOCKING ACTION OF PSYCHOTROPIC DRUGS ON SODIUM CHANNELS IN SINGLE GUINEA PIG VENTRICULAR MYOCYTES. T. Narahashi, N. Ogata* and M. Nishimura* (SPON: C. Wu). Department of Pharmacology and Reingold ECG Center, Northwestern University Medical School, Chicago, IL 60611.

A major side effect of the psychotropic drugs such as neuroleptics or antidepressants is cardiac toxicity. The mechanism underlying this side action remains to be clarified. We have shown that chlorpromazine, a phenothiazine neuroleptic, directly affects voltage-gated sodium and calcium channels in mouse neuroblastoma cells (Ogata, N. and Narahashi, T., Biophys. J., 51:430a, 1987). Such a direct action of chlorpromazine on the ion channels might also play a pivotal role in the generation of the cardiac toxicity. We, therefore, studied actions of several representative psychotropic drugs on the sodium channel kinetics in guinea pig ventricular myocytes. The myocytes were enzymatically isolated and voltage-clamped using the whole cell patch clamp technique at 20-22°C. Chlorpromazine, imipramine (a tricyclic antidepressant) and haloperidol (a butyrophenone neuroleptic) produced concentration-dependent and fully reversible block of the sodium current evoked after a long resting period at negative holding potential of -120 mV. The order of potency for this tonic block was chlorpromazine (KD, 3×10^{-6}M) > imipramine (10^{-5}M) > haloperidol (2.5×10^{-5}M). The blocks induced by these drugs were markedly enhanced when the holding potential was set to more positive values, in agreement with the shifts of steady-state inactivation curves in the negative direction. The concentration-response curves for all three drugs were best fit by a 2:1 stoichiometry for cardiac sodium channels whereas sodium channels in neuroblastoma cells exhibited a Hill coefficient of 1. All these drugs produced an additional block of sodium channels during a train of depolarizing voltage clamp pulses. This use-dependent block occurred even by a brief (10 msec) depolarizing pulse and a long (up to 2 sec) interpulse interval. Such a prominent use dependence was due to the extremely fast onset of drug-induced block and slow repriming of sodium channels from drug-bound inactivated state. The blocking action of psychotropic drugs was not affected by low temperature (12°C). The action of psychotropic drugs on cardiac myocytes is characterized by a tonic decrease of sodium channels which are available to open on membrane depolarization and a phasic decrease due to use-dependent block. These actions which occur at concentrations of therapeutic range and could be pronounced by pathological conditions such as excessive membrane depolarization, presumably underlie cardiac side effects commonly observed during a treatment by the psychotropic drugs.

29.14 INVESTIGATION OF HYDROGEN SULFIDE TOXICITY IN MOUSE NEUROBLASTOMA CELLS USING PATCH-CLAMP TECHNIQUE. M.W. Warenycia, J.A. Steele*[1], E. Karpinski*[1] and R.J. Reiffenstein. Departments of Pharmacology and Physiology[1], Faculty of Medicine, University of Alberta, Edmonton, Alberta, Canada, T6G 2H7.

Hydrogen sulfide (H_2S) and its soluble alkali salts are extremely toxic. Every year many cases of fatal exposure occur in the seventy or more occupational settings where H_2S is routinely encountered. Inhaled concentrations of greater than 500 ppm are lethal (717 ppm = 1 mg/L). The cause of death appears to involve abolition of respiratory drive in brainstem nuclei. The exact mechanism underlying respiratory failure has not been elucidated. Since H_2S has lipophilic properties, being five times more soluble in ether than water, it seemed of interest to examine membrane currents in cells poisoned with sodium hydrosulfide (NaHS), a precursor of H_2S in vivo. The cells chosen for these experiments were mouse N1E-115 neuroblastoma cells, a cell line with well-studied sodium channels. Cells were grown in Dulbecco's Modified Eagle Medium supplemented with 10% (v/v) fetal calf serum under an atmosphere of 95% O_2/5% CO_2 and were used on the second day postplating. Culture media was removed and replaced with a HEPES-buffered (10 mM) physiological salt solution. Cells were voltage-clamped using the giga-seal method employing micro-electrodes filled with 135 mm CsCl, 20 mM TEA, 10 mM HEPES and 2 mM EGTA. Membrane potential was maintained at -70 mV and sodium currents were examined at different test-potentials in the absence (control) or presence of 9 mM NaHS. This concentration of NaHS represents a 50-fold excess of the amount comprising the LD_{50} in mice (Reiffenstein, R.J. and Warenycia, M.W., Br. J. Pharmac., in press, 1987). The results of ten experiments did not reveal any significant changes in sodium currents. Current-voltage relationships appeared unaltered in poisoned cells as compared to controls. Similarly, channel kinetics also appeared to be unaffected.

These results in a model system suggest that alteration of sodium channel function in neuronal cell membranes does not appear to underlie the mechanism(s) leading to loss of central respiratory drive. However, it is also possible that smaller neurons, having higher respiratory rates, are selectively more vulnerable to poisoning with H_2S than N1E-115 cells, especially if in such cells resting membrane potential is highly dependent on Na^+-K^+-ATPase. In addition, it is distinctly possible that alteration of other ionic channel systems by H_2S, such as chloride, could still be a significant determinant in disrupting neuronal activity in brainstem respiratory centers.

29.15 Myelination: optimization, conduction velocity in small fibers and resolution of a paradox. M.V.L. Bennett, A. Einstein Coll. Med., Bronx, NY 10461, and D.H. Perkel (Univ. Cal., Irvine, CA 92717).

Rushton (J. Physiol. 115: 101, 1952) concluded that "a very small fiber must conduct faster if it is non-myelinated than if it is myelinated", but also cited Huxley and Stampfli's demonstration (ibid. 108: 315, 1949) that there is "an optimum internodal length for a maximum conduction velocity" with monotonic decrease in conduction velocity on either side of the maximum. Thus it appears, paradoxically, that shortening internodes of a very small myelinated fiber should both increase and decrease its conduction velocity. Rushton's conclusion derives from the relations between conduction velocity and diameter. For myelinated fibers velocity is proportional to diameter, as observed for large fibers and derivable from dimensional analysis provided the fibers are "similar", which means that their nodal membrane has the same capacitance and channel densities and that they observe certain geometric relations. Unmyelinated fibers of different diameters but with constant membrane properties are "similar", and velocity is proportional to the square root of diameter. Thus sufficiently small myelinated fibers of any "similarity" class conduct more slowly than unmyelinated fibers of the same diameter but of a different similarity class. The paradox is resolved as follows: Shortening the internodes of a Rushton fiber below the optimum length does decrease its conduction velocity whatever its diameter, but shortening the internodes to zero does not make it an unmyelinated fiber. In a Rushton fiber nodal length is negligible with respect to internodal length and as internodal length decreases, the number of nodes per unit length increases without limit; thus a Rushton fiber without myelin has infinite admittance and conducts with zero velocity. We calculated velocity for myelination with finite nodal length using the Merson numerical integration algorithm and a model with Hodgkin-Huxley channels and compartments of 0.25 and 0.125 length constants. We find that velocity can be increased by myelin of even a single wrap, which is optimum thickness for fibers of about 0.1 um diameter. Thinner myelin cannot occur, although permitted in a Rushton fiber. However, "myelination" by inserting plasma membrane without channels (a myelin sheath of zero thickness) can slightly increase conduction velocity, because nodal membrane has a greater than optimum density of channels for maximum velocity in an unmyelinated fiber (A. Hodgkin, Phil. Trans Roy Soc. Lond. B270: 297, 1975). Of course the same velocity could be achieved by uniformly distributing the channels. We conclude that myelination can increase conduction velocity down to the diameter permitted by the constraints of myelin structure.

ACTION POTENTIALS AND ION CHANNELS II

30.1 **CALCIUM DEPENDENCE OF VOLTAGE SENSITIVITY IN ADENOSINE 3',5'-CYCLIC PHOSPHATE-STIMULATED SODIUM CURRENT.** **Daniel J. Green and Rhanor Gillette.** Department of Physiology & Biophysics, and the Neural & Behavioral Biology Program, University of Illinois, Urbana, IL 61801.

Iontophoretic injection of cAMP into a voltage clamped neuron of the mollusc Pleurobranchaea caused a transient slow inward current (I_{si}) whose amplitude was enhanced by depolarization. Na^+-replaced salines suppressed the current, placing it with cAMP-stimulated Na^+ currents of other gastropod species.

I_{si} amplitudo was suppressed by extracellular Ca^{2+}. The amplitude increased up to 4-fold at holding potentials of -50 mV in nominally zero-Ca^{2+} saline. Ion substitutions showed that Ca^{2+} suppressed the I_{si} more effectively than Mg^{2+}, Co^{2+}, Cd^{2+}, Mn^{2+}, Ba^{2+}, or Sr^{2+}.

Voltage sensitivity of I_{si} was abolished both by low Ca^{2+} salines, by the Ca^{2+} current blocker Co^{2+} and by substitution of Ba^{2+} or Sr^{2+} as Ca^{2+} channel current carriers. In such salines the I_{si} showed no appreciable change in amplitude at holding potentials between -70 to -25 mV.

Intracellular injection of the Ca^{2+} chelator EGTA augmented both the amplitude of the current and its duration. EGTA injection failed to suppress the Ca^{2+}-dependent voltage sensitivity of the I_{si}. Intracellular injection of concentrated MOPS pH buffer to inhibit secondary, Ca^{2+}-dependent intracellular acidification also failed to suppress the voltage sensitivity, as did injections of mixed EGTA/MOPS solution.

While the data indicate a requirement for extracellular Ca^{2+} in conferring voltage sensitivity, they do not support a role for an intracellular action. An extracellular binding site for Ca^{2+} is likely to mediate the voltage sensitivity, either by local depolarization-dependent changes in extracellular Ca^{2+} concentration or through direct voltage-sensitive block of the I_{si} channel.

Conferral of voltage sensitivity to the cAMP-dependent Na^+ current by Ca^{2+} provides a novel positive feedback mechanism potentially involved in burst initiation and maintenance.

30.2 PROPERTIES OF THE RECTIFYING Cl^- CHANNEL IN CULTURED SWEAT GLANDS. M.E. Krouse* (SPON: J.J. Wine). Cystic Fibrosis Research Laboratory, Stanford University, Stanford CA 94305.

Single 45 pS Cl^- channels were found in 1/3 of the patches made on confluent monolayers of cultured human sweat glands. The channels showed outward rectification with a slope conductance of 30 pS at -75 mV and a slope conductance of 70 pS at +75 mV in symmetrical 150 mM NaCl Ringer at 20°C. The channels are selective for Cl^- over Na^+ by at least 4:1. The open probability of these channels is voltage dependent both in cell attached and excised configurations. The mean open time is 32 ms at +50 mV and increases e-fold for every 65 mV depolarization. The mean open time is almost identical in cell attached and excised patches. The mean closed time in the cell attached patch is 1100 ms which decreases to 24 ms in the inside-out patch (measured several minutes after excision). These mean closed times are also voltage dependent, decreasing e-fold for every 65 mV depolarization. Indirect evidence suggests that the open probability is Ca^{2+} dependent on cell and immediately upon excision, when the open probability excedes 0.9 (not analyzed). There is no Ca^{2+} sensitivity several minutes after excision, when the open probability equals .57 at +50 mV. One interpretation of these results is that Ca^{2+} increases the dissociation rate of a channel blocking molecule, which is loosely associated with the cytoplasmic face of the channel.

30.3 NONSELECTIVE CATION CHANNELS AND GENERATION OF BURSTING ACTIVITY IN CULTURED PITUITARY CELLS. R.E. Sheridan and M. Adler. Neurotoxicology Branch, USAMRICD, APG, MD 21010 and Dept. of Pharmacol., Georgetown University, Washington, DC 20007.

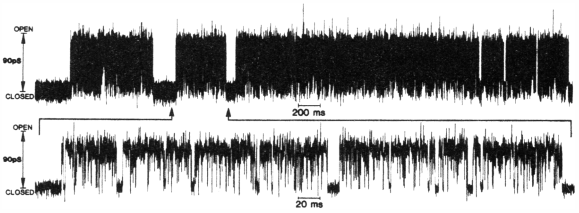
The clonal pituitary cell line AtT-20/D16-16 produces rhythmic bursts of spikes in response to certain neurotransmitters or after culture in dibutyryl cAMP. The current that initiates these bursts is unknown. We have identified a novel, nonselective cation channel in the AtT-20 cell line that has the necessary characteristics to act as the generator current for initiating burst activity.

AtT-20/D16-16 cells were grown in Ham's F12 medium supplemented with 10% fetal bovine serum and 1 mM dibutyryl cAMP. Cells were then transferred to HEPES buffered physiological salines of various cationic and anionic compositions for patch-clamp recording. In cell-attached patches an inward current was observed at the resting potential which reversed near 0 mV. The same channel could be seen in excised, inside-out patches and was equally permeable to Na^+ and K^+ but essentially impermeable to Cl^-. The channel had a conductance of 25 pS in symmetric solutions of 155 mM NaCl at 20° C. At least two open states were observed with lifetimes of 7.7 ms and 290 ms in the presence of 200 μM free Ca^{2+} at 20° C and -60 mV. However, unlike similar nonselective cation channels that have been described before, both lifetimes were voltage-dependent, increasing e-fold per 20 mV of depolarization. Also, the AtT-20 cation channel was active at sub-micromolar concentrations of intracellular Ca^{2+} and showed some short duration openings even in 10 nM free Ca^{2+}.

The characteristics of this depolarizing cation channel suggest that it could be responsible for initiating spike bursts in AtT-20 cells. Thus the activity of this nonselective cation channel, in conjunction with that of the Ca-activated K^+ channel, may be responsible for setting the level of excitability in these and other spontaneously active cells. Drugs that modify the nonselective cation channel could therefore change the firing patterns of such spontaneously active cells.

30.4 TETANUS TOXIN FORMS TRANSMEMBRANE CHANNELS IN LIPID BILAYERS AT NEUTRAL pH. F. Gambale* and M. Montal (SPON: R. Wurzburger). Department of Neurosciences, Roche Institute of Molecular Biology, Roche Research Center, Nutley, New Jersey 07110.

Tetanus toxin from *Clostridium tetani* forms channels in planar lipid bilayers. The channel forming domain was assigned to the amino terminus of the heavy chain (apparent Mr ~ 45,000). Channel formation proceeds at neutral pH. However, an acidic pH and a positive voltage in the compartment containing the toxin are required to detect the presence of channels in the membrane rapidly and effectively. The toxin channel is cation selective with significant intracation selectivity (K^+/Na^+ = 1.35). Acid pH markedly lowers the single channel conductance: for phosphatidylserine (PS) at 0.5 M KCl γ = 89.01 ± 0.30 pS at pH 7.0 while at pH 4.8, γ = 30.12 ± 0.33 pS. The toxin channel is voltage dependent: for PS membranes (see Figure), the probability of the channel being open is significant at positive voltage both at neutral and acidic pH. Single channel conductance histograms are best fitted with a sum of three gaussians with relative frequency of occurrence for PS of 38% for the closed state, 18% for the open subconductance state and 44% for the fully open state. The subconductance state is readily identifiable in the single channel recordings (see Figure, lowest panel). Probability density analysis of the open and closed dwell times of the toxin channel indicate the existence of a single open state with a lifetime, τ_O, of about 1 ms and two closed states with lifetimes $\tau_{C1} \leq 0.5$ ms and $\tau_{C2} \approx 1$ ms.



Legend: Single tetanus toxin channel currents at an applied voltage of 80 mV and at pH 7.0. The records were filtered at 3 kHz. The lower record displays the section delimited by the arrows at higher time resolution.

30.5 ANTERIOR PITUITARY CELLS POSSESS A CALCIUM-DEPENDENT CHLORIDE CONDUCTANCE THAT IS REGULATED BY GTP-ANALOGS. M.A. Rogawski, S. Suzuki*, K. Inuoe* and J.L. Barker. Neuronal Excitability Section, Medical Neurology Branch and Lab. of Neurophysiology, NINCDS, NIH, and FDA, Bethesda, MD 20892.

Voltage and/or Ca^{2+}-dependent Cl^- conductances have recently been identified in a variety of excitable cell types. In the present study, we characterized a Ca^{2+}-dependent Cl^- current in GH_3 cells, a clonal cell line derived from anterior pituitary. Whole cell voltage clamp recordings were made from GH_3 cells under conditions in which outward currents were substantially blocked by external tetraethylammonium (TEA; 20 mM) and internal CsCl or N-methylglucamine Cl (NMG). Depolarizing voltage clamp steps from a holding potential of -50 mV activated transient (decay time <100 msec; T-type) and sustained (L-type) inward Ca^{2+} currents. In addition, prolonged depolarization (>1 sec) invariably elicited a slowly activating inward current that persisted with maintained depolarization, and deactivated slowly (τ~1 sec) upon repolarization, resulting in a prominent inward tail current. The amplitude of the tail increased as the step duration was lengthened to a plateau at 6 sec. The tail current nulled at 0 mV with symmetrical Cl^- and showed a negative reversal potential with nominally Cl^--free internal solution. In addition, the tail current could be elicited under conditions where Ca^{2+} and Cl^- were the only permeant ions (symmetrical NMG). Ba^{2+} substituted for Ca^{2+} as a carrier of inward current, but did not activate the tail current. These observations suggest that Cl^- ions are the charge carrier of the slow inward tail current. The voltage-dependency for activation of the slow tail current was U-shaped with a peak at about -10 mV. This closely paralleled the voltage-dependency of the Ca^{2+} currents. The slow tail current was eliminated upon superfusion with the Ca^{2+} channel blocker Cd^{2+} or with Ca^{2+}-free medium. These results demonstrate that the current is dependent upon Ca^{2+} influx and it is therefore referred to as $I_{Cl(Ca)}$. In a high proportion of cells, $I_{Cl(Ca)}$ rapidly diminished in amplitude upon repeated activation. This rundown could be slowed by addition of the non-hydrolyzable GTP analogs GppNHp (100 μM) or GTPγS (100 μM) to the pipette solution; GTP, ATP, 8-bromo cyclic AMP or GTPβS did not prevent rundown. Neither pertussis toxin nor cholera toxin prevented the GTP analogs from slowing rundown or influenced $I_{Cl(Ca)}$. These results demonstrate that clonal pituitary cells possess a slowly activating and deactivating Ca^{2+}-dependent Cl^- current. The current may serve to dampen excitability under conditions of large rises in free intracellular Ca^{2+}, such as occurs during activation by secretagogues.

30.6 NOVEL Cl^- CHANNEL SEEN IN PLANAR BILAYERS AND PATCH-CLAMPED LIPOSOMES MADE USING SARCOPLASMIC RETICULUM PURIFIED FROM MAMMALIAN SKELETAL MUSCLE. G.D. Hals* and P.T. Palade* (SPON: D. Brunder). Dept. of Physiol. & Biophys., UTMB, Galveston, TX 77550.

We wish to report observations of a high conductance Cl^- channel seen in purified sarcoplasmic reticulum (SR) subfractions from New Zealand White rabbit skeletal muscle. The SR was prepared according to Saito, A., et al., J. Cell. Biol., 99:875, 1984, fractions R3 and R4. Both liposomes and planar bilayers were made from phosphatidylethanolamine and phosphatidylserine in a 50:50 ratio. This channel has been observed with similar frequency as SR K^+ channels using standard planar bilayer techniques. We have also modified a published method for obtaining SR K^+ channels in liposome patches (Tomlins, B. and Williams, A.J., Pflugers Arch., 407:341, 1986) to allow observation of SR Cl^- channels as well. The difference in our method is that the liposomes were made with SR that was not detergent treated. The Cl^- channel seen in liposome patches has a slope conductance of 462 ± 25 pS with 200 mM KCl in the bath, 100 mM KCl in the pipette. The channel is fairly selective for Cl^- ions over K^+ ions, with a $P_{Cl}/_K$ = 22, is not voltage-dependent, and normally remains open nearly all the time with frequent transitions to substate levels. We have also seen a 100 pS SR Cl^- channel similar to those previously reported (Smith, J.S., et al., Biophys. J., 50:921, 1986), but we observe this channel much less frequently. Other high-conductance Cl^- channels seen in muscle surface membrane (Blatz, A.L. and Magelby, K.L., Biophys. J., 43:237, 1983), and the mitochondrial anion channel (VDAC) have similar conductances , but are both strongly voltage-dependent, which makes these channels different from the SR channel we see. 660 μM 4,4' Diisothiocyanostilbene-2,2' Disulfonic acid (DIDS) added to the cytoplasmic surface of the channel in planar bilayer experiments results in a complete block of the channel after a period of 1 to 3 minutes.

30.7 STRETCH-ACTIVATED CHANNELS IN HUMAN FIBROBLASTS. L.L. Stockbridge and A.S. French, Department of Physiology, University of Alberta, Edmonton, CANADA T6G 2H7.

Stretch-activated channels were studied with single channel recordings from cultured human epidermal fibroblasts (Detroit 551) in the cell-attached and inside-out patch clamp configurations. Patch pipettes contained (mM): KCl 140, $MgCl_2$ 2, EGTA 11 and HEPES 10 (pH 7.2). The bath solution contained (mM): NaCl 150, KCl 5, $CaCl_2$ 2, $MgCl_2$ 1 and HEPES 10. Excised patches were exposed to isotonic KCl solutions containing (mM): KCl 140, HEPES 10 and various desired $CaCl_2$ concentrations made by buffering calcium with EGTA. To determine mechanosensitivity, 0-70 mm Hg suction was applied to the patch pipette with a 1 cc syringe and monitored with a pressure transducer.

Mechanosensitive channels were found only on the borders of cells. Although up to 18 channels have been seen in one patch, most patches contained no more than two channels and the probability of getting a channel in any given patch was low (p=0.21 in 71 patches). There appeared to be more than one type of mechanosensitive channel with slope conductances in the cell-attached configuration ranging from 30 pS to 204 pS. The channels of low conductance appeared to be rapidly adapting, closing 2-5 seconds after the onset of activity with stretch-activation. The larger channels did not appear to adapt and generally were less active than the smaller channels. All channels tested were selective for potassium over sodium, with some being only permeable to potassium. The permeability to calcium has not yet been directly tested. However, no stretch-activated channels have been observed under conditions where strontium has been the only permeant ion. There was no apparent calcium sensitivity or voltage sensitivity. The probability of a channel being open increased with increasing suction. The increased openings appeared to be due to an increase in the length of time a channel was open rather than a decrease in the closed times between channel openings.

Fibroblasts respond to mechanical stimulation with a hyperpolarization (Nelson et al., *J. Gen. Physiol.* 60:58-71, 1972). It is possible that these stretch-activated channels are the primary transducers for this response.

Support for this work was provided by the Canadian Medical Research Council and the Alberta Heritage Foundation for Medical Research.

30.8 DYNAMIC ANALYSIS OF THRESHOLD CHANGES IN AN INSECT SENSORY NEURON REVEALS TWO COMPONENTS OF RAPID ADAPTATION. A.S. French, Department of Physiology, University of Alberta, Edmonton, Canada T6G 2H7.

Rapid sensory adaptation in the cockroach femoral tactile spine can be demonstrated by electrical stimulation of the single sensory neuron in the base of the spine, showing that it occurs during action potential encoding, not transduction. The threshold for action potential production in the neuron is labile, increasing with depolarization and decreasing with hyperpolarization. It always exceeds the membrane potential of the neuron, preventing continuous firing at any stimulus level. Threshold behavior is very sensitive to chemicals which affect sodium channel inactivation, but insensitive to many other channel modifiers.

Threshold levels in cockroach tactile spine neurons were determined as rheobasic currents, using an extracellular current stimulus applied to the neuron at the axosomatic junction (French, *J. Comp. Physiol.* 159:757-764, 1986). Threshold levels were measured at intervals up to 1500 ms after step changes in polarizing current. Decreasing current steps were easier to apply because they did not elicit bursts of action potentials. However, threshold increases were also measured following current steps small enough to prevent firing by the stimulus.

Threshold changes as functions of time after step changes in polarizing current were always well-fitted by a relationship having two exponentially decaying components. The two time constants varied strongly with the initial polarization level of the cell membrane, but not with step size. The rapid component was maximal close to the resting condition at about 170 ms, while the other component was approximately 10 times slower. Minimum values of about 50 ms and 500 ms were obtained with strong initial depolarizations. The amplitude of the slow component varied approximately linearly with different step sizes, but saturated at the strongest hyperpolarizations. In contrast, the rapid component reversed strongly with initial hyperpolarizations. Reconstruction of the total threshold from the two components agreed well with static measurements, and indicated that the two components contribute approximately equally to the threshold under depolarized conditions but the slow component is dominant with hyperpolarization. Future experiments will attempt to identify the mechanisms responsible for the two components.

Supported by The Canadian Medical Research Council and The Alberta Heritage Foundation for Medical Research.

30.9 EFFECTS OF A LOCAL ANESTHETIC (QX-222) ON GATING PROPERTIES OF MOUSE-TORPEDO HYBRID ACETYLCHOLINE RECEPTORS EXPRESSED IN XENOPUS OOCYTES. R.J. Leonard, L. Yu*, C. Labarca*, N. Davidson*, and H.A. Lester. Divisions of Biology and Chemistry, California Institute of Technology, Pasadena, CA. 91125.

cDNA clones are available for all four subunits of the nicotinic acetylcholine receptor (AChR) from several species. The mRNAs transcribed in vitro from those cDNAs can be injected into Xenopus oocytes; the receptors synthesized and inserted into the membrane are amenable to electrophysiological recording. This approach promises to improve our knowledge of the structural correlates of AChR function. In an attempt to identify portions of the subunits' structure which may be involved in formation of the ion channel of the AChR, we are comparing the effects of a local anesthetic (QX222) upon the gating parameters of 'hybrid' AChRs constructed by mixing the individual subunit mRNAs derived from mouse and Torpedo cDNAs. Because the site of action of local anesthetics is presumed to lie within the ion channel, the sensitivity of hybrid, chimeric, or mutated AChRs to QX-222 may prove to be an additional probe for the assignment of particular regions or even individual residues to discreet parameters of channel function. So far, comparisons of mouse-torpedo hybrid channels indicate that some hybrids differing in mean open time in the absence of local anesthetic exhibit very similar open times in the presence of blocker, thus indicating that the forward blocking rate of QX-222 is only weakly influenced by subunit composition. On the other hand, the residence time of QX-222 (measured by the time constant of closings within an open channel burst) does appear to be influenced by subunit composition. (Supported by NIH Grant NS-11756 and an MDA grant. R.J.L. is an MDA Postdoctoral Fellow)

30.10 CHANNEL DURATION MAINLY DETERMINES VOLTAGE SENSITIVITY IN MOUSE-TORPEDO ACETYLCHOLINE HYBRIDS. L. Yu,* R. J. Leonard, C. Labarca,* N. Davidson* and H. A. Lester (SPON: J. F. Olavarria). Div. of Biol., Calif. Inst. of Technology, Pasadena, CA 91125.

At many nicotinic acetylcholine receptors, the agonist-induced conductance varies with the membrane potential, decreasing at more positive voltages. Our previous study with two-microelectrode voltage-clamp recording demonstrated that the β subunit plays the most important role in determining the equilibrium in mouse-Torpedo AChR hybrids expressed in Xenopus oocytes after the injection of mRNA synthesized in vitro from cDNA clones encoding the AChR subunits. The δ subunit plays a secondary role, interacting with the β subunit (Yoshii et al., Biophys. J. 51: 60a, 1987).

In the present work, we have examined voltage sensitivity at the level of single-channel recording with the following hybrid receptors: $\alpha_M\beta_M\gamma_M\delta_M$, $\alpha_M\beta_M\gamma_T\delta_M$, $\alpha_M\beta_T\gamma_T\delta_T$, $\alpha_T\beta_T\gamma_T\delta_M$, and $\alpha_T\beta_T\gamma_T\delta_T$. In outside-out patches, all combinations showed linear single-channel current-voltage relationship; but open duration depended on voltage. Average channel duration, τ, was measured at -60 mV and +60 mV. The extent of the voltage dependence of each combination was estimated by the ratio of $\tau_{-60mV}/\tau_{+60mV}$, and the results were in agreement with our previous conclusions from the macroscopic measurements. The voltage sensitivity of the closed times was assessed either by directly measuring the closed duration (in favorable cases where desensitization was minimal) or by subtracting the voltage sensitivity of the equilibrium conductance from that of the open duration. According to either method, closed times had less than 1/5 the voltage sensitivity of the open times. Thus, of the three possible parameters underlying voltage sensitivity (channel conductance, opening rate, and closing rate), the latter makes the major contribution to the voltage sensitivity of the macroscopic conductance of the AChR.

30.11 MULTIPLE CONDUCTANCE CLASSES OF ACETYLCHOLINE RECEPTOR CHANNELS IN LARVAL AMPHIBIAN SKELETAL MUSCLE. J.L. Owens, G.S. Hartig*, F.A. Laitinen* and R. Kullberg. Biology Department, University of Alaska, Anchorage, AK, 99508.

Two classes of ACh receptor channels with conductances of about 40 and 60 pS have been described in previous studies of amphibian and mammalian skeletal muscle. In addition to the 40 and 60 pS channels, we have often observed in nonjunctional recordings from larval Xenopus muscle two classes of smaller events, having amplitudes of about 1/3 and 2/3 of the 40 pS channel. These smaller events appear to represent the opening of ACh receptor channels since they were abolished by alpha-bungarotoxin. The frequency of observing them was variable. In some patches they were entirely absent while in others they were the predominant channels. We have seen them in all varieties of muscles which we have studied (myotomal, extraocular, and interhyoideus), and so far we have not noticed any relation between frequency and development. The smaller events do not appear to be subconductance states of the other two channels, since we have never observed transitions directly from the 40 or 60 pS openings to the lower conductance states, and in some patches only smaller events were observed. The larger of the two small channels had a slope conductance of 25±5 pS (n=17 sites) between 40 and 120 mV (applied pipette potential) and had an extrapolated reversal potential which was comparable to that of the 40 and 60 pS channels. The gating kinetics of this channel appear to be similar to those of the embryonic 40 pS channel in myotomal muscle. The apparent mean open time at resting potential was 2.7±1.2 msec (n=15 sites), and the open time increased e-fold for about every 80 mV of hyperpolarization. In a sample of 5 recordings, the smallest channel had a slope conductance of 10 to 15 pS. We have not yet examined its gating kinetics. The functional importance of these channels in larval muscle is not clear. We do not yet know whether they are exclusively nonjunctional or whether they play any role in neurotransmission.

30.12 KINETIC SCHEME FOR GABA-ACTIVATED CHANNELS IN CULTURED CHICK NEURONS. D. S. Weiss*, J. J. Hablitz+, and K. L. Magleby. Dept. of Physiol. and Biophys., Univ. of Miami Sch. of Med., P.O. Box 016430. Miami, FL 33101, and+Dept. of Neurology, Sect. of Neurophysiol., Baylor Coll. of Med., One Baylor Plaza, Houston, TX 77030.

In order to gain insight into the activation kinetics of a GABA-gated chloride channel, currents from single channels activated with 0.5-2.0 micromolar GABA were examined in patches of membrane from cultured chick cerebral neurons. Stability of channel kinetics was assessed by plotting the mean durations of every 50 consecutive open and shut intervals against interval number. Subsequent analysis was limited to periods over which these mean open and shut durations remained stable. The distribution of open and shut intervals of the GABA channel were both described by the sum of three significant exponential components, suggesting a minimum of three open and three shut kinetic states. Five different six state models were found which could accurately predict the observed interval distributions, so additional criteria were used to evaluate the different models. A plot of the mean duration of open intervals adjacent to shut intervals of specified durations revealed that, on the average, openings of shorter durations were adjacent to closings of longer durations. The distributions of open intervals adjacent to shut intervals of either short or long durations were both described by three exponential components with time constants similar to those observed in the distribution of all open intervals. The areas of the different components, however, were changed such that the open interval distribution adjacent to shut intervals of short duration was dominated by the component of open intervals with intermediate duration, and the open interval distribution adjacent to shut intervals of long duration was dominated by the component of open intervals with short duration. These observations suggest multiple pathways and gateway states between open and shut states. Two of the five proposed models did not predict the adjacent interval data. Two of the remaining models predicted that the channel should switch between two modes of behavior with markedly different mean open and shut intervals. The stability plots indicated that such moding behavior was not a characteristic of the channel. The single model left predicted the distributions of all open and shut intervals, the inverse relationship between durations of open and shut intervals, the distributions of open intervals adjacent to shut intervals of specified durations, and the stability of the channel kinetics with time. 30.13 SINGLE CHANNELS ACTIVATED BY GLUTAMATE AND ASPARTATE. J.R. Howe*, D. Colquhoun* & S.G. Cull-Candy* (SPON: C. Marshall). Dept. of Pharmacology, University College London, WC1E 6BT, U.K.

Glutamate-receptor channels in cerebellar Purkinje and hippocampal neurons possess multiple open levels and the proportion of openings to each level depends on the agonist used (Cull-Candy & Usowicz, *Nature* 325:525, 1987; Jahr & Stevens, *Nature* 325:522, 1987). We have obtained similar results in rat cerebellar granule neurons (Cull-Candy, Howe & Ogden, *J. Physiol., in press*). We now describe further the single channel currents produced by L-glutamate (Glu: 3-300μM) and L-aspartate (Asp: 10-100μM) in outside-out patches from these cells. Granule cells were maintained in culture. Solutions were nominally Mg^{2+} free. The amplitude and duration of single channel transitions were measured by fitting the signals (low pass filtered 2-5kHz, -3dB) with the known step response functions of the recording system. Up to 5 discrete peaks could be identified in amplitude histograms of Glu- or Asp-activated currents (results for both agonists were very similar and were pooled unless stated). Current-voltage (I-V) plots for each respective peak were linear between +60 and -100mV, and conductances of 8, 18, 34, 42 and 50pS were determined for the 5 open levels. At potentials negative to -100mV, large conductance openings (>40pS) showed significant inward rectification. Currents recorded at -150mV were ≈25% larger than expected from extrapolation of the linear portion of the I-V plots. The relative proportions of openings to each level were: 8pS, 2.3%; 18pS, 1.7%; 34pS, 4.9%; 42pS, 13.2%; 50pS, 78%. Of 7705 fully resolved direct transitions (time at each level >2.5 filter rise times), 62.2% were between the 50pS and shut levels. Transitions between the 42pS and 50pS levels and the 42pS and shut levels represented 12.6 and 9.4% of all transitions, respectively. Transitions between the 34pS and the 42 and 50pS levels comprised 4.9%; all other open level-open level transitions were <0.4% of the total number. There was no evidence for temporal asymmetry in any of the transitions.

Shut time distributions for each agonist were fit by the sum of 4 exponentials. The briefest two components, 63μs and 590μs for Glu (n=6) and 32μs and 660μs for Asp (n=10), appeared to represent shuttings within activations of one channel and were defined as gaps within bursts of openings. Distributions of burst lengths were fit by 3 exponentials. Time constants of 2.4 and 12.4ms for Glu (n=5) and 2.0 and 10.1ms for Asp (n=6) were determined for the slowest two components in the burst length distributions at potentials of -60 to -130mV and concentrations of 3-30μM. These time constants agree well with the two time constants we estimated from noise analysis of whole cell currents produced by these agonists. They were little changed if openings to levels other than the 50pS level were excluded. Thus they appear to reflect the gating kinetics of 50pS openings.

Supported by the Wellcome Trust, the MRC, and the NIH.

30.14 EFFECT OF 5-HT ON IONIC CHANNEL OF NG108-15 NEUROBLASTOMA CELLS BY PATCH-CLAMP STUDY.

C.J.V. Fueri* (1) and P.N.R. Usherwood* (SPON: European Neuroscience Association). Department of Zoology, University of Nottingham, Nottingham NG7 2RD, U.K.

Cells of the neuroblastoma glioma NG108-15 which have been known to have cholinergic properties (Hamprecht, B., Int. Rev. Cytol., 49:99, 1977; Nirenberg, M. et al., Science, 222:794, 1983) contain 5-HT and synthesize it (Furuya, S. et al., Brain Res., 361:77, 1985). The serotoninergic degrading enzyme, monoamine oxydase (Nagatsu, T. et al., 3:137, 1981) was detected in these cells.

In our work inward single channel currents were recorded from differentiated NG108-15 with giga-ohm patch clamp technique (Hamil et al., 1981) in cell attached, inside out and outside out patches. In each experiment the records were made in absence and in presence of 5-HT 10^{-6}M applied by perfusion procedure.

Channel opening and closing were modified by the presence of 5-HT. By potential variation applied to the tip of the pipette we measured a channel conductance of 130 pS. The reverse current, in cell attach conformation was estimated at the zero membrane potential. In inside out and outside out patches, the reverse current value was 0 mV, when the same ionic solution was used in the bath and in the pipette.

In absence of 5-HT, three exponential components to the open time distribution and four exponential components for the close time distribution could be fitted. In presence of 5-HT 10^{-8}M only three components to the close time distribution could be fitted and we observed change in the exponential components number to the open time.

A functional model for the ionic channel associated to the 5-HT receptor is proposed.

31.1 ANTIBODIES TO THE ALPHA-SUBUNIT OF SKELETAL MUSCLE VOLTAGE-SENSITIVE CALCIUM CHANNELS REGULATE PARATHYROID CELL SECRETION. H. Chin, L. Fitzpatrick*, M. Nirenberg, and G. Aurbach* Lab. of Biochemical Genetics, NHLBI and *Metabolic Diseases Branch, NIDDK, NIH, Bethesda, Maryland, 20892.

Dihydropyrydine (DHP)-sensitive Ca^{2+} channels regulate hormone secretion in many neuroendocrine tissues. The parathyroid cell is relatively unique in that opening of the Ca^{2+} channels by DHP agonists results in inhibition of parathyroid hormone (PTH) release, while closing the channels by antagonists stimulates parathyroid cell secretion (Fitzpatrick, L. *et al.*, Biochem. Biophys. Res. Comm. 138: 960, 1986). We prepared polyclonal, monospecific mouse antibodies against highly purified preparations of the α-subunit of voltage-sensitive calcium channels from rat T-tubules and tested the effects of the antibodies on parathyroid cell secretion. The three mouse antisera tested inhibited PTH release in medium containing 0.5 mM Ca^{2+}, but had little or no effect in medium containing 2.0 mM Ca^{2+}. In medium with 0.5 mM Ca^{2+}, the extent of inhibition of PTH release from parathyroid cells by antibody MC-4 (100- to 100,000-fold dilution) was a function of antibody concentration. No inhibition was found with MC-4 that previously had been incubated with rat T-tubule calcium channel α-subunit protein immobilized on nitrocellulose membranes. Incubation of dispersed bovine parathyroid cells with antibody MC-4 resulted in a marked increase in $^{45}Ca^{2+}$ uptake by the cells. Immunoblot analysis of bovine parathyroid membrane proteins fractionated by SDS-PAGE showed that MC-4 antibodies bind to a protein with an apparent M_r of 150,000. We conclude that: 1) bovine parathyroid cell membranes contain a 150,000 M_r protein similar to the α-subunit of voltage-sensitive Ca^{2+} channels from other excitable tissues. 2) monospecific antibodies bind to the 150,000 M_r protein and acitvate the Ca^{2+} channels. 3) the marked increase in Ca^{2+} uptake by parathyroid cells upon incubation with MC-4 antibody parallels inhibition of PTH release.

31.2 **Monoclonal Antibody Identifies a 200 kDa Subunit of the Dihydropyridine-Sensitive Calcium Channel** Mary E. Morton* and Stanley C. Froehner. Department of Biochemistry, Dartmouth Medical School, Hanover, N.H. 03756.

A monoclonal antibody, mab 1A, that immunoprecipitates the [^{3}H]PN200-110 binding complex from rabbit skeletal muscle has been used to study the subunit structure of the voltage-activated, dihydropyridine-sensitive calcium channel. Digitonin solubilized [^{3}H]PN200-110 binding component, purified by wheat germ agglutinin (WGA) chromatography, sediments as a 21S complex. The sedimentation coefficient of the complex is increased to about 24S after incubation with mab 1A and remains unchanged after incubation with control mab. Four polypeptides with apparent molecular weights under non-reducing conditions of 220,000, 200,000, 61,000, and 33,000 daltons co-sediment with the 21S complex. Mab 1A recognizes the M_r 200,000 polypeptide, as shown by Western blotting analysis.

[^{3}H]PN200-110 complex purified by WGA chromatography followed by immunoaffinity chromatography on a mab 1A column is comprised primarily of the same four polypeptides. When analyzed by SDS gel electrophoresis under reducing conditions, the M_r 220,000 protein migrates as a polypeptide of M_r143,000; the mobility of the M_r 200,000 protein recognized by mab 1A is unaffected by reduction of disulfide bonds.

In order to ascertain which component(s) of the [^{3}H]PN200-110 complex bind WGA, 1A immunoaffinity-purified material was examined for lectin binding ability. Nitrocellulose replicas were incubated with biotinylated-Con A or with biotinylated-WGA, followed by streptavidin, and detected with radiolabeled anti- streptavidin antisera. Both the M_r 220,000/143,000 and the M_r 200,000 polypeptides are labeled with Con A. In contrast, only the M_r 220,000/143,000 protein is labeled by WGA. Neither the M_r 61,000 nor the M_r 33,000 polypeptides are labeled by WGA. These results suggest that the M_r 200,000 protein is purified by WGA chromatography by virtue of its association with the M_r 220,000/143,000 polypeptide. Thus, the M_r 200,000 polypeptide appears to be a previously undescribed component of the dihydropyridine binding complex and, in association with the other polypeptides, may comprise the voltage-sensitive calcium channel.

31.3 MONOCLONAL ANTIBODY THAT IMMUNOPRECIPITATES SKELETAL MUSCLE 1,4-DIHYDROPYRIDINE RECEPTORS. H. Smilowitz, R.J. Chang* and C. Bowik*. Dept. of Pharmacology, Univ. of Conn. Health Center, Farmington, CT 06032.

Rabbit skeletal muscle membranes (10 pmole 1,4-dihydropyridine binding sites/mg protein) were pre-labeled with the dihydropyridine antagonist ^{3}H PN200-110, extracted with digitonin and subjected to wheat germ affinity chromatography (approximately 100-150 fold purification) followed by Sephacryl S-400 chromatography (approximately 2-fold purification). Generally 500 mg of starting membrane protein was used. When an eight protease inhibitor cocktail was used, about 0.5 to 1 mg of protein (40-50% 1,4-dihydropyridine receptor) was obtained in about 20 hours. SDS PAGE under non-reducing conditions (iodoacetamide) revealed two major broad α bands upon coomassie staining at about 142-155 Kd and 155-170 Kd as well as less prominent bands at ~57 Kd and ~30 Kd. When only four protease inhibitors were used, the lower α was selectively lost following Sephacryl S-400 chromatography. Under reducing conditions, most of the α material ran at 135-145 Kd while some of the protein stain remained in the 145-170 Kd region of the gel.

Wheat germ purified material (about 1000 pmole 1,4-dihydropryidine binding sites/mg protein) was used as immunogen. Mice were repeatedly injected until their serum gave a 1/2 maximum signal on ELISA at about a 1/5000 dilution. Spleen cells were fused with NSO myeloma cells. Screening of hybridoma supernatants was first by ELISA. Positives were screened again by immunoblot. Several hybridoma supernatants that immunoblotted to a ~170 Kd polypeptide were obtained and the cells were cloned. One such clone, antibody #78 (IgG_1), has been purified on Protein A agarose and investigated in greater detail. It has been found to:

(a) immunoblot to a 150-170 Kd polypeptide under both non-reducing and reducing conditions;

(b) immunoprecipitate 20-30% of the ^{3}H PN200-110 labeled material extracted from prelabeled skeletal membranes.

We are currently testing the hypothesis that antibody #78 binds to the skeletal muscle 1,4-dihydrcpyridine sensitive calcium channel. Supported by NIH grant HL33026.

31.4 OMEGA-CONOTOXIN BLOCKS DIHYDROPYRIDINE-INSENSITIVE CALCIUM CHANNELS IN THE INTACT NERVE TERMINALS OF THE FROG NEUROHYPOPHYSIS. A.L. Obaid*, R. Flores*, and B.M. Salzberg. (SPON: R.O. Davies) Dept. of Physiol., Univ. of Penn., Phila., PA 19104.

Multiple Ca^{++} channel types have been described in a variety of neuronal preparations and speculation has centered on their role in controlling release at nerve terminals. However, it has not yet been possible to characterize directly Ca^{++} channels in the intact nerve terminals of a vertebrate.

We have been using optical techniques that employ extrinsic potentiometric probes to record rapid changes of membrane voltage in the intact nerve terminals of a vertebrate neurohypophysis (Salzberg et al., 1983; Obaid et al., 1985), in order to establish the ionic basis of their action potential. We have shown, in the frog neurohypophysis, that Ca^{++} entrance contributes to the upstroke, and the after-hyperpolarization results from the activation of a very prominent Ca^{++}-dependent K^+-conductance. We have also demonstrated that Cd^{++} (200uM) eliminates the undershoot of the normal action potential, and completely abolishes the regenerative Ca^{++} response obtained in the presence of 1 uM TTX/5 mM TEA. We report here our attempts to define the pharmacological profile of the Ca^{++} channels present in the frog neurohypophysis. We used two dihydropyridine compounds (Nifedipine and Bay-K 8644) at concentrations ranging from 2 to 5 uM (0.1 to 0.25% EtOH), and the synthetic omega-conotoxin GVIA (Peninsula Labs, Inc., Belmont, CA) (1-3.3 uM). Neither of the dihydropyridine compounds had any effect on the Ca^{++}-dependent components of the action potential and the regenerative Ca^{++} response, as these spikes remained absolutely unchanged for up to 1 hr in the presence of Nifedipine and Bay-K 8644. Omega-conotoxin GVIA eliminated in 3 mins the after-hyperpolarization of the normal action potential, and dramatically reduced the height of the upstroke and the size of the undershoot in the regenerative Ca^{++}-spike.

These findings demonstrate that the type of Ca^{++} channel that dominates the behavior of intact vertebrate nerve terminals is blocked by omega-conotoxin and is insensitive to dihydropyridines.

Supported by USPHS grant NS 16824; NATO and Philippe Foundation fellowships to RF(INSERM). We thank M. Morad and G. Cota for their gifts of DHP compounds and to T.D. Parsons for helpful discussions.

31.5 OMEGA TOXIN PEPTIDE FROM CONUS MAGUS BLOCKS NEUROMUSCULAR TRANSMISSION AND VOLTAGE-GATED CALCIUM CHANNELS IN NEURONS. D.H. Feldman, Z. Bagabaldo*, B.M. Olivera*, and D. Yoshikami. Department of Biology, University of Utah, Salt Lake City, UT 84112.

Omega Conus geographus toxin (ωCgTX/GVIa), a 27 amino acid peptide from the venom of the marine snail Conus geographus, blocks synaptic transmission in the frog [Kerr & D.Y (1984) Nature 308, 282-4] and blocks calcium channels in cultured dorsal root ganglion (DRG) neurons from chick [D.H.F. & D.Y (1985) Soc Neurosci Abstr 11, 517; D.H.F. et al. (1987) FEBS Lett, in press]. The omega toxin from C. magus (ωCmTX/MVIIa) is a 25 amino acid peptide with a primary structure quite distinct from that of ωCgTX. Their structures are homologous however, particularly with regard to the positions of the six cysteine residues which are all disulfide-linked [B.M.O. et al. (1985) Science 230, 1338-43]. We report here that ωCmTX, like ωCgTX, also blocks neuromuscular transmission and neuronal Ca channels.

Extracellular recording of population endplate currents was used to monitor the effects of ωCmTX on frog cutaneus pectoris and 19-day embryonic chick biventer cervicis nerve-muscle preparations. In frog, ωCmTX reversibly inhibited synaptic transmission with a K_i of about 2 μM, and a half-life of block < 10 min. In contrast, the block by ωCmTX was essentially irreversible in chick.

Three clases of Ca currents (T, N, and L) have been identified in cultured chick DRG neurons [Nowyky et al. (1985) Nature 316, 440-3]. As previously observed with ωCgTX [McCleskey et al. (1986) Biophys J 49,431a (abstract); PNAS, in press], ωCmTX (10 μM) blocked 20-30% of the T current, and upon washout of toxin, T current recovered within 1 min. Also like ωCgTX, ωCmTX blocked N and L currents with a rate constant of block within a factor of two of 5000 M^{-1} s^{-1}, corresponding to a half-time for block of ~2 min for 1 μM ωCmTX. However, whereas ωCgTX blocks these currents relatively irreversibly, about one third of the current blocked by ωCmTX recovered readily upon washout of toxin (half-life ~15 min.), with both N and L components recovering at the same rate. It is not yet known why only partial recovery from ωCmTX-block is observed.

In summary, although the effects of ωCmTX and ωCgTX are similar, the toxins can affect Ca channels in various tissues of diverse animal species differently; this may be a reflection of changes in the structure of the Ca channels over the course of evolution.

Supported by NSF grant BNS 8316076.

31.6 **CHARACTERIZATION AND VISUALIZATION OF [^{125}I]OMEGA-CONOTOXIN GVIA BINDING SITES IN RAT BRAIN.** J.A. Wagner, A.M. Snowman, P.F. Worley, B.M. Olivera, A. Biswas, J.M. Baraban, S.H. Snyder. The Johns Hopkins Univ. Sch. of Med. and the Univ. of Utah.

Omega-conotoxin GVIA (CgTx GVIA) inhibits calcium movement through N and L channels, while dihydropyridine and phenylalkylamine calcium antagonists only inhibit L channel activity. N channels appear predominantly localized to nerve terminals, while L channels appear more restricted to nerve cell bodies. Characterization and visualization of [^{125}I]CgTx GVIA binding sites in brain may clarify the role of different calcium channels in neural function.

Monoiodinated CgTx (synthesized by R. Garlick, DuPont) bound to rat brain membrane homogenates and tissue sections saturably, reversibly, and with very high affinity. Homogenate binding was linear with protein concentration in the range from 0.1 to 10 ug/ml. Two sites were discriminated by Scatchard analysis (K_d 50 pM and 2 nM; B_{max} 3 and 30 nmoles/mg protein). The high and low affinity binding sites corresponded closely to high and low affinity inhibition by CgTx GVIA of calcium flux into synaptosomes (Reynolds et al, **PNAS 83:** 8804, 1986). Association kinetics were rapid (K_{on} = 1.3 min^{-1}) at 22°C. Dissociation induced by excess ligand was slow (K_{off} = 0.028 min^{-1}). Omega-conotoxin MVIIA also completely inhibited [^{125}I]CgTx GVIA binding.

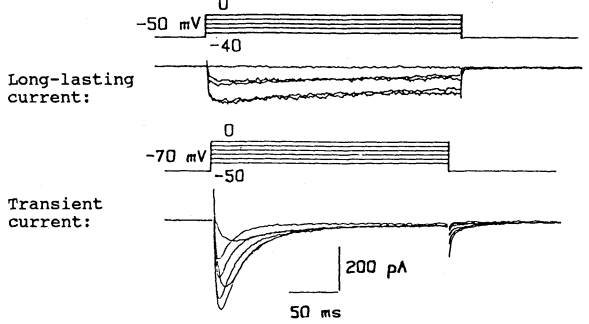
Slide mounted 10 uM coronal sections of rat brain were incubated in a 50 mM HEPES/0.2% BSA, pH 7.4 buffer with 20-35 pM [^{125}I]CgTx for 30 min at 22°C in the presence or absence of 200 nM cold CgTx GVIA. Sections were washed twice for 30 min at 4°C, dried, and exposed to film for 24 hrs.

[^{125}I]CgTx GVIA binding to rat brain sections was similar to homogenates. High grain densities were seen in the frontal cortex, hippocampus, and substantia nigra with highest levels in the superficial cortex. Low grain densities were seen in the striatum and thalamus. Specific binding was absent in white matter tracts such as the corpus collusum. The distribution of [^{125}I]CgTx GVIA binding sites differs from dihydropyridine or phenylalkylamine calcium antagonist binding sites , supporting the idea that [^{125}I]CgTx GVIA binds both to N and L channels.

31.7 CALCIUM CHANNELS IN FRESHLY-DISSOCIATED RAT CEREBELLAR PURKINJE CELLS. L.J. Regan* Dept. of Neurobiology, Harvard Med. Sch., Boston, MA 02115 (SPON: B.P. Bean).

I have used the whole-cell patch-clamp technique to record calcium currents from cerebellar neurons tentatively identified as Purkinje cells. 3 wk postnatal cerebellar cortices were dissociated in 20 U/ml papain for 1.5 hr at 34-37°C. Electrodes contained (in mM): 120-140 TEA- or Cs-glu, 10 EGTA, 5 $MgCl_2$, 3 Mg-ATP, 0.3- 0.8 GTP, 10 HEPES, and sometimes 12 phosphocreatine and 42 U/ml creatine phosphokinase. External solutions contained 10 Ba^{++} or Ca^{++}, 154 TEA-Cl, 2 $MgCl_2$, 10 glucose, and 10 HEPES, pH 7.4, 22°C.

Two components of calcium current have been identified. One current is transient (T_h= 30 ms at -30 mV), activates at potentials more positive than -60 mV, peaks at -30 mV, and has an inactivation range from -60 mV to at least -90 mV. Its properties are similar to those of the "T" current in peripheral neurons (Nowycky, Fox, and Tsien 1985, Nature, vol. 316). The second component is long-lasting, activates at potentials more positive than -40 mV, peaks at -20 to -10 mV, and has a range of inactivation which extends from -20 to at least -90 mV. The properties of this component are like those of the "L" current, except that its inactivation range is much broader. The possibility that the long-lasting component consists (at least in part) of a very slowly inactivating "N"-like current is being explored.



31.8 SPATIALLY RESOLVED CALCIUM CHANGES IN OSCILLATING NEURONS OF THE CRAB STOMATOGASTRIC GANGLION MEASURED WITH ARSENAZO III AND FURA-2. Katherine Graubard, Galen Eaholtz, William N. Ross and John A. Connor. Dept. of Zoology, Univ. of Washington, Seattle, WA 98195; Dept. of Physiology, New York Medical College, Valhalla, NY 10595; Dept. of Molecular Biophysics, AT&T Bell Laboratories, Murray Hill, NJ 07974.

Calcium transients in many regions of crab stomatogastric neurons were monitored with arsenazo III and a photodiode array, and with fura-2 and digital imaging. Measurements with the 10x10 array had time resolution in the millisecond range and (with signal averaging) could follow calcium oscillations in the neuropil correlated with membrane potential oscillations in the soma. Digital imaging (Connor, PNAS 83:6197, 1986) had higher spatial resolution and could reveal absolute levels of calcium, but had poorer time resolution.

As previously reported (Graubard and Ross, PNAS 82:5565, 1985), intrasomatic depolarizing current pulses elicited arsenazo-detectable calcium transients from the neuropil and somatic regions of stomatogastric neurons. When cells were loaded with fura-2 by iontophoretic injection of the dye into the soma, similar depolarizing pulses caused changes in fura-2 fluorescence indicating an increase in calcium concentration. In the first few seconds after stimulation, the increase in intracellular calcium was largest at the edge of the soma near the neurite hillock and was less in the center of the soma. As the calcium concentration recovered to resting levels (over a period of 60 to 90 s), the edge of the soma recovered more rapidly than the center. We could also detect calcium changes in the primary neurites, but changes in the finer processes were unresolvable with this simple protocol. Calcium concentrations in resting somata were in the range of 100 to 180 nM (indicator K_b = 800 nM). Intense repetitive stimulation drove levels into the micromolar range. Calcium levels in the primary neurites were about the same as somatic levels, both for resting and for stimulated neurons.

Calcium changes in spontaneously-oscillating pyloric neurons were analyzed with arsenazo III, a photodiode array, and an improved signal averaging algorithm. For many cells, step increases in calcium could be observed in the neuropil corresponding to each action potential. For some cells, it appeared that all of the rising phase of the calcium oscillation could be attributed to these steps. In other cells, there was clearly a contribution from the graded depolarization since the rise in calcium began before the action potentials. In some cells, no contribution from the action potentials could be detected. Careful examination of the calcium oscillations indicated that, for a few neurons, the relative contribution of action potential- and graded potential-evoked signals was different in different neuritic regions of the same cell.

31.9 CALCIUM CURRENTS IN EMBRYONIC CULTURES OF DROSOPHILA NEURONS
H.-T. Leung* and L. Byerly. Section of Neurobiology, Department of Biological Sciences, University of Southern California, Los Angeles, CA 90089-0371.

The electrical excitability of Drosophila neurons is being studied in the hope that genetic tools can be used to analyze the control of membrane channels. Embryonic cultures were prepared by dissociating whole gastrulating embryos as described by Seecof et al. (Exp. Cell Res 69:161, 1971). Whole-cell patch clamp studies were performed on neurons 20-72 hours after plating the cells. Na and K currents were eliminated by replacing external Na^+ and K^+ with $Tris^+$ and using Cs^+ for the internal cation. Aspartate was used as the major internal anion. Cells rapidly became leaky when Cl^- was the major internal anion, and the Ca current disappeared within 2-3 minutes with internal F^-. The neuronal cell bodies studied were about 5 µm in diameter and had one to three processes. Although the spacial control of voltage was clearly poor in some cells, in other cells the Ca current appeared well clamped, first activating at about -45 mV and reaching a maximum near -10 mV. Cells were usually held at -73 mV; more negative holding potentials did not increase the magnitude of the Ca current or shift the potential at which the inward current activated. Typically the current activated in about 5 ms and exhibited very little inactivation during a 100 ms depolarizing pulse. There was no evidence to suggest the existence of more than one type of Ca current.

The identity of the Ca current was confirmed by demonstrating that the inward current persisted when external Ca^{2+} was replaced by Ba^{2+} and was eliminated reversibly by replacing Ca^{2+} with Mg^{2+} or adding 0.1 mM Cd^{2+} to the external solution. The average value of the maximum Ca current with 5 mM external Ca^{2+} was 40 pA, ranging from 0 to 150 pA in individual cells. 10 µM nifedipine or 100 µM diltiazem had no blocking effect while 100 µM verapamil blocked about 30% of the Ca current. The Ca current "washed out" when the pipet solution contained only EGTA and other inorganic ions, typically dropping 50% in 5 minutes. Addition of ATP to the internal solution usually slowed the rate of washout and completely prevented washout in some cells.

Studies of on-cell patches with electrodes containing 120 mM Ba have found no currents through Ca channels. This suggests that either there are very few Ca channels on the upper side of the cell body of the neuron or the single-channel current of these Ca channels is less than 0.2 pA.

31.10 CALCIUM CHANNEL TAIL CURRENTS IN CHICK SENSORY NEURONS.
D.Swandulla* and C.M.Armstrong* (SPON: J.Kaltenbach) Dept. of Physiol., School of Med., Univ. of Pennsylvania, Philadelphia, PA, 19104.

We have studied deactivation of calcium channel currents in dissociated chick DRG cells which were free of processes 6 to 10 h after plating. Whole cell currents carried by Ca or Ba ions were recorded from single cells using an improved patch clamp circuit (Armstrong and Chow, Biophys.J., in press). Voltage steps were imposed on the membrane in 10-15µs and changes in membrane current could be measured 30µs after the initiation of the step. Tail currents, associated with the closing of Ca channels, decayed in two phases. The tails were fit with the sum of two exponentials. The fast time constant (τ_f) was near 160µs and the slow one about one order of magnitude larger when repolarizing to -80mV at 20°C. The slow component inactivated nearly completely as the pulse duration increased up to 200ms. Changing the holding potential to more positive values or adding 100-200µM Ni^{2+} to the external solution strongly reduced the slow tail component without affecting the decay kinetics of the fast one. These findings indicate that the slow tail component is due to deactivation of the low voltage activated (LVA) Ca channel current described in this preparation (Carbone and Lux, Biophys.J., 46, 1984, 413; Carbone et al., Pfluegers Arch.,408, 1987, R234). The fast tail component was fully activated with 10ms steps from -80 to +20 mV and inactivated to 40% in 100ms and 15% in 500ms. Deactivation kinetics (τ_f) did not change significantly as the channels activated with short steps, or inactivated with long ones. τ_f was voltage dependent and became progressively faster down to -100mV (35mV for an e-fold change in τ_f). 20 second long prepulses to potentials up to -40mV decreased the tail current amplitude presumably due to steady state inactivation of Ca channels but had no effect on the decay kinetics of the tail currents. Lowering the temperature from 20 to 10°C decreased τ_f by a factor of about 2.5. Our findings indicate that the fast tail current component is due to deactivation of current through a single population of Ca channels which can be activated from holding potentials as high as -40mV.

31.11 QUATERNARY AMMONIUM COMPOUNDS BLOCK CALCIUM CURRENTS IN PERFUSED NEURONS OF **LYMNAEA STAGNALIS.**
B. Yazejian, S.D. Hess & G.J. Augustine. Neurobiology Section, Dept. Biological Sciences, Univ. Southern California, Los Angeles, CA 90089-0371.

There once were some clampers of squid
to isolate currents, they did
  have need of a blocker
  which, during a shocker
stopped current through channels well hid.

As noted by Charlton, Horn and GJA (Biol. Bull. 171:489)
tetrapentylammonium ion, TPA
  blocked Ca current in squid
  so to follow, we did
turn to neurons of snails in LA

With the method of internal perfusion
to avoid other currents of confusion
  we used cesium as we clamped
  methods of Byerly & Yazejian, revamped (J. Physiol. 370:631)
to prevent Ca channel contusion

Blockade of Ca current we did see
with a 50-100 micromolar K_D
  washing out TPA
  caused block to go 'way
suggesting reversibility

The blockage is voltage dependent
at +40 mV more resplendent
  so now we confide
  the drug works from inside
and senses the potential gradient

In addition, ethylammonium four (TEA)
did not slam the Ca channel door
  we think TPA selective
  but need more work, detective
for statements in faith we'll have more

We implore you to come view our data
for which we will, somewhat later
  have numbers, kinetics
  and graphs, bon aesthetics
for questions from those who are greater!

Supported by NIH grants NS 15341 and NS 21624.

31.12 CHARACTERIZATION OF THE BINDING OF THE DIHYDROPYRIDINE CALCIUM CHANNEL BLOCKER [^{3}H]PN200-110 TO RINm5F MEMBRANES AND INTACT CELLS.
G. C. Yaney*, J. D. Henstenburg* and G.A. Weiland. Department of Pharmacology, New York State College of Veterinary Medicine, Cornell University, Ithaca, NY 14853.

The RINm5F is an insulin-secreting cell line derived from a pancreatic β-cell tumor induced in the NEDH rat by X-ray irradiation. This cell line has been used extensively as a model system for the study of the mechanism of insulin secretion. Although the cells do not respond to glucose, insulin secretion is stimulated by glyceraldehyde, K^+-induced depolarization. The presence of voltage-sensitive calcium channels on these cells has been demonstrated electrophysiologically and biochemically, and these channels appear to blocked by calcium antagonists. Based on these findings, the binding of the dihydropyridine calcium channel antagonist [^{3}H]PN200-110 to RINm5F membranes and intact cells was characterized.

Membranes were incubated with [^{3}H]PN200-110 for 1 hr in 10 mM MOPS, 1 mM $CaCl_2$ (pH 7.4) and free and bound radioligand were separated by vacuum filtration. Nonspecific binding was determined in the presence of 1 µM nitrendipine. Saturation isotherms of the specific binding of [^{3}H]PN200-110 demonstrated a single population of high affinity binding sites (K_d ~ 150 pM; B_{max} ~ 70 fmoles/mg protein, ~2000 sites/cell). Specific binding was displaced by the dihydropyridines nitrendipine, nisoldipine, and nimodipine with K_i values of approximately 1 nM. Specific [^{3}H]PN200-110 binding was Ca^{++} dependent; 2 mM EGTA or La^{+++} decreased specific binding by 60% and 80% respectively. Verapamil inhibited specific binding by less than 100% with an apparent IC_{50} of 0.3 µM, reflecting a 2-fold increase in the K_d. In the presence of EGTA, diltiazem increased specific binding with an apparent EC_{50} of 0.1 µM, reflecting a 2-fold decrease in the K_d. From these results we conclude that [^{3}H]PN200-110 binds to L-type calcium channels on RINm5F membranes.

Intact cells were incubated with [^{3}H]PN200-110 for 45 min in normal K^+ or high K^+ HEPES-buffered Krebs/Ringer/bicarbonate. Bound and free ligand were separated by vacuum filtration. [^{3}H]PN200-110 binding to the cells in either buffer was displaced by nitrendipine with an apparent IC_{50} of 1 nM. Specific binding to the cells was significantly lower in low K^+ *vs.* high K^+ buffer. The affinity of [^{3}H]PN200-110 binding to depolarized cells was similar to that in membranes (K_d ~ 100 pM). In polarized cells the affinity was at least 3-fold lower. Further characterization of this binding is currently underway.

These results demonstrate the potential usefulness of the RINm5F cell line as a model system to study the mechanism of action of calcium antagonists as well as calcium channel function.

Supported in part by an NIH grant (RO1-HL35467-02) to GAW.

31.13 PHENOBARBITAL BLOCK OF VOLTAGE-DEPENDENT CALCIUM CHANNELS IN NEUROBLASTOMA CELLS. D.A. Twombly*, M.D. Herman*, and T. Narahashi (SPON: S.-C. Cheng). Depts. of Pharmacol. and Neurosurg., Northwestern Univ. Med. Sch., Chicago, IL 60611.

Phenobarbital, a barbiturate effective in the treatment of many seizure disorders, has been shown to interfere with calcium fluxes through neuronal membranes. Calcium uptake into depolarized synaptosomes is inhibited by phenobarbital, and calcium action potentials of dorsal root ganglion cells are shortened in duration. However, the direct effects of phenobarbital on different types of voltage-dependent calcium channels have yet to be defined. This study examined the nature of calcium channel block in N1E-115 neuroblastoma, cells which express both inactivating (type I) and non-inactivating (type II) calcium channels during the process of differentiation.

Calcium channel currents of cultured cells were recorded with the whole-cell voltage clamp technique. Barium (50 mM) was included in the external medium to serve as charge carrier through calcium channels. Under control conditions (standard external solution, 35 - 37°C), type I currents activated at potentials positive to -45 mV; maximum amplitudes were obtained with test pulses to -20 mV or -10 mV. Current inactivation followed a single exponential time course (time constant, 10 - 30 ms). Type II currents activated at potentials positive to 0 mV, and displayed little or no inactivation during 200 ms test pulses. Their amplitudes were generally largest at potentials of +10 mV. Addition of 30 uM - 1 mM concentrations of phenobarbital to the external medium resulted in dose-dependent suppression of calcium channel currents. In this concentration range, both type I and type II currents were blocked to a similar extent. The lowest effective dose of 30 uM reduced both current types by approximately 15%. At 100 uM and 300 uM phenobarbital, currents were decreased by 36% and 40%, respectively. Although the amplitudes of calcium channel currents were suppressed by phenobarbital, the time courses of the two current types were not altered. Moreover, the voltage dependence of channel activation was not shifted, even in the presence of 1 mM phenobarbital.

Studies of CSF and brain tissue from epileptic patients have indicated that the therapeutic range of phenobarbital concentrations is 10 - 215 uM. Block of type I and type II calcium channel currents by phenobarbital therefore occurs at clinically relevant drug levels. Since voltage-dependent calcium channels are suspected to participate in epileptiform bursting activity, the channel blocking action of phenobarbital may constitute an important aspect of its anticonvulsant action in the nervous system. (Supported by the American Epilepsy Society, the Epilepsy Foundation of America, and N.I.H. grant NS14144).

31.14 PENTOBARBITAL REDUCES THE LARGE TRANSIENT AND SLOWLY INACTIVATING CALCIUM CURRENTS IN MOUSE SENSORY NEURONS BY DIFFERENT MECHANISMS. R.L.Macdonald and R.A.Gross, Department of Neurology, University of Michigan, Ann Arbor, MI, 48104, U.S.A.

Barbiturates reduce calcium currents in invertebrate neurons and dorsal root ganglion (DRG) neurons (Werz and Macdonald, Mol Pharmacol 28: 269, 1985). This block of calcium entry may underlie the suppression of neurotransmitter release by barbiturates. Three distinct calcium currents have been described in DRG neurons (Nowycky, Fox, and Tsien, Nature 316:440, 1985; Gross and Macdonald, PNAS, in press). Pentobarbital (PB) had selective effects on these currents, apparently by different mechanisms.

Intracellular recordings were obtained with micropipettes filled with 3M CsCl (20-30 MΩ) from mouse DRG neurons in culture. Recording medium (pH=7.3-7.4) suppressed Na and K currents and contained (in mM): Tris 13.0; choline-Cl 67; KCl 5; TEA 100; $CaCl_2$ 2.0; glucose 5.6; $MgCl_2$ 0.8. A single electrode voltage clamp was used to record calcium currents with a switching frequency of 6-8 kHz and a 70-30 duty cycle. Voltage steps were generated and digitized data stored (2-6 kHz sampling) using a microcomputer. PB and Cd^{2+} were applied by diffusion from blunt-tipped (10-20 µm) micropipettes. Three calcium currents were recorded. A small transient current was recorded at -60 to -50 mV when evoked from negative holding potentials (-100 to -90 mV) (T-type). A moderate very slowly-inactivating current was recorded at potentials positive to -20 mV when evoked from holding potentials of -50 to -40 mV (L-type). A large transient current (N-type) was recorded with the L-type current at potentials positive to -40 mV when evoked from holding potentials of -80 mV.

PB (500 µM) did not affect the T-type current. At all voltages tested, PB produced a 50-100% reduction in the L-type current throughout the voltage command. In combined N- and L-type currents, PB reduced the peak current and produced a more rapid rate of current decay. When evoked from holding potentials negative to -80 mV, peak reduction of current by PB was due to reduction of the L-type current. When evoked from holding potentials positive to -80 mV, peak suppression of current by PB was greater due to a -10 to -15 mV shift in the voltage-dependence of steady-state inactivation of N-type current. There was a voltage-dependent reduction in the inactivation time constants of all three currents above -30 mV; PB produced a further reduction of the N-type current inactivation time constant, accounting for the more rapid current decay. These effects may explain barbiturate suppression of neurotransmitter release and suggest specific roles for the N- and L-type calcium channels.

31.15 EFFECTS OF SPIDER TOXINS ON L AND N CNS CALCIUM CHANNELS: INHIBITION AND ENHANCEMENT OF BINDING. L.M. Kerr, J.K. Wamsley, F. Filloux, T.N. Parks and H. Jackson (SPON: R. Mullen). Departments of Psychiatry and Anatomy, Univ. of Utah Medical Center, Salt Lake City, UT 84132.

Two novel spider toxins with putative calcium antagonist effects were tested using filtration and in vitro quantitative autoradiography against radiolabeled forms of the know Ca channel blockers [3H]-nitrendipine [125I]-omega conotoxin. The former binds primarily to brain L-type Ca channels whereas the latter binds to both N- and some L-type channels (see Miller, Science 235:46). With autoradiography, the conotoxin shows a diffuse pattern of binding throughout rat brain with increased grains over synaptic areas such as the caudate-putamen and the molecular layer of the cerebellum. This is consitent with its action as a presynaptic Ca-channel blocker. The first spider toxin, AG1, blocks this binding in a dose-dependent manner with an EC50 of about 100 nM (all concentrations estimated from protein contents of partially-purified venom fractions). AG1 is physiologically similar but not identical to omega conotoxin (H. Jackson, unpub. observ.; R. Llinas and M. Sugimori, pers. comm.). The other spider toxin, AG2, also affects omega conotoxin binding. In contrast to AG1, however, AG2 enhances rather than suppresses conotoxin binding, producing an increased grain density over that seen with conotoxin alone. This enhancement is dose dependent with an EC50 of about 3 uM. AG2 is very different from both AG1 and omega conotoxin in its physiological effects; it blocks Ca currents in cardiac muscle unaffected by AG1 or conotoxin and its suppression of synaptic transmission in brain is readily reversibly in contrast to the other two toxins. It is possible that AG2 blocks both neuronal and cardiac L-type channels or that it blocks a type of Ca channel not previously described.

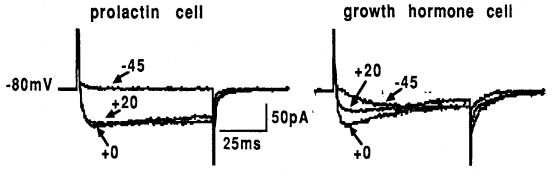
AG1 and AG2 were tested using a rat brain membrane preparation for effects on [3H]-nitrendipine binding. AG2 suppressed nitrendipine binding in a dose-dependent fashion with an EC50 of about 3 uM. This is consistent with an action at L-type channels. Conversely, AG1 enhanced nitrendipine binding with an EC50 of about 250 nM. Scatchard analyses of specific nitrendipine binding with and without AG1 demonstrated that AG1 caused an increase in Bmax (from 63 to 84 fmols/mg tissue; $p<0.05$, n=4) without changing the KD (0.07 mM). This suggests that AG1 allows nitredipine to bind to new sites either by uncovering sites or by changing sites that do not normally bind nitrendipine. These results raise the possibility that a given channel can express either N- or L-type characteristics in the presence of particular modifiers and that N- and L-type Ca channels are therefore not anatomically distinct entities.

31.16 **Calcium currents differ in FACS-sorted prolactin and growth hormone pituitary cells**

Deborah L. Lewis, Paul A. St. John, and Jeffery L. Barker, Laboratory of Neurophysiology, NINCDS-NIH, Bethesda, MD 20892

Adult rat anterior pituitary cells were enzymatically dissociated, sorted with a fluorescence-activated cell sorter (FACS), and cultured for 2-6 days. Prolactin cells were sorted with anti-prolactin antibodies, and growth hormone cells with ß subunit of cholera toxin. The whole-cell patch clamp technique was used to record voltage-dependent calcium currents, I_{Ca}. Cells were recorded in 10mM extracellular Ca^{2+} at 22°C. After recording, hormonal contents of cells were identified by immunohistochemical techniques.

Growth hormone cells had a fast inactivating I_{Ca} which activated at -50mV. This I_{Ca} showed faster activation with more postive potentials and reached peak amplitude at -20mV. This fast inactivating I_{Ca} could be completely inactivated at a holding potential of -40mV. A second I_{Ca} activated at more positive potentials and showed little inactivation. Prolactin cells exhibited a fast inactivating I_{Ca} which activated between -40 and -30mV and could be completely inactivated at a holding potential of -40mV. Prolactin cells expressed a second I_{Ca} which activated at more positive potentials, showed little inactivation, and reached a peak at +10mV. The peak of the I/V differed; growth hormone I/V peaked at -20mV and prolactin, at +10mV. This suggests that growth hormone cells have a greater proportion of a low threshold, fast inactivating I_{Ca}, and that prolactin cells have a greater proportion of high threshold, sustained I_{Ca}. This is further suggested by the effect of Bay K 8644, an agonist for the sustained calcium current, which greatly increased I_{Ca} amplitude of prolactin cells but had little effect on I_{Ca} of growth hormone cells. The calcium currents here differ from a recent report of I_{Ca} in the same cell types, gradient-separated and plaque-identified (S.A. DeRiemer and B. Sakmann, *Exp. Brain Res.* 14:139, 1986).



31.17 VOLTAGE-DEPENDENT CALCIUM CURRENTS IN CULTURED EMBRYONIC RAT HIPPOCAMPAL NEURONS.

Donald E.R. Meyers[+] and Jeffery L. Barker, Lab. of [+]Neural Control and Neurophysiology, NINCDS, NIH, Bethesda, MD 20892.

Voltage-dependent calcium currents (VDCC) in cultured embryonic (E18) rat hippocampal cells (HPCs) were investigated using the whole-cell patch-clamp technique. VDCC were isolated by removing K^+ from both internal and external solutions. Solutions contained (mM): (External) Ca^{++} or Ba^{++} 2, Mg^{++} 1, Na^+ 5, HEPES/Na OH 5 (pH 7.3) plus 1μM TTX; (Internal) N-methyl D-glucamine (NMG) methanesulphonate 110, NMG Cl 10, BAPTA or EGTA (Cs salts) 5, MgATP 5, Tris phosphocreatine 20, creatine kinase 50 U/ml, HEPES/CsOH 5 (pH 7.3).

Depolarizing commands from holding potentials (HP) between -100 and -40mV elicited inward currents that were increased by raising $[Ca^{++}]_o$ to 10mM and abolished by lowering $[Ca^{++}]_o$ to 0.1mM or by addition of 5mM Co^{++}. The leak subtracted I-V curve showed that maximal inward curent was obtained at -10mV in 2mM Ca^{++} and declined at more positive potentials. During steps from HP = -100mV to -50mV, a small inward current was elicited that decayed completely within 100ms. Commands to more depolarized potentials elicited a relatively sustained inward current.

After 24hrs in culture, maximal I_{Ca} was small (<20pA) and decayed completely during a 200ms depolarising command to -10mV from -60mV. After 72hrs in culture, maximal I_{Ca} ranged from 50-100pA and underwent only 40-60% decay during a 200ms command. The I_{Ca} in cells which had been in culture for more than 6 days showed no consistent differences. Maximal I_{Ca} was 200-400pA. The results reported below are from cells grown for 7-14 days in tissue culture.

When EGTA was used as the internal Ca buffer, I_{Ca} showed little decay during a 200ms step from HP = -40mV to -10mV but I_{Ca} decayed by 20-30% during a 200ms step from HP = -80mV to -10mV; maximal inward current was greater from HP = -80mV than from HP = -40mV. Replacement of 4 mM Ca^{++} with 2 mM Ba^{++} resulted in a substantial decrease in decay of the inward current during a 200ms step from -80 to -10mV. When BAPTA was used as the internal Ca buffer, mean decay during such steps was reduced from 26% to 8% ($n_1 = n_2 = 12$).

1μM BAY K 8644 invariably enhanced peak I_{Ca} (50-100%). 1μM nifedipine appeared to reduce I_{Ca} in a voltage-dependent manner. From HP = -40 mV, block was complete. From -60 and -80mV the maximum block was 60%. When significant decay was present, nifedipine produced a greater reduction in peak current compared to the current at the end of the step. The remaining current was blocked by 5mM Co^{++}.

The transient current may be similar to that already described ('T type' or low voltage-activated) in other preparations. The other type of VDCC in HPCs decays with time and this decay appears to be related to the rise of internal Ca^{++} during prolonged activation of VDCC, as suggested by the results with Ba^{++}_o or $BAPTA_i$.

31.18 WHICH TYPE(S) OF Ca CHANNELS ARE PRESENT IN MAMMALIAN BRAIN SYNAPTOSOMES?

M.M.Murawsky* and J.B. Suszkiw, Department of Physiol & Biophys. University of Cincinnati Sch. of Medicine, Cincinnati, OH 45267-0576.

Three types (T,N,and L) of the voltage sensitive Ca channels (VSCC) have been distinguished in vertebrate neurons (1,2). Based on ^{45}Ca flux measurements, the properties of presynaptic VSCC in brain synaptosomes appear to be dissimilar from those associated with either T or L type channels. It has been suggested that the presynaptic Ca channels may be of the N-type (2). The N channels recorded in neuronal soma have high activation threshold (> -10 mV) and are strongly blocked by the neurotoxin ω-CgTx (1,2). In this work we have examined voltage dependence, and sensitivity to ω-CgTx of the K^+-depolarization dependent ^{45}Ca influx in rat brain synaptosomes. Ca influx was measured in synaptosomes suspended in Na-deficient (Ch-substitution) media, during 1 sec exposures to 5-130 mM $[K^+]_o$; synaptosomal membrane potential was estimated as described previously (3). The results indicate that Ca influx in synaptosomes activates at about -50 mV, is half maximal at about -40 to -30 mV, and reaches maximum at about -10 to 0 mV. This voltage dependence of Ca influx is different from that which might be expected from mediation by the N-type channels. Preincubation of synaptosomes with ω-CgTx resulted in partial inhibition of Ca influx. 40% of Ca influx was blocked by ω-CgTx ($I_{50} \simeq 3.3$ μM); 60% of Ca influx is not inhibited by the toxin at concentration up to 10 μM. This suggests the presence in synaptosomes of two pharmacologically distinguishable, i.e., moderately CgTx-sensitive Ca channels as well as CgTx-insensitive channels. In conclusion, although single channel recordings of identified presynaptic VSCC are needed to establish this, the currently available evidence suggests that the properties of the presynaptic (P) channels inferred from ^{45}Ca influx measurements in rat brain synaptosomes, i.e., (1) low activation threshold, (2) slow inactivation (3) insensitivity to dihydropyridine drugs, and (4) moderate or lack of sensitivity to ω-CgTx, do not fully coincide with any of the extrasynaptic (E) channel subtypes (E_T, E_N, or E_L).

31.19 ELECTROPHYSIOLOGICAL, PHARMACOLOGICAL AND SPATIAL SEPARATION OF THREE CALCIUM CURRENTS IN RAT DENTATE GRANULE NEURONS.

C.E. Niesen*, T.J. Blaxter* and P.L. Carlen. Playfair Neuroscience Unit, Toronto Western Hospital, Addiction Research Foundation, Depts. of Medicine and Physiol., Univ. of Toronto, Toronto, Ontario, M5T 2S8 Canada and School of Pharmacy, University College, London, WC1N 1AX England.

Using the single electrode voltage-clamp technique (Axoclamp II), we investigated calcium currents in dentate granule neurons in the in vitro rat hippocampal slice preparation. Intracellular recordings were performed with microelectrodes (40-80 MΩ) filled with 3 M CsCl. The perfusion media included (in mM): 4 Ca^{2+}, 2 Mg^{2+}, 0.001 TTX, 10 TEA, 5 4-aminopyridine and 3 CsCl.

Three different voltage-dependent calcium currents could be distinguished by their waveform and activation characteristics, pharmacology and regional sensitivity. Voltage commands (1 sec) to -50 mV or more from a holding potential (V_h) of -70 to -80 mV activated a transient (<200 msec) inward current with an amplitude of 0.2-0.6 nA. Further depolarization to -30mV evoked a large (amplitude 0.8-6.0 nA), often difficult to clamp, slowly decaying inward current whose peak amplitude occurred at -15mV. This current was readily blocked by repetitive activation. Holding at more depolarized V_h's (≥-40mV) blocked the large current and revealed a smaller, non-inactivating inward current whose peak amplitude was evoked at +10mV. A similar non-inactivating inward current (? the same) was elicited at -50 to -60 mV from more negative V_h's. All currents were blocked in zero Ca^{2+}, 200 μM Cd^{2+}, 4 mM Mn^{2+} or 1 mM Ni^{2+} perfusate. These three calcium currents resemble the T, N and L currents described by Nowycky et al. (Nature, 316: 440, 1985).

Nimodipine (1 μM) perfusion selectively blocked the persistent inward current and Cd^{2+} (50 μM) decreased the N- and L-type currents with little effect on the transient current. Focal applications of 10-100 mM Ca^{2+} or cation blockers further separated these currents. The large N-type current was enhanced mainly by Ca^{2+} application on the mid- to distal dendrites. The persistent L-type current was increased by Ca^{2+} (or blocked by Cd^{2+}) ejected only at the soma, while the transient current was affected at all parts of the neuron tested (soma, dendrites and axon). Over 96% of the neurons (n=87) exhibited the full complement of all three calcium currents.

Supported by MRC, OMH and ABMRF.

31.20 MULTIPLE CALCIUM CHANNEL TYPES IN ASCIDIAN OOCYTES.

R. E. Hice. Dept. of Zoology, Univ. of Washington, Seattle, WA 98195.

Properties of macroscopic currents in oocytes from 5 species of ascidians have been studied using the two-microelectrode voltage-clamp technique. Transient inward calcium currents have been identified in the oocytes of all 5 species. The kinetics, ion selectivity, saturability, and mode of inactivation of these calcium currents varied even between oocytes of closely related species. However, a possible phylogenetic trend in the presence or absence of low threshold calcium channels has been observed. Oocytes from ascidians of the order phlebobranchia (Ascidia, Ciona) have low threshold calcium currents while oocytes from ascidians belonging to the order stolidobranchia (Boltenia, Pyura, Styela) do not.

Low threshold currents observed in Ascidia and Ciona oocytes reached peak current at steps to -30 mV (V_{hold} = -80 mV), but time to peak current differed by a factor of 2 (ca. 32 msec for Ascidia, and ca. 70 msec for Ciona). Both currents were enhanced by elevation of external Ca^{2+}; however, reduction of external Na^+ also reduced both currents. Possible co-existence of a Ca^{2+}-activated Na^+ current has not been discounted. Preliminary experiments with Ciona oocytes have shown that reduction of external Na^+ can also change the apparent divalent ion selectivity of the low threshold current. With normal external Na^+ (460 mM) substitution of Ba^{2+} for Ca^{2+} (10 mM) increases peak current ca. 2-fold: with reduced external Na^+ (8 mM) peak current is not significantly changed when Ba^{2+} is substituted for Ca^{2+} (10 mM).

High threshold calcium currents (peak current at ca. 0 to +10 mV) have been studied primarily in Boltenia, Pyura, and Styela oocytes since the low threshold currents in these species are Na^+-selective and easily blocked and because no large outward currents exist for the voltage range studied. The Boltenia oocyte Ca^{2+} current has the apparent divalent selectivity of Ca < Sr < Ba and shows Ca^{2+}-dependent inactivation. Substitution of either Ba^{2+} or Sr^{2+} for Ca^{2+} results in no significant inactivation for 1 sec duration pulses. In contrast Pyura and Styela oocyte Ca^{2+} currents show the apparent divalent ion selectivity of Ca < Ba < Sr and appear to undergo voltage-dependent inactivation. Times for peak current vary (ca. 12 to 40 msec) between the 3 species and with the divalent ion used. Relaxation of the Styela Ca^{2+} current requires several seconds to reach steady state in contrast to the more rapidly decaying Ca^{2+} currents of Boltenia and Pyura.

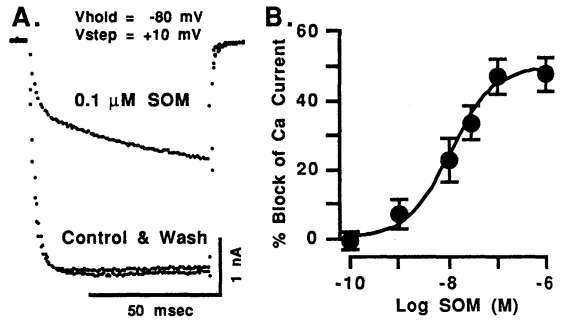
32.1 **SOMATOSTATIN BLOCKS A CALCIUM CURRENT IN ACUTELY ISOLATED ADULT RAT SUPERIOR CERVICAL GANGLION NEURONS.** Stephen R. Ikeda, Geoffrey G. Schofield and Forrest F. Weight. Section of Electrophysiology, Lab. of Physiologic and Pharmacologic Studies, National Institute on Alcohol Abuse and Alcoholism, Rockville, MD 20852.

It has been reported that somatostatin (SOM) blocks voltage-dependent Ca^{2+} channels and secretion in clonal cell lines (Lewis *et al., PNAS* **83**:9035-9039, 1986; Tsunoo *et al., PNAS* **83**:9832-9836,1986) and that SOM-like immunoreactivity exists in the somata and processes of neurons in the rat superior cervical ganglion (SCG) (Ariano, M.A. & Kenny, S.L., *Brain Res.* **340**:181-185,1985). Thus, we have examined the effect of SOM on Ca^{2+} currents in neurons isolated from the adult rat SCG.

Neuronal isolation and whole-cell patch-clamp recording techniques were similar to those previously described (Ikeda, *et al., Soc. Neurosci. Abs.* **12**:1343,1986). Superfusion of [D-Trp^8] SOM resulted in a rapid, concentration-dependent and reversible reduction of the Ca^{2+} current elicited by depolarizing voltage pulses from a holding potential of -80 mV. In addition, SOM slowed the rising phase of the Ca^{2+} current, especially at more depolarized potentials (fig A). The concentration-response relationship for SOM could be fit to a single-site binding curve with an apparent dissociation constant of 11 nM (fig B). We conclude that SOM blocks Ca^{2+} currents in postganglionic neurons of sympathetic ganglia and thus may play an important role in the modulation of neuronal excitability and/or neurotransmitter release.



32.2 SUBSTANCE P AND NEUROKININ A AUGMENT A CALCIUM CURRENT IN VOLTAGE-CLAMPED SPINAL DORSAL HORN NEURONS OF THE RAT. K. Murase and M. Randić. Information and Computer Sciences, Toyohashi University of Technology, Tempaku, Toyohashi 440 Japan, and Veterinary Physiology and Pharmacology, Iowa State University, Ames, IA 50011 USA.

Spinal dorsal horn neurons of 2-4 week-old rats in a slice preparation were studied by using the single-microelectrode sample-and-hold voltage-clamp technique. After Na spikes were blocked by 0.2-1µM TTX, the cells were held at -75 to -55mV. In the normal Krebs solution containing 2.4mM Ca, 1sec depolarizing commands to between -55 and -35mV induced slow inward current relaxations and inward current tails. Commands to -35mV, or above, evoked slow outward relaxations and outward current tails. The outward relaxations and outward tails appear to be due to the activation of a Ca-dependent K conductance, because they were substantially reduced in 10-20mM TEA or zero-Ca containing solution, by replacing Ca with Ba or Co, or by use of CsCl-filled pipettes.

The inward relaxations and inward tails evoked by voltage commands to between -55 and -35mV were clearly enhanced in the presence of TEA or by replacing Ca by Ba in the bath. The following results obtained in the Ba-containing solution indicate that the inward relaxations and tails are likely to be due to the activation of a Ca current since they were; increased in a dose-dependent manner when Ba replaced Ca in the bath; blocked by removing Ba, or replacing Ba with Co as well as by 10uM of nifedipine; only slightly modified when Na was replaced by Tris, or Cl with isothionate; and were inward in response to wide range of commands (-150 to -35mV). Raising the external K concentration from 3.1 to 10mM did not change the inward direction of the relaxations and tails. The current appears to activate at membrane potentials between -60 and -50mV and reaches the full activation at -45mV. Both on- and off-relaxations were not adequately described by a single exponential, two time constants obtained by the peeling-off method being in the range of 2.5 to 5s and 0.2 to 0.4s. Some properties of the current, such as the graded activation to command voltage and duration, the voltage dependency, and the slow time course of the activation and inactivation, resemble those of the persistent slow Ca current found in bursting neurons of the Helix pomatia and Aplysia, and in hippocampal and olfactory neurons of the guinea pig. However, determination of the Ca-channel type will await future single-channel recordings from dissociated spinal cord neurons.

Substance P, neurokinin A and cholecystokinin octapeptide enhanced the Ca current in a dose-dependent manner. The effect seemed to coexist with two other effects, namely an increase of an outward current having similar voltage dependency to the Ca-dependent K current and an increase in a voltage-insensitive inward current, the latter probably carried by Na and Ca ions.

32.3 SOMAN INCREASES POTASSIUM STIMULATED CALCIUM INFLUX IN RAT BRAIN CORTICAL SYNAPTOSOMES. M.G. Hamilton* and C. Posavad* (SPON: A. Miller) Biomedical Defence Section, Defence Research Establishment Suffield, Ralston, Alberta, Canada, T0J 2N0.

The potent organophosphorus (OP) acetylcholinesterase (AChE)inhibitor soman (pinacolyl methylphosphonofluoridate) causes severe clonic convulsions and eventual death by respiratory arrest. The convulsive episodes following soman challenge produce electrical changes in brain activity similar to those observed in epileptogenic phenomena. These types of seizures are known to alter the normal balance of many ions, including Ca^{++}, suggesting that OP AChE inhibitors may alter normal Ca^{++} homeostasis in a manner that could mediate at least some of the OP-induced hyperexcitability. Synaptosomes were isolated from the cortex of rats 1, 2, 3 or 7 days following poisoning with one or four LD_{50}'s of soman. (Animals challenged with four LD_{50}'s of soman were also treated with the cholinolytic atropine (17 mg/kg) and the oxime HI-6 (125 mg/kg) which prevented death, but not the convulsions). Both resting (5mM K^+) and depolarized (15 - 60mM K^+) Ca^{++} influx was estimated in 200 µL aliquots of synaptosome suspension using $^{45}Ca^{++}$ as a tracer. At various times from 1 to 240 seconds, influx was terminated by rapid dilution and filtration through 0.45 µM membrane filters and the radioactivity remaining was determined by liquid scintillation spectroscopy.

Beginning 24 hours after a challenge with 1 LD_{50} of soman (110 µg/kg, s.c.), K^+ - stimulated synaptosomal Ca^{++} influx was significantly elevated above that observed in control animals. This elevation of neuronal Ca^{++} influx was evident for the duration of the experiment and was apparently specific for depolarization-induced influx as there was no effect on resting Ca^{++} accumulation. The increases in Ca^{++} influx were observed with all depolarizing stimuli and at all time periods up to 4 minutes. Results obtained with synaptosomes isolated from animals challenged with 4 LD_{50}'s of soman were essentially identical to those collected from animals which had received a single LD_{50} dose. Ca^{++} influx in synaptosomes from animals treated with atropine and HI-6 alone was not significantly different from untreated rats. It is noteworthy that this increase in depolarization-induced Ca^{++} influx occurs at a time when there is a significant degeneration of certain central neurons.

32.4 INCREASING THE INTRACELLULAR CONCENTRATION OF cAMP REDUCES CA-DEPENDENT INACTIVATION OF CA CHANNELS. D. Kalman*, P. O'Lague and D. Armstrong*. Department of Biology, UCLA, Los Angeles, CA 90024.

Patch-clamp studies of a cell line (GH_3) derived from a rat pituitary tumor have revealed a class of voltage-activated Ca channels that inactivate reversibly when channel opening results in Ca ion entry and accumulation inside the cell (Kalman et al., Biophys.J. 51:432a, 1987). Like the Ca channels in many other cells, these dihydropyridine-sensitive channels stop responding to depolarization altogether when the cytoplasmic side of the membrane is exposed to standard saline solutions. Both inactivation and the washout that occurs in dialyzed cells can be slowed, but not prevented, by buffering the concentration of intracellular Ca ions below 0.1 µM. Given the similarity in their dependence on Ca, and the observation that washout in cell-free patches from GH_3 cells can be reversed by cAMP dependent phosphorylation (Armstrong & Eckert, PNAS 84: 2518 2522, 1987), we have investigated the effects of altering cAMP levels on the Ca-mediated inactivation of Ca current in GH_3 cells. Whole-cell recordings of the dihydropyridine-sensitive Ca current were obtained during voltage steps from -40 mV with patch clamp pipettes filled with 140 mM CsCl, 10 mM HEPES (pH 7.2) and 2 mM $MgCl_2$. Increasing the effective intracellular concentration of cAMP, either 'directly' with dibutyryl cAMP (2 mM), or indirectly by activating adenylate cyclase with forskolin (10-50 µM) or vasoactive intestinal peptide (VIP, 100 nM), quickly increased the peak Ca current. Although the Ca current continued to wash out, currents of equal magnitude inactivated much more slowly after cAMP levels had been increased. Thus, a roughly equal number of Ca ions entering the cell produced less inactivation when cAMP levels were elevated. In contrast to its effects on Ca current, forskolin had a much smaller effect on the current carried by barium, which does not inactivate. The phosphorylation-dependence of Ca channel activity demonstrated here provides the cell with a dynamic mechanism for regulating Ca fluxes in response to neurotransmitters, fluctuations in the concentration of intracellular Ca, and the metabolic state of the cell. It also supports the hypothesis that Ca ions promote both inactivation and washout by stimulating calcineurin, an endogenous Ca and calmodulin-dependent phosphatase, to dephosphorylate the channel (Chad & Eckert, J.Physiol. 378:31-51, 1986). This work was supported by USPHS grant NS-08364 to Roger Eckert, GM 07185 and the Greater Los Angeles Affiliate of the American Heart Association.

32.5 OPIOID AND ADRENERGIC MODULATION OF CALCIUM CURRENTS IN NEURONS FROM THE RAT MYENTERIC PLEXUS. M. Sturek*, L.D. Hirning* and R.J. Miller (SPON: B.H. Wainer) Dept. of Pharmacol. and Physiol. Sci., Univ. of Chicago, 947 E. 58th St. Chicago, IL 60637

Neurons of the myenteric plexus contain a multitude of neurotransmitter /neuromodulator substances. Several of these, including the opioid peptides and norepinephrine, have been suggested to have prominent roles in the inhibitory tone of the intestine. The modulation of Ca^{++} influx into nerves has been proposed as a mechanism of action by which neuromodulators alter release of neurotransmitters. In the present studies, neurons from the myenteric plexus of neonatal rats were dissociated from the small intestinal longitudinal muscle using a collagenase/dispase enzyme treatment (variation of the method of Nishi and Willard, Neuroscience 16:187, 1985). These neurons usually grew as single cells with a single large process and were specifically chosen to maintain consistent morphology. Ionic currents were studied using the patch clamp technique in the whole cell configuration. When depolarized to 0 mV from a holding potential (HP) of -100 mV in a 2 mM Ca^{++}, Tyrode's solution, these cells displayed a large fast inward Na^+ current and a prominent outward K^+ current. The K^+ current appeared to have two phases, a transient outward current which resembled the I_A of molluscan neurons and a more sustained delayed rectifier type current. The I_A was not TEA sensitive but was blocked by 4-AP (5 mM). Approximately 50% of the delayed outward current was also shown to be Ca^{++} activated as indicated by the reduction in the current after addition of 20 μM Cd^{++} to the external solution. After replacement of K^+ in the pipet with Cs^+ only the inward ionic currents were observed. Substitution of TEA for Na^+ abolished the fast inward Na^+ current. The remaining inward current was completely blocked by the addition of 20μM Cd^{++} in the external solution, confirming that this was a Ca^{++} current. The current appeared to have two components, an inactivating portion evident from HP=-100 mV and a sustained portion which was more prominent at more depolarized HP (-50 mV). These are very similar in appearance to the 'N' and 'L' currents described by Nowycky et al., (Nature 316:440, 1985). Nitrendipine (5 μM) had no effect on the calcium currents evoked from a HP of -100 mV. Surprisingly, from a HP of -50 mV, the currents evoked by test pulses to 0 mV were inhibited by only 10 ± 8% (mean ± S.E.M.) by 5 μM nitrendipine. Only when the HP was -30 mV (or more positive) was a significant effect of nitrendipine observed. However, ω-conotoxin (1 μM; 3 min exposure) had dramatic inhibitory effects on both phases of the whole cell calcium current. The inactivating phase was inhibited by 75 ± 7% while the more sustained current was inhibited by 47 ± 12%. The most remarkable characteristic of the currents in these cells was the modulation by neurotransmitters. Addition of the opioid peptide dynorphin (1-17) (3 μM) to the external solution produced a 61 ± 5% inhibition of the inactivating phase of the current. The sustained current appeared slightly less sensitive but was modestly inhibited 29 ± 8% when compared to control. These results are suggestive of the presence of κ-opioid receptors on these neurons. Similarly, norepinephrine (50 μM) inhibited the inactivating current by 43 ± 9% whereas the sustained current was only inhibited by 18 ± 10%. For both dynorphin and norepinephrine, it is obvious that the inactivating ('N' type) current is predominantly affected. Our previous studies have demonstrated that the 'N' type current contributes most of the calcium required for transmitter release in sympathetic neurons. The present data suggest that norepinephrine and the opioids may alter intestinal motility by inhibition of Ca^{++} influx via 'N' type channels into myenteric plexus nerve cells thus reducing neurotransmitter release.

32.6 G-PROTEIN ACTIVATION MODIFIES CALCIUM CHANNEL LIGAND ACTION ON WHOLE CELL CALCIUM CHANNEL CURRENTS. R.H. Scott* and A.C. Dolphin* (SPON: I. Harrow) Dept Pharmacology, St George's Hospital Medical School, London SW17 ORE, UK.

Voltage-dependent calcium channel currents were recorded (using Ba^{2+} as charge carrier) from cultured rat dorsal root ganglion neurones using patch pipettes (1-3MΩ) containing, inter alia, 2mM ATP Mg and 0.5mM GTP-γ-S. We have previously shown that the relatively non-hydrolysable GTP analogue (GTP-γ-S) inhibits calcium channel currents (J. Physiol. (1987) 386 1-17). The transient component appears to be particularly sensitive, and the sustained calcium channel current remaining in the presence of GTP-γ-S can be potentiated by Bay K 8644 (1μM), suggesting L-type channel activity underlies this slowly activating non-inactivating (T_{inact}>400ms) current.

The inhibitory actions of nifedipine (5μM), D_{600} (10μM) and diltiazem (30μM) on calcium channel currents activated from V_H -80mV, were masked in the presence of internal GTP-γ-S. Calcium channel currents modified by GTP-γ-S were enhanced by the calcium channel ligands. D_{600} induced an initial 4.3 fold (n=7) increase in the calcium channel current in the presence of intracellular GTP-γ-S. This decayed to a 2.9 fold (n=5) increase after 5 minutes application of D_{600}. This potentiation was prevented by pretreating the neurones with pertussis toxin. Depolarizing V_H from -80mV to -30mV resulted in control calcium channel currents being more rapidly inhibited by the calcium channel ligands. At V_H -30mV calcium channel ligands induced a biphasic action on GTP-γ-S modified currents. The slower inhibitory action which followed the initial potentiation was rapidly reversed by hyperpolarizing V_H to -80mV, subsequent currents were potentiated relative to those prior to application of the ligands.

In conclusion all three classes of calcium channel ligand have receptor sites which appear to be functionally linked with the site where activated G-protein associates with calcium channels. Interaction of activated G protein with L calcium channels may induce a functional switch, promoting the agonist action of calcium channel ligands.

32.7 THE ACTION OF PHOTOACTIVATABLE GTP ANALOGUES ON CALCIUM CHANNEL CURRENTS IN CULTURED DRGS J.F. Wootton*, D.R. Trentham*, A.C. Dolphin* and R.H. Scott* (SPON: D. Tapper) Dept of Pharmacology, St George's Hospital Medical School, London; Div. Physical Biochem, NIMR, London, U.K. and Dept of Physiology, Cornell University, Ithaca, N.Y.

Photoactivatable (caged) analogues of GTP were synthesized using the 1(2-nitrophenyl)diazoethane method (J. Physiol. 377, 100P). Photolysis by a 0.5ms flash (300-350nm) from a xenon arc lamp produced 1% conversion of caged GTP-γ-S to free GTP-γ-S with a $t_{\frac{1}{2}}$ of about 10ms.

Caged GTP-γ-S (2mM) was included in Cs acetate patch solution used to fill pipettes of 1-3MΩ resistance. Prior to photolysis, caged GTP-γ-S did not alter the characteristics of whole cell calcium channel currents recorded using 2.5mM Ba^{2+} as charge carrier. Calcium channel currents were then activated every 30 to 60 s following a single flash; the currents were reduced in amplitude with the $t_{\frac{1}{2}}$ for reduction of the peak current being 1.5±0.2 min (n=5). The peak and sustained currents were inhibited 5 minutes after the flash by 70% and 50% respectively, and the transient component of the peak current was usually completely abolished. Illumination of the cell in the absence of caged compound had no effect on the calcium channel currents, and the action of photochemically released GTP-γ-S was inhibited by preincubating the DRG neurones with pertussis toxin.

Photochemically liberated GMP-PNP also abolished the transient component of the calcium channel current activated by a voltage step command from -80mV to 0mV; the maximum current activated from V_H -30mV was reduced to a smaller extent.

In conclusion, caged guanine nucleotide analogues offer useful tools to examine the role of guanine nucleotide binding (G) proteins in regulating ion channels. Data from this study suggests that G-proteins with different affinities for GTP analogues or different GDP dissociation rates may be associated with different classes of calcium channel. The N-type channels which underlie the transient component of the maximum calcium channel current appear to be more sensitive to inhibition by guanine nucleotide analogues, but it is likely that in DRGs the L channels underlying the sustained component of the current are also inhibited by G protein activation.

32.8 AUGMENTATION OF BURSTING PACEMAKER ACTIVITY BY THE APLYSIA NEUROPEPTIDE ELH IS MEDIATED BY A CYCLIC AMP-DEPENDENT INCREASE IN CALCIUM AND POTASSIUM CURRENTS. Edwin S. Levitan, Richard H. Kramer*, and Irwin. B. Levitan. Graduate Department of Biochemistry, Brandeis University, Waltham, MA 02254

Neurotransmitters and hormones often cause complex changes in the pattern of electrical activity of neurons. However, the ionic and intracellular mechanisms of these changes are not well understood. For example, it has been shown previously that release of the neuropeptide egg-laying hormone (ELH) from Aplysia bag cell neurons augments the endogenous bursting pacemaker activity of neuron R15. ELH increases the number and frequency of spikes during bursts of action potentials, and also increases the amplitude of the interburst hyperpolarization of R15 (Mayeri et al., (1985) J. Neurosci. 5:2060-2077).

We have studied the ionic mechanisms underlying the effects of ELH in voltage-clamped R15 neurons. Both electrical discharge of the bag cells, which releases endogenous ELH, and application of synthetic ELH on cell R15, result in an increase in two discrete ionic currents. One of these currents activates with hyperpolarization, reverses near the K^+ equilibrium potential, is sensitive to the external K^+ concentration, and is blocked by addition of 5 mM Rb^+ or 1 mM Ba^{2+} to the bathing medium. This current appears to be identical to the inwardly rectifying K^+ current, I_R. The other current activates with depolarization, and is blocked by replacement of external Ca^{2+} with Co^{2+} or Mn^{2+}. This current appears to be a voltage-gated Ca^{2+} current, I_{Ca}. Hence ELH enhances two ionic currents, a Ca^{2+} current and a K^+ current. We propose that the ELH-induced increases in the depolarizing and the hyperpolarizing phases of bursting activity are due to the regenerative activation of I_{Ca} and I_R, respectively.

I_{Ca} and I_R in R15 have previously been shown to be enhanced by the neurotransmitter serotonin (5-HT), acting via intracellular cyclic AMP. We now report that increasing cyclic AMP in R15, by applying either serotonin, or the adenylate cyclase activator forskolin, mimics and occludes the action of ELH on neuron R15. Furthermore, application of ELH increases the cyclic AMP content of single R15 neurons by 71% over untreated R15 neurons, as measured by radioimmunoassay. Finally, the effects of ELH on I_{Ca} and I_R are potentiated by isobutylmethylxanthine, a phosphodiesterase inhibitor. These results suggest that the effects of ELH on neuron R15 are mediated by cyclic AMP.

This work was supported by NIH grant NS17910 to IBL.

32.9 PROTEIN KINASE C INHIBITORS PREVENT THE PHORBOL ESTER-INDUCED INCREASE IN CALCIUM CURRENT IN APLYSIA BAG CELL NEURONS. P. J. Conn, J. A. Strong, and L. K. Kaczmarek, Departments of Pharmacology and Physiology, Yale Univ. Sch. of Med., 333 Cedar Street, New Haven, CT 06510.

Stimulation of an afferent input to the peptidergic bag cell neurons of Aplysia induces a 30 minute afterdischarge of action potentials. This results in secretion of peptides which initiate egg-laying behavior. The afterdischarge is accompanied by enhancement of height and width of action potentials and by increases in cAMP concentrations and phosphoinositide hydrolysis.

Previous work has shown that activators of protein kinase C (PKC) and injection of PKC enhance the height of evoked action potentials in bag cell neurons grown in primary culture. Whole cell voltage clamp experiments showed that PKC activators increase Ca currents (ICa) without altering K currents. Cell attached single channel studies indicated that the increased ICa is mediated by expression of a previously covert Ca channel. Control cells have single class of Ca channel with a conductance of 12 pS. After treatment with PKC activators such as 20 nM TPA (12-O-tetradecanoyl-phorbol-13- acetate) or dioctanoyl glycerol, a second class of channel appears with a conductance of 24 pS. Control and TPA-induced ICa have very similar voltage dependence, kinetics, and pharmacological profiles.

We now present evidence that the small and large conductance channels may be differentiated on the basis of their sensitivity to two structurally distinct PKC inhibitors, H-7 (1-[5-isoquinolinesulfonyl]-2-methylpiperazine) and sphinganine. In cells impaled with a single microelectrode, TPA increased the height of stimulated action potentials. Subsequent addition of H-7 (100 μM) reversed the effect of TPA within 30 minutes. Furthermore, H-7 and sphinganine inhibited the TPA-induced increase in ICa measured under voltage clamp. Using the whole-cell patch clamp technique in cells internally dialysed with TEA- and Cs-aspartate, we observed voltage-activated ICa which peaked at 20 mV. Pretreatment with TPA increased ICa at all potentials. Prior addition of sphinganine (10 μM) inhibited TPA's effect (peak ICa densities (nA/nF): control= 6.6±1.0; TPA= 15.4±1.5; TPA ± sphinganine= 6.1±0.9). H-7 (100 μM) also inhibited TPA's effect (control= 8.3+1.2; TPA= 18.4+2.7; H-7 + TPA= 12.1±0.9). In the absence of TPA, ICa was not affected by H-7 (control= 7.0±1.1; H-7= 6.0±1.4) or sphinganine (control= 6.1±0.8, sphinganine= 5.7±1.5). This is consistent with the finding that the large conductance Ca channels were never observed in control cells, and suggests that basal levels of PKC activity are very low in these neurons.

These data support the hypothesis that the unmasking of the covert calcium channel is mediated by PKC. We are currently using these inhibitors to investigate the role of PKC induced calcium channels in the prolonged changes in excitability that occur in bag cell neurons.

32.10 INOSITOL 1,4,5-TRISPHOSPHATE (IP3) REDUCES THE VOLTAGE-DEPENDENT CALCIUM CURRENT OF APLYSIA BURSTING NEURONS. J. H. Byrne and K. P. Scholz, Department of Neurobiology and Anatomy, The University Texas Medical School, Houston, TX. 77225.

The left upper-quadrant bursting (LUQB) neurons of Aplysia display a regular burst-firing pattern of activity which is associated with fluctuations in the level of intracellular Ca. Because of the sensitivity of this bursting rhythm and several membrane conductances to intracellular Ca, neurotransmitters that alter the homeostasis of intracellular Ca could have profound effects on the generation of pacemaker activity. In view of this, we have begun to study the membrane currents modulated by intracellular pressure injection of IP3, a second messenger implicated in the release of Ca from intracellular stores.

Injection of IP3 into LUQB cells voltage-clamped within the pacemaker potential region (-35 to -50 mV) yielded a biphasic response which lasted 5-15 minutes and consisted of an early inward current followed by a slow outward shift in holding current. The outward current corresponds to a slowing of the bursting frequency and hyperpolarization in unclamped neurons. Control injections of D-myo-Inositol yielded no consistent response. Furthermore, the response was not due to contamination of the IP3 sample by Ca ions, since the response to injection of Ca did not mimic the time course of the response to IP3.

We have studied the slow outward current in over 100 cells at constant holding potentials and with small depolarizing pulses. The IP3-induced slow outward current was abolished by intracellular iontophoresis of EGTA but was insensitive to high concentrations of TEA that blocks I(K,Ca) in these cells. However, it is blocked by divalent cations (Co, Ni) that block the Ca current. These results suggest that IP3 causes release of intracellular Ca which inactivates the steady-state Ca current present within the pacemaker range of potentials.

To test this hypothesis further, small depolarizing pulses were elicited in cells that had been axotomized within 200 um of the soma and bathed in a solution that blocks outward currents. Depolarizing pulses (4 mV) yielded non-inactivating calcium-currents. This voltage-dependent Ca current was reduced following injection of IP3. These effects of IP3 were also abolished by intracellular EGTA. In addition, both the voltage-dependent inward current and the response to IP3 were blocked by ASW containing 15 mM Ni or 30 mM Co. These data indicate that IP3 decreases the Ca current of the LUQB cells by releasing intracellular stores of Ca and inducing Ca-dependent inactivation of the Ca current. The decreased Ca current appears to be responsible for the slowing of the bursting frequency that is seen in response to IP3 in unclamped cells.

32.11 EFFECTS OF INOSITOL TRISPHOSPHATE (IP3) AND ACTIVATORS OF PROTEIN KINASE C (PKC) ON TAIL MOTOR NEURONS OF APLYSIA. M. Sawada*, L. Cleary and J. H. Byrne (SPON: J. Wood). Department of Neurobiology and Anatomy, The University of Texas Medical School, Houston, TX 77225.

In the nervous system of Aplysia, the modulatory effects of cAMP have been established in several monosynaptic reflex pathways. Little is known, however, regarding the function of other second messenger systems in these reflexes. We have begun to examine a possible role for the inositol phospholipid pathway in motor neurons mediating the tail withdrawal reflex. The effects of both IP3 and an analogue of diacylglycerol (DAG) on membrane conductance were examined after intracellular injection.

Injection of 1.4 mM IP3, but not 10 mM myo-inositol, into motor neurons voltage-clamped at their resting potential produced an outward current that was associated with an increase in input conductance. The voltage-dependence, reversal potential and sensitivity to alterations of extracellular K suggested that the response to IP3 was due to an increased conductance to K.

One mechanism that could account for the outward current is activation of the Ca-dependent K current (Ik,ca) by Ca released from intracellular stores. Indeed, injection of 10 mM CaCl2 produced an increased conductance outward current virtually identical to that produced by IP3. Moreover, extracellular application of TEA at concentrations known to block Ik,ca (5mM) blocked these outward currents.

The other product of inositol phospholipid hydrolysis is DAG. Injection of 30 μM 1-oleoyl-2-acetylglycerol (OAG), an analogue that mimics DAG's effects on PKC, produced an inward current that did not appear to alter membrane input conductance. A similar effect was produced by injection of 200 uM phorbol 12,13-dibutyrate (PDBu), another activator of PKC. Since IP3 and DAG are generated together, one might expect that their effects are interrelated. To test this possibility, either OAG or PDBu was injected in short pulses that did not affect holding current. This treatment reduced the amplitude of the outward current produced by subsequent injection of either IP3 or Ca. Therefore, PKC appears to inhibit the ability of Ca to activate Ik,ca.

These results indicate that changes in phospholipid metabolism may modulate the properties of motor neurons mediating the tail withdrawal reflex. The receptor-mediated hydrolysis of inositol phospholipids would result in a hyperpolarization produced by IP3. Activation of PKC by DAG would tend to oppose that hyperpolarization.

32.12 **IP3 AND IP4 MIMIC ANTIGEN ACTIVATION OF A DEPOLARIZING CONDUCTANCE IN A RAT MAST CELL LINE.** S.V.P. Jones*, J.R. Cunha-Melo*, M.A. Beaven* and J.L. Barker. (SPON: P.A. St. John). Lab. of Neurophysiology, NINCDS and Lab. of Chemical Pharmacology, NHLBI, National Institutes of Health, Bethesda, MD 20892.

Stimulation of IgE-primed rat basophillic leukemia cells (RBL2H3) by antigen (DNP/BSA 10 ng/ml) induces time-dependent changes in inositide metabolism, cytoplasmic Ca^{2+} concentration and secretion of histamine. Using the whole-cell patch-clamp technique, DNP was shown to activate a time-dependent change in membrane conductance in RBL2H3 cells at room temperature. A similar membrane conductance was activated in the absence of antigen stimulation when inositol-1,4,5-trisphosphate (IP3) (10 μM) or inositol-1,3,4,5-tetrakisphosphate (IP4) (10 μM) was included in the patch pipette recording solution. Control recordings did not demonstrate any significant conductance changes over a 1 hour period.

Under current-clamp conditions, with KCl-filled patch pipettes, DNP stimulated and inositol loaded cells depolarized over a 5-10 minute period from resting membrane potentials of -65 to -75 mV to potentials in the range -15 to 0 mV. The depolarization persisted for a further 10-15 minutes, followed by repolarization to near resting potential.

Under voltage-clamp conditions, either DNP, IP3 or IP4 induced a time-dependent, reversible inward current at resting potentials. Current-voltage (I-V) plots showed that the current reversed polarity between -45 and -75 mV when recorded with patch pipettes containing K^+-gluconate and at around -10 mV when recorded with KCl-filled pipettes. Although these results suggest that the current is carried predominantly by Cl^- ions, replacement of nearly all of the Cl^- ions on both sides of the cell membrane with methane-sulphonate did not depress the current response.

Increasing the calcium concentration in the bathing medium from 1to 10 mM increased the magnitude of the DNP- or inositol-induced current responses. The current was blocked by 5 mM $CoCl_2$ or by 5 mM $BaCl_2$ but was insensitive to 20 mM TEA or 2 mM 4-AP. Replacement of K^+ in the pipette solution by N-methyl glucamine did not alter the current characteristics nor did reduction of the Na^+ concentration in the bathing medium to 5 mM.

Thus, DNP activates a conductance in which calcium and chloride are implicated as charge carriers. IP3 and IP4 are probably the mediators of the DNP-induced activation of the above conductance, which may be important in secretion of histamine from RBL cells.

32.13 CADMIUM ANTAGONIZES SODIUM CHANNEL AGENT-MEDIATED PHOSPHOINOSITIDE BREAKDOWN IN SYNAPTONEUROSOMES. F. Gusovsky, E. McNeal* and J.W. Daly. LBC, NIDDK, NIH, Bethesda, Md. 20892

Agents that increase intracellular concentrations of Na^+ stimulate phosphoinositide breakdown in guinea pig cerebral cortical synaptoneurosomes. Scorpion venom (Leiurus quinquestriatus) and pumiliotoxin B, which induce increases in influx of $^{22}Na^+$ in synaptoneurosomes, stimulate phosphoinositide breakdown and both effects are inhibited by tetrodotoxin (TTX). Batrachotoxin (BTX) and veratridine (VT), which cause a large increase in influx of $^{22}Na^+$ through activation of voltage-dependent sodium channels, induce a dose-dependent increase in phosphoinositide breakdown that is shifted to the right in the presence of 5 μM TTX. BTX- and VT-elicited influx of $^{22}Na^+$ into synaptoneurosomes is virtually completely blocked by 5 μM TTX. Agents that block voltage-dependent calcium channels, such as D-600, nifedipine and Co^{2+}, do not inhibit either influx of $^{22}Na^+$ or stimulation of phosphoinositide breakdown elicited by scorpion venom, pumiliotoxin B or BTX. Cadmium ions (200 μM), which are known to block TTX-resistant sodium channels, block phosphoinositide breakdown induced by agents that activate sodium influx through sodium channels. Cadmium blocks BTX-induced phosphoinositide breakdown with an IC_{50} value of 48 μM, while blocking BTX-induced $^{22}Na^+$ influx in synaptoneurosomes with lower potency (IC_{50}: 650 μM). However, in the presence of 0.5 μM TTX, the IC_{50} for Cd^{2+} inhibition of BTX-induced $^{22}Na^+$ influx is 70 μM. Neither TTX nor Cd^{2+} antagonize neurotransmitter- or monensin-induced phosphoinositide turnover. It appears likely that BTX-induced phosphoinositide turnover in guinea pig synaptoneurosomes is dependent primarily on activation of TTX-resistant, Cd^{2+}-sensitive sodium channels that account for only a small fraction of the total sodium influx induced by BTX in synaptoneurosomes.

32.14 THE EFFECTS OF INOSITOL PHOSPHATE DERIVATIVES ON MEMBRANE DEPOLARIZATION IN THE XENOPUS OOCYTE. B.J. Stith* and W.R. Proctor. Dept. of Pharmacology, Univ. of Colo. Hlth. Sci. Cntr., Denver, CO 80262

Inositol phosphate compounds are now recognized as important second messengers in many cell systems. For comparison of inositol phosphate action in an intact cell, a cell was required that readily withstands multiple impalements by microelectrodes. The Xenopus oocyte was chosen because of its large size (1.3 mm in diameter) and well-studied membrane characteristics.

Oocytes were prepared by manual removal of the follicular layer and maintained at 22-23°C in modified Ringer's media (O-R2). Stock concentrations (100-300 uM) of inositol trisphosphate (IP3), inositol tetrakisphosphate (IP4), and cyclic-inositol trisphosphate (cIP3, gift from P. Majerus) were pressure-injected (Picospritzer II, General Valve) into oocytes while the membrane potential was continuously monitored via an intracellular recording microelectrode. Calibration curves were constructed for each micropipette by varying the time (5-5000 msec) of pressure application and measuring the resulting drop diameter. This was done before and after oocyte impalement to allow calculation of the intracellular inositol phosphate concentration.

All three inositol phosphate compounds produced an early (D_1) and late (D_2) membrane depolarization. The introduction of one of these derivatives, IP3, into oocytes has been reported to cause similar early and late depolarizations, which were determined to be the result of an increase in intracellular calcium and subsequent opening of calcium-dependent chloride channels. In the present investigation, the dose-response relationship of each inositol phosphate was determined by the intracellular concentration (EC_{50}) that produced a half-maximal late depolarizing response (D_2). The mean EC_{50} ± s.e.m. and the number of cells (n) tested for each compound were as follows: IP3, 88 ± 16.5 nM (n=10); cIP3, 86 ± 29 nM (n=7); and IP4, 3440 ± 1230 nM (n=7).

Microinjection of calcium chloride mimicked the early and late depolarizations. Coinjection of EGTA with each inositol phosphate derivative blocked these responses. Injection of inositol 1-phosphate (IP) alone produced no detectable membrane potential changes. Therefore, these results suggest that IP3, cIP3 and IP4 can each trigger an increase of intracellular calcium that results in an increase in chloride efflux. Although IP4 is capable of producing this effect, it must be present at a 40-fold higher concentration than IP3 or cIP3.

32.15 EVIDENCE THAT DIACYLGLYCEROL MODULATES ACTION POTENTIAL FREQUENCY IN GH_3 CELLS STIMULATED WITH THYROTROPIN RELEASING HORMONE: CORRELATIVE BIOCHEMICAL AND ELECTROPHYSIOLOGICAL STUDIES. C.M. Gammon*, G.S. Oxford*, A.C. Allen*, K.D. McCarthy*, P. Morell. Departments of Biochemistry, Physiology, Pharmacology, and the Biological Sciences Research Center, Univ. of North Carolina, Chapel Hill, NC 27514

Thyrotropin Releasing Hormone (TRH) elicits a transient hyperpolarization followed by increased action potential frequency in GH_3 pituitary tumor cells. The time course of the electrophysiological response is correlated with increased intracellular calcium and prolactin secretion.

Cultured GH_3 cells were radiolabeled for 24 hours with either [^{3}H] myo-inositol (24 uCi/ml, to label phosphoinositides and inositol phosphates) or [^{3}H] arachidonate (0.2 uCi/ml, to label diacylglycerol and phosphatidic acid). Cells were harvested, washed to remove unincorporated radiolabel, and resuspended in tissue culture medium. Aliquots of the cell suspension were stimulated with 1.0 uM TRH for time intervals from 5 seconds to 3 minutes. Stimulation was terminated by organic extraction of lipids and inositol phosphates. Mono-, di-, and tri-phosphoinositides, diacylglycerol, and phosphatidic acid were resolved from each other and from other lipids by thin layer chromatographic (TLC) procedures. Inositol phosphates were separated by anion exchange high performance liquid chromatography. Stimulation with TRH resulted in significant increases in inositol 1,4,5-trisphosphate within seconds with a return to control levels by 1 minute. Increases in other inositol phosphates were also observed. Phosphoinositide analysis revealed corresponding decreases in phosphatidylinositol 4-phosphate and phosphatidylinositol 4,5-bisphosphate. In contrast to the transient increase in inositol 1,4,5-trisphosphate, stimulation with TRH also resulted in significant increases in diacylglycerol and phosphatidic acid which were sustained for several minutes. The time course of diacylglycerol and phosphatidic acid accumulation correlates with that observed for increased action potential frequency after TRH stimulation.

In order to investigate the role of diacylglycerol as a mediator of the TRH induced electrophysiological response, 1-oleoyl-2-acetyl-glycerol (OAG) (60 uM) and phorbol 12,13-dibutyrate (2 uM) were administered to GH_3 cells by a U-tube apparatus during patch clamp recording in the current clamp, whole-cell configuration. Both OAG and the phorbol ester increased action potential frequency in a manner similar to TRH. These results suggest that diacylglycerol produced in GH_3 cells in response to hormone acts to increase action potential frequency through a protein kinase C mediated event.

32.16 MULTIPLE EFFECTS OF ACTIVATION OF PROTEIN KINASE C IN THE RAT SPINAL DORSAL HORN. G. Gerber*, P. D. Ryu* and M. Randic (SPON: N. Myslinski). Dept. of Vet. Physiol. and Pharmacol., Iowa State University, Ames, IA 50011.

Protein kinase C (PKC), a calcium and phospholipid-dependent kinase is present in high concentration in the nervous system, where it has been shown to phosphorylate its substrates at the low levels of Ca ions present in resting cells. Kinase C activity is dependent upon intracellular levels of the second messenger, diacylglycerol (Nishizuka, Y., Science 225:1365, 1984). This action of diacylglycerol is mimicked by membrane-permeant, tumor-promoting phorbol esters. Since PKC activation can be mediated directly by phorbol esters, in the absence of phosphoinositide breakdown, we used these agents to examine the effects of such activation on electrophysiological properties of rat spinal dorsal horn neurons and fast and slow excitatory synaptic transmission.

Rats 14-20 days were used. Transverse or horizontal spinal cord slices, the latter with attached dorsal roots and ganglia were made. Cells were activated either directly with current injection via the bridge circuit, or synaptically by electrical stimulation of a lumbar dorsal root or dorsal root ganglion neurons. 4β-Phorbol-12, 13-dibutyrate and 4 -Phorbol-12, 13-diacetate, two phorbol analogues known to activate PKC, and synthetic diacylglycerol (1,-oleoyl-2 acetylglycerol, OAG) were applied by bath perfusion. Standard techniques were used for intracellular recording.

Phorbol esters (10^{-7} to 10^{-6}M for 10-20 min) produced a small, but prolonged membrane depolarization accompanied by an increase in input resistance and frequency of presumptive spontaneous synaptic potentials. In a smaller number of cells slow spontaneous action potential firing was also elicited. Low concentrations of phorbol esters reduced the amplitude of the slow phase of afterhyperpolarization and markedly increased rate of neuronal firing in response to a prolonged depolarizing pulse. With higher concentrations of phorbol esters, however, the dorsal horn neurons showed an enhancement in accommodation as manifested by a decline of the frequency of spike discharge. In the presence of TTX and TEA, phorbol esters or OAG produced a reversible decrease in the duration of calcium spikes. In addition, phorbol esters caused a marked and long-lasting increase in the amplitude and duration of both fast and slow excitatory postsynaptic potentials. The increase in the e.p.s.p.s often occurred in the absence of any change in membrane potential or when corrections were made for the change in resting membrane potential. Our results suggest that both the synaptic transmission and some of the membrane properties of rat dorsal horn neurons might be regulated through the C-kinase system and this modulation may have physiological relevance.

32.17 A NOVEL CALCIUM CURRENT IS ACTIVATED BY HYPERPOLARIZATION IN PARAMECIUM TETRAURELIA. T.M. Hennessey*. Dept. of Biol. Sci., State Univ. of N.Y. at Buffalo, Buffalo, N.Y. 14260. (SPON. Dr. M. Hudecki).

A new type of Ca++ current, a hyperpolarization-induced Ca++ current, is the Ca++ source for the Ca++-dependent K+ current which produces the "anomolous rectification" seen in response to hyperpolarizations in a solution containing 4.0mM K+ and 1.0mM Ca++. The hyperpolarization activated K+ current can be eliminated by: 1. EGTA injection, 2. A mutant with a defective Ca++-dependent K+ current (pant A), 3. Substitution of Mg++ for Ca++ in the bath, or 4. Removal of K+. Therefore, the K+ current seen upon hyperpolarization is a Ca++-dependent K+ current.

The hyperpolarization-induced Ca++ current is isolated for voltage clamp analysis by the use of 2M CsCl electrodes and $Ca(OH)_2$ only in the bath. Replacement of external OH^- with Cl^- does not affect this current. This inward Ca++ current is transient, peaking at $2.9\pm.90$ nA during the first 50-100 msec. of a 500 msec. voltage step from -40 to -100mV, but a sustained inward current of $-1.2\pm.45$ nA persists at 500 msec. Neither component of this Ca++ current is blocked by verapamil, nifedipine, diltiazem, or W-7 but both are blocked completely by high Mg++. Twin 100 msec pulses were used to show that the time constant for this inactivation is about 780 msec. The inactivation is removed by EGTA injection, suggesting a Ca++-dependent inactivation process. Two different Ca++ channels have been well described in Paramecium, an anterior mechanosensory and a ciliary voltage dependent Ca++ channel. The first is not blocked by Mg++ and is on the body membrane while the second is on the cilia and is eliminated by deciliation or by the pwB mutation. The hyperpolarization-induced Ca++ current is present in both the pwB mutant and in deciliated wild type. This suggests that this Ca++ current is on the body but it may also be on the ciliary membrane. This inward Ca++ current represents a new route for Ca++ entry in Paramecium. The role of the hyperpolarization-induced inward Ca++ current may be to help maintain a steady resting membrane potential by activation of the repolarizing Ca++-dependent K+ current during large hyperpolarizations.

PAIN MODULATION I

33.1 VAGAL AFFERENT MODULATION OF A NOCICEPTIVE REFLEX IN RATS. Ke Ren, Alan Randich and G.F. Gebhart. Department of Pharmacology, University of Iowa, Iowa City, Iowa 52242.

The vagus nerve is composed of approximately 80% afferent fibers. The physiological significance of these afferents is not completely understood, although accumulating evidence suggests a role in the modulation of nociception. In this study, modulation of the nociceptive tail flick (TF) reflex by vagal afferent stimulation (VAS) was parametrically characterized and spinal neurotransmitters mediating the descending inhibition examined.

Rats were anesthetized with pentobarbital (50 mg/kg) for cannulation of the femoral vein and artery and isolation of the right cervical vagus nerve via a dorsal approach. Following surgery, rats were subsequently maintained in a lightly anesthetized state (corneal and flexion reflexes present) with pentobarbital (3-6 mg/kg/hr iv). The proximal portion of the cut vagus nerve was electrically stimulated; pulse width (0.01-2.0 ms), frequency (1-50 Hz), intensity (5-100 μA) and the duration of continuous VAS were systematically varied to determine optimal parameters of VAS for inhibition of the TF reflex.

VAS at 2 ms pulse width and 20 Hz inhibited the TF reflex at lowest intensities of stimulation. The mean inhibitory threshold (T) intensity of VAS @ 2 ms, 20 Hz was 60 ± 3.3 μA. Subthreshold VAS (0.2-0.5 T) facilitated the TF reflex while 16 T was required to inhibit the TF reflex at 0.01 ms, 20 Hz VAS. The effect of VAS at T outlasted stimulation by 10-20 s. VAS generally produced a depressor effect (20.5 mmHg, n=43), but occasionally produced a pressor effect (20.7 mmHg, n=6) or no change in blood pressure (n=3). Subdiaphragmatic VAS also inhibited the TF reflex and always produced a pressor effect. Thus, inhibition of the TF reflex by VAS is independent of its effects on blood pressure.

The intensity of VAS to inhibit the TF reflex was significantly increased by the intrathecal administration of naloxone in a dose-dependent manner (5-20 μg) or a combination of phentolamine and methysergide (30 μg each), but not by phentolamine (15-30 μg) or methysergide (15-30 μg) given alone.

These results suggest that vagal afferents have a modulatory influence on nociception that may be either facilitatory or inhibitory depending on the intensity of stimulation, perhaps reflecting an influence on different fibers in the nerve. VAS engages a spinal opioid system and may simultaneously coactivate descending serotonin and noradrenergic systems. Supported by NS 19912 and DA 02879.

33.2 PERIAQUEDUCTAL GREY (PAG) INHIBITION OF CARDIAC INPUT TO T_2- T_6 SPINAL CELLS IN CATS. M.J. Chandler, D.W. Garrison, T.J. Brennan and R.D. Foreman, Depts. of Physiology & Biophysics and Allied Health Education, Univ. of Okla. HSC, Okla. City, OK 73190.

Stimulation of the periaqueductal grey (PAG) area of the brain produces analgesia and inhibits activity of lumbar cord neurons that respond to noxious somatic input. The present study examined the effects of PAG stimulation on thoracic cord dorsal horn neurons that responded to visceral input. Our hypothesis was that stimulation of the PAG will inhibit thoracic cord neurons that are activated by noxious input from thoracic somatic fields and from the heart.

Adult cats were anesthetized with α-chloralose and paralyzed with pancuronium. The grey matter of the upper thoracic spinal cord (T_2-T_6) was searched with microelectrodes for neurons antidromically activated from the medullary reticular formation (RF) and for spontaneously active spinal neurons. All cells received excitatory viscerosomatic convergent input from the left forelimb triceps and from cardiopulmonary (CP) sympathetic afferents. Electrical stimulation of the PAG or the midbrain RF (100 Hz, 100 μsec, 50-500 μA) inhibited spontaneous cell activity (36 of 44 cells) and cell activity that resulted from pinching the left triceps (40 of 44 cells). Visceral input to the neurons was elicited during electrical stimulation of CP sympathetic afferent fibers and after injection of the algesic compound, bradykinin, into the left atrium. Electrical stimulation of CP sympathetic afferents increased cell activity; stimulation of the PAG and adjacent RF reduced this response (38 of 47 cells). Intracardiac injection of bradykinin excited 29 of 46 cells; electrical stimulation of the PAG or midbrain RF reduced this response to bradykinin (28 of 29 cells). The inhibitory effects of electrically stimulating these midbrain areas could have resulted from activation of fibers of passage. Therefore, the effect of glutamate microinjections into the PAG or adjacent midbrain regions was tested against spontaneous activity of 9 cells. Spontaneous activity of 5 neurons was inhibited after glutamate was injected into the PAG. Injection of glutamate into adjacent midbrain regions did not inhibit spontaneous cell activity of 4 cells.

These results demonstrate that electrical stimulation of the PAG and adjacent midbrain regions inhibits noxious visceral input from the heart as well as noxious somatic input. Responses of thoracic cord cell activity to midbrain glutamate injections suggest that a portion of this descending inhibition may be mediated by cell bodies in the PAG. (Supported by NIH grants HL 22732, HL07430 & NS08150 & OUHSC Faculty Senate Award 43038700).

33.3 VISCEROSOMATIC NOXIOUS INHIBITION (VNI) OF PRIMATE T_2-T_5 SPINOTHALAMIC TRACT (STT) CELLS: NON-LINEAR REGRESSION OF THE INHIBITION VERSUS SPONTANEOUS ACTIVITY RELATION. T.J. Brennan, U.T. Oh* and R.D. Foreman. Dept. of Physiology & Biophysics, Univ. of Oklahoma HSC, Okla. City, OK, 73190.

Our laboratory has previously shown that upper thoracic STT neurons receive convergent excitatory input from the cardiopulmonary sympathetic afferents and somatic fields of the left triceps-chest region. In this series of experiments attention was focussed on the inhibitory inputs from the urinary bladder and hamstring regions of the hindlimbs; this convergent inhibition has been named viscerosomatic noxious inhibition (VNI).

Forty-one T_2-T_5 STT cells were antidromically activated from the contralateral thalamus in 20 anesthetized monkeys. Urinary bladder distension (UBD) inhibited 33 of 41 (80%) cells, right hindlimb pinch reduced the activity of 32 of 39 (82%) and left hindlimb pinch inhibited 21 of 38 (55%). While examining these inhibitory responses, it was apparent that greater decreases in activity were observed in cells with higher spontaneous activities and at very high levels of background activity a maximal inhibitory effect was elicited. These inhibitory inputs were analyzed by plotting the decrease in activity (expressed in imp/s) elicited by a stimulus (y-axis) versus the level of spontaneous activity (x-axis) for all cells. The relation was subjected to curve-fitting analysis to quantify the inhibition versus activity relation. The data fit the equation $y=a - be^{-kx}$ (r); a represents the maximal inhibitory effect, k is the rate constant for the curve, a-b is the y-intercept, and r is the correlation coefficient.

The inhibition versus activity relation for right hindlimb pinch was described by the equation $y=19-25e^{-0.089x}$ (r=0.70) and for left hindlimb pinch by the equation $y=13-13e^{-0.065x}$ (r=0.52). Overall, right hindlimb pinch produced a greater maximum inhibitory effect and a more homogeneous response (greater r value) than left hindlimb pinch. The rate constants were similar. Curves for UBD to 40, 60, and 80 cmH_2O were described by the equations $y=24-22e^{-0.015x}$ (r=0.55), $y=22-22e^{-0.039x}$ (r=0.73) and $y=25-26e^{-0.044x}$ (r=0.81), respectively. These curves suggest that as the magnitude of the distension increases a higher rate constant and a more homogeneous response were produced. Also, further analysis showed that, for a given level of spontaneous activity, higher distending pressures produced greater inhibition.

These curvilinear relations indicate that the amount that cell activity is decreased by VNI depends upon the spontaneous firing rate of the neuron. Comparisons among the curves show apparent differences between inhibition produced by left and right hindlimb pinch and inhibitory responses caused by increasing the intensity of UBD. Supported by NIH Grants HL22732.

33.4 SOMATOSENSORY AND CARDIOVASCULAR RESPONSES TO ISCHEMIC PAIN IN HEALTHY VOLUNTEERS. W. Maixner, G.R. Bloodworth*, J.S. Smith* R.H. Gracely* and J.R. Zuniga*. Dental Research Center, Univ. of North Carolina, Chapel Hill, N.C. 27514 and Neurobiology & Anesthesiology Branch, NIDR, NIH, Bethesda, MD 20205.

The outcomes of a variety of studies support the view that peripheral hemodynamic responses can modify pain perception (Randich & Maixner Neurosci. Biobeh. Rev. 8:343,1984; ANYAS 467:385,1986; Zamir and Maixner ANYAS 467:371,1986). However, few clinical studies have evaluated the relationship between pain and alterations in peripheral hemodynamics. In the present studies, we have evaluated the relationship between peripheral hemodynamic responses to acute ischemic pain with the perception of sensory and affective components of ischemic pain.

For these studies, five healthy male volunteers were instrumented for cardiovascular monitoring: Right ankle arterial pressure (systolic = SP; diastolic = DP; mean = MP); heart rate (HR); peripheral venous pressure (VP), measured from a superficial vein in the antecubital region of the dominant forearm; forearm blood flow (FAF) and venous capacitance (VC) measurements obtained from the dominant forearm using conventional strain gauge plethysmographic procedures. Following the measurement of baseline cardiovascular parameters, ischemic pain was induced in the non-dominant arm via the submaximal effort tourniquet procedure. Cardiovascular and somatosensory responses were obtained at two minute epochs during the tourniquet procedure. Somatosensory responses were also obtained by having the subjects select weighted verbal descriptors (Gracely et al., Science 203:1261,1979) that most closely described the sensory (i.e. intensity) and affective (i.e. unpleasantness) aspects of their perceived pain. The subjects also verbalized a number between 0 and 100 that most closely described their overall pain.

Following the application of the tourniquet, there was a progressive increase in pain (intensity, unpleasantness, overall). Arterial blood pressure (SP, DP, MP), HR, and forearm vascular resistance (MP-VP/FAF) increased during the tourniquet procedure while FAF and VC decreased. There was a significant correlation between various peripheral hemodynamic responses with the sensory, affective and overall estimates of pain.

This study demonstrates that there are unique and reproducible hemodynamic responses to acute ischemic pain that co-vary with particular dimensions of pain perception. The specificity of these changes as they relate to pain and the ability of these cardiovascular responses to modulate pain perception is currently under investigation.

33.5 IS SUBJECTIVE PAIN SENSATION CORRELATED WITH THE FLEXION REFLEX IN MAN? M. Dallaire* and C.W.Y. Chan. School of Physical and Occupational Therapy, McGill University, Montreal, Quebec, Canada H3G 1Y5.

The quantification of experimental pain in human subjects has always presented researchers with a formidable challenge. Psychophysical methods such as verbal report, numerical and descriptive scaling as well as analog scales are often used to provide a subjective measure of pain. Other studies favor the use of various physiological correlates to try to quantify pain sensation in an objective manner. Keeping in mind the complexity of pain experience, we felt the need to bridge the gap between psychophysical and physiological correlates of pain in this study.

The two pain indices we chose to compare are the visual analog scale (VAS) for its simplicity and sensitivity, and the lower limb flexion reflex (FR), known for its high correlation with pain sensation. Subjects (7 females, age 23 to 30) were seated comfortably in a semi-reclined position with right ankle and knee joints fixed in slight extension by partial casts to enhance FR excitability. The stimulus used to elicit the flexion reflex consisted of a 30 msec duration train of 1 msec square pulses at 200 Hz, delivered to the median arch of the right foot. Surface electromyographic (EMG) recordings were taken from the right biceps femoris (BF) muscle and processed on-line through an averaging program. Stimulus intensities were then determined for each subject's perceptual threshold and pain tolerance. The range in between was divided in 10% increments with respect to the normalized anchors (0%=perceptual threshold, 100%=pain tolerance). Subjects were then instructed to estimate stimulus intensity by moving a cursor along a VAS connected to a linear potentiometer. Each subject received 110 randomized stimuli (ie. ten stimuli at each 10% increment of the stimulation range).

Mean VAS ratings and mean FR EMG areas were computed at each stimulation level for each subject, and normalized with respect to her maximum value (=100%). The stimulus-response curves for subjective pain estimates and FR area were both found to increase linearly with increasing stimulus intensity, having correlation coefficient values of r=0.85 and r=0.95 respectively, as well as identical slopes. Interestingly, the cross-correlation between FR area and subjective estimates also yielded a high value of r=0.85.

These data therefore tend to support the existence, under our experimental paradigm, of a high correlation between subjective pain sensation and the flexion reflex in man. Further experiments will determine if the parallel relationship seen between these two pain indices still holds when subjected to peripheral pain modulation techniques such as vibration.

33.6 MAGNITUDE SCALING OF CHEMOGENIC PAIN AND HYPERALGESIA IN HUMANS. D.A. Simone, T.K. Baumann, C.N. Shain, and R.H. LaMotte. Dept. of Anesthesiology, Yale University Sch. of Med., New Haven, CT 06510

Although chemical sensitization of nociceptors may contribute to the hyperalgesia that follows tissue injury, there have been few psychophysical studies of the relationship between the concentration of algesic chemicals and measures of pain and hyperalgesia. In a study of the magnitude of chemical pain and hyperalgesia, different doses of capsaicin (CAP) were injected intradermally into the forearm in humans. CAP produced burning pain, a flare, local hyperalgesia to heat, and a larger surrounding area of mechanical hyperalgesia. Each subject judged the magnitude of pain produced by an injection of vehicle (Tween-saline) and CAP doses of 0.01, 0.1, 1, 10, and 100 ug in 10 ul.

The lowest dose of CAP which produced pain was 0.1 ug. The magnitude of pain increased with dose, yielding a power function with an exponent of 0.17. The duration of pain also increased as a function of dose and ranged from 1.2 to 16.7 min.

Both the magnitude and duration of heat hyperalgesia (lowered pain threshold) and the area of surrounding mechanical hyperalgesia (to light skin stroking) increased with CAP doses of 1 to 100 ug.

Measurement of pain response latency revealed that a light stroke within the area of mechanical hyperalgesia evoked two sensations of pain. The first was brief and immediate and was followed after a delay by a second pain lasting 5 to 20 sec. Latencies were consistent with conduction in fast and slow conducting C-fibers. An ischemic block of conduction in A-fibers with loss of touch and loss (or delay) of cool sensation did not alter these two components of pain. However, as the block progressed, the first pain disappeared, whereas the second pain persisted together with normal pain reactivity to an additional CAP injection.

We hypothesize that the two components of mechanically-induced pain following CAP are mediated by separate classes of C-fiber afferents. One mediates the first component of mechanical pain while the other mediates the second component as well as contributes to the chemically-mediated pain to CAP injection.

Supported by grant from the US PHS, no. 14624

33.7 ANTINOCICEPTION FROM PERIPHERAL NERVE STIMULATION IN RATS AND HUMANS. B. Pomeranz . Departments of Zoology and Physiology, University of Toronto, Toronto, Ont., M5S1A1.

We studied the roles of spinal cord endorphins and GABA in mediating electroacupuncture(EA) antinociception in rats, using low frequency/high intensity EA. In addition we developed a transcutaneous electrical nerve stimulation(TENS) device called Codetron for human patients using similar parameters (low frequency/high intensity), and tested it against conventional EA in patients with chronic pain.

Rats were anesthetized with continuous infusion of pentobarbital. Low frequency (4 Hz) high intensity (25x threshold) EA was applied for 15 minutes via needles to the 1st dorsal interosseus muscle, in order to suppress tail flick reflexes elicited by radiant heat. An intrathecal cannula was used to apply drugs to the cord. Naltrexone given before EA treatment prevented EA antinociception, but naltrexone given after EA failed to reverse the EA effect. Picrotoxin blocked EA effects, while diazepam enhanced EA antinociception.

In the human study, patients with chronic pain (N=171) were randomly assigned to one of two treatment groups: one receiving Codetron (TENS) treatments twice a week for 6 weeks, the other receiving a similar course of EA (with needles). In the short term (6 weeks) Codetron performed as well as EA, but in the long term followup (4–8 months) Codetron outperformed EA by a wide margin.

We conclude in the rat studies that antinociception from low frequency/high intensity stimulation is mediated by spinal cord endorphins and GABA. Moreover the endorphin effect produces a modulation which is preventable but not reversible by naltrexone. In the human study, Codetron was a successful means of delivering low frequency/high intensity TENS. Moreover, Codetron outperformed EA perhaps because it was designed to give high intensity stimulation without undue discomfort to the patients.

33.8 THE LOCAL EFFECT OF TRANSCUTANEOUS ELECTRICAL NERVE STIMULATION (TENS) AT LUMBAR SITES (L5-S1) ON SCALP SOMATOSENSORY EVOKED POTENTIALS (SEP): AFTER STIMULATION OF THE TIBIAL AND MEDIAN NERVES. S. Marchand* and L. Laurencelle* (SPON: A.M. Smith). Université du Québec à Trois-Rivières, C.P.500, Trois-Rivières, G9A 5H7 (Québec) CANADA.

The Gate Control theory by Melzack and Wall (1965) provided a theoretical rationale for the low intensity, high frequency transcutaneous electrical nerve stimulation (TENS) analgesia. In the present study, we investigated the local topographical effects of TENS analgesia.

The amplitude of the late component (P200) somatosensory evoked potential (SEP) seemed to be a good electrophysiological index of the analgesic effect. In the present study the localized effects of lumbar TENS were studied using the P200 component of the SEP amplitude. Scalp SEPS were obtained by stimulating the median nerve at the wrist and the tibial nerve at the popliteal fossa. SEP samples were taken before and after the application of TENS to a region of skin innervated by lumbo-sacral fibers (L5-S1).

The root mean square (RMS) voltage was calculated on each SEP in order to conduct a statistical analysis of the amplitude over time. The results showed that TENS produced a selective reduction of the SEP amplitude of the response evoked from the tibial nerve but no difference was found in the amplitude of the SEP evoked from the median nerve. In particular, TENS decreased the amplitude of the SEP surrounding the P200 component. The RMS voltage at a latency of 175-200 ms was compared with the PES evoked from stimulation of the median and tibial nerves with and without TENS. For the tibial nerve, there was a significant ($P<.050$) reduction in the SEP amplitude after TENS. For the median nerve, no difference was found between the two conditions.

The results are in accord with the assumption that TENS has a focalized topographical effect. The amplitude of the SEP of the tibial nerve was selectively reduced by the application of TENS; as predicted, the median nerve SEP was not affected.

33.9 PSYCHOPHYSICAL THRESHOLD OF THE HUMAN CORNEA TO CAPSAICIN. B. Dupuy,* H. Thompson,* and R.W. Beuerman. (SPON: L. Happel). LSU Eye Center, New Orleans, LA 70112.

Capsaicin is a pungent substance found in hot peppers. In rabbits, topical application of 1% capsaicin on the cornea leads to ocular irritation. Following repeated applications in the anesthetized rabbit twice a day for 5 days, the cornea showed no structural changes when observed by the slit-lamp, light or electron microscopy. Electrophysiologically, low capsaicin concentrations produced marginal responses, while higher concentrations reduced sensitivity. These results did not adequately explain the observed behavioral effects of capsaicin. Therefore, we sought to determine the psychophysical threshold of the human cornea to capsaicin in order to better describe its sensory effects on corneal free nerve endings.

Capsaicin (Sigma, 90% purity) in vehicle (10% ethanol, 10% Tween 80 in isotonic saline) was serially diluted in sterile isotonic saline to concentrations ranging from 3.3×10^{-8} M to 7.8×10^{-8} M. For testing, all solutions were warmed to 40°C and delivered as a 5 µl drop on the apex of the cornea. Five subjects were given diluted vehicle or capsaicin at one of the following concentrations: 3.3×10^{-8} M, 4.4×10^{-8} M, 5.8×10^{-8} M, 7.8×10^{-8} M in each eye. Each subject underwent two experimental sessions in which concentrations were presented in ascending order. Isotonic saline washes preceded and followed each stimulus. Subjects, unaware of the order or concentrations of the stimuli presented, were asked to report when a drop was irritating. Following each session, subjects were examined by slit-lamp.

The population probabilities of reporting irritation were as follows: vehicle, $P = 0.06$; 3.3×10^{-8} M, $P = 0.09$; 4.4×10^{-8} M, $P = 0.14$; 5.8×10^{-8} M, $P = 0.59$; 7.8×10^{-8} M, $P = 0.83$; ($n = 20$ at each concentration). By probit analysis, the ED_{50} (threshold) was calculated to be 5.9×10^{-8} M with 95% confidence limits ranging from 5.3×10^{-8} M to 6.6×10^{-8} M. Threshold is equivalent to 1.2×10^{-8} gm/5 µl drop. Slit-lamp examinations showed no epithelial staining or corneal changes in any of the subjects.

The extreme sensitivity of corneal free nerve endings is demonstrated by the low psychophysical threshold to capsaicin. Furthermore, determination of the threshold to capsaicin allows the implementation of more diverse experimental models such as JND and signal detection analysis. Lastly, the reliability of capsaicin to evoke a sensation at low concentrations and the absence of tissue damage following topical application suggest that capsaicin may prove to be useful in understanding corneal nociceptors.

33.10 EFFECTS OF SYSTEMIC MORPHINE ON SECOND PAIN REACTIONS OF PRIMATES. D.C. Yeomans*, B.Y. Cooper and C.J. Vierck, Jr. Dept. of Neuroscience and Center for Neurobiological Scs., Univ. of Florida Col. of Med., Gainesville, FL 32610.

Previous human psychophysical studies have demonstrated that systemic morphine acts preferentially to inhibit second pain sensations attributable to activity in unmyelinated (C) peripheral afferents (Cooper et al., 1986). Therefore, a behavioral paradigm was devised to evaluate responses of monkeys to pain sensations elicited by C or A-delta afferent activity. Stimulus parameters that evoked only second pains were determined by human subjects who rated pain magnitudes evoked by 500 msec contacts of a preheated thermode with skin of the lateral calf. Within series of 7 contacts at a frequency of 0.33 Hz, pain sensations increased with successive contacts. Conduction velocities of 0.8 to 1.8 M/s were obtained from latencies of responses to proximal vs. distal stimulation. In addition, pain magnitudes were increased by topical capsaicin.

The paradigm for monkeys presented 3 trial types: A) 16 C pain trials in which a preheated thermode (50 or 56 deg C) contacted the lateral calf as described above. Escape periods (defined by a tone) occurred when the animals experienced second pain in the interstimulus intervals. B) 16 A-delta pain trials, involving a single, 4.5 sec contact of the thermode (48 or 50 deg C) or electrocutaneous stimulation. Escape periods coincided with peak A-delta pain. C) 8 avoidance trials in which non-pain-specific effects of morphine were examined. Systemic morphine suppressed C fiber pain responses at doses which did not affect responses to A-delta pain. Morphine at these doses also had no effect on avoidance responses or reflexive responses.

33.11 **USE OF A REPEATED-MEASURES DESIGN TO STUDY ANALGESIA PRODUCED BY OXOTREMORINE (OX) AND NICOTINE (NC) IN THE MOUSE TAIL IMMERSION TEST.** K.C. Retz and T. V. Tran*. Dept. of Pharmacology, Texas College of Osteopathic Medicine, Fort Worth, TX 76107-2690.

The feasibilty of using a repeated-measures factoral design to study the analgesia produced by oxotremorine (OX) and nicotine (NC) in the tail immersion test was investigated. Two separate groups of 20 male HSD:ICR(BR) mice, 2-4 mo., were further divided into five subgroups of four animals. To test for analgesia, each of the OX subgroups received saline vehicle, OX 0.005, OX 0.01, OX 0.02, and OX 0.04 mg/kg with a 3-4 day interval between each treatment. Latencies were measured immediately prior to injection and at 15 and 30 min post-injection using the 50°C tail immersion test (Sewell & Spencer, Neuropharmacology 15:683-688, 1976). Analgesia produced by NC was assessed by measuring latencies immediately prior to injection and at 2 and 5 min post-injection using saline vehicle, NC 0.32, NC 0.64, NC 1.25 and NC 2.50 mg/kg. To examine the effects of order, a 2-way ANOVA on the pre-injection latencies was conducted with subgroups (5 levels) as a between factor and order of presentation, the repeated measure, (5 levels) as a within factor. In the "OX" group neither subgroup main effect ($F(4,15)=1.3$, $p=0.32$) nor order main effect ($F(4,60)=2.1$, $p=0.09$) reached statistical significance. In the "NC" group neither subgroup main effect ($F(4,15)=1.4$, $p=0.28$) nor order main effect ($F(4,60)=1.7$, $p=0.16$) reached statistical significance. These findings implied that prior exposure to the test and/or administration of drug or vehicle had no appreciable effect upon the pre-injection performance on subsequent days. With regard to the drugs themselves, a dose-dependent and time-dependent increase in latency was observed following injection of both OX and NC. To verify the effects of each drug, a 2-way ANOVA on latencies was conducted on the data pooled from all subgroups with both dose (5 levels) and time (3 levels) as within factors. Following OX, main effects due to dose ($F(4,76)=8.2$, $p=6.9E-05$), time ($F(2,38)=11.9$, $p=2.3E-04$), and the dose x time interaction ($F(8,152)=4.6$, $p=1.3E-04$) were all highly significant, as were the simple main effects of the 0.005, 0.01 and 0.04 mg/kg doses. Following NC, main effects due to dose ($F(4,76)=80.1$, $p=2.1E-10$), time ($F(2,38)=81.1$, $p=3.1E-08$), and the dose x time interaction ($F(8,152)= 43.9$, $p=1.7E-11$) were also all highly significant, as were the simple main effects of the 1.25 and 2.50 mg/kg doses. These findings demonstrate the validity of using a repeated measures factoral design in the tail-immersion test to study the analgesia produced by OX or NC in mice. Supported by Texas College of Osteopathic Medicine grant #34107 awarded to K.C.R.).

33.12 INTERMITTENT SHOCK TITRATION IN THE RHESUS MONKEY. J.L. Bloss and D.L. Hammond. Department of CNS Diseases Research, G.D. Searle & Co., Skokie, IL 60077.

Several criticisms have been made of the shock titration paradigm (STP) used for analgesiometric determinations in the monkey. Foremost criticisms are 1) the animal's ability to avoid the stimulus and maintain shock intensity at less than painful levels, and 2) poor localization of the stimulus such that current densities are too low to be nociceptive. This study evaluated a modification of the discrete trial STP in which well-localized electric stimuli of suprathreshold intensity were interspersed among a sequence of titratable stimuli. The effect of morphine on response parameters was also examined.

Male rhesus monkeys were trained to terminate an electric stimulus (0-6 mA, 25 equal steps) delivered to the mid-lateral calf via two 10 mm^2 electrodes. A trial consisted of a train of 60Hz alternating constant current square wave pulses (40 msec on, 200 msec off) of 2.2 s duration delivered every 10 s. A lever press terminated the trial and decreased the intensity of the subsequent trial by one step (0.24 mA/mm^2). In the absence of a response, the intensity of the subsequent trial increased by one step. After every third titratable trial, an unavoidable suprathreshold stimulus of either step 10 (0.24 mA/mm^2) or step 18 (0.43 mA/mm^2) intensity was presented. These trials were also terminated by a lever press. Mean shock titration threshold and response latency, and percent response were calculated from 6 min segments of the record corresponding to 25 titratable trials and 4 presentations each of the two suprathreshold stimuli.

Sixty min after saline, mean titration threshold was step 2.6 ± 0.7 (0.07 mA/mm^2) and mean response latency was 0.74 ± 0.05 s. In contrast, mean response latencies to the suprathreshold stimuli were 0.46 ± 0.05 s (step 10) and 0.42 ± 0.05 s (step 18), significantly shorter than titration response latency. Presentations of step 10 and step 18 intensity were terminated 94% and 100% of the time, respectively. Morphine (0.3-6 mg/kg i.m.) produced a dose-dependent increase in mean titration threshold and decrease in % response. Responses to presentations of step 10 and step 18 intensity were reduced to 55% by 3.0 and 6.0 mg/kg, respectively. Morphine also produced a dose-dependent increase in response latencies to step 10 and 18 intensities with significant increases occurring at doses $\geq$ 3.0 mg/kg.

The significantly shorter response latencies and the virtual 100% response to presentation of step 10 and step 18 stimulus intensities suggest that these stimuli are suprathreshold for pain. With respect to the titratable stimuli, it appears that these stimuli are sufficiently localized to yield current densities in the range that elicit response latencies normally associated with nociceptive stimulation. Intermittent STP permits simultaneous evaluation of drug effects on titratable threshold stimuli and on response to suprathreshold nociceptive stimuli.

33.13 DEVELOPMENTAL CHANGES IN THERMAL NOCICEPTIVE THRESHOLD AND ITS RELATIONSHIP TO IMMUNOREACTIVE CALCITONIN GENE-RELATED PEPTIDE AND SUBSTANCE P AFTER NEONATAL ADMINISTRATION OF CAPSAICIN TO THE RAT. D.L. Hammond & M.A. Ruda. CNS Diseases Research, G.D. Searle & Co., Skokie, IL 60077 and Neurobiology and Anesthesiology Branch, NIDR, NIH, Bethesda, MD 20892.

Neonatal administration of capsaicin is reported to increase the threshold to nociceptive stimuli and to decrease the levels of calcitonin gene-related peptide (CGRP) and substance P (SP) in the spinal cord. Both these peptides are found in small diameter primary afferent axons. Although the depletion of CGRP and SP has been confirmed, the increase in threshold to noxious thermal stimuli has been disputed. This study examines the alteration in thermal nociceptive threshold between 10 days and 4 months after neonatal administration of capsaicin and correlates it with changes in the distribution of immunoreactive CGRP and SP in the lumbar spinal cord.

Sprague-Dawley rats were treated with either capsaicin (50 mg/kg, s.c.; Sigma) or vehicle on day 2 of life. Hot plate latency (HPL) was measured at 10 days, 2, 3, 4, 6, 8, 12 and 16 weeks of age in groups of 7-9 rats. After measurement of response latency, the rats were perfused with 4% paraformaldehyde in 0.1 M phosphate buffer. Transverse sections of lumbar spinal cord were incubated in antiserum either to human CGRP (1:15,000, Peninsula) or SP (1:10,000, Immunonuclear) for 24-48 hrs at 4°C and processed for immunocytochemistry using standard PAP methodology.

HPL was significantly increased in capsaicin-treated (CAP) rats as compared to values in vehicle-treated rats (controls). At 8 weeks, HPL in CAP rats was 36.1 ± 2.9 s as compared to 7.0 ± 0.6 s controls. At 12 weeks of age, HPL in CAP rats had decreased to 24.2 ± 4.2 s, but was still significantly greater than in controls (9.3 ± 1.4 s). At 16 weeks of age, HPL in CAP rats had decreased further to 11.2 ± 1.4 as compared to 6.2 ± 0.7 s in controls. A reduction in CGRP and SP immunoreactivity in laminae I, II and V of the lumbar spinal cord was visible as early as 10 days after capsaicin administration. At 12 weeks of age, the reduction in CGRP immunoreactive axons in the superficial dorsal horn of CAP rats was less evident and an increase in CGRP axons migrating dorsoventrally through laminae III and IV was observed. These changes in CGRP immunoreactivity were also present at 16 weeks of age. In contrast, there was no apparent increase in SP immunoreactive axons in laminae III and IV.

These data indicate that there is a time dependent return of thermal sensitivity in CAP rats between 8 and 16 weeks of age, and that the reduction in HPL may be related to alteration in CGRP immunoreactive primary afferent axons.

33.14 EVALUATION OF THE ANALGESIC AND NEUROTOXIC ACTIONS OF THE CAPSAICIN ANALOG N-OCTYLHOMOVANILLATE. T. R. LaHann, J. Shafii*, S. Shetty*, G. S. Yost*, and W. S. Ritter. The Colleges of Pharmacy and Veterinary Medicine, Washington State University, Pullman, WA 99164.

Systemic administration of capsaicin produces a profound analgesia in a variety of different animal models of pain. The mechanism underlying this analgesic action is not known. However, since capsaicin is neurotoxic to sensory neurons, there is speculation that its analgesic activity may be the result of damage to sensory neurons. To evaluate the possibility that analgesia and neurotoxicity are dissociable, we have measured the analgesic and neurotoxic actions of the capsaicin analog n-octyl homovanillate (OHV). This compound has previously been reported to be neurotoxic when injected sc in neonatal rats (Jancso and Gabor, Brain Res, 210:83, 1981). Adult, male Sprague-Dawley rats were injected sc with capsaicin (100 mg/kg), OHV (200 or 400 mg/kg) or vehicle (ethanol/Tween 80/saline or DMSO/water/ethanol). The 55°C hot plate model was used to evaluate analgesia, and pain thresholds were measured prior to injection and at 1, 5 and 11.5 hours post-injection. Injection of capsaicin elicited significant analgesia (581% increase in pain threshold), while injections of OHV or vehicle were without effect (<5% increase in pain threshold). Twelve hours after the injections, rats were perfused with phosphate buffered saline and 4% paraformaldehyde and the spinal cords removed. After post-fixation in paraformaldehyde and 30% sucrose, the spinal cords were sliced on a cryostat and thaw-mounted on gelatin subbed slides. Neurodegenerative changes were detected by the Carlsen and DeOlmos cupric-silver technique. Rats treated with capsaicin showed clear signs of terminal degeneration in the substantia gelatinosa of the dorsal horns. Spinal cords of vehicle-treated rats showed no evidence of neurodegeneration. Spinal cords of HVO-treated rats showed little or no evidence of terminal degeneration. In adult rats, then, the sc injection of capsaicin produced both analgesia and degeneration of neurons which terminate in the substantia gelatinosa of the dorsal horn. SC injection of the capsaicin analog HVO failed to elicit either analgesia or neurodegenerative changes. Thus, HVO is not a suitable analog for demonstrating a dissociation of capsaicinoid induced analgesia and sensory nerve damage. While capsaicin is neurotoxic to either neonatal or adult rats, HVO appears to be neurotoxic only to the neonatal rat.

33.15 CHANGES PRODUCED BY LOCAL APPLICATION OF CAPSAICIN TO A PERIPHERAL NERVE ON INPUTS TO SPINOTHALAMIC TRACT CELLS IN THE MONKEY. J.M. Chung, J.S. Kim*, K.S. Paik*, S.C. Nam*, K. Chung and W.D. Willis. Marine Biomedical Institute and Departments of Anatomy & Neurosciences and Physiology & Biophysics, University of Texas Medical Branch, Galveston, TX 77550.

Capsaicin is a neurotoxin which produces selective degeneration of unmyelinated fibers when systematically injected into a neonatal animal. Topical application of capsaicin onto a peripheral nerve produces conduction block of unmyelinated fibers. The purpose of this study was to investigate a long term effect of topical application of capsaicin to a peripheral nerve on the responsiveness of spinothalamic tract (STT) neurons and the correlated anatomical change in the fiber population in the nerve.

Ten monkeys were anesthetized with sodium pentobarbital and capsaicin (1.5% solution) was applied onto the tibial and common peroneal nerves of one side for 30 min. The nerves on the other side in some monkeys were untreated or treated with vehicle only in other animals for the control. After a 3 to 4 week survival period, the monkey was reanesthetized and extracellular recordings were made from identified STT cells in the lumbosacral spinal cord. The responses of STT cells to graded mechanical, thermal and electrical stimuli applied to the receptive fields in the foot were tested. The responses were compared to those recorded from the opposite (control) side. After the experiment, about 2 cm lengths of the tibial nerves on both sides were taken out and processed for examination under the electron microscope.

As compared to the cells recorded from the control side, STT cells recorded from the experimental side showed much weaker noxious thermal responses. Electrical stimulation of peripheral nerve elicited smaller C fiber evoked responses. However, there was no obvious difference in responses to graded mechanical stimuli between the two sides. Preliminary results of the examination of the tibial nerve fiber population in electron micrographs indicated a significant reduction of unmyelinated fibers in the nerve treated with capsaicin.

These data suggest that a brief exposure of capsaicin onto a peripheral nerve produces a long-lasting, selective degeneration of unmyelinated fibers in primates. The most vulnerable peripheral fibers to capsaicin application seem to be those that carry noxious thermal inputs. Topical application of capsaicin or a similar agent may be a useful technique for selective, long-lasting peripheral nerve block in some clinical situations. (Supported by NIH grants NS09743, NS11255 and NS21266 and NIH RCDA NS00995).

33.16 PERIPHERAL PROSTAGLANDINS ENHANCE NOCICEPTIVE INPUT TO THE NEONATAL RAT SPINAL CORD IN VITRO. M.N. Perkins*, J.A. Bettaney and A. Dray. (SPON. A. Nistri) Sandoz Institute for Medical Research, 5 Gower Place, London WC1E 6BN, UK.

We have used the neo-natal rat spinal cord-tail preparation in vitro (Yanagisawa et al Eur. J. Pharmacol. 106:231,1984) to investigate possible prostaglandin involvement in peripheral mechanisms of nociception.

The spinal cord with tail attached was isolated from 1-2 day old rat pups following decapitation, and the surface of the skin removed from the tail with forceps. The preparation was maintained at 22°C with the cord and tail perfused separately with artificial CSF. Extracellular recordings were made from one of the lumbar ventral roots (L3-L5) with stimulation of the corresponding dorsal root.

Capsaicin (caps. 0.5-1μM) or bradykinin (Bk 0.5-1μM), which specifically activate peripheral nociceptive nerve terminals, were applied to the tail for 10-12s. This resulted in a depolarizing response in the ventral root of up to 2mV. Similar responses were obtained by dropping hot CSF (>45°C) onto the tail for 5-10s.

Perfusion of the tail with CSF containing PGE_2, E_1, F_2 and D_2 at 0.6-25μM enhanced the amplitude and duration of the responses to Bk and caps varying extents. The response to noxious heat was enhanced in some cases. In addition, the prostaglandins produced a transient ventral root depolarization when applied to the tail. Arachidonic acid (0.7-1.4μM), nifedipine (20μM), BayK8644 (1μM) and $CoCl_2$ (1-2mM) applied to the tail had no effect on the response to Bk, caps or noxious heat. Indomethacin (100μM) had no consistent effect on the responses to Bk or caps. Perfusion of the tail with Ca^{2+} free CSF plus 100μM EGTA enhanced the responses to Bk and caps. Verapamil (2μM) also potentiated of the responses to Bk and caps. However, $CoCl_2$ (1-2mM) prevented or reduced the prostaglandin-induced enhancement of the noxious stimuli.

These results show that prostaglandins can directly stimulate peripheral nerve terminals and enhance peripheral nociceptive activity induced by noxious chemical stimuli. This enhancement may involve calcium in its mechanism of action.

33.17 THE DEAFFERENTATION SYNDROME IN THE RAT: EFFECTS OF INTRAVENTRICULAR APOMORPHINE. Mark A. Lyerly*,Eugene Rossitch,Jr.,M.D.*,Janice Ovelmen-Levitt,Ph.D., and Blaine S. Nashold, Jr.,M.D., Div. of Neurosurgery, Duke Univ. Med. Ctr., Durham, NC 27710

A deafferentation syndrome (DS) produced in rats is expressed as scratching of partially deafferented and/or biting of anesthetic limb areas. This self-mutilation may be objective evidence of dysesthesias, thus serving as an experimental model to study chronic dysesthesias and/or pain from deafferentation in man. This study included behavioral observations of the DS and the effects of intraventricular apomorphine (Apo-M) on its expression. Apo-M, a dopamine agonist, has been shown to produce analgesia in rats when administered intrathecally or intraventricularly, possibly mediated through the dopaminergic diencephalic pathway whose cell bodies localized periventricularly project through the dorsal lateral fasciculus to terminate in the dorsal horn at all spinal levels. Forty-eight female Sprague-Dawley rats underwent unilateral C5-T2 dorsal root ganglionectomies followed immediately by stereotactically guided cannulation of the right lateral ventricle in 30 of the rats. For 2 weeks continuously via an osmotic minipump, 10 rats received Apo-M (5ug/hr), 10 L-ascorbate (the Apo-M vehicle), and 10 lactated mammalian ringers(LR). Rats with ganglionectomies only (DO), as well as those receiving either L-ascorbate (ASC) or LR, demonstrated early onset, more severe and later onset, less severe biting groups ($P<0.05$). The more severe autotomy DO, ASC, and LR groups were of the same population with respect to bite onset and autotomy, while the late onset, less severe groups of ASC and LR fell outside 1 std dev of the mean bite onset of the late DO animals. Animals receiving Apo-M, irrespective of bite onset, correlated with only the late onset, less severe autotomy DO group regarding autotomy. The DO and ASC groups demonstrated an association of early onset of biting with more severe autotomy, while the Apo-M group failed to demonstrate any predictive value of bite onset as an indication of the autotomy to be reached.

This study has 2 major indications: One, the late onset groups of both ASC and LR rats having earlier bite onsets than late onset DO indicates that there may be stress from the presence of the minipump which accelerates biting; and two, that stereotactically applied Apo-M can affect the dysesthesias and/or pain referred to denervated limb areas as indicated by the absence of a severe Apo-M autotomy group and lack of relationship between bite onset and autotomy.

33.18 THE DEAFFERENTATION SYNDROME IN THE RAT: AN EVALUATION OF SEVERAL PARAMETERS. Eugene Rossitch,Jr.*, M.D., Mark A. Lyerly*, Jacob N. Young, M.D.*, Janice Ovelmen-Levitt, Ph.D., and Blaine S. Nashold, Jr., M. D. (SPON: P.G. Shinkman). Div. of Neurosurgery, Duke Univ. Med. Ctr., Durham, NC 27710.

A deafferentation syndrome (DS), produced in rats is expressedas scratching of partially deafferented and/or biting of anesthetic limb areas. This self-mutilation may be objective evidence of dysesthesias, thus serving as an experimental model to study chronic dysesthesias from deafferentation in man. There is evidence that genetic factors, CNS lesions, type of deafferentation, and location of the deafferentation may affect the DS expression. This study examines the effects of sex, age, cortical lesions, and type and locale of lesions on the expression of the DS in rats. A total of 71 Sprague-Dawley rats were involved in 4 protocols. In the first, 18 female and 14 male rats underwent unilateral C5-T2 dorsal root ganglionectomies. In the second, 13 female rats had C5-T2 dorsal root avulsions plus ganglionectomies. The third protocol involved 21 female rats with 1 of 4 surgical combinations: 5 with cortectomy only (C); 7, ganglionectomy only (GO); 6,C then GO; and 3, GO then C (the latter two types separated by 14 days). The cortectomy, at the level of bregma, 2-5mm lateral to the sagittal sinus, consisted of suction removal of 1mm cortex of S1 representation. In the fourth protocol 5 female rats had unilateral L2-S1 dorsal root ganglionectomies. In all protocols, the rats' behavior were quantified using an autotomy grading scale ranging from 0-19. Both female and male rats demonstrated early onset, more severe and later onset, less severe biting groups. Of all rats in the early onset, severe biting groups, the males bit significantly earlier than the females. Both sexes demonstrated an association of early onset of biting with high autotomy scores. The male group was examined with respect to age, which was found not to affect the DS. In avulsion (A) and ganglionectomy (GO) groups, onset of autotomy, autotomy score 10d after the onset of biting, and total autotomy scores were recorded. Both groups appeared to progress in autotomy in parallel fashion. Although the A animals had a decreased latency to autotomy onset (7.5d) vs ganglionectomy (21.8d)($p< 0.025$), the autotomy scores 10 days after the onset of biting were not significantly different. No cortectomy animals expressed autotomy, while the GO animals express the most. Animals having had both the cortectomy and GO deafferentation, in either order, showed markedly decreased autotomy vs GO animals ($p<0.05$). Comparing lumbosacral vs cervical ganglionectomy there appeared to be no difference in onset or degree of biting; however, no lumbosacral deafferentation rats scratched while this behavior occurred in 50% of cervical deafferentations. In conclusion no differences were found in the expression of the DS with respectto age and locale of lesions. However, sex, cortical ablations and type of lesion did alter the syndrome.

34.1 LOCAL AXON COLLATERALS FROM SPINAL LAMINAE I AND II NEURONS WHICH PROJECT TO THE BRAIN STEM. M.J. Sedivec, M.A. Dunnigan*, A.M. Kavookjian*, and A.R. Light. Dept. of Biology, Appalachian State University, Boone, NC, 28608 and Dept. of Physiology, UNC-Chapel Hill, Chapel Hill, NC, 27514.

Recent studies in our laboratories have demonstrated that many nociceptive neurons in laminae I and II have projecting axons which terminate at least as far rostral as the parabrachial region in the midbrain. Some of these neurons have local axon collaterals which terminate in laminae I,II and in deeper laminae (III,IV and V). In this study we have examined these collaterals with both the light and electron microscopes.

Single neurons were recorded in the spinal cords of anesthetized cats. Nociceptive neurons which were antidromically activated from the parabrachial region of the brain stem were intracellularly labeled with horseradish peroxidase. The tissue was perfused with buffered paraformaldehyde and glutaraldehyde, removed and postfixed, and then sectioned on a Vibratome at 50μm. Following a reaction with DAB + H_2O_2, selected sections were reacted with osmium and embedded in plastic between Teflon-coated coverslips. Neurons were reconstructed with a drawing tube at 1000X and selected portions were cut from the plastic wafers and recut with an ultramicrotome into serial sections. These sections were examined with a Zeiss 10C electron microscope unstained. Later these sections were post-stained with lead citrate and uranyl acetate.

Nociceptive neurons which projected to the parabrachial region were found in both laminae I and II. Local axon collaterals were found which terminated in laminae I and II and which continued deeper to terminate in laminae III and V. These local collaterals were unmyelinated and demonstrated many *en passant* and a few terminal varicosities. These varicosities were small synaptic boutons which were about 1μm in diameter. These synaptic boutons were Gray's Type I, in that they contained clear, round vesicles about 45 nm in diameter, a few large dense core vesicles approximately 85nm in diameter, and established one or two asymmetric contacts with dendritic profiles.

These results demonstrate that long projection neurons in laminae I and II that respond to nociceptive stimulation of their receptive fields have local axon collaterals which may be capable of exciting neurons in laminae I-V in the same spinal cord segment. Thus, these long projection neurons may be important in local integration of nociception. *Supported by NINCDS grants #NS16433, and #DA4420 to A.R.L. and a grant from the University Research Committee and Cratis D. 34.2 LATERAL VERSUS MEDIAL SPINOTHALAMIC NEURONS AND THEIR AXON COLLATERALS TO THE PERIAQUEDUCTAL GRAY AND MEDULLARY RETICULAR FORMATION IN THE RAT. Constance M. Pechura. Dept. of Anatomy, Uniformed Services University of the Health Sciences, Bethesda, Md. 20814-4799.

Fluorescent, retrograde tracing studies were undertaken to compare laterally versus medially projecting spinothalamic tract neurons in terms of their axon collaterals to the periaqueductal gray (PAG) or medullary reticular formation (MRF). The tracers used for these double-label experiments were fast blue or fluorogold in combination with rhodamine-labeled latex microspheres. Under general anesthesia, the tracers were injected into the lateral thalamus and MRF (L-STT/MRF,N=6), lateral thalamus and PAG (L-STT/PAG,N=5), medial thalamus and MRF (M-STT/MRF,N=6), or medial thalamus and PAG (M-STT/PAG,N=5). After 7 days, the animals were deeply anesthetized and perfused transcardially with saline followed by 10% formalin. The brains and spinal cords were removed and processed according to standard protocols. Locations of single- and double-labeled STT neurons were plotted for the spinal enlargements, mid-thoracic and upper cervical segments.

In all segments examined, single- and double-labeled L-STT and M-STT neurons were commonly observed in contralateral laminae V-VIII and, at upper cervical levels, in ipsilateral laminae VII-VIII. The percentages of STT cells which were double-labeled (10-40%) in these areas were similar across the experimental conditions, but were generally highest in the upper cervical and lowest in mid-thoracic segments. The lateral spinal nucleus contained double-labeled STT neurons in all four experimental groups. More L-STT than M-STT neurons were observed in lamina I in the cervical enlargement and these were double-labeled only from the PAG. In the lumbar enlargement, many L-STT neurons, none of which were double-labeled, were seen in the ventromedial dorsal horn. These neurons have been shown to respond to both proprioceptive and cutaneous stimuli and, thus, have been proposed to function in transmitting information regarding locomotion to the thalamus (Menetrey, D., et al., J. Neurophysiol. 52:612,1984). In this context it is interesting that heavy labeling in this region was associated with involvement of the ventral lateral nucleus in the L-STT injection sites. Such populations of exclusively single-labeled L-STT neurons were also found at upper cervical levels in the internal basilar and lateral cervical nuclei. Heavy labeling in the internal basilar nucleus was associated with L-STT injections which impinged upon the posterior nucleus.

These data suggest that many L-STT and M-STT neurons issue axon collaterals to the PAG or MRF. Further, L-STT neurons which project directly to the thalamus without axon branches are located in restricted spinal regions and may function in highly specific types of sensory processing. (Supported by USUHS Grant FE5500.)

34.3 COLLATERALS OF SPINOTHALAMIC TRACT (STT) NEURONS TO THE PAG: A DOUBLE LABELING STUDY IN THE MONKEY. D. Zhang*, S.M. Carlton, L.S. Sorkin, P.A. Harmann* and W.D. Willis (SPON: D. Trevino). Dept. of Anatomy & Neurosciences and Marine Biomedical Institute, Univ. of Texas Medical Branch, Galveston, TX 77550.

The STT is an important pathway transmitting nociceptive information to the brain. Electrophysiological evidence suggests that the STT also sends collaterals into the PAG. The present study employs retrograde transport of fluorescent tracers, granular blue (GB), diamidino yellow (DY) and rhodamine conjugated latex beads (RB) to identify the location and distribution of neurons in the spinal cord which project to both the thalamus and the PAG.

Two adult monkeys (M. fascicularis) received bilateral injections via Hamilton syringes of 5% GB (0.6μl each side) in the VPL thalamus and unilateral injections of 50% RB (0.2μl) or 2% (0.2μl) in the lateral PAG. After 10 to 15 days, animals were perfused with 4% paraformaldehyde in 0.1M phosphate buffer. The brains and spinal cords were removed and stored in 30% sucrose overnight. Cervical and lumbar segments and the injection sites were frozen sectioned (30 μm), mounted and air dried. Thalamic injection sites were centered in the VPLc. Midbrain injection sites were located in the dorsolateral PAG; however, in one animal, the ventral inferior colliculus was also included.

Single labeled GB neurons were found in all dorsal horn laminae and laminae 7 and 8 in both cervical and lumbar segments. However, the majority of GB cells were observed in lamina 5. Cervical lamina 1 contained a greater number of GB cells than lumbar lamina 1. However, the reverse was true for lamina 7, in that more GB cells were observed in lumbar lamina 7 than cervical lamina 7. Single labeled RB neurons were found almost exclusively in laminae 1 and 5 and the majority were contralateral to the PAG injection site. No DY labeled cells were found in the spinal cord. Several double labeled GB-RB neurons were observed in cervical and lumbar cord in both laminae 1 and 5. They were of a size similar to single labeled RB neurons. The actual percentage of double labeled neurons is under further investigation.

This preliminary study demonstrates that some STT neurons that send collaterals to the PAG have the same distribution as PAG-projecting neurons in the lumbar and cervical segments. The STT collaterals to PAG provide a mechanism for activation of descending, as well as ascending control of noxious input. (Supported by NS 11255 and NS 09743.

34.4 SPINAL AND TRIGEMINAL PROJECTIONS TO THE PARABRACHIAL AREA: AN ELECTRON MICROSCOPIC STUDY WITH REFERENCE TO PAIN PATHWAYS. Wu Ma* and Marc Peschanski (SPON. D. Forman), INSERM U 161, 2 rue d'Alésia, 75014 Paris, France.

Recent anatomical and electrophysiological studies have demonstrated that the parabrachial area of the pons (PB) receives projections from the spinal and trigeminal lamina I neurons, some of which are activated by noxious stimulation. This suggests that PB is a relay for a pain-related system running parallel to the well documented thalamic relays. In previous studies, we have indicated that the fine structure of spinal and trigeminal afferent terminals possibly involved in pain pathways are remarkably similar in the different thalamic nuclei of the rat. These terminals are large (average diameter: 2-3 μm), contain round vesicles and form asymmetrical contacts with dendritic protrusions, large dendrites, and more rarely, the soma. In line with these results, the present study was undertaken to analyze the spinal and trigeminal afferent terminal morphology in PB.

Injections of wheat-germ agglutinin conjugated to HRP were carried out in the spinal cord or in the trigeminal subnucleus caudalis (SNC) of 6 rats. Two days later, rats were perfused with mixed aldehydes and processed for the visualization of HRP using benzidine dihydrochloride as a chromogen (Peschanski, et al., Somatos, Res., 3, 1985) and embedded flat in Epon. The lateral and dorsal areas of PB containing labeled or degenerating terminals were trimmed out and thin-sectioned for ultrastructural studies.

Labeled spinal and trigeminal axons were large and myelinated. Labeled terminals made contacts with large and medium size dendrites, and rare axo-somatic contacs were observed. The synaptic contacts exhibited two different morphologies: (i) the majority of labeled terminals contained round synaptic vesicles (R type) and formed typical Gray type I (asymmetrical) synapses, (ii) the second type of terminal contained a pleomorphic population of synaptic vesicles (P type) and formed symmetrical contacts (Gray type II). The quantitative analysis carried out on 91 labeled contacts showed that the average diameter of the terminals ranged between 0.4 and 1.8 μm (mean: 0.98 ± 0.12 μm SD). The smallest diameters of the terminals on contacted dendrites varied widely, between 0.2 and 3.6 μm (mean: 1.13 ± 0.50 μm SD). No quantitative difference was observed between the R and P terminals.

These results indicate that spinal and trigeminal afferents to the PB exhibit morphological features which differ from those of the afferents originating from the same structures which terminate in the thalamus. The functional significance that can be assigned to these morphological results is presently a question beyond our reach, but it is reasonable to suggest, nevertheless, that the dissimilarities in synpatic arrangements may correspond to similarities in input-output relationships.

34.5 LAMINA I SPINOTHALAMIC TRACT (STT)/SPINOMESENCEPHALIC TRACT (SMT) PROJECTION NEURONS IN THE RAT ASCEND VIA THE DORSOLATERAL FUNICULI (DLF). R.L. Nahin, F. Anton* and J.L.K. Hylden. Neurobiology and Anesthesiology Branch, NIDR, NIH, Bethesda, MD 20892.

Previous studies in our laboratory concerning the characterization of lamina I neurons with projections to the midbrain of the cat, have shown these cells to be nociceptive-specific, to project bilaterally through the DLF and to have collateral projections to the thalamus. The present study was aimed toward investigating the distribution and funicular projection of the analogous population of neurons in the rat and to examine the extent of collateralization to the thalamus by the use of retrograde labeling techniques.

Projection neurons were labeled following injection of WGA-HRP (0.1 µl, 25%, 72 h) into the midbrain (area surrounding the brachium conjunctivum at the pontine-mescencephalic junction). The distribution of retrogradely labeled cells was examined in transverse 50 µm sections of cervical and lumbar enlargements after reaction of the tissue sections with tetramethylbenzidine (TMB). Concentrations of labeled cells were observed bilaterally in lamina I, lateral lamina V and the lateral spinal nucleus, with more scattered cells occurring in deeper laminae and around the central canal. Bilateral lesions of the DLF at lower thoracic levels resulted in a profound decrease (62-91%) in the number of labeled lamina I cells caudal to the lesion.

Collateral projection of SMT/STT neurons were examined by combining large injections of the fluorescent dye fluorogold (FG; Fluorochrome Inc.; 0.3 µl, 3%, 14 d) into the thalamus with WGA-HRP midbrain injections. The combination of retrograde labeling by FG and WGA-HRP revealed that many lamina I STT cells had collaterals to the midbrain, but it was apparent that the very dense TMB reaction product obscured much of the FG fluorescence. Subsequent experiments combined FG labeling from the thalamus with labeling by rhodamine microspheres (Tracer Technology; 0.3 µl, 14 d) retrogradely transported from the ipsilateral midbrain. Frozen, parasaggital (25-50 µm) sections of cervical and lumbar enlargements were examined uncoverslipped using an epi-fluorescense microscope with appropriate filter combinations. In 2 rats with thalamic injections centered on VPL, 85-95% of labeled lamina I STT cells also contained the tracer from the ipsilateral midbrain, implying that the majority of lamina I STT cells have collateral branches to the midbrain. The converse was not true (i.e., many single-labeled SMT neurons were present). Double-labeled neurons were also noted in deeper laminae, but were not as likely to occur.

Our data indicate that there is a large population of lamina I neurons with projections through the DLF to the midbrain in the rat. A subset of this population also innervates the thalamus.

34.6 PHYSIOLOGICAL CHARACTERIZATION OF NOCICEPTIVE LAMINA I PROJECTION NEURONS IN HYPERALGESIC RATS. J.L.K. Hylden, R.L. Nahin and R. Dubner, NAB, NIDR, NIH, Bethesda, MD 20892.

Spinal lamina I neurons are excited by noxious stimuli, project to the brainstem and thalamus and are potentially involved in pain transmission. Since much of the characterization of these neurons has been done with acute noxious stimuli (pinch, heat) in normal animals, it is of interest to examine the behavior of such nociceptive neurons after tissue injury and inflammation. We have addressed this question by examining the responses of superficial lumbar dorsal horn neurons in rats 5 days after a s.c. injection of Complete Freund's Adjuvant (CFA) into the plantar surface of the ipsilateral hindpaw (0.15 ml, CFA:saline, 1:1). Rats treated in this way develop an inflammed hindlimb as evidenced by the presence of edema, erythema and hyperalgesia (decreased threshold to noxious stimuli) and demonstrate biochemical changes localized to the ipsilateral lumbar spinal cord (Iadarola & Naranjo, NS Abstr., 1986). Lamina I projection neurons were identified in chloralose-anesthetized rats by antidromic activation from upper cervical spinal cord.

Lamina I projection neurons (20 cells) in control rats had relatively small receptive fields (RF) with sharp borders (usually comprised of one or more toes) and responded exclusively to noxious cutaneous stimuli (pressure, pinch, heat). Heat thresholds (47° ± 1.8°C) and mechanical thresholds (4.9 ± 0.4 g) were consistent with classification of these cells as nociceptive-specific (NS). Five cells were noted as having spontaneous activity of less than 5 hz. In rats pretreated with CFA, lamina I projection neurons (37 cells) demonstrated heat thresholds similar to those of cells in untreated rats (47° ± 2.8°C) and only slightly lower mechanical thresholds (4.4 ± 0.8 g). However, the distribution of RF size for cells in CFA-treated rats included many larger RFs ($p < 0.05$, X^2), often including the entire surface of the ipsilateral hindpaw. In addition, 50% of these cells responded to movement of joints or deep tissue or had discontinuous RFs and were classified as NS/complex. Eighty-seven percent of cells in CFA rats demonstrated background firing rates of 2 to 30 Hz (10 ± 2) with some bursting-type activity. The spontaneous activity of a majority of cells tested was inhibited by electrical stimulation at C2 and/or the ipsilateral sciatic nerve.

The present data provide evidence that a population of lamina I nociceptive projection neurons demonstrates increased activity in a model of hyperalgesia. The increased responsiveness of these neurons, which are known to project to the midbrain and thalamus, may result in a range of pain sensations, including pain in the absence of stimulation of the affected part of the body and referred pain.

34.7 CHARACTERIZATION OF SOMATIC CONTACTS ON SPINOTHALAMIC NEURONS IN THE MONKEY. K.N. Westlund, and S.M. Carlton. Dept. of Anatomy & Neurosciences and Marine Biomedical Institute, Univ. of Texas Medical Branch, Galveston, TX 77550.

The population of terminal and non-terminal elements contacting spinothalamic (STT) somata in the lumbar spinal cord of monkeys was examined by electron microscopy. Comparison was made between somata localized in laminae I and V. Monkeys were anesthetized and the hindlimb representation in the thalamus was located electrophysiologically. Animals received either a total of 3 µl of 25% HRP into the thalamus via a Hamilton syringe or physiologically characterized STT neurons in the cord were injected intracellularly with HRP. Following an appropriate survival time, animals were perfused with a brief saline rinse and fixative (2.5% paraformaldehyde, 0.2% glutaraldehyde). Spinal cord sections were cut on a vibratome (50 µm) and reacted for HRP using cobalt chloride and diaminobenzidine (Bowker et al., 1982). Tissue sections containing HRP labeled STT cells were immunostained for dopamine-β-hydroxylase (DBH), stained with 1% osmium and uranyl acetate, dehydrated and flat embedded in plastic. Labeled STT neurons were serially thin sectioned and sampled every 1-1.5 µm. Photographic montages of the perimeter of STT somata were constructed (x24,270) for analysis with the following results for one pair of neurons:

	LAMINA I (retrograde)		LAMINA V (intracellular)	
R	63.3%	(194)	69.0%	(376)
F	1.0	(2)	10.1	(55)
D1	12.1	(37)	12.8	(70)
D2	6.6	(20)	5.5	(30)
L1	12.1	(37)	1.5	(8)
L2	4.9	(15)	1.1	(6)
Total	100.0%	(305)	100.0%	(545)

Contacting neuronal terminals were classified as either containing round clear vesicles (R), round clear vesicles with >30% flat or oval vesicles (F), round clear vesicles with 2-4 dense core vesicles (DCV, 37-50 µm) (D1), round clear vesicles with large DCV (>50 µm) (L1), round clear vesicles with 5 or more small DCV (D2), or clear round vesicles with >5 large DCV. The population of terminals surrounding the cells in each lamina were similar in many respects. The predominant type of terminal observed contained round clear vesicles. Terminals containing flat or oval vesicles were a feature of the lamina V population, whereas the L1 classification was more abundant in lamina I. DBH terminals were observed contacting the somata of lamina I cells (4.4% or 17 terminals) but were not observed contacting lamina V somata to date. An additional 488 non-terminal elements (glia, dendrites, axons) were observed contacting a lamina I STT neuron compared to only 23 non-terminal elements contacting a lamina V neuron.

34.8 A SPINO-DIENCEPHALIC RELAY THROUGH THE PARABRACHIAL NUCLEUS IN THE CAT. A. Blomqvist and K.J. Berkley. Dept. of Psychology, Florida State Univ., Tallahassee, FL 32306-1051.

The results of recent anatomical and electrophysiological studies have suggested that the parabrachial nucleus (PBN) serves as an important brainstem relay for ascending nociceptive information from neurons in lamina I of the spinal and medullary dorsal horns. Using single and double anterograde and retrograde tracing methods to compare the location of terminals in PBN of fibers from the spinal cord with the location of neurons projecting to the thalamus, it was recently found (Blomqvist and Berkley, 1986) that there is a dense non-topographically organized spinal input to the lateral parabrachial nucleus, part of which overlaps the location of thalamic-projecting PBN neurons (but fails to overlap the location of amygdala projecting neurons) and part of which overlaps neurons with unknown targets.

The present study extended these observations by comparing the spinal input to PBN with PBN's output to the hypothalamus. It was found that hypothalamic-projecting PBN neurons filled the region with previously unknown targets. Taken together, the results of these experiments indicate that a major portion of the spinal input to PBN appears to be relayed to the diencephalon, part to the thalamus and part to the hypothalamus via different populations of PBN neurons. The functional significance of this connective pattern awaits the results of physiological investigations.

34.9 CONVERGENCE UPON AND EFFERENT CONNECTIONS OF A SPINAL CORD CENTER WHICH RECEIVES NOCICEPTOR INFORMATION FROM THE CRANIAL VASCULATURE. G.A.Lambert*, A.S.Zagami* and J.W.Lance* (SPON: D. Ferrington) Dept. of Medicine, University of New South Wales, NSW, 2031. Australia

We have recently reported on the occurrence in the upper cervical cord of an area (probably the lateral cervical nucleus-lcn) which receives input from the sagittal sinus. This area receives both A-delta and C-fibre input from the trigeminal system. In the experiments reported here, we have characterised the output connections of this area to the thalamus and examined the degree of convergence onto the area from several components of the cranial vasculature. Cats were anesthetized with urethane/chloralose and prepared for single unit recording in the upper cervical cord and the thalamus. A length of the dura and falx containing the superior sagittal sinus (SSS) was isolated from the the rest of the dura, placed on platinum hook electrodes, and stimulated electrically with supra-maximal shocks (40-120V, 250 usec, 1 per 5 sec). Additionally, segments of the middle meningeal artery (MMA) or the superficial temporal artery (STA) were similarly exposed and prepared for stimulation. Glass or glass-coated tungsten electrodes were used to record single unit activity. In the C2 region of the spinal cord cells having convergent input from three separate components of the cranial vasculature were found, as follows:

Numbers of convergent units				
SS	SS/STA	STA	SS/MMA	MMA
21	16	3	9	1

Stimulation of the SS or MMA evoked activities in the thalamus with both A-delta and C-fibre latencies as well as activity with very short latencies (2-3 msec). Responsive units were found in the thalamo-cortical projection (fibres) and a "shell region" of the vpm nucleus. Units only occasionally had receptive fields on the contralateral face and scalp. HRP injections into thalamic regions in which responsive cells were found labelled both the lcn and the sub-nucleus caudalis of the trigeminal nucleus. The degree of convergence from different vascular components is greater in the spinal cord than it is in the trigeminal sub-nuclei (Davis, K.A. & Dostrovsky,J.O., Soc Neurosci Abstr., 12, 230) but there is less convergent input from the facial and cranial skin. This indicates that the primary centre for processing of craniovascular sensation may be the cord and that referral of pain in migraine may be related more to convergence in the trigeminal nucleus. Occurrence of reactive units in and around the vpm nucleus is additional evidence for the processing of craniovascular information in the lcn, as well as in the trigeminal nucleus.

34.10 BRAINSTEM RELAYS MEDIATING STIMULATION-PRODUCED ANTINOCICEPTION FROM THE LATERAL HYPOTHALAMUS IN THE RAT. L.D. Aimone, C.A. Bauer* and G.F. Gebhart. Department of Pharmacology, University of Iowa, Iowa City, Iowa 52242.

Several lines of evidence have demonstrated a role for the lateral hypothalamus (LH) in an endogenous system of descending inhibition. The present study, in rats lightly anesthetized with pentobarbital, was undertaken to systematically examine neuronal pathways mediating descending inhibition of the nociceptive tail flick (TF) reflex produced by focal electrical stimulation in the LH. The local anesthetic, lidocaine, and the neurotoxin, ibotenic acid, were used to produce reversible, nonselective or irreversible, somata selective lesions, respectively, in the brainstem. Pharmacologic antagonists were employed in other experiments to determine the neurotransmitter(s) mediating the inhibition at the level of the medial medulla.

Rats were initially deeply anesthetized with pentobarbital (45 mg/kg) for craniotomy and cannulation of the femoral vein and artery. The rats were subsequently maintained in a lightly-anesthetized state (corneal and flexion reflexes present) with an i.v. infusion of pentobarbital (3-6 mg/kg/hr). Constant current stimulation (100 Hz, 100 µsec, 20-200 µA) with monopolar cathodal electrodes (0.15 mm dia.) was begun 10 sec prior to and continued during the application of heat to the tail.

The microinjection of lidocaine (4%, 0.5 µl) into the midbrain, dorsolateral pons or medial medulla resulted in significant increases in stimulation thresholds in the LH for inhibition of the TF reflex (89.1%, 67.4% and 73.6%, respectively). Selective lesions of cell bodies in these supraspinal sites, by ibotenic acid (10 µg, 0.5 µl), revealed relays in the periaqueductal gray and the nucleus raphe magnus (NRM) between the LH and the lumbar spinal cord.

The intracerebral administration of pharmacologic antagonists (5 µg, 0.5 µl) into the NRM revealed that the glutamate receptor antagonists gamma-D-glutamylglycine and 2-amino-5-phosphono-valerate produced the largest increases in stimulation thresholds in the LH for inhibition of the TF reflex (107.6% and 102.6%, respectively). Methysergide, a serotonin receptor antagonist, also produced a significant increase (81.5%) in the LH stimulation threshold; the opioid receptor antagonist naloxone, however, was without effect, producing only a 4.0% increase in the LH stimulation threshold for inhibition of the TF reflex. These results suggest that serotonin and/or an excitatory amino acid are transmitters at the bulbar relay in the medial medulla mediating descending inhibition of the TF reflex produced by focal electrical stimulation in the LH.

34.11 CHARACTERIZATION OF T13-L2 SPINAL NEURONS RESPONSIVE TO NOXIOUS DISTENSION OF THE GUT IN SPINALIZED AND INTACT RATS. T.J. Ness and G.F. Gebhart, Dept. Pharm., U. Iowa, Iowa City, IA 52242

Distension of the descending colon and rectum is a noxious visceral stimulus since it evokes reports of pain in humans and aversive behavior in rats. In the present study, 132 neurons responsive to graded colorectal distension (20-100 mm Hg, 20s) were characterized in 35 spinalized and 7 deeply pentobarbital-anesthetized rats for long ascending projections (antidromic invasion from medulla), convergent cutaneous receptive fields (brush, pinch, heat, cold) and responses to the intraarterial administration of the algesic peptide bradykinin. Using the terminology of a previous study of L6-S1 spinal neurons (Ness and Gebhart, J. Neurophysiol. 57: June, 1987), neurons were grouped into four classes based upon responses to a standard 80 mm Hg, 20 s distending stimulus: [1] short latency-abrupt (SL-A; fast ONset of response, abrupt OFF-termination of response), [2] short latency-sustained (SL-S; fast ON, slow OFF), [3] long latency (LL; slow ON, slow OFF) and [4] inhibited (INHIB). The following table summarizes some of the data:

Neuronal Class	n (spinal:intact)	convergent cutaneous receptive field	long ascending projections	excited by bradykinin
SL-A	46 : 9	55/55	6/9	10/13
SL-S	31 : 11	42/42	9/11	12/12
LL	0 : 4	3/4	0/4	-
INHIB	24 : 7	31/31	3/8	1/4 3 (inhibited)

Neurons with convergent cutaneous input were mostly Class 2 and Class 3 (responsive to non-noxious and noxious or only noxious stimuli, respectively). Stimulus-response functions were linear, accelerating and monotonic. The threshold for response for SL-A neurons is near 0 mm Hg whereas SL-S neurons have a higher threshold (mean, 15 mm Hg for intact rats). Tonic inhibition or excitation in individual SL-A and SL-S neurons was demonstrated by spinal cold block of the cervical cord. LL neurons, not apparent in spinalized rats, 'converted' to SL-S neurons with cold blocks.

These data indicate that spinal neurons encoding for colorectal distension in the T13-L2 spinal cord of the rat are similar, if not identical, to neurons characterized in the L6-S1 spinal cord and likely are visceral nociceptors. Supported by DHHS awards NS 19912 and DA 02879; T.J.N. is supported by a Life and Health Insurance Medical Research Fellowship.

34.12 NOCICEPTIVE ACTIONS OF NMDA IN THE RAT SPINAL CORD L. M. Aanonsen* and G. L. Wilcox (SPON: L. Lichtblau) Department of Pharmacology, University of Minnesota, Minneapolis, MN 55455.

An abundant literature now supports involvement of receptors for excitatory amino acids (EAA) in the mediation of synaptic transmission in the mammalian spinal cord. Recent studies have indicated involvement of glutamate in spinal nociceptive transmission (Schneider and Perl, Brain Res. *360* [1985]: 339; Willcockson *et al.*, J. Neurosci. *6* [1986]: 2509). While these experiments suggest that EAAs act as sensory neurotransmitters, few studies have been performed which systematically examine the role of the three EAA receptor subtypes in sensory pathways. The experiments presented here have compared excitation elicited by EAA receptor agonists (NMDA, Quis and KA) on identified spinal neurons in the rat and the effect of iontophoretically applied PCP on EAA-induced excitation.

Extracellular recordings were made from a total of 34 neurons in the lumbar spinal cord of 27 rats. We found that 65% of the cells tested were excited by at least one EAA. The modality of each neuron was classified as low threshold (LT), wide dynamic range (WDR) or high threshold (HT). NMDA-responsive cells were primarily identified as WDR or HT neurons:

Iontophoretic Agent	LT + Proprioceptive	WDR + HT	% Nociceptive
NMDA	3 (15)	12 (15)	80*
Quis	7 (16)	9 (16)	56
KA	5 (8)	3 (8)	38

* $p<0.05$ NMDA compared with KA, Chi-squared test

Cell firing induced by NMDA was inhibited in 100% of the cells tested with PCP. This is in contrast to Quis-induced firing in which 33% of Quis-excited cells were inhibited by PCP. PCP was also shown to enhance Quis-induced firing in 40% of the cells tested. KA-induced firing was not inhibited by PCP in any of the cells tested; however, firing induced by KA was enhanced by PCP in 43% of the cells tested. We concluded from these experiments that NMDA, more potently than Quis or KA, selectively excites neurons responsive to noxious stimuli and that the responses to NMDA are selectively blocked by PCP.

These results together with recent behavioral experiments (Aanonsen and Wilcox, JPET [accepted, pending revision], 1987) suggest that receptors for NMDA are selectively involved in nociceptive processing in the rodent spinal cord. (Supported by USPHS grants DA-01933, DA-04274 and DA-04090).

34.13 INTRACELLULARLY STAINED CELLS and AFFERENT FIBERS IN NUCLEUS CAUDALIS AND THE SPINAL TRIGEMINAL TRACT.
R.C. Shults and A.R. Light. Depts of Orthodontics and Physiology, UNC-Chapel Hill, NC 27514.
In anesthetized cats, primary afferent fibers and cells with nociceptive specific, multimodal (responding at higher frequencies to noxious pinch and noxious heat than to low threshold mechanical stimuli) and cooling specific response characteristics were recorded and then labeled by intracellular or intra-axonal injection of horseradish peroxidase. A cooling specific primary afferent fiber with a receptive field on the tip of the tongue was exceptionally well stained from rostral nucleus oralis (NO) through caudal nucleus caudalis (NC). The parent fiber gave off collaterals with terminal boutons in islands of neuropil termed the interstitial nucleus of the spinal trigeminal tract (ISVT) overlying NO and nucleus interpolaris (NI) rostral to obex. We have previously reported that these islands become apparent in the tract at the level when layers I and II break up and become separated from the underlying nucleus at the transition between NI and NC and continue in the tract rostrally as far as NO. Other collaterals from this same fiber terminated in layers I and II of NC. Therefore, collaterals from the same parent fiber terminated in ISVT, rostral to obex, and layers I and II of NC.
All but two labeled postsynaptic cells were distributed throughout the full width of layer IIo. Dendrites of cells with multimodal input traversed several laminae (layers I through IV). In contrast dendrites of cells with nociceptive specific responses were confined within layers I and II of NC. Two exceptional neurons were recorded; these cells had nociceptive response properties, were located in ISVT and had nociceptive receptive fields limited to midline perioral and oral structures.
These findings are consistant with the hypothesis that ISVT is homologous to NC layers I and II. Previous reports hypothesized this homology based on neuro-transmitters found in ISVT which are the same as those in NC layers I and II. However, the specificity of receptive fields to midline perioral and oral structures in ISVT is unique and thus ISVT may represent a nociceptive relay specific for these structures.

34.14 Dental Surgery Induces Neck Muscle Inhibition in the Rat. V.A. Lewis, Department of Pharmacology, University of Texas, Dental Branch, Houston, Tx 77225.
Wall(1) has hypothesized that injury induces consecutive behavioral (pain related) states, identified as immediate, acute and chronic pain states. The effects of a dental extraction on identified sleep state indexes were studied to determine if Wall's post injury states could be measured. Sprague-Dawley rats were prepared with indwelling electrocorticographic (ECG), neck muscle electromyographic (EMG) electrodes and an indwelling intrajugular cathter and allowed to recover for 1 week. Under pentobarbital anesthesia (40 mg/Kg), the right three maxillary molars were extracted in 10 experimental rats. An equal number of control animals received all surgical drugs but no extraction. Recording of EEG and EMG activity were made at 3,9 and 27 hours following surgery. The recorded sample consisted of 60 2 second samples with a 30 second interval between recordings. Raw EEG and EMG recordings were converted to the following indexes for comparisons: integrated EEG zero crossing index(Z), EEG amplitude index(D), EEG theta/delta frequency ratio (F), integrated EMG(M), and integrated gross motor activity(T). Comparisons between the extraction and control were assessed using analysis of variance followed by a T test. Because the Z, M and T indices decrease with time, data for samples in minutes 4-8 and 16-20 were compared separately. Three hours following surgery integrated EMG was 21% of control in minutes 16-20, a significant reduction, $P=<0.05$. No other indices were significantly changed. Wall's hypothesis suggests that injury is followed by arousal and then depression. In this experiment the sleep state indexes were not altered by an injury that did depress neck muscle activity.

34.15 RESPONSES OF TRIGEMINAL NUCLEUS CAUDALIS NEURONS TO MECHANICAL AND CHEMICAL STIMULATION OF CRANIAL BLOOD VESSELS.
A. Strassman, J. Pile-Spellman*, R. Oot*, P. Mason, M Moskowitz, R. Maciewicz. Neurology, Neurosurgery, and Radiology services, Massachusetts General Hospital, Harvard Medical School, Boston MA 02114.
Stimulation of cranial blood vessels in humans during neurosurgical or angioplastic procedures typically evokes painful sensations that are referred to the ipsilateral forehead and eye. Previous work by this laboratory has shown that electrical stimulation of dural blood vessels activates a population of neurons in rostral trigeminal nucleus caudalis; many of these cells also have nociceptive cutaneous receptive fields in the ipsilateral first trigeminal division. The visceral and somatic convergence on single trigeminal neurons may explain the pattern of cutaneous referral of cranial vascular pain.
In order to further characterize the vascular responses of this population of caudalis neurons, extracellular unit activity was recorded during mechanical or chemical stimulation of cranial blood vessels in anesthetized cats. Neurons that responded to electrical stimulation of the superior sagittal sinus (SSS) were tested with mechanical stimulation by inflating an intraluminal balloon-tipped catheter in the internal maxillary artery (IMA), or by applying upward traction to the SSS. The neuronal response usually consisted of a short duration, high frequency burst of firing that did not outlast the stimulus. Chemical stimulation was carried out by perfusion of algesic substances either through a catheter positioned trans-femorally in the IMA at the origin of the middle meningeal artery, or through a needle advanced into the SSS through the dura. Approximately one-third of the neurons that responded to electrical stimulation of the SSS also responded to injection of 0.2-0.5 ml of bradykinin (10^{-4}M - 10^{-5}M) into the IMA or SSS. Neuronal responses to bradykinin injection were usually 30-90 seconds in duration. Responses were also found following injections of serotonin (200 ug/ml) and KCl (300mM), but not normal saline. Control injections into the inferior vena cava were similarly ineffective.
Systemic pretreatment with intravenous lidocaine in doses that relieve clinical vascular head pain in humans (2mg/kg) completely suppressed the neuronal response to bradykinin injection into SSS for a period of 15-20 minutes. Intravenous lidocaine had no effect on the cutaneous responses of brainstem trigeminal neurons, however, suggesting that this dose of lidocaine blocks the bradykinin response through a local effect on the blood vessel wall.
These results provide further evidence that brainstem trigeminal neurons with vascular responses are involved in mediating the painful sensations evoked by stimulation of cranial blood vessels; such neurons may also play an important role in the pathogenesis of clinical syndromes of vascular head pain.

35.1 **DOES CNS REMYELINATION RECAPITULATE CELLULAR AND MOLECULAR EVENTS OF MYELINATION?** C. A. Jordan,* V. L. Friedrich, Jr., F. de Ferra,* D. G. Weismiller,* N. K. Zeller,* K. V. Holmes* and M. Dubois-Dalcq. Laboratory of Molecular Genetics, NIH, Bethesda, MD 20892, The Wistar Institute, Philadelphia, PA 19104, and Department of Pathology, USUHS, Bethesda, MD 20854.

The major events characterizing CNS myelination in rodents consist of (1) the migration and proliferation of glial progenitor cells and their differentiation into oligodendrocytes expressing galactocerebroside, a myelin glycolipid, and (2) the subsequent expression by these oligodendrocytes of myelin proteins such as myelin basic protein (MBP), proteolipid protein (PLP) and myelin associated glycoprotein (MAG), which will be incorporated into the myelin sheath. In the course of a demyelinating disease in mice induced by the A59 strain of mouse hepatitis virus, extensive remyelination occurs but it is not known whether the remyelinating cells regulate the synthesis of myelin gene mRNAs and proteins as developing oligodendrocytes do or whether these cells are derived from precursors identical to those present in the neonatal CNS. With the recent elucidation of surface molecules characteristic of progenitor cells and with the cloning and sequencing of myelin protein genes, it is now possible to approach these questions.

Dividing glioblasts were detected at 2 and 3 weeks post-inoculation (PI), when infected animals were pulsed with tritiated thymidine 2 hours before sacrifice. In order to correlate the presence and location of precursor cells and specific transcripts with proper myelin staining and inflammatory cell identification, we combined a series of techniques on frozen sections of optimally fixed spinal cord tissue of demyelinating animals. Demyelinating lesions, clearly delineated by Sudan black staining, contained inflammatory cells differentially stained by cresyl violet and the lesions also had increased immunostaining for glial fibrillary acidic protein. Adjacent sections were hybridized with single stranded DNA or RNA probes labeled with ^{35}S and specific for MAG, PLP or MBP transcripts. Binding of all probes was considerably decreased in the demyelinating lesions at 2 and 3 weeks PI, while transcripts appeared variably increased in the spinal cord tissue around the lesion at 3 weeks. There are four species of MBP transcripts which are differentially spliced during development. Exon 2 genetic information is characteristic of myelinating tissues during early development. Consequently, we performed Northern blot analysis on mRNA of spinal cord of demyelinating animals using an MBP exon 2 specific probe. Demyelinating animals showed a 50% increase in MBP exon 2 specific binding.

These observations suggest that demyelination and remyelination are associated with a series of proliferative and differentiational events which resemble, at least in part, the tightly regulated events of myelination during development. Topographic considerations suggest that factor(s) diffusing from lesioned areas to adjacent intact white matter may trigger these events.

35.2 COMPARATIVE FRACTURE FACE MORPHOLOGY OF MYELIN: IS PRIMATE MYELIN DIFFERENT FROM RABBIT AND RAT. R.G. Miller and L. Lalonde*. Dept. of Anatomy, The University of Calgary, Calgary Alberta Canada.

When myelin is prepared for freeze-fracture with the standard methods of glutaraldehyde fixation and glycerol impregnation, there is little difference between the P and E fracture faces. Major differences exist between these faces when tissue is frozen without fixation or glycerol impregnation. We have examined the face morphology of peripheral myelin obtained from the rat, rabbit, chicken and primate (Macaca nemestrina). Sciatic nerve was excised from anesthetized animal, briefly rinsed in phosphate buffered saline, cut into 1-2 mm pieces, mounted on gold Balzers specimen stubs, and frozen in partially solidified freon. Total time from excision to freezing was less than 2 min. Care was taken not to stretch the tissue.

In all species studied, lamellar myelin demonstrated two face morphologies. One face was smooth with few globular particles typic of other biological membranes. The other face contained a few globular particles but a high density of "string-shaped" particles which are packed so closely as to prohibit counting of the particles. By counting fracture planes from the Schwann cytoplasm and from the axon, the smooth face was determined to represent the P face while the face with stringy particles is the E face. The string-shaped particles were more distinct in the deeper lamellar myelin than in the juxta-cytoplasmic layer in all species.

The interperiod line of myelin represents the apposition of the extracellular surfaces of Schwann cell plasma membrane and has been shown to be a lanthanum penetrable gap. In fresh freezing of myelin, dendritic ice forms in aqueous compartments of the lamellar myelin. In the case of the rabbit, rat and chicken, this aqueous compartment containing dendritic ice was always found to be within the interperiod line. In contrast, in the monkey, dendritic ice was frequently found in the major dense line compartment which represents the apposition of the intracellular surfaces of the Schwann cell membrane.

Other species differences were noted in the axolemma and periaxonal Schwann cell membrane. In particular, clusters of bar shaped particles on the axolemma and hexagonal rosettes of large particles on the periaxonal Schwann cell membrane were present in the rat, but not in any other species studied. Clusters of small pleomorphic particles on the axolemmal P face seen in all other species studied may be analogous to the rosette seen in the rat. This work was supported by grants from NSERC and MRC.

35.3 DECREASED IRON LEVELS IN THE MYELIN-DEFICIENT RAT. J.R. Connor, B. Garber*, L. Potter*, and A. Oni*. Depts. of Physiology and Medicine, Geo. Washington Univ. Sch. of Med., Washington, DC 20037

Recent studies have demonstrated iron, transferrin (the iron mobilization protein) and a mRNA for transferrin in oligodendrocytes of the rat CNS. Furthermore, 80% of the iron content of the brain is reportedly in myelin. Also, iron uptake from plasma and the appearance of transferrin in the nervous system coincide with the onset of myelination. These observations strongly suggest a relationship between iron (mobilized by transferrin) and myelin formation and maintenance. The purpose of the study reported here is to determine the effect of dysmyelination on iron levels in the rat CNS. The animals used were a strain of Wistar rat with an X-linked recessive mutation which is characterized by dysmyelination (Csiza & deLahunta, Am. J. Pathol.,1979). These animals have ataxia and tremors and usually die within 3-4 weeks of birth. There is virtually no CNS myelin and most of the oligodendrocytes have ultrastructural abnormalities. Myelin-deficient (md) rats were matched with unaffected littermate controls and sacrificed between 25-30 days of age for either histological examination for iron (Perl's Reaction) or atomic absorption spectrophotometry (AAS). For the histology, animals were perfused with 10% neutral buffered formalin; followed by removal of the brain, cerebellum and pons. Sections were cut at 50 µm thickness and placed into Tris buffered saline. The Perl's reaction consisted of incubating tissue in 2% HCl and 2% Potassium Ferrocyanide (1:1) for 30 minutes followed by 15 minutes in 3-3'diaminobenzidine (DAB) to enhance the iron reaction product. Sections incubated in DAB only were used as control tissue. For AAS, the animals were perfused with saline, the tissue removed and frozen on dry ice and then stored at -20°C until time for assay. The tissue was prepared for assay by weighing it, lyophilzation and then digested with hydrogen peroxide. Iron samples were read on a Varian-Techtron Atomic Absorption Spectrophotometer. Only cells in the white matter of both the control and md rats contained iron reaction product. In the normal animals, the iron-positive cells had a round soma and short, sinewy processes. In the md rat, the somata were amorphous or rectangular and some of the processes had a broad initial segment. The cells in both cases are presumably oligodendrocytes, but ultrastructural confirmation is necessary. Quantitative analysis with AAS revealed a decrease of iron (meq/gm wet wt) in the brain (91.8% difference); pons and cerebellum (100%); liver (75.8%) and heart (33.3%) of the md rat compared to normal. The quantitative data demonstrate a severe lack of iron in the md rat which is not confined to the CNS. This latter observation suggests that uptake of iron may be effected in the md rat perhaps at the level of the transferrin receptor. JRC is supported by NS 22671 and 25 07 RR05359-23 (GWU).

35.4 OLIGODENDROCYTES IN DEVELOPING JIMPY MUTANT MICE: A QUANTITATIVE IMMUNOCYTOCHEMICAL ANALYSIS. M.S. Ghandour*, P.E. Knapp and R.P. Skoff (SPON: D. Michael). Dept. of Anat. and Cell Biol., Wayne State Univ. School of Med., Detroit, MI 48201.

The processes leading to the abnormalities in the CNS of jimpy mutant mice and the defects in cell differentiation and/or maturation are still not elucidated. To determine if either the oligodendrocyte differentiation or maturation is affected we analyzed the number of oligodendrocytes at different ages in tissue sections labeled for oligodendrocyte markers, and in primary cultures at light and scanning electron microscopic levels. We examined the cerebellum and corpus callosum of jimpy mice at 6, 10 and 15 days postnatally using the immunogold labelling techniques for galactocerebroside (GC). The cell surface labelled with gold particles was examined at scanning electron microscope level for GC. Brains from 6, 10 and 15 day old normal and jimpy mice were removed after perfusion with 4% paraformaldehyde in PBS with or without 0.1% glutaraldehyde, and then postfixed for 72 hrs at 4°C. 100 um vibratome thick sections were used for immunohistological study. Sections were incubated with monoclonal antibody to GC for 1hr at room temperature. Afterwards the sections were incubated for 2 hrs at room temperature with colloidal gold and peroxidase conjugated goat anti-mouse IgG. Living cells in culture from 5 day old cerebella and from newborn cerebral hemisphere were stained for GC and analysed at light and scanning electron microscope levels after labelling with gold particles and silver enhancement. The number of oligodendrocytes (GC+) in cerebellum and corpus callosum per section in normal animals at 6d of age are 75±18 and 80±22 respectively. This number increases to 122±20 and 137±16 at day day 10 and to 126±24 and 160±18 at 15 days respectively. No significant differences in the numbers of stained cells in jimpy cerebellum and corpus callosum at the same ages was observed. For jimpy cerebellum the number of cells is 65±18, 111±15 and 130±16 at 6, 10 and 15 days of ages respectively, while in corpus callosum the number of stained cells is 77±22, 126±16 and 154±24 at 6, 10 and 15 days respectively. Our data suggests that the differentiation of oligodendrocytes in vivo in the jimpy mutant occurs according to the normal developmental clock. The cells are able to express the different markers (MBP, CAII, and CNP). These differentiated oligodendrocytes are unable to reach maturation.

35.5 JIMPY MYELIN LACKS PLP AND HAS A DEFECT IN THE INTRAPERIOD LINE. I.D. Duncan, J.P. Hammang* and K.F. Jackson*. Department of Medical Sciences, School of Veterinary Medicine, University of Wisconsin, Madison, WI 53706.

The jimpy mouse, an X-linked myelin mutant, has been the subject of considerable recent molecular biological investigation. The localization of the proteolipid protein (PLP) gene to the X chromosome, and the subsequent finding of a mutation in this gene with the production of a PLP message which has a 70-74 base pair deletion, has focused interest on this major CNS myelin protein. The present study follows similar work which we have done with another X-linked myelin mutant, the myelin deficient rat, where we showed that the myelin produced was myelin basic protein (MBP) positive, yet PLP negative, with an abnormally compacted intraperiod line (Duncan, et al. PNAS, submitted). To compare these findings with jimpy, 10 jimpy mice at 16 days of age, and age matched controls were perfused with a modified Karnovsky's fixative (3) or mercuric chloride (2), or 0.1% glutaraldehyde (2), or immersion fixed in formalin (3), and the C_1-C_2 and L_1-L_2 spinal cord segments processed for embedding in epon, paraffin or vibratome sectioning. Plastic sections were stained with toluidine blue or etched and reacted with antisera to either MBP or PLP, and stained with the PAP technique. Paraffin and vibratome sections were similarly stained. The plastic sections were further trimmed for thin sectioning . Numerous myelinated fibers were seen throughout the spinal cord white matter. Immunocytochemistry showed that these fibers stained strongly for MBP yet were negative for PLP. This was consistent for tissue fixed and processed in the different ways noted above. EM examination showed that many fibers had thick, compacted myelin sheaths (up to 23 lamellae). However, higher power examination revealed an abnormal intraperiod line, with rare evidence of a double leaflet. This was in marked contrast to controls. These results add further weight to the role of PLP in the pathogenesis of the mutation but question the role that this protein plays in the formation and compaction of CNS myelin.

35.6 DEMYELINATION IN A TISSUE CULTURE MODEL OF PERIPHERAL NERVE BY SERUM FROM PATIENTS WITH GUILLIAN-BARRE SYNDROME (GBS). C.L. Koski*, M.B. Clark, and S. Mane* Depts. of Neurology and Anatomy, Univ. of Maryland, Sch. of Med., Baltimore, MD 21201.

Using an assay that detects antibody (Ab) by fixation of the first component of complement this laboratory has previously shown that titers of Ab to peripheral nerve myelin (anti-PNM Ab) are elevated 6-56 times over controls in the serum of acute phase GBS patients, that anti-PNM Ab titers fell dramatically during the first 2 to 3 weeks following hospitalization, and this decline in anti-PNM Ab titer correlated with clinical improvement (Koski et. al. PNAS 82:905 1985). It has been suggested that the primary demyelination of peripheral nerve associated with GBS is immunologically mediated, although no specific mechanism of myelin destruction has been demonstrated. To study a possible role for anti-PNM Ab in demyelination of peripheral nerve, we compared serums from acute-phase GBS patients with high anti-PNM Ab titers (100-220 units/ml) to serums of the same patients during the recovery-phase (0-14 units/ml) and to serums of normal controls without disease (0-10 units/ml)for their ability to mediate complement dependent demyelination in a tissue culture system in which rat Schwann cells have myelinated dorsal root ganglion neurons.

Groups of well myelinated cultures were treated with heat inactivated (HI) serums diluted 10 fold in tissue culture media which contained ascorbic acid (50 ug/ml). Factor B depleted normal human serum (Bd-NHS), 20%, was used as a source of fresh complement in order to prevent activation of the complement cascade by the alternative pathway in the absence of specific Ab. Cultures, maintained in serum free media for 48 hrs, were incubated with experimental serums and observed after 6,12,24 and 48 hours. Myelin integrity was assessed by light microscopic observations of living and aldehyde fixed, Sudan black stained cultures. Only HI-serums from acute-phase GBS patients with high anti-PNM Ab titers in the presence of Bd-NHS caused demyelination in the cultures. Myelin breakdown occurred progessively. Swellings appeared along myelin internodes followed by segmentation of the internode into ovoids and smaller balls of myelin.Demyelination was obvious as early as 6 hrs in some cases and pronounced by 24 hrs. Nerve cells were not obviously affected by GBS serum. Neither HI - control or low titer GBS serum with Bd-NHS, GBS HI-serum alone or Bd-NHS alone caused demyelination or Schwann cell death. These studies, using a tissue culture model in which the effects of other cellular agents can be eliminated suggest that anti-PNM Ab in the serum of GBS patients can mediate demyelination of peripheral nerve and that in this in vitro system, the effect is dependent on the classical pathway of complement. (Supported by NIH-NINCDS grant# 2 P01 N 220022-04.

35.7 SUPPRESSION OF SCHWANN CELL PROLIFERATION IN CULTURE BY ETHANOL. F.A. Mithen, M.M. Wessels* and R. Birchem*. Dept. of Neurology, St. Louis Univ., St. Louis, MO 63110 and John Cochran Veterans Administration Medical Center, St. Louis, MO 63106

It is possible to treat dissociated embryonic rat dorsal root ganglia in culture to inhibit proliferation of all non-neuronal cells except Schwann cells. Neurons have been shown to elaborate a mitogenic stimulus to Schwann cells under these conditions. Groups of sibling cultures (10-15 cultures per group) were exposed to various concentrations of ethanol (0, 43, 86, or 172 mM) for 4 weeks. Cultures were assessed weekly in a blind fashion for evidence of Schwann cell proliferation by light microscopy. There was a 94% reduction in Schwann cell proliferation in the presence of 172 mM ethanol (P less than .001 by Fisher's one-tailed t-test with four separate trials), but not in lower concentrations. No obvious differences in neuronal morphology were observed among the various groups of cultures by light or electron microscopy.

These observations suggest that ethanol might interfere with Schwann cell proliferation in culture by one or both of the following means: (1) inhibit neuronal production of Schwann cell mitogens or (2) impede Schwann cell response to neuronally produced mitogens. Investigation of these possibilities in culture may provide insight into neuropathological mechanisms operative in the fetal alcohol syndrome or alcohol associated peripheral neuropathy in humans.

35.8 TRANSFECTION OF SCHWANN CELLS WITH SV40 LARGE T ANTIGEN GENE UNDER THE CONTROL OF WILD TYPE AND SYNTHETIC METALLOTHIONEIN PROMOTER (MT-1). G. Tennekoon* and K. W. C. Peden* (SPON: G. McKhann). Department of Neurology and Department of Genetics and Molecular Biology, Johns Hopkins University School of Medicine, Baltimore, MD 21205.

The availability of immortal Schwann cell lines with properties identical to those of secondary Schwann cells would have obvious advantages for studying Schwann cell-axon interaction. Neonatal rat Schwann cells were transfected with SV40 large T antigen gene under the control of the wild type MT-1 promoter. The transfection efficiency was 0.01% and the cells that had integrated the foreign DNA were selected with G418. After single cell cloning, it was apparent that the cells expressed SV40 large T antigen, but the expression of this protein was not stringently regulated by the activity of the MT-1 promoter (by changing zinc concentration in the medium). Although large T antigen decreased by about 50% when zinc was eliminated from the medium, the transfected cells continued to express proteins and enzyme activities characteristic of untransfected cells, albeit at a reduced level. Moreover, the rapid doubling time (20 hr) also was maintained. Since it was likely that the continued expression of the large T antigen was due to basal activity of the MT-1 promoter, we attempted to provide more stringent regulation by using synthetic metallothionein promoters. The synthetic promoter contained either 4 or 5 metal regulatory elements (MRE) and a TATA box, but none of the sequences responsible for basal activity. Each synthetic promoter was ligated to either chloramphenicol acetyltransferase (CAT) or SV40 large T antigen gene. The wild type MT-1 promoter was much stronger than the synthetic promoter. After transfection, selection with G418, and single cell cloning, stably integrated lines were examined for large T expression. With both synthetic promoters in the presence of zinc, cells divided rapidly but they were contact-inhibited and had none of the features of a transformed cell. One clone containing the 4 MRE promoter demonstrated tight regulation of large T antigen expression as examined by indirect immunofluorescence and Western blot and lysis. Moreover, when zinc was eliminated from the medium these cells divided more slowly. Currently other cell lines are being examined for large T expression.

35.9 MODIFICATIONS OF MORPHOLOGY AND ANTIGENIC EXPRESSION BY CULTURED, TRANSFECTED SCHWANN CELLS. T.J.Neuberger, J.Yoshino *+, G.H. DeVries° and C.J. Cornbrooks+. Dept. of Anat. & Neurobiol., UVM, Burlington, VT.; +Dept. of Psych., Colgate Coll., Hamilton, N.Y. and °Dept. of Biochem., VCU, Richmond, VA.

Differentiation of Schwann cells (Sc) during development or regeneration occurs in a sequentially ordered series of biochemical stages which normally proceed with exquisite precision. These stages are directly influenced by environmental factors and include interactions with soluble molecules as well as extracellular matrix (ECM) and other cells. One approach toward characterizing the molecules which regulate the progression of Schwann cell differentiation is to examine transfected cells. Accordingly, we have begun to study a transfected Schwann cell line established by utilizing a plasmid containing the SV40 large T oncogene regulated by the mouse metallothionein (MT-1) promoter (Trans. Am. Soc. for Neurochem.(1986) 17, 114). Transfected Schwann cells (tSc) were established on three substrates: glass, type 1 collagen and Matrigel, a mixture of ECM molecules. The cells were assessed for alterations in their morphology, rate of proliferation and the expression of known Schwann cell antigens. Indirect immunohistochemical methods were used to describe the localization of actin, vimentin, glial fibrillary acidic protein (GFAP), plasminogen activator and laminin or heparan sulfate proteoglycan and C4, two antigens expressed by Sc after neuronal contact.

Unlike pure populations of normal Sc which only maintain a bipolar to round morphology in vitro, tSc also assumed a multipolar or fibroblast-like shape on the three substrata. Moreover, tSc usually formed aggregates and fascicles which radiated from the cellular masses. The transfected cells continued to proliferate on the three types of substrates although those seeded on Matrigel divided at a reduced rate. While the cytoskeletal proteins, actin and vimentin, were both expressed by normal and tSc, the filamentous pattern was more apparent in the pleomorphic cells. Further, GFAP expression was prominent in the cell line but minimal in normal Sc. In comparison to normal Sc, laminin immunoreactivity was diminished and plasminogen activator immunoreactivity was increased in or on the transfected cells. Surprisingly, both the proteoglycan and the C4 antigen were expressed by aggregated tSc; whereas, normal Sc require axonal contact before expressing the same staining characteristics.

These observations demonstrate that tSc, which are suspended in an early stage (proliferation) of differentiation, assume a morphological shape and a partial antigenic repetoire which hallmark the more mature stages of Sc differentiation.

35.10 cDNA CLONING OF SPECIFIC TRANSCRIPTS FROM A MOUSE CEREBELLAR ASTROGLIAL PERMANENT CELL LINE. +T. Rhyner *, ++ E. Lecain *, + J. Mallet *, and ++B. Pessac (SPON:B. Zalc). +Centre de Génétique Moléculaire, CNRS, 91190 Gif-Sur-Yvette, France. ++Centre de Biologie Cellulaire, CNRS, 94200 Ivry-Sur-Seine, France.

We have previously reported the derivation from 8 day post natal mouse cerebella of two permanent clonal cell lines with astroglial properties which might be the in vitro counterparts of the velate protoplasmic astrocytes (clone D19) and of the Golgi Bergmann epithelial cells (clone C8S) (Alliot, F. and Pessac, B. Brain Res. 306, 283-291, 1984). These two clonal cell lines originated from the same culture and have been spontaneously immortalized. These two astroglial clones provide for an excellent survival of embryonic cerebellar neuroblasts and furthermore clone D19 triggers the differentiation of the majority of these neuroblasts into granule cells (Pessac, B. and Alliot, F., Soc. Neurosci. Abstr., vol 12, Part 1, p. 397, 1986).

We then decided to use the techniques of molecular genetics, described by Rhyner T. et al. (J. Neurosci. Res., 16, p. 167-181, 1986), in an effort to isolate mRNAs that are specifically expressed in D19 as compared to C8S cells.

A subtracted cDNA library was constructed from cytoplasmic poly(A)$^+$ RNA of D19 cells. Single stranded cDNA was hybridized in liquid medium with an excess of C8S poly(A)$^+$ RNA. The unhybridized cDNA was then purified by hydroxylapatite chromatography, transcribed into a double-stranded form inserted into a plasmid and cloned in E. Coli.

This library was enriched about 12-fold for sequences selectively expressed in D19 cells, as 92% by weight of the cDNAs were eliminated by hybridization. The average size of the inserted sequences was about 200 bp.

4000 cDNA-clones were differentially screened with subtracted cDNA probes derived from D19 and C8S cells. The D19 cDNA-probe subtraction was carried out as above and the C8S cDNA-probe subtraction was performed with C8S poly(A)$^+$ mRNA in order to enrich this probe for low abundance sequences. The clones which only reacted positively with the subtracted D19 cDNA-probe were further analyzed by Northern-blot using poly(A)$^+$ RNA from D19 and C8S cells. 5 clones hybridized to transcripts selectively expressed in D19 relative to C8S cells while two clones were overexpressed in D19 cells.

The distribution of these mRNAs was studied by Northern-Blot analysis in various mouse tissues and at least one of them was found specifically expressed in the CNS.

35.11 **MOLECULAR CLONING OF A RAT BRAIN S100 ß cDNA.** D.C.Hilt[1] and D.Kligman[2]. ([1]Lab of Biochem. Genetics, NHLBI, [2]Lab of Cell Biology, NIMH, NIH, Bethesda Md. 20892).

We have previously shown that a Neurite Extension Factor (NEF) purified from bovine brain (PNAS, 82,7136-9) shows virtual protein sequence homology with a glial cell protein-S100 ß. NEF is a disufide bonded form of S100ß that stimulates neurite extension from dissociated chick embryo cerebral cortical neurons and murine neuroblastoma cells (Neuro-2A cells) in defined medium. In order to characterize the expression of NEF and S100 ß at the molecular level, we undertook the cloning of a cDNA for S100 ß/NEF. A 36 base oligonucleotide probe corresponding to a homologous segment near the C-terminal region of S100 ß and NEF was synthesized. This probe was used to screen a rat brain lambda gt11 cDNA library. Ten positive clones were plaque purified and further characterized. Clone 9.3 had the longest cDNA insert which was 1.7kb in length. This cDNA was mapped with restriction enzyme digestion and restriction fragments were subcloned into M13 and completely sequenced in both directions. The cDNA was also subcloned into a SP6/T7 promoter vector to generate single stranded probes which were used for Northern and Southern blot analyses. Northern blot analysis of rat brain, C6 glioma, and murine NS20Y neuroblastoma RNAs was performed. A broad single 1.7kb mRNA hybridizing species was detected in rat brain and C6 RNA, but not in NS20Y RNA. Southern blot analysis of rat genomic DNA after digestion with BamHI and EcoRI with this probe showed multiple hybridizing species. In order to determine if related but nonhomologous RNA species are present, RNAse protection studies are presently being performed. This full length cDNA probe is currently being used to study the regulation of S100 ß expression in C6 glioma cells.

35.12 MORPHOLOGICAL ASSESSMENT OF INTACT "PROTOPLASMIC" ASTROCYTES ISOLATED FROM RAT CEREBRAL CORTEX. A. K. Salm and K. D. McCarthy*. Department of Pharmacology, University of North Carolina, Chapel Hill, North Carolina, 27514.

The technique of bulk-isolating intact astrocytes (Farooq and Norton, 1978) is attractive to investigators as it allows biochemical and morphological analysis of individual cells. In such preparations we have consistently (18+ isolations) observed two morphologic extremes of glial fibrillary acidic protein immunoreactive (GFAP+) astrocytes which correspond to previous descriptions of "fibrous" and "protoplasmic" astrocytes. Intermediate forms are also often seen. Here we describe the protoplasmic phenotype observed in these preparations. We have isolated these cells from adult (110+ days) rat cerebral cortices and examined them with a number of corrolative approaches including fluorescence and peroxidase immunocytochemistry (ICC), phase contrast microscopy, stereo scanning electron microscopy (SEM), computer-assisted morphometry, and enzymatic variation during the isolation procedure. Unlike the morphological variety exhibited by other isolated astrocytes, the protoplasmic cells exhibit marked structural consistency both within and between preparations. This subtype is seen to have a spherical form with symmetrically projecting GFAP+ processes radiating from a central nuclear area. These processes branch extensively until subbranches are no longer discernable with fluorescence microscopy. Superimposed upon this infrastructure is velate material which, comparatively, immunostains only slightly with anti-GFAP. A number of processes often project beyond the spherical bounderies of these cells and terminate in endfoot-like profiles. When viewed with phase contrast microscopy the surface topography of these cells appears rough and highly convoluted. At high magnification with stereo SEM this is seen to be due to the presence of innumerable membraneous protrusions on the cell surface. Occasional thin processes are visible coursing over the cell surface. Double immunostaining of these preparations with antibodies to the 200K neurofilament (NF) protein, although resulting in immunopositive processes elsewhere in the cell fractions, show only sporadic NF+ fibers associated with the GFAP+ protoplasmic cells. Computer-assisted morphometry of 67 of these cells determined the average area to be $\sim 1709 \pm 500\ \mu m^2$ ($\bar{X}$ + S.D.). Assuming a sphere-shape, volume estimates indicate that processes of these cells distribute within a volume of neuropil of $\sim 54{,}882 \pm 24{,}822\ \mu m^3$ cell. We have altered the enzymatic conditions of the isolation procedure and have observed a persistent appearance of these cells in preparations obtained after dissociation with trypsin, dispase II, or no enzyme. From these assessments we conclude that we are able to obtain isolated protoplasmic astrocytes in these preparations which resemble those seen with in situ HRP and Lucifer Yellow injections, Golgi impregnation and GFAP ICC of tissue sections. These preparations will prove useful in future studies of protoplasmic astrocyte structure and function. (Supported by NIH grant #NS20212).

35.13 STRUCTURAL CHANGES OF ASTROGLIAL MEMBRANES IN VITRO. J. H. Tao-Cheng, J. Bressler and M. W. Brightman*.
Lab. of Neurobiology, NINCDS, NIH, Bethesda, MD 20892.

Astrocytes have characteristic orthogonal arrays of particle assemblies in the P fracture face of their plasma membranes. These assemblies are distributed heterogeneously in vivo, with distinctly localized high concentrations (300-500/μ^2) in the astroglial membranes facing the blood vessels and the pia. To test whether the apposing blood vessels or the pia membranes have an effect on the concentration of the astroglial assemblies, astrocytes from 2-3 day old rats were cultured alone or co-cultured with bovine brain endothelial or rat meningeal cells and examined with freeze-fracture electron microscopy. The possible effect of the secondary messenger, cyclic-adenosine monophosphate (cAMP), on the astroglial assemblies was also studied.

Secondary, enriched astrocyte cultures (McCarthy and de Vellis 1980) have much lower concentrations of assemblies (1-10/μ^2) than the primary cultures (5-60/μ^2), and therefore, serve as a better baseline for monotoring any increase of assemblies brought about by various factors. The assembly concentration in solo, secondary astroglial cultures increased gradually over time up to 23 days in culture, the longest time the cultures were maintained. Co-culturing the secondary astrocytes with brain endothelium or meningeal cells consistently increased the assembly concentration at least 3-6 fold at all time points between 6-17 days. Bovine pulmonary artery, aortic endothelium and a tracheal derived cell line did not increase assembly numbers in astrocytes. However, fibroblasts from subcutaneous tissue of 2-3 day old rat did increase the astroglial assembly concentration ~ 5 fold. This result is not surprising because (a) fibroblasts are present in the adventitia of blood vessels larger than capillaries and (b) meningeal cells are a form of specialized fibroblasts. Thus, brain endothelial cells, meningeal cells and fibroblasts consistently induce an increase in astroglial assembly concentration.

cAMP may be an important second messenger for the increase in assemblies. Forskolin, which at 50 µM increases cellular cAMP levels in astroglia, augmented assembly concentration in solo astroglial cultures by 3-4 fold after 18-24 hours of incubation, and by ~15 fold after 3 days of incubation. In addition, the beta-agonist isoproterenol (10 µM) which also raises cAMP levels in astrocytes, induced an increase in assembly concentration and this induction was augmented if 3-isobutyl-1-methyl-xanthine, which inhibits cAMP degradation, was included. These results suggest that cAMP may be linked to the presence of assemblies in the astroglial plasma membrane. The consistent and substantial increase in astroglial assembly concentrations by these agents may be useful in isolating the assembly protein in order to ascertain its function.

35.14 **ROLLER TUBE EXPLANT CULTURES FOR STUDIES OF CNS PATTERN FORMATION.** **Dennis A. Steindler and Kristine L. Harrington*. Dept. of Anatomy and Neurobiology, Univ. Tenn. Memphis, 38163.**

One of the shortcomings of in vivo studies of nervous system pattern formation is establishing causality in the sequence of events leading to the development of functional circuitries. Attempting to uncover conditions responsible for the sorting of a given population of CNS neurons into a geometrically ordered functional unit requires examination of a myriad of extrinsic factors (e.g. afferents) which might provide cues to pre-aligned neurons. We have set out to use the roller tube explant system, originally described by Gähwiler (Neurosci., 11:751, 1984) for studies of the anatomy and physiology of identified neurons in slices, to determine intrinsic versus extrinsic factors involved in CNS pattern formation. Our initial focus is on the maturation of glial elements in slice cultures of neonatal mouse CNS. Previous studies performed in vivo (Cooper, N.G.F. & D.A. Steindler, Brain Res. 380:341, 1986; Steindler and Cooper, Dev. Brain Res. in press) implicate glia and associated glycoconjugates during pattern formation in numerous CNS areas. Brains from neonatal mice were rapidly sectioned at 400 um in the parasagittal or tangential planes. Slices, collected in Geys balanced salt solution (BSS), were then transferred to a plasma clot on a cover slip and cultured in test tubes in a medium made up of horse serum (25%), basal Eagle medium (50%), and Hank's BSS (25%) supplemented with glucose. The test tubes were rotated in a roller-drum (Bellco) rotated at 10 rev/hr in an incubator for up to 12 days. Parasagittal slices containing numerous, synaptically-related brainstem, midbrain, and forebrain structures were viable throughout the culturing period. Fixed slices processed for immunocytochemistry using antibodies to glial fibrillary acidic protein (GFAP) or vimentin show a differentiation of glial elements within explants that mimicked that observed in vivo. Slices cultured on postnatal day 2 and fixed 9 days later reveal immunoreactive cortical astrocytes with laminar organization that resembled that observed in vivo on postnatal day 11. In addition to an apparent normal maturation process of glial elements and cortical laminar arrangements of neurons in these explants, numerous glial boundaries were observed between various structures as seen during postnatal development in situ. These boundaries are made up of bundles of glial elements including radial fibers and astrocytes. The findings indicate that slice cultures can be used to study the development of CNS patterns with little or no compromising of normal morphogenetic processes.

35.15 ASTROCYTE-INDUCED DETACHMENT OF CULTURED NEURONS. PREVENTION AND LOCALIZATION OF THE ACTIVITY. G.M. Gilad, V.H. Gilad*, D. Dahl and A. Bignami. Department of Pathology, Harvard Medical School, Spinal Cord Injury Research, Veterans Administration Medical Center, West Roxbury, MA 02132 and The Center for Neurosciences, The Weizmann Institute of Science, Rehovot, Israel.

We have recently observed that detachment of neurons in primary embryonic CNS cultures is caused by the growing co-cultured astrocytes. Neurons degenerate secondary to their detachment from the substratum and this is probably caused by an activity associated with the astrocyte membrane. The present study demonstrates that in such primary culture systems, peripheral sensory neurons and motoneurons which project outside the CNS, as opposed to intrinsic neurons of the CNS, remain attached and closely associated with the growing astrocytes. Detachment of central neurons can be prevented by a variety of drugs which prevent the proliferation of astrocytes. Several types of proteinase inhibitors did not affect the process of detachment, while among several types of glycosaminoglycans only heparan sulfate could reversibly inhibit neuron detachment. Antiserum to membranes of cultured astrocytes that can block the astrocyte-induced detachment of central neurons, was localized immunocytochemically on surface membranes of astrocytes. These in vitro findings imply that in the CNS astrocytes may express a membrane-associated activity which can disturb the contacts of growing or regenerating central axons with their growth substrata.

36.1 DENDRITIC TRANSPORT OF RNA: AN ENERGY DEPENDENT PROCESS. L. Davis, C. Dotti*, G. Banker, and O. Steward. Department of Neuroscience, University of Virginia, Charlottesville, VA 22908, and Department of Anatomy, Albany Medical College, Albany, NY, 12208.

We have recently described a dendritic transport system for the selective delivery of RNA into dendrites using hippocampal neurons grown in culture (Davis, et al., Soc. Nesc. Abst. 12;1572, 1986). Dendritic transport of RNA occurs at a rate of around 0.5 mm/day, and the rate is linear over time suggesting an active transport system. To further investigate whether dendritic transport is an active energy-dependent process we evaluated whether transport was blocked by metabolic poisons in the same way that axonal transport is.

Hippocampal neurons were prepared as described previously and plated onto poly-lysine coated glass coverslips (Bartlett & Banker, J. Neurosci. 4;1944-1953, 1984). Cultures were incubated with 3H-uridine for 1 hour, rinsed in unlabelled medium to remove radioactivity and then transferred into either a medium containing an excess of cold uridine, or a medium containing azide (10mM) or DNP (10mM). After 6 hours, the cultures were fixed with paraformaldehyde and processed for autoradiography. In both azide and DNP-treated cultures as well as in control preparations (no metabolic poisons) the bulk of the labelling was found over the nucleus and cell body. In control preparations, the dendrites were labelled, indicating transport of RNA. In contrast, cultures that had been treated with azide or DNP exhibited only a small amount of labelling over proximal dendrites.

Some cultures were pulsed with 3H-uridine, incubated with azide for six hours, and then stained with fluorescein diacetate, a marker for viable cells. Fluorescein diacetate stained cells also showed very little transport of labelling out of the cell body. To assess viability in a different way, cultures were incubated with azide followed by a 30 minute pulse application of 3H-leucine; these cultures showed incorporation of label over the cell bodies and dendrites. These results indicate that cells were viable following treatment with metabolic poisons, yet the transport of RNA was inhibited. Taken together, these results suggests that the selective dendritic transport of RNA is an energy-dependent process, similar to that of fast axonal transport. Supported by NIH NS23094 to G.B., O.S., and C.D. and predoctoral fellowship NIH NS07199 to L.D.

36.2 TRANSSYNAPTIC TRANSFER OF THE BINDING FRAGMENT OF TETANUS TOXIN. P. S. Fishman, J. M. Savitt, and D. R. Carrigan (SPON: S. R. Max). VA Research Labs, Dept. of Neurology, Univ. of Maryland Sch. of Med., Baltimore, MD 21201.

Both tetanus toxin and its 45 kD binding fragment (C-fragment) are transferred extensively from retrogradely labeled motorneurons to presynaptic terminals in the spinal cord. We have used immunocytochemistry and enzyme histochemistry on both the light microscopic and ultrastructural level to elucidate the cellular basis for this unique property. C-fragment (CALBIOCHEM) was injected intramuscularly into the forearm or tongue of mice. Animals were sacrificed at intervals from 1 to 21 days, and tissue processed for immunocytochemistry using antisera raised in rabbits against purified C-fragment. Within two days following injection, there is extensive movement of label from motorneurons to the adjacent neuropil. Over the next several days, there is a slow expansion of the region of labeled neuropil around the originally labeled motorneurons. The neuropil is uniformly labeled without distinct labeled neurons seen with other transsynaptic labels such as WGA-HRP. Supraspinal neurons were rarely labeled. A second series of animals were injected with C-fragment conjugated to horseradish peroxidase. Spread of C-fragment-HRP through the neuropil after intramuscular injection, as demonstrated by enzyme histochemistry, is identical to that of native C-fragment detected with immunocytochemistry. C-fragment-HRP was also localized on a subcellular basis. Motorneurons had many labeled vesicles characteristic of uptake by endocytosis. Virtually all axosomatic synapses onto motorneurons were labeled within two days after injection. Synaptic clefts were densely labeled, as well as both post and presynaptic membranes. Synaptic vesicles of presynaptic terminals also were frequently labeled, regardless of whether terminals contained round or eliptical vesicles. Non-synaptic vesicles of presynaptic terminals were only infrequently labeled. Membrane not adjacent to synaptic terminals rarely showed HRP reaction product. It appears that C-fragment accumulated at the neuromuscular junction is selectively directed to synaptic regions of the motorneuron. It is intercalated into the postsynaptic membrane where it is able to pass into the synaptic cleft and to membrane of the presynaptic terminal. C-fragment remains in the presynaptic terminal where it is incorporated into synaptic vesicles. Little C-fragment in the synaptic regions appears available for further retrograde transport to the cell bodies of presynaptic neurons. C-fragment, like tetanus toxin, has a high affinity for its receptor, which is concentrated at synapses. The transfer of C-fragment from post to presynaptic structures may refect the transfer of a normal synaptic component.

36.3 LOSS OF MATERIAL FROM THE RETROGRADE AXONAL TRANSPORT SYSTEM. R.E. Snyder* (SPON:R.S. Smith). Dept. of Appl. Sci. in Med., Univ. of Alberta, Edmonton, Canada T6G 2G3.

It is well-known that protein is lost (or deposited) from the rapid anterograde transport system. Loss from the retrograde system has as yet not been investigated. Knowledge of whether or not loss occurs is important to our understanding of the purpose of retrograde transport, however, is difficult to obtain using conventional approaches such as ligature techniques. We have developed a method for the continuous monitoring of a pulse of anterogradely moving radiolabelled protein and, following reversal at a lesion, the retrograde movement of a second pulse of radiolabel (Snyder, R.E., J. Neurobiol., 17,637, 1986). We report here upon the loss of radiolabel from the retrogradely moving pulse.

A pulse of ^{35}S-methionine labelled material was created in a 50-55 mm length of amphibian sciatic nerve maintained *in vitro* at 23.0±0.2°C. Continuous observations were made for 18-22 h of the anterograde movement of the pulse, and, following reversal at a ligature, the retrograde movement of a fraction of the anterograde pulse by placing the nerve in contact with a position-sensitive detector of ionizing radiation. By monitoring the progress of both the anterograde and retrograde pulses it was possible to determine their transport rates and, using these rates, estimate the ratio of the retrogradely to anterogradely moving label which traversed each segment of the nerve. This ratio should increase by a factor of $1/[(1-a)(1-r)]$ for each segment of nerve moved in the distal direction where a(r) is the fraction of label lost (deposited) to each segment from the anterograde (retrograde) pulse. By comparison of the plateau of activity in each segment following the passage of the anterograde pulse to the activity in the pulse it was possible to determine an upper limit to the fraction a.

Seven nerves were studied. The retrogradely to anterogradely moving label which traversed 4-6 contiguous 3.18-mm segments of nerve which contained no terminating axons was estimated, as well as the fraction of label lost from the anterograde pulse. It was found that $a \leq 0.056 \pm 0.003$(±SEM) and $r \geq 0.049 \pm 0.014$, indicating that endogenous protein is lost from the retrograde transport system.

Supported in part by the Medical Research Council of Canada.

36.4 SLOW TRANSPORT OF SCa AS SOLUBLE COMPONENTS SHOWN BY BEADING PARTITIONING OF NERVE FIBERS. Sidney Ochs and Ralph Jersild Jr. Dept. of Physiology/Biophysics and Dept. of Anatomy, Indiana Univ. School of Med., Indianapolis, IN 46223.

The slow transport of tubulin and neurofilament triplet proteins in nerve fibers at the SCa rate of 0.25-2.0 mm/day has been proposed in the Structural Hypothesis to represent an outward movement of microtubules and neurofilaments in assembled form following the incorporation of their subunits into these cytoskeletal organelles in the cell bodies. Alternatively, in the Unitary Hypothesis, the tubulin and neurofilament triplet subunits are considered to be transported down into the fibers as such, and to turn-over in their respective organelles within the fibers.

To differentiate between the two possibilities, beading was used to partition the filamentous cytoskeleton from the soluble components in the fibers of the cat L7 dorsal roots at times from 7-30 days after injection of the precursor ^{3}H-leucine into the L7 dorsal root ganglia. After slow transport had carried labeled proteins out into the roots at rates corresponding to SCa, the roots were removed, lightly stretched to bead them, fast-frozen and freeze-substituted to hold the beading in place, and the tissue prepared for autoradiography. Beading is seen as a series of constrictions interspersed between relatively normally expanded regions along the nerve fibers. In the constrictions the microtubules and neurofilaments are found to be closely packed into a cross-sectional axonal area as small as 5% that of the normal myelinated fiber (Neuroscience, in press).

In the autoradiographs of the beaded fibers the density of radioactive grains per unit area over the constrictions was very small while over the nonconstricted regions the density was high at times corresponding to SCa rates. This is in accord with the labeled proteins carried down by SCa being present mainly as soluble proteins able to move with the axoplasmic fluid as it and other soluble components are squeezed away from the cytoskeleton left remaining in the beading constrictions.

A small increase in the grains over the constrictions in the beaded fibers was seen later at 3-4 weeks, times too long for the SCa proteins to be carried down within the cytoskeleton at that rate. This later increase is indicative of a slow uptake of the labeled precursors into the microtubules and neurofilaments.

The findings indicate that the carrier which accounts for fast transport could serve also for slow transport if it allows for an early drop-off of tubulin and neurofilament subunits to provide for their turn-over in the stationary cytoskeletal organelles.

Supported in part by the NIH RO1 NS 8706, NSF 82-17727, and the Biomedical Research Committee of the Indiana University School of Medicine.

36.5 THE OCCURRENCE OF mRNA AND BIOLOGICALLY ACTIVE POLYRIBOSOMES IN THE SQUID GIANT AXON A. Giuditta, C. Perrone Capano, E. Menichini[1], E. Castigli[1], A. Gioio[2], R. Martin[3], and B.B. Kaplan[2] Dept. Gen. & Environ. Physiol., Univ. of Naples (Italy); [1]Inst. Cell Biol., Univ. of Perugia (Italy); [2]Dept. Psychiatry, Univ. Pittsburgh (USA); [3]Sec. Elec. Microsc., Univ. Ulm (FRG)

Axons and nerve terminals are unique subcellular structures of nervous tissue that are widely believed to lack an endogenous protein synthetic capacity. In accord with this view, the proteins synthesized in the isolated squid giant axon are believed to derive entirely from ada-axonal glia cells. We have previously reported, however, that axoplasm extruded from isolated squid giant axons contains an RNA fraction that can program protein synthesis in a rabbit reticulocyte cell-free translation system (Giuditta et al., Neurochem. Intern. 8:435, 1986). Here we report that the squid giant axon contains a diverse population of poly(A)$^+$mRNAs and biologically active polyribosomes.

Total axoplasmic RNA obtained from the giant axon of the squid, Loligo paelii, and was used as a template for cDNA synthesis in standard reactions containing AMV reverse transcriptase and oligo(dT) as primer. The cDNA synthesized was heterogeneous in size with most fragments larger than 450 nucleotides (nt). Results of a RNA-cDNA hybridization analysis indicate that the sequence complexity of axoplasmic RNA is approximately 3.1 x 10^5 nt, a value sufficient to code for 200 poly(A)$^+$mRNAs averaging 1500 nt in length. The presence of axoplasmic poly(A)$^+$RNA was also determined by in situ hybridization histochemistry. In these experiments, glutaraldehyde-fixed, paraffin-embedded tissue sections of stellate ganglia and nerves were hybridized to [^{3}H]poly(U). Upon autoradiography, a significant number of silver grains were visualized in the giant axon. This signal was decreased substantially by pretreatment of the tissue with RNase A. In control experiments, little hybridization was observed when [^{3}H]poly(A) was used as a probe. Additionally, isolated giant axons were incubated in filtered sea water containing [^{35}S] methionine and polyribosomes isolated from detergent-treated axoplasm by sedimentation through 2.0 M sucrose. The resulting pellets were displayed on linear sucrose gradients, and the alkali-resistant, acid-precipitable radioactivity of each gradient fraction was determined. Importantly, radioactive polysome profiles were consistently obtained from axoplasm. The radiolabeled amino acid associated with axoplasmic polyribosomes was sensitive to disruption by treatment with both EDTA and RNase. Consistent with these findings, preliminary results of an electron microscopic study, reveal dense, osomophilic structures resembling polyribosomes in axons located in both the giant fibre lobe and stellate ganglion. These images appear especially abundant beneath the neurolemma and postsynaptic elements of axon-axonic synapses.

36.6 IMMUNOCYTOCHEMICAL LOCALIZATION OF KINESIN IN THE SQUID GIANT AXON. T.P.O. Cheng, B. J. Schnapp, M.P. Sheetz, and T.S. Reese, Laboratory of Neurobiology, NINCDS, NIH, at MBL, Woods Hole, MA 02543.

We have examined the distribution of kinesin in the squid giant axon and stellate ganglion by post-embedding immunocytochemistry. Araldite sections of either fixed (aldehyde/OsO_4) or quick-frozen and freeze-substituted (OsO_4/acetone) axons or stellate ganglia were etched with potassium ethoxide and sodium meta-periodate for 5 min before incubation with various dilutions of serum from rabbits immunized with affinity-purified kinesin or a monoclonal antibody against the 110 kD subunit of kinesin; distributions of antibody were then visualized by indirect immunofluorescent or immunogold labeling. Fluorescent label in the chemically fixed specimens was in numerous discrete small spots near or at the surfaces of small cytoplasmic organelles, apparently inside of some other larger organelles, and in numerous discrete patches in the cytoplasm. The spotty labeling near or at the surfaces of organelles did not coincide with parallel labeling done with an antibody to tubulin. In contrast, the distribution of fluorescent label in the freeze-substituted axoplasm was uniform and diffuse, and labeling near organelles was not apparent. However, at the ultrastructural level, anti-kinesin immunogold in the freeze-substituted axoplasm was concentrated in small spots at the surfaces of small cytoplasmic organelles, and near or at axoplasmic subdomains where small organelles cluster in the vicinity of microtubules. The immunogold was also seen, though only occasionally, in the narrow gaps between organelles and microtubules. Examination of the distribution of immunofluorscence or immunogold in continuous serial sections suggested that kinesin is distributed in discrete spots at the surfaces of organelles instead of enveloping them in a continuous layer. Control plastic sections treated with normal serum or antiserum pre-absorbed with kinesin were unlabeled by immunofluoresce and immunogold. Our findings indicate that some of the kinesin in the squid axoplasm is associated with organelles, an interpretion which is consistent with previous biochemical evidence that kinesin binds to organelles. Our findings also provide further evidence that there are two pools of kinesin in the axon: a cytoplasmic pool diffusely distributed throughout the organelle-rich domains of axoplasm as well as the discrete fraction which is bound to organelles.

36.7 DIFFERENT NEUROFILAMENT DENSITIES SHOW IDENTICAL RANDOM DISTRIBUTIONS IN SIDE-BY-SIDE AXONS.
P.Paggi*#, R.L.Price*, R.J.Lasek and M.J.Katz*
*Bio-architectonics Center, Medical School, Case Western Reserve University, Cleveland, OH 44106; and #Dept. Cell and Developmental Biology, University "La Sapienza", Rome, 00185, Italy.

We have studied the space-filling properties of neurofilaments (NFs) in two different types of axons that each have a large NF content -- somatic motor axons and parasympathetic axons of the oculomotor system. These axons originate in the oculomotor nucleus, and they course together (side-by-side) through the oculomotor nerve; nonetheless, the packing density of the NFs in the parasympthetic axons is 30% greater than it is in the somatic motor axons. Visual inspection of electron micrographs of parasympathetic and somatic motor axons suggested that the NFs are uniformly distributed in both types of axons. To test this possibility, we quantified the distributions of the NFs, and then we compared those distributions with ideal randomly generated (Poisson) NF distributions. Axons in 28-day-old chickens were fixed by perfusion with 4% paraformaldehyde, 2% glutaraldehyde, 0.005% CaCl2, in 0.1M cacodylate buffer, pH=7.4, and post-fixed for 1hr in 1% OsO4, and then dehydrated and embedded in Polybed 812. Areas of cross-sectioned axons (from more than 250 axons of each type) were measured with a Vanguard Digitizer and NF densities were determined by placing an acetate sheet with 72 hexagonal areas (0.93 cm2, spaced 1.3 cm apart) over 58000x prints. (Areas containing more than 10% membranous organelles or in which NFs were not cut in cross section were excluded from the analyses.)

NFs are more densely packed in the parasympathetic axons (average density X=10.8NF/hexagon, n=2877NF) than in the somatic motor axons (X=8.6NF/hex, n=3512NF). Histograms of the NF distributions for the two types of axons were compared with ideal Poisson distributions. The Poisson curves closely matched the actual distributions of NF densities in both the parasympathetic axons (p>0.99, chi-square test) and somatic motor axons (p>0.95, chi-square test). This indicates that, although the average densities differ, NFs are similarly and homogeneously distributed in the cross-sectional planes of both types of axons. A homogeneous Poisson distribution can be produced by intracellular mechanisms that distribute NFs via simple and essentially random forces within the axonal cross-section. Thus, in these axons, the NF polymers behave as if they are independent "molecules," organized by simple and non-specific stochastic forces. On this basis, we propose that more constraining forces, such as interactions between NF sidearms, are relatively weak and that in vivo the NFs are not extensively crosslinked irto a rigid network.

36.8 SUBCELLULAR LOCALIZATION OF AXONALLY TRANSPORTED MACROMOLECULES BY HIGH RESOLUTION IMMUNOELECTRONMICROSCOPY. M. Ellisman, T. Deerinck*, P. Taylor¶. Lab. Neurocytology, Dept. Neurosciences and ¶Dept. Pharmacology, UCSD, La Jolla, CA 92093.

Axoplasmic membrane systems have been examined with respect to their movement in axonal transport (Ellisman & Lindsey, J. Neurocytol. 12:393, 1983). Distinctions are made between vesicles, vesiculo-tubular structures, the axoplasmic reticulum, dense cisternae, and multilamellar and multivesicular bodies. To further define the roles of each, the precise locations of specific macromolecules are being determined. At issue is whether separation of different transported molecules is maintained in the axon. Since antigen concentration is expected to be low and the experiments require precise localizations we have employed the most sensitive and discerning immunolabeling techniques available. Our progress toward both localization of the NaK ATPase and acetylcholinesterase, representing macromolecules components transported at different rates, as well as an adaptation of ultrathin-frozen section labeling technologies will be described. A battery of polyclonal antibodies with demonstrated specificities for NaK ATPase and acetylcholinesterase have been used. NaK ATPase antibodies (which recognize alpha and alpha+ forms and the beta subunit [439-2, Ariyasu et al., J. Neurosci. 5:2581, 1985]), localizes the antigen to discrete vesicles and vesiculo-tubular structures in axons from rat trigeminal nerve. No staining of the axoplasmic reticulum, dense cisternae, multilamellar or multivesicular bodies was observed with this antibody. A subpopulation of vesicles and vesiculo-tubular structures within 50μ of the nodes of Ranvier exhibit a high level of staining. Antibodies to guinea pig NaK ATPase that reacts predominantly with the alpha+ form of NaK ATPase (GP-17, McDonough & Schmitt, Am. J. Physiol. 248:247, 1985; Ariyasu & Ellisman, in press) stains similarly. Antibodies to acetylcholinesterase (Lee et al., J. Biol. Chem. 257:12283, 1982) that recognize both the hydrophobic dimer and the asymetric form of the enzyme (and thus both rapidly and slowly transported varieties) labels the axoplasmic reticulum. To enable this level of localization modifications of ultrathin cryosectioning and labeling procedures were required. Technical refinements include: Cryoprotection and freezing of paraformaldehyde fixed tissue to minimize the formation and size of ice crystals. After immunolabeling a glutaraldehyde secondary fixation and OsO_4 incubation is followed by UA staining and re-embedded in a thin matrix of LR white. This results in intra-axonal membrane systems that are preserved, delineated with great detail, and specifically labeled. Thus with technical enhancements and specific antibodies we have determined that these different axonally transported macromolecules are located in differing membrane systems.

36.9 VISUALIZATION OF MITOCHONDRIA IN AXOPLASMIC TRANSPORT.
H. Gotoh§, T. Takenaka, T. Kawakami*, and N. Hikawa. Yokohama City University, School of Med., Dept. of Physiol., Fukuura, Kanazawa, Yokohama, Japan 232.

Visualization of mitochondria during axonal transport was accomplished using specific fluorescent labelling. We stained cultured cells from dorsal root ganglia of mice with such vital staining dyes as pinacyanol, neutral red and rhodamine. Rhodamine 123 was especially useful for specific fluorescent labelling of mitotochondria without cytotoxicity or phototoxicity. Cultured cells grown on coverslips were incubated with rhodamine 123 (10 ug/ml) for 5 min in a 5% CO_2 incubator at 37°C. The coverslips were rinsed twice and the cells were observed under a fluorescence microscope. Overall movements of mitochondria vary from the axon to the axon. The flow rate of the mitochondria was on the average one mitochondrion per some ten seconds. At any time, more than half of the mitochondria (density ≈ 1 mitochondrion per 1 um length of the axon) were observed to move in both anterograde and retrograde directions in a jerky, stop-and-go fashion.

The instantaneous velocity of the transport was 0.55 ± 0.11 um/sec in the anterograde direction, and 0.60 ± 0.10 um/sec in the retrograde direction. These velocities were compared with velocity histograms obtained with a non-specific light microscope technique: contrast enhancement Nomarsky optics. The histograms of both the anterograde and retrograde directions appeared to be composed of slow and fast components. A single slow component for both directions corresponded to the transport of mitochondria. In contrast, the fast component of the anterograde transport corresponded possibly to the transport of storage vesicles or smooth membranes, while the fast component of the retrograde transport corresponded possibly to the transport of prelysosomal organelles.

This new technique appears to offer a reliable method of studying both the normal and pathological aspects of mitochondrial transport in the axon.

36.10 EFFECT OF PARATHYROID HORMONE (PTH) ON FAST AXONAL TRANSPORT: SPECIFICITY OF BIO-ACTIVE FRAGMENTS ON MYELINATED AND UNMYELINATED AXONS.
M.B. Atkinson,* C.M. Ferrario and A.C. Breuer (Spon: David B. Averill). Departments of Brain and Vascular Research and Neurology, The Cleveland Clinic Foundation, Cleveland, OH 44106.

Parathyroid hormone (PTH) has been demonstrated to increase fast axonal transport speed of organelles in both the anterograde (antero) and retrograde (retro) directions as observed by differential interference contrast optics and computer image processing techniques [Breuer AC and Atkinson MB: Neurology 37 (Suppl 1): 187, 1987]. The increases occur with topical application of PTH to mammalian axons in in vitro experiments. A similar response is seen in rats following continuous infusion of PTH with Alzet mini-pumps. Response to the application of PTH by axons in vitro occurs within minutes. To evaluate the species specificity of the PTH effect on myelinated and unmyelinated axons, either human PTH (synthetic fragment, 1-34) or rat PTH (synthetic fragment, 1-34) was applied to excised rat sciatic nerve axons at a concentration of 0.025 µg/ml. All other variables (pH, buffer, temperature, etc.) were kept constant. Resulting speed distributions were compared using the Kolmogorov-Smirnov test. Control mean speeds for myelinated axons were antero = 1.49 ± 0.04 µm/sec (n = 88) and retro = 1.81 ± 0.03 µm/sec (n = 317). Control mean speeds for unmyelinated axons were antero = 1.44 ± 0.03 µm/sec (n = 60) and retro = 1.85 ± 0.02 µm/sec (n = 303). Application of either rat or human PTH to myelinated axons induced anterograde increases of 24.2% (1.85 ± 0.04 µm/sec, n = 156, $p < 0.01$) and 17.4% (1.75 ± 0.07 µm/sec, n = 48, NS) and retrograde increases of 23.2% (2.23 ± 0.02 µm/sec, n = 454, $p < 0.001$), and 13.2% (2.05 ± 0.03 µm/sec, n = 225, $p < 0.001$), respectively. Application of either rat or human PTH to unmyelinated axons induced no significant changes in the anterograde transport [1.47 ± 0.03 µm/sec (n = 104) and 1.52 ± 0.04 µm/sec (n = 70) respectively] or in the retrograde transport [1.94 ± 0.02 µm/sec (n = 300) and 1.75 ± 0.02 µm/sec (n = 369) respectively]. Thus axonal transport in myelinated axons is responsive to the application of either rat or human PTH whereas unmyelinated axons are unaffected. This PTH-induced alteration of fast axonal transport suggests the presence of PTH receptors on myelinated axons (which may alter transport directly or indirectly) and the absence of such receptors on unmyelinated axons. These results imply the existance of an axonal transport modulator selective for functionally different axon types. (Supported in part by a grant from the Whitaker Foundation).

36.11 EFFECT OF PARATHYROID HORMONE (PTH) ON FAST AXONAL TRANSPORT: TIME COURSE OF RETURN TO NORMAL FUNCTION.
A.C. Breuer, M.B. Atkinson*, C.M. Ferrario. Departments of Brain and Vascular Research and Neurology, The Research Institute, The Cleveland Clinic Foundation, Cleveland, OH 44106.

Previous results from this laboratory have demonstrated an increase of mean axonal transport speed after treatment with parathyroid hormone (PTH, Bovine Fragment 1-34, Synthetic) on both anterograde (Antero) and retrograde (Retro) transport as analyzed by differential interference contrast optics and computer image analysis techniques. The PTH effect was found in both in vitro [Breuer AC and Atkinson MB: Neurology 37 (Suppl 1): 187, 1987] and in vivo (unpublished results) experiments on rat sciatic nerve. These changes could result from long-term structural (anatomic) changes in the axonal transport machinery or short-term, functional (physiologic) changes by either direct action of the PTH or indirect action through an intermediary (Ca++, cAMP, etc) as suggested by the immediate effect of the in vitro experiments. To assess the mode of action, Alzet mini-osmotic pumps (Model 2001) were implanted in rats with a dosage of PTH known to induce speed increases (2.5 units PTH/hour). The pumps were removed after one week, the animals sacrificed and transport speeds in the sciatic nerve analyzed at four time periods. Resulting speed distributions were compared using the Kolmogorov-Smirnov test. The speed found immediately after pump removal in the antero transport was increased from 1.47 ± 0.03 µm/sec (n = 148) in controls to 2.14 ± 0.04 µm/sec (n = 122) with PTH ($p < 0.001$). Retro transport was increased from 1.82 ± 0.02 µm/sec (n = 620) in controls to 2.71 ± 0.03 µm/sec (n = 321) with PTH ($p < 0.001$). At 6 hrs the antero speed increase had been reduced by 41.8% (1.86 ± 0.03 µm/sec, n = 66, $p < 0.001$ vs. controls) and the retro by 64.0% (2.14 ± 0.02 µm/sec, n = 220, $p < 0.001$ vs. controls). At 24 hrs the antero speed increase had been reduced by 79.1% (1.61 ± 0.03 µm/sec, n = 85, $p < 0.01$ vs. controls) and the retro by 88.8% (1.92 ± 0.02 µm/sec, n = 316, $p < 0.01$ vs. controls). There were no significant differences between the experimental group [antero = 1.59 ± 0.05 µm/sec, n = 101 and retro = 1.91 ± 0.02 µm/sec (n = 349)] and the control group at 72 hrs. The relatively rapid reduction of speeds following removal of the PTH source in these in vivo experiments along with the in vitro results suggest a physiological modulatory effect of PTH on the regulation of fast axonal transport. (Supported in part by the Whitaker Foundation).

36.12 N-CAM ANTIBODIES CAN HALT INTRAAXONAL MOTILITY FOLLOWING DISPERSION OF LFA BINDING SITES.
E. Koenig and B. Edmonds* Dept. of Physiology, SUNY at Buffalo, Buffalo NY 14214.

Ganglion cell axons of goldfish retinal explants have varicosities and intervening phase-dense inclusions (IPDIs) that undergo bidirectional movements representing a bulk form of transport [Koenig, et al., 1985, J.Neurosci., 3:715]. Recent work indicates that Limax Flavus agglutinin (LFA), a lectin specific for sialic acid residues, binds preferentially to the surfaces of varicosities, IPDIs and growth cones and causes a complete arrest of all transport that is irreversible [Edmonds & Koenig; submitted]. Succinylated WGA (sWGA), which is specific for N-acetylglucosamine (GlcNAc), does not arrest transport but causes a dispersion and redistribution of the contents of most but not all varicosities [Edmonds & Koenig, unpublished]. The LFA receptors that are largely associated with varicosities and IPDIs undergo a dispersion into intervening axonal segments pari passu with the dispersion of the contents of varicosities.

As neural cell adhesion molecules (N-CAM) are polysialated membrane glycoproteins in developing brain [Hoffman et al., 1982, J. Biol. Chem., 257:7720], experiments were conducted to test for an effect on transport. Based on immunocytochemistry of axonal fields, antibodies raised against N-CAM from either rat brain or chick brain, kindly supplied by Dr. Joshua Sanes, show generally a preferential distribution that is similar to that of LFA. When antibodies against either rat or chick brain N-CAMs are introduced into the viewing chamber while organelle transport is being monitored by video microscopy, most axons appear normal. Although organelle transport activity seems largely unaltered, occasional axons appear hyperdense with phase-contrast or DIC optics, wherein it is not possible to discern organelle movement activity. If axonal fields are first treated with sWGA, and the sWGA is then removed by treatment with GlcNAc, exposure to N-CAM antibodies now causes an arrest of virtually all transport within 5 minutes, and the development of arrest is accompanied by structural changes involving a reduction in axonal girth and proliferation of lateral processes.

The significance of the pretreatment and subsequent reversal of sWGA for inducing an arrest of transport by N-CAM antibodies is unclear. Whether it is related to a possible redistribution of putative N-CAM in response to sWGA is uncertain; nevertheless, these preliminary results suggest a potential for transmembrane modulation of the axonal cytoskeleton. Supported by grant NS21843 from the NINCDS.

36.13 SELECTIVE NEURONAL INVOLVEMENT IN MOTOR NEURON DISEASE (WOBBLER MOUSE): UNIMPAIRED SLOW AXONAL TRANSPORT IN THE UNAFFECTED HINDLIMBS. K. KURAHASHI*, H. MITSUMOTO, G. BUNGE*. Cleveland Clinic Foundation, Cleveland, OH 44106.

Since motor neuron disease in the wobbler mouse predominantly affects the forelimb system but not the hindlimb, this animal model offers an unique opportunity to study why certain groups of motor neurons are selectively affected while others are not in motor neuron disease. The rate of slow axonal transport was impaired and the relative amount of transported neurofilaments was reduced in the affected forelimb system (Ann Neurol 19:36, 1986). We investigated slow axonal transport in the hindlimb system to study whether impaired slow axonal transport actually corresponds to the disease process in this model. All mice were studied at three months of age. All experimental procedures were done under halothane anesthesia. ^{35}S-methionine (1280Ci/mmol, adjusted to 250 uCi/ul, Amersham) was stereotaxically injected into five locations of the right ventral horns at the L5 and L6 spinal levels. At 1, 2, or 3 weeks after injections, the mice were perfused with saline through an intracardiac catheter. The nerves were dissected from the spinal cord, including the corresponding ventral roots down to the ankle level. The nerves were cut into 2 mm segments. The radioactivity of each nerve segment was determined in an aliquot, and the remainder was processed for one dimensional sodium dodecyl sulfate-polyacrylamide gel electrophoresis (SDS-PAGE). After superimposing the fluorogram, major bands were cut from dried gels and their radioactivity was determined.

The rate of the transport, based on the distance at which the cumulative 50th percentile transported radioactivity was reached, was 0.9 mm/day in controls (normal littermates) and 0.8 mm/day in wobbler mice. There were no differences in the polypeptide composition. Individual polypeptides, such as actin, tubulin, and neurofilament (145KD and 68KD) were also conveyed in the same fashion in both groups of animals, and the ratios of neurofilament proteins to actin and tubulin were the same.

In conclusion, slow axonal transport in the unaffected hindlimb system was unimpaired in contrast to the affected forelimb system. Thus, abnormal slow axonal transport seems to closely correspond to the disease process, suggesting an underlying pathogenic significance in this motor neuron disease. (Grant support by NIH, NS-21742)

36.14 PROLONGED ALTERATIONS IN RETROGRADE AXONAL TRANSPORT TO THE CELL BODY AFTER SCIATIC NERVE TRANSECTION. D. Fink, D. Purkiss*, and M. Mata. Neurology Research Laboratory, University of Michigan and VA Medical Center, Ann Arbor, MI 48105.

In order to better define the nature of the signal from axon to cell body of irreversible nerve injury, we undertook this study of retrograde axonal transport after nerve cut injury using ^{3}H NSP labeling.

Male Sprague Dawley rats were anesthetized with chloral hydrate, and the sciatic nerve cut at the knee. A 5 mm segment was removed and the proximal stump ligated with suture to prevent regeneration. At 1,3,5,7 days and 2,3 or 5 weeks after cut the animal was reanesthetized and the nerve injected with 125 microCuries of ^{3}H NSP about 1 cm proximal to the cut end, using a 31 gauge needle attached to an infusion pump. One day or 7 days after ^{3}H NSP injection the animals were sacrificed and the amount of TCA precipitable radioactivity in the L4, L5 and L6 dorsal root ganglia and in the ventral horn of spinal cord determined.

In a parallel set of experiments, after identical operations and injections the animals were sacrificed by intracardiac perfusion and the distribution of radioactivity determined by light microscopic autoradiography.

Transport to the cell bodies in the DRG and in ventral horn of spinal cord measured 1 day after ^{3}H NSP labeling was not significantly altered by nerve transection, although there was a tendency towards increased values beginning in animals injected 5 days after cut in 1 day transport to DRG, and beginning 7 days after cut in 1 day transport to the spinal cord. This was more obvious in the cell body/nerve ratios.

7 day accumulation in the cell bodies showed a complex pattern. There was a significant increase in transport to the spinal cord in animals injected 5 and 7 days after nerve transection, which fell to lower than normal values which persisted to 3 and 5 weeks. Similarly in the DRG neurons a transient increase in transport was seen in animals injected 5 days or 7 days after transection, followed by a decline to less than normal values. By 5 weeks however those values had begun to return towards normal.

Autoradiography confirmed the intracellular localization of the labeled proteins and in general the amount of grains followed the pattern of total counts. Grains were found both in cell bodies which appeared relatively normal, as well as in those with eccentric nuclei suggesting central chromatolysis.

The similarities and differences between the pattern of changes after nerve transection and those which we have previously observed during regeneration after nerve crush, and the implications of these changes, will be discussed.

Supported by VA Merit Review Grants to Dr. Fink and Dr. Mata.

36.15 ALTERED AXONAL TRANSPORT IN RAT SCIATIC NERVE FOLLOWING ACUTE AND CHRONIC ETHANOL EXPOSURE. J.A. McLane and J. Gomez*. Veterans Administration Hospital, Hines, IL 60141 and Department of Biochemistry, Loyola University Stritch School of Medicine, Maywood, IL 60153.

The axonal transport system supplies essential proteins and other cellular components to the distal portions of peripheral nerve axons. Interference with this process may lead to peripheral neuropathies associated with metabolic disorders or neurotoxin exposure. We have carried out studies to test whether ethanol has detrimental effects upon axonal transport in peripheral nerves, which may contribute to the development of peripheral neuropathy in chronic alcoholism. Rat dorsal root ganglia-sciatic nerve preparations were exposed acutely to ethanol by incubating 18 hr in vitro. The ganglia were exposed to (^{35}S)-methionine to radiolabel newly synthesized protein and the nerves were exposed to 79, 198 or 395 mg % ethanol in Krebs-Ringer solution. Transport was evaluated by measuring the amount of (^{35}S)-methionine-labeled protein accumulated at a distal sciatic nerve ligation at the end of the incubation period. Exposure of the nerves to 395 mg % ethanol significantly reduced the accumulation of radiolabeled protein by 70%. Chronic ethanol exposure was accomplished by pair-feeding an ethanol or isocaloric control diet to rats for 9, 16 or 28 weeks. In vitro axonal transport experiments were again carried out, but without the acute ethanol exposure. Transport was found to be unchanged in nerves of rats fed the ethanol diet for 9 weeks, but was significantly reduced 44% after 16 weeks and 47% after 28 weeks of ethanol feeding. There was no significant difference in the level of incorporation of radiolabeled precursor into the dorsal root ganglia in either study. Retrograde axonal transport is also being examined in chronically ethanol-fed rats by injecting (2,3-^{3}H)N-succinimidyl propionate into the midthigh region of the sciatic nerve and measuring the accumulation of label in the dorsal root ganglia 7 days later. Preliminary data from these experiments suggest that movement of protein by this mode of transport is also decreased in chronic ethanol-fed rats. These combined results suggest that both fast anterograde and retrograde axonal transport are being affected through a single mechanism. One possibility is that microtubule stability is being altered. Microtubules have been shown to be a necessary component of the fast transport machinery. In liver it has recently been shown that acetaldehyde formed from ethanol metabolism forms covalent adducts with tubulin protein and thereby interferes with its polymerization into microtubules. Similarly, acetaldehyde-tubulin adduct formation in nerves may be altering axonal transport.

36.16 p-XYLENE INHALATION DEPRESSES AXONAL TRANSPORT OF [^{3}H]LABELED GLYCOPROTEINS AND [^{35}S]LABELED PROTEINS IN THE RAT RETINAL GANGLION CELLS. S. Padilla* and D. Lyerly*[1]. (Sponsor: W. Boyes). US Environmental Protection Agency and Northrop Services[1], Research Triangle Park, North Carolina, 27711.

Xylene, a solvent used extensively in industry and agriculture, is suspected of producing nervous system malfunctions in animals and humans. Little is known, however, about the neurochemical consequences of xylene inhalation. The intent of this study was to determine the effect of p-xylene exposure (0 or 800 ppm for 6 hrs/ day, 5 days/week for 1.5 weeks) on the synthesis and axonal transport of glycoproteins and proteins within the retinofugal tract of rats (male, Long Evans hooded, 60 days old).

Immediately after removal from the inhalation chambers each animal received an intraocular injection of 5.0μCi [^{3}H]fucose and 2.5μCi [^{35}S]methionine to measure glycoprotein and protein synthesis. After sacrifice at 0.25, 0.5, 1, 2, 3, or 4 hours postisotope injection, the retinas were removed, and the distribution of soluble and precipitable (ppt) radioactivity (10% trichloroacetic acid/ 0.5% phosphotungstic acid: TCA/PTA) was determined by liquid scintillation counting (LSC). p-Xylene treatment did not alter either the rate or the amount of radiolabel incorporated into either TCA/PTA soluble or ppt material, but by 4 hours post-injection, the [^{3}H]/[^{35}S]ratio of the retinal TCA/PTA ppt material was significantly increased in the p-xylene-exposed animals. In a separate but similar experiment, animals were exposed to the same p-xylene inhalation regimen and axonal transport was measured by intraocular injection of [^{3}H]fucose and [^{35}S]methionine followed by sacrifice 20 hours later. At this time all areas of the retinotectal tract were removed, and the amount of TCA/PTA ppt radiolabel determined by LSC. The [^{3}H]/[^{35}S] ratio was increased in the retinofugal tract of the p-xylene-treated animals; this apparent increase was due to a decrease in transport of both [^{3}H] and [^{35}S]labeled material with a relatively larger decrease in the transport of [^{35}S]labeled material. Specifically, the p-xylene treated animals (n=6) had a significant reduction in the axonal transport of both [^{3}H]glycoproteins and [^{35}S]proteins to the optic tract and of [^{35}S]proteins to the superior colliculus.

These data indicate that although p-xylene inhalation did not disrupt the initial rate or amount of synthesis of retinal [^{3}H] glycoproteins or [^{35}S] proteins, it did decrease the amount of newly synthesized glycoproteins and proteins supplied to the projections of the rat retinal ganglion cells. This submaximal availability of necessary materials to the axon and nerve ending regions may play a role in the nervous system dysfunction noted in solvent-exposed animals and humans.

37.1 EFFECTS OF 2,4-DICHLOROPHENOXYACETIC ACID (2,4-D) ON NEUROTRANSMITTERS AND THEIR METABOLITES IN VARIOUS BRAIN REGIONS OF THE RABBIT. C.S. Kim* and G.R. Breese (Spon: C.G. Lineberry). Biol. Sci. Res. Ctr. and Dept. of Psychiatry, Univ. of North Carolina Sch. of Med., Chapel Hill, NC 27514

2,4-D is known to produce a variety of neurotoxic effects in man and experimental animals such as myotonia, lethargy, stupor and coma prior to death (IARC Monogr. 15:111-138; 273-300, 1977). During 2,4-D intoxication, its level is increased in various brain regions. The brain stem and cerebellum accumulate more 2,4-D than other brain areas. The present in vivo study was undertaken to determine the changes in the level of neurotransmitters and their metabolites after 2,4-D administration. Albino rabbits (New Zealand) were injected i.p. with either saline or 2,4-D (80 or 160 mg/kg). Two hours later, rabbits were sacrificed by decapitation and their brains were rapidly removed. Various brain regions (caudate nucleus, pon, medulla and hypothalamus) were dissected, weighed and immediately frozen on dry ice. Levels of dopamine (DA), serotonin (5-HT) and their metabolites, 3,4-dihydroxyphenylacetic acid (DOPAC), homovanillic acid (HVA), 5-hydroxyindoleacetic acid (5-HIAA) were determined by high performance liquid chromatography (HPLC). Injection of 2,4-D (160 mg/kg) increased the levels of both 5-HT and 5-HIAA by 32% ($P < 0.01$) in the medulla and by 25% and 27% ($P < 0.05$), respectively, in the pons compared to saline-treated rabbits. However, the contents of DA and DOPAC were unchanged. The concentration of HVA was increased by 17% and 25% ($P < 0.05$, $P < 0.01$) in the caudate nucleus and hypothalamus, respectively. The level of 5-HT was increased by 44% ($P < 0.01$) in the hypothalamus when 80 mg/kg of 2,4,-D was injected. However, these injections produced no change in the concentration of 5-HIAA or DA in the hypothalamus. These results indicate that the induced-increase of both 5-HT and 5-HIAA by 2,4-D primarily affects the brain stem suggesting that 2,4-D interacts with the serotonergic mechanism in this area. Supported in part by NIH grants: HD-03110 and ES-03458.

37.2 ATTENUATION OF INCREASES IN CEREBRAL BLOOD FLOW AND OXYGENATION ARE CORRELATED DURING REPETITIVE SEIZURES. B. L. Brizzee* and N. R. Kreisman. Dept. of Physiology, Tulane Univ. School of Medicine, New Orleans, LA 70112.

Cerebral oxygenation normally increases during individual seizures because cerebral blood flow (CBF) and O_2 delivery increase more than oxygen consumption ($CMRO_2$). After 1-2 hrs of status epilepticus, however, CBF diminishes, despite maintained $CMRO_2$. Meldrum and Nilsson (Brain 99:523-542, 1976) proposed that brain oxygen supply may be insufficient to meet demand under these conditions. In order to test this hypothesis, we measured cerebral oxygenation and blood flow in 16 anesthetized, paralyzed rats in which generalized seizures were induced repetitively (at 5-10 min intervals) with pentylenetetrazol.

Cerebral tissue Po_2 was measured polarographically with microelectrodes and relative changes in the oxidation/reduction state of cytochrome aa_3 were measured with a dual wavelength reflection spectrophotometer. Local CBF was measured intermittently by the method of H_2 washout, and cerebrovascular resistance (CVR) was estimated by dividing the mean arterial blood pressure by CBF. Cerebral oxygenation increased phasically during early seizures in all rats as indicated by increased tissue Po_2 and greater oxidation of cytochrome aa_3. The increases in cerebral oxygenation gradually attenuated in all 16 rats. By 1.5 to 2.5 hrs of seizures, cerebral oxygenation either failed to increase at all or decreased, despite normal systemic oxygenation (n=8). These changes in cerebral oxygenation are in agreement with those reported previously (Kreisman et al Brain Res. 218:175-188, 1981). During early seizures, CBF increased 200-400% and CVR decreased to about 50% of pre-seizure values. Both the 2- to 4-fold increase in CBF and the fall in CVR were sustained in animals that maintained phasic increases in cerebral oxygenation during periods of increased seizure activity. In rats that developed decreased cerebral oxygenation, the increase in CBF tapered off to less than 160% of pre-seizure values, and CVR returned to control levels. The data suggest that there is a critical level of CBF, about 160% of control, below which cerebral oxygenation is compromised. Attenuation of the increase in CBF suggests there is maladjustment in cerebrovascular tone and reactivity during repetitive seizures. Derangements in cerebrovascular reactivity and cerebral oxygenation may contribute to tissue damage during status epilepticus.

37.3 SPATIAL STATISTICAL MAPPING: A THREE DIMENSIONAL ANALYSIS OF CEREBRAL METABOLIC ACTIVITY PATTERNS IN RATS WITH AND WITHOUT NIGRAL STIMULATION. H.H.HOLCOMB, H. LOATS, M. KADEKARO, P. GROSS, E MATTHEW and A. PERT. Lab. of Cerebral Metabolism, NIMH, Bethesda, MD, and Loats Assoc., Inc., Westminster, Md. 221157.

Movement is partially regulated by neurons projecting from the motor cortex (MCTX) to the dorsal caudate-putamen. Unilateral electrical stimulation of the substantia nigra results in ipsilateral elevations in local cerebral glucose utilization (rCMRglu) and turning behavior. Following 20 minutes of electrical stimulation to the substantia nigra reticulata(SNr), some ipsilateral structures exhibit unequivocal, robust metabolic increases (globus pallidus, entopeduncular n., subthalamic n., superior colliculus). Others increase consistently, but only for restricted, highly localized regions (MCTX). In an effort to provide a three dimensional analysis of activated regions we have quantified the location, area, projection and volume of regions exhibiting elevated rCMRgl in the cortex, caudate, globus pallidus and entopeduncular nuclei of electrically stimulated (unilateral SNr, 750 microAmps) rats and sham controls. Serial autoradiographs were obtained and processed by the methods described by Sokoloff and colleagues (J. Neurochem 1977). The three dimensional, registered images were statistically transformed to reflect volumetric, isoactivity curves. Area projection and centroid location measurements demonstrate the rostro-caudal trajectory of cortico-striate activity. Three dimensional maps of statistically transformed metabolic data are especially useful devices for reducing and simplifying complex image data. Stereotaxic organization of histologically matched brain sections further enhances the interpretation of these data rich studies.

37.4 PARIETAL CORTEX STIMULATION IN THE RAT INHIBITS CORTICAL AND THALAMIC GLUCOSE METABOLISM. J.W. Sharp*, M.F. Gonzalez, M.T. Morton*, and F.R. Sharp, Dept. Anatomy, U.C. Davis, and Dept. Neurology, UCSF and VAMC, S.F., CA 94121.(SPON:R. Kitchell)

Cortical and thalamic glucose metabolism were measured in six adult rats using the (14C) 2-deoxyglucose method. Bipolar electrodes were implanted into either the right hindlimb motor and sensory cortex or into the right face parietal cortex. Hindlimb cortical stimulation produced repetitive left hindlimb movements.

Electrical stimulation increased the glucose metabolic rate of cortex around the stimulating electrode in all subjects. Local cerebral glucose utilization (LCGU) decreased in immediately adjacent areas of cortex compared to control regions in far left lateral cortex. LCGU increased in the contralateral (left) cortex in broad as well as narrow columns. Alternating with these columns were columns of low LCGU which were less than the control areas of cortex. These contralateral cortical columns of increased and decreased LCGU were abolished by sectioning the corpus callosum. Lesioning cortex did not lead to contralateral columns of high or low LCGU, implying that columns of decreased LCGU produced by stimulating cortex were due to activation of inhibitory pathways rather than being due to decreased excitation.

Hindlimb and face parietal cortical stimulation also increased LCGU in portions of the ventrobasal (VB) and posteriomedial (POm) nuclei of the ipsilateral thalamus. However, surrounding areas of both VB and POm showed decreased LCGU. Similarly, ipsilateral lateral posterior and lateral dorsal nuclei had decreased LCGU compared to the contralateral unstimulated side of the thalamus. It is proposed that since the reticular nuclei perikarya increased their LCGU and were therefore activiated by parietal cortical stimulation that their GABA inhibitory terminals in thalamus led to the inhibition of thalamic glucose metabolism. Alternative explanations for the decreases of thalamic metabolism include corticothalamic inhibition, and basal ganglia inhibition of thalamus. It is suggested that the metabolically activiated areas of thalamus represented a sum of the reticular inhibiton and direct cortical excitation. The inhibition of cortical and thalamic LCGU produced by parietal cortical stimulation is relevant to selective sensory attention and gating as well as to the greater epileptogenicity of motor compared to sensory cortex.

37.5 EFFECTS OF APAMIN ON LOCAL GLUCOSE UTILIZATION IN THE BRAIN AND IN THE SPINAL CORD IN RATS. S. Cohen*, M. Kadekaro, M.L. Terrell*, H. Gary, Jr.* and H.M. Eisenberg. (SPON: B. Moore). Div. of Neurosurgery, Univ. of Tex. Medical Branch, Galveston, Tex. 77550.

Apamin is an 18 residue polypeptide component of bee venom. It possesses powerful neurotoxic properties derived from its ability to block one class of Ca^{2+}-dependent K+ channels, which is responsible for the long-lasting after potential hyperpolarization. Systemic administration of apamin in rats and mice elicits, in a dose-dependent manner, gross, uncoordinated movement of the whole body, with eventual lethal respiratory insufficiency. The symptoms are mediated by the actions of apamin on the central nervous system, although this neurotoxin poorly crosses the blood-brain barrier.

The objective of the present study was to identify with the quantitative autoradiographic [^{14}C]deoxyglucose method neural structures involved in the production of symptoms of apamin neurotoxicity in rats.

Male Spraque-Dawley rats (280-320g) were anesthetized with halothane and polyethylene catheters were implanted in one femoral artery and vein. The animals were allowed to recover from the effects of anesthesia for at least two hours before administration of apamin (2 mg/kg, ip) into experimental animals (n=7) or saline into control animals (n=8). After the administration of apamin the animals lost exploratory behavior, remaining completely immobile, with the four limbs overextended, unresponsive to auditory stimuli. The symptoms started to occur 45-60 min after injection of apamin. Arterial blood pH, PCO_2, PO_2, arterial blood pressure, hematocrit and plasma glucose concentration were not significantly affected by apamin. The deoxyglucose experiments started 75 min after injection of apamin.

Glucose utilization was significantly decreased in nine out of 25 neural structures examined. These structures included the cochlear nucleus, superior olivary nucleus, inferior colliculus, medial geniculate body, fastigial nucleus, globus pallidus, caudate-putamen, nucleus accumbens and the lumbar ventral horn of the spinal cord. These results imply that the effects of apamin on functional activity of the brain is not generalized but rather specific to the auditory and motor structures.

37.6 TAURINE MAY REGULATE CELLULAR HYDRATION AND CELL VOLUME IN THE BRAIN. J.V. Wade[1]*, J.P. Olson[2], S.R. Nelson[3], F.E. Samson[3] and T.L. Pazdernik[1] (SPON: E.J. Walaszek). Department of Pharmacology, Toxicology and Ther.[1], Department of Anatomy[2], and Ralph L. Smith Research Center[3], University of Kansas Medical Center, Kansas City, Kansas 66103, USA.

Changes in free extracellular amino acids within the rat brain were measured during intracranial microdialysis with hypo-osmotic media or during systemic water intoxication. Dialysis fibers implanted in the piriform cortex were perfused (1 ul/min) with Krebs-Ringer bicarbonate (KRB, 305 mOsm) for a 1 hr baseline period and then switched, in steps, to media of decreased osmolarity (KRB with adjusted NaCl content) and then stepwise back to standard KRB as follows: 295/285/295; 280/255/280; and 205/105/205 mOsm (n=3 each group). Effluent perfusate samples were collected at 30 min intervals in the awake, freely moving rat and analyzed for amino acids using HPLC. In order to examine the effect of a generalized increase in brain water content, an additional group (n=4) was perfused with standard KRB, anesthetized, and then given a 20% body weight dose of distilled water, I.P. Perfusate samples were collected at 30 min intervals for 3 hr, at which time rats were sacrificed and brains removed. The specific gravity of piriform cortex contralateral and ipsilateral to the dialysis fiber was measured with a bromobenzene density gradient column and percent tissue volume increase calculated. Measurements were also made in rats without dialysis fibers, receiving the same treatment, to establish the time course of tissue volume increase. Extracellular taurine (Tau) increased markedly during hypo-osmotic perfusion, mean levels reaching 2, 5, and 15-fold baseline, dependent upon the degree of osmotic change. In all cases, Tau levels returned to normal upon perfusion with standard KRB. No significant changes were noted in aspartate, glutamate, asparagine, serine or glutamine. Systemic water intoxication produced a 12.5% volume increase in the piriform cortex on both the fiber and contralateral sides. Extracellular Tau increased within the first 60 min, reaching over 6-fold baseline levels at 150 min. Again, other extracellular amino acids were not affected. Taurine is one of the most abundant free amino acids in the brain. These findings suggest that Tau may play an important role in the regulation of cellular hydration and cell volume within the CNS. 37.7 AMILORIDE REVERSAL OF ALKALINE INTRACELLULAR pH IN HIPPOCAMPAL SLICES. J.C. LaManna, H. Assaf*, T.J. Sick, and T.S. Whittingham. Case Western Reserve University School of Medicine, Cleveland, OH 44106.

The transport of intracellular protons to the extracellular space by exchange with extracellular sodium ions through the action of an amiloride-sensitive H^+/Na^+ antiporter has been described for a number of tissues. The presence of the antiporter has yet to be shown in intact, electrophysiologically functional mammalian central nervous system tissue.

Blood-free hippocampal slices (400-500 μ) were made from brains removed from ether-anesthetized rats after thoracotomy and perfusion through the ascending aorta by cold buffer solution. Slices were kept in oxygenated holding containers at room temperature until use. Half of the slices were placed in a 50 μM solution of the pH indicator dye, Neutral Red (NR) in standard buffer, for 30 minutes, then removed, washed twice and placed in a separate holding container at room temperature until used. The spectrum of light passing through an unstained slice was determined in a modified recording chamber with a scanning spectrophotometer. This spectrum was used as a reference spectrum for slices which were stained with NR. NR absorption curves were obtained as the log of the ratio of spectra from slices containing NR to that of the reference slice. Use of the reference spectrum removed all non-specific absorption, leaving only the NR absorption spectrum. Calibration curves were constructed from homogenized brain tissue. The ratio of absorbance at the maximal wavelengths of absorption for the acid and base forms of the dye is linearly related to the pH over the range 6-8 and is independent of, and insensitive to, changes in dye concentration.

Under resting conditions (125 mM NaCl, 3 mM KCl, 1.4 mM KH_2PO_4, 1.3 mM $MgSO_4$, 26 mM $NaHCO_3$, 2.4 mM $CaCl_2$, 10 mM glucose; equilibrated with 95% O_2/5% CO_2, pH = 7.4 at 37 °C), the intracellular pH of these hippocampal slices averaged 7.64 ± 0.02 (by the NR method; n = 12) and 7.68 ± .05 (by the creatine kinase equilibrium method; n = 8). Thus, pHi of normally prepared hippocampal slices is not only more alkaline than found in vivo, but is more alkaline than the external medium. Switching the bathing solution to contain 1 mM amiloride resulted in an intracellular acidification to near neutrality within 1 hour (pHi = 7.08 ± .05; NR method, n = 12), and which was maintained for at least another hour. This pHi is closer to the expected in vivo pHi and represents a restored proton gradient. The acidification due to amiloride suggests that the H^+/Na^+ antiporter is abnormally activated in the hippocampal slice preparation.

37.8 Intracellular pH of Astrocytes Rises Rapidly with Cortical Stimulation. M. Chesler and R.P. Kraig. Department of Neurology, Cornell University Medical College, New York, New York 10021

Glial cells play an important role in brain homeostasis, and accordingly, are thought to increase their metabolic rate in response to neuronal activity. This response may be elicited by elevations in external K^+ (Orkand et al., Brain Res. 55:467), but whether other ion shifts are implicated is unknown. Small changes in intracellular pH (pH_i) can profoundly alter glycolytic rate (Fidelman et al., Am. J. Physiol. 242:C87) and gap junctional conductance (Spray et al., Science 211:712), and thus, could significantly modulate glial function. Interstitial pH (pH_o) transients accompany brain stimulation (Kraig et al., J. Neurophysiol. 49:831), but how electrical activity impacts on glial pH_i is unknown. We have therefore monitored pH_i of mammalian cortical astrocytes in vivo during evoked activity and cortical spreading depression (CSD).

Wistar rats were anesthetized with halothane, immobilized and artificially ventilated. Double-barrel, pH sensitive microelectrodes were inserted into frontal cortex bathed with warm (35-37°C) Ringer gassed with 5% CO_2 in O_2. Glia were identified by a high membrane potential and lack of injury or synaptic discharge. Their resting pH_i was 7.04 ± 0.02 with a membrane potential of 73 ± 1 mV (mean ± SEM; n=43).

In 44 records from 37 glial cells, bipolar stimulation of the cortical surface produced a rapid glial depolarization, attributable to a rise in external K^+, accompanied by an intracellular alkaline shift (IAS). The size of the IAS correlated with the degree of depolarization and ranged from 0.05-0.40 pH. With prolonged stimulation pH_i reached a peak, slowly became less alkaline, and after stimulation, rebounded to a more acid level than baseline. Stimulation in the presence of 1-2 mM Ba^{2+} caused a hyperpolarizing response (Ballanyi et al., J. Physiol. 382:159) and completely blocked the IAS. Similar, but generally larger pH_i responses occurred with CSD, with an IAS of 0.11-0.78. After withdrawal from cells, the predominant interstitial response to stimulation and CSD was a slow acidification.

The mechanism of the IAS remains to be elucidated but available data indicate that it requires an active acid extrusion mechanism or internal consumption of protons. Its sensitivity to Ba^{2+} suggests that glial depolarization is necessary to elicit the response. The observed lability of glial acid-base status suggests that pH_i shifts may serve to rapidly modify the functional state of glial cells in response to demands imposed by surrounding neurons.

37.9 pH SHIFTS IN THE CA1 LAYER OF THE HIPPOCAMPAL SLICE. W. Walz. Dept. of Physiology, College of Medicine, University of Saskatchewan, Saskatoon S7N 0W0, Canada.

Changes in the pH of the extracellular space in the pyramidal cell layer (CA1) of slices (500 um thick) from rat hippocampus were monitored with the aid of microelectrodes. The electrodes were double-barreled, thick septum microelectrodes manufactured according to a method introduced by Ransom and co-workers (Borrelli et al., J. Neurosci. Methods 15 (1985): 141). One channel tip was filled with the Fluka proton cocktail for measuring the pH signal and the other one contained a hepes-buffered salt solution for measuring the field potentials. The pH response was calculated from the difference of both signals. The salt solution bathing the slice was a bicarbonate buffered saline with a pH of 7.35. During stepwise impalement of the slice with the double-barreled microelectrode towards the site with the highest field potential amplitude during stimulation of the Schaffer's collaterals the pH decreased to 7.1. Hence, there is a pH gradient within the slice with more acidic values at areas which have higher activity and are in the center of the slice. This gradient was present also without stimulation of the Schaffer's collaterals. Stimulation showed two frequency-dependent features: A transient alkaline shift at the onset of stimulation was followed by a sustained acidic shift. The transient alkaline shift was apparent at 20 Hz stimulation (0.04), had a maximum at 50 Hz (0.07) and was reduced at 100 Hz. The sustained acidic shift reached values of 0.15 (5 Hz), 0.2 (20 Hz), 0.26 (50 Hz) and 0.17 (100 Hz). After the end of the stimulation the pH slowly returned to the resting level with a time course of 0.03 pH units per min. A one minute stimulation with 50 Hz was selected for drug analysis of the phenomenon. The Na^+/H^+ exchange blocker amiloride (1mM) did not influence the resting pH level. During stimulation the transient alkaline shift was not influenced. However, the amplitude of the acidic shift was reduced by one third. Acetazolamide (1 mM) a blocker of the carbonic anhydrase, which is probably a glial specific enzyme, elicited a slow acid shift of the resting pH level (0.05 pH units per min). Stimulation during the presence of acetazolamide caused a three times increased transient alkaline shift (0.2 pH units) which lasted almost one min, but did not influence the acid shift. When acetazolamide and amiloride were added together, the acid shift almost disappeared and the most prominent feature was the trained feature was the transient 0.2 alkaline shift. It is concluded that the alkaline and the acid shift are features of two different processes involved in neurotransmission, which overlap each other. The glial specific enzyme carbonic anhydrase plays a major role in one of these processes.

37.10 COMPENSATORY CHANGES THAT PROMOTE SURVIVAL OF TURTLE BRAIN DURING ANOXIA. Zi-Cai Feng. Myron Rosenthal and Thomas Sick, Department of Neurology, Univ of Miami Medical School, Miami, FL 33101

Previous studies demonstrated that extracellular potassium ion activity (K^+o) rose only 3-5 mM during 24 hours of anoxia in turtle brain and recovered within a few minutes following restoration of normoxia. This is in contrast to rat brain in which K^+o rose to over 70 mM after only a few minutes of N_2 inspiration. Recent studies indicate that ion transport in anoxic turtle brain was maintained through energy from anaerobic glycolysis since transmembrane gradients were lost during ischemia (1 hr) or during anoxia with glycolytic inhibition (superfusion of brain with iodoacetate). The question remains whether other compensation processes, such as those that may decrease brain energy demand, also contribute to ion homeostasis during prolonged anoxia in turtle brain. In these studies, K^+o was recorded with ion-selective microelectrodes in intact brains of turtles anesthetized with pentobarbital. Turtle brains were stimulated to increased activity by two methods: a) application of electrical pulses to the brain surface (2 sec trains, 20 Hz, 0.5msec/pulse) to record amplitudes of K^+o efflux provoked by this stimulation and rates of K^+o reaccumulation at the stimulus site; and b) application of electrical pulses to the olfactory nerve for recording evoked potential activity in the olfactory bulb. Amplitudes of evoked potentials declined within 30 minutes of N_2 inspiration and decreased to approximately 40% of normoxic levels at 2 hours. Magnitudes of K^+ efflux were also decreased and rates of reaccumulation of K^+o were slowed. These data demonstrate that synaptic transmission was inhibited by anoxia as was ion transport that occured in response to neuronal activation, suggesting that turtle brain compensates for anoxia by decreasing excitability and also by decreasing the rate of K^+o-stimulated transmembrane cation transport. The slowing of K^+o reaccumulation is in apparent contrast with findings that K^+o reaccumulation is unchanged by hypoxia in rat brain. In turtle brain, K^+o recovery rates were most retarded at low K^+o values suggesting that the presence of high K^+o "loads" either overcomes the apparent compensatory decrease in ion transport rate or that an addition transport mechanism is activated to promote rapid reaccumulation when stimulus-provoked K^+o increments are high. This secondary process may not be present in mammalian brain and it may protect turtle brain against anoxic depolarization. It remains to be determined whether protective mechanisms of turtle are novel to that species, or whether thay can be adapted or encouraged in mammals. However, it is clear that turtle provides an extraordinary model for studies of brain survival since it demonstrates basic features of vulnerability and also of adaptation which may be present in mammal but are not easily available for investigation because of the rapidity of degenerative events. 37.11 ACIDOSIS CORRESPONDS WITH GLUCOSE UTILIZATION IN FOCAL ISCHEMIA. K.E. Peek, M. Izumiyama*, A.H. Lockwood,* E.W.H. Yap*, J.Y. Labove*. Univ. of Tex. Med. Sch., Houston, TX 77025.

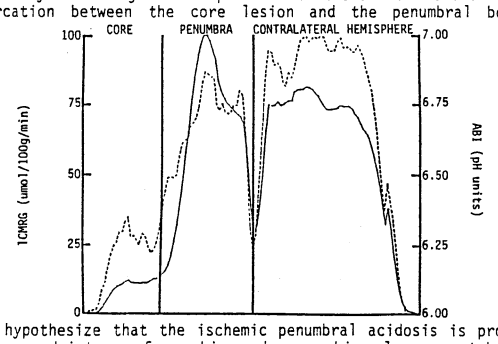
Post-ischemic recovery potential may be compromised by tissue acidosis. Focal cerebral ischemia was produced in anesthetized male Wistar rats by insertion of a silicone-tipped 4-0 nylon suture via the internal carotid to the origin of the middle cerebral artery (Koizumi, Jpn J Stroke 8:1-8, 1986). [^{14}C]-dimethyloxazolidine dione (DMO, 175 µCi/kg) was injected iv followed 1 h later by [^{14}C]-deoxyglucose (DG, 100 µCi/kg). After 45 min of timed arterial blood sampling, the animal was killed and 20µbrain sections were autoradiographed. After DMO sublimation a second autoradiograph was prepared. Following computer-controlled digitization, image subtraction produced DMO and DG images from which local cerebral metabolic rate for glucose (lCMRG) and acid-base index (ABI) were computed. Two hours of tamponade-induced focal ischemia reduced lCMRG and ABI in frontal to occipital cortex, lateral caudate-putamen (CPU) and thalamus, amygdala, and internal capsule. In the penumbra of the reduced lCMRG zone, regions of increased lCMRG were observed affecting medial CPU, hippocampus, cortical columns, and more medial thalamic nuclei. Less severe acidosis was seen in regions of abnormally high lCMRG. The graph shows a topographic profile of calculated lCMRG (solid line) and ABI (dotted line) values along a line transversely bisecting a frontoparietal section. Note the sharp demarcation between the core lesion and the penumbral border.



We hypothesize that the ischemic penumbral acidosis is produced by an admixture of aerobic and anaerobic glucose metabolism. Tissue survivability may be enhanced by improving tissue oxygenation, titrating metabolic acids, and limiting the availability of excess glucose.

37.12 THE DIFFERENTIAL EFFECTS OF HYPOXIA ON NEUROTRANSMITTER RELEASE MECHANISMS. G.B. Freeman, T. Manger and G.E. Gibson. Cornell Univ. Med. Coll. at the Burke Rehab. Ctr., White Plains, NY 10605.

Diminished oxygen availability differentially alters the K^+-stimulated release of acetylcholine (ACh), glutamate and dopamine (DA). In mouse striatal slices, anoxia (100% N_2) under depolarizing K^+ concentrations reduces media levels of ACh and increases those of DA and glutamate (Freeman et al., 1987). In order to determine if the presynaptic terminal is the origin of the excess extracellular DA and glutamate, the effects of anoxia on release were measured in partially purified striatal presynaptic terminals (i.e. synaptosomes; Leslie et al., 1983). Chemical hypoxia was induced by the addition of KCN (0.5 mM). Anoxic-induced changes in total media concentrations of the neurotransmitters differed with the concentration of Ca^{2+} in the incubation media. In low Ca^{2+} media (0.1 mM), increases were evident for ACh (5.7%), DA (168%) and glutamate (318%) whereas, in 2.3 mM- Ca^{2+}, ACh decreased 63% but DA and glutamate were elevated 30% and 112%, respectively. Anoxic-induced alterations of ACh and glutamate release also occurred with a purified rat striatal synaptosomal preparation (Hajos, 1975). Total concentrations during anoxia with 0.1 mM-Ca^{2+} were reduced 50% for ACh and increased 170% for glutamate. With 2.3 mM-Ca^{2+}, ACh concentrations declined 40% with anoxia while glutamate increased 79%. The results suggest that the increased extracellular concentrations of DA and glutamate that accompany anoxia and ischemia in vivo and in vitro are due to alterations in presynaptic release mechanisms that are related to changes in calcium homeostasis.

37.13 SENSITIVITY OF SYNAPTIC ACTIVITY IN THE CA1 REGION OF THE HIPPOCAMPAL SLICE PREPARATION TO COMBINED HYPOXIA AND HYPOGLYCEMIA: A MEDIAN-EFFECT ANALYSIS.
K. H. Reid, C. B. Shields, W-Q Dong*, and A. Schurr. Laboratory for Cellular Neuroscience, Departments of Physiology, Surgery and Anesthesiology, School of Medicine, University of Louisville, Louisville KY 40292.

Hippocampal slices from 200-300 g Sprague-Dawley rats , cut 400 um thick, were maintained in an interface chamber at 34°C and subjected to various combinations of hypoglycemia and hypoxia. Synaptic responsiveness was evaluated by stimulating Schaffer collaterals once/min at 2x threshold, and recording the CA1 population spike. Slices were considered unresponsive if this stimulation did not evoke a response > 1 mv in amplitude. The typical prehypoxic response to this stimulus intensity was a population response 10-20 mV in amplitude.

The exposure to low glucose (hypoglycemia) lasted 60 minutes. During the last 10 minutes of this period, oxygen was replaced partially or completely by nitrogen, to impose a hypoxic stress. Baseline conditions were restored for 30 minutes post-stress before testing for recovery of synaptic function.

A total of 1063 slices were tested under 16 different combinations of hypoglycemic and hypoxic stresses. Median-effect analysis was used to establish ED50 loci for 2 conditions: constant oxygen tension with varying glucose concentration, and constant glucose concentration with varying oxygen tension. The two loci agreed within 5%. This analytic approach was also found effective in a previous study of the interactions of ACSF K^+ and temperature (Soc. Neurosci. Abstr 16:1526, 1986). We conclude that median-effect analysis is an appropriate tool for the analysis of the effects of a variety of interacting environmental stresses on brain tissue, and may prove useful in evaluating both the relative importance of different mechanisms contributing to brain damage and the value of putative protective agents.

37.14 MODERATE INCREASES OF BLOOD FLOW TO CAT WHITE MATTER IS INDICATIVE OF AN INCREASED LATENCY OF THE CORTICAL COMPONENT OF THE SOMATOSENSORY EVOKED POTENTIAL AND A PERIOD OF ELECTRICAL RECOVERY FOLLOWING SYSTEMIC HYPOXIA. P.E. Coyer and F.A. Simeone* . Department of Neurosurgery, The Pennsylvania Hospital, Philadelphia, PA 19107.

We have reported the finding of a linear increase in the latency of the cortical component of the somatosensory evoked response (SEP) during contralateral forepaw stimulation in response to systemic hypoxia in cats (Coyer, Michele, Simeone; Neurosci. Abstr 12: 1130, 1986). The dependency of the cortical wave latency on oxygen concentration seemed to be a function of the rate and degree to which hypoxemia was achieved as suggested by comparing the responses of two groups of 12 cats each ventilated under a different oxygen/nitrous oxide regimen.

In this paper we report the observations of several other parameters related to these studies. First, oxygen availability to the brain tissue remained relatively constant over ventilation concentration of 9-18%. This observation probably reflects the maintenance of blood flow to the gray matter and the significant rise in blood flow to the white matter especially at 7% O_2. Additionally, the frequency of spontaneously-occurring activity increased during decreases in oxygen availability although initially there was a transient depression in observed multi-unit action potential generation. Thus, these experiments indicate that hyperperfusion of the white matter is associated with maintenance of the somatosensory evoked potential although the latency is extended due to a slowing of conduction associated with a constant metabolic rate and accumulation of lactate (Lesnick et al., Stroke 17: 1247-120, 1986).

In several animals whose electroencephalographic (EEG) activity recovered following exposure to hypoxia and a return to normal oxygen atmosphere, there was still an extension of the cortical component of the somatosensory evoked response. This could indicate that white matter is dependent upon hyperperfusion,which was observed,and its recovery upon a period of time to restore normal electrical conditions.

The results of these experiments suggest that the SEP cortical wave latency is a sensitive indicator of hypoxemia during hyperperfusion of the white matter conduction pathways. Perhaps, oxygen availability in the cortex remains relatively undisturbed in the gray matter due to maintenance of blood flow and accounts for the continued excitability of neurons there. On the other hand, white matter pathways are blocked and the SEP cortical component's appearance is extended. Resumption of EEG activity without restoration of the normal SEP cortical wave latency may suggest that a period of time is necessary for recovery of metabolism following hypoxic insults in white matter.

37.15 FOCAL CORTICAL PERFUSION, BRAIN pH AND EEG DURING PROLONGED HYPOCAPNIA: HALOTHANE VS. ISOFLURANE. M.A. Morón*, R.E. Anderson*, T.L. Yaksh* and T.M. Sundt, Jr.* (SPON: D.W. Klass). Departments of Pharmacology and Neurologic Surgery, Mayo Clinic, Rochester, MN 55905.

Though both halothane (HAL) and isoflurane (ISO) are halogenated anesthetics, they have different effects on the regulation of cerebral blood flow (CBF), particularly in response to changes in arterial $PaCO_2$. The present studies were designed to examine the effects of equi-anesthetic concentrations (1 MAC) of these two anesthetics on focal cortical and regional CBF (fCBF and rCBF), intracellular brain pH (pHi) and EEG in response to changes in $PaCO_2$, and also to determine any changes in fCBF and rCBF during prolonged hypocarbia. fCBF and rCBF were estimated in cats maintained at 1 MAC of HAL or ISO by measuring the clearance of the molecular form of umbelliferone (UMB), and xenon-133. UMB is a lipid soluble intracellular pH indicator (Brain Res. 186:355, 1980). For each cat a CO_2 response curve was generated using $PaCO_2$ values of 40, 60, 30 and 20 measured at 15-min intervals (feline normocapnia: 34-38). Subsequently, each cat was maintained at a $PaCO_2$ of 20 for 3 hr. In a third group of animals under ISO, a similar protocol was followed, but the $PaCO_2$ was maintained at normocapnia for 3 hr. EEG and BP/HR were monitored throughout the experiment.

CBF-CO_2 response: The slope (ml/100 g/min/torr) of the HAL and ISO CO_2 response curves were: 0.658 ± 0.133 and 0.463 ± 0.120 with UMB; 1.520 ± 0.224 and 1.218 ± 0.144 with xenon-133 for HAL and ISO, respectively. CBF over time: For the HAL-hypocapnic groups CBF had returned to normocapnic flow levels by 1 hr while arterial $PaCO_2$ remained low. The ISO-hypocapnic group showed a progressive CBF reduction of 23%, 37% and 35% at 1, 2 and 3 hr, respectively ($P < 0.05$). The normocapnic ISO group showed no change in flow over time. Brain pH: Normocapnic intracellular pH was 7.03 ± 0.1 for all groups. After 1 hr of hypocapnia the pH was 7.12 ± 0.04 and 7.14 ± 0.03 for HAL and ISO, respectively. At 2 hr the HAL group displayed a normal pH while for the ISO group the pH was 7.18 ± 0.03 ($P < 0.05$). The pH of the ISO-normocapnic group remained stable throughout the period of normocapnia. EEG: HAL EEG activity was normal throughout the experiment. A burst suppression pattern was seen in five of the seven cats in the ISO-normocapnic and all the cats in the ISO group. This pattern was more severe in the latter group.

This investigation shows that for prolonged hypocapnic ISO in contrast to HAL anesthesia that CBF remains reduced and a significant intracellular alkalosis ensues. EEG activity for both ISO groups demonstrated a burst suppression pattern which was exaggerated during hypocarbia. (Supported by NIH grant NS-24329, TLY.)

37.16 NADH FLUORESCENCE CHANGES IN RESPONSE TO SPREADING DEPRESSION IN RAT BRAIN CORTEX AND HIPPOCAMPUS. J. Ott, S. Brewster*, C. H. Barlow* and J. J. Kelly*. Humphrey Laboratory, The Evergreen State College, Olympia, WA 98505.

The brain's metabolic response to spreading depression results in changes in the redox state of NAD^+/NADH. These changes may be followed by imaging NADH fluorescence. Using this approach we have compared the metabolic responses to spreading depression of the cortex with the response in the hippocampus in rat brain.

Pentobarbital anesthetized Sprague-Dawley rats were used without artificial ventilation. The skull was exposed and a 1mm hole was drilled through the skull 2mm caudal to and 2mm to the right of the bregma. Spreading depression was initiated by insertion and removal of a 25 gauge needle to the appropriate depth. The brain was then funnel frozen at specified times following initiation of spreading depression. Photographs recorded the NADH fluorescence from polished surfaces of the frozen brain.

When spreading depression was induced in cortex only, a narrow zone of oxidized NAD^+ immediately followed by a wide zone of reduced NADH moved across the cortex at 2-3mm/minute. The metabolic response did not spread to the hippocampus. Simultaneous stimulation of cortex and hippocampus resulted in the same cortical response, however in the hippocampus the entire ipsolateral side became reduced within approximately 6 seconds with no evidence of the metabolic response on the contralateral side. After 3 minutes the hippocampus had recovered (disappearance of NADH fluorescence), while the cortex was still reduced and did not show oxidized NAD until 20 minutes.

Clearly different nervous structures have differential responses to the onset and recovery of spreading depression. The fact that spreading depression rapidly affects the entire hippocampus may be related to the structural organization of the hippocampus as compared with the cortex.

Allowing the animal to breath 95% O_2/5% CO_2 for 10 minutes prior to the elicitation of spreading depression prevented the metabolic response to spreading depression in both the cortex and hippocampus. These studies suggest that the metabolic rate of the affected cells is accelerated during spreading depression and drives the tissue into anoxia. This anoxic state can be overcome with adequate prior oxygenation of the tissue.

The rapidly reversible nature of the metabolic response to spreading depression in the hippocampus suggests the possibility of employing spreading depression as a temporary inhibitor of hippocampal function in studies of spatial behavior and memory.

Supported by Professional Development Grant from The Evergreen State College.

37.17 PROTON MAGNETIC RESONANCE SPECTROSCOPY IN A RAT MODEL OF CEREBRAL HYPOXIA AND RECOVERY. E.A. Crisostomo, J.A. White*, C.M. Gasparovic*, R. Griffey*, and G.A. Rosenberg. Dept. of Neurology and Center for Non-Invasive Diagnosis, University of New Mexico, Albuquerque, New Mexico 87131.

Oxygen deprivation in the brain leads to a series of biochemical events which include augmentation of glycolysis, accumulation of polyenoic free fatty acids and inhibition of mitochondrial respiratory enzymes. ^{1}H magnetic resonance (MR) spectroscopy allows the detection of energy metabolites and membrane phospholipids which are sensitive to cerebral O_2 perturbation. We applied this technique to a rat model of hypoxia with subsequent recovery to study changes in the spectral pattern of intact brain.

Male Sprague-Dawley rats, with free access to food and water, were anesthetized with pentobarbital and ventilated (70% N_2O/30% O_2). The paralyzed animal was fitted into a probe with the head positioned directly over a two-turn proton surface coil. ^{1}H MR spectra were obtained using a 9-cm bore 7-T superconducting magnet operating at a proton frequency of 300 MHz. Brain localization was achieved by means of a modified depth selective pulse sequence. An initial 30-min period of normoxia was followed by 30 min of hypoxia (15% O_2). Subsequently, recovery was attempted for 1-2 hr with restoration of O_2 to 30%. Arterial blood gases and mean arterial blood pressures were monitored during the course of each experiment.

Proton spectra collected during baseline normoxic periods contained well-resolved resonances at 2.0 ppm and 1.5-1.7 ppm. We tentatively assigned these resonances to the methyl group of N-acetylaspartate and to lipids, respectively, although we could not exclude the possible contributions of other metabolites. Spectral peaks of amino acids at 1.9 and 2.1 ppm, and of lactate β-CH_3 at 1.3 were less consistently identified. Hypoxia induced a prominent and rapid reduction of the 2.0 ppm peak. Peak levels of resonances assigned to lipids were simultaneously increased in some animals. A late but persistent increase in the signal corresponding to β-CH_3 resonance of lactate was invariably associated with lack of recovery. A return to normoxic level quickly restored the signal at 2.0 ppm. Failure of this peak to recover to baseline level, as well as substantial increases in the signals at 1.3, 1.5 and 1.7 ppm usually correlated with the animal's death.

These results suggest that ^{1}H MR spectroscopy is a useful tool for characterizing specific metabolic changes during hypoxia and recovery. The availability of this system to study animal models of hypoxia and ischemia has potential utility in screening drugs that will facilitate recovery.

37.18 ANTIHYPOXIC EFFECT OF FLUNARIZINE ON NEURONAL TISSUE IN VITRO. A. Schurr, C.A. West*, M.T. Tseng*, W.-Q. Dong* and B. M. Rigor. Departments of Anesthesiology and Anatomy, University of Louisville School of Medicine, Louisville, KY 40292.

It has been suggested that flunarizine, a fluorinated derivative of cinnarizine (Jenssen Pharmaceutica), possesses antimigraine properties. The possibility that the antimigraine action stems from flunarizine's calcium blocking capability has been refuted. Nevertheless, flunarizine's action against hypoxic damage has been investigated using different ischemic/hypoxic models, where it has been shown to have such activity. In a recent study we failed to demonstrate flunarizine's antihypoxic effect using the rat hippocampal slice preparation and attributed it to the drug's poor solubility (<1 μM) in the artificial CSF (ACSF). In the present study we used the same in vitro system while supplying flunarizine as a liposomal suspension. Rat hippocampal slices (400 μm) were maintained in a dual interface chamber, supplied with humidified 95% O_2/5% CO_2 and ACSF. Evoked field responses from the CA1 pyramidal cell layer were recorded (once/min) from one slice in each compartment of the chamber, following orthodromic stimulation of the Schaffer collaterals. Additional slices (10-15/compartment) were checked for the presence of such response at the beginning and at the end of the experiment. After 15 min of baseline recordings, slices in one compartment were perfused with phosphatidyl-choline (PC) : dicetylphosphate (DP) (10 : 0.6 μmole) liposomal suspension in ACSF (control), while the slices in the other compartment were perfused with liposomal suspension made of PC : flunarizine : DP (10 : 10 : 0.6 μmole). Each suspension (25 ml) was recirculated for 45 min. Thirty min following the application of liposomes, hypoxia was produced in both compartments (95% N_2/5% CO_2) for 15 min, after which time O_2 atmosphere was restored for 30 min.

Of 30 control slices only 5 exhibited recovery of synaptic function (evoked response>3 mV) following 15 min hypoxia. In contrast, 16 of 30 experimental slices showed such recovery following the insult ($P<0.01$). Flunarizine's lipophilicity limits its use in aqueous solutions. However, when applied as a liposomal suspension, it is readily available to the target tissue and may exert its effect in a dose-dependent fashion. Using this approach we were able to demonstrate flunarizine's antihypoxic effect on neuronal tissue in vitro.

37.19 INCREASED BRAIN AMINOPEPTIDASE A ACTIVITY IN THE SPONTANEOUSLY HYPERTENSIVE RAT. M. J. Sullivan and A. K. Johnson. Departments of Psychology and Pharmacology, and the Cardiovascular Center, University of Iowa, Iowa City, IA 52242

The spontaneously hypertensive (SH) rat exhibits an increase in the half-life of angiogensin II (ANG II) and III (ANG III) introduced into the lateral ventricle compared to its normotensive counterpart, the Wistar-Kyoto (WKY) rat (Wright et al., J. Neurochem, in press). Angiotensin-induced pressor responses in the SH rat are greater in magnitude and duration than those observed in the WKY. An increase in sensitivity to other peptides has also been noted in the SH rat. These findings suggest aberrations in peptidase metabolism in the SH rat.

Aminopeptidases (APs) play a primary role in the degradation of angiotensins and other peptides in the central nervous system. In the periphery, Ang II is hydrolyzed to Ang III by membrane bound AP-A (angiotensinase). Central degradation of Ang II follows a similar pattern (Abhold and Harding, submitted). Recent data suggest that Ang III may be the biologically active form of angiotensin in the central nervous system (Fink and Brunner, 1985, Am. J. Physiol. 249; Harding and Felix, Brain Res. in press). One explanation of the sensitivity to Ang II displayed by the SH rat is an increase in Ang III production. In this study we investigated the possibility of increased central AP-A activity in the SH rat.

Adult, male SH and WKY rats were anesthetized and perfused with cold, buffered saline to remove contaminating blood peptidase activity. The whole brain was homogenized and an enriched synaptosomal fraction prepared. Colorometric assays employing L-glutamic acid -(4-methoxy- naphthylamide) as a substrate were used to quantify AP-A activity.

Brain tissue from the SH rat exhibited an increase in the metabolism of the substrate compared to tissue from the WKY. The activity was enhanced by calcium and inhibited by amastatin. Bestatin, did not significantly inhibit degradation of the substrate.

The results suggest an increase in the capacity of the SH rat to metabolize peptides such as Ang II in the central nervous system while half-life studies indicate a decrease in metabolism. These data suggest that the rate limiting step in metabolism of Ang II in the ventricles of the rat may occur following the production of Ang III. This could result in increased amounts of Ang III available to bind the angiotensin receptors and an increase in subsequent pressor responses in the SH rat. (Supported by NIH Grant HL 14388)

38.1 AMNIOTES AND ANAMNIOTES MAY POSSESS HOMOPLASTIC RETINOPETAL PROJECTIONS FROM THE ISTHMIC TEGMENTUM. T. F. Schilling* and R. G. Northcutt . (SPON: C. Gans). Dept. of Biology, Univ. of Michigan, Ann Arbor, MI 48109 and SIO Neurobiology Unit and Dept. of Neurosciences, UCSD, La Jolla, CA 92093.

Retinopetal projections that arise in the isthmus have been reported in lampreys (Vesselkin et al. 1980) and a boney fish, Polypterus (Meyer et al. 1983), as well as reptiles and birds, but do not appear to exist in cartilaginous fishes, amphibians or mammals. In the process of examining the retinofugal projections of the northern pike, Esox lucius, we discovered an isthmal nucleus with retinopetal projections, suggesting that this cell group may be widely distributed among boney fishes. Retrogradely labeled cells were observed bilaterally in a cell column in the dorsal tegmentum of the isthmus following application of HRP by either of two methods.

Gel foam pledgets saturated with a 20% HRP solution were inserted into one orbit following eye removal in each of 4 fish. After 4-6 day survival periods the animals were perfused with 0.1 M phosphate buffer followed by 4% gluteraldehyde in phosphate buffer. Transverse frozen sections cut at 35um were reacted by the method of Hanker-Yates ('77) or with diaminobenzidine as the chromagen. Fusiform cells, heavily labeled in the contralateral isthmus, occupied a position ventrolateral to labeled cells of the trochlear nucleus. These same cells were lightly labeled ipsilaterally.

In two additional fish, following eye removal, the proximal stump of the optic nerve was sucked into a small piece of polyethylene tubing and the HRP solution was injected into the tube. Brains were processed as above. In these animals the isthmic tegmental cells were labeled while trochlear cells were not. Retrogradely labeled axons of these cells left the isthmus in a compact bundle coursing through the midbrain and diencephalon to enter the medial optic tract. Therefore we are sure that they project through the optic nerve and not to extrinsic eye muscles.

It seems unlikely that this retinopetally projecting cell group in pike is homologous to the isthmo-optic nucleus of sauropsids. While the isthmo-optic nucleus receives an input from the optic tectum, unilateral HRP injections into the tectum of six pike failed to reveal a projection to this isthmic nucleus. Instead, several cell bodies were labeled ipsilaterally and apparently project to the tectum. Therefore, given the differences in phyletic distribution as well as connectivity it seems most parsimonious to conclude that isthmic nuclei with retinopetal projections have evolved independently in amniotes and anamniotes. (Supported in part by NIH grants NS11006 and EY02485.)

38.2 DOES NUCLEUS ELECTROSENSORIUS OF GYMNOTOIDS HAVE A HOMOLOGUE IN THE DIENCEPHALON OF NON-ELECTRORECEPTIVE TELEOSTS? Georg F. Striedter* (SPON: M.S. Northcutt). SIO Neurobiol. Unit and Dept. Neurosci's., UCSD, La Jolla, CA 92093.

As part of an effort to arrive at rules governing the central neural changes associated with the evolution of electroreception in teleosts, where this sensory modality has evolved at least twice independently, I have asked whether nucleus electrosensorius in the diencephalon of gymnotoids can be homologized to nuclei in the diencephalon of closely related, non-electroreceptive teleosts.

Nucleus electrosensorius (NE), which receives a massive input from the torus semicircularis, could be homologous to either a preglomerular, a pretectal, or a dorsal thalamic nucleus, or it may not have a strict homologue in non-electroreceptive teleosts and thus be a de novo structure. In cyprinids, the sister group of gymnotoids and catfishes, both the preglomerular complex (PG) and the central posterior nucleus (CP) of the dorsal thalamus receive toral input, but only the former has been shown to have connections with the telencephalon. The pretectal nuclei, in contrast, are not known to receive a toral input, but are typically interconnected with the retina and/or the optic tectum. To discriminate among the four hypotheses I injected HRP into the telencephalon and tectum of Apteronotus leptorhynchus (6 and 4 cases, respectively) and, after survival times of up to 14 days, examined the brains for label according to the method of Hanker-Yates. Although I find labelled fibers passing near NE after both tectal and telencephalic injections, I can observe neither labelled cells nor terminal fields in NE. However, after telencephalic injections both cells and terminals are clearly labelled in the preglomerular area just ventral to NE. The pretectal area of gymnotoids has several derived features, including a hypertophied nucleus paracommissuralis and a hypertrohpied dorsal periventricular nucleus. NE, however, receives neither tectal nor retinal (Sas and Maler, '86) input, and is therefore probably not a pretectal nucleus.

Thus, using strict connectional criteria, NE is not homologous to any pretectal or preglomerular nucleus in cyprinids. NE may be homologous to CP of the dorsal thalamus in cyprinids, but additional information on the connections of CP is needed to test this hypothesis. Alternatively, NE may be a de novo structure without a strict homologue in non-electroreceptive teleosts. Supported by NIH grants NS24869 and NS24669 to R. G. Northcutt.

38.3 TELENCEPHALIC AND RETINAL PROJECTIONS ALLOW REINTERPRETATION OF THE DIENCEPHALON IN MORMYRIDS. M. F. Wullimann and R. G. Northcutt. SIO Neurobiol. Unit and Dept. Neurosci's., UCSD, La Jolla, CA 92093.

African mormyrid fishes are one teleost group that has evolved electroreception. The related neuroanatomical changes obscure a comparative morphological interpretation of certain brain subdivisions in mormyrids. One example is the diencephalon, which contains relay centers of ascending and descending sensory systems. Most teleosts exhibit - from dorsal to ventral - four retinofugal diencephalic nuclei, which project in turn to the cerebellum: dorsal periventricular pretectal (PPd), central pretectal (CPN), dorsal (DAON) and ventral accessory optic nucleus (VAON)(Northcutt and Wullimann, '86). Recently, it was demonstrated that in the mormyrid Gnathonemus petersii three diencephalic nuclei project to the corpus cerebelli: nucleus of the posterior commissure (NPC), nucleus glomerulosus (NG) and dorsal anterior pretectal nucleus (DAP)(Meek et al., '86). Only NPC, however, receives retinal input (Lazar et al., '84) and might therefore be homologous to PPd of other teleosts. Two explanations for this discrepancy seem possible: 1) NG and DAP have lost the retinal input due to a reduction in vision in mormyrids, and the nuclei are indeed homolcgues of CPN and DAON in other teleosts; 2) alternatively, the cerebellopetal pattern in mormyrids is derived among teleosts, and the nuclei under consideration are not homologous to CPN and DAON. To evaluate these two hypotheses we used horseradish peroxidase (HRP, Sigma VI) to examine retinal projections and telencephalic connections of the diencephalon in Gnathonemus petersii. After 2 - 7 days survival times at 27^{0}C the animals were perfused with 1% Heparin in teleost ringers, followed by 4% glutaraldehyde in phosphate buffer (0.1M, pH 7.4). Transverse brain sections (35u) were reacted according to a Hanker-Yates or Adams (heavy metal intensification of DAB) protocol. Our results indicate that NG may be homologous to CPN, as its lateral portion receives retinal input. No DAON or VAON can be identified, however, based on a retinal terminal field. Although DAP is devoid of optic fibers, it does receive extensive projections from the telencephalon and, in addition, gets an input from the torus semicircularis (Finger et al. '81), all of which is typical of nucleus preglomerulosus in other teleosts (Northcutt and Wullimann, '86) but not of DAON. We therefore suggest, that DAP is a subdivision of the preglomerular nucleus, related to electrosensory information, which has evolved a new cerebellar projection rather than being a homologue of DAON. Supported in part by the Swiss National Science Foundation (MFW) and NIH grants EY02485, NS24869, and NS24669 (RGN).

38.4 DEVELOPMENT OF THE MECHANO- AND ELECTROSENSORY SYSTEMS IN EIGENMANNIA VIRESCENS (Gymnotiformes, Teleostei) H.A. Vischer, W. Heiligenberg and R.G. Northcutt
S.I.O. A-002, UCSD, La Jolla CA. 92093

South American weakly electric fish of the species Eigenmannia virescens were induced to spawn by simulating the conditions of the rainy season. Developmental stages were determined by age and mean standard length (MSL). Mechanosensory neuromasts and electrosensory ampullary and tuberous organs were studied by means of Scanning Electron Microscopy (SEM), whole-mount skin preparations, serial sections, and vital staining with 0.015% Methylene Blue, so that details of individual neuromast receptor cells could be recognized in live embryos.

The first neuromasts appear on the head (3.5 days, 5.9 mm MSL), while the lateral line primordium of the trunk begins to migrate ventro-caudally. At day 4 (6.3 mm MSL) the neuromasts on the head begin to form supra- and infraorbital and mandibular lines. The neuromasts on the trunk begin to give rise to a ventral and then a median line at day 6 (7.1 mm MSL). Those of the preopercular and otic line arise at day 5 (6.6 mm MSL). After day 10 (8.3 mm MSL) the total number of neuromasts remains fairly stable, with small variations among the different areas. The neuromasts develop roughly in four stages. First the neuromast receptor cells form an apical cavity which is situated just below the surface; subsequently the overlying epidermal layer subsides and fuses with the cavity, and the receptor rises to the surface. At day 8 (8.0 mm MSL) the first cupulae of the neuromasts begin to elongate in an axis perpendicular to the major axis of the later canals. The head canals start to close on day 17 (13 mm MSL), while the trunk canal begins to form on day 22 (16 mm MSL).

Tuberous organs can first be recognized on day 6 (7.0 mm MSL), while ampullary organs are identifiable from day 7 (7.4 mm MSL) on. On the head, both types develop in rows parallel to the neuromast lines. On the trunk, ampullary organs appear rostrally to caudally in three parallel lines.The first ampullary organs occur among the neuromasts of the median trunk line. Subsequently more dorsal and ventral accessory lines develop adjacent to the dorsal midline of the trunk and on the anal fin. Tuberous organs develop along the myosepta.

Supported in part by NIH grants to R.G.N.

38.5 DEVELOPMENT OF THE LATERAL LINE SYSTEM OF THE CHANNEL CATFISH. R. Glenn Northcutt. SIO Neurobiol. Unit and Dept. Neurosci's., UCSD, La Jolla, CA 92093

Silurid teleosts, like most nonteleost fishes, possess electroreceptive and mechanoreceptive lateral line organs. However, the phylogenetic distribution of teleost electroreceptors, as well as their anatomy and physiology, suggest that they are homoplastic to the ampullary organs of nonteleost fishes. Although there is considerable information on the origin and development of mechanoreceptive neuromasts from ectodermal placodes in amphibians and fishes, there is little information on the development of silurid electroreceptors (Sato, '56, Annot. Zool. Jap. 29:207-212).

Developing embryos and larvae of Ictalurus punctatus were staged following Armstrong and Child (Stages in the Development of Ictalurus nebulosus, Syracuse Univ. Press, 1962) and fixed in 4% glutaraldehyde in 0.1M phosphate buffer (pH 7.4). Head and trunk ectoderm were removed by microdissection and stained with 1% methylene green to reveal differentiating lateral line organs. Whole embryos were postfixed in 1% osmium tetroxide and prepared for scanning electron microscopy. Finally, embryos and larvae were embedded in methacrylate and transverse sections (3µm) cut to compare with the ectodermal preparations. At 22-24°C embryos hatch at stage 43 (day 8). By this stage the lateral line placodes of both the head and trunk have completed migration, and primordia of the neuromasts can be recognized. Neuromast primordia of the head differentiate and erupt to the surface by stage 47 (days 10 and 11), and canal formation begins by stage 49 (day 12). Formation of the trunk canal begins much later (approximately 40 days post-fertilization). The first primordia of external taste buds can be recognized at stage 43 (day 8), and the primordia of electroreceptors can be definitely recognized by stage 48 (day 11). Taste bud primordia erupt by stage 48 (day 11) and electroreceptor primordia by stage 50 (day 13). Similarities in the early development of taste buds and electroreceptors complicate the interpretation of the embryonic origin of the electroreceptors. However, the first recognizable electroreceptors develop adjacent to the tissues forming canal neuromasts, which is consistent with a hypothesis that both electroreceptors and neuromasts arise from the same placodes.

Supported in part by NIH grants EY02485, NS24869, and NS24669.

38.6 TYROSINE HYDROXYLASE AND SEROTONIN IMMUNOREACTIVITY IN THE BRAIN OF AN ELASMOBRANCH, PLATYRHINOIDIS TRISERIATA. W. L. R. Cruce, S. L. Stuesse, and R. G. Northcutt. Neurobiology Dept. N.E. Ohio College of Medicine, Rootstown, OH 44272; and Dept. of Neurosciences, Univ. of California, San Diego, La Jolla, CA 92093.

Elasmobranchs exhibit a wide range of brain to body weight ratios, overlapping those of bony fishes, as well as birds and mammals. We determined the distribution of immunoreactivity to tyrosine-hydroxylase (catecholaminergic cell groups) and 5-hydroxytryptamine (5HT, serotonergic) in the brain of the thornback guitarfish, an elasmobranch with a low brain:body ratio. 5HT and TH cell groups have been well characterized in rats, thus the presence or absence of various nuclei in this elasmobranch could be compared with a mammalian brain. Thirteen P. triseriata were collected and kept in the laboratory. Nine were given injections of colchicine to block axonal transport; 4 were untreated. The guitarfish were anesthesized, perfused, and 20-40 um frozen transverse serial sections were made of the brain. The sections were incubated with rabbit antibodies to either TH or 5HT. Antibody location was determined by a goat anti-rabbit secondary antibody conjugated to fluorescein or by a biotinylated secondary antibody and avidin-biotin peroxidase histochemistry.

TH positive cells were found throughout the dorsal and lateral pallium. Numerous TH positive cells were found in the diencephalon (preoptic, suprachiasmatic, ventromedial and ventrolateral thalamic nuclei, and the posterior tuberculum). In the mesencephalon, TH cell groups were found in raphe linearis, the ventral tegmental area, and substantia nigra. The rhombencephalon contained TH positive cells in the locus coeruleus, subcoeruleus and possibly an A7 group. Probable A2/C2 and A1/C1 groups were also located, but no group which corresponded to A5 was found. Many serotonergic cell groups were found in the paraventricular hypothalamic organ and extended into the pituitary. In the mesencephalon, 5HT cells were found in raphe linearis and in the nucleus reticularis pedunculopontinis pars compacta. Cells in metencephalon were found in reticularis pontis oralis lateralis and medialis, the reticulo-tegmental nucleus, nucleus centralis superior, reticularis magnocellularis, and reticularis pontis caudalis. In the mylencephalon additional 5HT cells were found in raphe pallidus, reticularis paragigantocellularis lateralis, and reticularis ventralis pars alpha. The cell morphologies of these reticular groups were strikingly similar to those of rat. Thus this guitarfish has most of the 5HT and TH cell groups found in rats with the major exception that no 5HT cells were found in a nucleus which might correspond to raphe dorsalis. (Supported by grants from the Ohio Board of Regents and the National Institutes of Health.)

38.7 **PROJECTIONS OF GIANT FIBERS IN THE BRAIN OF THE HATCHETFISH (GASTEROPELECUS).** M.A. Barry and M.V.L. Bennett. Dept. of Neuroscience, Albert Einstein College of Medicine, Bronx, NY 10461.

Giant fibers (GFs) are large axons which receive excitatory input at axo-axonic synapses from both Mauthner cells and in turn form excitatory synapses on pectoral fin motoneurons. GFs are responsible for the bilateral components of the Mauthner cell-mediated startle response. The present study revealed extensive GF projections to central targets other than the pectoral fin motoneurons.

Physiologically identified giant fibers were filled intracellularly with Lucifer yellow. The GF cell bodies are located in a column adjacent to the IVth ventricle just dorsal and lateral to the medial longitudinal fasciculus (MLF). The dendrites are numerous and very fine. The single axonal process decussates at the level of the cell body, and bifurcates to form ascending and descending branches within the MLF. The descending process and its projections to the pectoral fin motoneurons have been described previously (Gilat et al., Brain Res. 365: 96, 1986). However some collaterals project into the dorsal columns at the level of the rostral spinal cord. The ascending branch has numerous collaterals which appear to terminate in the trigeminal, facial, and oculomotor nuclei, but probably not the abducens nucleus. Collaterals also terminate on small cells adjacent to the Mauthner cell ventral dendrite, which are probably part of the Mauthner inhibitory network (PHP cells, Korn and Faber, J. Neurophysiol. 38: 452, 1975). There are no direct GF projections to the Mauthner cell. Other collaterals at many levels of the rhombencephalon terminate in medial parts of the reticular formation. These projections may participate in later components of the startle response or may constitute part of a general arousal pathway.

The morphology and projections of GFs in adult hatchetfish are virtually identical to those of T-reticular neurons described in zebrafish larvae (Kimmel et al., J. Comp. Neurol., 233: 365, 1985); thus these cells can be considered as homologs. The cranial relay neurons described in goldfish (Hackett and Faber, Neurosci. 8: 317, 1983) have rostral projections similar to those of GFs and T-reticular cells, but lack a descending process and projections to the reticular formation.

Fishes possess a startle reflex system not requiring Mauthner cell activation (Eaton et al., J. Comp. Physiol. 145: 485, 1982). The presence of numerous synapses on GF somata (Model et al., Brain Res. 45: 288, 1972) and of an extensive dendritic field suggests that GFs are capable of operating independently of the Mauthner cell. Thus, they may participate in non-Mauthner as well as Mauthner mediated startle reflexes.

38.8 AFFERENT CONNECTIONS OF THE VENTRAL TELENCEPHALON OF THE GOLDFISH. H.E. Sloan and L.S. Demski. School of Biological Sciences, University of Kentucky, Lexington, KY 40506.

Neurons of the telencephalon and diencephalon were labeled following injections of 60-80 nl of 4% horseradish peroxidase into the pars ventralis (Vv) and pars supracommissuralis (Vs) of the ventral telencephalon. In the telencephalon labeled cells occurred bilaterally in the central area of the dorsal telencephalon (Dc). In the following areas a preponderance of ipsilateral positive cells were observed in: 1) the central area of the ventral telencephalon (Vc) ; 2) the dorsal nucleus of the ventral telencephalon (Vd); 3) Dc, Vd, Vv, Vs and the anterior portion of the nucleus preopticus parvocellularis (PPa) at the level of injection; 3) Vd, Vs, PPa caudal to the injection site at the level of the anterior commissure. Filled cells were found only on the ipsilateral side in: 1) an area ventrolateral to Vd and the postcommissural nucleus of the ventral telencephalon (Vp); 2) the intermediate nucleus and the medial portion of nucleus taenia of the caudal telencephalon. Labeled fibers of an unknown origin were found in the ipsilateral lateral zone of the dorsal telencephalon. Other filled fibers (mostly ipsilateral) were observed in the olfactory tracts, in Vd, in the medial forebrain bundle and the laterally extending tracts from the anterior commissure.

Bilaterally in the diencephalon filled cells were present in the nucleus dorsalis posterior of the thalamus at the level of the posterior commissure (PC). Labeled neurons were also found in the nucleus tuberis posterior and the periventricular nucleus of the posterior tuberculum also at the level of PC (mostly ipsilateral). Positive cells, only observed on the side of the injection, were found: 1) in the lateral preoptic are situated between the entopeduncular nucleus and PPa; 2) at the lateral perimeter of the nucleus preopticus magnocellularis, pars magnocellularis; 3) in the dorsal hypothalamic zone at the level of the habenular nuclei; 4) dorsal to the caudal hypothalamic zone. Fibers of an unknown origin were observed in the medial forebrain bundle, lateral to the dorsal hypothalamic zone at the level of the habenular nuclei, and in the area dorsal to the caudal hypothalamic zone, at the level of and caudal to the posterior commissure. Most of these are ipsilateral.

Larger Vv-Vs injections labeled terminal nerve ganglion cells, olfactory mitral cells and somata in the locus coeruleus. Supported in part by a Biomedical Sciences Research Support Grant RR 07114.

38.9 **AN IMMUNOCYTOCHEMICAL ANALYSIS OF THE DISTRIBUTION OF CATECHOLAMINE-SYNTHESIZING ENZYMES IN THE GOLDFISH BRAIN.** P.J. Hornby* and D.T. Piekut. Neuroendocrine Unit, University of Rochester, Rochester, NY 14642.

The distribution of presumptive-dopaminergic and noradrenergic neurons is elucidated in the goldfish brain for the first time by use of immunocytochemical techniques and antibodies to the catecholamine-synthesizing enzymes, tyrosine hydroxylase (TH), dopamine beta-hydroxylase (DBH), and phenylethanolamine-N-methyltransferase (PNMT). The use of these antibodies provides a means for specifically marking each neuronal system, i.e., dopaminergic structures are TH-immunoreactive (-ir) only, noradrenergic structures are TH-and DBH-ir, and adrenergic neurons are PNMT-ir.

In the hindbrain, presumptive-dopaminergic and noradrenergic neurons are codistributed in three anatomically distinct and separate regions which are; 1) the dorsal surface of the postobecular region, 2) the central medullary tegmentum from the level of the greatest expansion of the vagal lobe to the medullospinal transition, and 3) the isthmal tegmentum dorsolateral to the medial longitudinal fasciculus in the locus ceruleus. DBH-ir neurons are not observed rostral to the hindbrain; however, a dense DBH innervation of the diencephalon is observed in periventricular regions, basal hypothalamus, and inferior lobe. Presumptive-dopaminergic neurons are observed following the diencephalic regions; 1) the posterior tuberal nucleus, 2) the paraventricular organ, 3) the ventromedial thalamic nucleus, 4) the nucleus pretectalis periventricularis, pars ventralis, 5) the suprachiasmatic nucleus, and 6) the preoptic nucleus. In the telencephalon, TH-ir neurons are observed in the area dorsalis telencephali, pars centralis, the area ventralis telencephali, and the olfactory bulb. Controls for the specificity of immunocytochemical staining included the preadsorption of both antisera with their respective enzymes prior to incubation of tissue sections, in which cases the immunoreaction product is completely eliminated. PNMT-ir structures are not observed in the goldfish brain.

These data provide an anatomical basis for the functional role of catecholamines in the fish brain, for example, the localization of dopaminergic neurons which modulate the release of pituitary hormones. In addition, this study has provided evidence for fundamental similarities in the organization of hindbrain catecholamine systems in vertebrates, for example, TH- and DBH-ir neurons are localized in the medullary tegmentum and locus ceruleus in both fish and mammals. Finally, certain features of the catecholamine system may be unique to teleosts, for example, the presence of presumptive-dopamine neurons in the telencephalon.

Supported by NIH grant NS 18626 and NSF grant BNS-8310914

38.10 CHOLINERGIC STRUCTURES IN THE BRAIN OF A SONIC ("VOCALIZING") FISH LOCATED WITH A MONOCLONAL ANTIBODY TO CHOLINE ACETYLTRANSFERASE. R. K. Brantley and A. H. Bass. Section of Neurobiology and Behavior, Cornell University, Ithaca, NY 14853.

A well-characterized monoclonal antibody to choline acetyltransferase (ChAT) has allowed localization of putative cholinergic structures (ChAT-like immunoreactive, ChAT-IR) in the brain of a teleost fish, the midshipman, Porichthys notatus (Batrachoididea, toadfishes). ChAT-IR cells were found in: cranial motor and sensory nuclei, the reticular formation, mesencephalic tectum, and the telencephalon. Ten male midshipmen were used in the study. Brains were sectioned and free floating sections reacted with primary antibody (gift of Dr. Bruce Wainer, University of Chicago) and then visualized with the peroxidase anti-peroxidase method. Visualization of terminals and fibers was enhanced through osmium tetroxide treatment.

Cranial motor nuclei III, IV, V, VI, VII, IX, and X are robustly immunoreactive. The sonic motor nucleus, which is located at the junction of the spinal cord and medulla, and which innervates swimbladder "drumming" muscles, also labels intensely. ChAT-IR cells are sparsely distributed within three cranial sensory nuclei: nucleus solitarius, the trigeminal descending nucleus, and the trigeminal principal nucleus.

Superior, medial, and inferior divisions of the reticular formation contain subpopulations of ChAT-IR cells, which often send long processes ventrolaterally. The cerebellum also contains a few labelled cells in the granule cell layer.

Other ChAT-IR brainstem sites include nucleus isthmi, the periventricular layer of the tectum, and the octavolateralis efferent nuclei which project to peripheral lateral line, acoustic, and vestibular end organs.

In the telencephalon, ChAT-IR cells are found in the ventral nucleus of area ventralis (Vv), an area that has been compared to the medial septal nucleus of tetrapods (Northcutt and Braford, in: Comp. Neurol. of the Telencephalon, Ebbesson, ed., Plenum, 1983), a location of cholinergic neurons in mammals. ChAT-IR fibers and dense patches of punctate structures suggestive of terminals are found in restricted portions of the central (Dc), dorsal (Dd), and medial (Dm) zones of area dorsalis. Dd has been compared to the dorsal pallium, and portions of Dc and Dm to the striatum of tetrapods. Among mammals, these zones are also sites of cholinergic terminals. The source of cholinergic inputs to the pallium of Porichthys is not clear, although it does not appear to be the ChAT-IR cells found in Vv.

Supported by NIH Training Grant GM 07469 (RKB) and a DuPont Young Faculty Award, Hatch Grant NYC19140, NIH NS19942 (AHB).

38.11 LONG ASCENDING FIBERS IN THE WEAKLY ELECTRIC TELEOST GNATHONEMUS PETERSII. T. Szabo, S. Libouban°, Dept. Neurophysiol. Sensorielle, Lab. Physiol. Nerveuse, C.N.R.S., 91190 Gif sur Yvette, France.

The existence of long descending pathways has been demonstrated in teleost fishes with tracing techniques (Kimmel et al., JCN 205: 113, 1982, Hlavacek et al., J.Hirnforsch. 25:603, 1984); in contrast, similar information about long ascending fibers in this category of vertebrates is still lacking.

Experiments with the Fink-Heimer degeneration method and HRP axonal transport were conducted in order to identify long ascending fibers in the spinal cord of the mormyrid G.petersii. Sections of the spinal cord or injections of 30% HRP were performed at the 30-32nd segments (total number of 42). After a survival time of 2-3 weeks the animals were fixed either by immersion in 10% formaldehyde or by transcardial perfusion with a 2% glutaraldehyde and 2% formaldehyde mixture. In HRP injected animals the brain sections were treated according to Hanker et al. (1977).

Observations of degenerated as well as labeled fibers permitted detection of three ascending fiber systems in the spinal cord of G.petersii. The largest is the dorsal column which receives direct fibers from the periphery entering via dorsal roots at each segment into the spinal cord. The fibers course up to the medulla where they end in the posterior lateral funicular nuclei (Fl2). The latter do not correspond to a lemniscal system of higher vertebrates since they project to the cerebellum and not to the thalamus (Libouban and Szabo, Neurosci.Lett.6:115, 1977). A second ascending fascicle is revealed in the ventral marginal sector of the lateral column. It originates from large cells in the ventral horn and runs towards the medulla giving off numerous collaterals to the lateral reticular nucleus. Coursing further rostrally it passes anteriorly round the lateral lobe and enters into the caudal lobe where it terminates after crossing the midline. This pathway may correspond to the ventral spinocerebellar tract of higher vertebrates. A third long fiber fascicle is detected in the dorsal part of the lateral column next to the dorsal gray. The fine fibers which constitute this ascending bundle extend to the medulla where they likely terminate in the anterior region of the descending trigeminal nucleus. Their origin could not be identified.

The earliest phylogenetic appearance of long ascending fibers previously demonstrated has been in the amphibian dorsal column (Szabo, Arch.Sc.Physiol. 9:27, 1955). The results show that long ascending fibers occur in fish, although their existence may be a peculiarity of the family Mormyridae, as is the hypertrophied cerebellum.

38.12 CALCITONIN-GENE-RELATED-PEPTIDE-LIKE (CGRP) AND CHOLECYSTOKININ-LIKE (CCK) IMMUNOREACTIVITIES ASSOCIATED WITH BRAINSTEM VISCERAL AND GUSTATORY NUCLEI IN THE GOLDFISH. T. E. Finger and C.E. Adams, Dept. Cellular & Structural Biol., U. Colo. Hlth. Sci. Ctr., Denver, CO 80262.

In the brainstem of goldfish, the general visceral sensory and gustatory sensory functions are processed in separate primary sensory nuclei. The primary gustatory nuclei are themselves divisible into vagal, glossopharyngeal and facial lobes, each of which deals with gustatory afferentation from a single cranial nerve. Further, the visceral motor nuclei are clearly divisible into branchiomotor and general visceral subnuclei. In our continuing series of studies on these nuclei, the distribution of two neuropeptides, CCK and CGRP, was studied in relation to the known visceral and gustatory centers. CCK-like and CGRP-like immunoreactivities were studied by means of the peroxidase-anti-peroxidase technique as applied to frozen free-floating sections prepared from goldfish, Carassius auratus, which had been perfused with 4% paraformaldehyde in 0.1 M phosphate buffer.

Both CCK and CGRP immunoreactive (ir) fibers are present in layer ii in the superficial part of the vagal lobe. The CGRPir fibers enter the vagal lobe with the superficial roots of the vagus nerve to fan out across the surface of the vagal lobe, as has been described previously for substance P-ir fibers (Finger, 1984). The CCKir plexus is coincident with that of the CGRPir plexus, but CCKir fibers could not be seen entering with the vagal sensory fibers. CGRPir but not CCKir is present in low levels within somata of the motor neurons situated deep in the vagal lobe. In contrast, a plexus of CCKir fibers and terminals is present in the outer, neuropil layer (layer xiii) of the motor layer of the vagal lobe. The CCKir terminals in this layer arise from a CCKir fiber bundle which courses along the ventrolateral margin portion of the pontine and medullary tegmentum. This CCKir fiber bundle also gives rise to a terminal plexus in the vicinity of the proximal dendrites and somata of some vagal general visceral efferent neurons (= dorsal motor nuc. of vagus).

Populations of CGRPir somata exist within the tegmentum of the pons and caudal medulla. The strongly immunoreactive CGRPir neurons of the pons lie dorsal to the lateral lemniscus at approximately the level of the locus coeruleus. A less immunoreactive, but more numerous population of CGRPir neurons extends from the rostral pons into the caudal midbrain. These neurons are situated at the ventral margin of the secondary gustatory and secondary general visceral nuclei. A heavy plexus of CGRPir fibers occurs around the nuclei surrounding the lateral recess of the third ventricle within the inferior lobes.

38.13 LUNGFISH POSSESS A NERVUS PRAEOPTICUS (PINKUS' NERVE) AND A NERVUS TERMINALIS. D.L. Meyer* and C.S. von Bartheld* (SPON: D. Bonke). Dept. of Neuroanatomy, University of Göttingen, Federal Republic of Germany.

Pinkus (1894, 1895) described a new cranial nerve in the lungfish. This nerve was later named the "Nervus praeopticus" (Sewertzoff 1902). However, Locy (1905) identified Pinkus' nerve as the homologue of the Nervus terminalis, a cranial nerve that had been described in several other vertebrates. This interpretation has to the present time been accepted. Our study provides evidence that Pinkus actually described a cranial nerve other than the terminal nerve.

Our data are obtained from the African lungfish (Protopterus dolloi) which received injections of horseradish peroxidase (HRP) into the olfactory epithelium. Brain sections were cut in a cryostat and processed for HRP activity. In addition to the primary olfactory projection, a fasciculated fiber tract, consisting of four bundles, was labeled in the brain. This pathway courses with the olfactory nerve and bypasses the glomerular layer of the olfactory bulb on its caudal course through the dorsomedial telencephalon (archipallium). One fascicle branches off ventrally, passes through the archipallium, and reaches the neuropil adjacent to the septum. The dorsal fascicles partly terminate in the archipallium, and partly turn ventrally towards the septal areas just rostral to the anterior commissure. No other structures in the brain were labeled. Therefore, we discard the possibility of false positive results by transneuronal (secondary olfactory) transport of the tracer.

We identify this fiber tract as the central projection of the terminal nerve. The terminal nerve of Protopterus is clearly distinct from the Nervus praeopticus (Pinkus' nerve) which follows an extracerebral course below the telencephalon and enters the brain in the preoptic area. Therefore, Protopterus possesses two distinct rostral cranial nerves: the terminal nerve, associated with the olfactory nerve and tract, as in other vertebrates, and a Nervus praeopticus, which has obviously been misinterpreted as being the terminal nerve of lungfish for almost a century. The Nervus praeopticus has so far only been described in the lungfish (Dipnoi). Hence, Pinkus did not describe what nowadays is considered the terminal nerve, but rather he discovered a structure which has not yet received appropriate scientific interest.

38.14 COMPARATIVE STUDIES OF LHRH AND CRF NEURONAL SYSTEMS IN TWO SPECIES OF TELEOST. T.O. Bruhn, E.L.P. Anthony, and I.M.D. Jackson. Division of Endocrinology, Brown University/Rhode Island Hospital and Department of Biology, Rhode Island College, Providence, RI 02902.

Previously we reported the isolation and characterization of a LHRH-like peptide in codfish (Gadus morhua) brain. Our studies revealed that the peptide was identical to salmon LHRH (sLHRH). We also partially characterized a CRF-like peptide in codfish brain and showed that this material was different from known mammalian CRFs and urotensin I, a CRF-like peptide previously isolated from the urophysis of sucker fish. In the present study we report the immunohistochemical localization of LHRH and CRF in the hypothalamus of two species of teleost, codfish and alewife (Alosa pseudoharengus), respectively. Fish were obtained from the New England Aquarium (Boston, MA); brains and pituitaries were rapidly removed and immersed in either acrolein (5% for 2 hr) or paraformaldehyde/glutaraldehyde (4%/1% for 6-12 hr). Fifty to 100 um sections were cut and processed for immunohistochemistry using standard methods. Antisera #292 (anti sLHRH) and #C-24 (anti-oCRF; gift of Dr. W. Vale) were used at a final dilution of 1:500 in conjunction with the PAP-DAB technique or at 1:2,000 with the ABC-DAB technique. Both antisera were previously characterized by RIA and immunohistochemistry. Specificity was demonstrated by complete absorption of immunostaining by 1 ug peptide/ml undiluted antiserum.

Our studies revealed a striking species variation in the innervation of the pituitary gland. LHRH-immunoreactive (LHRH-i) and CRF-i fibers appear to project directly to the pars distalis of codfish, whereas few immmunoreactive fibers were seen in the neurointermediate lobe. In the alewife, on the other hand, the majority of LHRH-i and CRF-i fibers were found in the neurointermediate lobe; few scattered fibers could be demonstrated in the pars distalis. This different pattern of projection is interesting since perikarya for each peptide were found in similar locations in both fish, the nucleus praeopticus (LHRH) and nucleus lateralis tuberis (CRF), respectively.

Since the hypophysial portal system is absent in most fish, hypophysiotrophic neurons may directly innervate the target organ or reach the pars distalis via the neurointermediate lobe. This anatomical variation suggests a difference between these teleost species in the regulation of pituitary function by LHRH and CRF.

38.15 CENTRAL PROJECTIONS OF THE PRIMARY OCTAVOLATERALIS AFFERENTS IN THE TOADFISH. R. D. Kitch*, S. M. Hightein, and R. Baker (SPON: C. Scudder). Dept. Otolaryngology, Washington Univ., St. Louis, MO. 63110 and Dept. Physiol. and Biophys., New York Univ., N.Y. 10016.

Eighth nerve branches of anesthetized adult toadfish were labeled with HRP and alternate frozen brainstem sections reacted with TMB/DAB. The octavolateralis area was divided into seven nuclei after McCormick (J. Morphol. 171:159 ,'82). The three lateral line nerves terminated in the most dorsally located cell column, in n. medialis and n. caudalis. These nuclei form a long, continuous cell column bounded laterally by the ascending and descending LL tracts. The three LL nerves terminate throughout the length of the entire cell column; the territory of the PLL nerve is predominantly dorsal, that of the fifth nerve division of the ALL nerve is ventral, while that of the seventh nerve division of the ALL nerve occupies an intermediate territory. Each of the LL nerves projects as well to the dorsal region of n. magnocellularis (see below).

Ventral to the LL column, throughout its length, five contiguous nuclei can be distinguished. From rostral to caudal these are the anterior octavus n. (AO), n. magnocellularis (Mg), n. tangentialis (T), descending octavus n. (DO), and posterior octavus n. (PO). The central projections of the three SCCs are overlapping and will be described together. They cover the entire territory of AO, T and PO, and the lateral and ventral aspects of both Mg and DO. The saccular and lagenar projections to the AO and PO overly those of the SCC; however, they do not project to T, and, in contrast to the SCC, project dorsally to DO and Mg. The utricular nerve projections cover the entire territory of AO, T, and PO, go to the medial and ventral regions of Mg, and are seen diffusely throughout DO, overlying both saccular and SCC projections.

All nine of the octavolateralis nerves send primary afferent fibers to the eminentiae granulares (EG). Canal input was substantial and diffuse to both the lateral and medial portions of the rostral EG. LL input was mainly to a more caudal portion of the lateral EG but there was a consistent tract that projected to the rostromedial EG and may represent some overlap of octavus and lateralis innervation. Of the seven nuclei discussed above, only Mg receives dual innervation from lateralis and octavus afferents. (Supported by NIH NINCDS-52946 and NS 21055).

38.16 PROJECTIONS OF THE PINEAL COMPLEX IN THE SILVER LAMPREY. R. L. Puzdrowski and R. Glenn Northcutt. Div. Biol. Sci., Univ. of Michigan, Ann Arbor, MI 48109 and SIO Neurobiol. Unit and Dept. Neurosci.'s, UCSD, La Jolla, CA 92093.

Recently, experimental anatomical techniques have been applied in the investigation of the pineal connections in a variety of vertebrates. As a continuation of these investigations the central connections of the pineal complex of the silver lamprey, Icthyomyzon unicuspis, were determined utilizing HRP techniques.

Both juvenile and adult silver lampreys were used in this study. The central projections of the pineal complex were determined by innoculation of the pineal complex with HRP paste on the tip of a sharpened insect pin. Following survival times of 5-7 days, at 10-18°C, the animals were reanesthetized with MS222 and transcardially perfused with phosphate buffer (pH 7.4) followed by a 2% glutaraldehyde solution. The brains were transversely sectioned at 35µm and alternate sections processed according to a Hanker-Yates ('77) protocol or the Adams ('81) heavy metal intensification protocol.

The pineal tract courses caudally through the tela choroidea along the left side of the habenular commissure. A few fibers penetrate the brain through the caudal most portion of the habenular commissure; however, the majority of fibers continue caudally and enter the brain at the level of the posterior commissure. The pineal tract projects bilaterally to the subcommissural organ, nucleus of the posterior commissure, posterior tubercular nucleus, subhabenular nucleus, dorsal and ventral thalamus and hypothalamus, the optic tectum and the tegmentum. A few fibers were observed decussating in the ventral tegmental commissure. The course of these decussated fibers could not be followed. No retrogradely labeled cells were found in the present study.

With the exception of projections to the optic tectum, the pineal projections of lampreys are similar overall to those reported in teleosts (Ekstrom and van Veen, '83) and amphibians (Eldred et al., '80). It appears that these connections represent the primitive condition for vertebrates and that there has been a reduction in pineofugal connections in the amniotic vertebrates.

38.17 RETROCEREBRAL PROJECTIONS FROM THE BRAIN AND SUBESOPHAGEAL GANGLION OF THE CRICKET. D. Moore and W. Loher*. Department of Entomological Sciences, University of California, Berkeley, CA 94720

Occupying a critical position in the control of physiological and behavioral events in insects, the retrocerebral complex consists of the paired corpora cardiaca (CC) and corpora allata (CA) as well as nerves connecting these structures to the brain, to each other, and, in some orders, to the subesophageal ganglion (SEG). The CC is a neurohemal organ for the release of neurosecretory material produced by neurons in the brain and also contains intrinsic hormone-producing cells. The CA is an endocrine gland for the production of juvenile hormone, which has significant effects on metamorphosis, egg production, and sexual behavior. Despite the importance of the brain and, possibly, the SEG as regulators of numerous neuroendocrine and endocrine functions, in no insect have the axonal pathways between these ganglia and the retrocerebral complex been completely characterized.

The origins and axonal trajectories of neurons projecting to the retrocerebral complex of the cricket, Teleogryllus commodus, were examined in silver-intensified nickel backfills. Spatially separate groups of somata in the pars intercerebralis (PI) and in the pars lateralis (PL) of the brain, commonly accepted as neurosecretory loci, were found to give rise to axons terminating in the nervus corporis allati 2 (NCA 2), the CA, or the CC. Additional findings demonstrated a distinct group of somata from the PI whose axons run in the esophageal nerve (stomatogastric nervous system), nine somata in the SEG with axons that project through the NCA 2 as far as the CA but do not invade the CC, and also a small cluster of tritocerebral perikarya with axons terminating in the CC. Most significantly, somata residing in the PI and PL were found to be compartmentally organized, based upon the retrocerebral destinations of their axons.

Fibers from the brain neurosecretory centers have apparent terminals in several different retrocerebral locations: the CC, CA, NCA 2 (nerve connecting the CA with the SEG), and the NCA 1 (nerve between the CA and CC). Thus, all of these structures may be considered putative neurohemal release sites. The NCA 2 in crickets has previously been proposed as a neurohemal organ, based on the presence of "synaptoids" as viewed in EM sections of the nerve (Weber, W. & Gaude, H., Z. Zellforsch. 121:561, 1971). We show that these terminals originate from somata in both the PI and PL of the brain. Classically considered as distinct protocerebral loci, the PI and PL in T. commodus exhibit an unexpected proximity; at their closest points, they are separated by no more than 40 micrometers.

PEPTIDES: OPIATE RECEPTORS

39.1 **ANTI-MET-ENKEPHALIN ANTI-IDIOTYPIC ANTIBODIES: OPIATE RECEPTOR BINDING STUDIES.** Bingci Liu* and Y.Y. Thomas Su (SPON: L. Denner). Center for Biotechnology, Baylor College of Medicine, 4000 Research Forest Drive, The Woodlands, Texas 77381

Anti-idiotypic (anti-ID) antibodies specific for a variety of hormone andneurotransmitter receptors have been produced following immunization against specific anti-ligand antibodies. These anti-ID antibodies are able to interact with the ligand binding sites on the membrane. In this communication, we report the generation and characterization of anti-Met-enkephalin (anti-ME) anti-ID antibodies.

Partially purified monoclonal anti-ME antibody was used as an immunogen to produce anti-ID antibodies from rabbits. Rabbits were immunized with 0.1 mg of immunogen in Freund's adjuvant biweekly. The first bleeding for testing of antiserum was made one week after the third injection. The effect of antiserum on ^{3}H-ME and anti-ME interaction was employed for testing the production of anti-ID antibodies. In these experiments rabbit anti-ME was used to test against the anti-ID antibodies.

Anti-ID antibodies that inhibited ^{3}H-ME and anti-ME interaction were further testing for their ability in the inhibition of ligand-receptor binding. In these experiments different amounts of anti-ID or preimmune serum (as the control) were incubated with 400 µg of membrane protein overnight 4°C in the presence (nonspecific binding) or absence (total binding) of 250 nM naloxone. Samples without any serum or membrane protein were also prepared. ^{3}H-DADL was then added to the reaction mixtures (final concentration 2 nM in 400 µl of solution) and incubated for one hour at 4°C. ^{3}H-DADL bound to opiate receptors was measured in a scintillation counter. The results from these studies demonstrated that anti-ID serum exhibit a concentration dependent inhibition of ^{3}H-DADL binding to the opiate receptors.

In other experiments the effect of anti-ID antibodies on saturation binding of ^{3}H-DADL to the opiate receptor was also studied. In the presence of anti-ID serum ^{3}H-DADL saturation binding to the opiate receptor was decreased. Scatchard analysis of the bindings yielded a set of parallel straight lines (for the control and the sample) with a K_D of 0.62 and 4.80 nM. It appeared that anti-ID antiserum produced a noncompetitive inhibition of DADL binding. All these studies indicated that anti-ID antibodies specific for the opiate receptor have been produced.

Supported by NIH grant EY03701.

39.2 AUTORADIOGRAPHIC LOCALIZATION OF 3H-alpha-MSH and of 3H-DESACETYL-alpha-MSH BINDING SITES IN RAT BRAIN. W. Lichtensteiger, M. Schlumpf and A. Eberle*. Inst. of Pharmacology, Univ. of Zürich, CH-8006 Zürich, and Zentrum für Lehre u. Forschung, CH-4031 Basel, Switzerland.

Systemic administration of alpha-MSH influences brain function, but it is still uncertain whether these effects reflect actions of the peptide released from pituitary intermediate lobe cells into the circulation, or of peptide released from alpha-MSH containing central nerve terminals. However, manipulation of endogenous alpha-MSH levels by systemic antiserum injection affects the functional state of adult central transmitter systems (Monnet and Lichtensteiger, 1981), while early postnatal antiserum injection causes a permanent alteration of the responsiveness of hypothalamic dopamine neurons to this peptide (Lichtensteiger and Schlumpf, 1986).

In an attempt to further elucidate the interaction of alpha-MSH with the central nervous system in adulthood and ontogeny, we are investigating central binding sites for alpha-MSH. The brain of adult male Long Evans rats was cut on a cryostat and processed for qualitative and quantitative in vitro-receptor autoradiography, using alpha-MSH and desacetyl-alpha-MSH tritiated according to Eberle and Zeller (1985; specific activity 115 Ci/mmol). Specific saturable binding was observed by computer assisted image analysis in several areas of the rat forebrain, i.a., in hippocampus, cortex and mediobasal hypothalamus, and in hindbrain regions. The hippocampal location is interesting in view of earlier EEG data; this area receives a projection of the non-POMC alpha-MSH-like neuron system (Khachaturian, Lewis, Kang Tsou and Watson, 1985). Binding of 3H-desacetyl-alpha-MSH is studied because the desacetylated form of the peptide appears to predominate in brain. Its general distribution resembled that of 3H-alpha-MSH. A detailed characterization of binding sites is under way.

39.3 LOCALIZATION OF MU OPIOID RECEPTORS WITHIN THE A10 REGION OF THE RAT. R.P. Dilts, P.W. Kalivas, Dept. of VCAPP, Washington State Univ., Pullman, WA.

Recent evidence indicates that stimulation of the mu opioid receptor increases output from the A10 dopaminergic cell group, including the ventral tegmental area (VTA) (Latimer et al., J. Pharmacol. Exp. Ther., 1987). To study whether this effect was caused by mu opioid receptors situated upon dopaminergic neurons or whether the enhanced activity was mediated by other neurons present within the A10 region, we utilized quantitative receptor autoradiography. The highly selective mu opioid ligand, ^{125}I-Tyr-D-Ala-Gly-N-MePhe-Gly(ol) (DAGO) was employed to assess the anatomical location of the mu opioid receptors within the mesencephalic tegmentum. Additionally, the neurotoxins 6-hydroxydopamine (6-OHDA) (10 µg free base in 1.5 µl, 0.2% ascorbate) and quinolinic acid (QUIN) (300 nmoles) were utilized to remove, unilaterally, dopaminergic and intrinsic perikarya, respectively.

Quantitative analysis of the autoradiographic pattern of DAGO binding sites within the A10 dopamine cell region showed a moderate density of mu receptors in the nucleus parabrachialis pigmentosa, the nucleus paranigralis and the interfascicular nucleus. Furthermore, particularly intense binding was apparent in the area circumscribing the fasciculus retroflexus.

Unilateral loss of dopaminergic perikarya induced by 6-OHDA treatment failed to significantly alter DAGO binding within the A10 region while invoking a unilateral loss of high affinity neurotensin receptors, assayed with the selective ligand ^{125}I-Tyr^3-Neurotensin (Palacios and Kuhar, Nature 294: 587, 1981). However, unilateral administration of QUIN, directed towards the VTA, produced a maximum 70% loss of DAGO binding on the injected side with a concomitant reduction in NT-3 binding.

These results suggest that the enhanced activity of the A10 dopaminergic cell group produced by intra-VTA administration of mu receptor agonist is mediated, at least in part, by a group of non-dopaminergic neurons intrinsic within the A10 region of the rat.

39.4 MU OPIOID ([^{3}H] DAGO) BINDING IN THICK SLICES OF RAT BRAIN: CHARACTERIZATION AND INHIBITION BY SODIUM IONS, GUANYL-5'-YL-IMIDODIPHOSPHATE, DSP4 AND XYLAMINE. M. Wilkinson, D.A. Wilkinson* and W. Jacobson*. Dept. of Physiology and Biophysics, Dalhousie University Medical School, Halifax, N.S., CANADA B3H 4H7.

We and others have suggested that the examination of receptors in a more physiological environment - such as in ionic buffers and/or in intact cells - may be of some benefit to a more complete understanding of receptor-mediated processes (Life Sci. 39:2037, 1986). For opioid receptors the opportunity to examine agonist binding with some degree of subtype specificity would be valuable.

We have now characterized and quantified the binding of the µ-opioid agonist [^{3}H] DAGO to 300 µm slices of hypothalamus and cerebral cortex. The receptors have many of the opioid characteristics previously demonstrated in homogenate assays. Binding is reversible, saturable, stereospecific and of high affinity (nM). The δ-opioids DTLET and DSLET are 36- and 30-fold respectively, less effective than DAGO in competing for the binding site. Assays can be routinely performed in the presence of physiological concentrations of sodium, though in TRIS buffer the affinity and the number of receptors is increased. Protection of the ligand against proteolytic degradation (bestatin and bacitracin) is unnecessary. Since binding is rapidly reversible and is unaffected by ouabain, cellular uptake of label seems unlikely. Unexpectedly, we observed that GppNHp inhibits [^{3}H] DAGO binding to brain slices. This effect is normally seen only in broken cell preparations. Thus, the drug is either readily able to penetrate cell membranes or it can induce an allosteric modification of the µ-receptor itself.

We have previously demonstrated that the noradrenergic neurotoxins DSP4 and xylamine bind to [^{3}H] naloxone receptors. We now show that the µ-receptors are also blocked by DSP4 and xylamine. This re-emphasizes our contention that care should be exercised in the use of these drugs.

The assay technique is simple, rapid and involves minimal disruption of tissue. It should provide new opportunities for the study of cell surface opioid receptor subtypes in intact tissue.

Supported by the Canadian MRC.

39.5 INTERACTIONS OF DIMERIC DERMORPHIN ANALOGS WITH δ AND µ OPIATE RECEPTORS ON RAT BRAIN SYNAPTOSOMES. L.H. Lazarus, A. Guglietta, W. E. Wilson*, P. Melchiorri*, and R. De Castiglione*. LBNT, NIEHS, Research Triangle Park, NC 27709, Institute of Medical Pharmacology III, University of Rome, 00185 Rome, Italy, and Farmitalia Carlo Erba SpA, 20146 Milan, Italy.

The amphibian skin peptide dermorphin (DM) (Tyr-D-Ala-Phe-Gly-Tyr-Pro-Ser-NH_2) is the only known opiate peptide with a naturally occuring D-amino acid. Studies in vivo (analgesia, catalepsy) and in vitro (muscle relaxation and receptor binding) indicate that DM acts primarily as a µ-opiate receptor agonist. Recent results on dimeric DM analogs (peptides which contain 2 identical peptide chains coupled through the C-terminal amide nitrogen atoms directly, or with the use of intervening methylene groups) indicated that these compounds retain selectivity for µ receptors in vivo and with isolated tissue preparations; however, several dimeric enkephalin analogs (with a D-amino acid in position 2) selectively binds to δ opiate receptors. In order to delineate opiate receptor selectivities of the dimeric DM analogs, rat brain synaptosomal receptor affinities were determined with the aid of the specific ligands [^{3}H]-DADLE (δ agonist) and [^{3}H]-DAGO (µ agonist). Dimeric-penta-DM_2 (I)(subscript represents the number of CH_2 units bridging the peptides) and dimeric-tetra-DM_2 (II) were slightly more δ receptor specific than dimeric-penta-DM_0(III), [Sar^4]-dimeric-penta-DM_0 (IV) and [D-Arg^2,Sar^4]-dimeric-penta-DM_0(V), which show weak µ-type selectivity.

Opiate Receptor Affinities of Dimeric Dermorphin Analogs

Peptide	Receptor Type δ IC_{50} (pmoles)	Receptor Type µ IC_{50} (pmoles)	Selectivity Ratio δ/µ
DM	2.7	11.1	0.24
I	34.0	18.8	1.81
II	61.0	54.5	1.21
III	5.7	6.8	0.84
IV	1.5	1.8	0.87
V	28.0	32.0	0.88

The affinities of peptide IV for either type of receptor exceeded that of DM, while those of compounds I, II and V were less than DM; analog II exhibited the weakest interaction with the receptors. These results corroborate positively with the consequences of icv administration of the same peptides on inhibition of gastric secretion (Guglietta et al., Neuroscience Abs., 1987): those studies indicated that µ-opiate receptors appear to regulate gastric acid secretion in rats.

39.6 PURIFICATION AND CLONING OF A 23kD MORPHINAN-BINDING PROTEIN FROM RAT BRAIN. E. Hanneman, D. K. Grandy*, J. Salon*, C. Machida*, J. Bunzow*, M. Shih*, J. Bidlack^, E. Herbert* and O. Civelli*. Vollum Institute for Advanced Biomedical Research, Oregon Health Sciences University, Portland, OR 97201 and Center for Brain Research, University of Rochester Medical Center, Rochester, NY 14642^.

In an attempt to clone the mu opioid receptor, membrane proteins isolated from rat brain minus cerebellum were stereospecifically eluted from a morphinan (^{14} ß-bromoacetamidomorphine) (ß-AM) affinity column using different agonists. Five major and several minor proteins were isolated as judged by silver-stained SDS polyacrylamide gels. The protein population eluted from the ß-AM affinity column retains stereospecific opiate-binding activity in soluble binding assays. To further purify individual proteins, the ß-AM column eluate was injected onto a C4 reverse-phase HPLC column and eluted in an acetonitrile gradient. The major purified protein (23,000 MW) was digested with trypsin and the sequences of the five largest proteolytic fragments were determined. A search for homology among several protein and nucleic acid data bases suggests that this is a novel protein.

For three of the peptide sequences oligonucleotide probes were synthesized, labeled with ^{32}P, and independantly used to screen a rat brain lambda GT10 cDNA library. Several phage clones which hybridized with all three probes were purified and the insert sizes determined. The longest clone so far characterized is 1.2 kb in length (p23K1). The DNA sequence of the insert confirms the sequences of the peptides obtained by tryptic digestion. The p23K1 insert was nick-translated with ^{32}P-dCTP and used to probe a Northern blot of rat tissue and NG108-15 poly A$^+$ mRNA and a Southern blot of rat genomic DNA. The Northern blot autoradiograph revealed a single mRNA species of 1.2 kb that is found in brain minus cerebellum, cerebellum, liver, and NG108-15 cells. The Southern blot autoradiograph showed several bands resulting from EcoRI, HindIII, and BamHI restriction digestions. These findings suggest that the 23kd protein is not a proteolytic fragment of a larger protein and that it may belong to a multi-gene family.

While the concentration, localization and size of the 23kd protein probably preclude it from being the ligand binding subunit of the mu opioid receptor, it might be involved in modulating the receptor specificity or secondary events following ligand-receptor interaction. To further our understanding of the function of this protein, a polyclonal antibody is being used to analyze its distribution in rat tissues. Supported by NIADDK-NIH DK37231.

39.7 IMINODIPROPIONITRILE CAUSES DOWNREGULATION OF OPIATE MU RECEPTORS IN RAT BRAIN: A QUANTITATIVE AUTORADIOGRAPHIC STUDY. V. Jackson-Lewis, J.L. Cadet, B. Kuyatt, S. Fahn, and E. de Souza. Department of Neurology, Columbia University, New York, NY 10032 and NIDA, Baltimore, MD 21224.

Chronic administration of IDPN leads to the development of a persistent syndrome characterized by random circling and lateral and vertical head shakes which are similar to those induced by some receptor agonists such as the enkephalins. These abnormalities also bear some similarities to human disorders of movement such as spasmodic torticollis or Huntington's chorea. In mice, the IDPN-induced abnormalities can be blocked by the opiate antagonist naltrexone. In vitro homogenate binding studies have revealed a significant downregulation of total and delta opiate receptors in the striata of IDPN-treated animals (Cadet and Rothman, Neurosci. Lett. 72: 84, 1986). In the present study, we have used in vitro autoradiography using ^{3}H-dihydromorphine (DHM) in order to evaluate the effects of IDPN on the opiate mu receptor in some areas of rat brain that might be related to the motor phenomena.

Male rats were treated with IDPN (100mg/kg, ip) or saline until the development of the dyskinetic abnormalites. After an interval of one month, the animals were killed by decapitation and their brains were rapidly removed and frozen at -70°C. In vitro ^{3}H-dihydromorphine (DHM) binding was assessed in 8 um coronal sections. Briefly, slides were preincubated with 50uM GTP and 100mM NaCL in 50mM Tris HCl, pH 7.6, at room temperature. After a 5 minute wash in .17M Tris HCl (pH 7.6), incubation was carried out in the presence of 1.8nM ^{3}H-DHM at room temperature. After two 5 minute washes in buffer at 4°C, the slides were dipped in deionized water and dried. Labelled slides were apposed to LKB Ultrofilm for six weeks. Binding was measured by computer assisted densitometry.

This study revealed that, as previously described, the binding of DHM occurs in patches in the striatum and in laminae 4-6 of the neocortex. Chronic IDPN treatment results in significant decreases in DHM binding in all of these areas. The results of the effects of IDPN on delta and kappa receptors will also be presented.

The results add more evidence for the possible involvement of the opioid systems in the manifestation of the IDPN-induced abnormalities. They also raise the possibility of a role for these systems in human movement disorders.

39.8 EVIDENCE FOR KAPPA OPIOID RECEPTOR SUBTYPES IN GUINEA PIG CORTEX. M.D.Hall*, J.A.M.Smith*, J.C.Hunter*, R.G.Hill and J.Hughes* (SPON:European Neuroscience Association). Parke-Davis Research Unit, Addenbrookes Hospital Site, Cambridge, CB2 2QB, UK.

Kappa opioid agonists produce a characteristic profile of behaviour in animals, mediating analgesia, sedation and diuresis (Martin et al., J.Pharmac.Exp.Ther., 197, 517-532, 1976). In contrast to mu analgesics, kappa ligands have minimal addiction liability and respiratory depressant properties. Kappa receptors have been defined by both in vivo behavioural criteria and in vitro biochemical and pharmacological studies. To date there is limited evidence for the existence of kappa receptor subtypes (Su et al., J.Pharmacol.Exp.Ther., 232, 144-148, 1985). In this study, using a radioligand with high kappa selectivity, [^{3}H]U69593, we provide strong support for the proposal of kappa opioid receptor heterogeneity.

The binding of three radiolabelled probes, [^{3}H]etorphine, [^{3}H]bremazocine and [^{3}H]U69593, was investigated in guinea pig cortical membranes in the presence of unlabelled $_5$ (D-ala^2,N-methyl-phe-gly-ol)enkephalin (DAGO) and (D-ala^2,D-leu^5)enkephalin (DADLE) to saturate mu and delta sites respectively. Binding studies with [^{3}H]etorphine and [^{3}H]bremazocine were performed in the presence of a 160-fold excess of DAGO and DADLE, and parallel studies with [^{3}H]U69593 used a 20-fold excess. Results from saturation analyses are presented below.

	Bmax (fmol/mg prot)	Kd [nM]	n
[^{3}H]Etorphine	127 ± 2	0.69 ± 0.04	4
[^{3}H]Bremazocine	130 ± 2	0.22 ± 0.01	4
[^{3}H]U69593	64 ± 6*	3.9 ± 0.4	4

* $P < 0.01$ (Mann Whitney U-Test)

Scatchard transformation of the specific binding data indicated the presence of a heterogeneous population of kappa sites in the guinea pig cortex. [^{3}H]U69593 recognised only ~50% of kappa sites labelled by both [^{3}H]etorphine and [^{3}H]bremazocine. Similar results have been obtained with our own kappa selective ligand [^{3}H]PD117302 (Hill et al., Brit.J.Pharmacol., 1987, in press). From these results we propose that [^{3}H]U69593 and [^{3}H]PD117302 label kappa-A sites in guinea pig cortex, whereas [^{3}H]etorphine and [^{3}H]bremazocine label, in addition to kappa-A sites, a U69593-insensitive site, kappa-B. These findings were confirmed in competition experiments performed in parallel against [^{3}H]U69593 and [^{3}H]etorphine. Etorphine, naloxone and dynorphin A(1-8) were approximately equipotent at both kappa-A and kappa-B sites, confirming the opioid nature of kappa-B sites. In contrast, U69593 and PD117302 preferentially displaced from kappa-A sites, with only weak activity at kappa-B sites.

39.9 EVIDENCE FOR MULTIPLE KAPPA OPIATE BINDING SITES IN RAT MIDBRAIN. T. Devlin* and W.J. Shoemaker. Neuroscience Program, Univ. of Connecticut Health Center, Farmington, Ct. 06032.

In the course of studies to determine possible alterations in opiate receptors following prenatal ethanol exposure, it became evident that the determination of kappa-type opiate receptors using ethylketocyclazocine (EKC) was inadequate (SN Abst. 12:613,1986). The heterogeneity of kappa-type opiate binding sites in rat midbrain was, therefore, investigated. Displacement binding assays were carried out using the opiate agonists ^{3}H-EKC and ^{3}H-bremazocine in the presence of various blocking ligands known to block mu and delta receptors. 24 point Scatchard plots were generated from displacement data, and kinetic analysis was carried out using the LIGAND computer program. ^{3}H-bremazocine binding, in the absence of any blocking agents and the presence of .4M NaCl, best fit an apparent single site model with a K_d of .44 nM and a B_{max} of 132 fmoles/mg protein. Incubation with 1 uM morphiceptin, a mu-type receptor ligand, blocked 28% of total ^{3}H-bremazocine binding, while incubation with .1 uM DSLET, a moderately selective delta ligand, blocked 36% of total ^{3}H-bremazocine binding. The K_d values calculated under these two blocking conditions were .12 nM and .15 nM respectively. Incubation with morphiceptin and DSLET together blocked 45% of total ^{3}H-bremazocine binding, with a single site model best fitting the data. Residual ^{3}H-bremazocine binding in the presence of morphiceptin and DSLET (55% of total ^{3}H-bremazocine binding), defined as "kappa" binding, was further investigated. It was found that kappa binding sites resolved into both a DADLE-sensitive and a DADLE-insensitive population. When 5 uM DADLE was used as a blocking ligand in assays, an additional 19% of the total ^{3}H-bremazocine binding was blocked, above and beyond the 45% blocked in the presence of morphiceptin and DSLET. Similar results were obtained using ^{3}H-EKC where, under mu and delta receptor blocked conditions, residual ^{3}H-EKC binding resolved into both a DADLE sensitive and a DADLE insensitive site. The effect of Na^+ on binding of ^{3}H-bremazocine binding in the presence and absence of mu and delta blocking ligands was also investigated. When ^{3}H-bremazocine binding was carried out in the absence of NaCl, the capacity of binding decreased by an average of 50% and the change in the K_d indicated a shift to a slightly lower affinity state. This effect confirms earlier reports of enhanced agonist binding to kappa sites in the presence of Na^+, and will be useful in formulating new protocols to resolve opiate receptor subpopulations. In summary, mu and delta sites comprise 45% of the total binding sites in rat midbrain, and, kappa sites can be further divided into at least two distinct populations. (Supported by NIAAA# 06927)

39.10 COMPARATIVE DISTRIBUTION OF KAPPA OPIOID RECEPTOR IN HUMAN FOREBRAIN USING [^{3}H]U69,593 AND [^{3}H]BREMAZOCINE. C. Pilapil, J. Magnan* and R. Quirion. Douglas Hospital Res. Centre and Dept. of Psychiatry, Faculty of Medicine, McGill Univ., 6875 LaSalle Blvd., Verdun, Québec, Canada H4H 1R3 and Departement de Pharmacologie, Faculté de Médecine, Université de Montréal, Montréal, Québec, Canada.

While various highly selective mu and delta radiolabelled probes are available for autoradiographic studies, a selective kappa radioligand was not available. Previous studies had to be performed using non-selective probes such as [^{3}H]ethylketocyclazocine or [^{3}H]bremazocine in presence or saturating concentrations of mu and delta opiates to block possible binding, of these ligands to mu and delta opioid receptor sites. Recently, the characterization of a new possibly highly selective kappa ligand, [^{3}H]U69,593 has been reported. In the present study, we describe the autoradiographic distribution of putative kappa opioid receptor binding sites in human brain using the highly selective kappa agonist [^{3}H]U69,593 and the previously used radioligand [^{3}H]bremazocine. Control human brains (n=4, 52-71 years old) were obtained at autopsy (post mortem delay = 12.4 hours). For in vitro receptor autoradiography, forebrain sections were incubated for 60 min at 25°C in 50 mM Tris.HCl buffer, pH 7.4 containing either 1.0 nM [^{3}H]U69,593 (42 Ci/mmol; New England Nuclear, Boston, MA) or 1.0 nM [^{3}H]bremazocine (27.8 Ci/mmol, NEN). 100 nM DAGO (Peninsula Labs, Belmont, CA) and 100 nM DSLET (peninsula Labs) were added to [^{3}H]bremazocine incubation buffer to prevent binding of this ligand to putative mu and delta sites. Sections were then rinsed for 12 min in cold incubation buffer, dipped in cold distilled water to remove ions, dried and juxtaposed against tritium-sensitive film. Specific binding was determined as the difference in radioactivity bound in the presence and absence of 5.0 µM (-) cyclazocine. Our results show that the autoradiographic distributions of [^{3}H]U69,593 and [^{3}H]bremazocine (plus blockers) binding sites are identical strongly suggesting that the two radioligands bind to the same population of sites in human brain. In the forebrain, high densities of sites are present in the deep layers of the cortex, claustrum, nucleus basalis of Meynert and amygdaloid body. Much lower densities are observed in the caudate, putamen, globus pallidus and nucleus accumbens. Interestingly, the distribution of these sites is apparently heterogeneous in the caudate. Mu and delta opioid binding sites are differentially distributed in human brain (Pilapil et al, in press). Thus, [^{3}H]U69,593 appears to be a highly specific ligand for the characterization of kappa opioid receptors.

40.1 INTERACTION OF EFFERENT ACTIVITY AND HUMORAL FACTORS IN CONTROLLING THE STRUCTURE OF THE RETINA OF *LIMULUS POLYPHEMUS*.

B.G. Calman*, S.C. Chamberlain, H.K. Lehman, and R.B. Barlow Jr.. Institute for Sensory Research, Syracuse University, Syracuse, N.Y. 13244-5290.

The structure of the retina of the lateral eye of *Limulus polyphemus* is controlled by the diurnal light cycle and by a circadian rhythm of efferent impulses from the brain. The rhabdom and aperture are long and narrow in the daytime light-adapted state, and short and wider in the nighttime dark-adapted state. When an eye is removed from a light-adapted animal in mid-afternoon and placed in darkness in organ culture at 15°C, the rhabdom and aperture progressively shorten and after approx. 20 hrs. approach the nighttime state. An acetone extract of Limulus blood added to the organ culture medium stops the drift in structure toward the nighttime state. The aperture length is particularly sensitive to shortening in organ culture and to the effect of the blood extract. The aperture length in organ culture after 24 hrs. darkness is 5-10 *u*m., near the normal value for dark-adapted animals at midnight. With the addition of the blood extract, the aperture length is maintained at 40-45 *u*m., in the range of daytime light-adapted values.

The addition of the acetone blood extract to organ culture also enhances *in vitro* membrane shedding from the rhabdom of the lateral eye retina at light onset. If lateral eye slices are maintained in organ culture in darkness for 24 hrs., and then exposed to light for 15 min. before fixation, little membrane shedding is observed. However, if blood extract is added to the incubation medium, the number and size of membrane whorls formed at light onset is greatly increased. Work is in progress to fractionate the crude acetone extract and identify an active factor.

These results suggest that the structure of the retina is controlled by two systems with opposite effects; efferent activity, which occurs only at night, moving the retina to the nighttime high sensitivity state, and humoral factors moving the retina to the lower sensitivity daytime state in the absence of efferent input.

40.2 THE TWO-LIGHT EXPERIMENT IN *DAPHNIA MAGNA*. T.R. Consi, B. Passani* and E.R. Macagno. Dept. of Biological Sciences, Columbia University, New York, NY 10027.

The single compound eye of the crustacean *Daphnia magna* performs a variety of oculomotor behaviors, including fast rotatory movements (eye "flick") in response to light flashes, and fixation and tracking when stimuli of longer duration are presented (T.R. Consi and E.R. Macagno, *Neurosci. Abstr.* 12:461, 1986). As previously observed, a spatially restricted flash of light elicits eye rotations of different size or different direction, depending upon what particular region of the eye is stimulated and the intensity of the stimulus. In the experiments reported here, a narrow stimulus (10° in the dorso-ventral direction and 30° to each side of the midplane of the eye) of 66 msec duration was used. With this stimulus, only the ommatidia located adjacent to the midplane are stimulated (D, A, B and C ommatidia in a dorsal to ventral direction). A stimulus located a few degrees dorsal to the D ommatidium causes no response, independent of stimulus intensity; when the stimulus is placed further dorsally, a dorsal rotation is elicited. In contrast, when the A or B ommatidia are stimulated, a ventral eye movement is produced. For both dorsal and ventral rotations, the size of the response increases with intensity up to a maximum.

To assess how information from different spatial locations is integrated by the oculomotor system, we have examined responses to pairs of stimuli delivered simultaneously to two different regions of the visual field. The two experimental conditions used were: (1) stimulation of the A and B ommatidia, which individually elicit a ventral eye flick when illuminated; (2) stimulation of either the A or the B ommatidium and stimulation of the D ommatidium in the region that elicits a dorsal eye flick. The paired light flashes were delivered at increasing intensities from threshold to saturation of the response. We found, for the first experimental paradigm, that the magnitude of the eye movement produced by two stimuli which individually elicit a ventral rotation is not a linear summation of the two single-stimulus responses. Instead, the magnitude is the same as that of the response to the single stimulus that produces the larger ventral rotation. This occurred at light intensities at which either stimulus alone induces a rotation well below the maximum eye movement possible. When two stimuli that produce rotations in opposite directions were flashed simultaneously, however, either very little or no eye rotation was observed, even at light intensities for which the individual dorsal and ventral rotations were of different magnitudes.

These initial observations indicate that the integration of information from different spatial locations by the *Daphnia* oculomotor system, as measured by eye movement responses, is complex and non-linear. Further experiments, utilizing pairs of stimuli of different intensities and at more positions around the eye, are currently underway in order to elucidate the neural mechanisms that control eye movements in *Daphnia*.

40.3 LATERAL INHIBITION IN THE COMPOUND EYE: NON-LINEAR INTERACTION BETWEEN RECEPTOR CELL TERMINALS STUDIED WITH WHITE NOISE ANALYSIS. M. Järvilehto*, M. Weckström*, E. Kouvalainen*, and K. Djupsund* (SPON: S. M. Martin). Department of Zoology and Department of Physiology, University of Oulu, 90220 Oulu, Finland.

Spatial information is known to be processed already in the first synaptic ganglion in the insect peripheral retina (Zettler F., Järvilehto M., Z. vergl. Physiol., 76:233, 1972). Lateral interaction has previously been studied with respect to the maximum amplitude of the response, and the mechanisms responsible are under debate. The influence between the functional elements in the ganglion has been suggested to act through gap junctions between the photoreceptor terminals (Ribi, W., Cell Tissue Res., 195:299, 1978) or via extracellular field potentials channeled by proposed high resistance barriers (Shaw, S. R., Nature, 255:480, 1975). The mechanism of lateral interaction is also undoubtely a function of frequency. We therefore studied lateral interaction in the frequency domain in order to reveal the responsible mechanism by investigating the differences in the linear transfer functions. Blowfly photoreceptors were stimulated with pseudorandomly (white noise) modulated light from a green (555 nm) LED. Transfer functions as well as coherence functions were calculated by FFT and compared at the center of the receptive field (on-axis) and at 2°/4° off-axis stimulation. The mean amplitude and the peak-to-peak level of the intracellularly recorded responses at off-axis stimulation were adjusted by the mean and the modulation degree of the stimulation intensity to match the on-axis responses, thus providing the same operating point on the intensity-response function. The transfer function obtained on-axis is similar to a system of five cascaded low-pass filters (corner frequency at 63 ±12 Hz) with at least one second-order term and a pure delay element. Surprisingly, the corner frequency of the 4° off-axis stimulation is decreased about 30 Hz, indicating inhibition at higher frequencies. The phase part of the function shows an increasing time lag in off-axis responses. The coherence function (a measure of linearity) begins to decrease at about the same frequency as the gain part of the function, pointing out an additional non-coherent input which is different from the initial membrane noise found in on-axis stimulation. The findings were verified by comparing the recorded impulse responses of equal amplitudes and also those obtained by inverse FFT with each other.

The non-coherent input inhibiting the responses at higher frequencies, a finding that has not been previously documented, is characteristic of capacitive coupling between photoreceptors. This is caused by high resistance barriers between receptor cell terminals in different neuro-ommatidial cartridges surrounded by glial cells. Our findings also explain the lateral inhibition reported in the lamina monopolar cells.

40.4 SEX-SPECIFIC NEURONS IN THE VISUAL SYSTEM OF BLOWFLIES (Calliphora erythrocephala) REPRESENT CONCENTRICALLY ORGANIZED RETINOTOPIC DOMAINS AND ARE SEGREGATED OUT TO END AT SPECIFIC REGIONS OF PREMOTOR DESCENDING NEURONS. N. J. Strausfeld. Arizona Research Lab. Div. Neurobiol. Univ. Arizona, Tucson, AZ 85721.

Certain species of Diptera exhibit visually induced behavior during which the male, but not the female, computes interception trajectories during high-speed pursuit of a small contrasty object such as another fly (Land, M.F., Collett, T.S. J. Comp. Physiol. A., 89: 331, 1974). Land and Eckert, H (J. Comp. Physiol. A., 156: 525, 1985) have demonstrated that male flies, such as C. erythrocephala have a specialized dorso-frontal area of retina where the divergence angle between neighboring photoreceptor axes is smaller than elsewhere, thus comprising a region of high acuity. Since each photoreceptor has a precise structural relationship with a set of columnar interneurons that extends through successive layers of synaptic neuropil retinotopic organization in the neuropil can be accurately extrapolated out into visual space by virtue of the mapped optical alignments of receptors. Iontophoresis of cobalt ions or Lucifer Yellow dye into the lateral deutocerebrum has revealed 13 morphologically distinct types of neurons that originate exclusively from the male optic lobes, in addition to those known to be cobalt-coupled to descending neurons (DNs: Strausfeld, N.J. Nature: 283, 381, 1980). Each species of male-specific neuron comprises a population of between 1 (unique) and 30 nerve cells, the latter having a columnar organization and small overlapping dendritic domains. The populations, resolved by cobalt uptake and silver intensification, can be stained in conjunction with the retinotopic inputs from the retina. Hence, each male-specific cell type can be related to the photoreceptors and their optical alignments into visual space. Using Land and Eckert's eye maps, each assembly of male-specific neurons has been projected out into the visual hemisphere to identify idealized receptive fields - assuming that these coincide with the dendritic spread of the neurons. These maps demonstrate that the assemblies of male-specific neurons subtend concentric fields, the innermost belonging to columnar neurons, the outermost and largest belonging to male lobula unique neurons. These neuronal types are further distinguished by their projections centrally onto premotor DNs. Small columnar neurons terminate at multibranched dendritic arbors, in parallel with other columnar neurons common to both sexes and representing the entire monocular visual field. In contrast, unique neurons or small populations of male-specific tangential cells characteristically end at the main trunks of descending neurons or even more proximally at their outgoing axons from the brain. This arrangement suggests that large-field sex-specific neurons are arranged to gate the activity of DNs, whereas small field endings interact peripherally with a variety of other parallel visual inputs.

Supported by NIH BRSG funds awarded to the University of Arizona.

40.5 EVOLUTION OF RHABDOMERE ASYMMETRY AND PHOTORECEPTOR AXON PROJECTIONS IN THE EYES OF PRIMITIVE DIPTERA. S.R. Shaw and I.A. Meinertzhagen, Dept. of Psychology, Dalhousie Univ., Halifax, N.S., Canada B3H 4J1.

Under the lens in a compound eye of an advanced fly, each photoreceptor has a separate light-absorbing rhabdomere, one of seven arranged in a characteristic asymmetric trapezoidal pattern, such that each rhabdomere images a slightly different point in space. Conversely, certain rhabdomeres in adjacent ommatidia point in the same direction, and it is the axons of such groups that selectively associate synaptically in the cartridges of the lamina. The advanced Muscomorpha evolved from ancestors of the more primitive subdivision, Nematocera, most of which have symmetrical rhabdomere patterns. Extending our interest in the cellular evolution of this system (Shaw, S.R. and Meinertzhagen, I.A., PNAS 83: 7961, 1986), we have investigated the point at which the asymmetric pattern arose, using in vivo optical inspection or microscopy. In the nematoceran family closest to the common ancestor (Anisopodidae), the pattern is horseshoe-shaped but not trapezoidal, as in parts of the eye in the related Bibionidae (Zeil, J., J. comp. Physiol. 150: 379, 1983). In the advanced muscomorphan series, the families that diverged earliest (Stratiomyidae, Xylophagidae, Rhagionidae, Tabanidae) already show the advanced pattern, as do all later groups, making it taxonomically diagnostic for Muscomorpha.

The asymmetric pattern carries maximum optical advantage only if the axons converging upon one cartridge have a matching asymmetric distribution, rotated 180° (Kirschfeld, K., Exp. Brain Res. 3: 248, 1967), while the prototype (bibionid) projection is reportedly less well optimized and more diffusely connected (Zeil, 1983). We therefore investigated whether the "modern" projection developed simultaneously with the asymmetric rhabdomere configuration, or whether it evolved later. Light-facilitated dye uptake (Wilcox, M. and Franceschini, N., Science 225: 851, 1984) can be adapted to chart the axonal projection, and shows that a member of one of the oldest muscomorph families (Stratiomyidae) already possesses a fully developed modern projection.

A possible anomaly remains that in Bibionidae, regrouped photoreceptor axon bundles first appear to associate with one cartridge before diverging again as in higher flies, to synapse in others (Zeil 1983). Having connections in two cartridges would degrade visual resolution. Our EM observations on Bibio confirm Zeil's interpretation of Golgi preparations, that the first of these associations is non-synaptic, comprising small bundles of photoreceptor axons lying in the spaces between cartridges. An evolutionary transition to the advanced form of the photoreceptor projection thus becomes simpler to imagine, starting from the non-divergent projection of dipteran ancestors.

40.6 CORRELATIONS BETWEEN STRUCTURE, TOPOGRAPHIC ORGANIZATION, AND SPECTRAL SENSITIVITY OF PROTHORACIC, INTERGANGLIONIC INTERNEURONS OF THE CRICKET. G. Atkins* and G.S. Pollack. Department of Biology, McGill University, Montreal, Canada H3A 1B1.

Recent studies have identified nine sound-sensitive, interganglionic interneurons in the cricket Teleogryllus oceanicus (Atkins, G. and G.S. Pollack, Soc. Neurosci. Abst. 12:858). Each neuron receives input in the prothoracic ganglion, but only two are potentially directly post-synaptic to auditory receptor cells. Five of the neurons are most sensitive to high frequencies (> 12 kHz) whereas four respond best to low frequencies (3-10 kHz). The morphology of the individual neurons was studied by filling them with Lucifer Yellow and examining their processes in wholemount and in sectioned preparations. Comparison of the structural characteristics of these neurons to their spectral-sensitivity reveals several correlations. (1) The processes of high frequency neurons are primarily located in the dorsal portion of the prothoracic ganglion whereas low frequency neurons are positioned ventrally. This arrangement indicates that sound stimuli of low and high carrier frequencies are processed in different regions of the cricket's nervous system, and is the first example of topographic arrangement of higher order, sound-sensitive interneurons in insects. (2) The descending axons of the neurons are also spatially separated; axons of high frequency neurons are positioned laterally in the pro-mesothoracic connective whereas those of low frequency neurons are positioned medially. (3) The overall structure of the cells is also correlated to their spectral-sensitivity. High frequency neurons share structural features (soma position, neurite trajectory, axon position) which, in the locust (another orthopteran insect) are indicative of inhibitory neurons (Pearson, K. and R.M. Robertson, Cell Tissue Res., in press). This raises the possibility that the high frequency cells might have inhibitory effects. None of the low frequency neurons have inhibitory-type morphology.

40.7 NEURAL CIRCUITS OF THE BOLLWORM MOTH ACOUSTIC SYSTEM. Herndon R. Agee. Insect Attractants Behavior, and Basic Biology Research Laboratory, USDA, ARS, P.O. Box 14565, Gainesville, FL. 32604.

The axonal terminations of the paired acoustic receptors (A1 and A2) and the B cell from the tympanic ear of the bollworm moth, Heliothis zea were studied after infiltration with cobalt chloride to determine their dendritic patterns in the central nervous system.
The most sensitive acoustic receptor (A1) produced a monosynaptic axon that had branches in the meso-metathoracic ganglia and was tracked to the anterior junction of the subesophageal-protoracic ganglia connective.
Neurophysiological data (Agee, H. R., J. Agric. Entomol. 2:277-285, 1985) indicated that the A1 axon was present in the dorsal midline of the brain. However, I have not been able to get the cobalt chloride to infiltrate the A1 axon beyond the subesophageal ganglion, probably due to injury to the connection.

The A2 axon (20 decibel less sensitive acoustic receptor, Agee, H. R., J. Econ. Entomol. 60:366-369, 1967) after entering metathoracic ganglion branches posteriorly and anteriorly. The anterior branches terminate in the same region of the mesothoracic ganglions as the dendrites of the motor neurons that drive the flight muscles of the metathoracic ganglion.

The non-acoustic B cell axon leaves the tympanic ear and follows a path parallel to the A1 axon through the CNS to the anterior limits of the subesophageal - prothoracic connective. There are some short dendritic branches of the B axon in the mesothoracic and prothoracic ganglia.
Neurophysiological data indicate that the B axon also enters the brain as does the A1 axon.

Behavioral data (Agee, H. R., J. Agric. Entomol. 2:345-350) and these histological and neurophysiological data indicate that the directed evasive maneuvers made by the bollworm moth when only the A1 receptors detect ultrasound signals are controlled by neural connections in the brain of the moth. The A2 cell axon does not extend beyond the mesothoracic ganglia. The A2 receptor is an important part of the sensorimotor circuit that generates the undirected evasive reactions that moths display when the receptor detects intense bursts of ultrasound (60-80+ dB) (Agee, H. R., 1969, Ann. Entomological Soc. Amer. 62:801-807).

40.8 MOLECULAR STUDIES OF INSECT PHEROMONE RECEPTION: VARIATION AND ONTOGENY OF SENSORY HAIR PROTEINS. R.G. Vogt*, A.C. Koehne* and G.D. Prestwich* (SPON: A. Carlson). Dept. of Chemistry, SUNY, Stony Brook, NY 11794.

The extracellular space of the pheromone sensitive sensory hairs of male gypsy moths, Lymantria dispar, contain high concentrations of two small soluble proteins (both 15K daltons). N-terminal sequence analysis shows these proteins are aprox. 50% homologous with each other, and about 60% homologous (in combination) with the pheromone binding protein (PBP) of the silk moth Antheraea polyphemus. (Vogt,R.C. et al., Proc. Natl. Acad. Sci USA 82:8827, 1985). Antisera prepared against the A. polyphemus PBPs cross reacts specifically with the gypsy moth proteins, as well as with specific antennal proteins of other moths, but not with antennal proteins of non-lepidopteran insects. Antisera prepared against the respective gypsy moth PBPs show similar specific cross reactivity patterns (Western blot analysis). Presumably due to differences in the primary antigen structures, these three antisera each reveal different proteins while maintaining specificity to antennal tissue. These studies are documenting a class of proteins, PBPs, which function in lepidopteran sensory hairs to effect pheromonal signal processing at the molecular level.

Gypsy moth adult development requires about 9 days (27°C). We have established criteria for selecting animals at specific, visually recognizable stages during the last half of adult development. Electrophoretic studies reveal that the gypsy moth PBPs are first synthesized 3 days prior to adult emergence (E-3), synthesis continuing at a high rate for at least several days into the brief adult life. However, the PBP concentrations in the antenna (aprox. 10 mM) plateau by E-1, remaining at that level for the duration, indicating an extremely high rate of turnover for these proteins. This turnover suggests that a metabolically active cell membrane at the base of each hair (Steinbrecht, R.A., Naturwissenschaften 73:275, 1986) functions as a high capacity pump for the delivery and removal of PBPs from the hair lumen. Considering the PBPs' role as a pheromone carrier, this also suggests an additional cleanup mechanism for ridding the hair lumen of residual pheromone molecules, by pumping them out with the PBPs, thus maintaining a low noise level within the hair and a high sensitivity to incoming signal.

40.9 FREQUENCY-DEPENDENT RESPONSES TO PULSED SEX PHEROMONE STIMULATION IN CENTRAL OLFACTORY NEURONS OF *MANDUCA SEXTA*. T.A. Christensen and J.G. Hildebrand. Arizona Research Laboratories, Division of Neurobiology, University of Arizona, Tucson, AZ 85721.

Female moths, among other insects, release sex pheromones that attract males over long distances. Several recent lines of evidence indicate that the pheromone plume is highly variable and furthermore that males orient to an intermittent stimulus more accurately than to a uniform concentration. We are interested in how the male moth extracts from this odor trail the information necessary to locate a "calling" female. Using intracellular methods, we recorded the responses of olfactory neurons in the CNS of male *Manduca sexta* to pulsed stimulation with sex pheromones. All recordings are from a subset of projection neurons (PNs) which represent a major pathway of pheromonal information flow between the first-order olfactory centers (the antennal lobes) in the deutocerebrum and higher-order centers in the protocerebrum. Electrodes were directed toward the area of the macroglomerular complex, the sexually-dimorphic area in the male antennal lobe neuropil to which the pheromone-responsive afferent axons project. Each cell was tentatively identified as a PN by its response to electrical stimulation of the antennal nerve. PNs are characteristically inhibited (indirectly) by electrical stimulation of sensory afferents and the IPSP is followed by brief excitation, and sometimes by later inhibition (Christensen & Hildebrand, *J. Comp. Physiol.*,in press).

PNs followed 1:1 with repeated pheromone stimuli as short as 15 msec and up to frequencies around 10 Hz. The cells responded to each stimulus pulse with a burst of spikes preceded by a transient IPSP. The excitatory burst elicited by the last stimulus pulse was often followed by a period of inhibition before the cell returned to its background rate of spiking. As the inter-stimulus interval was decreased, the inhibitory period between pulses was reduced and each excitatory burst began to merge with the one preceding it. At frequencies well above a given cell's cut-off range for repeated bursting, responses consisted of a single phasic burst of spikes followed by a prolonged inhibition.

In the presence of bicuculline, the IPSPs are blocked and the burst structure is altered. This indicates that GABA-mediated inhibition, as previously described (Waldrop *et al.*, *J. Comp. Physiol.*, in press), helps maintain the separation between bursts, thereby reflecting the changing temporal characteristics of the pheromone stimulus. The inhibitory neurons that help structure the bursts are, in all probability, the GABAergic local interneurons in the antennal lobe (Hoskins *et al.*, *Cell Tissue Res.*, 244, 243-252 (1986).

40.10 NEURONAL PROCESSING BY CENTRAL OLFACTORY NEURONS RELATED TO THE INITIATION OF MATING BEHAVIOR IN THE MALE SILKWORM MOTH. +R. Kanzaki* and T. Shibuya*. (SPON:H.Itagaki) Biol. Sci., Univ. of Tsukuba, Ibaraki 305 Japan
+Present address: ARL Division of Neurobiology, Univ. of Arizona, Tucson, AZ 85721

Olfactory stimuli play a major role in initiating insect behaviors such as mating, feeding, oviposition and so on. Recently, there has been considerable progress in unraveling central olfactory mechanisms underlying mating behavior which occurs in response to sexual pheromones.

Male silkworm moths (Bombyx mori) show a remarkable mating behavior consisting of wing vibration, walking and occasional abdomen curvature in their so-called "mating dance" when the receptor cells of their antennae are stimulated with sexual pheromone (bombykol and bombykal) released by females. The mating dance can also be initiated by synthetic bombykol.

To elucidate central mechanisms by which mating behavior of male moths is initiated, we have examined the activity of brain neurons related to stimulation of the antennae with pheromone. We have recorded from more than 600 neurons located in the deutocerebrum (1st order olfactory center) and the protocerebrum (higher olfactory center) and have characterized the morphology of 101 of these by intracellular staining with Lucifer yellow.

Two types of deutocerebral interneurons (Ia and Ib) were identified that projected from the deutocerebrum to the protocerebrum. Both types have arborizations in the macroglomerular complex, a male-specific neuropile region, and respond to pheromone (bombykol) stimuli with accelerated firing followed by inhibition. The excitatory part of the response includes an initial phase of higher frequency firing followed by a prolonged phase of firing at a lower frequency (PTI type). Local interneurons restricted to deutocerebral glomeruli were also identified.

Neurons were identified whose cell bodies and processes were restricted to the protocerebrum. These responded to antennal stimulation by bombykol with tonic increases in firing. Other protocerebral neurons were identified that have axons descending in the ventral nerve cord. These also responded with accelerated firing that often outlasted the bombykol stimulus. Dose-response curves generated with bombykol stimulation show that accelerated firing of descending protocerebral neurons parallels increased wing vibration, one of the components of mating behavior in male moths, that is observed using similar stimuli. We think that these neurons may be important for initiating and maintaining wing vibration during the mating dance.

40.11 TEMPORAL ANALYSES OF THE ACTIONS OF PROPANOL ON FLY TASTE RECEPTOR CELL RESPONSES TO SODIUM CHLORIDE. D.M. Bourassa* and L.M. Kennedy. Dept. Biology, Clark Univ., Worcester MA 01610.

Normal alcohols (n-alcohols) suppress fly behavioral and taste receptor cell action potential responses to sucrose(1,2,3). The receptor cell effects are biphasic over time-- firing is first suppressed and then increased and irregular, as are effects of the selective, sweetness-suppressing taste modifiers, gymnemic acids, ziziphins and hodulcin(3,4). For the initial suppression produced by n-alcohols, the duration and magnitude increases as alcohol chain length or concentration increases(3). Using the same paradigm as (3), we studied the effects of propanol, on Phormia regina taste receptor cell action potential responses to NaCl in order to test differential actions of the alcohol.

Single taste sensilla in isolated proboscises were tested in two-trial sequences. In the first trial, sensilla were treated with Tris (15mM,pH 7) for 2 min and then beginning at 1 min posttreatment, responses to NaCl 500mM were recorded continuously for 10 min. In the second trial, sensilla were treated with propanol 1.2 or 9M (in Tris), or with Tris, for 2 min and then responses to NaCl recorded as before. For each fly, the numbers of spikes in 0.1 or 1.0 sec excerpts, taken at 15 or 30 sec intervals from second trial responses, were expressed as ratios to the numbers of spikes in excerpts taken at the same times from first trial responses. Ratios were averaged over 1 min intervals.

For responses to sucrose after propanol 1.2M, the duration of the inital suppression is 1-2 min posttreatment(3). For responses to NaCl after propanol 1.2M, we found no suppression during the 10 min posttreatment. Yet when n-alcohols are mixed with the NaCl stimulus, responses are suppressed immediately after application of the mixture(2). For responses to sucrose after propanol 9M, there is a recovery from the initial suppression at 10 min posttreatment(3). We found that responses to NaCl after propanol 9M also are suppressed initially and then recover at 5.5 min posttreatment. The initial suppression produced by n-alcohols is similar for sucrose and NaCl in the effects of chain length(2). After propanol, the initial suppression is similar in the biphasic form and in the effects of alcohol concentration. Yet the time course of suppression differs for responses to NaCl or to sucrose. These data have important implications for studies of the selective actions of taste modifiers.

41.1 COOLING SENSITIVE MECHANORECEPTORS AND TEMPERATURE COMPENSATION IN THE GRASSHOPPER, SCHISTOCERCA AMERICANA. C.I. Miles, Dept of Zoology, University of Washington, Seattle, Wa. 98195.

Mechanosensory hair neurons of grasshoppers are sensitive to temperature, responding to hair deflections with higher firing frequencies if temperature increases. Stronger hair deflections will also produce higher firing frequencies. A central nervous system (CNS) neuron which receives inputs from such neurons might thus be incapable of distinguishing changes in their firing frequencies due to different stimuli from those due to temperature changes. A population of mechanosensory hairs located on the dorsal head surface, the wind sensitive head hairs, have especially high temperature sensitivities. For a CNS neuron receiving their inputs, the situation is further complicated by the temperature variability of the head. In freely moving animals, the temperature of the wind hairs can be up to 5°C different from the brain, and wind hairs are exposed to temperature fluctuations not experienced by the brain.

The Tritocerebral Commissure Giant (TCG) is a brain interneuron which receives wind hair input (Bacon & Tyrer, J. comp. Physiol., 126:317-325, 1978). If temperature of the wind hairs is changed while that of the TCG is not, the interneuron's spike output shows very little sensitivity to the temperature-induced changes in the levels of its sensory inputs. This study describes a mechanism by which this compensation could be produced.

A subgroup of wind hair neurons were found which exhibit responses to temperature change alone, without deflections of their associated hairs. These neurons display a cooling response, or increase in firing frequency with decreasing temperature. They also decrease their firing rate, or may cease firing entirely if temperature increases. When their hairs are deflected, these neurons can be as temperature sensitive as other wind hairs, but only if the deflections are brief. During tonic deflections, they are nearly insensitive to temperature change.

Information about head surface temperature provided by cooling sensitive wind hairs could enable the TCG to compensate for temperature's effects on the mechanosensory responses of its other wind hair inputs, as long as at least some of the cooling sensitive neurons are not stimulated with brief hair deflections. A natural wind stimulus would likely deflect individual hairs differently, due to the varied orientations of hairs on the head surface and the contours of the head. Fluctuations in head surface temperature should thus not affect the function of the wind hair-TCG system or the behaviors it mediates.

41.2 MECHANICAL AND PHYSIOLOGICAL PROPERTIES OF SLOWLY AND RAPIDLY ADAPTING SENSORY NEURONS OF THE DIPTERAN WING BLADE. M. H. Dickinson* (SPON: R. Pinter). Dept. of Zoology, Univ. of Washington, Seattle, WA 98195.

Mechanosensory fields of most animals are rarely homogeneous assemblages of neurons with identical physiological properties. Rather, individual cells within a single modality often differ with respect to absolute threshold, directional sensitivity, and dynamic response. This herteogeneity may result from differences in either extrinsic physical properties of the accessory structures utilized in mechanical coupling, or cell intrinsic membrane properties involved in the processes of transduction and encoding.

The wing blade of many dipteran species contain eight identifiable campaniform sensilla, mechanosensory structures that encode deformation of the cuticle. Four of the neurons adapt rapidly to step deformations and can follow sinusoidal stimulation at high frequencies. The other four cells are slowly adapting, respond maximally to lower frequencies, and show a lower threshold sensitivity. A preparation has been developed for examining the role of campaniform dome compliance setting the dynamic response properties within these two distinct groups of neurons. The campaniform dome is indented directly with sinusoid or noise stimuli using a microprobe that allows measurement of the force of indentation while simultaneously recording the impulse frequency of the neuron (see Chapman and Duckrow 1975, J. Comp. Physiol. 100:251-268). Both the compliance of the dome and the firing rate of the sensory cell may then be examined over a wide frequency range.

Preliminary evidence suggests that the rate sensitivity of these campainiform neurons is not primarily a function of the dynamic characteristics of the dome compliance, an observation that is supported by direct electrical stimulation. Thus the differences between rapidly and slowly adapting behaviors must be assigned to membrane intrinsic electrical properties. However, dome compliance may be an important parameter in setting the treshold sensitivites between the two classes of neurons.

Future studies will examine the roles that these two classes of neurons might play in the flight behavior of flies.

41.3 EXTRACTION OF SENSORY INFORMATION FROM A COMPUTATIONAL MAP BY INTERNEURONS IN THE CRICKET CNS. J.P. Miller and G.A. Jacobs. Zoology Dept., UC Berkeley, Berkeley, Ca. 94720

The cercal sensory system of crickets is a model for the study of computational maps of sensory space, and for the mechanisms by which single neurons extract and encode information from such maps. This system mediates the detection of the direction, velocity and acceleration of wind currents directed at the animal. Previous studies have shown that the excitatory receptive fields of several primary sensory interneurons (INs) are determined by the location of their dendrites within the afferent map, inhibition from other INs plays a significant role in shaping the directional sensitivity of some cells,and the threshold and response characteristics of several primary INs vary over a broad range. Shimozawa & Kanou (1984) have classified cells as either velocity or acceleration detectors, and demonstrated the basis for this variation in threshold and response characteristics. For that work, sinusoidally oscillating air currents were used as stimuli. We have tested and extended this earlier work using constant velocity wind stimuli. Intracellular recordings were obtained from nine different types of identified INs, including several from which no data was previously available. 1.) Most cells showed marked directional selectivity, but several showed very little. 2.) In all cells with marked directional selectivity, inhibition was observed to play an important role in shaping the response characteristics. The amplitude of inhibition was demonstrated to be dependent upon wind direction and velocity. 3.) With few exceptions, the predictions of Shimozawa & Kanou were observed to be correct: ie. a.) INs 10-2 and 10-3 (innervated by long hairs) had very low thresholds, had opposite directional selectivities, and generated responses proportional to wind velocity. b.) LGI and MGI (innervated by short hairs) had high thresholds, and generated responses proportional to wind acceleration. 4.) Other cells were found which had intermediate and complementary properties. For example, cell 11-1 had relatively high threshold, showed very little directional sensitivity, and generated "on-off" responses proportional to wind acceleration. 5.) Several aspects of neuronal response properties were different than predicted by Shimozawa & Kanou. a.) All cells showed substantial adaptation to maintained wind current, ie: all were "phasic". b.) 9-3 was the "least phasic"; 10-2 and 10-3 were intermediate; LGI, MGI and 11-1 were among the most phasic. The different cell types have complementary response characteristics which allow the system as a whole to sense and encode a wide range of direction, velocity and acceleration parameters of wind stimuli. Based upon this data, a preliminary assessment of feature extraction and information coding by this system will be presented. (Shimozawa & Kanou, J. Comp. Physiol. A 155:485-505.)

41.4 **INTEGRATION OF DIRECTIONAL WIND FIELD INFORMATION IN THORACIC INTERNEURONS OF THE COCKROACH** **R.E. Ritzmann, A.J. Pollack* and J. Westin. Dept. of Biology, Case Western Reserve University, Cleveland, OH 44106.**

We have identified several thoracic interneurons in the cockroach that respond directly to ventral giant interneuron (vGI) activity. At least one population of these interneurons, members of the dorsal posterior group (DPG), also excites the leg motor neurons that are activated during the GI mediated escape response. Both the wind receptive fields and the synaptic responses to individual GI's of several of these interneurons have been examined. These data support the contention that the DPG interneurons serve to integrate the information on wind direction which is encoded in the vGIs.

In an attempt to understand the details of this integration process, we have studied the potential connectivity of each GI with the various DPG interneurons. For two of the thoracic interneurons in question, this study is now complete. Both Lambda and the Reverse-J cells receive excitatory inputs from each of the 8 vGIs but fail to receive inputs from any dGI interneurons. In studies where two vGIs were impaled in conjunction with DPG interneurons, evidence was found for summation of inputs both from vGIs in the same connective and from pairs including one vGI in each connective.

These experiments also permit us to compare the relative strength of synaptic excitation between specific pairs of vGIs. Two questions were addressed for this aspect of the study: (1) What are the relative amplitudes of EPSPs generated in thoracic interneurons by stimulating each of the two impaled GIs intracellularly? In order to eliminate spatial considerations, especially in cases where GIs are tested in both connectives, all DPG recordings were taken on the midline of the thoracic ganglion. (2) What are the relative contributions to generation of action potentials in the thoracic interneuron for inputs from each GI? Since, in most cases, inputs from individual GIs do not depolarize the thoracic interneurons to threshold, they were depolarized by current injection to a level that allowed at least one of the two GI inputs to evoke action potentials. In this way we hope to establish a ranking of synaptic efficacy for each of the vGIs. This, along with the wind fields that have been established for each vGI, should begin to explain the origin of wind fields which we have observed for the thoracic interneurons.

41.5 DUM INTERNEURONS ARE EXCITED BY VENTRAL GIANT INTERNEURONS OF THE COCKROACH A.J. Pollack* and R.E. Ritzmann (SPON: J. Westin). Dept. of Biology, Case Western Reserve University, Cleveland, OH 44106.

A considerable amount of data has been brought forward implicating the giant interneurons (GIs) of the cockroach P. americana in the initial movements of the wind-evoked escape response. In an attempt to identify the neurons that integrate the information encoded in GIs, we have recorded from a variety of thoracic interneurons while stimulating GIs intracellularly. Among those we have tested are a variety of Dorsal Unpaired Median (DUM) cells. Several of these cells have been shown to release octopamine which, at least in the periphery, can augment excitatory synaptic responses from other neurons.

The results of our tests indicate that none of the DUM cells that have large somata, including those with peripheral axons, receive inputs from either ventral or dorsal GIs. These cells are only weakly wind sensitive, and intracellular stimulation of GIs consistently fails to generate PSPs. Nevertheless, we have recorded from 4 different DUM cells which do respond to ventral GI stimulation with large short latency EPSPs. Each of these cells has a small soma and no peripheral axons. Three of the cells are local intraganglionic interneurons in the metathoracic ganglion. One of them has processes in both T2-T3 thoracic connectives.

Evidence exists indicating that in locust all of the DUM cells synthesize the neuromodulatory transmitter octopamine (Goodman et.al., 1979, Science 204:1219). If the DUM interneurons that receive inputs from GIs also release octopamine, it would be tempting to hypothesize that they may serve to modulate synaptic activity in the CNS in the same way that the larger peripheral DUM cells modulate synaptic activity in the periphery.

(Supported by NIH grant NS-17411 to R.E.R.)

41.6 DESCENDING PATHWAYS CARRYING WIND AND TACTILE SENSORY INFORMATION IN THE NERVE CORD OF THE COCKROACH Periplaneta americana. J.A. Burdohan* and C.M. Comer. Dept. Biological Sciences, Univ. of Illinois at Chicago, Chicago, IL 60680.

Much of the work on the wind-evoked escape behavior of the cockroach has focused on its control by a set of giant interneurons (GIs) which ascend the ventral nerve cord (VNC) carrying cercal-derived wind sensory information. However, recent behavioral studies in our lab (Comer et al., Neurosci. Abstr. 12:203, 1986) have demonstrated that after complete elimination of the ascending GI system by surgical section of the abdominal portion of the VNC, animals can still turn and run in response to wind puffs. Such "non-GI" wind-evoked responses are similar in form to normal escape, but are somewhat longer in latency. They were nearly eliminated by subsequent removal of the antennae, although evasive turning and running in response to tactile stimulation of other rostral structures persisted. We have begun characterizing descending wind and tactile sensory pathways of the sort implied by our behavioral results, and provide here an initial electrophysiological description of their properties.

Recordings (extracellular and/or intracellular) were made simultaneously from the neck connectives and from the connectives just rostral to the metathoracic ganglion. Robust unit responses were recorded at these sites in response to wind puffs similar to those used in our behavioral experiments, and in response to tactile stimulation of the antennae, the head, and the pronotum. These responses persisted following complete section of the nerve cord between the abdomen and the thorax. At the level of the metathoracic ganglion, descending wind-evoked activity arrives approximately 50 msec later than ascending GI activity. This accords reasonably well with the shift in latency of wind-evoked escape responses seen following elimination of the GI pathway.

The source of input to these wind sensory units was ascertained by experiments involving removal or covering of rostral sensory structures. A major source of input is the antennae, as their removal leads to a dramatic decline in descending wind-evoked responses. Additional wind-evoked activity is mediated by sensory hairs on the head and pronotum. These descending units appear to have a slightly higher threshold for wind than the GIs. We are now beginning to examine single descending units in relation to leg motor neurons and the GIs.

(Supported by NSF grant #BNS 83-11980 to C.M.C.)

41.7 ANATOMICAL AND ELECTROPHYSIOLOGICAL CORRELATES OF A SOMATOTOPIC AFFERENT-TO-MOTORNEURON MAP IN LARVAL MANDUCA SEXTA. G.A. Jacobs, B.A. Peterson and J.C. Weeks. Dept. of Zoology, Dept. of Physiology-Anatomy, and Dept. of Entomological Sciences, Univ. of California, Berkeley, Berkeley, CA 94720.

Each abdominal segment of the tobacco hornworm caterpillar, Manduca sexta, bears hundreds of singly innervated sensory hairs that relay mechanosensory information. The only larval abdominal appendages are the paired sets of prolegs, which are used for locomotion and other behaviors. The highest density of hairs on the abdomen of 5th instar larvae occurs on the distal tip of each proleg, the planta, with each planta bearing ca. 40-50 long, stout hairs in a compact array. Tactile stimulation of the planta hairs elicits a proleg retraction reflex that is mediated by monosynaptic excitatory connections between the planta hair afferents and proleg retractor motorneurons (J. Comp. Physiol. 1987, 160:315-330). Anatomical contact between the afferents and motorneurons occurs in ventral (sensory) neuropil, to which the motorneurons send a small dendritic projection. Intracellular motorneuron recordings indicate that the size of the afferent-evoked EPSP varies consistently as a function of the location of the hair within the planta array. To investigate the possible anatomical basis of this pattern, we determined the central projections of individual afferents by cobalt filling via the cut hair shaft. The long axis of the planta hair array is in the anterior-posterior direction and the dorsal-ventral axis is narrow. The terminal arbors of the afferents formed a well defined somatotopic map in sensory neuropil, with the anterior-posterior axis of the hair array mapped along the anterior-posterior axis of the ganglion. Afferent position was also reflected in the extent of contralateral branching within the ganglion, and in differences in interganglionic axonal projections. The map orientation was the same as that reported by Levine et al (J. Comp. Physiol. 1985, 157:1-13) for non-proleg abdominal hairs, but planta afferents had larger arbors than did non-proleg afferents, and the planta hair map occupied a disproportionately large portion of neuropil given the small size of the planta hair array on the body surface. Thus, as might be predicted on behavioral grounds, the proleg region of the body is relatively overrepresented in sensory neuropil. The finding of strong somatotopy in the planta hair afferent projections is consistent with an anatomical contribution to the observed pattern of EPSP sizes in proleg motorneurons, a hypothesis that can be further tested experimentally.

This research was supported by an NIH grant (NS23208) and a Sloan Fellowship to JCW, and an NIH Fellowship (NS07882) and Whitehall Foundation grant-in-aid to GAJ.

41.8 INTERSEGMENTAL PROCESSING OF MECHANOSENSORY INFORMATION BETWEEN LOCAL CENTRES CONTROLLING THE LEGS OF THE LOCUST. G. J. Laurent* (SPON: M. Burrows) Dept. Zool., Univ. Cambridge, CB2 3EJ, England.

The local interneurones involved in the control of the movements and position of one leg must be informed of the state of the adjacent legs so that coordinated movements can occur. A population of more than 30 paired intersegmental interneurones that could subserve that role between the meso- and meta-thoracic segments is being studied in the locust. The range of their inputs from various extero- and proprio-ceptors on a middle leg has been defined and the way the sensory signals are integrated by them, studied in detail.

Each interneurone in this population can be identified by its morphological features elaborated from a common ground plan (Laurent, 1987, J. Comp. Neurol., 256, 412-429) and by its mechanosensory receptive field on one middle leg (Laurent, 1987, J. Neurosci., in press). In this way, a given interneurone is, for example, excited by extension, and inhibited by flexion of the tibia; another interneurone is excited by touching a patch of hairs on the dorsal femoro-tibial joint, and inhibited by pressure applied on the ventral surface of the tarsus.

The excitatory regions in the receptive fields of these interneurones are due to direct excitation from proprioceptive or exteroreceptive afferents. The spikes of the afferents evoke excitatory post-synaptic potentials in the interneurones with a consistent central latency of about 1msec. The projections of the interneurones and the corresponding afferents overlap in the neuropile.

By contrast, the inhibitory regions in their receptive fields are due to disynaptic inhibition mediated by a layer of spiking local interneurones. A spike in a local interneurone, evoked directly by a set of afferents causes an inhibitory post-synaptic potential in a given intersegmental interneurone with a latency of less than one msec. The inhibition can result from converging inputs from several local interneurones.

These intersegmental interneurones send an axon to and arborize in the ipsilateral metathoracic neuropile. Immunocytochemical labelling combined with unitary intracellular staining has allowed GABA to be identified as one of the putative transmitters, suggesting inhibitory effects.

This work was supported by an SERC (UK) grant to M Burrows.

41.9 PROPRIOCEPTIVE AND TACTILE INTEGRATION BY IDENTIFIED INTERNEURONS IN THE SAND CRAB EMERITA. D.H. Paul (SPON: N.M. Sherwood). Biology Department, University of Victoria, B.C., Canada V8W 2Y2.

The tailfan (telson flanked by the uropods) in crustaceans such as the crayfish is a major source of sensory information which is used in balancing, steering and initiating locomotory behaviors. In crayfish, who swim by tailflipping, ~55% of the 50 paired neurons with somata in the terminal ganglion (G6) and axons projecting anteriorly through the connective are individually identified mechanosensory interneurons, MSI (Sigvardt et al., 1982. J comp Physiol 148: 143). G6 of crayfish is probably representative of the ancestral neuronal organization of this ganglion with respect to sensory integration. In sand crabs, the uropods are reoriented to flank the abdomen, not the telson, and Emerita swims by beating the uropods (Paul, 1981. J exp Biol 94: 159). Because the arrangement of sensory fields on the tailfan is phylogenetically stable, homologous nerves of G6 in different taxa are recognizable (Paul et al., 1985. Biol Bull 168: 106). In Emerita uropod stretch receptors, absent from crayfish, provide reafference from uropod movements through one of these nerves (Paul, 1976. J exp Biol 65: 243). The questions raised are: Does uropod stretch receptor input impinge on homologs of any of crayfish's identified MSIs? And, if so, are these the neurons that in crayfish handle proprioceptive information from other sources?

Cobalt backfills of one hemiconnective into G6 of Emerita reveal a population of ~ 25 projection neurons with somata clustered into 3 contralateral groups similar in position to the caudal, medial, and rostral clusters of neurons projecting anteriorly from G6 in crayfish (Sigvardt et al.). My data on structures of individual MSIs, from connective backfills and dye injections into single cells, suggest that most members of the rostral cluster are retained in Emerita and that the reduction in numbers has been among interneurons with caudal and medial somata. Preliminary physiological data, from repeated intracellular recordings of exteroceptive and proprioceptive input to 11 different MSIs, suggest that stretch receptor afference impinges on homologs of certain cells that in crayfish respond only to exteroceptive input. I am currently persuing this investigation in order to discover how signals from the phylogenetically new stretch receptor are integrated with other afference from the tailfan.

41.10 DIRECTIONAL CODING BY CRAYFISH MECHANOSENSORY INTERNEURONS. Lon A. Wilkens. Department of Biology, University of Missouri-St. Louis, 8001 Natural Bridge Road, St. Louis, Missouri 63121.

The sensitivity of crayfish mechanosensory interneurons to directional stimuli, as observed initially in the caudal photoreceptor (CPR) (Wilkens and Larimer, 1972), is useful in characterizing morphologically identified cells (Sigvardt, Hagiwara and Wine, 1982; Reichert, Plummer and Wine, 1983; Wine, 1984). Until now, descriptions of directionality have been limited to the rostral/caudal axis, due in part to the difficulty of sequentially generating quantifiable stimulus currents from various directions. For aquatic animals relatively finite recording chambers must be employed which have inherent resonant frequencies and produce interference in the form of reflected traveling waves. In the present experiments, these difficulties have been overcome by the use of stimulus currents in the vertical axis generated by modified sinusoidal movements of the chamber floor. With this arrangement there are no traveling waves and water displacements are synchronous and uniform throughout the chamber. The tailfan, along with the 6th abdominal ganglion, is mounted vertically on the end of a horizontal supporting rod. Rotation of the support rod (up to ±90°), as water moves up and down in the plane of the tailfan, effectively simulates currents from any direction desired. Interneuronal responses are recorded en passant by electrodes attached to the support rod.

The CPR has been reported variously as being headward and/or bidirectionally sensitive. In the present experiments the CPR is consistently most responsive to transverse currents directed toward the tailfan appendages ipsilateral to the cell axon and dendrites. Headward and tailward responses are greatly attenuated and the opposite is direction without effect. The contribution of bilateral excitatory and inhibitory input from receptive fields on the telson and uropods has been assessed by unilateral section of the ganglionic roots while recording simultaneously from both CPRs. Ipsilateral input underlies the CPR response in the "preferred" direction, but responses based solely on excitatory input are less narrowly tuned. Contralateral input alone depresses the endogenous activity of the CPR for stimuli in the opposite direction. In simultaneous recordings from up to 6 sensory interneurons, the direction of peak sensitivity is seen to vary from one cell to the next. These results demonstrate in part that directional specificity is constant along with cell morphology and the somatotopic axon position in crayfish interneurons. Supported by grants from the Whitehall Foundation and Weldon Springs Fund.

41.11 FUNCTIONAL MORPHOLOGY OF NONSPIKING UROPOD STRETCH RECEPTORS IN THE SAND CRAB (EMERITA ANALOGA). L.J. Wilson* and D.H. Paul. Dept. of Biology, University of Victoria, Victoria, B.C. Canada. V8W 2Y2.

The uropod stretch receptor (USR) in Emerita is an elastic strand, arising from the dorsal surface of the telson and inserting on the uropod, which is innervated by 4 giant mechanosensory cells (SRs) with somata in the terminal abdominal ganglion (Paul,1972. Science 176:680). Reafference from USRs is required for the power stroke of the uropod in the 'treading water' swimming pattern (Paul, 1976.J Exp Biol 65:243). We are using light and electron microscopy (EM) in conjunction with cobalt and horseradish peroxidase peripheral filling techniques to examine the structure of the USR, looking for characteristics of nonspiking cells and morphological corellates of stretch.

Each SR has 3 morphologically distinct zones within the strand. 1)Zone of dendrite entry(ZDE):large (»10μm) branches resemble axons of motoneurons except that the dendrite membrane is thickened in all zones. Each has abundant neurofilaments and neurotubules, peripheral mitochondria, glial ensheathment and sparse extracellular matrix (ECM). SRs may have evolved from motoneurons. 2)Transitional zone(TZ):medium sized (1-10μm) branches are surrounded by connective tissue containing fewer glial cells and more ECM. ECM fibres in the TZ and ZDE exhibit the 64nm banding pattern of collagen. 3)Zone of dendrite termination(ZDT):dendritic endings are embedded without glial wrapping in dense ECM oriented parallel to the long axis of the strand. The ECM is similar to structures called 'vacuolated strings' containing 0.1μm SR endings of thoracico-coxal receptors (TCRs) of other decapods (Whitear,1965.Phil Trans Roy Soc B 248: 437). The vacuolated strings in Emerita contain small (0.25-0.5 m) dendritic processes and 0.1μm holes which may also be neuronal. Strand stretching causes cross-sectional profiles of the vacuolated strings to become longer and thinner. This may deform the dendrites either by compression by ECM or by stretching if the endings are attached to the ECM (Krauhs & Mirolli,1975.J Neurocytol 4:231). ECM fibres of the ZDT, including those in the vacuolated strings, belong to the special category of invertebrate elastic fibres that: 1)have a distinctive EM appearance, 2)are physically elastic and 3)stain with potassium permanganate/spirit blue (Elder & Owen,1967. J Zool Lond 152:1;Elder,1973.Biol Bull 144:43).

Thus, large branches of the SRs are anchored by collagen as they enter the strand while their termini are embedded in an elastic matrix. We continue to study how the site of receptor potential generation changes with stretch. The USR is less specialized than its putative homolog the TCR and appears to have the minimum elements essential for mechanosensory transduction.

41.12 MECHANOSENSITIVE SENSILLA INNERVATING THE SWIMMERETS OF THE LOBSTER. K.A. Killian and C.H. Page. Rutgers University, Bureau of Biological Research, Piscataway, NJ 08854

Mechanical stimulation of the swimmerets modulates postural activity produced within the abdominal nerve cord (Kotak, V.C. and Page, C.H., J. Comp. Physiol. A. 158:225-233, 1986). To better understand this response, the properties of several tactile sensitive receptors located on these appendages were investigated. Swimmerets consist of two flat leaf-like rami, the exopodite and endopodite, attached to a stalk-like coxa. We have examined the three most characteristic types of receptors responding to tactile stimulation: cuticular receptors underlying the rami surfaces and large and small feathered hairs which fringe the outer edges of each ramus.

An isolated third swimmeret with attached ventral nerve cord was prepared. Responses of receptors to mechanical stimulation were recorded with a suction electrode en passant from the first root. The mechanical stimulator consisted of a small (2 mm) diameter wooden probe glued to the center of a miniature loudspeaker. The blunt probe was used to stimulate cuticular receptors directly while hairs were deflected by slipping a small loop attached to the distal tip of the probe over individual hairs. Preliminary experiments indicate that both hair types also respond to near field pressure waves.

Large feathered hairs responded phasically by discharging a single action potential in response to mechanical stimulation. Small feathered hairs and cuticular receptors exhibited a more phasic-tonic response dependent on the strength of the applied stimulus. Receptive fields of individual cuticular receptors varied in size from large fields that include almost an entire surface of a ramus, to small restricted fields of a few millimeters diameter. Those receptors with larger fields innervate the more pliant cuticle within the center of the ramus while those with smaller fields are located under hard cuticular bands along the outer edges of the ramus. The sensory neurons that innervate the large feathered hairs responded to all directions of deflection of the hair. Their responses to sinusoidal movements were maximal between the frequencies of 100 and 200 Hz. The threshold for discharge within this range of frequencies was approximately 2-10 degrees which corresponds to 5-25 microns of linear movement measured at the midpoint of the hair shaft. The latency for recording spikes in the afferent axons was long and variable (15-30 msec) suggesting spike conduction is very slow in these fibers. This slow conduction velocity agrees with the unusually long latencies Kotak and Page (1986) observed for initiation of abdominal flexion inhibition responses produced by deflection of the feathered hairs. (Supported by NIH grant NS 19983-04 to CHP).

41.13 MODULATION OF THE RECEPTOR POTENTIAL IN CRUSTACEAN MECHANO-SENSITIVE AFFERENT NEURONS BY PROCTOLIN, SEROTONIN AND OCTOPAMINE. V.M. Pasztor and B.M.H. Bush* Biology Department, McGill University, Montreal, Canada, and Physiology Department, Bristol University, England

We have shown recently that the sensory response of mechano-sensitive afferents can be modulated by proctolin, serotonin and octopamine. (Nature, 326:793 - 795, 1987). Using intracellular recordings from the three primary afferents of a simple lobster stretch receptor, lacking centrifugal control, we observed that the two neuroamines depressed stretch-evoked impulse discharge, whereas the pentapeptide proctolin enhanced it. The drugs, which are known to be present in Lobster, were bath applied at concentrations of 10-6M. This mechano-receptor, the oval organ, is a favorable system for studying peripheral events because, not only are the afferents large enough to permit the introduction of microelectrodes near the transducer site, but their unusually large space constants (>10 mm) result in the receptor potentials being conducted along the afferents with very little decrement. Thus both receptor potentials and impulses are accessible for experimentation. The present study was undertaken to determine the target of neuromodulation: transducer membranes, adaptation systems or spike initiation zones.

Responses to trapezoidal stretches recorded in the presence of 10-6M TTX to block spiking, showed that the amplitude, but not the shape of the receptor potential was increased or decreased by 20 - 30% by physiological concentrations of the neuroactive substances. The rate and extent of both short and long-term adaptation was unchanged.

Spiking patterns, induced by standard depolarizing currents injected into the afferents near the spike initiation zone, showed no modulation by any of the three substances.

The lack of modulation of either adaptation or spiking threshold implies that the increased sensory responsiveness induced by proctolin, and the decrease seen with octopamine and serotonin may be explained by modulation of channel populations primarily linked with mechano-transduction.

41.14 ANATOMICAL AND PHYSIOLOGICAL EVIDENCE FOR A NOVEL INHIBITORY CIRCUIT IN THE CRAYFISH LATERAL GIANT ESCAPE RELFEX. E.T. Vu, S.C. Lee, and P.B. Krasne. Neuroscience Program, Dept. of Psychology, and Brain Research Institute, University of California, Los Angeles, CA 90024.

The key role of the pair of lateral giant (LG) command neurons in the neural network underlying the LG-mediated tailflip escape reflex of the crayfish has prompted us to undertake a detailed anatomical study of the LG dendrites and their synaptic inputs. By physiological criteria, the sensory inputs received and integrated by the LG dendrites in each abdominal ganglion have long been thought to be mediated purely be excitatory, electrical synapses. In contrast, our electron microscopy (EM) studies have revealed a complex mixture of synapse types onto the LG's. Of particular interest, some EM profiles believed to be excitatory afferents to the LG's have been seen to make synapses upon presumed GABAergic neurons which in turn form nearby synapses on the LG's. Since GABA is known to produce inhibition in LG cells, these observations suggest the possible existence of a "feed-forward" inhibitory circuit onto the LG's which parallels, and is driven by, the physiologically demonstrated excitatory one. The expected consequence of such a circuit would be the occurrence of inhibition of the LG's shortly after activation of their excitatory inputs, thus possibly helping to temporally tune the LG command cells to respond best to sharply arising stimuli. Physiological evidence for this inhibition, which we call "post excitatory inhibition", has been obtained. Supported by USPHS grant NS08108 (FK) and a Predoctoral NSF Fellowship (EV).

DRUG EFFECTS ON RECEPTORS I

42.1 PHENCYCLIDINE ACTIONS ON MODULATION OF THE NMDA-ACTIVATED CATIONIC CHANNEL. M. Bertolino, S. Vicini and E. Costa. FIDIA-Georgetown Institute for the Neurosciences, Georgetown University Medical School, Washington, D.C. 20007.

Phencyclidine (PCP) reduces $^{45}Ca^{2+}$ ionic fluxes induced by the glutamate receptor agonist N-methyl-D-aspartic acid (NMDA) in cultured granule cells from post-natal rat cerebellum (1). The action of PCP on NMDA-activated cationic channel was investigated with the single-channel patch-clamp recording technique on outside-out patches excised from post-natal rat cerebellar neurons and neonatal rat cortical neurons in primary culture. The recording solution contained in mM NaCl 145, $CaCl_2$ 2, KCl 5, Glucose 5, HEPES-NaOH 5 at pH 7.4. The pipette solution contained $CsSO_4$ 145, $CaCl_2$ 1 mM HEPES-NaOH at pH 7.2 to avoid potassium and chloride fluxes. The NMDA-activated channel opened with a mean frequency of 0.5 sec^{-1} in cerebellar neurons, 1.03 sec^{-1} in cortical neurons in presence of NMDA 2 uM. At -50 mV holding potential and room temperature with NMDA 2 uM, the main conductance state of the channel was 50 pS in both models and the mean open time was 3.8 ± 1.1 msec (mean ± SD, n=10) and 6.4 ± 2.6 (mean ± SD, n=40) in cerebellum and cortex, respectively. In cortical cell, low PCP concentrations (2 uM) reduced the channel opening frequency by 60% (n=5) while high PCP concentration (20 uM) reduced the channel open time (n=8) BY 50%. Both effects were observed only when the channel was conducting in the inward direction (negative membrane potential), meaning that the action of PCP is voltage dependent. It is possible that the reduction of open time could be due to an open channel block mechanism with a relatively slow off-rate while the more specific action on opening frequency could be due to the allosteric modulation of the channel-receptor complex. Since the report that NMDA channel opening could be modulated by glycine presumably acting as an allosteric endogenous modulator (2), we investigated the combined action with PCP of this amino acid. At negative holding potential glycine (1 uM) was not able to completely counteract the action of phencyclidine while at positive membrane potential PCP failed to decrease channel opening frequency while glycine was still increasing it. This suggests that the two compounds are acting at different recognition sites located presumably in the NMDA receptor.

42.2 EVIDENCE FROM 2-DG AUTORADIOGRAPHY THAT PHENCYLIDINE'S FUNCTIONAL EFFECTS ARE MEDIATED BY SPECIFIC PCP RATHER THAN SIGMA RECEPTORS. C.Ray*, G.D.Vogelsang and M.F.Piercey, (Spon. P.Broderick), CNS Research, The Upjohn Company, Kalamazoo, MI. 49001.

Sokoloff's 2-deoxyglucose (2-DG) autoradiographic technique (J. Neurochem. 28:897, 1977) was used to identify neural structures underlying the behavioral effects of the psychedelic drug phencyclidine (PCP, "angel dust") and to compare the distribution of PCP's functional effects to the distribution of specific 'PCP' and sigma receptors, both of which bind PCP (Vignon et al. Brain Res. 378:133, 1986). Phencyclidine, 5 mg/kg, was administered i.p. to male Sprague-Dawley rats 15 min prior to 25 uCi i.v. (^{14}C)-2-DG. Animals were sacrificed 45 min later. Autoradiograms of coronal sections were prepared from the prefrontal pole to the cervical cord. Computerized image analysis yielded quantitative measurements of regional energy metabolism. PCP dramatically increased metabolism in discrete brain regions, nearly all of which were located in diencephalic and telencephalic structures rich in PCP receptors (Largent et al., JPET 238:739, 1986). These effects were greatest in the limbic circuit described in 1937 by the neurologist James Papez (mammillary bodies, anterior thalamus, cingulate gyrus, entorhinal cortex, hippocampus, fornix), which was dramatically excited throughout, and the terminal zones of dopaminergic projections (caudate, n. accumbens, olfactory tub., prefrontal cortex). In general, anterior cortical regions, (especially sensory-motor cortex), were only weakly stimulated or even depressed, compared to more caudal cortical zones, (particularly striate 18), giving rise to an anteroposterior gradient similar to that reported in schizophrenia. Brainstem areas rich in sigma receptors (Largent et al., ibid) were generally unaffected. The inferior colliculus and the lateral habenula were inhibited. Chi-square analysis revealed a strong positive correlation for the areas stimulated with the presence of PCP receptors and a negative correlation with the presence of sigma receptors. Haloperidol (HAL), which binds to sigma but not PCP receptors, antagonized PCP's stimulant effects in most dopaminergic areas, but not in Papez' circuit. Even HAL's effects were negatively correlated with the presence of sigma receptors. HAL tended to depress PCP's cortical stimulation throughout without altering the anteroposterior gradient; indeed, some anterior cortical regions were severely depressed below controls. HAL did not significantly affect PCP's intense cingulate stimulation. Although HAL stimulated the lateral habenula, it only partially reversed the depression evoked by PCP. It is concluded that PCP elicits its extreme psychotropic effects by intense stimulation of Papez' limbic circuit and dopamine release, all of which are probably mediated either directly or indirectly through the PCP receptor.

42.3 **BLOCKADE OF CALCIUM CURRENT BY COCAINE IN CULTURED SENSORY GANGLION NEURONS OF THE MOUSE.** **R.Y.K. Pun. Dept. of Physiology and Biophysics, Univ. of Cincinnati, Cincinnati, Ohio, 45267-0576.**

The use of cocaine in the United States has reached an epidemic level. The number of people hospitalized, seeking help, and the number of deaths related to drug overdose has increased dramatically. In humans, inhalation of cocaine produces a bout of euphoria followed by irritability and dysphoria. In some cases, use of the drug also may produce psychotic symptoms such as acute anxiety, paranoia, or hallucinations. The cellular mechanism underlying the actions of cocaine is not fully understood, but it is thought to be mediated by enhancement of the responses to monoamines since cocaine is a potent blocker of re-uptake in synaptosomal preparations.

Another possibility to explain the enhanced synaptic response is that cocaine increases transmitter release by altering Ca^{++} influx at the presynaptic terminals. To test this hypothesis, I have studied the actions of cocaine on the transmembrane Ca^{++} current in primary cultures of mouse dorsal root ganglion (DRG) neurons.

Spinal cords with the sensory ganglia attached were isolated from 12-14 days old fetal mice. The cords were then enzymatically treated, dissociated and maintained in culture. Experiments were performed on cells plated for 3-8 weeks. Only DRG cells were studied because they are known to have larger Ca^{++} currents. Whole-cell recording was done with patch pipettes filled with a HEPES-buffered EGTA solution containing cesium (110mM) and TEA (20 mM). Voltage-clamp (VC) experiments were performed under the discontinuous single electrode VC mode with the Axoclamp amplifier. All experiments were done in the presence of TTX (2μM) at 22°C. To facilitate recording, the growth medium was changed to a HEPES-buffered medium containing TEA (50 or 100 mM), 4-AP (1mM), and $CaCl_2$ (3 or 5mM).

In DRG neurons during current-clamp recording, long duration action potentials (APs > 100msec) could be evoked by short depolarizing pulses at low stimulation frequencies (0.1 to 0.2Hz). Cocaine at 100 and 500μM was found to reduce the duration of the AP by about 65 % and 80 %, respectively. Neurons less than 30μm in diameter were used for VC studies since larger cells displayed axonal Ca^{++} spike which was not adequately clamped. In the majority of the cells examined, at holding potentials of either -40 or -90mV, a slowly inactivating inward current was recorded when depolarizing steps to -30 or -20mV were made. Peak current was obtained by depolarizing to 0mV (see Jia and Nelson, J. Neurophysiol., 56, 1257, 1986). On several occasions, a current of larger amplitude with a more rapidly inactivating time course could be evoked. The amplitude of both the slowly and rapidly inactivating currents were attenuated by cocaine (100 and 500μM). The antagonistic action of cocaine on presynaptic Ca^{++} currents cannot account for the potentiating effects of cocaine on monoamine responses, and may well reflect its local anesthetic action. Experiments are being conducted currently to examine the effects of lower concentrations of cocaine on the Ca^{++} current and on the process of synaptic transmission.

42.4 THE COCAINE BINDING SITE ASSOCIATED WITH DOPAMINE UPTAKE INHIBITION AS LABELED BY ^{3}H-GBR 12935. J. Sharkey* and M.J. Kuhar. Neuroscience Branch, NIDA Addiction Research Center, Baltimore, MD 21224

Recent studies have indicated that the reinforcing properties of cocaine and related compounds are mediated by dopamine uptake inhibition, as defined by ^{3}H-mazindol binding in the rat striatum. (Ritz MC and Kuhar MJ, 1987: Fed. Proc 46(3): 508). However, in addition to labeling dopamine uptake sites, ^{3}H-mazindol also labels norepinephrine and serotonin uptake sites. To further define the mechanisms underlying behavioral reinforcement, we have examined the effects of cocaine and related compounds at the dopamine uptake site using the new and putatively more selective ligand ^{3}H-GBR 12935.

In rat striatal membranes, ^{3}H-GBR 12935 exhibited saturable, high affinity binding (K_D= 0.5 nM; B_{max}=400 fmol/mg tissue). Comparable binding characteristics were also observed within the nucleus accumbens, an area thought to subserve cocaine's reinforcement behaviors in the rat. In these brain areas, ^{3}H-GBR 12935 binding was competitively displaced by mazindol, cocaine and its analogues. Competition studies indicate that the affinities of cocaine, its stereoisomers and 7 structurally-related analogues at the ^{3}H-GBR 12935 binding site significantly correlate with their potencies at the ^{3}H-mazindol binding site and in cocaine reinforced behaviors ($r=0.84$, $p< 0.01$; $r= 0.92$, $p< 0.001$ respectively). This is consistent with the correlation, previously reported, between the relative potencies of these compounds in producing behavioral reinforcement and in displacing ^{3}H-mazindol from the dopamine uptake site.

In summary, 3H-GBR 12935, a more potent and selective dopamine uptake inhibitor than mazindol is similar to mazindol in that it presumably labels the site mediating the reinforcing behaviors of cocaine. Moreover, these data further support the hypothesis that inhibition of dopamine uptake systems underlies the reinforcing properties of cocaine.

42.5 COCAINE INHIBITS QNB BINDING TO MUSCARINIC RECEPTORS IN RAT BRAIN AND HEART. M.C. Ritz*, J. Sharkey* and M.J. Kuhar (SPON: Stephanie Bird). Molecular Pharmacology Laboratory, Neuroscience Branch, NIDA Addiction Research Center, Baltimore, Maryland, 21224

The action of cocaine at monoamine uptake sites has been well established in both CNS and peripheral tissues. However, the effects of cocaine at pre- or postsynaptic cholinergic binding sites have not been well described. The results of current experiments from our laboratory indicate that cocaine binds to muscarinic receptors in rat brain and heart tissues.

^{3}H QNB was used to label muscarinic M_2 in rat heart and brainstem. Tissue homogenates were incubated with 0.1 nM ligand at 37 degrees C. Nonspecific binding was defined by the addition of 5 uM atropine. Drug affinities at these binding sites were determined by analysis of competition curves. (+)- and (-)-cocaine had K_i values of 0.4 uM and 4.6 uM, respectively, in the brainstem. Similar K_i values of 0.57 uM and 3.5 uM were observed for these stereoisomers in the heart. In comparison with its binding characteristis at monoamine uptake sites, cocaine exhibits a reverse stereospecificity at muscarinic receptor sites. This is similar to our previous observation of reverse stereospecificity at ^{3}H hemicholinium labeled choline uptake sites in the brainstem. The affinity of cocaine at choline uptake sites, however, is relatively low and suggests that there is little cocaine binding at these sites at pharmacologically relevant blood concentrations. Cocaine competition at ^{3}H QNB binding sites was not modulated in the presence of 10 uM Gpp(NH)p, indicating that cocaine does not act as an agonist at these sites.

These data represent the first demonstration of cocaine binding to muscarinic receptor sites in cardiac and cerebral tissues. The affinity exhibited by cocaine at these muscarinic sites is similar to that reported for its actions at the adrenergic, serotonin and dopamine uptake sites. Micromolar concentrations have been shown to be pharmacologically relevant and are associated with the psychostimulant effects of cocaine in humans. It is possible that inhibition of muscarinic binding in the heart may be related to the cardiotoxic effects of cocaine.

42.6 COCAINE SUPPRESSES THE ACTIVITY OF NORADRENERGIC AND SEROTONERGIC NEURONS RECORDED FROM MOUSE BRAIN SLICES IN VITRO. K. Knudsen* and M.E. Trulson (SPON: L.L. Keeley). Dept. Anat., Coll. Med., Texas A&M Univ., College Station, TX 77843.

The psychotropic and behavioral effects of cocaine are thought to be mediated by its actions on central monoaminergic neurons, in particular, norepinephrine (NE)-containing neurons in the locus coeruleus (LC) and serotonin (5HT)-containing neurons in the dorsal raphe nucleus (RD). Recent studies have reported that cocaine suppresses the activity of NE- and 5HT-containing neurons in intact, anesthetized rats. However, it is not possible to determine from these studies whether the action of cocaine on the monoamine neurons is direct or indirect. We examined the effects of cocaine on 5HT- and NE-containing neurons recorded from mouse brain slices in vitro. Mice were decapitated and the brains were removed and cut into 400 μm coronal sections. Extracellular unit activity was recorded as previously described (Eur. J. Pharmacol. 124, 1986, 189; Brain Res. Bull., 18, 1987, 179). After obtaining a stable baseline of unit activity cocaine was added to the incubation medium by a nonpulsating exchange pump. Cocaine produced a dose-dependent decrease in the activity of LC cells, with an ED_{50} value of 6.7 μM. The suppression of LC unit activity was reversed by addition of the α_2 antagonist, piperoxane (5 μM) in all cells tested. Cocaine also produced a dose-dependent decrease in the activity of RD neurons, with an ED_{50} value of 4.3 μM. The suppressant effect of cocaine on RD neurons was also reversed by piperoxane in approximately 60% of the cells tested. The suppressant effect of cocaine on both 5HT- and NE-containing neurons persisted in an altered incubation medium containing low calcium (0.5 mM) and high magnesium (10 mM). The suppressant effect of cocaine on 5HT- and LC-containing neurons was rapidly reversible by drug washout. Administration of procaine, at a dose of 10 μM, produced no significant change in the discharge rate of 5HT- nor NE-containing neurons. These data demonstrate that cocaine suppresses the activity of both 5HT-containing RD neurons and NE-containing LC neurons by a direct action on the cells. The effect is not mediated by afferent input to these neurons since most afferents would be severed in the brain slice preparation. Any afferent inputs that may remain intact in the tissue slice preparation are rendered inactive in the low calcium/high magnesium medium. Furthermore, the in vitro slice preparation demonstrates that the changes in the activity of the monoamine neurons is not attributable to altered blood pressure or other physiological variables. The fact that procaine, a structurally related local anesthetic, produced no significant effect on the monoamine neurons indicates that the suppression of unit activity by cocaine is not due to the local anesthetic properties of the drug.

42.7 BENZODIAZEPINE RECEPTOR SUBTYPES AND MODULATION OF ELECTRICAL ACTIVITY IN CORTEX, HIPPOCAMPUS AND OLIVO-RUBRO-CEREBELLAR LOOP OF RABBITS. D.DeMedici* and M. Massotti (SPON:R.del Carmine). Lab. di Farmacologia, Istituto Superiore di Sanita', 00161 - Roma, Italy.

After administration of diazepam (0.1-10 mg/kg iv) and flunitrazepam (0.03-3.0 mg/kg iv), which bind at central BDZ_1 and BDZ_2 and peripheral BDZ receptor subtypes, increase of the amplitude (from 50-100 to 150-200 µV) and decrease of the frequency (from 40-50 to 20-30 Hz) of the electrical activity can be recorded from red nucleus and nucleus interpositus. Clonazepam (0.02-5.0 mg/kg iv), which binds at central BDZ_1 and BDZ_2 receptor subtypes, and the triazolopyridazine derivative CL 218,872 (0.2-10 mg/kg iv), which selectively binds at central BDZ_1 subtypes, both elicit a slight increase of the amplitude (to 80-120 µV) without significantly affecting the frequency in both areas.

At the level of the associative cortex, diazepam, flunitrazepam and clonazepam induce changes of electrical activity consisting of a lengthening (from 0.5-1.0 to 2-4 sec) of the spindle bursts (7-12 Hz; more than 300 µV) and the appearance of 25-30 Hz activity. On the contrary, selective activation of the BDZ_1 receptor subtype by Cl 218,872 induces the above reported modifications of the spindle bursts only.

All drugs also elicit disruption of the hippocampal theta waves. A slowing of the electrical activity emerges with the presence of sharp waves.

Present data would suggest that activation of BDZ_1 receptors modulates the appearance of the spindle bursts in the associative cortex with a limited effect on the activity of the olivo-rubro-cerebellar loop.

The BDZ antagonist Ro 15-1788 counteracts the EEG modifications induced by the highest doses of the various agonists in all brain areas with different potency. Doses of 0.1 and 0.2-0.4 mg/kg iv antagonize the effects of diazepam and CL 218,872, respectively. On the contrary, higher doses (0.4-1.0 mg/kg iv) are required to inhibit the effects of both flunitrazepam and CL 218,872 in all leads.

This work has been supported in part by the CNR contract n. 86.02039.56.

42.8 A NOVEL GABA ANTAGONIST: 1,7-DIMETHYL-6-IMINO-2-THIOXOPURINE. G.J. Patel*, P.C. Harrison*, K.G. Grozinger* and V.B. Ciofalo. Boehringer Ingelheim Pharmaceuticals, Inc., Ridgefield, CT 06877.

Two compounds, 1,7-dimethyl-6-imino-2-thioxopurine (compound A) and 1-methyl-6-imino-2-thioxopurine (compound B) were found to have significant affinity for GABA receptors (IC_{50}'s for displacement of [3H] muscimol = 640 and 220 nM, respectively) in an in vitro rat brain receptor binding preparation. Since a compound interacting at the level of GABA receptors in the brain could be a GABA agonist or antagonist, we selected compound A as representative of the two compounds and conducted the following in vitro and in vivo studies.

Compound A failed to display significant affinity for benzodiazepine, opiate, noradrenaline, dopamine or serotonin receptors in rat brain in vitro receptor binding assays. In in vivo studies, intracerebroventricular (i.c.v., third ventricle) administration of compound A resulted in convulsions in rats ($ED_{50} \leq 2$ µg). Bicuculline, a known GABA receptor antagonist, also produced convulsions in rats when it was administered i.c.v. at similar dose levels ($ED_{50} \leq 2$ µg). Compound A (2 µg, i.c.v.) induced convulsions were completely antagonized by a known GABA-receptor agonist, muscimol (400 ng, i.c.v.) in a preliminary study.

Compound A was also tested for its ability to selectively block muscimol induced contralateral turning in rats after unilateral administration of muscimol into the substantia nigra, pars reticulata (SNR). The contralateral turning is believed to be the result of unilateral stimulation of GABA receptors within the SNR by muscimol. Bicuculline, administered unilaterally into the SNR, has been reported to selectively block this muscimol-induced turning (Arnt and Scheel-Kruger, Psychopharmacol. 62: 267-277, 1979), suggesting that this animal model can be used to test novel GABA antagonists. Compound A (0.5 µg/0.5 µl) administered unilaterally into the SNR 30 minutes after muscimol (25 ng/0.5 µl), completely blocked muscimol induced contralateral turning in rats. Saline (0.5 µl) did not antagonize muscimol-induced turning in rats which lasted for more than 60 minutes. Muscimol treated rats displayed a frequency of 9-16 turns/minute at the time of compound A or saline administration. Collectively, these data suggest that compound A is a novel GABA-receptor antagonist.

42.9 COMPARISON OF TRIOXABICYCLOOCTANE BINDING TO THE PUTATIVE CHLORIDE CHANNEL IN TORPEDO ELECTRIC ORGAN AND RAT BRAIN. R.G. Thompson, D.E. Menking* and J.J. Valdes. Dept. of Environ. Health Sciences, The Johns Hopkins University and Biotech. Div., Chem. Res. Devel. & Engr. Ctr., Aberdeen Proving Ground, MD 21010-5423.

Trioxabicyclooctanes of the structure $X\text{-}(OCH_2)_3\text{-}Y$ represent a class of potent convulsants that are believed to antagonize GABA neurotransmission by blocking the conductance of anions through the Cl^- channel. The most potent of these compounds occur when a phosphorous substituent (P, P=O, P=S) in the X position is coupled with a branched alkyl group ($t\text{-}C_4H_9$, $i\text{-}C_3H_7$) in the Y position. In view of observations that ^{35}S-t-butylbicyclophosphorothionate (^{35}S-TBPS) appears to bind at two different sites in rat brain, we sought to determine and compare the relative potency and selectivity of different bicyclophosphate congeners for displacing ^{35}S-TBPS from both the GABA-independent voltage sensitive Cl^- channels found in Torpedo electric organ and the GABA-A type receptor-gated channels found in rat brain.

^{35}S-TBPS binding in electric organ gave estimates of 2.4 uM and 35.4 pmol/mg protein for the ligand's binding constant and maximal number of binding sites, respectively. The most potent of the bicyclophosphates in displacing ^{35}S-TBPS from electric organ membranes were unlabelled TBPS, with an IC_{50} of 3 uM, and the t-butylphospho-oxide derivative with an IC_{50} of 84 uM. All of the bicyclophosphates proved at least two orders of magnitude less potent than the hexachlorocyclohexane insecticide, lindane, which showed an IC_{50} of 45 nM. In addition, none of the bicyclophosphates were found to affect binding of ^{3}H-PCP to the Na^+ channel in electric organ membrane preparations.

Binding of ^{35}S-TBPS to rat brain membranes yielded an apparent dissociation constant of 150 nM and a maximum of 18.5 pmol bound per gram of original tissue. In contrast to the results obtained in electric organ, the t-butylphosphorothionate and the t-butyl and isopropyl- phosphooxide derivatives appeared equipotent with lindane in displacing ^{35}S-TBPS with IC_{50}s between 366 and 457 nM. GABA was also observed to inhibit ^{35}S-TBPS binding with an IC_{50} of 30 uM and this effect was reversed in a dose-dependent manner by the GABA antagonist bicuculline, which also significantly increased binding when added to the incubation alone. In the reverse situation where the ability of bicyclophosphates to affect GABA receptor binding was assessed, only TBPS in high concentrations (IC_{50}~100 uM) was found to inhibit the binding of ^{3}H-muscimol to rat brain membranes. We conclude that the pharmacological binding profile of voltage-gated channels in Torpedo electric organ is significantly different from the GABA receptor-gated channels in rat brain with the isopropylbicyclophosphooxide providing the best discrimination between them (selectivity index >2000). Further studies are underway in efforts to discriminate between receptor and voltage-gated sites in brain.

42.10 INVOLVEMENT OF GABAERGIC TRANSMISSION IN THE ELECTROPHYSIOLOGICAL EFFECTS OF NICOTINE. R.K. Freund, D. A. Jungschaffer*, and J. M. Wehner. Institute for Behavioral Genetics, Univ. of Colorado, Boulder, CO 80309.

Bath-application of nicotine to submerged hippocampal slices from mice produces an increase in the amplitude of the evoked population spike (PSA) and the appearance of multiple spikes measured in the CA1 pyramidal cell layer (Freund and Wehner, J. Neurogenet., in press). A number of GABA-related agents were used to investigate the possibility that nicotine may interfere with GABAergic transmission to produce these effects in DBA/2Ibg mice. Bath-application of GABA (400 uM) reversed the increase in the initial PSA and abolished the secondary spiking induced by nicotine (800 uM). Similarly, the GABA uptake inhibitor nipecotic acid (1-5 mM) reversed these effects of nicotine. L-C-Allylglycine (4 mM), an inhibitor of GABA synthesis, and bicuculline methiodide (1-8 uM), a GABA receptor antagonist, both produce electrophysiological effects similar to those produced by nicotine. These results suggest that the excitatory effects of nicotine on CA1 pyramidal cells may be mediated at least in part by disrupting inhibitory GABAergic transmission, since agents known to interfere with GABA transmission mimic the effects of nicotine. Furthermore, these effects of nicotine appear to involve a reduction in local GABA levels and not to be direct effects at the level of the GABA receptor, since pharmacological manipulations which should increase synaptic GABA levels resulted in effective inhibition in the presence of nicotine.

42.11 ANTAGONISM BY Ro 15-4513 OF ETHANOL EFFECTS ON GABA-EVOKED RESPONSES IN FROG SPINAL CORD. R. Afar*, A. Sevigny*, P. Polc* & A.L. Padjen. Department of Pharmacology & Therapeutics, McGill University, Montreal, Quebec.

Recent reports demonstrated that Ro 15-4513, a "partial inverse agonist" at GABA-benzodiazepine receptor, antagonizes some effects of ethanol on the central nervous system (Polc, 1985; Suzdak et al., 1986). In the present work, we have examined the interaction of Ro 15-4513 with ethanol effects on GABA-evoked responses on dorsal root ganglia, and on GABAergic and taurinergic synaptic transmission in frog spinal cord. The experiments were done on isolated dorsal root ganglia and hemisected spinal cord of frogs; electrical signals were recorded by sucrose gap technique.

Ethanol (50 - 100 mM) caused a concentration dependent increase of dorsal root ganglion responses to GABA (10 - 100 μM), with a leftward shift of concentration - response curve; at 20 μM of GABA, the increase was 63 ± 15 %, SE, n=8, $p<<0.01$; responses to 1 mM of GABA and taurine on dorsal root terminals were only occasionally increased by ethanol (cf. Padjen et al. 1987). Addition of Ro 15-4513 (100 nM) significantly and reversibly suppressed this increase; e.g. at 20 μM GABA, ethanol increase was attenuated by 22 ± 8 %, SE, n=8, $p<0.05$. Depolarizing effect of ethanol on dorsal root ganglia (up to 1.5 mV) was insensitive to bicuculline and was not affected by Ro 15-4513.

Selective effects of ethanol (100 mM) on synaptic potentials (increase in amplitude and decrease in duration of GABA and taurine mediated dorsal root potentials and suppression of spontaneous activity, cf. Padjen et al. 1987), were inconsistently reversed by Ro 15-4513 (up to 2 μM).

In conclusion, our results demonstrate:

1. Partial reversal of ethanol effects on GABA-evoked responses by Ro 15-4513, in agreement with the hypothesis that GABA-benzodiazepine receptor is a site of ethanol action in the nervous system. 2. Direct depolarizing effect of ethanol on primary afferents appears to be mediated by another site.

42.12 Ro5-4684 AND MIDAZOLAM RELAX AIRWAY SMOOTH MUSCLE IN VITRO: A ROLE FOR A BENZODIAZEPINE PERIPHERAL RECEPTOR IN BRONCHODILATION? D. Raeburn* and L.G. Miller (SPON: D. Kline). Depts. of Pharmacology and Medicine, LSUMC, New Orleans, LA 70112.

A peripheral, non-neuronal benzodiazepine (BZD) binding site or receptor has been described in cardiac muscle and vascular smooth muscle. In these tissues BZDs have Ca^{2+} antagonist-like properties especially at higher (>1 μM) concentrations and it is postulated that a μM affinity BZD receptor may be associated with Ca^{2+} channels in peripheral organs (Holck, M. and Osterrieder, W., Eur. J. Pharmac. 118: 293, 1985). Ro5-4684 is a selective agonist at the peripheral receptor where its actions are blocked by the selective antagonist PK11195 (Le Fur, G. et al. Life Sci. 32: 1849, 1983). We decided therefore to examine the actions Ro5-4684 and midazolam in guinea-pig tracheal smooth muscle to assess their potential as Ca^{2+} antagonists in the airways. Preliminary binding studies using [^{3}H]-Ro5-4684 indicate the presence of a peripheral receptor with a K_D of approximately 4 nM and B_{max} of 6 pmol/mg protein. In tension studies however, no activity was seen for Ro5-4684 at concentrations below 1 μM. Higher concentrations relaxed the airway smooth muscle under basal tone, the effect was augmented significantly ($p < 0.05$) by epithelium removal (pD_2 +EPI, 4.19 ± 0.14; -EPI, 4.42 ± 0.12). Similar results were obtained in tissues precontracted with methacholine. The relaxant effects of Ro5-4684 were antagonised by PK11195 (10 nM - 1 μM) but were unaffected by the central BZD receptor antagonist (Ro151788, 0.1 μM). Midazolam relaxed airway smooth muscle in the same concentration range as Ro5-4684 (pD_2 +EPI, 4.18 ± 0.03; -EPI, 4.38 ± 0.02). PK11195 (0.1 μM) reduced the maximum response to midazolam in -EPI tissues but had no effect in intact tissues. Ro151788 (0.1 μM) was without effect in the presence or absence of the epithelium. In K^+-depolarized tracheal strips bathed in a zero Ca^{2+} solution, the re-addition of Ca^{2+} (0.1 - 2.5 mM) produced a concentration related contractile response. Midazolam (100 μM) significantly ($p < 0.05$) attenuated the response to Ca^{2+} in the K^+-depolarized tracheal strips, the effect was greater at low Ca^{2+} concentrations. The rate of Ca^{2+} entry was reduced by midazolam, the time to half maximum response increasing by 60 to 250% over control. These results indicate a similar profile of activity for BZDs in airway and vascular smooth muscle. The compounds appear to be Ca^{2+} antagonists in airway smooth muscle. However, Ro5-4684 and midazolam may be acting via different mechanisms. If BZDs are Ca^{2+} antagonists then they are not typical as shown by their ability to reduce basal tone in airway smooth muscle, a property not found in the "classical" Ca^{2+} antagonists.

DRUG EFFECTS ON RECEPTORS II

43.1 ION CHANNEL KINETICS FOR TWO POTENT, SEMIRIGID NICOTINIC AGONISTS. C.E. Spivak and J.A. Waters*. Neuropharm. Lab., NIDA Addiction Res. Ctr., Baltimore, MD 21224, Dept. Pharmacol. & Exp. Ther., Univ. of MD Sch. Med., Baltimore, MD 21201; NIADDK, Bethesda, MD 20205.

The mechanism for recognition of an agonist and the consequent opening of the ion channel by the nicotinic receptor is obscure at the molecular level. The kinetics of both steps depend upon the agonist (e.g. Colquhoun, D. and Sakmann, B. J. Physiol. 369:501 1985). Thus, a single transduction process is seen to be composed of four or more kinetic constants, each of which may have independent structure-activity relationships. An understanding of each of these relationships can yield insight into the mechanism of each step.

Semirigid agonists are most useful in probing the mechanism for molecular recognition. Of the semirigid nicotinic agonists, one of the most potent is isoarecolone methiodide (ISO) (Spivak, C.E. et al., Eur. J. Pharmacol., 120:127 1986), which is 50-times more potent than carbamylcholine at the frog neuromuscular junction. In this abstract, we compare this agonist to the analogue, dihydroisoarecolone methiodide (H_2-ISO), which is 9.1-times more potent than carbamylcholine.

Patch clamp records were obtained at junctional regions (only) of dissociated interosseal muscle fibers (Allen, C.N. et al., J. Physiol. Paris, 79:338, 1984) from toes of the frog Rana pipiens. The agonist concentration was 100 nM, and the temperature was 10°C. The effective bandwidth was 7.5 kHz, so gap durations as brief as 40 microseconds were recorded reliably. With both agonists, closed time histograms showed three (major) components, given below as time constants and relative areas (in parentheses):

	ISO	H_2ISO
tau (fast)	0.036 ms (0.51)	0.055 ms (0.43)
tau (med.)	0.78 ms (0.30)	0.78 ms (0.35)
tau (slow)	163. ms (0.19)	510. ms (0.22)

Bursts were defined as open events separated by 3 ms or less. Two components were resolved:

	ISO	H_2ISO
tau (fast)	0.46 ms (0.12)	0.62 ms (0.28)
tau (slow)	7.6 ms (0.88)	10.6 ms (0.72)

These two structurally similar agonists clearly produced similar, though distinctly different effects on gating kinetics.

Events per burst histograms showed two clear geometric distributions, indicating two open states of the ion channel. A five-state cyclic model, therefore, was adopted, and the rate constants were estimated.

43.2 COMPARATIVE EFFECTS OF OXYBUTYNIN (DITROPAN®) AND ITS ENANTIOMERS IN THE GUINEA PIG BLADDER. J.S. Peterson*, D.E. Wilkins*, V.C. Lowe*, J.F. Kachur*, J.P. Carter*, W.J. Rzeszotarski*, L. Noronha-Blob* and R.C. Hanson*. (Spon: W.J. Kinnier). Nova Pharmaceutical Corp., 6200 Freeport Centre, Baltimore, Maryland 21224-2788.

Oxybutynin HCl (OXY), in its racemic mixture form, has been used for many years in the treatment of symptoms related to neurogenic bladder and stress or urge incontinence. Its therapeutic effects have been ascribed to antimuscarinic, antispasmodic and local anesthetic actions. In order to judge the effect of stereochemistry on the biological activity of OXY, it was necessary to resolve the enantiomers. The (+) and (-) optical isomers of OXY were prepared and evaluated in several in vitro assays and in the in vivo cystometrogram (CMG) using the anesthetized guinea pig.

Isomers of OXY were prepared as HCl salts by first resolving cyclohexylmandelic acid and then coupling it to 4-diethylamino-1-hydroxy-2-butyne using Mitsunobo conditions (triphenylphosphine/diethylazodicarboxylate) producing the desired esters in high yield.

Guinea pig bladder detrusor strips were prepared to examine antimuscarinic and antispasmodic activities in vitro against carbachol induced and potassium evoked contractions, respectively. Inhibition of phosphoinositide (PI) breakdown was measured in minced bladder tissue using acetylcholine (100 μM) to stimulate PI turnover. Cystometrograms were performed on urethane anesthetized guinea pigs in vivo to determine peak intravesicular pressure when contracting in response to a slow infusion of saline.

Test ($n \geq 3$; $\bar{x}$ ± S.E.M.)	(+/-)OXY	(+)OXY	(-)OXY
Antimuscarinic; K_b (μM)	.042 ± .01	.557 ± .255	.021 ± .002
Antispasmodic; IC_{50} (μM)	11 ± 2	14 ± 2	12 ± 4
PI breakdown; K_i (μM)	.017 ± 0.8	.654 ± .044	.004 ± .0002
CMG; ID_{50} (mg/kg, i.v.)	0.14 ± 0.03	2.13 ± 0.69	0.10 ± 0.03

Stereoselectivity is evident, (-)OXY > (±)OXY > (+)OXY, for muscarinic receptors in guinea pig bladder while no selectivity was observed for antispasmodic actions. The similar rank order of potency of these compounds in the in vivo assay suggests that muscarinic receptors play an important role in mediating bladder contractions.

43.3 EFFECT OF MONOAMINE UPTAKE INHIBITORS ON NOREPINEPHRINE STIMULATED PHOSPHATIDYLINOSITOL HYDROLYSIS IN RAT CEREBRAL CORTICAL SLICES. M.Mosaddeghi* and R.A.Gonzales, Dept. of Pharmacology, Louisiana State Univ. Med. Ctr., New Orleans, LA 70112.

It has recently been discovered that phosphoinositides are a storage form of molecules that carry signals across the membrane as second massengers in response to extracellular agonists. In brain, neurotransmitter activated phosphatidylinositol (PI) hydrolysis probably plays a role in the regulation of neuronal function. The effect of NE uptake inhibitors cocaine (COC), desipramine (DMI), and nisoxetine on norepinephrine (NE) stimulated PI hydrolysis was investigated. Rat cortical tissue slices were labelled with [^{3}H]inositol and incubated in the presence of 8 mM LiCl and various concentrations of NE and the monoamine uptake inhibitor as described by Gonzales and Crews (J. Neurochem. 45:1076, 1985). All tissue slices were treated with pargyline for 30 minutes during labelling. Labelled tissue slices were incubated with the uptake inhibitor for 10 minutes before stimulation with NE. Norepinephrine stimulated PI hydrolysis was stopped by adding 1.0 ml chloroform-methanol (1:2) solution. [^{3}H]Inositol phosphates were eluted from Dowex 1-X8 with 6 ml of 1.0 M ammonium formate/0.1 M formic acid and radioactivity was determined. Cortical tissue slices incubated with 1 uM and 10 uM COC in the presence of NE caused an increase in the maximum PI hydrolysis by 15 and 30 percent respectively, in addition to a shift to the left of NE dose response curve. The EC50 for NE stimulated PI hydrolysis shifted from 3.82 uM for control to 2.63 and 2.07 uM in the presence of 1 and 10 uM COC, respectively. The potentiating effect of COC was dependent upon the concentration of COC and the level of stimulation by NE with a maximum effect at 100 uM COC in the presence of 0.3 uM NE. The norepinephrine concentration-effect curve was shifted to the right 100-fold in the presence of 0.1 uM prazosin. The potentiating effect of 10 uM COC on NE-stimulated PI hydrolysis was not seen in the presence of 0.1 uM prazosin. Nisoxetine (0.1 uM) caused a significant shift to the left of the concentration effect curve for NE-stimulated PI hydrolysis with a decrease in the EC50 from 2.54 uM for the control value to 1.04 uM with presence of nisoxetine and a 12 percent increase in the maximum response. DMI at concentrations of 0.1 and 1.0 uM did not significantly affect NE-stimulated PI hydrolysis. The negative effect of DMI may be due to its alpha adrenergic blocking properties. These data suggest that some of the central effects of the COC may be mediated through alpha-1 adrenergic receptors. However, the possible interaction between COC and prazosin at pre- or postsynaptic sites is unknown. (Supported by LSUMC BRSG and NIAAA grant AA07223)

43.4 INHIBITION OF BINDING OF [^{3}H] BTX-B TO VOLTAGE-SENSITIVE SODIUM CHANNELS BY CONFORMATIONALLY RIGID 2,4-OXAZOLIDINEDIONES. T. M. DeLorey, G. B. Brown, and W. J. Brouillette, Department of Chemistry and The Neurosciences Program, University of Alabama at Birmingham, Birmingham, AL 35294.

A number of clinically effective anticonvulsants, as well as other classes of pharmacological agents, have been investigated as competitive binders of the voltage-sensitive sodium channel. Especially significant are the findings that the commonly used anticonvulsants diphenylhydantoin (IC_{50}=40 μM) inhibit the binding of [^{3}H] batrachatoxin A 20-α-benzoate ([^{3}H] BTX-B) in rat brain synaptosomes at concentrations consistent with mean therapeutic brain levels. However, the anticonvulsants sodium valproate, ethosuximide, phenobarbital, and trimethadione (3,5,5-trimethyl-2,4-oxazolidinedione) do not alter [^{3}H] BTX-B binding at concentrations up to 1 mM. We examined this effect for a series of synthetic 2,4-oxazolidinediones. We found that 5-ethyl-5-phenyl-2, 4-oxazolidinedione and 5-ethyl-3-methyl-5-phenyl-2,4-oxazolidinedione, like trimethadione, exhibited only slight effects on [^{3}H] BTX-B binding. However, two analogs with conformationally restricted 3- and 5-alkyl substituents, namely 1-aza-8,9-dioxo-7-oxa-6-phenyl-bicyclo [4.2.1] nonane and 1-aza-9,10-dioxo-8-oxa-7-phenylbicyclo [5.2.1] decane, exhibited significant inhibition of [^{3}H] BTX-B binding (approximate IC_{50}=300 and 150 μM, respectively). These results suggest that the correct conformation of side-chain alkyl substituents in these systems may be essential for efficient binding to the voltage-sensitive sodium channel.

In addition, these oxazolidinediones and their analogs were evaluated on their ability to effect GABAergic binding.

Currently, NIH is evaluating these compounds on animal seizure models. With this information it should be possible to establish correlation between compound structure, site of action and efficacy as anticonvulsants.

43.5 **A RAPID SCREENING PROCEDURE FOR THE DETECTION OF COMPOUNDS ACTIVE AT THE VOLTAGE-SENSITIVE SODIUM CHANNEL.** G. B. Brown and J.E. Gaupp*, The Neuropsychiatry Research Program, University of Alabama at Birmingham, Birmingham, AL 35294.

The objective of these studies has been to develop a rapid, reliable and simple screening assay of broad scope and sensitivity for the detection of compounds acting at the voltage-sensitive sodium channel that can accomodate the screening of large numbers of samples. These requirements have been met in the form of an *in vitro* radioligand binding assay in which the binding of [^{3}H]batrachotoxinin-A benzoate (BTX-B) serves as a sensitive indicator of test compound interactions at any of at least five different binding domains on the sodium channel. Previous work from this laboratory and others has shown that binding of [^{3}H]BTX-B is modulated by several other classes of sodium channel toxins and ligands, including α-scorpion toxins, pyrethroid insecticides, local anesthetics and certain anticonvulsants, and the heterocyclic guanidinium channel blockers tetrodotoxin and saxitoxin. Each of these is known to bind to a different site on the sodium channel and, in doing so, to either increase (α-scorpion toxin, pyrethroids) or decrease the affinity for the binding of [^{3}H]BTX-B. Using a radioligand binding paradigm, a tracer amount of [^{3}H]BTX-B is equilibrated with the vesicular synaptoneurosome preparation from rat brain cerebral cortex in the presence of TTX, deltamethrin, and α-scorpion toxin from *Leiurus quinquestriatus*, each at a concentration approximately at the mid-point of the respective dose-response curve for enhancement or inhibition of BTX-B binding. By selecting these particular concentrations, the level of BTX-B binding in control assays is in a delicate balance and highly sensitive to the presence of agents added in test assays which might act at any of these sites. Assay tubes are incubated at room temperature for 1 hr and the samples collected by automatic filtration on a 30-place manifold prior to scintillation counting. To further simplify the practical aspects of the assay, conditions are described by which the synaptoneurosomes may be prepared in bulk and successfully stored in a frozen state at -70°C for up to 4 months. The time required from set-up of the assay to initiation of sample counting is less than two hours with the use of pre-prepared synaptoneurosomes, thus large numbers of samples may be processed easily. This assay should prove to be very useful for programs which require preliminary screening of multiple samples such as might arise in testing of chromatographic fractions from the purification of sodium channel-active agents, screening of panels of antibodies directed against the sodium channel or its ligands, or in the identification of new potentially therapeutic compounds arising from a broad-based synthetic program.

43.6 THE EFFECTS OF BETA-ADRENERGIC ANTAGONISTS ON NEUROMUSCULAR TRANSMISSION IN RAT SKELETAL MUSCLE. JF Howard, Jr., BR Johnson and SR Quint[1]. Dept. of Neurology, Neurobiology Curriculum and [1] Division of Biomedical Engineering, University of North Carolina, Chapel Hill, NC 27514.

Beta-adrenergic blocking drugs are used to treat a variety of medical disorders including hypertension, migraine, glaucoma, hyperthyroidism and angina. Patients with one of the above medical disorders and in addition a neuromuscular disorder have reported symptomatic worsening of strength when treated with beta-blocking drugs. Although much is known about beta-adrenergic blocker action in the central and sympathetic nervous systems, little is known about the effects of these drugs on neuromuscular transmission in skeletal muscle. If beta-blockers reduce the safety factor for neuromuscular transmission then these drugs should be used with caution in those patients whose transmission is already compromised by a disease state. In this study we examined the effects of the beta-blocking drugs atenolol, labetolol, metaprolol, nadolol, propranolol and timolol on neuromuscular transmission in rat skeletal muscle.

Conventional intracellular recording techniques were used to measure end-plate potentials (EPPs) and miniature end-plate potentials (MEPPs) in forearm flexor digitorum longus muscle from adjult rats (T-24-27 deg.C); EPP and MEPP waveform properties and quantal content were analyzed with an on-line computer. At test concentrations from 1-100uM, all drugs produced a dose dependent reduction in the amplitude of both MEPPs and EPPs. Resting potentials of motor end-plate regions were not affected by any drug treatments. The drugs most effective in reducing MEPP amplitude were, in descending order of potency, propranolol, metaprolol, nadolol, timolol, labetolol and atenolol. At the highest test concentration timolol, nadolol and propranolol decreased MEPP rise time while all drugs but atenolol decreased MEPP duration. Atenolol was the only drug to increase MEPP duration. Labetolol produced a large increase in MEPP frequency, propranolol a smaller increase, while atenolol and metaprolol reduced MEPP frequency. The most effective blockers for EPP amplitude were propranolol, timolol, metaprololol, labetolol, nadalol and atenolol, in order of descending potency. Again, at 100 uM all drugs but atenolol decreased EPP rise time and duration. Atenolol had no effect on EPP rise time but greatly increased EPP duration. Propranolol, labetolol and metaprolol decreased quantal content.

Our results demonstrate that different beta-blocking drugs may have reproducibly different pre- and post-synaptic effects on neuromuscular transmission in rat skeletal muscle. These differential effects may be related to the differences these drugs display in their beta-receptor selectivity, agonist activity and/or local anesthetic activity. Although the concentrations we found to affect neuromuscular transmission are higher than those used to treat medical disorders, the effects noted here may be important for patients with diseases such as myasthenia gravis or myasthenic syndrome where neuromuscular transmission is already impaired. Supported in part by NS00941.

43.7 IRREVERSIBLE AGONIST BINDING TO THE ß-ADRENORECEPTOR: EVIDENCE FOR SUSTAINED ACTIVATION. K.M. Standifer, Y. Chida*, J. Pitha*, and S.P. Baker. Dept. of Pharmacology, University of Florida College of Medicine, Gainesville, FL 32610, and GRC-National Institute on Aging, Baltimore MD 21224.

Irreversible antagonists have been shown to be useful probes for the ß-adrenoreceptor. However, it is well known that agonist interactions with the receptor are modulated by a variety of factors, whereas antagonist interactions are not. Therefore, it would be of interest to investigate the effects of an agonist that binds irreversibly to the ß-adrenoreceptor. In the present study, the effects of 2 carbostyril congeners, Carbo-Amine (C-Am) and Carbo-Bromoacetyl (C-Br) were investigated using the rat reticulocyte ß-adrenoreceptor system.

Competitive binding studies using [^{125}I]iodocyanopindolol (ICYP) in the presence of 100 µM guanyl-5'-yl imidodiphosphate gave IC_{50} values of 7.6 ± 0.3, 21 ± 0.6, and 813 ± 66 nM for C-Br, C-Am, and (-)isoproterenol (iso), respectively. The EC_{50} values for adenylate cyclase activation by these drugs was C-Br, 8.1 ± 2.1 nM; C-Am, 17.8 ± 3.1 nM; and iso, 241 ±17 nM. Furthermore, both compounds exhibited the same intrinsic activity as iso. The initial rate of adenylate cyclase activation by 1 µM of C-Br and C-Am and 10 µM iso was blocked with concurrent addition of 20 µM propranolol. If, however, propranolol was added 7 min into the assay, cAMP production by C-Br and C-Am remained linear throughout the 14 min time course, while further cAMP production by iso was immediately blocked.

Pretreatment of membranes with 1 µM of either C-Br or C-Am for 30 min followed by washes showed a 70-92% loss of receptor sites, with no change in the K_D for ICYP binding to receptors remaining. In both cases, receptor loss was prevented by simultaneous addition of 10 µM nadolol with drug, and could not be reversed by the addition of nadolol subsequent to the 30 min incubation. However unlike C-Br treated membranes, C-Am binding was reversed by incubation at 45°C in the presence of nadolol.

This data indicates that the 2 carbostyril congeners are potent full agonists at the ß-adrenoreceptor, and that C-Br appears to be an irreversible agonist.

43.8 BHT-920 IS A FULL AGONIST AT THE D-2 DOPAMINE RECEPTOR IN RAT INTERMEDIATE LOBE. L.D. Artman*, M.S. Ackerman*, R.G. MacKenzie and J.W. Kebabian. Abbott Laboratories, Abbott Park, IL 60064.

The azepine derivative, BHT-920, is an agonist at the alpha-2 adrenoceptor and is reported to act as a dopamine D-2 agonist selective for presynaptic autoreceptors (Anden, N.-E. et al.. Naunyn-Schmiedeberg's Arch. Pharmacol. 321:100, 1982). Recently, BHT-920 was also shown to inhibit acetylcholine release from striatal slices which is indicative of a post-synaptic action at the D-2 receptor (Schmidt, C.J. et al. Naunyn-Schmiedeberg's Arch. Pharmacol. 334:377, 1986).

The present study tested BHT-920 in biochemical models for activation of the two dopamine receptor subtypes, D-1 and D-2 (Kebabian, J.W. and Calne, D.B. Nature, 277:93, 1979). D-1 activation was measured as stimulation of adenylate cyclase in homogenates of fish retina whereas D-2 activation was measured as inhibition of cholera-toxin stimulated adenylate cyclase activity in homogenates of rat intermediate lobe. These dopamine receptors in these tissues are postsynaptic to the dopamine-containing terminals. In addition, binding to the D-2 receptor in membranes from rat neurointermediate lobe (NIL) was studied by competitive binding assays using [125I]-N-(p-aminophenethyl)spiperone to label the D-2 receptors.

BHT-920 was found to be inactive at the D-1 receptor at concentrations up to 100uM. At the D-2 receptor, BHT-920 inhibited cyclase activity to the same extent as the full D-2 agonist (-)-apomorphine (APO) and was only slightly less potent (ED_{50}s:BHT-920 = 235 nm; apomorphine = 158 nM). The BHT-920 effect was not mediated via alpha-2 adrenoceptors because (1) it was reversed by the dopaminergic antagonist fluphenazine but not by the alpha antagonist phentolamine and (2) alpha-2 adrenergic agonists such as clonidine and BHT-933 had no effect on cyclase activity at concentrations up to 100uM. The potency hierarchy established in the cyclase assay was maintained in the binding assay in which APO>BHT-920>>BHT-933. We conclude that BHT-920 is a dopaminergic agonist with high selectivity for the D-2 receptor and question its description as a selective autoreceptor agonist.

43.9 REVERSAL OF ANTICHOLINESTERASE-INDUCED CONTRACTIONS IN ISOLATED TRACHEALIS. S.A. Reutter*+, M.G. Filbert*, D.H. Moore*, and M. Adler. Neurotoxicology Branch, Pathophysiology Division, USAMRICD, APG, MD, 21010-5425

Inhibitors of cholinesterase (ChE) produce profound, sustained contractions of isolated airway smooth muscle, in the absence of any external stimulus. The response is blocked by muscarinic antagonists and is thought to be mediated by accumulation of basally released acetylcholine (ACh) following blockade of ChE (Adler et al., in: Cellular and Molecular Basis of Cholinergic Function, 1987). The present study was designed to investigate the mechanism(s) by which antiChE-induced tracheal contractures can be prevented or alleviated and thus to identify compounds useful for prophylaxis and treatment of tracheobronchial constriction following ChE inhibition. Isometric contractions were recorded from isolated bovine trachealis (mucosa removed) in standard tissue chambers at 37° C. The efficacies of several types of drugs that have been used for clinical or experimental treatment of bronchoconstriction were tested on tissue strips contracted with the organophosphorous compound soman (100 nM) or the carbamate physostigmine (3 uM). Maximal concentrations of the beta-adrenergic agonist isoproterenol (Iso) completely relaxed soman-treated tissues in less than 10 min; the EC_{50} was 2 uM. Theophylline (Theo) was also effective in alleviating soman-induced contractions, but it was considerably less potent, with an EC_{50} of 1 mM. Combined treatment with Theo and Iso was additive. Dibutyryl cyclic-AMP (dBcAMP) (up to 1 mM for 4 h) produced no significant decrement in soman-induced tension. The Ca^{2+} blockers verapamil, nifedipine and diltiazem (1 to 50 uM for up to 1 h) did not produce significant or sustained relaxation in tissues exposed to either physostigmine or soman, but Ca^{2+} blockers did antagonize contractions induced by sub-maximal concentrations of acetylcholine (≤100 nM). Prostaglandin E_2 (10 uM), which has been reported to produce transient, partial relaxation of soman-induced contractions in canine tissue (Moore, D.H. and Hawkins, T., Proc. I.U.P.S., 16:213.24, 1986), had no effect on similarly contracted bovine tissue. Of the compounds tested only Iso and Theo were effective in alleviating contractions induced by ChE inhibitors. The action of Iso is mediated by activation of beta adrenergic receptors. Theo may potentiate such beta responses via inhibition of phosphodiesterase. However, the absence of similar relaxation by dBcAMP suggests that Theo may instead be acting on adenosine receptors. Contrary to their reported efficacy in asthma, Ca^{2+} blockers do not appear to be effective against antiChe-induced contractions.

43.10 Characterization and Localization of [^{3}H]-Clozapine Binding Sites in Rat Brain. E.J. McConnell*, F.M. Filloux*, T.M. Dawson, and J.K. Wamsley. [SPON: B.I. Grosser] Dept. of Psychiatry, Univ. of Utah School of Medicine, Salt Lake City, UT 84132.

Clozapine has been shown to be an effective antipsychotic in European clinical studies. Its exact mechanism of action is currently unknown, but a portion of [^{3}H]-clozapine binding has been shown to be displaceable by the muscarinic agent, atropine, and to a lesser extent by [+]-butaclamol, a dopaminergic antagonist. The authors have used the technique of in vitro receptor autoradiography and membrane homogenate studies to localize and further characterize [^{3}H]-clozapine binding sites in rat brain.

Tissue sections of forebrain corresponding to the striatum, for initial biochemical studies, and from various areas of forebrain for anatomical distribution studies. For routine autoradiographic studies the slide mounted tissue sections were incubated in a 50mM Tris-HCl buffer [pH 7.4] containing 120mM NaCl, 5mM KCl, 2mM $CaCl_2$, 1mM $MgCl_2$ and 1.0nM [^{3}H]-clozapine. Specific binding was assessed by simultaneously incubating adjacent tissue sections in the same solution with the additional presence of 10^{-6}M atropine or 10^{-6}M [+]-butaclamol. Binding displaceable by atropine accounted for 39% of the total binding and that displaceable by butaclamol accounted for 13% of the total. In order to further characterize the nature of [^{3}H]-clozapine binding sites, displacement studies using muscarinic, dopaminergic, serotonergic, benzodiazapine and sigma opiate agents were conducted on whole brain homogenates. Synaptosomal membranes were obtained by centrifugation of homogenized forebrain at 40,000xg. The resulting pellet was resuspended in Tris-HCl buffer and .250ml aliquots of the membrane preparation were incubated in the presence of 1nM [^{3}H]-clozapine. Various displacers at 10^{-6}M concentrations were added followed by rapid filtration and rinsing with fresh buffer. [^{3}H]-clozapine was displaced only by atropine [39%], SCH23390 - D-1 antagonist - [14%], and MJ 14802-1 - a selective sigma opiate agent - [15%][$p<0.01$, $p<0.01$, $p<0.05$ respectively]. The other compounds, including sulpiride [D-2 antagonist], did not significantly displace [^{3}H]-clozapine binding under these conditions. Examination of the autoradiograms revealed the presence of heterogeneously distributed [^{3}H]-clozapine binding sites in several areas of the brain. [^{3}H]-clozapine binding sites were concentrated in basal ganglia structures (i.e. caudate putamen, nucleus accumbens, and olfactory tubercle), hippocampus and cortex.

These results suggest that[^{3}H]-clozapine binds to muscarinic receptors, D-1 receptors and sigma opiate receptors; but not to D-2 receptors in specific brain regions. It is possible to speculate that the antipsychotic action of clozapine is based primarily on its capacity to block sigma opiate receptors rather than D-2 receptors.

43.11 Δ^9-TETRAHYDROCANNABINOL INCREASES ARACHIDONIC ACID LEVELS IN GUINEA PIG CEREBRAL CORTEX SLICES. M. Reichman*, W. Nen*, and L.E. Hokin* (SPON: A.W. Clark) Dept. of Pharmacology, Univ. of Wisconsin Med. School, Madison, WI 53706

Although there is much information on the behavioral and cellular effects of the major active ingredient in marihuana, Δ^9-tetrahydrocannabinol (THC), its mechanism of action remains elusive. There is considerable evidence that THC increases the mobilization of arachidonic acid (AA) in non-neural cell cultures; however, the effects of THC on AA mobilization in CNS preparations with intact synapses have not been examined. To study the effect of THC on lipid metabolism in the mammalian brain, we prelabeled guinea pig cortex slices with [^{14}C]AA and measured changes in the disposition of radioactivity in membrane lipids upon incubation with the psychoactive (-) as well as the non-psychoactive (+) stereoisomers of THC.

Cerebral cortex slices (350 x 350 µm) were incubated with 1 µCi/ml of [^{14}C]AA for 1 hr at 37°C in Krebs-Henseleit bicarbonate saline (KHBS). The labeled slices were washed twice by incubation in 1% BSA in KHBS for 10 min to remove excess label. Prelabeled slices were incubated at 37°C in KHBS in the presence of vehicle or increasing concentrations of THC for 30-120 min. At the end of the incubation, the lipids in the tissue were extracted and the DPM values in the individual phospholipids and neutral lipids were measured following their separation by thin-layer chromatography.

The psychoactive stereoisomer of THC significantly increased [^{14}C]AA levels compared with the vehicle (0.25% dimethylsulfoxide) controls. At 30 min, 8.0 µM (-)THC significantly increased unesterified [^{14}C]AA levels by 42% ± 5%. The level of radioactivity in monoacylglycerol (MG) was elevated 25% ± 5% while the radioactivity in diacylglycerol (DG) and triacylglycerol (TG) decreased by 25% ± 5% and 18% ± 5%, respectively. There were no significant changes in the phospholipids at 30 min. At 1 hr, free [^{14}C]AA levels were elevated 2-fold. The levels of MG increased by 80% ± 5%, and DG and TG levels both decreased by 33% ± 4%. At 1 hr, we observed a loss of label from phosphatidylinositol and phosphatidylethanolamine as well. To determine if the THC-induced stimulation in unesterified [^{14}C]AA was stereospecific, slices were incubated with (+)THC or (-)THC for 1 hr. The effect of (-)THC was dose-dependent and saturable over a range of concentrations between 2 µM and 32 µM. The EC_{50} and maximal response were 4 µM and 12 µM, respectively. Twelve µM (-)THC produced a stimulation of 125% ± 19%. On the other hand, (+)THC was significantly less potent: 8.0 µM (+)THC increased free AA levels by 29% ± 6%. In marked contrast to the saturable effect of the active stereoisomer, the (+)THC-induced increases in free [^{14}C]AA were linear up to 160 µM, which was the highest concencentration tested. At this concentration, free AA levels were increased 3.2-fold.

The stereospecificity of THC in stimulating free AA levels in brain cortex slices and the finding that the effective concentrations were within the range found in plasma at the time of intoxication suggest that the mechanisms underlying cannabinoid action may involve the mobilization of AA from membrane lipid stores.

43.12 EFFECT OF ACETYLCHOLINE ON Ca $^{2+}$- ACTIVATED K^+CHANNELS IN BOVINE CHROMAFFIN CELLS. M. I. Glavinovic, Dept. Anaesthesia Research and Physiology and Biomedical Engineering Unit, McGill University, Montreal, Quebec, Canada.

There is no doubt that synaptic vesicles prepared from cholenergic nerve terminals contain acetylcholine (ACh). Acetylcholine appears also to be stored free in the nerve terminal cytoplasm. During intense electrical nerve stimulation, the cytoplasmic ACh concentration can change substantially with a complex time course (Dunant et. al, Brain Res. 125, 123-140, 1977; Dunant et al. J. Physiol. 325, 441-460, 1982). The cytoplasmic ACh concentration is not known with precision but may be high (Katz & Miledi; Proc. Roy. Soc. Lond., 196, 59-72, 1977). Large conductance Ca^{2+} activated K^+ channels are now known to exist in a variety of membranes including those from secretory cells (chromaffin cells, Marty, Nature, 291, 497-500, 1981; motor nerve terminals, Mallart, J. Physiol., 368, 577-591, 1985). Blockade or activation of such channels by ACh may alter the resting membrane potential and the amplitude as well as the time course of the action potential and hence also the amount of transmitter released by nerve stimulation. This is an attempt to determine whether such an action of ACh on Ca^{2+} activated K^+ channels is present.

Experiments were done on excised inside-out patches from bovine chromaffin cell membranes. The microelectrodes were filled with Locke solution which consisted of (mM): 154, NaCl; 2.2, $CaCl_2$; 1.2, $MgCl_2$; 2.5, KCl; 2.15, K_2HPO4; 0.85, KH_2PO_4; and 10, dextrose. The internal solution contained (mM): 160 KCl/KOH; 10, Hepes; 1.0, $MgCl_2$; 5 EGTA; and 0.382 $CaCl_2$ at pH 72, and nominally had 0.3 µM free Ca^{2+}. When ACh was used in the internal solution, a sufficient amount of 1-M stock solution was added to the standard internal solution, to make the desired concentration. Solutions were changed at the intracellular membrane surface of the patch by placing the recording pipette and attached membrane in a microchamber. Experiments were performed at room temperature (20-23°C).

ACh concentrations ranging from 20 to 200 µM did not alter the probability of the open state (P) of these channels. Higher concetrations (2mM) led to a small (10-15%) decrease of P which was reversed with return to control solution. The amplitude of the single channel currents did not change at any ACh concentration used. There was no evidence of a flickery block either. It is concluded that even large changes in cytoplasmic ACh, that may occur with stimulation and ACh release do not change the current passing through large conductance Ca^{2+} - activated K^+ channels.

43.13 UTILIZATION OF MUSCLE MEMBRANE INPUT RESISTANCE IN THE STRETCHER MUSCLE OF THE SHORE CRAB (PACHYGRAPSUS CRASSIPES) TO CHARACTERIZE IVERMECTIN AND RELATED COMPOUNDS. J.W. Bowman* and D.P. Thompson. The Upjohn Company, Kalamazoo, MI 49001.

The avermectins are a group of naturally occurring macrocyclic lactones, produced by Streptomyces avermitilis, that exhibit potent nematocidal activity. Ivermectin (IVM), 22,23-dihydroavermectin B_1, is the derived commercial product. Preliminary studies indicate IVM's mode of action as potentiating the release and binding of the inhibitory neurotransmitter GABA (gamma-aminobutyric acid) and the subsequent opening of GABA mediated Cl^- channels, leading to a reduction of muscle membrane resistance (MMR) (Wang, C.C. & Pong, S.S., Proq. Clin. & Biol. Res., 97, 373-395, 1982). More recent work indicates that IVM may have a broader mode of action, opening non-GABA mediated Cl^- channels as well (Scott, R.H. & Duce, I.R. Pest. Sci., 16, 599- 604, 1985).

Our lab has developed an efficient assay to monitor MMR in GABA innervated muscle fibers of the shore crab, Pachygrapsus crassipes. We have used this model to "fingerprint" IVM and related compound effects on MMR and specific ionic conductances. The experimental set up utilizes the exposed stretcher muscle from an isolated crab walking leg. Two microelectrodes placed 50µ apart are inserted into an individual muscle fiber. A 500 msec, 100 nA hyperpolarizing current pulse is applied through one electrode and MMR is monitored via the second electrode.

Results show that IVM reduces MMR in a dose dependent manner. At 1 µM, IVM induces a 70% drop in MMR from baseline levels within one min and an 85% reduction by 15 min. Replacement of IVM with Cl^- channel blockers (picrotoxinin or lindane) results in partial recovery of the MMR to 40% of baseline. Other specific channel blockers including tetraethylammonium, 4-aminopyridine, tetrodotoxin, etc. and various ion substituted ringer solutions have been utilized to determine the ionic dependence of IVM action on shore crab muscle. Results of these studies point to the central nature of the Cl^- channel in the action of IVM on this preparation. Additionally, utilizing GABA to desensitize the GABA receptor, our results suggest that IVM may influence non-GABA mediated Cl^- channels as well as those associated with GABA.

Data generated testing IVM analogs reveal that small structural changes of the molecule result in significant loss of biological activity. The nature of these quantitative structure- activity relationships will be discussed.

44.1 DEGRADATION OF "NEW" RECEPTORS INSERTED INTO DENERVATED VERTEBRATE NEUROMUSCULAR JUNCTIONS AND THEIR RESPONSE TO REINNERVATION. S.-L. Shyng* and M.M. Salpeter. Section of Neurobiology & Behavior, Cornell University, Ithaca, NY 14853.

A progressive change in degradation rate of acetylcholine receptors at vertebrate endplates seen after denervation could reflect the combined rates of "original" junctional receptors present at denervation, and "new" receptors inserted into the denervated junction (Levitt & Salpeter, Nature 291:239, 1981). Studies on degradation of original receptors using a gamma-counting technique have shown that for about 10 days after denervation the original receptors retain an 8-day degradation half-life (t1/2) equivalent to that of innervated junctional receptors. Thereafter degradation accelerates to a t1/2 of 2.5 days. Reinnervation reverses the t1/2 of these prelabeled receptors back to 8 days (Salpeter et al., J. Cell Biol. 103:1399, 1986).

Here we determined the degradation rate of new receptors. The gamma counting technique, which assumes uniform distribution of extrajunctional label, could not be used since postdenervation extrajunctional receptors develop preferentially near the endplate. EM autoradiography was used to study only the receptors localized on the postjunctional folds. First we inactivated all original receptors in the sternomastoid muscle of anaesthetized mice by topical application of non-radioactive α-bungarotoxin (BGT). The nerve was cut and ligated to prevent reinnervation. New receptors were similarly labeled with I-125-BGT 6 and 14 days later, and their degradation half-life determined by EM autoradiography. At both times after denervation, these new receptors had a t1/2 of 1 day, when the "original" receptors were degrading with a t1/2 of 8 and 2.5 days respectively. Thus "new" receptors inserted into denervated junctions do indeed degrade as do embryonic or postdenervation extrajunctional receptors. EM autoradiography also shows that new and original receptors are interspersed on the postjunctional membrane.

To determine the effect of reinnervation, we again inactivated all original receptors with cold toxin, and denervated the muscle by nerve crush. To prevent reinnervation until a sufficiently large number of "new" receptors was accumulated, the nerve was re-crushed every second day for 10 days. Two days later, the new receptors were labeled, and their degradation followed by gamma counting. (Gamma counting used here could cause an underestimate of the t1/2 but could not cause degradation to slow down). The new receptors initially degraded with a t1/2 of 1 day (as seen above) and by 6 days after last crush, the t1/2 slowed to 5 days. Fine structure showed reinnervation occurred between 3 and 6 days after last crush. We conclude that, as with original receptors, reinnervation can slow the degradation of new receptors already inserted into the postjunctional membrane. (NIH grant NS 09315)

44.2 IN VITRO BLOCKADE OF NEUROMUSCULAR TRANSMISSION BY MONOCLONAL ANTI-ACETYLCHOLINE RECEPTOR ANTIBODIES. R. Maselli,* B. Jow,* D. P. Richman,* D. J. Nelson.* (SPON: B.G.W. Arnason), Dept. of Neurology, The Univ. of Chicago, Chicago, IL 60637.

We studied the miniature endplate potentials (MEPPs) of the chicken posterior latissimus dorsi (PLD) muscle exposed in vitro to either anti-AChR mAb 370A, which blocks the binding of alpha bungarotoxin (BT) and induces hyperacute experimental allergic myasthenia gravis (EAMG) in chickens or anti-AChR mAb 132A, which has no effect on the binding of BT and does not induce the hyperacute disease. Only PLD muscles exposed to mAb 370A (n=6) showed a decrease in MEPP amplitudes: before mAb exposure, 0.729± 0.02 mV (mean ± SEM of 57 endplates); after exposure, 0.475 ± 0.02 mV (52 endplates) ($p < 0.005$). No reduction of MEPP amplitude was found after exposure of the preparations to mAb 132A (n=4). In addition, we examined the effects of both mAbs on the amplitude and decay phase of endplate currents (EPCs) in fibers which had been previously treated with 2M formamide to block excitation contraction coupling. Results of studies using mAb 370 (n=4) showed a decrease in current amplitude with no change in either reversal potential or the rate of EPC decay. No significant change in current amplitude or rate of decay was observed in the presence of the mAb 132A (n=3). Using a patch pipette internal perfusion technique, we were able to observe channel activation in single cell-attached rat myotube patches in the presence and absence of mAb. Results with mAb 421H, which induces EAMG in chickens and rats, showed a partial block of channel activation and a decrease in mean channel open time when the membrane patch was exposed to mAb (0.05 mg/ml) simultaneously with the cholinergic agonist suberyldicholine (400 nM). Thus, anti-AChR mAbs can produce in vitro reduction of MEPP and EPC amplitudes as well as single channel activity which appears to depend on pharmacologic blockade of the cholinergic binding site. Antibodies of this type may play a role in the disordered neuromuscular transmission in myasthenia gravis.

Supported by NIH Grants GM 36823 and PO1-NS24304.

44.3 LIPID SOLUBILITY AND NOT STEREOSELECTIVITY APPEARS TO DETERMINE BLOCKING KINETICS OF SINGLE ACETYLCHOLINE RECEPTOR CHANNEL CURRENTS. L. A. Merriam and J. E. Fiekers. Dept. Anatomy and Neurobiology, UVM College of Medicine, Burlington, VT. 05405.

Lincosamide antibiotics have been shown to have a direct action on the postsynaptic acetylcholine (ACh) receptor-channel complex during neuromuscular transmission, resulting in voltage- and concentration-dependent alterations of miniature end-plate current (mEPC) and end-plate current (EPC) decay. The two clinically used lincosamides, lincomycin and clindamycin exhibit marked differences in end-plate current decay characteristics: lincomycin produces a current decay which is described by two exponential components, while that for clindamycin can be described by a single exponential. Lincomycin and clindamycin differ in chemical structure at the C-7 position. Lincomycin has an R-hydroxy group at the 7 position, while clindamycin has an S-chloride group which imparts a greater lipid solubility. Voltage-clamp studies of mEPC and EPC decays show that while there was little difference between the channel blocking rates of the lincomycins and clindamycins, the unblocking rates for clindamycin and epiclindamycin were slower than the less lipid soluble lincomycin antibiotics.

In order to examine directly the influence of lipid solubility and stereoselectivity on blocking kinetics of the ACh receptor-channel complex, we have measured ACh-induced single channel currents in the presence of lincomycin and clindamycin and their stereoisomers epilincomyin and epiclindamycin in rat myotubes. Bursts of ACh-induced currents recorded in the presence of lincomycin were interrupted by brief closed gaps due to blocking of the open channel by lincomycin. In contrast, the single channel currents recorded in the presence of clindamycin were shorter in duration than the control currents. This is consistent with the slower unblocking rate for clindamycin seen in end-plate current decay studies. These effects of the lincosamide antibiotics were both concentration and voltage-dependent. High concentrations of clindamycin reversed the voltage-dependence of the mean open time such that at hyperpolarized membrane potentials the mean duration of open channels was less than at depolarized potentials. These data obtained from single channel analysis confirm the results seen in voltage clamped end-plates. The compounds with comparable octanol/H2O ratios exhibited greater similarity in blocking and unblocking characteristics than did the compounds with similar stereospecificity, suggesting that lipid solubility has a greater role than stereoselectivity in determining the kinetics of single channel blockade.

44.4 THE CHANNEL CURRENTS ACTIVATED BY ADENOSINE 5'-TRIPHOSPHATE IN CULTURED XENOPUS SKELETAL MUSCLE CELLS. Yukio Igusa.* (SPON:M.Kimura) Dept. of Physiol., Jichi Med. Sch. Tochigi-pref., Japan,329-04.

At the muscarinic neuromusclar junction, high amounts of adenosine 5'-triphosphate (ATP) are contained in cholinergic synaptic vesicles (Whittaker et.al.,1972;Dowdall et.al.,1974) and ATP and ADP are caused extracellulary by repetitive stimulation of the phrenic nerve of rat(Silinsky,1975),suggesting that ATP with ACh are released from motor nerve ending. Recently it is found that there are cation channels activated by ATP in cultured chicken skeletal muscle cells (Kolb & Wakelam,1983). The purpose of the present study is to investigate whether ATP act to the ACh recepter channels in the nicotinic neuromusclar junction. Single channel currents activated by ATP (10^{-7}-10^{-3} M) and by ACh (0.2μM, 10^{-10} M) were recorded in cultured muscle cells using the cell-attached patch clamp technique at room temperature. Dissociated myotomal muscle cultures were prepared from 19-22 stage embryos of Xenopus laevis. Two types of channel currents activated by 10μM ATP, high conductance (High-γ; 60pS) and low conductance (Low-γ; 42pS), were observed during 1-6 days cultures after dissection. Reversal potentials corrected by -85mV of the resting potential were around -10mV in both currents. Both types of ATP-activated currents were reduced to appear by treatment of 20-50μM d-tubocurarine (Curare). Since these characteristics of ATP-currents were essentialy the same as those of the ACh receptor channel currents in cultured Xenopus muscle cells, it is strongly suggested that ATP activate the nicotinic ACh receptor channel. At 10^{-7}-10^{-5} M ATP, occurrence frequency of both currents increased linearly proportional to the logarithm of the concentration of ATP. Mean open times of both currents were 0.93±0.29ms and 0.86±0.34ms in High-γ and Low-γ currents, respectively. Both values,especially of Low-γ currents, were significantly shorter than those in ACh receptor channels. When the patch was exposed in 10^{-7}-10^{-5}M ATP combined with 10^{-10} M ACh, occurrence frequencies of both currents were higher than those at ATP alone, indicated that ATP and ACh mutually facilitate the opening of the ACh receptor channel. At 10^{-5}M ATP with 10^{-10}M ACh,the patches showed distinct two classses of event occurrence which the frequencies were high (about 23 events/sec) or low (about 1.5 events/sec). Frequencies of channel currents decreased to 1-1.5 events/sec at 10^{-5}-10^{-3} M ATP with or without 10^{-10}M ACh. Two types of channel currents having the same conductances as the ACh recepter channels were also recorded by 0.5mM AMP-PNP. Neither AMP(1-100μM) nor ADP(1-100μM) were effective on the examined muscle cells.

44.5 INTERACTION OF GABA AND GLUTAMATE IN THE GATING OF CHLORIDE CONDUCTANCE IN THE ROSTRAL WHITE CELLS OF APLYSIA. W.M. King and D.O. Carpenter. Wadsworth Laboratories, NYS Department of Health and School of Public Health, University at Albany, Albany, NY 12201.

Rapid microperfusion and voltage-clamp techniques have been used to investigate the effects of gamma-aminobutyric acid (GABA) and l-glutamate (GLU) on the neurosecretory rostral white cells (RWCs) of the parieto-visceral ganglion of Aplysia californica. Ganglia were desheathed surgically after incubation for 30 min in artificial sea water to which sucrose had been added to yield a hypertonic solution with a total osmolarity of approximately 1.7. The neuronal shrinkage so induced greatly reduced damage to the RWCs during desheathing.

In previous investigations we have shown that Cl^- conductances elicited by GABA and GLU in the medial pleural neurons of Aplysia differ in dose-response relations, kinetics of activation and desensitization, and voltage-dependence. Despite these differences, however, prior exposure to GABA could completely block the response to GLU while previous exposure to GLU reduced the response to GABA. In the RWCs we have found the 2 mM GLU elicits a response similar to that in the medial pleural cells, i.e., an initial rapidly activating and decaying inward current that is sensitive to $[Na^+]_o$ followed by a more slowly activating and decaying current that varies with $[Cl^-]_o$ and intracellular Cl^- injection. In both groups of cells the initial inward current varied greatly in amplitude relative to the slower Cl^- current. In contrast, GABA, which elicits Cl^- current in the medial pleural cells with a threshold concentration of 1-3 micromolar, was without effect at a 100 micromolar concentration in the RWCs. At this concentration GABA could completely block the Cl^- current response to GLU in the medial pleural cells but had no effect on the response to GLU in the RWCs. Dose-response experiments, however, revealed that higher concentrations of GABA elicited large desensitizing Cl^- conductance in the RWCs with a threshold concentration of 1-3 mM. In addition, exposure to 10 mM GABA completely blocked the response of the RWCs to 2-10 mM GLU, while exposure to 10 mM GLU reduced their response to GABA to approx. 50% of control. Thus, the responses of the RWCs to GABA and GLU as well as their interactions were similar to those in the medial pleural cells except that the dose-response curve for GABA was shifted to the right. For each group of neurons both activation and cross-inhibition occurred within the same dose range while that dose range differed between the groups for GABA but not GLU.

(Supported by NIH Grant NS 18435)

44.6 PROPERTIES OF $GABA_A$-ACTIVATED CONDUCTANCE IN RAT LOCUS COERULEUS NEURONS IN VITRO. S. S. Osmanovic and S. A. Shefner. Department of Physiology and Biophysics, University of Illinois College of Medicine, Chicago, IL 60680.

Effects of gamma-aminobutyric acid (GABA) on rat locus coeruleus (LC) neurons were studied in a totally submerged brain slice preparation under current- and voltage-clamp conditions. GABA was applied in known concentrations (10 μM-2 mM) in the bath or by pressure ejection from a micropipette located near the recording site. GABA increased conductance, inhibited spontaneous firing and hyperpolarized or depolarized the membrane depending on the internal Cl^- concentration. The mean reversal potential for the GABA-induced changes in membrane potential (E_{GABA}) was -72 mV in cells impaled with K-acetate microelectrodes (n=20) and -48 mV in cells impaled with KCl electrodes (n=15). E_{GABA} was shifted in a depolarizing direction when the external Cl^- concentration was reduced as predicted by the Nernst equation (about 55 mV per ten-fold change in external Cl^-). The GABA concentration-conductance curve was sigmoidal with an apparent EC_{50} of 330 μM (n=25 cells). Bicuculline (10-40 μM) and bicuculline methiodide (40-100 μM) antagonized GABA-induced effects and shifted concentration-conductance curves to the right (n=9).

GABA currents elicited by short (5-100 ms) pressure pulses from pipettes containing GABA (1-10 mM) decayed with an exponential time course which could be fitted by a single exponential in most LC neurons. GABA-induced currents were voltage-dependent and showed outward rectification as indicated by a decrease in the slope of the I_{GABA}/V relation with membrane hyperpolarization. The magnitude of the GABA-induced conductance change was decreased by membrane hyperpolarization and increased by depolarization. The conductance change measured at the peak of the GABA-induced current was linearly related to the membrane potential, decreasing two-fold per 40 mV hyperpolarization. Furthermore, the time constant of decay of the GABA-induced current was increased by depolarization and decreased by hyperpolarization. The voltage dependency of GABA-induced currents was observed both in cells impaled with KCl and K-acetate microelectrodes, which indicates that this phenomenon can not be due to changes in intracellular Cl^- concentration due to leakage from the recording electrode.

We conclude that GABA increases Cl^- conductance in LC neurons through activation of bicuculline-sensitive ($GABA_A$) receptors. The voltage dependency of this GABA-activated Cl^- conductance suggests that changes in membrane potential can significantly alter the extent of GABA-mediated inhibition of LC neurons.

44.7 SPATIAL DISTRIBUTION OF GABA RECEPTORS AT THE TIME OF THEIR APPEARANCE ON SPINAL NEURONS DIFFERENTIATING IN CULTURE. Greg L. Harris and Nicholas C. Spitzer. Department of Biology, University of California, San Diego, La Jolla, CA 92093.

Spinal neurons of *Xenopus* embryos differentiate in dissociated cell culture and are useful for studies of the development of neurotransmitter sensitivity. Cultures contain sensory, motor and interneurons (Spitzer & Lamborghini, 1976; Bixby & Spitzer, 1984; Lamborghini & Iles, 1985) and cells are initially insensitive to γ-aminobutyric acid (GABA), glutamate (Glu) and glycine. During the first day in culture they become sensitive to one or more of these neurotransmitters (Bixby & Spitzer, 1984). The present study examines the spatial localization of the initial expression of GABA sensitivity, with respect to the cell soma, outgrowing neurites and growth cones.

Dissociated cell cultures were prepared from the neural plates of embryos at stage 15. Neurons begin to extend processes after 6 hrs (Spitzer & Lamborghini, 1976), corresponding to the time of initial neurite extension *in vivo* and were studied at times ranging from 6 to 32 hrs after plating. An intracellular electrode in the soma was used to record changes in membrane potential and input resistance following the application of GABA or Glu (50-100 μM) to the soma, neurites or growth cones. Focal application was achieved by pressure ejection of neurotransmitter from fine tipped micropipets (<1 μm tip diameter). The lengths of neurites examined ranged from 15-185 μm. Application of KCl to neurites revealed that depolarizations could spread passively and were easily detectable at sites 185 μm from the soma.

At early stages of development, only 25% of neurons responded to GABA (6-9 hrs; n=12); these cells were sensitive on their cell bodies but not along their neurites or at their growth cones. Between 9 and 12 hrs, 60% of neurons responded to GABA (n=27); 40% of these were sensitive only on the soma, and 60% were sensitive both on the soma and along their processes. Sensitivity of the growth cone was always accompanied by sensitivity of the full extent of the neurite, at this and subsequent stages of development. By one day in culture, 80% of neurons responded to GABA (20-26 hrs; n=10) and 90% of these were sensitive over their entire surface. At later times, all neurons responded to GABA (26-32 hrs; n=13) and 90% of these were sensitive over their entire surface.

These cultures contain neurons that respond to GABA with an exotic cation-selective depolarization (putative sensory neurons), as well as those which respond to Glu and exhibit the more common chloride-selective hyperpolarizing response (probable motor neurons; Bixby & Spitzer, 1984). Responses obtained from different points along a neurite were the same, with respect to the neurotransmitter to which the membrane was sensitive and the polarity of the response to GABA. Furthermore, both neurites of bipolar cells exhibited the same sensitivities.

These results are consistent with a temporal and spatial gradient for the acquisition of GABA sensitivity, which begins in the cell soma and spreads rapidly along the neurites and to the growth cones. We are presently characterizing more fully the acquisition of GABA sensitivity at the level of single receptor channels.

44.8 NERVE GROWTH FACTOR POTENTIATES BRADYKININ INDUCED RELEASE OF CALCIUM FROM INTRACELLULAR STORES IN PC12 CELLS. A. Bush, L. Borden*, A. Rukenstein*, L.A. Greene, F.R. Maxfield*. Dept. of Pharmacology, N.Y.U. Medical Center, New York, NY 10016.

Although calcium is known to be a critical determinant of neuronal function, little is known about the release of Ca^{2+} from intracellular stores in neurons (For review see McBurney, R. Neering, I. TINS, 1987, 10, 164). We have been studying this process in the PC12 neuronal cell line. When PC12 cells are exposed to bradykinin (bk), a nine residue neuropeptide, phospholipid turnover is activated. Inositol trisphosphate (IP_3) is released into the cytosol where it subsequently stimulates Ca^{2+} release.

Untreated PC12 cells were plated on polylysine-collagen coated glass coverslips attached to 35mm culture dishes and loaded with Fura-2AM. All Ca^{2+} measurements were conducted at room temperature (23-27°) since we have found that the cells remove the dye rapidly at higher temperatures. Groups of 10-20 PC12 cells were examined using a Leitz Diavert microscope spectrofluorometry system. Bath application of bk produces a dose dependent increase in cytosolic $[Ca]_i$; the EC-50 is approximately 50 nM. The average peak increase in Ca^{2+} (peak minus resting) is approximately 400 nM. Resting $[Ca]_i$ is 37 nM ± 2 nM; n=75 (mean ± S.E.M.). The peak response is generally attained within the first 20 seconds after bk addition followed by a steady return towards baseline. Two minutes after application of 10 nM bk, most cells have reestablished a $[Ca]_i$ level within 20% of prestimulation baseline. The release of Ca^{2+} does not require extracellular Ca^{2+}.

NGF treatment enhances the potency of bk. A large enhancement was seen when cells were cultured in the presence of NGF for 1-3 weeks. The EC-50 for bk was reduced to 5nM while the maximal increase in Ca^{2+} elicited by a saturating dose was unchanged. In addition, one hour preincubation with NGF augmented the response. After one hour preincubation with NGF at 37°, the average maximal increase in response to 10nM bk was 250nM±25; control (bk alone, no NGF) was 107nM±25. After one hour preincubation at 24°, the increase in response to 1nM bk was 163nM±31; control was 44nM±15. Under our conditions, NGF by itself did not affect $[Ca]_i$.

Preliminary experiments suggest that NGF sensitizes Ca^{2+} release neither by up-regulating bk receptors nor by generating greater amounts of IP_3. Preincubation of cells with NGF for one hour at 37° does not significantly change [^{3}H]bk binding (1 and 10 nM). Although NGF alone appears to slightly stimulate phospholipid turnover, there is no potentiation of the IP_3 generated by bk.

44.9 SENSITIVITY OF CULTURED SPINAL NEURONS TO PRIMARY SENSORY TRANSMITTERS, MONITORED BY INTRACELLULAR CALCIUM. M.D. Womack*[1], A.B. MacDermott, and T.M. Jessell (SPON: A. Calof). Center for Neurobiology and Behavior and Howard Hughes Medical Institute, Columbia University, New York, NY 10032; [1]Department of Neurobiology, Harvard Medical School, Boston, MA 02115.

Dorsal root ganglion (DRG) neurons that terminate in the dorsal horn release transmitters that elicit fast and slow epsp's in spinal cord neurons. The transmitter mediating fast epsp's is probably l-glutamate while several neuropeptides may mediate slow epsp's. Transmitters co-released from sensory neurons may act on the same subset of post-synaptic spinal cord neurons. However the consequences of activation of excitatory amino acid and peptide receptors on neurons in the spinal cord have not been well defined.

Peptide agonists have been shown to cause release of calcium from intracellular stores in many non-neuronal cell types. We have, therefore, studied the effect of sensory neuropeptides on intracellular calcium concentration, $[Ca^{2+}]_i$, in spinal cord neurons using the fluorescent indicator Fura-2 and have compared the changes in $[Ca^{2+}]_i$ in response to peptides and to l-glutamate. Neurons were isolated from either the whole spinal cord or the dorsal horn of embryonic or newborn rats by enzymatic dissociation and plated onto a monolayer of cortical astrocytes in supplemented F12 medium. After 3-14 days in vitro, neurons were incubated with Fura-2 AM (2 μM) for 10 min. at 37°C. The fluorescence of single neuronal somata was measured on an inverted microscope fitted with a photomultiplier. The excitation wavelength was alternated between 350 and 380 nm by means of a motorized filter changer operating at 0.5 Hz and the 350/380 ratio was used to determine $[Ca^{2+}]_i$.

In individual cultures, between 10 and 70% of Fura-2-loaded spinal cord neurons exhibited spontaneous oscillations of $[Ca^{2+}]_i$ which were inhibited by 1 μM TTX. Application of l-glutamate (50-100 μM) by pressure ejection (0.5-1.5 sec., 1.5 psi) resulted in a rapid increase of $[Ca^{2+}]_i$ in about 80% of neurons tested. The $[Ca^{2+}]_i$ rose to a concentration of about 1 μM then recovered to resting levels in 10-15 seconds. A lower proportion (15-20%) of spinal cord neurons responded to substance P (SP) (100 nM) (3-5 sec, 1.5 psi). Responses to SP varied with increases in $[Ca2+]_i$ ranging from less than 500 nM to greater than 1 μM with the duration of enhanced $[Ca^{2+}]_i$ ranging from 15 to 40 seconds. Other peptides released from DRG neurons also enhanced $[Ca^{2+}]_i$ in spinal neurons. Neurokinin A (100 nM) evoked increases in $[Ca^{2+}]_i$ in about 20% of neurons examined; over 80% of these neurons also responded to SP. GRP and CCK (100 nM) and enhanced $[Ca^{2+}]_i$ in a smaller percentage of spinal neurons.

These observations indicate that i) spontaneously released transmitters and exogenous application of l-glutamate and peptides increase $[Ca^{2+}]_i$ in cultured spinal neurons, ii) a higher percentage of neurons respond to l-glutamate than to peptides, and iii) the duration and magnitude of changes in $[Ca^{2+}]_i$ elicited by l-glutamate and peptides vary considerably.

44.10 A ROLE FOR PHOSPHATIDYLINOSITOL (PI) TURNOVER IN THE MUSCARINIC BLOCKADE OF THE M-CURRENT IN HIPPOCAMPAL PYRAMIDAL CELLS. P. Dutar and R.A. Nicoll, Depts. of Pharmacol. and Physiol., Univ. of Calif., San Francisco, CA 94143.

In hippocampal pyramidal cells, the cholinergic agonist carbachol (carb), acting on muscarinic receptors, has 4 distinct actions. At low concentrations (1 μM) it depresses EPSPs by a presynaptic action, depolarizes the membrane potential, and blocks the afterhyperpolarization (AHP) which follows a series of action potentials; at 10-fold higher concentrations it blocks the K^+ current termed I_M. However, little is known concerning the coupling of the muscarinic receptors to these 4 responses. The goal of the present experiments was to differentiate these responses pharmacologically and to determine the nature of the coupling.

Conventional intracellular current-clamp or single electrode voltage-clamp recordings were obtained from CA1 pyramidal cells in rat hippocampal slices. Cholinergic drugs were added to the superfusing medium. For intracellular administration the recording electrode was filled with 3M KCl plus inositol trisphosphate (IP_3) (60 mM), EGTA (200 mM), or BAPTA (200 mM).

Cholinergic agonists have been classified according to their ability to stimulate PI turnover in the brain (Fisher et al., J. Biol. Chem., 258:7358, '83). We therefore tested the ability of these agonists to elicit the muscarinic responses. Carb (n=23) and oxotremorine-M (oxo-M) (n=13), which are full agonists for stimulating PI turnover, completely blocked I_M at 20 μM and also completely blocked the AHP, depressed EPSPs, and depolarized the membrane potential at 1 μM. On the other hand, although arecoline (n=5), pilocarpine (n=9) and oxotremorine (oxo) (n=8), which are weak agonists for stimulating PI turnover, had effects comparable to carb on the membrane potential, AHP, and EPSP, they had little effect on I_M. In fact, in agreement with the biochemical studies, oxo antagonized the action of carb and oxo-M on I_M.

The activation of PI turnover leads to the formation of diacylglycerol (DG), which activates C-kinase, and IP_3 which can release Ca^{++} from intracellular pools. In accord with previous experiments (Malenka et al., J. Neurosci., 6:475, '86), activation of C-kinase with phorbol esters failed to block I_M. On the other hand intracellularly applied IP_3 caused a dramatic and reproducible depression of I_M (n=22), but failed to affect I_Q, an anomalous rectifier current. Finally muscarinic blockade of I_M was unaffected by chelating intracellular Ca^{++} with EGTA or BAPTA, indicating that a rise in intracellular Ca^{++} is not required for this response.

In conclusion, these results strongly suggest that stimulation of PI turnover is involved in the muscarinic suppression of I_M, but may not be required for the other actions of carb seen at lower agonist concentrations. Furthermore, we suggest that IP_3 or one of its metabolites mediates the muscarinic blockade of I_M.

44.11 CONTROL OF M-CURRENT IN DIALYSED SYMPATHETIC GANGLION NEURONS. P.J. Pfaffinger. Physiol & Biophys, U Wash, Seattle, WA (Spon: B Hille).

Muscarinic and t-LHRH control of M-current were studied in isolated frog sympathetic ganglion neurons using a whole-cell voltage clamp. M-current was recorded for long periods of time in cells dialysed with solutions containing Mg-ATP. Using no ATP or using ATP derivatives APP(NH)P or ATPγS caused spontaneous loss of M-current, suggesting that a functional M-current channel is a phosphoprotein. M-current was shut off reversibly with muscarine or t-LHRH added to the bath; the protease inhibitor leupeptin added to the intracellular solution enhanced the sensitivity and stability of this response. The role of a GTP-binding protein was tested. GTP was not a required ingredient in the internal solution; nevertheless, addition of the known G-protein activators GTPγS (at 50 μM) or fluoride (10 mM NaF or KF) spontaneously and irreversibly shut off the M-current. At lower GTPγS concentrations with added GTP (1 μM:100 μM; 5 μM:100 μM), muscarine or t-LHRH were required to produce an irreversible shutoff of the M-current. These experiments strongly suggest the involvement of a G-protein. The irreversible action of GTPγS was not prevented by 5 mM BAPTA, thus a long term Ca rise is not obligatory for G-protein action. This G-protein is not of the G_o or G_i type: First, activation by GPP(NH)P is poor. Dialysis with 100 μM GPP(NH)P did not shut off the M-current spontaneously. Addition of muscarine or t-LHRH did shut off M-current more than usual, but on washout the response reversed about 75%. Finally, overnight applications of Pertussis toxin (IAP at 0.1 μg/ml) had no effect on muscarinic or t-LHRH shutoff of M-current. In addition, no labeled substrate could be seen after ^{32}P-NAD/IAP labeling of solubilized membranes, suggesting that little to no IAP-sensitive G-proteins exist in these cells. Other experiments using the putative G-protein antagonist GDPβS produced paradoxical results. GDPβS can both block the response and give irreversible responses. This might be explained by variable enzymatic phosphorylation of the GDPβS inside the cell creating an irreversible GTP analogue. Unlike microelectrode studies, with long applications of muscarine or t-LHRH the shutoff of M-current was not sustained (7% of the M-current returned per min). This rate seems too slow to be explained by Ca buffering (1 mM EGTA or 5 mM BAPTA). Such desensitization occurred whether the cell had been dialysed only 5 min or 25 min; perhaps the agonist liberates some component that dialyses away. Finally, we tested the possible role of Protein Kinase C. The phorbol ester PMA (1 μM) produced an irreversible 50% loss of M-current when applied to the bath. PMA was slightly more effective with 200 nM Ca_i solutions. Subsequent addition of 1 μM t-LHRH on top of the PMA completely shut off the M-current. When t-LHRH was washed out, the M-current returned to the 50% level. These results suggest that the G-protein activated pathway cannot be entirely mimicked by PMA. Supported by NIH #NS08174 and the ARCS Foundation.

44.12 INOSITOL TRISPHOSPHATE ACTIVATES K^+ CHANNELS THROUGH ELEVATION OF INTRACELLULAR CALCIUM IN PEPTIDERGIC NEURONS OF APLYSIA. L. Fink*, J.A. Connor and L.K. Kaczmarek. Depts. Pharmacology and Physiology, Yale Univ. Sch. Med., New Haven, CT 06510 and Bell Labs, Murray Hill, NJ 07974.

Stimulation of a 30 minute discharge in the bag cell neurons of Aplysia is accompanied by increased production of water soluble inositol phosphates. We investigated the effect of inositol trisphosphate (IP3) on the intracellular calcium concentration of these neurons in Ca^{2+}-containing and Ca^{2+}-free media, and have characterized the effects of IP3 on their excitability.

Isolated bag cell neurons growing on glass coverslips were loaded with the calcium indicator fura-2 by pressure injection. Fluoresence (475-525 nm) of single neurons was measured with a CCD-based imaging system. Localized calcium concentrations were estimated from the ratio of fluorescence images taken at 340 and 380 nm excitation. Pressure injection of IP3 (0.8mM in 0.6M KCl) through a microelectrode for 1-15 seconds produced a significant increase in the calcium signal which recovered 1-2 minutes after injection. IP3-induced elevation of cytosolic calcium was also observed when cells were bathed in Ca^{2+}-free medium, indicating that the rise in calcium occurred through release from intracellular stores rather than entry across the plasma membrane. Injection of 0.6M KCl had no effect. The localization of calcium released by IP3 differed from that evoked by trains of action potentials. The rise in calcium produced by IP3 injection was localized to the soma, whereas action potentials produced dramatically increased calcium levels primarily in the neurites.

We also examined the electrophysiological consequences of IP3 injection. We reported previously that brief injection of IP3 hyperpolarizes the bag cell neurons, and that this response is accompanied by a conductance increase (Fink et al., Soc. Neurosci. Abstr. 11:854, 1985). This effect is mimicked by direct injection of calcium ions and is blocked by TEA. To investigate the basis of this IP3-induced hyperpolarization at the single channel level, bag cell neurons in culture were impaled with an IP3 containing microelectrode and also sealed to a patch pipette for cell-attached patch recording. IP3 injection produced a dramatic increase in the probability of opening of a channel passing outward current at rest and at more positive potentials. This channel had a slope conductance of ~50 ps and an extrapolated reversal potential close to E_K. Channel activity increased 2-5 seconds after a 1 second injection and returned to baseline within approximately 1 minute. Injection of calcium elicited similar increases in channel activity. In cell-free patches, exposing the cytoplasmic side of the membrane to IP3 did not affect the opening of this channel, but channel openings did increase with application of calcium. Our data is consistent with the hypothesis that IP3 activates a Ca^{2+}-dependent K^+ channel through an elevation of intracellular calcium.

Preliminary work shows that at least one additional channel is also modulated by IP3. In 4 experiments, IP3 injection led to the increased opening of a channel passing inward current. It is not yet known if this channel is modulated directly by IP3 or by elevated intracellular calcium.

44.13 **TRANSLOCATION AND ACTIVATION OF PROTEIN KINASE C IN STRIATAL NEURONS IN PRIMARY CULTURE.** S. Weiss, J. Ellis, D. Hendley*, and R.H. Lenox. Neuroscience Research Unit, Department of Psychiatry, University of Vermont, Burlington, VT 05405.

Reports from many laboratories have indicated that diacylycerol produced during phosphoinositide (PI) metabolism activates protein kinase C (PKC). Tumor-promoting phorbol esters are also able to bind to and activate PKC. The increase in PKC activity may provide negative feedback to receptors coupled to PI metabolism. We have been studying these processes in striatal neurons in primary culture. The preparation is maintained as a monolayer that is >93% neuronal; thereby, diffusional barriers and complexities due to contributions from non-neuronal cells are minimized. In these cells, both carbachol (EC_{50}, 80 μM) and epinephrine (EC_{50}, 200 nM) cause a marked increase (5- to 10-fold) in PI hydrolysis. However, treatment of the cells with the active phorbol ester PDBu reduces the efficacy of both agonists; in a 20 min incubation, half-maximal reduction is achieved at 100 nM PDBu. These observations have prompted us to evaluate the actions of several agents on translocation and activation of PKC in these neurons.

For studies of PKC activity, striatal neurons (maintained for 7-10 days in vitro) are incubated with appropriate agents for 20 min, rinsed, harvested, homogenized, and centrifuged to yield membrane and cytosolic fractions. The activity of PKC in the two fractions is measured as the ability to transfer the terminal phosphate of γ-[^{32}P]ATP to histone, by a filter-binding assay. A centrifugation method is used to measure the binding of [^{3}H]PDBu to the membrane fraction. We have found 12 μM 1-stearoyl-2-arachidonoyl-glycerol to be more effective than 100 nM PDBu in activating PKC in the cytosolic fraction, although these respective concentrations of the two substances are equally effective at stimulating membrane-bound PKC. Pretreatment of cells with 1 μM PDBu for 20 min results in a shift of PKC activity from the cytosol to the membrane, such that the activity in the membranes is increased by 240%; the binding of [^{3}H]PDBu to the same membranes is also increased (by 250%). Pretreatments with 1 mM carbachol or 100 μM 1-oleoyl-2-acetyl-glycerol lead to smaller increases in the binding of [^{3}H]PDBu to the membrane fraction (32% and 37%, respectively).

Supported by grants PHS RO1 AG05214, PHS RO1 MH41571, NSF-VT EPSCoR Project 5 grant, and a grant from the Cummings Memorial fund of the American Federation for Aging Research. S.W. is a fellow of the Medical Research Council of Canada.

44.14 **CHRONIC LITHIUM ALTERS THE PKC-MEDIATED PHOSPHORYLATION OF AN 83kDa PHOSPHOPROTEIN IN THE RAT HIPPOCAMPUS.** R.H. Lenox, D.D. Hendley,* J. Ellis and Y. Ehrlich. Neuroscience Research Unit, Dept. of Psychiatry, Univ. of Vermont, Burlington, VT 05405.

Protein Kinase C (PKC) is one of two major classes of calcium dependent protein kinases known to exist in a variety of cell systems including the brain. This protein phosphorylation system has been shown to be involved in multiple cellular functions including cellular proliferation and regulation of neurotransmitter release and receptor activation. Receptor mediated hydrolysis of phosphoinositides liberates diacylglycerol, known to be a potent activator of PKC. Since chronic lithium has been shown to significantly alter the phosphoinositide metabolites in brain, our laboratory has initiated a series of studies to examine the effect of chronic lithium administration on PKC activity in rat hippocampus.

Male Sprague Dawley rats (150-175g) were administered a lithium diet (40mM kg/60mM kg) for three weeks and were matched to animals receiving a control diet. Following sacrifice by decapitation the brain was frozen in liquid nitrogen and hippocampus was dissected free. Plasma and brain concentrations of lithium were determined using atomic absorbtion spectrophotometry (emission mode). Cytosolic and membrane fractions were isolated from hippocampus by centrifugation. PKC activity was determined as the incorporation of [^{32}P] from the terminal phosphate of γ-[^{32}P]ATP into endogenous proteins of each fraction in the presence and absence of phosphatidylserine (PS) and a phorbol ester (PDBU) at 1μM free calcium. Quantitation was carried out using scanning laser densitometry of autoradiograms following SDS-PAGE.

Brain and plasma concentrations of lithium were 1.23±.05 meq/kg (n=5) and 1.33±.09 meq/l (n=5) respectively. Studies in our laboratory under similar conditions demonstrated no evidence for an alteration in the distribution of PKC activity between cytosolic and membrane fraction in the hippocampus of animals receiving chronic lithium. However, we now report a significant reduction in the in-vitro phosphorylation in the presence of PS/PDBU of a protein band with an apparent MW 83kDa in the cytosolic fraction of hippocampus from chronic lithium animals. Our data indicate this phosphoprotein band to be one of the most active substrates for PKC in the cytosolic fraction of the hippocampus. This phosphoprotein appears to be similar to that reported by Wu et al. (PNAS 79:5249, 1982) which has been shown to be a substrate for PKC, is phosphorylated in response to depolarization induced calcium influx, and may be related to neurotransmitter release.

Supported in part by PHS RO1 MH41571.

44.15 CONTINUATION OF Ca^{2+}/CALMODULIN-DEPENDENT PHOSPHORYLATION IN THE SYNAPTIC JUNCTION AFTER Ca^{2+} ELIMINATION. T. Suzuki[1*], T. Fujii[2*], and R. Tanaka[1*] (SPON: R. S. Aronstam). 1, Dept. of Biochemistry, Nagoya City Univ. Med. Sch., Nagoya 467, Japan; and 2, Dept. of Functional Polymer Science, Fuculty of Science and Technol., Shinshu Univ., Ueda 386, Japan

Synaptic junction (SJ) isolated from rat cerebrum contained independent protein kinase activity: SJ phosphorylated intrinsic proteins even in the absence of cAMP or Ca^{2+} plus calmodulin (CaM) exogenously added. The activity was affected neither by Ca^{2+} concentrations in the physiological range nor by the addition of specific ligands such as glutamate, aspartate, acetylcholine, and concanavalin A. The activity was not due to cAMP-dependent protein kinase in SJ, since the activity was not inhibited by an inhibitor protein for cAMP-dependent protein kinase, and since synapsin I was not specifically phosphorylated, whereas cAMP-dependent kinase appeared to phosphorylate selectively the protein in SJ. The apparent K_m for ATP was estimated to be 700 µM. Proteins of 16K Mr and 117K Mr were specifically phosphorylated under the basic condition (in the absence of the substances known to activate specifically protein kinases), and the other 6 proteins, both under the condition and in the presence of Ca^{2+} plus CaM. The phosphorylation of 150K Mr, 60K Mr, 51K Mr, and 16K Mr SJ proteins was enhanced after pre-phosphorylation of SJ proteins by intrinsic kinase in the presence of Ca^{2+}plus CaM. The fact suggest that a part of the independent kinase activity is attributable to the autonomous form of Ca^{2+}/CaM-dependent kinase which is derived from the autophosphorylation of the kinase, and that the Ca^{2+}/CaM -dependent autophosphorylation continues even after the elimination of Ca^{2+} from the postsynaptic region and affects the microtubules in the postsynaptic region inasmuch as 16K Mr protein occurs in both the brain cytosol and microtubule protein fraction prepared from rat brain. The continuation of Ca^{2+}/CaM-dependent type phosphorylation in SJ (or postsynaptic density, PSD) may represent a Ca^{2+}-triggered molecular switch (Miller, S. G. and Kennedy, M. B., Cell, 44, 861, 1986) and may modulate neuronal transmission, especially in posttetanic potentiation, long-term potentiation, and memory and learning.

44.16 EFFECT OF ALUMINUM FLUORIDE ON INOSITOL PHOSPHATE GENERATION IN GH_3 CELLS: COMPARISON WITH THE EFFECT OF TRH. L. Grandison and D. Bruno*. UMDNJ-Robert Wood Johnson Medical School, Piscataway, N.J. 08854-5635.

Aluminum fluoride (AlF_4) acts on Gs, a guanine nucleotide binding protein with the resultant activation of adenylate cyclase. A similar interaction between fluoride and the guanine nucleotide binding protein that associates with phopholipase C has also been reported in several tissues and indicates that AlF_4 increases polyphosphatidylinositol hydrolysis. The effect of fluoride on inositol phosphate generation was characterized in GH_3 cells and its action was compared to that of TRH. Cultures of GH_3 cells were incubated with ^{3}H myo-inositol for 36 hrs. The cells were then suspended, centrifuge, incubated in a balanced salt solution with lithium chloride (10 mM) for 15 mins., centrifuged, and incubated with treatments in the presence of lithium chloride for varying times. The incubation was terminated by addition of perchloric acid and the samples were neutralized and fractionated by Dowex 1-X8 resin prior to scintillation spectrometry. Sodium fluoride induced a dose dependent (1-10mM), time related (1-30 mins.) increase in inositol phosphates (IP_1, IP_2, and IP_3). This response was not blocked by pertussis toxin pretreatment but was diminished by prior treatment of cells with PMA, a phorbol ester. TRH and bombesin also induced inositol phosphate generation in GH_3 cells. The combination of TRH and bombesin at maximal doses (1 µM) produce greater (but not additive) stimulation than that produced by either receptor ligand alone. AlF_4 induced a 2 to 4 fold greater increase in inositol phosphates than that produced by TRH, bombesin or the combination of TRH plus bombesin. Addition of TRH or bombesin plus AlF_4 produced no greater stimulation than that produced by AlF_4 alone. In summary AlF_4 produces maximal stimulation of polyphophatidylinositol hydrolysis in GH_3 cells unlike its reported action in several other cell types where plasma membrane receptor ligands are found to be more effective. Consequently, AlF_4 may be a useful stimulus for studying inositol phosphate generation and metabolism in GH_3 cells.

44.17 EFFECTS OF HYPOXIA ON BASAL AND CARBACHOL-STIMULATED PHOSPHOINOSITIDE TURNOVER IN RAT HIPPOCAMPAL SLICES. S. Leventer*, J. Corey*, E. Wulfert* and I. Hanin (Spon.: P. Rowell). Loyola Univ. Stritch Sch. of Med., Maywood, IL 60153 and UCB s.a. Pharmaceutical Sector, Brussels, Belgium.

The receptor-stimulated hydrolysis of phosphoinositides is thought to be an important event mediating neuronal signal transduction. Hypoxia, in vivo and in vitro, has been shown to alter phospholipid metabolism. The purpose of the present investigation was to study the effects of hypoxia on phosphoinositide turnover in rat hippocampal slices in vitro.

Rat hippocampal slices (0.5 mm) were preincubated (60 min, 37°C) in Krebs-Ringer bicarbonate buffer (KRB) bubbled with 95% O_2/5% CO_2. The slices were then washed, and placed in KRB containing 0.3 μM [^{3}H]inositol. After 30 min of incubation, the slices were again washed and placed in KRB containing 10 mM LiCl to block the hydrolysis of [^{3}H]inositol-1-phosphate (IP). This buffer was bubbled either with 95% O_2/5% CO_2 or 95% N_2/5% CO_2, and, in some experiments, contained carbachol (10^{-5}M-10^{-3}M). After 60 min of incubation, as an index of phosphoinositide turnover, accumulated [^{3}H]IP was determined, with only slight modifications, as described by Berridge et al. (Berridge M.J., Downes C.P. and Hanley M.R., Biochem. J. 206:587-595, 1982). In addition, in some experiments, in order to investigate the effects of prior hypoxia on subsequent phosphoinositide turnover, the 60 min preincubation period was split into two 30 min periods. During the second 30 min preincubation period, slices were bubbled with 95% N_2/5% CO_2 or 95% O_2/5% CO_2.

In the absence of carbachol, 0.56% of the accumulated [^{3}H] was present as [^{3}H]IP. Direct hypoxia had no effect on basal [^{3}H]IP levels. Carbachol (10^{-5}, 10^{-4}, and 10^{-3}M) increased the amount of [^{3}H] present as [^{3}H]IP to 154%, 336%, and 554% of control, respectively. In the presence of 95% N_2/5% O_2, these percentages decreased to 136%, 177%, and 234% of control, respectively. Prior hypoxic exposure greatly decreased the total amount of [^{3}H] subsequently accumulated by the slices, but had no effect on the percentage of [^{3}H] present as [^{3}H]IP under basal or carbachol-stimulated conditions.

In summary, prior exposure to hypoxia may reduce subsequent [^{3}H]inositol uptake by hippocampal slices. In addition, direct hypoxia has little effect on basal phosphoinositide turnover. In contrast, carbachol-stimulated phosphoinositide turnover is greatly reduced by direct hypoxia. These changes in phospholipid metabolism may be involved in the mediation of hypoxia-induced tissue damage. Supported by UCB s.a. Pharmaceutical Sector, Brussels, Belgium.

44.18 CEREBRAL INOSITOL-1-PHOSPHATE AND EXTRACELLULAR AMINO ACIDS DURING CONVULSIONS INDUCED BY MICRODIALYSIS PERFUSION OF THE RAT DEEP PIRIFORM CORTEX WITH CARBACHOL. K.M. Savolainen[1]*, J.V. Wade[1]*, S.R. Nelson[2], F.E. Samson[3], and T.L. Pazdernik[1], Department of Pharmacology, Toxicology and Ther.[1], Department of Anatomy[2], and Ralph L. Smith Research Center[3], University of Kansas Medical Center, Kansas City, Kansas 66103, U.S.A.

In order to study the relationship of cholinergic convulsions to brain phosphoinositide (PI) turnover and amino acid transmitters, the extracellular amino acids within the rat deep piriform cortex (DPC) were measured during microdialysis perfusion of carbachol with subsequent determination of brain IP_1 concentrations. Rats were pretreatd with saline or LiCl (5 mEq/kg) 24 hr prior to carbachol perfusion. Dialysis fibers were perfused (1 ul/min) with Krebs-Ringer bicarbonate (KRB) for a 2 hr baseline period, then switched to carbachol (1 or 5 mM) or maintained on KRB (control) for an additional 2 hr. Effluent perfusate samples were analyzed for amino acids with HPLC. Gas chromatography was used to analyze brain IP_1 in bilateral DPC, frontal cortex, piriform cortex, and midline cerebellum. In saline pretreated rats, the low dose of carbachol (1 mM) induced mild clonic convulsions in 1/4 rats, whereas 4/4 rats had clonic convulsions with the high dose of carbachol (5 mM). With LiCl pretreatment, all rats (5/5) had clonic convulsions after the low dose of carbachol. In saline pretreated rats, no changes in regional IP_1 levels (range 0.32-0.42 mmole/kg dry weight) or amino acid concentrations occurred after the low dose of carbachol. However, the high dose of carbachol induced a 7-fold increase of IP_1 levels in the ipsilateral DPC, and a 4-fold increase in extracellular aspartate levels. With LiCl pretreatment, basal IP_1 levels increased to 3.5-4.2 mmole/kg dry weight and the low dose of carbachol produced a further 1.85-fold elevation of IP_1 in the ipsilateral DPC. Extracellular aspartate concentrations increased slightly in these LiCl pretreated rats. However, no major changes occurred in the other amino acids, or in the concentrations of brain IP_1 in other brain regions after carbachol in saline or LiCl pretreated rats. Thus, local application of carbachol into the rat DPC, unilaterally, induces generalized clonic convulsions and this response is potentiated by LiCl pretreatment. Moreover, increased PI turnover, as indicated by IP_1 levels in the ipsilateral DPC, and increased extracellular aspartate concentrations, are associated with carbachol-induced clonic convulsions elicited from the rat DPC. Therefore, increased PI turnover and release of aspartate into extracellular fluid may be involved in carbachol-induced clonic convulsions. Supported by Fogarty International Research Fellowship F05 TWO 3632 and U.S. Army DAMD 17-83-C-3242.

POSTSYNAPTIC MECHANISMS II

45.1 A FAST INHIBITORY POSTSYNAPTIC POTENTIAL IN CAT BLADDER PARASYMPATHETIC GANGLIA. E. Kumamoto*, M. Nohmi* and P. Shinnick-Gallagher (SPON: H. Rudenberg). Dept. of Pharmacology and Toxicology, Univ. of Texas Medical Branch, TX 77550.

In parasympathetic ganglia of the cat urinary bladder neurons respond to a single orthodromic pulse with a fast excitatory postsynaptic potential (f-EPSP) mediated through nicotinic receptor activation. Recently, we have observed two types of responses to orthodromic stimulation: one having only a f-EPSP (type SI, n=20) and the other, a f-EPSP followed by fast inhibitory postsynaptic potential (f-IPSP; type SII, n=41).

The f-IPSP had a duration comparable to that of the afterhyperpolarization (AHP) following an orthodromic spike. In type SII cells, the half-maximum duration (HMD) of the AHP following an orthodromic spike was longer than that of a direct spike (elicited with a depolarizing current injected through the recording electrode); in type SI cells, these durations were comparable. It appears that the f-IPSP contributes to the time course of the AHP following an orthodromic spike.

The f-EPSP - f-IPSP sequence was blocked completely and reversibly by nicotinic receptor antagonists (hexamethonium and d-tubocurarine). Antagonists of muscarinic, alpha-2 noradrenergic, and purinergic receptors, had no effect on the f-IPSP. Thus, the f-EPSP and the f-IPSP are nicotinic responses.

There was no correlation between the amplitudes of the f-EPSP and the f-IPSP recorded consecutively in type SII cells. The appearance of the f-IPSP was not dependent on the presence of a f-EPSP. In type SII cells, spontaneous EPSPs were not followed by a hyperpolarization. Depolarizing the membrane (by passing cathodal current through the recording electrode) to an amplitude comparable to that of a f-EPSP also did not elicit a membrane hyperpolarization in type SII cells. In addition, stimulating one nerve trunk induced a f-IPSP, but activating another nerve trunk innervating the same neuron did not.

Increasing the stimulus strength applied to the presynaptic nerve trunk potentiated the amplitudes of the f-EPSP and the f-IPSP. The f-IPSP was not associated with appreciable changes in input resistance. When the membrane was hyperpolarized, the amplitude of the f-EPSP increased, but that of the f-IPSP decreased. This decrease in f-IPSP amplitude was attributed in part to anomalous rectification at hyperpolarized membrane potentials. A reversal potential for the f-IPSP was not observed.

These results are consistent with the hypothesis that the f-IPSP is due to passive decay of the AHP following an action potential generated by acetylcholine released from nerve terminals in a region remote from the soma, probably the distal dendrites. Supported by NS16228.

45.2 SYNERGISTIC INTERACTIONS AMONG IDENTIFIED CENTRAL SYNAPSES. D.S. Faber and H. Korn, Dept. Physiology, SUNY, Buffalo, NY 14214 and INSERM U261, Institut Pasteur, Paris.

We previously suggested, on the basis of a pharmacological study, that the conductance change produced in the teleost Mauthner (M-) cell by synchronous activation of a pool of inhibitory interneurons is greater than the sum of this cell's responses to impulses in the individual presynaptic units (Korn, H. and Faber, D.S., Soc. Neurosci. Abst., 9:456, 1983). To further test this hypothesis we have paired inhibitory postsynaptic responses due to stimulation of 1) a single presynaptic interneuron and 2) the contralateral eighth nerve at a weak stimulus strength which excited neurons in the inhibitory pool other than the one activated intracellularly. The conductance changes (g_{ipsp}) were quantified, according to equations described earlier (Faber, D.S. and Korn, H., J. Neurophysiol., 48:654, 1982), on the basis of either the reduction of the M-cell's antidromic action potential, or, in Cl^--loaded cells, from measurements of depolarizing inhibitory postsynaptic potentials (IPSPs), The unitary response was timed to occur at, or one to two msec later than, the peak of the eighth nerve evoked inhibition. In approximately half of the experiments, the inhibition evoked when the two stimuli were paired was greater than the sum of their individual effects (i.e. $g_{VIII+unit} > g_{VIII} + g_{unit}$). The enhancement, defined as the percent increase in inhibitory conductance beyond that predicted on the basis of linear summation, ranged from 11 to 46% (m=29%, SD=13%, n=7). This effect occurred when only a few cells were activated by the eighth nerve, since the inhibitory conductance produced by stimulating this nerve alone was at most 7 times that due to direct activation of a single interneuron.

Arguments against a presynaptic mechanism for this synergism include: i) the absence of axo-axonic contacts on terminals of these interneurons, ii) its short latency, and iii) previous findings that field effects do not alter the magnitude of transmitter release. However, these observations are consistent with a postsynaptic mechanism. For example, adjacent boutons may have overlapping postsynaptic receptor domains (Faber et al., PNAS, 82:3504, 1985), with the enchancement occurring as the transmitter, glycine, spreads to the fringes of neighboring synaptic regions. If so, quantal size would be increased under these conditions and the hypothesis that its invariance is due to receptor saturation at some central synapses (Jack, et al., J. Physiol., 321:65, 1981) would be ruled out for this system.

45.3 SYNAPTIC ACTIVATION OF CA1 PYRAMIDAL CELLS DURING BLOCKADE OF VOLTAGE-SENSITIVE SODIUM AND POTASSIUM CHANNELS. M.D. Mauk & J.D. Kocsis. Depts. of Neurology, Yale Medical School and VA Medical Center, Palo Alto, CA 94303.

Current pulses delivered to the stratum radiatum of the hippocampus (CA1) activate presynaptic fibers which in turn synaptically activate the dendrites of pyramidal cells. In hippocampal slice preparations, bath application of tetrodotoxin (TTX;0.5 uM) abolishes these responses by blocking voltage-sensitive sodium channels. We have found that when 1) voltage-sensitive sodium channels are blocked by TTX, 2) potassium channels are also pharmacologically blocked (with TEA & 4-AP, 5.0 & 0.5 mM) and 3) relatively long current pulses are used (0.1-0.4 msec), responses are elicited with two distinct components. Both components involve local sink currents as revealed by extracellular field potentials, and a large (20-30 mV) depolarization of pyramidal cells as revealed by intrasomatic recordings. The initial component of the field potential has a relatively long latency to onset, a duration of 15-25 msec, and an amplitude of 0.5 to 1.5 mV. This is followed by a second component of similar amplitude but longer duration (150-500 msec).

Subsequent experiments suggest that both components are produced by synaptic activation of pyramidal cells. The responses are abolished by the addition of calcium channel blockers (Co^{++}, Mn^{++},Cd^{++}). They are absent in slices in which the pyramidal cells have been killed by isolation of the stratum radiatum, indicating no contribution from presynaptic activity (e.g. presynaptic calcium). The postsynaptic depolarizations are sodium-dependant in that they are reversibly abolished by application of zero-sodium solutions. Finally, direct activation of pyramidal cells may be excluded by the long latency of the responses which increases linearly with conduction distance with a propagation rate of 0.05 m/sec. Thus, these responses appear to involve sodium-dependant, excitatory postsynaptic potentials in the pyramidal cells.

The initial component is insensitive to the excitatory amino acid receptor antagonist kynurenic acid and to the NMDA receptor antagonist APV. However, the second component is greatly attenuated by kynurenic acid, moderately attenuated by APV and completely abolished by both, indicating glutamate is the neurotransmitter mediating the second component.

These data indicate that when voltage-sensitive sodium and potassium channels are pharmacologically blocked in hippocampus, presynaptic fibers may be activated in a manner that promotes transmitter release and occasions postsynaptic depolarization of pyramidal cells. Furthermore, this activation appears to propagate slowly down the length of the presynaptic fibers. This situation may permit the study of hippocampal synaptic physiology in the absence of voltage-sensitive sodium and potassium conductances.

45.4 IDENTIFICATION OF COMPONENTS OF EVOKED COMPOSITE EPSPs in CA1 HIPPOCAMPAL PYRAMIDAL NEURONS. D.A. Turner, Dept. of Neurosurgery, VAMC and University of Minnesota, Minneapolis, MN 55417.

Dendritic afferents onto CA1 pyramidal cells were stimulated at low intensity (< 10 μA) during intracellular recording in vitro. The resulting composite EPSPs were digitized at high resolution and amplitude histograms of the EPSP peak and noise were calculated. A number of these histograms demonstrated clearly separated peaks (by more than 1.5-2.0 noise standard deviation (nsd) units), often including failures. The EPSP component of each histogram peak was identified by a subgroup average of only those responses falling within a certain voltage range. The variance, time course and probability of each component was compared to other components and to the entire composite EPSP ensemble. The quantal content was calculated under several assumptions (variance, failures and co-efficient of variation (CV), to assess the applicability of Poisson statistics.

Thirty-four EPSP ensembles (out of 84 cells) demonstrated clearly separable peaks, failures and components with a CV less than 0.2. Fourteen ensembles showed only failures and a single component, 12 had 2 components and failures and 8 had 3 or more components. The separation between components was highly statistically significant due to the small standard deviation around each component. Most components within an ensemble showed similar EPSP waveform characteristics but some components were clearly different in terms of risetime or halfwidth values. The spacing between components averaged 0.46±0.19 mV (n=69), compared to the average nsd value of 0.22±0.08 mV. In a few instances the components were stable on increased afferent stimulation, but the probability of components clearly shifted to larger amplitudes and fewer failures of response. The quantal content values for the smallest components ranged from 1 to 9 by the variance method, but these values were much lower than the quantal content calculated by either failures or CV (assuming Poisson statistics).

These results show that components can be identified in small EPSPs in CA1 pyramidal cells, with a number of EPSPs fluctuating only between failures and 1 or 2 states. However, the spacing between components was uneven, the statistics clearly did not fit standard Poisson assumptions and in many instances the components appeared to originate from different dendritic sites. Thus, each component or histogram peak may represent a single synaptic site or cluster of nearby sites, with its own characteristic voltage at the soma and a certain probability of occurrence. The identification of components may be helpful in pinpointing dendritic origin and in searching for changes at an individual site or cluster of sites.

45.5 A COMPARISON OF THE CURRENT SOURCE DENSITY (CSD) PROFILES THROUGH IN VITRO SLICES OF RAT HIPPOCAMPUS AND VISUAL CORTEX IN RESPONSE TO SYNAPTIC ACTIVATION OF DISTAL APICAL DENDRITES. A.T.Perkins,IV*, L.J. Cauller* and T.J. Teyler. Dept. of Neurobiology, N.E. Ohio Univs' College of Medicine, Rootstown, OH.

In vitro slices of rat hippocampus and visual cortex were prepared as previously described (Shaw and Teyler, Br. Res., 243:35, 1982). Extracellular evoked field potentials were recorded at regularly spaced points (50 or 100um separation) by sequential penetrations across a vertical tract, perpendicular to pyramidal cell body layers. Afferent pathways were activated by discrete electrical impulse stimulation (75um, gold-sputtered, concentric bipolar electrodes; 100us biphasic pulses).

In hippocampal slices, stimulation was applied at least 0.5mm horizontal to the recording tract to either stratum oriens to activate basal dendrites, or distal stratum radiatum to activate distal apical dendrites. As reported previously (Cauller, et al., Neurosci. Abst. 11:505, 1985), synaptic input did not cross cell body layers into other dendritic branches (ie. from basal to apical) unless stimulation was sufficiently strong to evoke a somatic population spike (SPS). Such suprathreshold activation generated a somatofugal sink that ascended from the SPS into apical dendrites at a velocity of approximately 0.1 m/s. Distal stimulation generated a similar somatopetal travelling sink that descended from the level of synaptic input to distal apical dendrite toward the cell body layer at about the same velocity. These travelling sinks are thought to reflect active spikes propagating along the apical dendrites of pyramidal neurons.

Somatofugal sinks were observed to ascend from middle to superficial layers in cortical slices following stimulation of subcortical white matter at a velocity of approximately 0.05 m/s. Such ascending sinks are a common finding of cortical CSD studies whether evoked by peripheral or intracranial stimulation (Mitzdorf, Physiol. Rev 65:37, 1985; Vaknin, et al., Neurosci. Abst. 11:505, 1985). We have observed somatopetal sinks, travelling at about the same velocity, that descend from superficial to middle layers following stimulation of layer I at least 0.5 mm horizontally.

These observations of somatopetal and somatofugal sinks have been incorporated into a general model of cortical sensory processing. The possibility that cortical processing in general involves active dendritic spikes that transmit information between the cell body and distal dendrites is considered and methods to test this hypothesis will be discussed.

45.6 **PHYSIOLOGICAL RECORDINGS FROM HUMAN HIPPOCAMPAL SLICES.** H.L. Haas*, R.W. Greene, M.G. Yasargil* and V. Chan-Palay. Depts. of Neurosurgery and Neurology, Univ. Hosp., Zurich 8091, Switzerland.

We have recorded from in vitro slices prepared from hippocampi immediately after removal, by unilateral hippocampamygdalatomy in patients with intractible temporal lobe epilepsy. The collection and use of these tissues in this research are consistent with NIH guidelines for the use of human tissues and approved by the Ethics Committee. Slices were studied in perfusion chambers for periods up to 15 hours. Field potentials, in particular the population spikes following electrical stimulation of afferent fibers to the CA1 and area dentata were recorded. Paired pulses revealed excitation and, more prominently, inhibition of the test pulse. This may be attributable to the anti-epileptic treatment of the patient from which the hippocampi were taken. Spontaneous epileptiform discharges were not observed. Tetanization (100-400 Hz for 40 to 1000 ms) was followed by a comparatively small post-tetanic potentiation and occasionally by long-term potentiation (LTP) or a long lasting depression of the synaptically evoked population spikes. Intracellular recordings of high quality were obtained from 11 CA1 and 3 dentate neurones. With potassium chloride filled recording electrodes, epsp-ipsp sequences consisted of an early large depolarizing and a late hyperpolarizing component. LTP of this potential was demonstrated in two cells. In the presence of TTX, slow (calcium) spikes were observed and enhanced by the addition of 10mM TEA to the medium. The following neuroactive substances were tested: D,L-homocysteic acid (1mM bolus application) depolarized 2 cells by 15 mV and increased the synaptic potential. Carbachol (1uM) depolarized one cell by 3 mV, decreased the conductance by 12.5 %, blocked the accommodation of firing during depolarizing current injection, and reduced the synaptic potential. Serotonin (10 uM) hyperpolarized one cell by 6 mV and increased the membrane conductance by 50 %. This action was followed by a rebound excitation and block of accommodation. Baclofen (5uM) hyperpolarized one cell by 6 mV and increased conductance by 25 % (measured at the resting voltage, -69 mV). Adenosine (10-100uM) hyperpolarized 3 cells by 6,7,10 mV and caused an outward current of 150 pA (1 cell, 10 uM). Long lasting afterhyperpolarizations, accommodation of firing and an outward tail current after depolarizing voltage jumps were enhanced. Neurons were identified and their precise hippocampal locations verified in each slice by histological methods. Neurons in CA1 of the human hippocampus and dentate area display properties typical for hippocampal neurons as previously described by recordings from slices of non-human species. The results are remarkable in showing the consistency in basic physiological cell function in similar brain regions in phylogeny, despite the inherent increase in hippocampal network complexity that is evident in humans. This emphasizes the validity of animal models in cellular neurophysiology. Supp. in part by US AFOSR 86-0176 and SNF 3002.0.84.

45.7 PROPERTIES OF SUBTHRESHOLD EPSPs IN RAT NEOCORTICAL NEURONS. B. Sutor and J. J. Hablitz. Sect. of Neurophysiol., Dept. of Neurol., Baylor Col. of Med., Houston, TX 77030

Cortical neurons have been reported to possess excitatory postsynaptic potentials (EPSPs) that are mediated in part by receptors for the excitatory amino acid agonist N-Methyl-D-aspartate (NMDA). The evidence for an NMDA-mediated EPSP was an unusual voltage sensitivity and blockade by magnesium and APV. However, little attention was given to the influence of the rectifying properties of cortical neurons. We have further examined properties of EPSPs in neocortical neurons.

Neocortical slices were prepared from rats using standard techniques. Intracellular recordings were made from layer II-III neurons using K-acetate filled pipets. Bipolar stimulating electrodes were placed in layer IV-V and stimuli were applied at 0.1-0.4 times the value needed to evoke an action potential. Hyperpolarizing current steps were used to measure input resistance (Rin) as the membrane potential (MP) was changed with DC current.

Subthreshold stimulation evoked an EPSP which was free of IPSP contamination as determined from analysis of effects of changing MP. EPSP amplitude was 2-4 mV and was unchanged by varying frequency from 0.1-2.0 Hz. EPSP amplitude and duration decreased with hyperpolarization (RMP = 78 +/-4 mV) due to an accompanying decrease in Rin and membrane time constant. Depolarization by 10-15 mV caused in increase in Rin and a slight increase in EPSP amplitude and duration. Further depolarization, below threshold for action potentials, led to decreases in EPSP amplitude. Concentrations of D-APV (10-20 µM) which blocked direct NMDA responses did not affect the unusual voltage dependence of the EPSP. Slight increases in stimulus strength evoked a late depolarizing potential occurring on the falling phase of the initial EPSP. This second EPSP disappeared at stimulus frequencies greater than .4 Hz and was sensitive to D-APV. This component partially resembles an NMDA-mediated synaptic potential but did not have the same voltage dependence as direct NMDA responses. Bursts of high frequency stimulation produced sustained increases in the late synaptic potential which resembled long-term potentiation in other brain regions. APV blocked the induction of this increase and, when applied after induction, reduced enhanced EPSPs.

These results indicate that a variety of subthreshold EPSPs can be evoked in neocortical neurons and display use-dependent plasticity. It also appears that NMDA-mediated contributions to EPSPs are present in voltage ranges where they are often assumed to be blocked by magnesium. Since apparent changes in EPSP amplitude and time course can result from changes in intrinsic membrane properties, we are currently using voltage clamp techniques to study cortical EPSPs. (Supported by NS-22373.)

45.8 PAIRED SHOCKS INDUCE A VERY HIGH AMPLITUDE FACILITATION OF LATE EPSPs IN DEEP NEURONS IN PIRIFORM CORTEX. G.-F. Tseng and L. B. Haberly. Dept. of Anatomy, Univ. of Wisconsin, Madison, WI 53706.

Cells in layer III of the rat piriform (olfactory) cortex and the underlying endopiriform nucleus have been studied with combined physiological-anatomical methods in 500µm thick, transverse slices maintained in vitro. Physiological properties of neurons were studied by intracellular recording with micropipettes containing either 4M KAcetate or 8% Lucifer Yellow in 0.5M Li_2SO_4. The morphology of cells was studied after iontophoresis of Lucifer Yellow either by fluorescence microscopy or by conventional light microscopy after processing with an antibody against Lucifer Yellow. Approximately 1/2 of the dye injected neurons (n=37) were pyramidal cells with a single apical dendritic trunk extending to the cortical surface. The remaining cells were multipolar with spiny, varicose dendrites confined to layer III. Axons from both types of cells arborized extensively in layer III. Stimulation of afferent or association fibers typically evoked variable, multicomponent EPSPs in deep pyramidal cells in contrast to a single component EPSP in layer II pyramidal cells. Deep multipolar cells either failed to respond to afferent fiber stimulation or responded at relatively long latency, but consistently displayed high amplitude, multicomponent EPSPs in response to association fiber stimulation. Spike thresholds were consistently lower for deep pyramidal and multipolar cells than for layer II pyramidal cells. An apparent Ca^{2+} activated K^+ conductance was observed in approximately 25% of deep pyramidal cells (compared with 5% or less of layer II pyramidal cells) and in approximately 50% of multipolar cells. Both cell types displayed early and late IPSPs as observed in layer II pyramidal cells (Tseng & Haberly, Neur. Abs. 12:667).

The most striking finding was an increase in amplitude of the late, multicomponent EPSPs evoked by the second of a pair of shocks by a factor of up to 30X in both types of cells. The facilitated long latency components (but not a brief latency component, when present) were blocked in 1.3mM Ca^{2+}/4 mM Mg^{2+} medium, suggesting that the facilitation is di- or multisynaptically mediated. We postulate that this extreme degree of facilitation results from an amplification of the effects of conventional monosynaptic facilitation (Bower & Haberly, PNAS 83:1115) via convergent excitatory input from superficial cells onto deep cells and positive feedback between deep cells by way of direct excitatory interconnections. The high amplitude facilitation of late EPSP components could play a role in epileptiform activity generated either by kindling (see Hoffman & Haberly, this vol.) or by injection of convulsant drugs into the deep layers of piriform cortex (Piredda & Gale, Br. Res. 377:205). Supported by NINCDS grant NS19865 to LBH.

45.9 REPEATED TETANI OF PERFORANT PATHWAY REVERSIBLY REDUCES SLOW AHPs IN DENTATE GRANULE NEURONS IN VITRO. A. Baskys and P. L. Carlen. Playfair Neurosci. Unit, Toronto Western Hospital, Addiction Research Foundation, and Departments of Physiology and Medicine, Univ. of Toronto, Toronto, Ont. M5T 2S8, Canada.

Pressure-ejected serotonin (5-HT) reversibly blocks AHPs in hippocampal dentate granule (DG) cells in vitro by reducing gK(Ca) [Baskys et al., Brain Res, 1987, in press]. The diffuse distribution of 5-HT fibres in the hippocampus suggests that high frequency tetanic stimulation used to evoke long-term potentiation (LTP) may also release 5-HT from serotonergic terminals and possibly block the gK(Ca). We examined AHPs in DG neurons before and after tetanic stimulation was applied to the perforant path 1-2 mm away from the recorded neuron. Intracellular recordings with 3 M CH3COOK filled electrodes were made in 8 neurons in slices taken from Fischer 344 rats (age 4-7 mos.). Three to 10 mV AHPs followed the train of 4-8 action potentials induced by an intracellular depolarizing current pulse of 100 ms. Concentric bipolar electrodes were used to deliver 400 Hz stimuli (.1 ms, 50-150 uA; 8 trains of 8 pulses/train). Following the tetanus there was a significant decrease in the AHP amplitude (mean decrease 24.6± 6.3%, P<.01). AHPs returned to the control level in 1 to 10 min. In 4/6 cells the AHP suppression was associated with an increase in EPSP amplitude. In a DG cell (figure below) the thick lines represent control responses, thin lines-posttetanic responses. The EPSP is an average of 20 responses at .1 Hz. These data show that tetanic stimulation normally used to evoke LTP can reduce AHPs in a way similar to externally applied 5-HT or norepinephrine.

45.10 A TRANSIENT CA-DEPENDENT K POTENTIAL FOLLOWS A BRIEF SPIKE TRAIN IN HIPPOCAMPUS. A. Williamson and B. E. Alger. Dept. Physiol., Univ. of Maryland Sch. of Medicine, Baltimore, MD 21201.

Brief trains of action potentials induced by direct depolarizing current steps in rat hippocampal CA1 pyramidal cells maintained in the in vitro slice preparation are followed by a complex afterhyperpolarization (AHP). The latter phase of the AHP is due to a slow calcium-dependent potassium current, I_{AHP}, which can be blocked by a number of compounds including NE, ACh, histamine, and active phorbol esters. When I_{AHP} is blocked, a fast component of the AHP is clearly visible. This potential has been called the middle AHP or mAHP to distinguish it from the first AHP following individual APS and the slow AHP mediated by I_{AHP}. The mAHP is poorly understood.

Our data indicate that the mAHP is a composite potential, part of which is Ca dependent. First, the amplitude of the mAHP varies directly with the extracellular Ca concentration. It increased from 3 mV in control saline (2.5 mM Ca) to 6 mV in 5 mM Ca and decreased to 1 mV in 1.5 mM Ca. These effects are reversible. Second, there is a distinct reduction of the mAHP amplitude in the presence of Ca channel antagonists such as Co and Cd. Third, similar reductions in mAHP amplitude can be obtained by bath application of 5 mM TEA and charybdotoxin, a component of scorpion toxin, both of which block a fast Ca-dependent K current known as I_C. The mAHP is resistant to block by phorbol esters, as is I_C. The mAHP is either all or partly mediated by K as it is seen in cells impaled with KCl-filled electrodes. None of the compounds tested completely abolished the mAHP, indicating that there is also a Ca-independent potential.

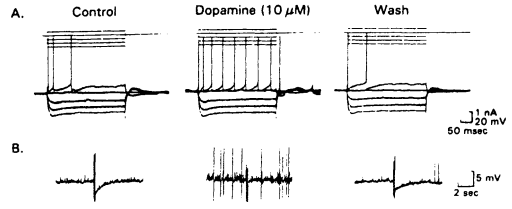
Thus, I_C, which is activated after individual action potentials and is involved in action potential repolarization, can also be seen at the end of a direct depolarizing pulse.

The AHP following direct activation of these cells is, therefore, made up of at least three distinct K-mediated potentials: a slow Ca-dependent potential, a fast Ca-dependent potential and a fast Ca-independent potential. We have previously presented evidence that the initial component of the AHP following epileptiform burst discharges is also mediated by I_C (Williamson and Alger, 1986, Soc. Neurosci. Abst. 12, 728), suggesting that this current plays a role in terminating burst potential discharges. (Supported by NIDA F31 DA05312 (A.W.) and NIH grant NS22010 (B.E.A.))

45.11 DOPAMINE BLOCKS SPIKE ACCOMMODATION AND AFTERHYPERPOLARIZATION IN NEOCORTICAL PYRAMIDAL NEURONS *IN VITRO*. N. Traverse Slater and Linda J. Larson-Prior. Departments of Physiology and Psychiatry, Northwestern University Medical School, Chicago, IL 60611

Dopamine (DA) has excitatory effects on neocortical neurons *in vivo* [1] mediated via the activation of receptors of the D-2 subtype [2]. Despite a wealth of information on the electrophysiologic actions of biogenic amines in other areas of brain, little data is available regarding the actions of biogenic amines in the cerebral cortex. Intracellular recordings were made with KCl or KAc-filled microelectrodes (30-50 MΩ) from 'regular spiking' pyramidal neurons in Layers III-IV in coronal slices of guinea-pig somatosensory cortex maintained completely submerged at 30-33°C. 'Regular spiking' pyramidal neurons were identified by their response to white matter stimulation and their rapid accommodation of spike discharge to depolarizing current injection [3].

DA (1-10 μM) applied by bath perfusion produced a reversible reduction of spike accommodation (Fig 1A) and afterhyperpolarizations (AHPs) (Fig 1B). In the presence of TTX-containing solution, both slow outward rectification during depolarizing current pulses and AHPs were reduced. Calcium spikes recorded in the presence of TTX and TEA were unaffected by DA. These effects of dopamine were also associated with a slow depolarization (3-8 mV) and an increase in the apparent frequency of spontaneous, depolarizing ipsps recorded with KCl-filled microelectrodes, suggesting an excitatory effect on recurrent interneurons. No significant effect of DA was observed on membrane resistance or inward rectification to hyperpolarizing current pulses.



These results provide evidence that the excitatory effects of DA on neocortical neurons observed *in vivo* [1,2] may result from the blockade of a calcium-activated potassium conductance which underlies spike accommodation and AHPs. Pharmacologic evidence for the mediation of these effects *in vitro* by a specific DA receptor subtype is lacking, and the contribution of adrenergic receptors which mediate similar effects in the hippocampus [4] cannot be excluded.

45.12 RELATION BETWEEN THE SHAPE OF DEPOLARIZING PULSE POTENTIALS AND FIRING PROBABILITY OF CAT NEOCORTICAL NEURONS A.D. Reyes*, E.E. Fetz, & P.C. Schwindt, (SPON.: A.J. Berger) Dept. of Physiology & Biophysics and Primate Ctr., Univ. of Washington, Seattle, WA 98195

Excitatory post-synaptic potentials (EPSP's) produce a change in the firing probability of neurons that is given by the cross-correlation histogram of neuron firing aligned with the onset of the EPSP's. The relation between the time course of the EPSP and the correlogram has been studied directly only in rhythmically firing motoneurons (1,2). In the present study, we investigated how parameters of brief depolarizing potentials affect features of correlogram peaks in neocortical neurons.

Intracellular recordings were obtained from layer V pyramidal cells in slices of cat sensorimotor cortex (3). The neurons were impaled with either KCl or K-MeSO4 electrodes with resistances of 10-20 megohms. To mimic synaptic EPSP's, depolarizing membrane potentials were evoked by injecting brief rectangular current pulses into the cell. The resultant voltage deflections were characterized by a near linear rise of membrane potential during the pulse, followed by an exponential decay. The size and shapes of the "pulse potentials" (PP) were controlled by varying the amplitude and duration of the current pulses. After measuring the average PP with the cortical neuron at rest, rhythmic discharge was induced by injecting constant depolarizing current through the microelectrode. The effect of the PP on firing probability was determined by cross-correlating the stimulus train with the neuron's action potentials. Preliminary observations suggest that the effects of PP's on firing probability are similar to those of postsynaptic potentials evoked in these neurons by electrical stimulation of white matter.

To investigate the relation between PP's and correlograms, we systematically varied the amplitudes and rise times of the pulse potentials. Preliminary results indicate that the correlogram peak height was most strongly related to the rising slope of the PP (r = 0.76) and the correlogram peak area to the PP amplitude (r = 0.76). These relations were very similar to the relations between single-fiber Ia EPSP's and their corresponding correlograms in cat motoneurons (2).

45.13 DESYNCHRONIZATION AND REDUCTION OF EPILEPTIFORM ACTIVITY WITH ELECTRICAL STIMULATION. D. Durand. Applied Neural Control Laboratory, Department of Biomedical Engineering, Case Western Reserve University, Cleveland, OH 44106.

Recent studies have shown that electrical stimulation can reduce the amplitude of population spikes of synchronized neuroelectric activity resulting form epileptogenic drugs. A current pulse synchronized with the epileptiform activity can decrease the amplitude of the population spikes by 80 to 100% (see fig.1). The mechanisms responsible for the large decrease are unclear, but a possible explanation could involve the stimulation of another pool of neurons firing in opposite phase from the original set of neurons. This mechanism would then produce a desynchronization of neuronal firing leading to a reduction in extracellular potential amplitudes. Intracellular recordings were then used to test this hypothesis.

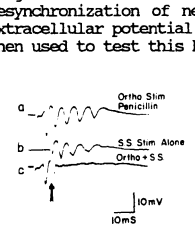

Fig. 1

Transverse hippocampal slices were prepared from Sprague-Dawley rats (150-200g). Repetitive firing was induced by adding penicillin (7000 units/ml) to the bathing medium. Orthodromic responses were triggered with a stimulation electrode in the stratum radiatum (fig.1a). Intracellular and extracellular activity were recorded simultaneously with standard glass microelectrode techniques. A 50um diameter stainless steel (ss) electrode located close to the recording electrode was then activated (arrow) with a current generator delivering pulses of various amplitudes and widths. The current pulse was applied following orthodromic stimulation with a variable delay.

Experiments on 10 CA1 cells showed that 5 cells were not affected by the stimulation even in the presence of a large decrease in the amplitude of the extracellular spikes. For the 5 cells that did show an effect, 3 cells were firing in opposite phase from the extracellular potential (synchronized with positive peaks), and 3 cells showed a marked depression in the amplitude of the action potentials (1 cell showed both effects).

These preliminary experiments confirm our hypothesis that the delayed stimulation pulse activates a pool of neurons firing in opposite phase from the first neurons and also suggest another mechanism by which the amplitude of the action potentials are reduced following depolarization. Both mechanisms are under investigation with further intracellular recordings, current-source density analysis and finite difference modelling.

45.14 **FURTHER STUDIES ON FEED-FORWARD AND RECURRENT INHIBITION IN THE CA1 REGION OF THE HIPPOCAMPUS.** **H.V. Wheal, S. Phelps & S. Radpour. Department of Neurophysiology, University of Southampton, Southampton SO9 3TU, U.K.** (SPON: J. Chad)

There is evidence for both feed-forward and recurrent i.p.s.p.s in CA1 pyramidal cells in the in vitro hippocampal slice preparation (Dingledine et al. J. Physiol. 305: 297-313, 1980). Furthermore putatative inhibitory interneurones and feed-forward i.p.s.p.s can be evoked by low threshold stimulation of the Schaffer/commissural afferents (Ashwood et al. Brain Res. 293: 279-291, 1984; Turner, Neurosci. Lett. 22: S511, 1985). We have used a modified heterosynaptic paired-pulse protocol (Lynch et al. Exp. Neurol. 71: 527-540, 1981) to study functional feed-forward inhibition. Also, following reports that the ventral hippocampus is more prone to epileptiform activity (Lothman et al. Brain Res. 218: 299-318, 1981) we have measured synaptic inhibition at the septal and temporal poles of the hippocampus.

Feed-forward inhibition was demonstrated using heterosynaptic paired-pulse stimuli applied to the stratum radiatum of the CA1 region. In order to prevent any contamination of the inhibition with a recurrent component, two extracellular recording electrodes were carefully positioned in the stratum pyramidale of CA1. The second recording electrode was used to ensure that the orthodromic conditioning stimulus intensity was subthreshold for activation of all pyramidal cells, including those closest to the site of the stimulus. With these precautions and a C-T interval of 22msec, the test population spike was significantly inhibited (n=10), thus demonstrating a functional component of feed-forward inhibition in the hippocampal slice.

To compare the levels of synaptic inhibition in the septal and temporal poles of the hippocampus the tissue was either sliced transversely or longitudinally along its septo-temporal axis. Recordings were made from a single extracellular electrode placed in the CA1 stratum pyramidale. Suprathreshold paired-pulse stimuli were applied via a single bipolar electrode to the stratum radiatum. The data from 20 pairs of septal and temporal slices showed a significant difference in the percentage inhibition of the test response. Very little inhibition was seen in the temporal hippocampal slices and no advantage was found in cutting the slices longitudinally. This observation may explain why the temporal or ventral hippocampus has been reported to be more prone to epileptiform activity. We are presently investigating regional differences in inhibition in a chronic model of temporal lobe epilepsy.

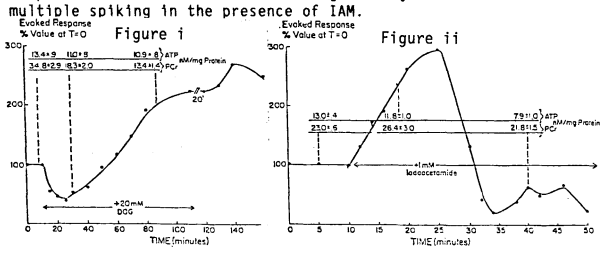
45.15 SOME NOVEL EFFECTS OF GLYCOLYTIC INHIBITORS ON SYNAPTIC TRANSMISSION IN GUINEA PIG HIPPOCAMPAL SLICES. J. Waalen* and P. Lipton (SPON: H. Karavolas). Dept. Physiol., U. Wisc., Madison, WI 53706

In the course of studies to determine the role of glycolysis in synaptic transmission two classical blockers of glucose utilization were added to the buffer perfusing guinea pig hippocampal slices. Their effects were quite surprising and are shown in the figures below where the ordinate represents the height of the population spike recorded in dentate gyrus following stimulation of the perforant path.

Figure (i): 20 mM deoxyglucose was added to slices incubated 10 mM glucose/10 mM pyruvate-containing buffer. After an early depression in the population spike there is a slow and profound increase over the course of the next 60-90 minutes. Deoxyglucose is incorporated into glycoproteins and this may be a mechanism for its enhancement of transmission. Figure (ii): 1 mM iodoacetamide (IAM) was added to slices incubated in 10 mM glucose-containing buffer. There is a rapid profound enhancement of the population spike and a more slowly developing inhibition of glycolysis which leads to the abolition of the population spike. All evidence indicates these are two independent actions.

We assume the IAM-enhancement is a -SH effect; it may indicate a way in which synaptic transmission is affected in physiological situations. We are studying the effect of IAM on release of endogenous transmitters; both glutamate/aspartate and serotonin. In preliminary results IAM enhances basal release of serotonin and depresses K-stimulated release. IAM appears not to stimulate basal release of glutamate and profoundly depresses release evoked by 50 mM K. Thus, the enhanced population spike is probably not mediated by an increase in release of neurotransmitter. This suggests either a post-synaptic site of action or a depression of GABA release as mechanisms for the enhanced response. The latter is militated against by the absence of multiple spiking in the presence of IAM.



45.16 DECREASE OF EXCITATORY SYNAPTIC TRANSMISSION IN CAT SPINAL CORD BY NH_4^+ IS ACCOMPANIED BY NEURONAL DEPOLARIZATION. W. Raabe. Neurology, VA Med. Ctr. and Univ. of MN, Minneapolis, MN 55417.

A systemic ammonia intoxication decreases excitatory synaptic transmission in cat spinal cord (Neurosci. Abstr. 12:825, 1986). Possible mechanisms underlying this effect of NH_4^+ are i) a decrease of the utilization of glutamine as a precursor for transmitter-glutamate because of the inhibition of glutaminase by NH_4^+ (J. Neurochem. 33:1295, 1979), and ii) a depletion of transmitter-glutamate in nerve endings because of inhibition of Na^+-dependent uptake of glutamate into synaptosomes by NH_4^+ (Exp. Neurol. 89, 1985). To further investigate the mechanisms of action of NH_4^+ this study investigates the effects of NH_4^+ on presumed glutamatergic synaptic transmission in cat spinal cord in relation to cholinergic synaptic transmission.

Cats, deeply anesthetized with pentobarbital and paralyzed with gallamine triethiodide, were used. The PBST nerve was stimulated (1.5 x T) and the motoneuron pool EPSP (VR-EPSP) recorded from the S1 ventral root. The L7 ventral root was stimulated and the Renshaw cell discharge was recorded in the spinal cord by an extracellular electrode. Ammonium acetate (NH_4Ac), 20% solution in H_2O adjusted to pH 7.4, was given i.v.

NH_4Ac i.v. reversibly decreased the VR-EPSP. During NH_4Ac i.v., VR-EPSPs of decreased amplitude suddenly triggered discharges of motoneurons. Discharges ceased when the VR-EPSP was less than 10% of control. During recovery from NH_4Ac i.v., decreased VR-EPSPs also transiently triggered discharges. Before NH_4Ac i.v., stimulation of L7 ventral root readily evoked repetitive discharges of Renshaw cells. When the VR-EPSP decreased to less than 10% of control, stimulation of the L7 ventral root did no longer evoke Renshaw cell discharges. The negative phase of the antidromic motoneuron population potential evoked by stimulation of the L7 ventral root markedly increased when NH_4Ac i.v. began to decrease the amplitude of the VR-EPSP. When the VR-EPSP was maximally decreased, the negative phase of the antidromic motoneuron potential suddenly decreased below control values. With recovery of the VR-EPSP, the negative phase of the antidromic motoneuron potential recovered to control values.

These observations suggest that NH_4^+ does not selectively affect presumed glutamatergic excitatory synaptic transmission in cat spinal cord. The experimental data indicate that NH_4^+ depolarizes neurons and eventually produces a depolarization block of neuronal excitation. This may be due to a direct effect of NH_4^+ on the neuronal membrane. Alternatively, inhibition of Na^+-dependent glutamate reuptake into synaptosomes and extracellular accumulation of glutamate may decrease the VR-EPSP and depolarize neurons, respectively.

45.17 ARE RETINAL GANGLION CELLS ISOPOTENTIAL? R.F. Miller and P.A. Coleman* Dept. of Ophthalmology, Washington University School of Medicine, St. Louis, MO 63110.

We have obtained electrophysiological evidence which suggests that retinal ganglion cells are isopotential as determined by a current pulse injected into the soma. The results which support this conclusion were obtained by a newly developed whole cell recording (WCR) technique applied to ganglion cells in the superfused retina-eyecup preparation of mudpuppy or tiger salamander. In this preparation, retinal neurons retain their synaptic connections and maintain normal light evoked activity. Because a "giga-seal" is formed between the cell membrane and the tip (1-2 μm) of the patch electrode, high quality, long duration recording are possible. With this approach, we measured the input resistance of more than 20 different ganglion cells with values ranging from a few hundred megohms to more than two gigaohms. The mean time constant in these cells was 70 msec. Assuming a value of 1 uF/cm^2 for the membrane capacitance, the time constant measurements suggest that the average specific membrane resistance (R_m) for retinal ganglion cells is 70,000 ohms cm^2. In addition, the rising phase of the voltage transient, produced by a current pulsed injected into the soma was usually well described by a single exponentional function. These findings suggest that the electrotonic lengths of ganglion cell dendrites are short, due to a high value of R_m.

Anatomical measurements from retrogradely labelled, horseradish peroxidase filled ganglion cells, coupled with our physiological measurements, were used in computer simulations to determine the average electrotonic length of the dendritic processes. For a ganglion cell with 5 primary dendrites, each approximately 200 μM long, the dendritic to somatic conductance ratio was approximately 2, with an average electrotonic length of 0.3λ, using our experimentally obtained R_m value of 70,000 ohm cm^2. These findings support the idea that synaptic inputs along the dendritic tree are nearly equipotential in their ability to charge the soma and hence modulate the excitability of the cell. Thus, we believe that previous models of retinal ganglion cells may have considerably underestimated R_m.

45.18 **THREE-FOLD OVERESTIMATION OF DENDRITIC ELECTROTONIC LENGTH BY SINGLE EQUIVALENT CYLINDER MODELS.** Loyd L. Glenn and Brad G. Samojla. *Department of Physiology, Ohio College of Podiatric Medicine, University Circle, Cleveland, Ohio 44106-3082.*

The electrotonic length of dendrites have been estimated by analysis of the voltage response to a pulse or step of current, where the neuron is assumed to be represented by a single, equivalent cylinder. It has been shown that this model describes dendritic trees under the condition that dendritic branch point meet the $d^{3/2}$ constraint of Rall, and that dendritic lengths are equal. The $d^{3/2}$ constraint is met in most neurons, but the equal-lengths constraint is not met. In order to test the effects of nonuniform dendritic lengths on estimates of the average electrotonic length, mathematical models were developed that describe neurons with multiple dendrites of unequal length.

Three boundary conditions were applied to the general solution for the cable equation: (1) a sealed end on the distal dendrites, (2) conservation of current between dendrites, and (3) equality of voltage at the proximal ends of all dendrites. The resulting equation was:

$$\tan \alpha_1 L_1 + \tan \alpha_1 L_2 + \tan \alpha_1 L_3 + \ \ldots \ + \tan \alpha_1 L_n = 0$$

$$\tau_1/\tau_0 = 1 / (1 + \alpha_1^2)$$

where $L_1, L_2, \ldots, L_n$ are the electrotonic lengths for the dendrites of a neuron with n dendrites, and α_1 is the lowest, non-zero positve root of the transcendental equation. Once α_1 is determined, the ratio of the membrane tim constant (τ_0) to the first equalizing time constant (τ_1) can be claculated. When the dendrites are equal in length ($L_1 = L_2 = \ldots = L_n$), the first equation reduces to that for a single cylinder (sin $\alpha_1 L = 0$).

The τ_1/τ_0 ratio was related to the average length of dendrites in the special case of uniform dendrites. However, contrary to our expectations, this was not true when dendrites of the multipolar model differed in length. When lengths differed, the τ_1/τ_0 ratio reflected the electrotonic distance from the tip of the longest dendrite in a model multipolar neuron to the tip of the second longest dendrite. Inasmuch as natural dendrites do not meet an equal-lengths constraint, we conclude that the values presently reported for the electrotonic length of neurons are actually the maximal tip-to-tip electrotonic distance for a neuron.

The consequence is that dendritic lengths have been overestimated in the literature by a factor of 3. The factor of 3 is simply the maximal tip-to-tip electrotonic length divided by the average dendritic electrotonic length of a neuron, as ascertained from published intracellular HRP labeling studies. For spinal motoneurons, the dendrites are not 1.5 λ in length, but actually 0.5 λ. For hippocampal neurons, such as CA1-CA3 pyramidal cells and granule cells, the electrotonic length is 0.3 λ rather than 0.9 λ. This shortening has the effect of reducing the synaptic propagation losses for the most distal synapses on dendrites from 50% (presently accepted) to only 5%. [Supported by Ohio Board of Regents Research Challenge Program]

45.19 NEURON SIMULATIONS USING SABER.

K.Flach*[1], N.T.Carnevale[2], and S.E.Sussman-Fort*[1]. Dept. of Electrical Engineering[1], and Depts. of Neurology and Neurobiology and Behavior[2], State Univ. of New York, Stony Brook, N.Y. 11794.

Hypotheses of neuronal function that are closely linked to anatomical and biophysical data require realistic quantitative simulations for verification. Some groups have used commercially available programs such as SPICE (1,2) for these simulations. Others have developed their own programs for reasons including efficiency and user interface (3,4). We now report our experience using SABER, a new general purpose simulator. This program uses algorithms (5) that make it faster and more general than SPICE, so it may be especially well suited for modeling individual and interconnected neurons.

Most simulation programs were designed specifically for electronic circuits and need special dodges to deal with voltage-, ion-, or neurotransmitter-dependent conductances. For example, spike currents have been implemented under SPICE (2) by incorporating what are effectively analog computer models for gNa(v,t) and gK(v,t).

SABER is not restricted to a predefined set of components, but allows modeling of biophysical properties directly from the empirically determined functions and differential equations that describe their kinetics. Because this program can handle non-electrical elements, models can readily incorporate fluxes and local concentrations of ions and neurotransmitters. SABER also allows formulation of models in terms of user-defined subunits, which would facilitate the construction of complex models of individual neurons, and in turn, the assembly of circuits of interconnected cells.

We have used SABER to simulate anatomically detailed neuron models as well as simplified models that were derived from extensive anatomical and biophysical data using: our previously described empirical approach to the optimization of neuron models (6); our recently developed methods for the automatic optimization of simplified neuron models (7). SABER was particularly helpful for exploring the sensitivity of simulations to changes of model parameters. We also examined the effects of voltage-dependent membrane conductances on the accuracy with which simplified models could reproduce the properties of anatomically detailed models.

SABER is a trademark of Analogy, Inc.

TRANSPLANTATION I

46.1 **REGENERATIVE RESPONSE OF AMPUTATED LIMBS AFTER IMPLANTATION OF CULTURED CNS AND PNS EXPLANTS.** Betty F. Sisken. Center for Biomedical Engineering and Dept. of Anatomy, University of Kentucky, Lexington, KY 40506.

Previous studies have described the responses of four day chick embryo limbs after amputation and implantation with freshly-dissected neural tube (Fowler and Sisken, 1982; Sisken et al, 1983-6). These responses include: induction of complete regeneration (formation of middle and distal segments) in approximately 1/3 of the operated animals, restoration of the ratio of the area of nerve:area of the amputated limb, and preservation of sensory and motor components of the amputated stump.

We have reported that only neural tissue taken from 2 to 4 day donor embryos is capable of inducing a regenerative response. Although central nervous tissue (CNS), or peripheral nervous tissue (PNS) freshly-dissected from older donor embryos are ineffective, we asked if culturing these tissues in vitro for periods of 3-10 days restores the inductive properties. Pieces of cerebral cortex, spinal cord, dorsal root ganglia, or heart obtained from 6-8 day chick embryos were cultured in separate 60 mm culture dishes. The cultures were washed 2X and single explants from these cultures were implanted into the stumps of 4 day chick embryos using our standard procedure (Fowler and Sisken, 1982). The eggs were incubated for an additional nine days, stained in Alcian Blue and the limbs examined for a regenerative response. From the results of the studies presented in Table 1, we conclude that: (1) culture for a minimum of three days of CNS and PNS tissue obtained from older embryos restores the limb-inducing potential and, (2) culture of non-nervous tissue does not promote this capability.

Table 1

Tissue	Regenerative Response	% Successful Regeneration
Dorsal root ganglia, 8 day embryo		
Fresh	0	0
Culture 3-10 days	+	45%
Spinal Cord, 2-4 day embryo		
Fresh	+	32%
8 day embryo		
Fresh	0	0
Culture 3-10 days	+	36%
Cerebral Cortex, 4 day embryo

46.2 EXPRESSION OF L2/HNK-1 FAMILY OF CELL ADHESION MOLECULES AND GFA ANTIGENS IN CEREBELLAR ALLOGRAFTS IN MICE. M. Poltorak*, W.J. Freed and M. Schachner+. Preclinical Neurosciences Section, Neuropsychiatry Branch, NIMH, Washington, D.C. 20032 and +Department of Neurobiology, University of Heidelberg, Federal Republic of Germany.

Cell-cell interactions are of primary importance in the morphogenesis of the nervous system. Cell surface molecules have been implicated in molecular mechanisms of cerebellar development. Since embryonic cerebellar fragments deprived of input fibers can survive and develop as grafts when transplanted to the host adult brain, we were interested in the expression of L1, BSP-2/N-CAM, J1, MAG (myelin-associated glycoprotein) and GFA (glial fibrillary acid protein) antigens as well as the L2 epitope in cerebellar tissue transplanted into the lateral ventricle.

The donor cerebella were taken from C57/Bl mouse embyros at gestational day E14-E15 and implanted into the lateral ventricles of adult host mice. Indirect immunofluorescence staining was performed on fresh frozen sections after 2 to 6 weeks survival. Routine cresyl violet staining revealed that the implanted cerebellar neurons had developed a normal trilaminar organization. Immunoreactivity with antibodies against cell adhesion molecules (L1, BSP-2/N-CAM, J1, MAG) showed patterns generally similar to those observed during normal development of the cerebellum. Since the cytoarchitecture of transplanted tissue was maintained and migration of granule cells occurred it is likely that the postulated molecular basis of granular cell migration also occurs in transplanted cerebellar tissue. The characteristic GFA positive elongated Bergmann glia were not detected even though the migration of granule cells from their germating zone to the internal granular layer was observed. These data confirm the importance of cell adhesion molecules during cerebellar morphogenesis, but suggest that the behaviour of migrating granule cells has multiple mechanisms and does not depend entirely on interactions between granule cells and GFA positive Bergmann glia.

46.3 FETAL BRAIN TRANSPLANTS INDUCE FUNCTIONAL RECUPERATION OF TASTE AVERSION LEARNING AND NORMAL CONNECTIVITY IN CORTICAL LESIONED RATS. J. Fernández*, M.L. Escobar*, R. Guevara and F. Bermúdez-Rattoni. Instituto de Fisiología Celular and Facultad de Medicina. Universidad Nacional Autónoma de México. Apdo. Postal 70-600. 04510 México, D.F.

Recently, it has been reported that fetal brain transplants have been used to study recovery of brain damaged regions of adult rats. Thus, it has been shown that fetal transplants establish functional and anatomical connections with the host. On the other hand, it is well-established that the gustatory neocortex (GN) mediates conditioned taste aversion (CTA). The involvement of this area in CTA learning has been demonstrated by the observation that lesion of GN disrupts both acquisition and retention of a learned taste aversion response. In this study we are demonstrating that fetal cortical transplants can induce recovery of a previously lost acquired CTA, and the reestablishment of normal connectivity.

Rats were divided into an unoperated control group, and a group who sustained large electrolytic lesions of the GN. Following postoperative recovery each group received CTA acquisition; saccharin (.1%) was added into the drinking solution, followed by lithium chloride (190 mg/kg). After 2 days, taste solutions were presented again and those GN lesioned rats which showed disrupted taste aversions were divided in two groups; one group (GGN; n=8) was transplanted with homologous GN tissue, the other group (TGN n=7) received heterogeneous brain stem tissue, both obtained from 17 old fetuses. Eight weeks later all the animals were given an acquisition trial and two tests trials again. We compared the taste aversion scores before and after the graft for the GN groups and for the unoperated group. At the end of the experiment all grafted animals were anesthetized and the brain removed for Histological verification; of graft characteristics. The behavioral results showed a significant aversive recuperation of the GN group after brain transplants, since the aversive scores became similar to those of unoperated control group. In contrast, those animals which received brain stem transplants did not recuperated the taste aversion and were significantly different from the control group ($p<0.01$). In addition, horseradish peroxidase histochemistry revealed that HRP injections in the homologous cortical transplant produced retrograde neuronal labeling to the VPM nucleus of the thalamus. This suggests that there were establishment of connections between graft and host. These results support the hypothesis that homologous but not heterogeneous fetal brain transplants can restore the association of taste with its visceral consequences and restablished normal connectivity between graft and host.

46.4 TRANSPLANTATION OF OLFACTORY BULBS INTO OLFACTORY AREAS AFTER BULBECTOMIES. J. N. Kott[1], M. H. Hankin[2], L. E. Westrum[3], and R. D. Lund[2]. (SPON: D.F. Farrell). Depts of Neurosurg.[3], Biol. Structure[3], and Psychology[1], Univ. of Wash., Seattle, WA 98195 and Dept. of Neurobiol., Anat. and Cell Sci.[2], Univ. of Pittsburgh, Pittsburgh, PA 15261.

Factors influencing successful grafting of olfactory bulb (OB) into other olfactory areas are being studied in neonatal and adult rats. The effect of transplantation at differing times after OB removal on the survival of the grafted tissue is of especial interest at present. OB ablations are performed in newborns, postnatal (PN) 0-3 days, or young adults of approximately PN 100 days. Post-ablation times include acute (same day), intermediate (3-4 days) or chronic (2-4 weeks). Then OBs from fetal rats of known gestational age are either used whole or dissociated in trypsin and used in suspension. Implantations are done with a cannula manually placing the donor tissue/cells into the olfactory peduncle or rostral prepiriform area on the ablated side. The host subjects are sacrificed 2-3 months later. The forebrains are either dissected and removed from the calvarium with all obvious bulbar tissue intact and subsequently frozen sectioned or processed in situ by decalcification and paraffin embedment. Cell body stains and silver stains (unsuppressed Nauta and Loots) for fibers are done on alternate sections. The preparations show clearly successful grafts, especially in those with intermediate and chronic OB ablations. Same day implants may be less successful. Neuronal clusters often are glomerulus-like in appearance. Extensive fiber patterns occur within the graft and sometimes between the implant and adjacent host tissue. A particularly impressive situation is the grafts in or onto the anterior olfactory nucleus (AON), an area normally innervated by the OB. In these cases numerous fibers pass between the grafted OB and host AON suggestive of connectivity between the two tissues. The findings emphasize the importance of a deafferenting lesion and that either a few days' or weeks' recovery may be used in preference to lesion and graft on the same day. Also in this system the AON, after ipsilateral OB removal, is a promising host site in which to study some of the morphological events of fetal OB development.

46.5 ELECTROPHYSIOLOGY OF MORPHOLOGICALLY IDENTIFIED SEPTAL NEURONS GRAFTED INTO RAT HIPPOCAMPUS. L.J. Reece and P.A. Schwartzkroin. Dept. Neurological Surgery, Univ. Washington, Seattle, WA 98195.

Fetal neurons grafted into the brains of animals with previous lesions have been shown to survive and mature in the new location in the host and to ameliorate both lesion-induced enzyme alterations and behavioral deficits. We have been interested in the viability of septal neurons transplanted into the hippocampal formation. While septal grafts into the hippocampus have been shown to be functional by biochemical, histological, and behavioral techniques, little information is available on the physiological characteristics of morphologically identified grafted neurons.

We have previously reported data from recordings of putative grafted cells, including functional synaptic connections from the host onto the graft. The present study combines intracellular recording with subsequent dye injection in order to positively identify the grafted nature of the neuron and to further characterize cell morphology and host-graft interactions. Here we report recordings from cells which are morphologically identified as non-hippocampal cells by intra-cellular injection of lucifer yellow.

Adult female Sprague-Dawley rats were given unilateral lesions of the fimbria-fornix. One week later, the animals were given 2 injections of dissociated fetal basal forebrain neurons in the dorsal hippocampus. These cells were prepared from embryonic day 13-15 rat fetuses (crown rump length approximately 16 mm.), incubated in trypsin, dissociated by trituration, and resuspended with a fluorescent marker. The marker, rhodamine-labelled microspheres, is taken up by the cells and allows subsequent localization of the graft in the host parenchyma. Animals were sacrificed at 1-12 weeks after surgery and cell physiology was studied in the in vitro hippocampal slice preparation. Intracellular recordings were made with lucifer yellow-filled micropipettes (3%); grafted neurons were dye filled following physiologic characterization.

The morphology of the grafted cells is consistent with that of cells in the medial septum-diagonal band area as determined by our studies in normal animals. Labelled cells are distinct from those cells normally found in the hippocampus. They exhibit either a bipolar or multipolar soma with extensive processes. The graft could be stimulated from a variety of sites in the host, depending upon location of the graft within the host. Intracellular recordings were consistent with our previous report.

46.6 ADRENAL MEDULLARY TRANSPLANTS: I. VIABILITY OF HUMAN ORGAN DONOR ADRENALS. D.M. Gash, M.F.D. Notter, J.T. Hansen and S.H. Okawara*. Dept.'s of Neurobiology and Anatomy and Surgery, Div. of Neurosurgery, Univ. of Rochester Sch. of Med., Rochester, NY 14642

This study was conducted to determine the factors important for maintaining viable human organ donor adrenal chromaffin cells which might later be used for transplantation. The present report summarizes the results from 11 donors, 6 males and 5 females, ranging in age from 3 years to 51 years old. In each instance, adrenals were obtained through the Rochester Region Organ Donor Program after receiving informed consent for use of the organs for research. Upon removal from the donor, the adrenals were placed in ice cold lactate-Ringer's solution. Under a dissecting microscope, the adrenal was cut into cross-sections approximately 1 cm thick and the medulla carefully dissected free from the cortex and minced. The small tissue blocks, approximately .5 mm in their largest dimension were then stored in sterile cold calcium, magnesium-free buffer. Samples from six donors were taken within time periods ranging from 30 minutes to several hours following cessation of circulation and processed for light and electron microscope examination. Other samples were prepared for tissue culture using differential plating procedures slightly modified from those described by others (Lillien and Claude, Exp. Cell Res. 161:255, 1985). Essentially the cortical cells attach at a faster rate than chromaffin cells to a collagen substrate which allows enriched populations of chromaffin cells to be obtained from the supernatant. The time from cessation of donor circulation to complete dissection of the adrenal medulla was approximately 2 hours for six of the cases and processing the tissue for culture required another 1 1/2 hours. In a seventh case, the adrenal tissue was maintained in ice cold lactate-Ringer's solution for 10 hours following death before cell cultures were prepared.

Fine-structure analysis of the dissected blocks revealed that great caution had to be exerted to obtain pure medullary tissue. Only blocks dissected from the center of the medulla were completely free from cortical contaminants which implies that those extensive portions of the medulla close to or in direct contact with the cortex should not be used for transplantation. However the differential plating procedures seemed to be very effective for obtaining relatively pure populations of viable chromaffin cells. High yields of viable chromaffin cells were found when the adrenals were obtained from the donors within two hours of death. In the one instance where 10 hours intervened between cessation of circulation and preparation for cell culture, only 5 to 10 viable chromaffin cells could be identified in vitro. The human chromaffin cells could be maintained in culture for periods of up to at least eight weeks. The age of the donor did not appear to be a factor in chromaffin cell survival.

46.7 ADRENAL MEDULLARY TRANSPLANTS: II. FINE STRUCTURE OF HUMAN ORGAN DONOR ADRENALS. J. T. Hansen, M. F. D. Notter, S. Okawara and D. M. Gash. Dept. Neurobiology and Anatomy, and Dept. Surgery, Div. Neurosurgery, Univ. Rochester School of Medicine, Rochester, NY 14642.

The chromaffin cells of the human adrenal medulla obtained from our organ donor program were examined ultrastructurally to characterize their general morphology and assess their potential for use as CNS grafts in the treatment of Parkinson's disease. Samples were obtained from 3 females (ages 12, 48, and 49) and 3 males (ages 3, 22, and 24). Entire adrenal glands were received from surgery in cold media (4° C), the medulla quickly and carefully dissected free from the cortex, and then immersion fixed in cold 3% glutaraldehyde, 2% paraformaldehyde in 0.1M cacodylate buffer. The chromaffin cells were post-fixed in osmium tetroxide and routinely processed for electron microscopy. The fine structure of the chromaffin cells was directly related to the time span required for removal of the organ until immersion in the primary fixative. Nevertheless, the overall morphology of the chromaffin cells was good, and if the cells were placed in culture for several days, their fine structure improved to the point that the cells appeared quite robust. Although adrenalin and noradrenalin secreting cells can be identified in lower mammals based upon the appearance of the chromaffin cell vesicles, this distinction was not clear in the human medulla. Chromaffin cell vesicles often were quite uniform in size and density, and significant departures from this pattern correlated directly with a delay in fixation. The cells interdigitated with one another and were innervated by small unmyelinated nerve fibers whose terminals contained many small electron-lucent synaptic vesicles and several larger dense-core vesicles. Omega figures indicative of exocytosis were observed along the plasma membrane of the chromaffin cells. In addition to chromaffin cells, the human adrenal medulla also contained Schwann cells, fibroblasts, vascular elements such as endothelial cells and pericytes, and blood-borne cells which were trapped in the capillaries. Autografts of the medulla would naturally contain at least all of these different cell types as well as small groups of isolated cortical cells which occasionally penetrated into the medulla. However, even though several hours may pass between the time at which the medulla is harvested and then cultured, the chromaffin cells are viable as evidenced by their survival and robust appearance in vitro.

46.8 ADRENAL MEDULLARY TRANSPLANTS: III. PHENOTYPIC PLASTICITY IN VITRO. M.F.D Notter, J.T. Hansen, S.H. Okawara* and D.M. Gash. Dept. of Neurobiology and Anatomy and Dept. of Surgery, Div. of Neurosurgery, Univ. of Rochester Sch. of Med., Rochester, NY 14642

Adrenal medulla from several species of mature animals was examined for phenotypic plasticity when exposed to different growth factors in vitro to establish the potential of this tissue for transplantation in to the central nervous system. Chromaffin cells from adult rat, monkey and human glands were obtained by a trypsin-collagenase procedure and subjected to differential plating on collagen-coated surfaces. With both human and monkey tissue, initial attachment of non-chromaffin cells was obtained followed by replating of an enriched chromaffin cell population. Adult rat adrenal medulla cells survived very poorly in vitro and could not be enriched in this procedure. Cultured human and monkey chromaffin cells survived in vitro as epithelial cells; however, treatment with nerve growth factor (NGF) (100 ng/ml) induced neuritic outgrowth after eight days. These cells showed strong catecholamine histofluorescence, tyrosine hydroxylase (TH) and dopamine beta hydroxylase staining. Electron microscopic observations of these cultured cells indicated that neurites from NGF treated cells contained granules of variable density and that cell bodies exhibited well preserved organelles. Electron microscopy also confirmed that all differentially plated medulla cells examined were chromaffin cells. Cultures were routinely maintained for at least eight weeks in the neuronal phenotype. In contrast, less than ten percent of adult rat chromaffin cells survived in culture. These cells could be rescued by treatment with NGF in which thirty percent of the cells survived, extended neurites after one week in vitro and stained positively for TH.

In order to provide a continuous supply of growth factor(s) for these medulla cells in vitro, chromaffin cells were cocultured with C_6 glioma cells. These astrocytic cells secrete a non-NGF factor(s) which sustains sympathetic neurons in vitro. Glioma cells were treated with mitomycin C bromodeoxyuridine to inhibit mitosis and were plated with the various medulla cells in a one to one ratio. Both human and monkey chromaffin cells expressed extensive neuritic arborization within eight days of coculture and appeared to have contact with the glioma cells as seen at the ultrastructural level. Importantly, survival of adult rat adrenal medulla cells was enhanced by 50% or more and chromaffin cells extended neurites when cocultured with glioma cells for seven days. Chromaffin cells from all three species stained for TH in co-culture and were histofluorescent. These data indicate that primate adrenal medulla can be maintained in vitro for long periods of time as the neuronal phenotype and that adult rat chromaffin cells can survive preferentially in vitro in the presence of different growth factors.

46.9 **ADRENAL MEDULLARY TRANSPLANTS IV. COGRAFTS WITH GROWTH FACTOR PRODUCING CELLS.** G. Bing*, M.F.D. Notter, J. T. Hansen, C. Kellogg, J. H. Kordower, and D.M. Gash.(Spon: M.Blair)
Department of Neurobiology and Anatomy, University of Rochester, School of Medicine and Dentistry, Rochester, NY 14642

Transplantation of adrenal medullary cells into the striatum of rats with unilateral 6-OHDA lesions can attenuate the drug induced asymmetric rotational behavior. Recently, attempts at ameliorating the symptoms of Parkinson's disease by implanting autografts of adrenal medullary cells into the striatal system have been tried clinically. Since nerve growth factor is very low in the striatum, the survival and phenotypic differentiation of grafted adrenal medullary cells needs to be enhanced. In the present study, we have cografted amitotic C6 glioma cells (which are known to produce neurotrophic factor(s) which promote the survival of dissociated adrenal medullary cells) in an attempt to improve chromaffin cell survival and phenotypic differentiation.

Thirty-seven young adult, male, Long Evans rats were used as recipients. The host animals, all with unilateral 6-OHDA nigrostiatal lesions, were divided into four groups: (1) Adrenal medullary cells co-transplanted with C6 glioma cells (n=11); (2) adrenal cells alone (n=8); (3) glioma cells alone (n=8) and (4) vehicle control (n=10). All rats were sacrified one month after transplantation. Electron microscopic, immunohistochemical and autoradiographic methods were used to identify and characterized the grafted cells. Tyrosine hydroxylase-like (TH) immunoreactive cells were found in all animals which received grafts of the adrenal alone or received adrenal grafts co-transplanted with C6 glioma cells. The co-transplanted hosts had more cells and more intense TH immunoactive staining than the hosts receiving the adrenal grafts. Additionally, more cells formed processes in the former group. All three groups (adrenal medullary , C6 glioma cell, and cografted animals) had a significant reduction ($p<0.05$) in ipsilateral rotations after amphetamine (0.5 mg/kg) injection compared to the control group. Morever, the reduction in rotation was more robust in cografted hosts than in the other two implanted groups ($p<0.05$). Reduction in the rotational behavior in rats receiving the C6 glioma graft alone suggests that trophic factor(s) produced by the C6 glioma cells could promote regeneration of damaged host catecholamine nerve fibers or sprouting from the surviving intact fibers. Our studies demonstrate that intraparenchymal transplantation of both adrenal medullary and C6 glioma cells can significantly reduce the rotation induced by amphetamine in 6-OHDA lesioned rats, and the combination of these two results in a greater reduction than adrenal or C6 grafts alone. Analysis of catecholamine content with HPLC in the striatum of the rats in all four experimental groups is in progress. **Support: PHS S7RR05403-25 (JTH). and a grant from the American Health Assistance Association(DMG).**

46.10 NEURAL GRAFTS ENTRAPED IN A COLLAGEN HYDROGEL: A POTENTIAL TOOL TO REPAIR REGIONS OF THE CNS. R. Marchand, S. Woerly and L. Bertrand, Lab. Neurobiol., Hôp. Enfant-Jésus, Qué., Can. G1J 1Z4

The adult mammalian CNS tissue is lacking in extracellular matrices (E.C.M.). In the peripheral nervous system and other organs, ECM are present and play an important role to channel and to pattern cell movements in developing, remodeling and regenerating events. This led us to formulate the following hypothesis: would the presence of a three-dimensionally organized ECM-like structure containing young immature neurons injected into a transplantation site of the CNS favor integration and differentiation of the embryonic material? Artificially made cavities in the neostriatum and in the cortex of adult rat brains were therefore infiltrated with an ice-cold neutral prepolymerised type I collagen solution (concentration 2.4 mg/ml, Vitrogen, Collagen Corp.) containing, respectively, a dopaminergic-rich cell suspension from E14 rat embryos and cortical implants from E15 rat embryos. Cryosections of brains harvested 1 week to 4 months post-implantation were examined for the presence of collagen, for axons growing in the matrix and for the response of the host tissue to the presence of the bioimplants. Methods were used to visualize catecholamine, cholinesterase, collagen and cell bodies. Bioimplants were also examined using scanning electron microscopy. Our results demonstrate (1) that the gelling behavior of the collagen dispersion is initiated in situ at the temperature of the brain parenchyma and results in a highly porous sponge-like gel composed of a meshworks of fibrils and wide interfibrillar spaces (2) the gelled collagen completely fills the space of premade cavities and fuses intimately with the adjacent host tissue making with it a tight interface (3) after collagen fibrillogenesis, the neural grafts become immobilized within the structure of the gels and spatially positioned inside the cavities (4) the implanted dopaminergic nerve cells survive and elaborate processes that extend along the fibrilar elements inside the gel. The cortical implants survive and undergo cytoarchitectural differentiation (5) the host tissue responds to the presence of the gel by sending processes into the bioimplant. Although the gels were partially resorbed by macrophages, these observations reveal 3 features on which can be based strategies to repair a local brain injury with an artificial three-dimensionally organized collagen derived E.C.M.:(1) by its capacity to swell in a restricted volume, the hydrogel restores a physical continuity between the edges of the healthy tissue (2) it provides a physical scaffolding for cell attachment and growth (3) by its high void volume it provides (i) an extracellular environment of least resistance mechanically favorable for extensive growth of nerve fibers, (ii) an extracellular compartment for the diffusion of nutrients. (Supported by the MRC and FRSQ).

46.11 THE EFFECT OF FETAL SUBSTANTIA NIGRA GRAFTS ON DOPAMINE RECEPTORS IN THE CORPUS STRIATUM. E. Korfali* (Sponsor: J.P. Conomy). Department of Neurosurgery, School of Medicine, Uludag University, Bursa, Turkey.

Much research has been devoted to transplanting fetal brain tissue into adult host animals. One of the most commonly studied systems is the dopamine (DA) containing substantia nigra. Most of these studies utilized fetal substantia nigra tissue grafted into the DA innervated caudate nucleus of adult recipient animals. These grafts have been shown to be capable of re-establishing DA innervation of a host caudate, forming ultrastructurally normal synapses within a previously denervated corpus striatum. In addition, graft derived catecholamine axons appear to release DA within the host CNS. These grafts have also been shown to restore a variety of motor and sensorimotor deficits associated with destruction of the DA pathway. However, only one previous study has investigated the effects of nigral grafts on DA receptors (Freed, W.J. et al., Science 222: 937-939, 1983). In this study fetal substantia nigra grafts were found to restore DA receptor densities to normal levels in adjacent areas of the corpus striatum, demonstrated by light microscopic autoradiography with [^{3}H] spiroperidol.

The present study utilized [^{3}H] spiroperidol homogenate binding in 34 randomly bred Norvegicus albino rats (Bursa, weight 180-250 grams) to evaluate the effects of nigral grafts on DA receptors. Four weeks after the intraventricular injection of 6-hydroxydopamine (6-OHDA, 250 µg/ 25 µl), a 2 mm X 3mm cavity was made by suction unilaterally on the surface of the caudate nucleus. Four to six weeks later, after a new vessel rich pia had grown over the surface of the cavity, the cavity was re-opened, and in 20 rats fetal grafts were inserted. These monoamine containing ventral mesencephalon grafts were obtained from rat embryos of 17-18 days gestation (crown to rump length 19-22 mm). The remaining rats (n = 14) served as sham operated controls and did not receive grafts. Two months after grafting, 81% of the grafts appeared grossly to have survived. In the sham operated control rats, [^{3}H] spiroperidol binding to the caudate was reduced 53.7% ($p < 0.01$). In contrast, in grafted rats there was a 25% decrease ($p > 0.05$) in binding to the graft-bearing caudate, and a 15% decrease ($p > 0.05$) in binding on the non-grafted side. These findings suggest that fetal substantia nigra grafts may cause an increase toward normal levels of binding in corpus striatum DA receptors previously depleted by 6-OHDA.

46.12 ELONGATION AND ALIGNMENT OF ASTROGLIA PROCESSES IN INTRACRANIAL PC12 CELL GRAFTS. C. B. Jaeger, Dept. Physiol. & Biophys., New York Univ. Med. Ctr., New York, NY 10016.

Radial glia may guide axons and migrating neurons to distant locations during development of the CNS. Such glia have the shape of long processed ependymal cells, stretching between the ventricular lining and the pia. Radial glia give rise to astroglia with short processes, subsequent to migration of neurons and axons. This study sought to answer the question whether short astroglia could give rise to long processed astroglia similar to radial glia. This is an important issue because glia with such morphologies may be necessary for neo-pathway formation of regenerating neurons and neural transplants. It was hypothesized that short processes of glia cells could grow longer in response to mechanical stretch of the surrounding environment, as neurites do, in response to a tensile force (Bray D., Devel Biol 102: 379, 1984). Grafts consisting of PC12 cells were used because they grow extensively within the brain of Sprague Dawley rats and do not themselves contain astroglia, but host brain astroglia migrate into such grafts. Moreover, it has been shown that Millipore filters provide a good attachment substrate for cultured astroglia. Therefore, in addition to PC12 cell grafts, such "inert" nitrocellulose filters were implanted into the cerebral cortex either by themselves or together with clusters of PC12 cells. It was thought that the astroglia attached to a filter and their processes could elongate as the surrounding PC12 cell graft grew in size (Fig. 1).

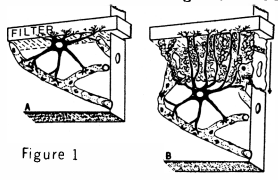

Figure 1

Schematic drawing of glia process elongation as a result of growth in surrounding tissue. A. Glia cell attached to filter (top) and capillary. B. Growing PC12 cell graft leads to lengthening of glia processes.

It was found that short astroglia in different brain regions extended furry filopodia into filters at variable densities. Filters became suspended within PC12 cell grafts but they were connected at different points by bands of long astroglia that were continuous with the host brain interface. Processes of glia in such bands were parallel oriented, they stained with antisera to glia filament protein and attached to the filter edge, thus confirming the notion of glia process elongation in response to a mechanical 'stretch' mechanism. Supported by the American Parkinson Disease Assoc. and BRS grant S07 RR-5399.

46.13 TRANSPLANTS OF FETAL NEOCORTICAL TISSUE FAIL TO IMPROVE BEHAVIOR OF MICRENCEPHALIC RATS. A. Rabe, M.H. Lee, P.C.M. Wang* and R. Recce*. Dept. of Psychobiology, NY State Institute for Basic Research in Developmental Disabilities, Staten Island, NY 10304.

The rat with transplacentally induced cerebral hypoplasia (micrencephaly) and the associated behavioral deficits provides a reasonable animal model of several developmental brain abnormalities. We are investigating whether transplants of tissue from normal fetal neocortex into infant micrencephalic brains could alleviate the behavioral deficits characteristic of micrencephalic rats.

Micrencephaly was induced by an injection into the pregnant Long-Evans rat of 30 mg/kg of methylazoxymethanol acetate on day 15 of gestation. On postnatal day 10 ± 2, some of the micrencephalic rats received 10 mm^3 of neocortical tissue from normal E18 fetuses. The donor tissue was injected into the posterior aspect of the host neocortex. Such transplants are partially intraparenchymal, grow very large, and appear to be permanent. At 2 months and 1 year, normal (N), micrencephalic (MAM), and transplant-bearing micrencephalic (MAM+TR) rats of both sexes were trained to escape from a water-filled Lashley maze (3 daily trials for 5 days) and tested for ambulatory activity during a 30-min session in an open field. After the tests, the presence of a grossly acceptable transplant has been confirmed in a substantial sample of brains, but a microscopic analysis of the transplant and transplant-host interface still remains to be done.

In the maze, at both ages the MAM rats made significantly more errors than the N rats, 123 (n=15) vs 43 (n=15) average errors at 2 months, and 107 (n=11) vs 30 (n=9) errors at 1 year. The MAM+TR rats were similarly inferior to the N rats as they made essentially the same number of errors as the MAM rats, 136 (n=29) at 2 months and 81 (n=11) at 1 year. In the open field, at both ages the pattern of results was similar: both the MAM and the MAM+TR rats (while not differing from each other statistically) ambulated significantly more than the N animals. The average number of infrared beams crossed at 2 months were 1361 (n=17) for N, 1915 (n=26) for MAM, and 2297 (n=46) for MAM+TR groups. At 1 year the respective values were, 976 (n=24), 1626 (n=24), and 1672 (n=30).

These results indicate that the presence of a large transplant of normal fetal neocortical tissue did not reduce the maze learning deficit and hyperactivity of the micrencepahlic rat.

46.14 NEUROBLASTOMA CELLS AS A POSSIBLE DONOR FOR TRANSPLANTATION IN ANIMAL MODELS OF PARKINSON'S DISEASE. M.A. Mena, J.G. de Yebenes, A. Dwork, N. Latov, S. Fahn, J. Herbert. The Neurological Institute, Psychiatric Institute, Columbia University, New York, NY 10032.

We studied the pharmacologic, immunohistochemical and immunological features of human neuroblastoma cell lines as possible candidates for transplant in animal models of PD. Subcultures of neuroblastoma cell lines (CHP100, CHP126, IMR32, LAN1, LAN5, NB69 and SKNSH) were used. Endogenous levels of DA were high in CHP126 (9.9±1.6ng/mg prot), LAN5 (8.8±1.5) and NB69 (14±2.8) and low (<1ng/mg prot) in other cell lines. Maximal values of NE were found in NB69 (27.8±3.9ng/mg prot) and much lower levels (<6ng/mg) in the other lines. Pharmacological responses to DA receptor blockade were tested measuring DA metabolism in the presence of sulpiride (10^{-3}M). Extracellular DOPAC levels increased to 180% of baseline in the NB69 cells. DOPAC and HVA rose to around 200% of baseline in the LAN5 cells. The response to NGF was evaluated by measuring protein content, monoamine levels and rate of division according to ^{3}-H-thymidine uptake in the presence and absence of NGF. Protein content was not significantly changed by NGF in any of the cell lines examined. NGF induced a very mild increase in DA (10%) and NE (20%) in respect to the baseline in NB69 cells but the small changes were apparently due to a decrease in firing rate since an opposite effect of the same magnitude was found in the levels of HVA and MHPG. In LAN5 cells NGF induced a 50% increase in the levels of DA ($p=0.017$), almost a 100% increase in the levels of DOPAC ($p\leq0.001$), and a smaller increase in the levels of HVA, suggesting that LAN5 respond to NGF. The rate of cell division, measured as ^{3}-H-thymidine uptake was unchanged by NGF in LAN5 cells and slightly decreased (22%, $p\leq0.05$) in NB69. Treatment of the catecholamine-rich cells with prostaglandins and cAMP induced a dose-dependent elevation of the DA levels (up to 5-fold in LAN5 and 2-fold in NB69) and a dose-dependent decrease in the division rate, as measured by the uptake of ^{3}-H-thymidine (up to 55% of values found in untreated LAN5 cells and 16% of values in untreated NB69 cells.) Immunohistochemical studies on paraffin-embedded cell blocks, using the avidin-biotin-peroxidase technique with a primary antibody to tyrosine hydroxylase, provided qualitative confirmation of the relative catacholaminergic activities of the native cell lines. The presence of cell surface MHC Class I and Class II (Ia) molecules was tested by flow cytometry using monoclonal antibodies to MHC determinants. Class I antigens were present in LAN1 and Ia in IMR32. Other lines lacked MHC antigens. LAN5 are best for transplant.

46.15 POSSIBLE ROLE OF TERMINAL CONNECTIVITY IN THE EXPRESSION OF PERIKARYAL IMMUNOREACTIVITY TO THE MONOCLONAL ANTIBODY RT97 IN BASAL FOREBRAIN NEURAL GRAFTS. L.C. Doering, O.G. Nilsson, A. Björklund, and A.J. Aguayo. Neuroscience Unit, Montreal General Hospital and McGill University, Montreal, Quebec, Canada and the Department of Histology, University of Lund, Lund, Sweden.

Cytoskeletal abnormalities develop in embryonic telencephalon grafts when isolated for 6-12 months in peripheral nerve (Doering, L.C. & Aguayo, A.J., Brain Res. 401:178, 1987). In these neurons, filamentous inclusions known as Hirano bodies form in dendrites and there is an intense immunoreactivity for the monoclonal antibody (MA) RT97 in the perikaryon. The MA RT97 normally recognizes the phosphorylated 200 kD neurofilament subunit in axons. Although the underlying mechanisms responsible for these changes in long term grafts are unknown, inappropriate or lack of connections with target tissues may play a role in the expression of these abnormalities.

To determine if neuronal interactions with a target influence the formation of these cytoskeletal alterations we examined long term CNS transplants that make connections with the host brain. For these studies, a series of adult rats with bilateral fimbria-fornix transections were implanted with embryonic day 13 basal forebrain tissue. This type of transplant develops connections with the host hippocampus (Björklund, A. et al., Brain Res. 173:57, 1979). The animals were prepared for histological and immunocytochemical studies after 12-14 months of survival.

Networks of axons were defined by immunoreactivity to the MA RT97 in the 6 grafts examined. When sectioned in the appropriate plane, long axonal tracts were seen to extend from neurons in the grafts to the host hippocampus. These neurons showed no perikaryal immunoreactivity to the MA RT97. However, in 5 of the grafts, isolated groups of neurons that did not appear to have extended their processes to the hippocampus displayed a strong perikaryal affinity for the MA RT97.

These observations provide additional evidence that neurons in basal forebrain transplants can project axons into the host hippocampus for prolonged time periods. Neurons that do not appear to connect with their hippocampal targets show cell body immunoreactivity to the MA RT97, a finding that suggests that terminal interactions may be important for the regulation of the phosphorylated neurofilament proteins and other phosphoproteins possibly recognized by the MA RT97.

46.16 INJURY INDUCED SPROUTING INTO THE CAUDATE NUCLEUS, AFTER SOLID TISSUE IMPLANTATION IN MPTP-INDUCED PARKINSONIAN MONKEYS.

K.S. Bankiewicz, D.M. Jacobowitz, R.J.Plunkett*, E.H. Oldfield* and I.J. Kopin. NIH, NINCDS/NIMH, Bethesda, MD 20892

MPTP administered i.v. into primates damages nigrostriatal neurones and causes a parkinsonian syndrome. When given into the internal carotid artery, the ipsilateral nigrostriatal dopaminergic (DA) neurones are destroyed and the animal becomes HP affecting the contralateral extremites. The HP animals circle toward the damaged side; the direction of the circling is reversed after treatment with drugs which stimulate DA receptors. We used these two primate models to quantify objectively motor deficits and their response to treatment and to assess changes in function, histology, and chemistry of the basal ganglia after implantation of DA-containing tissue. The caudate nuclei (CN) were exposed via a transcallosal approach, biopsies were obtained from the CN for assay of DA by HPLC, and the cavities were filled with trypan blue-stained gelfoam. Implantation was performed 1-6 weeks later. The full parkinsonian animal received a unilateral solid rhesus fetal mesencephalic (FM) graft; 4 HP animals received bilateral implants and 1 received a suspension of FM cells. The other 4 HP monkeys received bilateral adrenal medulla allografts. Another group of HP (n=3) animals was implanted with sural nerve autografts bridging the left and right CN. Control HP animals received adrenal cortex (n=2) or fetal cerebellum (n=2); 2 control monkeys were untreated. Before and after implantation, each animal was tested for spontaneous, apomorphine, and amphetamine-induced turning. HP monkeys which received fetal DA tissue recovered from motor deficits whereas animals which received adrenal medulla showed only transient behavioral recovery. The full parkinsonian animal that received a unilateral FM graft recovered to normal motor function with 1 week. One month after surgery this animal consistently turned away from the implant side during spontaneous activity. This increased markedly after amphetamine and was reversed (towards the implant) after apomorphine. Seven months after implantation, TH-immunohistochemistry showed large numbers of TH-positive cell bodies and many fluorescent varicose fibers growing from the implant into the surrounding CN. On the contralateral side, there were many TH-positive fibers that eminated from the ventral striatum towards the site of the surgical cavities in the CN. The density of TH fibers in the n.accumbens were normal bilaterally. The DA cell bodies in the ventral tegmental area (A10, VTA) which innervate the n.accumbens were normal, whereas the substantia nigra cells (A9) were markedly depleted. The HP animals that received nerve graft recovered from apomorphine-induced turning. Six months after the nerve graft there were many catecholamine glyoxyic acid stained fibers within the MPTP treated CN. In MPTP-induced parkinsonian primates, sprouting occurs from DA nerves which probably emanate from the remaining A10 mesolimbic cells. This sprouting may be induced by creation of a cavity in the caudate or implantation of tissue in the caudate.

46.17 **SOME FACTORS AFFECTING THE INFLUENCE OF CORTICAL GRAFTS ON THE BEHAVIOURAL RECOVERY OF RATS WITH MEDIAL FRONTAL CORTEX LESIONS.** B.D.Fantie, B.Reynolds*, D.Di Lullo*, R.Anchan*, and B.Kolb, Psychology Department, University of Lethbridge, Lethbridge, Alberta, Canada T1K 3M4

We have shown that cortical grafts in rats with medial frontal cortex lesions can produce a greater disruption of behaviour than that caused by the lesion alone (Fantie & Kolb, 1985).

Since this result is not consistent with previous studies (e.g., Labbe, Furl, Mufson, & Stein, 1983), we examined several variables that might resolve the discrepancy including: 1) the size of the lesion, 2) the age of the donor tissue, 3) postoperative recovery time, and 4) the behaviour tested. In addition, we looked at the morphology of the grafts using various techniques, especially Golgi-Cox staining and electron microscopic analysis.

Adult rats were given bilateral medial frontal cortex lesions and 1-2 wks later most received either embryonic (E17 or E19) or perinatal (<24 hr or 48-72 hr after birth) cortical tissue implants. The animals were later tested on a variety of measures including spatial navigation in the Morris water task, spontaneous alternation, running wheel activity, noxious prod burying, grooming, and nail clipping.

The performance of some tasks by rats with very small or very large lesions was better if they had received grafts. Generally, rats with grafts tested one month after implantation were impaired. If, however, testing occurred within the first postoperative week, rats with grafts showed a modest improvement although this improvement was less than that shown by rats with similar lesions and no grafts after at least one month recovery from surgery. Age of the donor tissue appeared to be important since tissue taken at E19 attenuated the behavioral deficits whereas tissue taken at other ages potentiated it. Overall, the grafts produced greater behavioural impairments.

Anatomically, the Golgi studies showed that graft tissue was organized differently than normal tissue. The dendrites of pyramidal cells failed to orient in any consistent direction, often appearing similar to the dendrites of stellate cells. Dendrites and axons were never observed to invade the host. EM analysis showed no physical barrier between host and graft tissue. Preliminary examination suggests a higher density of synapses in the graft compared to the surrounding host tissue.

Our findings lead us to be conclude that the implanted tissue probably has a dual effect with the components influencing recovery in opposite directions. The net behavioural result of these opposing events is determined by factors such as lesion size, the type of tissue implanted, the behaviour tested, and the nature of the relationship between the structures involved.

46.18 MOUSE NIGRAL TRANSPLANTS INTO THE BRAINS OF DOPAMINE-DEPLETED NEONATAL RATS. R.K. Carder*, A.M. Snyder-Keller, R. D. Lund, (SPON: M. Ontell), Dept. of Neurobiology, Anatomy and Cell Science and Center for Neuroscience, Univ. of Pittsburgh, Sch. of Medicine, Pittsburgh, PA 15261

When embryonic CNS tissue from CD-1 mice is transplanted into the brain of neonatal Sprague-Dawley rats, the transplant frequently survives for long periods, sending projections to the host brain. However, the xenograft is still susceptible to rejection by the host immune system. Using a mouse skin graft to induce an immune response, one can obtain a gradual rejection of the neural xenograft. This approach offers a useful tool for investigating the function of nigral transplants placed into the striatum of dopamine (DA)-depleted neonatal rats.

Bilateral injections of 6-hydroxydopamine were administered to rat pups 2-3 days postnatally. Cell suspensions of E13 mouse substantia nigra were then placed unilaterally into the rostral striatum 5-6 days postnatally. These animals were tested for amphetamine-induced (2.0 mg/kg, i.p.) and stress-induced (tail pinch) turning at approximately one month of age. In response to both types of stimuli, animals made tight contraversive turns (1-40 turns per minute). A group of animals was perfused and prepared for histological examination at this time. Transplants and their projections were identified using tyrosine hydroxylase immunocytochemistry and antibodies specific for mouse neural tissue. The transplants appeared viable and well-integrated with the host brain. After the initial behavioral tests, a second group of animals received a mouse skin graft on their flank. These animals were then retested at various post-grafting intervals. The rotation behaviors were completely abolished with longer survival periods (13 days post-grafting). Histological examination of these animals revealed no evidence of viable transplanted neurons.

These results show that a temporal coincidence exists between the immunological rejection of the xenograft and the disappearance of these DA-mediated behaviors, thus emphasizing the importance of the xenograft in eliciting the behavioral response.

46.19 ANATOMICAL CORRELATES OF THE DEVELOPMENT OF AMPHETAMINE- AND STRESS-INDUCED TURNING IN DOPAMINE-DEPLETED RAT PUPS WITH UNILATERAL NIGRAL TRANSPLANTS. A.M. Snyder-Keller, R.K. Carder, M.J. Zigmond, and R.D. Lund. Dept. of Neurobiology, Anatomy and Cell Science, Dept. of Behavioral Neuroscience, and Center for Neuroscience, Univ. of Pittsburgh, Pittsburgh PA

We have previously demonstrated that embryonic mesencephalic tissue produces an extensive innervation of striatum by dopamine (DA)-containing fibers when transplanted into the striatum of infant rats pretreated with 6-hydroxydopamine (6-HDA). Furthermore, we have reported behavioral evidence suggesting that these terminals can respond to both pharmacological and environmental challenges (Carder et al., Dev. Brain Res., 1987). In the present experiments we have examined the anatomical basis for such behavioral responses. Rats were given intraventricular injections of 6-HDA (110 ug) at 3 days of age and 3 days later given unilateral striatal injections of a cell suspension consisting of ventral mesencephalon from 13 day rat embryos. At intervals thereafter, rats were challenged with amphetamine (2 mg/kg, i.p.) or the stress of a brief tail pinch. Animals were found to turn away from the transplanted side in response to amphetamine by 15 days post-transplantation at a rate of 5-55 turns per minute. In cases where animals were retested at a later time, a higher rate of turning was observed. Contralateral turning also was observed in response to stress, but this turning did not occur until 25 days post-transplantation. An immunohistochemical analysis of DA fiber outgrowth was carried out by visualizing terminals containing tyrosine hydroxylase. At 15 days post-transplantation a correlation was observed between the extent of outgrowth of DA fibers coming from the transplant and the number of amphetamine-induced turns. Fibers grew primarily into the medial striatum, even when the transplant was located centrally, and the innervation frequently assumed a patchy appearance. At 25 days post-transplantation the DA innervation still was varied in its extent and density, and often was no greater than that seen in animals killed at 15 days. The hyperinnervation of serotonergic projections from raphe that occurs after neonatal 6-HDA treatment (Snyder et al., J. Comp. Neurol., 1986) was unaffected by the transplant. No obvious difference in the extent or topography of DA innervation was noted between those animals that were turning at high rates to both stress and amphetamine and those turning less well to stress than to amphetamine. These observations suggest that something in addition to the dopaminergic outgrowth underlies the development of the behavioral response to stress. (Supported in part by USPHS grants NS19608 and EY05283.)

NEURAL PLASTICITY IN ADULT ANIMALS: SPINAL CORD

47.1 MORPHOLOGICAL STUDIES OF THE INTRAMEDULLARY AXON COLLATERAL SYSTEMS OF AXOTOMIZED α-MOTONEURONS. L. Havton* and J-O. Kellerth* (SPON: G.Grant). Dept. of Anatomy, Univ. of Umeå, S-901 87 Umeå, Sweden.

Intact axon collaterals have been suggested to exert a general protection against retrograde degeneration in axotomized neurons. However, little is known about the reactions of these axon collaterals in the axotomized cells. Therefore, the aim of this investigation was to study the effects of peripheral motor nerve transection on the intramedullary axon collateral systems of axotomized α-motoneurons in the cat spinal cord.

The medial gastrocnemius (MG) nerve was transected and prevented from reinnervation. Three, six and twelve weeks later axotomized MG α-motoneurons were labeled intracellularly with horseradish peroxidase (HRP) through microelectrodes. Intravascular perfusion and processing of the spinal cord tissue permitted subsequent morphological analysis of the HRP-labeled cells.

Compared with normal gastrocnemius α-motoneurons (Cullheim and Kellerth, 1978) there was a successive reduction of the number of intramedullary axon collateral trees in the axotomized MG α-motoneurons. Twelve weeks postoperatively approximately 40% of the axon collateral trees had been eliminated ($p<0.02$). The size and projection areas of the remaining axon collateral systems in the axotomized cells appeared unaffected by the injury. Ultrastructurally, however, some terminals of the latter systems contained dense-cored spheroid vesicles or amorphous material instead of the clear spheroid synaptic vesicles found in the motoraxon collateral boutons of normal unoperated cats (Lagerbäck et. al. 1981).

We conclude that following transection of a peripheral motor nerve the axotomized α-motoneurons may exhibit a partial loss of axon collateral systems together with ultrastructural changes in the terminals of the remaining axon collateral trees.

This work was supported by grants from the Swedish Medical Research Council (Project 02886).

47.2 COLLATERAL SPROUTING OF SAPHENOUS AFFERENTS IN THE ADULT RAT DORSAL HORN FOLLOWING PRONASE INJECTION OF THE SCIATIC NERVE. S.E. Kapadia* C.M. Kocol* and C.C. LaMotte. (Spon E. Manuelidis) Sec. of Neurosurgery, Yale Univ. Sch. of Med., New Haven, CT 06510

A past study (Fitzgerald, JCN 240:407) has reported sprouting of saphenous nerve terminals in the rat spinal cord following early postnatal sciatic nerve section in the rat; however there was a failure to sprout if the lesion was made after day 6. Similarly, thigh nerves failed to sprout collaterals in the dorsal horn following section of sciatic and saphenous nerves in the adult rat (Seltzer and Devor, Br. Res. 306:31). One explanation may be that while peripheral nerve section induces severe ganglion cell death and central terminal atrophy in the neonate (Bondok & Sansone, Exp Neurol. 86:322; Yip et al., J. Neurosci. 4:2986), in older animals more ganglion cells may survive (Aldskogius and Arvidsson, J. Neurocytol. 7:229; Sugimoto and Gobel, Br. Res. 248:377) and fewer primary afferent terminals degenerate; hence the stimuli for sprouting would be reduced. In order to determine if a profound loss of sciatic afferents can produce collateral sprouting in the adult rat, we injected Pronase, which produces death of ganglion cells and degeneration of their central terminal fields (LaMotte and Kapadia, JCN in press), into the sciatic nerve of adult rats, and examined the terminal fields of the saphenous with HRP labelling.

Adult Sprague Dawley rats were anesthetized with Nembutal. Then a unilateral injection of Pronase (Calbiochem, San Diego, CA) was injected into the sciatic nerve. After 4 months, the saphenous nerves on both the lesioned and control side were cut and the proximal end dipped in a mixture of HRP (7.5 mg) and WGA-HRP (.5mg) in PO4 buffer. Two days later the animals were perfused, and vibratome sections of L2-L6 reacted using the TMB technique.

On the control side of each animal, HRP/WGA-HRP labelled terminals followed the map of normal distribution of the saphenous in L2-L3. The saphenous terminal field on the lesioned side was identical to the control side at L2; however, beginning at the L2-L3 border, the saphenous terminal field of the lesioned side expanded laterally and medially into sciatic areas. The expansion increased to a maximum in caudal L3 and tapered to a narrow area in rostral L4; no label was found beyond mid L4.

The results indicate the adult rat does have the capacity for dorsal root afferent collateral sprouting when the appropriate lesion is made. The stimulus needed to induce sprouting may require a critical balance between too little deafferentation (nerve section) and too much deafferentation [rhizotomy, which may induce post-synaptic dendritic atrophy and gliosis (Kapadia and LaMotte, JCN in press)]. (Supported by NIH grant NS10174)

47.3 ANDROGENIC ORGANIZATION OF SYNAPTIC INPUT TO SPINAL MOTONEURONS IN ADULT RATS. A. Matsumoto*, P.E. Micevych and A.P. Arnold (SUM: C.H. Sawyer), Depts. of Anatomy and Psychology, Brain Research Institute, University of California, Los Angeles, CA 90024.

The motoneurons in the spinal nucleus of the bulbocavernosus (SNB) in male rats innervate the muscles bulbocavernosus and levator ani which attach to the penis. Both the SNB motoneurons and their target muscles contain androgen receptors. Castration of adult male rats results in a significant decrease in both soma size and dendritic length of the SNB motoneurons, and androgen treatment reverses this effect. This androgenic regulation of soma and dendritic membrane area implies a concomitant regulation of synaptic inputs to these membranes. We studied androgenic influences on synaptic inputs to SNB motoneurons using quantitative electron microscopic analysis. Adult male rats (Sprague-Dawley) were castrated and implanted subcutaneously with Silastic capsules containing testosterone or nothing. Sham-castrated males served as controls. There were 5 animals per group. Four weeks following castration, 1 ul of 0.2 % cholera toxin-horseradish peroxidase (CT-HRP) was injected bilaterally into the bulbocavernosus muscle and animals were sacrificed 2 days later. The spinal cords containing the SNB were sectioned at 50 um, processed with a modified tetramethylbenzidine (TMB) method for visualization of retrogradely transported CT-HRP and examined ultrastructurally. Montages were made of 141 TMB-labeled SNB motoneurons. The synaptic covering of SNB cells was analyzed by measuring the percentage of soma and proximal dendritic membrane contacted by synapses with clear membrane specializations, by synapses without specializations, and by other kinds of contacts such as soma-soma, soma-dendrite or dendrite-dendrite. In general, castration profoundly reduced the percentage of soma and dendritic membranes covered by synapses, and androgen prevented this effect. For example, all synaptic types covered 46.7 $\pm$ 1.3 % (mean $\pm$ SE) of soma membrane in sham castrates, 49.7 $\pm$ 2.3 % in castrates given testosterone, and 17.7 $\pm$ 1.0 % in castrates given blank capsules ($p<.0001$, ANOVA). Proximal dendritic synapses were similarly influenced by androgen. Castration also reduced the size and number of synapses per unit length of soma and dendritic membrane. For example, the average length of somatic synapses with membrane specializations was 1.76 $\pm$ 0.03 um in sham castrates, 1.43 $\pm$ 0.04 um in castrates given blank implants, 1.78 $\pm$ 0.03 um in castrates given testosterone ($p<.0001$). The average frequency of synapses was 0.229 $\pm$ 0.011 per um of soma membrane, 0.098 $\pm$ 0.005, and 0.253 $\pm$ 0.012 for the same groups ($p<.0001$). These results indicate that androgen is critical for maintaining the organization of synaptic input to these spinal motoneurons in adult male rats. (Supported by NIH grants NS23468 and HD15021).

47.4 SPINAL LOCALIZATION OF A PRIMATE MEMORY SUBSTRATE: OPERANTLY CONDITIONED H-REFLEX ASYMMETRY SURVIVES CORD TRANSECTION. J.R. Wolpaw and C.L. Lee. Wadsworth Labs, NYS Dept Hlth, Albany, NY 12201; and Depts Neurol & Anat, Albany Med Coll, Albany, NY 12208.

Study of primate memory substrates requires an experimental model in which the persistent CNS alterations are accessible to study. Our recent work (J Neurophysiol 50:1296-1319, 1983 & 57:443-459, 1987; Cell Molec Neurobiol 5:147-165, 1985) shows that the wholly spinal, largely monosynaptic, spinal stretch reflex and its electrical analog, the H-reflex, can be operantly conditioned: monkeys can gradually change reflex amplitude if reward depends on amplitude.

To learn whether H-reflex conditioning produces persistent spinal alterations, we measured triceps surae (TS) H-reflexes in previously conditioned (HR↑ or HR↓) monkeys before and after thoracic (T9-10) cord transection. In each monkey, we compared the conditioned leg to the unconditioned leg to determine whether reflex asymmetry persisted after removal of supraspinal control by transection.

Twelve previously conditioned monkeys (Macaca nemestrina) were deeply anesthetized throughout study and sacrificed by overdose. Recording cuffs were placed around TS nerve branches in both legs. L6-S1 dorsal roots (DR) were cut, and the proximal DR bundle on each side was placed in a stimulation (stim) cuff. A stim cuff was also placed around the intact L6-S1 ventral roots (VR) of both sides. The reflex response to 0.5 Hz supramaximal DR stim was measured in terms of the response to supramaximal VR stim which was the maximum possible response. Data from both legs were collected repeatedly before and for up to 72 h after transection.

In 7 HR↑ monkeys prior to transection, the response to DR stim in the HR↑ leg averaged 227% ($\pm$64%SE) of that in the other leg. Conversely, in 5 HR↓ monkeys prior to transection, the response to DR stim in the HR↓ leg averaged 67% ($\pm$10%SE) of that in the other leg. These asymmetries were still present after transection and persisted through the three days of study.

The results indicate that H-reflex operant conditioning causes persistent spinal cord alteration, a potentially accessible memory substrate. Current studies are further defining these physiologic data and beginning to seek anatomic correlates

47.5 RAPID NEURONAL AND GLIAL CHANGES IN THE PHRENIC NEUROPIL FOLLOWING SPINAL CORD INJURY: QUALITATIVE AND QUANTITATIVE RESULTS. H. G. Goshgarian and J. A. Rafols. Dept. of Anatomy and Cell Biology, Wayne State Univ. Sch. of Med., Detroit, MI 48201.

It is generally believed that injury induced morphological changes of the spinal cord take at least a few days to develop, especially in regions which are far removed from the initial site of injury. We have, however, observed, at the C4 segment of the spinal cord, specific morphological alterations of the normal ultrastructure of the rat phrenic neuropil occurring within 4 hours after spinal cord hemisection at C1. The phrenic neuropil is defined as the area of the spinal cord within the phrenic nucleus and immediately adjacent to phrenic cell body profiles. Phrenic neurons and their processes were identified at EM levels by retrograde HRP labeling. Several morphological features of the phrenic neuropil in uninjured animals and at 4 hours, 1, 2 and 4 days after injury were qualitatively analyzed and then quantitated with a computerized Bioquant morphometric system. Data was obtained from 100 micrographs of the phrenic neuropil taken from 4 animals in each group. Our results demonstrate: 1) astroglial process retraction away from their normal position in between adjacent phrenic dendritic profiles, 2) increases in direct membrane apposition among phrenic dendrites, and 3) an increase in the number of multiple synapses contacting phrenic motoneuron profiles. Multiple synapses are defined as contacts established between a terminal and more than one postsynaptic profile in the same plane of section. In the uninjured group, 80 $\pm$ 8.9 (S.E.M) multiple synapses were counted. The number of multiple synapses increased significantly (118 $\pm$ 8.9, $P < .0005$) as early as 4 hours after spinal cord injury and this high number persisted for as long as 4 days after injury (122 $\pm$ 9.3 at 1 day, 121 $\pm$ 10.1 at 2 days, and 117 $\pm$ 11.0 at 4 days). The percentage of phrenic dendrodendritic membrane appositions in the uninjured group was 35.4 $\pm$ 6.0. The increase in dendrite membrane appositions took at least 2 days after injury to reach significant levels (54.6 $\pm$ 8.4 at 2 days and 65.6 $\pm$ 10.0 at 4 days, $P < .005$).

It is possible that the above injury induced neuronal and glial changes may have a functional significance. In previous studies (Exp. Neurol. 66: 547-55, 1979 and 72: 211-25, 1981), we have associated functionally ineffective synapses to a delayed expression of a respiratory reflex in spinal cord injured rats. In this model, the conversion of the ineffective synapses to effective ones results in the functional recovery a portion of the animal's diaphragm which had been paralyzed by spinal cord injury. Evidence exists which suggests that the above neuronal and glial alterations could represent the morphological substrate for the unmasking of functionally ineffective synapses in our spinal cord injury model. Supported by U.S. Public Health Service Grant NS-14705.

47.6 EFFECTS OF SPINAL CORD TRANSECTION ON ONUF'S NUCLEUS MOTONEURONS OF CATS. J.C. Bresnahan, M.G. Leedy, M.S. Beattie. Depts. of Anatomy and Surgery, The Ohio State University, Columbus, OH 43210.

Urination and defecation reflexes are affected by spinal cord transection. Such changes may reflect alterations of the neural circuitry occurring within the sacral spinal cord (Thor,K. et al., Development and Plasticity of the Mammalian Spinal Cord, ed. M.E.Goldberger, A. Gorio, M. Murray, 1986). The present study sought to determine whether spinal cord transection results in changes in the organization of presynaptic elements to those motoneurons, located within Onuf's nucleus of the S1 spinal cord, which innervate the sphincters, Three groups of female cats were used: spinally intact, acute spinal transection (survival time of 4 days), and long term spinal transection (survival time of 10-11 weeks). Motoneurons in Onuf's nucleus were labelled by applying HRP to the pudendal nerve. Following a survival time of four days, all animals were perfused and the S1 spinal cord segments were prepared for electron microscopy. Onuf's nuclei from four animals per group were chosen for ultrastructural examination in which micrographs were obtained through the perimeter of five labelled cells per animal. From the resulting montages, the numbers and types of terminals contacting each labelled neuron, as well as the percentage of the perimeter contacted by terminals, with or without active zones, were determined. We found a tendency towards a decrease in the percentage of the motoneuron perimeter directly apposed by terminals for both spinal cord transection groups, compared to the spinally intact animals. When the percent of the neuronal perimeter contacted by synaptic active zones was examined, this decrease was more apparent for the short term transection animals, with some recovery seen for the long term animals. No changes were seen when the number of terminals per 100 um of perimeter were compared, although the long term transection group tended to have a larger number of terminals containing dense cored vesicles than did the other two groups. We conclude that changes in synaptic input to Onuf's nucleus motoneurons do occur following spinal cord transection, including changes in the amount of synaptic interaction, and, in the case of the long term transection group, shifts in terminal types. Such changes may reflect reorganization of the reflexes involved in urination and defecation following spinal cord transection, and may be indicative of both an initial decrease in synaptic efficacy, and in later reorganization of the reflex pathway. (Supported by NIH grants NS-10165 and NS-07747)

47.7 TESTOSTERONE DEPENDENT ULTRASTRUCTURAL ALTERATIONS IN THE SPINAL NUCLEUS OF THE BULBOCAVERNOSUS (SNB) IN MALE RATS. M.G. Leedy, J.C. Bresnahan and M.S. Beattie. Dept. Anat., Div. Neurosurg., and Neurosci. Res. Program, Ohio State Univ., Columbus, OH 43210.

The size of the motoneurons innervating the bulbocavernosus muscle (BC) in adult male rats have been shown to be sensitive to tesosterone (T) levels (e.g. Breedlove and Arnold, Science, 1981). While hormone dependent ultrastructural changes have been reported in hypothalamic neurons, no such analysis has been performed in the spinal cord. In the current study, 12 male rats were castrated and randomly assigned to the following groups; No T replacement; 48 hr T replacement initiated 6 weeks after castration; Long term T replacement initiated immediately after castration. SNB motoneurons were labelled by injection of HRP into the BC muscle. L6 spinal cords segments were processed for sequential light and electron microscopy (EM).

The SNB is characterized by dense bundles of rostrocaudally oriented dendrites. EM montages of the perimeter of 5 labelled neurons per animal indicated that approximately 4.6% of the somatic and attached proximal dendritic surfaces of the labelled cells in the nucleus was apposed by other somatic and dendritic elements, and frequently these appositions exhibited puncta adherentia (0.5% of the neuronal surface). Overall, 67% of the terminals in apposition to the labelled motoneurons contained round vesicles, 32% contained pleomorphic vesicles, and less than 1% contained flat vesicles; 23% of all terminals contained at least one dense cored vesicle.

Light microscopic analysis of labelled neurons in the SNB indicated that somatic ($p<0.05$) and nuclear size ($p<0.001$) decrease following castration without T replacement, with no reversal seen in the 48 hr group. Differences in nucleolar size were also seen (Long term T= 22um2, 48 hr T=20um2, and No T= 21um2, $p<.005$). The proportion of the somatic and proximal dendritic surface of the labelled motoneurons that was contacted by synaptic terminals was significantly increased by T replacement, and this effect was observed within 48 hours ($p<.005$). Similar results were found for the number of terminals per 100 um of membrane perimeter. An inverse response was observed in glial apposition ($p<.005$).

These results suggest that testosterone can not only affect neuronal morphology but also synaptic connections in the spinal cord. (Supported by NS-10165 and NS-07747)

47.8 CLARKE'S NUCLEUS IN THE ADULT RAT: CELL SURVIVAL AFTER AXOTOMY AND ITS RELATIONSHIP WITH RETROGRADE TRANSPORT. E. LOWENGER*, M.E. GOLDBERGER, and M. MURRAY. (SPON: L.L. Ross) Dept. of Anatomy, The Medical College of Pennsylvania, Philadelphia, PA 19129

Axotomy of intrinsic CNS neurons results in structural and metabolic changes culminating either in cell death, or survival without full functional recovery. The factors determining survival are uncertain. We have therefore studied the response of neurons within Clarke's nucleus (CN) in the rat to axotomy. CN is a continuous cell column within lamina V of Rexed in thoracic and upper lumbar spinal cord segments, their axons forming the DSCT within the ipsilateral lateral funiculus.

In adult female Long Evans rats (250-350g body wt) CN neurons from segments T12-L1 were studied. Cell morphology, number and size were studied using cresyl violet staining of 15μm paraffin sections. Gelfoam soaked in 40% HRP was placed bilaterally into the lateral funiculi at T5 48hrs prior to sacrifice to investigate retrograde transport. The tissue was then frozen-sectioned at 35μm and processed for TMB histochemistry.

In the normal animal CN from T12-L1 is bilaterally asymmetrical with 5.043±0.203 cells/section ($\bar{x}$±s.d.) on the right side and 4.432±0.543 cells on the left, but with equivalent cell sizes. About 70% of these cells label retrogradely with HRP symmetrically on both sides, and are thus projection neurons, indicating that about 30% of CN neurons do not contribute axons to the DSCT at T5 and may be interneurons. In experimental animals the right DSCT was lesioned by lateral funiculotomy at T1. One week after axotomy ipsilateral cell loss is about 9%. The ability to transport HRP is impaired with both number and intensity of labeled cells being greatly reduced, and many cells are chromatolytic. By two weeks, cell loss has increased to about 34%. However, the ability of surviving cells to transport HRP has recovered and the intensity of HRP labeling has returned. Cell survival was not limited to a specific cell size class within CN, and the average nuclear diameter and somal area of the axotomized neurons was comparable to those of controls.

CN neurons respond to axotomy initially with a decrease in retrograde transport, followed either by cell death or by a recovery of the transport. Liu ('55) described a similar dichotomy in cat CN, where axotomy led to two distinct forms of chromatolysis, only one of which led to cell death. This would indicate that the metabolic response to axotomy within CN is not uniform, and that CN projection cell survival is associated with a functional retrograde transport system.

47.9 PLASTICITY OF INTRINSIC AND EXTRINSIC SYSTEMS AFTER RHIZOTOMY OF RAT SPINAL CORD. S.D. Wang*, T. Eckenrode*, M.E. Goldberger and M. Murray. Dept. of Anatomy, The Medical College of Pennsylvania, Phila., PA 19129.

Previous studies of intrinsic (Tessler et al., Brain Res. 191:459, '84) and extrinsic (Goldberger & Paige, Soc. Neurosci. Abstr. 12:512, '86) systems in cat spinal cord had shown anatomical plasticity in response to complete lumbosacral rhizotomy. In the present study, we used the same paradigm to examine the plasticity of intrinsic and extrinsic systems in rat spinal cord in which previous studies had suggested a lack of plasticity. Thiamine monophosphatase (TMP), substance P (SP) and serotonin (5HT) were examined after acute and chronic unilateral dorsal root deafferentation. TMP was found across lamina II_i of the dorsal horn and was bilaterally symmetrical in normal animals. Ipsilateral to rhizotomy, TMP disappeared completely by 4 days and did not recover by 8 months. The contralateral dorsal horn was unaffected. An image analysis system was used to measure density of SP and 5HT immunochemical reaction product in dorsal horn of rats. After deafferentation in adult rats, SP decreased 22.3% on the experimental side in lamina I and II_o by 4 days and the density of SP staining had decreased 72.8% by 10 days. After six weeks postoperative, SP staining had recovered to 64.5% of normal values. Therefore the density of SP doubles between 10 days and six weeks postoperative. After deafferentation in 5 day-old rats, SP decreased and partially recovered on the experimental side more rapidly than in adult rats. In contrast to SP, 5HT did not decrease after deafferentation. Rather, we found a several-fold increase in 5HT staining at 4 days, 10 days and after six weeks postoperative in laminae I and II. Therefore, these three markers exhibited different responses to rhizotomy. TMP, an extrinsic system marker disappeared and did not recover. SP, present in extrinsic and intrinsic systems, exhibited a decrease and then a partial recovery. 5HT, an extrinsic system did not decrease but increased in response to partial denervation of a shared terminal field. This plasticity, comparable to that seen in cats, may be a result of sprouting terminals by the undamaged intrinsic and extrinsic systems or may represent an increased production of their markers.

47.10 MYELINATED FIBERS CONTRIBUTE TO DORSAL ROOT SPROUTING AFTER PARTIAL DEAFFERENTATION IN RATS. Dean POLISTINA*, Marion MURRAY and Michael E. GOLDBERGER. (SPON. T.J. Cunningham) Department of Anatomy, The Medical College of Pennsylvania.

Evidence for sprouting, following partial deafferentation, was obtained by comparing chronic and acute sides of the spinal cord (intra-animal) in cat. Inter-animal comparisons in the rat however, have provided no evidence for sprouting. The present study uses an intra-animal design in rats to demonstrate sprouting of the dorsal root terminals. Cholera-toxin HRP (CT-HRP) was used to see if myelinated fibers contribute to the dorsal root's response. For transganlionic labeling CT-HRP was injected into the sciatic nerve in rats with lumbosacral rhizotomies sparing L5. Controls included: 1.unoperated controls and 2.operated controls a) unilateral acute and b) bilateral acute rhizotomies. Experimental animals had a chronically spared root (>30 days) on one side and an acutely spared root on the other. In the unilateral controls labeling was ipsilateral except in S1 where some projections crossed the midline. There was no labeling in lamina II. Labeling in lamina I shifted from the lateral 2/3 in L6 to the medial 2/3 in L4 and was nearly absent in L3. From rostral L6 to rostral L4 the projection to laminae III and IV occupied the width of the dorsal horn, except the lateral 1/5. Operated controls unlike unoperated controls showed alternating bands of labeling density most noticeable in the more rostral projections to laminae III and IV. The absence of a banding pattern in these laminae in unoperated controls is presumably due to the overlapping terminal fields of the L4 and L6 dorsal roots. Projections to laminae V-VII were seen from S1 to mid L2 in the acute unilateral operated control, whereas in the unoperated controls labeling in these laminae was more dense and extended further caudally and rostrally. In rostral L2 only Clarke's nucleus and the fasciculus gracilis were labeled in either control preparation. Projections of the L5 dorsal root were variable; some animals had projections as caudal as S2, while some had projections to Clarke's nucleus as high as the T9-T8 border. These variations were always bilaterally symmetrical. In contrast, in animals with a chronic and acute spared root labeling was assymetric; the chronic side showed greater labeling than the acute side in laminae III-VII, Clarke's nucleus, and nucleus gracilis. Using an image analysis system, an increased density was shown quantitatively in lamina III and Clarke's nucleus. Cell measurements in the DRG showed that large cells were among the population labeled. The number of dorsal root ganglion cells labeled on the chronic and acute L5 ganglia was similar (± 7%) indicating that the increased projection on the chronic side was not due to diferences in CT-HRP application. Results suggest that the increased labeling may be due to collateral sprouting of the spared root or metabolic changes in the chronically isolated L5 DRG.

48.1 REINITIATION OF OUTGROWTH FROM DORMANT NEURONS IN CELL CULTURE. D.S. Grega and S.B. Kater. Program in Neuronal Growth and Development and Dept. of Anatomy, Colorado State Univ., Ft. Collins, CO 80523 and Boehringer Mannheim Diagnostics, Indianapolis, IN 46250.

Individual adult Helisoma neurons placed in culture, grow for several days after which time, they attain a stable, non-changing morphology. Growing growth cones are flattened and phase-dark, with very active filapodial and lamellapodial processes. With cessation of outgrowth, the growth cones are distinctly different; they become rounded and phase-bright and show no motility. Once attaining stable morphology, neurons remain viable for at least 7 to 10 days. This stable morphological state previously has been considered a non-reversible, terminal phase for growing neurons.

We report here that these morphologically stable neurons are in fact in a **reversible, dormant state.** Neurons from the pedal (P5) and buccal (B5 & B19) ganglia were grown in cell culture until they reached a stable morphology. At that time Helisoma serum was added to the culture dishes to a final concentration of 10%. Within hours,the majority of the neurons responded with a change in their stable state growth cone morphology from rounded, phase-bright neurite ends to flattened, phase-dark endings with active filapodial and lamellapodial processes. By 24 hours after the addition of serum, 70% of the P5's (n =33), 48% of the B5's (n = 29) and 39% of the B19's (n = 23) had grown, adding more than a criterion level of 50 μm in total neurite length. In fact many P5's increased more than 40 to 150% of their initial total neurite length (increased 800 to 7,000 μm).

Although the predominant neuroplastic change in response to serum is the initiation of outgrowth, there were neurons that responded with a net retraction of neuritic processes. In response to serum addition, 70% of P5 neurons (n=33) increased their number of neurites and the total neurite length, one did not change and the remaining 30% exhibited a net retraction of neurites. Thus, serum can significantly alter existing neuronal architecture.

The effect of outgrowth-modifying factors is clearly dependent upon the timing of their appearance.Serum can reverse a transmitter effect: B19 neurons whose growth was prematurely stopped by the addition of serotonin (40μM) exhibit the reinitiation of outgrowth in response to serum. In fact, serum itself is not uniquely able to reevoke outgrowth. Dopamine,which inhibits particular growing neurons, can reinitiate outgrowth from particular dormant neurons. Dopamine (100 μM) mimics the effect of serum on P5's with an increase in neurite length. B19 and B5 were unaffected by dopamine.

From these results our view of neuronal architecture of Helisoma neurons in cell culture is significantly modified. Given the proper stimulus even previously "stable" neurons can reinitate outgrowth,therefore demonstrating greater potential for remodeling than previously thought.Supported by N.I.H., N.S. 18819-04 to S.B.K.

48.2 CYTOARCHITECTURE OF THE NEUROMUSCULAR JUNCTION OF TENOTOMIZED-REPAIRED MUSCLE FOLLOWING IMMOBILIZATION. B.R. Pachter and N. Spielholz* Dept. of Rehab. Med., New York Univ. Med. Ctr., New York, NY 10016.

Rupture of the Achilles tendon is a common sports injury. Conventional surgical treatment involves tendon suture and immobilization using plaster cast with the foot in plantar flexion. Tenotomy as well as limb immobilization are known to have multifold effects on the muscle. Limb immobilization, especially in a shortened position, has been shown to produce denervation-like changes at the neuromuscular junctions which lead to terminal sprouting and an ultrastructural remodelling (Pachter, B.R., and Eberstein, A., J. Neurocytol.,13:1013,1984). The present study examined limb immobilized muscle in female Wistar rats (200-250 g) following tendon-repair. The Achilles tendons were cut and immediately suture repaired. These animals had their hind limbs immobilized in a shortened position by the application of a plaster cast; the knee was extended, the ankle fixed in plantar flexion, thereby shortening the soleus muscle. After two weeks, the soleus muscles were removed whole and prepared for electron microscopic examination. The innervation zone was localized and ultrathin sections were taken. Morphologically, the immobilized soleus muscle fibers appeared atrophic and their mitochondria and fibrillar size reduced. Autophagic vacuoles were observed and contained mitochondrial remnants and granular debris. Concentric membranous bodies were abundant. The majority of endplates of experimental animals contained one or more of these large concentric lamellated bodies juxtaposed to the postjunctional folds. In many endplates, the folds appeared highly-irregular shaped and attenuated. In addition, many of the synaptic clefts contained two or more axonal terminals separated by Schwann cell cytoplasm. Quantitatively, the mean postsynaptic area of junctional folds and clefts per nerve terminal in the tenotomized-repaired, immobilized endplates was significantly larger than those of controls. It would appear that Achilles tenotomy, tendon suture and immobilization in a shortened position results in an altered muscle morphology as well as a disrupted neuromuscular junction. Such damage to the muscle and endplate appear to be factors in the observed decreased strength following such a surgical approach. Supported in part by NIHR Grant G008300071.

48.3 EFFECTS OF DENERVATION AND REINNERVATION ON DENTATE GRANULE CELL FIRING. T.M. Reeves and O. Steward. Dept. of Neuroscience, Univ. of Virginia Sch. of Med., Charlottesville, VA 22908.

There is extensive evidence that following unilateral entorhinal cortex (EC) lesions, the ipsilateral dentate gyrus is reinnervated through sprouting of surviving afferents. One sprouting system, the crossed temporo-dentate (CTD), originates in the contralateral EC and shares an overlapping terminal field with the lesioned system. The time course of sprouting by the CTD is highly correlated with behavioral recovery after unilateral EC lesions (Reeves and Smith, 1987). However, the actual mechanism that sprouting plays in recovery remains unknown. A sprouting system may contribute to recovery by providing information normally conveyed by the lesioned system. Alternatively, sprouting may elevate the level of excitation in denervated cells, and thus restore processing regardless of information content. The present experiment approached this problem by examining the firing properties of dentate granule neurons before and after EC lesions.

Twenty-two adult male Sprague-Dawley rats (250-300 gm.) were prepared for single-unit electrophysiological recording under chloralose-urethane anesthesia. Twisted-wire stimulating electrodes were lowered into the right EC at 3, 4 and 5mm lateral to midline, with exposed tips at 2, 4 and 6mm below the cortical surface. A recording electrode (micropipette filled with 2M NaCl and 1% HRP, or glass-insulated tungsten) was lowered into the right dentate granule cell layer, and extracellular single-unit activity was amplified and stored on magnetic tape. Granule cells were identified by firing monosynaptically to EC stimulation, and in some cases by subsequent histological verification of HRP uptake. After 30 min. of baseline activity was obtained for each cell, the EC was lesioned by passing current (1 mA for 45 sec) through each wire used for stimulation. The mean spontaneous firing rate prior to the lesions was 6.48/s, but fell to 2.51/s immediately after the lesion. Firing rates remained significantly depressed (range of t values: 2.66-4.07;$p<.05$) even in cells held for up to 8 hr. Nine additional rats were given EC lesions and survived for 2, 4 or 6 days prior to recording. Mean firing rates were significantly depressed at 2 days (0.79/s) and at 4 days (2.3/s), but not at 6 days (4.94/s). Pattern of cell firing, as measure by joint interval histograms and coefficients of variation, was not altered by the lesions.

Following the EC lesions there was a clear recovery of dentate granule cell firing rate, but no such time-dependent change was observed for firing pattern. These results suggest that reinnervation may contribute to recovery by raising excitation in denervated cells, and not by supplying information normally conveyed by the lesioned system.

48.4 NEONATAL TRANSECTION OF THE INFRAORBITAL NERVE RESULTS IN TRIGEMINAL GANGLION CELLS WITH MULTIPLE PERIPHERAL AXONS. R.W. Rhoades, N.L. Chiaia, B.G. Klein, W.E. Renehan and M.F. Jacquin (SPON: S.E. Fish). Dept. of Anatomy, University of Medicine and Dentistry of New Jersey-School of Osteopathic Medicine and Robert Wood Johnson Medical School, Piscataway, NJ 08854.

Two different anatomical techniques were employed to demonstrate that neonatal transection of the infraorbital (IO) nerve in rats results in trigeminal (V) ganglion cells with multiple peripheral axons. In 19 neonatally nerve damaged, adult rats, horseradish peroxidase (HRP) was applied directly to the IO nerve proximally to the point of the initial lesion. In all animals, this procedure resulted in labelled V ganglion cells, and in 14, axons in mandibular V branches were also labelled. Such labelling was interpreted as an indication that some ganglion cells labelled by application of HRP to the IO nerve also sent axon collaterals into at least one other V branch. This phenomenon was never observed in identically treated, normal adults rats (N=4). In 28 additional, neonatally nerve damaged animals, multiple labelling techniques were used to verify the reorganization suggested by the HRP tracing. Here, diamidino yellow (DY) was injected directly into the regenerate IO nerve and true blue (TB) was deposited subcutaneously into non-IO peripheral territory. These experiments invariably produced a small number (46-401) of double labelled cells in the ophthalmic-maxillary portion of the ipsilateral V ganglion. Identical experiments in 9 normal adult rats never produced more than 6 double labelled cells per ganglion. Additional control experiments demonstrated further that this labelling could not be completely accounted for by peripheral sprouting of undamaged V primary afferents (see Chiaia, N.L. et al., this meeting).

Two additional series of sequential double labelling experiments showed further that multiply projecting V ganglion cells probably arose in two ways: 1. Development of non-IO projections by ganglion cells that contributed axons to the IO nerve at the time of the lesion, and 2. Elaboration of IO axon branches by primary afferents that had only non-IO projections at the time of the lesion.

Supported in part by DE 06528, DE 07734, and BNS 85-15737 (R.W.R.) and DE 07662 (M.F.J.). N.L.C. was supported by NRSA NS 07774.

48.5 PERIPHERAL SPROUTING OF UNDAMAGED TRIGEMINAL AXONS AFTER NEONATAL INFRAORBITAL NERVE LESIONS IN THE RAT. H.L. Enfiejian*, N.L. Chiaia and R.W. Rhoades (SPON: F.J. Wilson). Dept. of Anatomy, University of Medicine and Dentistry of New Jersey-School of Osteopathic Medicine and Robert Wood Johnson Medical School, Piscataway, NJ 08854.

We have used retrograde axonal tracing techniques to determine whether undamaged trigeminal (V) primary afferents sprout into denervated skin after transection of the infraorbital (IO) nerve in either newborn or adult rats. The IO nerve was transected behind the whisker pad either within 12 hours of birth or at about 60 days of age. After a 60 day survival period, the IO nerve was retransected and and 2 mm segment was removed. The second transection was carried out to insure that any labelled ganglion cell transported tracer from the periphery via a non-IO, V axon. Horseradish peroxidase conjugated to wheatgerm agglutinin (WGA-HRP) or diamidino yellow (DY) was then injected into the central portion of the ipsilateral whisker pad. Accomplishment of this experiment in otherwise normal, adult rats, normal neonates, or animals that sustained adult IO nerve transections produced no labelled cells in either the ipsilateral or contralateral V ganglia. Thus, the IO nerve provides the sole V innervaton of the whisker pad in both newborn and adult rats and IO nerve transection in adulthood does not result in peripheral V sprouting that is detectable by these methods.

Retrograde tracing in rats that sustained neonatal nerve transections invariably produced labelled cells in both the ipsilateral and contralateral V ganglia. Labelled cells on the contralateral side were restricted to the medial portion of the ophthalmic-maxillary part of the ganglion while those on the ipsilateral side were located more laterally. A few of these cells were in the mandibular part of the ganglion. In WGA-HRP labelled material, the average number of labelled cells in the contralateral ganglion was 19.5 $\pm$ 17.7 and their average diameter was 23.1 $\pm$ 4.0 um. The average number of labelled cells on the ipsilateral side was 84.5 $\pm$ 7.8 and their average diameter was 27.0 $\pm$ 6.6 um. The last value is somewhat greater than that for V ganglion cells labelled after injection of WGA-HRP into the whisker pad of normal rats (21.9 $\pm$ 6.1 um).

These data demonstrate that neonatal, but not adult, transection of the IO nerve results in both ipsilateral and contralateral peripheral sprouting of V axons. They indicate further that the primary afferents that sprout on the ipsilateral side arise from large V ganglion cells.

48.6 ENTORHINAL LESIONS, SPROUTING AND BEHAVIORAL RECOVERY. W. L. Isaac*, A. J. Nonneman & S. W. Scheff. University of Kentucky, Lexington, KY 40506.

Lesions resulting in partial loss of neuronal inputs signal undamaged residual inputs to sprout and replace lost synaptic connections. Coupled with the initial denervation is a marked change in specific behaviors which appears to recover with a time course parallel to the axonal growth. Glucocorticoid treatment suppresses sprouting of some afferents in the hippocampus following partial lesions. Glucocorticoid suppression of sprouting was paired with behavioral recovery on a DRL-20 task to explore this relationship.

Sprague-Dawley rats (2 mos) learned a DRL-20 task prior to surgery. The animals were assigned to one of 4 surgical groups: 1) unilateral entorhinal cortex lesion (UE), 2) bilateral entorhinal cortex lesion (BE), 3) unilateral occipital lesion (UO), and 4) bilateral occipital lesion (BO). Half of each surgical group received daily subcutaneous injections of hydrocortisone (H) (2 mg/kg) or vehicle beginning with surgery and continuing throughout all DRL-20 testing. Subjects further had either a 3 or 30 day interval before retention testing. Number of bar presses, reinforcements obtained and efficiency of performance were evaluated. Animals with UE lesions and a 3 day recovery interval (UE+3) received a lesion of the contralateral E after completion of retention testing. Bilateral operates with a 3 day recovery interval (BE+3) were given sham operations following retention testing. Both of these groups were allowed 3 days recovery following the second operation, followed by a second retention test. Thirty day recovery rats were subjected to a transection of the dorsal psalterium, which eliminates the crossed entorhinal-hippocampus projection. The occipital lesions failed to disrupt retention testing. UE+3 show an initial deficit in retention testing but return to preoperative levels. UE+H+3 subjects increased their bar pressing throughout testing, with no change in reinforcements obtained. BE+3 subjects showed increases in bar pressing following the lesion, with the vehicle treated subjects returning to control levels while H subjects failed to decrease responding. UE+30 animals failed to demonstrate any deficit during first retention testing while UE+H+30 subjects were severely impaired throughout testing. BE+30 rats were impaired on all measures regardless of treatment group. The second lesion (UE or dorsal psalterium) did not alter the subjects' response rates regardless of lesion or treatment group. It appears that, while entorhinal cortex is not mediating behavioral recovery in this situation, glucocorticoids and experience can alter behavioral recovery in this system.

48.7 PHORBOL ESTERS ALTER MORPHOLOGY AND N-myc EXPRESSION IN NCB-20 NEUROBLASTOMA. S.A. Berman, R.L. Kinnard,* W. Lu,* Neil Cashman and B.G.W. Arnason. Dept. of Neurology, Univ. of Chicago, Chicago, IL 60637.

Expression of myc oncogenes has been reported in several tumors and cell lines. The amplification of N-myc has been shown to correlate with degree of malignancy in human neuroblastoma (Brodeur et al. Science, 224, 1121, 1984), yet oncogenes, including N-myc, have been found to show expression at specific times in normal neurodevelopment (Zimmerman et al. Nature, 319, 780, 1986). Previous work in our laboratory and in laboratories of others has shown correlations between oncogene levels, differentiation, and treatments with agents such as dibutyryl cyclic AMP (db-cAMP) which affect the protein kinase A system. In particular we can demonstrate a correlation between db-cAMP treatment, apparent differentiation, and N-myc mRNA levels in NCB-20 cells, a hybrid cell line made from mouse neuroblastoma and chinese hampster embryonic brain cells. It was of interest, therefore, to extend our studies to examine the effects of stimulating the protein kinase C system with agents such as phorbol myristate acetate (PMA).

When NCB-20 cells are treated with PMA the following morphological changes are apparent: 1) appearance of short, stubby outgrowths quite unlike the slender neurite-like extensions produced with db-cAMP, 2) a rounding of the cell bodies and 3) an increase in the size of the cell bodies. These changes become apparent after 6 hours and are more distinct after 24 hours. Three levels of PMA treatment were studied: 10^{-8}M, 10^{-7}M, and 10^{-6}M.

Levels of N-myc were monitored by hybridizing ^{32}P labelled N-myc cDNA to mRNA in situ, in cells grown upon plastic cover slips. (Lawrence and Singer, Nuc. Acids. Res. 13, 1777, 1985). Stimulation with PMA appeared to produce a three fold increase in N-myc production.

When cells are treated with a combination of 10^{-6}M PMA and 10^{-3}M db-cAMP they appear similar to cells treated with db-cAMP alone. However the db-cAMP treated cells frequently cluster together and form ganglion-like structures whereas the cells treated with both PMA and db-cAMP do not form these organized aggregates. This feature may related to an alteration in surface membrane properties. Cells receiving combined PMA and db-cAMP treatment exhibit N-myc levels not significantly different than cells receiving PMA alone.

48.8 EFFECTS OF THE CALCIUM IONOPHORE A-23187 ON INJURED CENTRAL NEURONS OF THE LAMPREY. S. Clausse* and M.J. Cohen. Department of Biology, Yale University, New Haven, CT 06511.

In the lamprey, giant reticulospinal neurons sprout following axotomy. Moreover, shortly after axotomy, a large current has been measured entering the cut end of the axon. A large part of this current is due to an influx of calcium. In several in vitro preparation, calcium seems to be involved in regulation of growth cone elongation. The purpose of these experiments was to observe, in vivo, the effects of calcium on sprout elongation in regenerating vertebrate central neurons.

The axons of the giant reticulospinal cells of the larval sea lamprey were severed about 150 µm from their cell bodies. A 1 mm cube of gelfoam, soaked in 0.5-2 µM of the calcium ionophore A-23187, was placed in the fourth ventricle adjacent to the lesion. A-23187 increases the passive plasma membrane transport of calcium, leading to an increase in the intracellular concentration of calcium. Controls were treated in the same way, except that the gelfoam did not contain A-23187. Eight days after axotomy, the morphology of the cells was examined by injecting them with intracellular dyes.

We found that after axotomy, the sprouts from the soma-dendritic complex emerge earlier from cells treated with A-23187 than from control cells. These sprouts can reach a length of 60 µm by eight days. They differ from the thin sprouts usually seen in regenerating giant reticulospinal cells in that the entire length of these new processes are thick and swollen, rather than only the growing tip. The effect of A-23187 differs with the distance of the axotomy from the cell body. The sprouts appear less numerous and shorter when the axon is severed farther from the soma. With A-23187, when the axotomy is at an even more distant site, no soma dendritic sprouting is observed; however, there is a reduction in the size of the cell body.

Using an in vivo preparation, we have shown that the intracellular augmentation of calcium accelerates and increases the extension of new sprouts from injured neurons. The increased diameter of these new processes may be related to the abnormal level of the calcium in the cytoplasm of the treated cells. Thus calcium may act by affecting the incorporation of membrane or the rearrangement of cytoskeleton elements all along the length rather than only at the tip of the sprout.

48.9 MICROTUBULE-NEUROFILAMENT SEGREGATION AND INHIBITION OF NEURITE GROWTH IN CULTURED CHICK EMBRYONIC DORSAL ROOT GANGLIA CAUSED BY B,B'-IMINODIPROPIONITRILE (IDPN). R.G. Nagele, K. Bush*, E. Hunter* and H. Lee*. Univ. Med. Dent. of New Jersey - Sch. of Osteopathic Med. and Rutgers University, Camden, New Jersey, 08103.

IDPN has been shown to induce a distinctive reorganization of the cytoskeleton of large diameter axons such as those in the sciatic nerves of adult rats in which microtubules (MTs) are completely segregated from neurofilaments (NFs) (Papasozomenos et al., J. Cell Biol., 95:672, 1982; Griffin et al., J. Neurosci., 3:557, 1983). Furthermore, slow axonal transport of NFs along these axons is inhibited with no apparent effect on the rate of fast axonal transport. In the present study, we have investigated the effects of short- and long-term exposure of IDPN on neurite initiation and elongation and on established neurites. Particular attention was given to the neurite cytoskeleton in an attempt to resolve the separate roles of MTs and NFs in neurite initiation and elongation.

Dorsal root ganglia (DRG) were isolated from day 8 chick embryos and grown as either organized or dissociated cultures on glass coverslips coated with carbon and poly-L-lysine. Cultures were treated with the following concentrations of IDPN (1, 2.5, 5, 10, 20, 50, 100 and 150 ug/ml). At intervals during incubation, cultures were examined to determine the effects of IDPN on the extent of neurite sprouting, rate of elongation, number of neurites, and length of neurites. Randomly selected cultures from each treatment group were processed for conventional transmission electron microscopy.

In organized DRG cultures, IDPN treatment caused a reduction in the number and length of neurites and the radial growth of non-neuronal (glial) cells in a dose-related manner. At doses up to and including 50 ug/ml, the effects of IDPN appeared to be reversible. In cultures with neuritic outgrowths established for 48 h before treatment, IDPN was found to induce segregation of MTs and NFs, which were organized into separate clusters. MT-NF couplers (Nagele and Roisen, Brain Res. 253: 31, 1982) were redistributed and remained associated preferentially with MTs. Quantitative evaluation of neurite sprouting in dissociated cell cultures revealed that IDPN-treated neurons were able to extend only fewer and shorter neurites which contained predominantly MTs. This finding provides further evidence for the hypothesis that MTs are more important for the initial sprouting of neurites, but NFs are probably required for the subsequent extension and maintenance of longer neurites.

48.10 CORRELATION BETWEEN MOSSY FIBER SPROUTING AND SEIZURES IN KAINATE-TREATED RATS. J. Cronin and F. E. Dudek, Dept. of Psychology, Tulane University and Dept. of Physiology, Tulane Univ. Sch. of Med., New Orleans, LA 70112.

The neurotoxin, kainate, preferentially kills hippocampal pyramidal cells; the CA4/CA3 subfields are especially vulnerable. The CA4 forms associational and commissural fibers which project to the dentate granule cells, so their loss removes an input to the dentate granule cells. The mossy fiber (MF) axons of the granule cells sprout collaterals that appear to reinnervate the granule cell dendrites. Field potential recordings from dentate granule cells of kainate-treated rats have suggested these MF collaterals form functional connections (Tauck, D. L. and Nadler, J. D., J. Neurosci., 5:1016, 1986), which may then cause recurrent excitation. Since spontaneous seizures occur in kainate-treated rats, the present study was conducted to calculate the correlation between MF sprouting and spontaneous seizures.

Rats were systemically injected via the lateral tail vein with kainate at 14 mg/kg body weight. For 4 wk after the injection, subjects were observed daily (blind to experimental treatment), and the frequency and severity of any seizures was recorded. The daily scores were summed and divided by the number of observations to give a total behavior score. The animals were then sacrificed (n=36 kainate-treated, 29 vehicle-injected controls), brains removed, and hippocampi dissected out. The hippocampi were divided into thirds along the septo-temporal axis, and sections from each third were stained with a modified Timm's stain, which visualizes the MFs. The extent of MF sprouting in these tissues was scored subjectively as well as analyzed by densitometry using an image analysis computer.

When sprouting occurred, it was found almost exclusively in sections from the temporal third of the hippocampus; therefore, only data from the temporal sections were included in calculations of correlations. A significant correlation ($r=0.50$, $p<0.001$) was found between the subjective Timm's ratings and behavioral scores, and also between the densitometry-based Timm's score and the behavioral score ($r=0.24$, $p=0.05$). The two methods of quantifying the Timm's score also were highly correlated ($r=0.67$, $p<0.001$). No seizures were observed in the control animals, although 16 of the kainate-treated animals (44%) were observed experiencing seizures. Only one control animal showed MF sprouting (possibly miscoded), while 19 of the 36 (53%) kainate-treated animals had MF sprouting. These results indicate that kainate-treated animals showing spontaneous seizures are likely to have MF sprouting in the temporal hippocampus.
Supported by NIH grant NS 16683.

48.11 INTRAVENTRICULAR INFUSION OF NGF IN THE RAT DOES NOT ELICIT SYMPATHETIC INGROWTH. B.N. Saffran*, W.C. Mobley' and K.A. Crutcher (SPON. G.C. Schoenwolf) Dept. of Anatomy, University of Utah School of Medicine, Salt Lake City, UT, 84132 and 'Dept. of Neurology, Univ. of Calif. San Francisco, CA, 94143.

Substantial evidence suggests that central neurons in the mature mammalian brain can grow long distances given the proper environment (e.g., Aguayo et al., 1981), and that "reactive synaptogenesis" occurs after lesions to specific tracts in the CNS. Axonal elongation within the mature brain, however, is rare. One particular example of directed axonal growth within the adult CNS is the sprouting of perivascular sympathetic axons into the hippocampal formation following damage to the septohippocampal projection. Current evidence suggests that sympathohippocampal sprouting is specific in that it only occurs in response to septal denervation and is topographically restricted, at least in the rat, to the dentate gyrus and CA3 region of the hippocampus.

Since this example of axonal elongation represents collateral sprouting, i.e., the responsive neurons are uninjured, the stimulus responsible for its initiation must arise external to the growing axons. NGF, or a factor very similar to NGF, has been implicated in this particular sprouting model. In fact, NGF is present, and synthesized, in the rat hippocampal formation and the total amount of hippocampal NGF protein increases following septal denervation. In addition, injection of NGF antiserum has been reported to block sympathetic sprouting in response to septohippocampal denervation.

To test whether elevation of NGF levels in the CNS would elicit sympathetic sprouting without septal denervation, rats received intraventricular injections of NGF (or a vehicle control) via an osmotic minipump for a period of two weeks. Bisbenzimide was added to the vehicle in order to be certain that the pump solution was ejected. The brains were removed and immediatly frozen for histological analysis. Cryostat sections were reacted for norepinepherine flouresence using the SPG method of de la Torre to detect sympathetic sprouting and acetylcholinesterase staining was used to monitor the integrity of the septohippocampal innervation.

In none of the cases where there was evidence of successful infusion of the pump solution into the ventricular system (as determined by the presence of bisbenzimide labeling in the choroid plexus) was there any evidence of sympathetic sprouting in the hippocampal formation or any other brain region. The absence of sympathetic sprouting suggests that intraventricular injection of NGF is insufficient, by itself, to elicit sympathetic sprouting. Possible explanations for these findings include: 1) that NGF is not involved in the sprouting response, 2) intraventricular NGF is not available to the perivascular sympathetic fibers, 3) a gradient of NGF is necessary for the elicitation of sympathetic sprouting and such a gradient is not established by intraventricular infusions of the protein during the time period we studied, 4) NGF is necessary but not sufficient for sympathetic sprouting to occur, suggesting that removal of septal fibers results in other changes in addition to effects on hippocampal NGF. (Supported by NIH grant #NS-17131)

49.1 SMOOTH PURSUIT EYE MOVEMENTS ARE NOT DRIVEN SIMPLY BY TARGET VELOCITY. R.J. Krauzlis* and S.G. Lisberger (SPON: S. Bodary). Dept. of Physiology, Div. of Neurobiology, University of California, San Francisco, CA 94143

The primate smooth pursuit system uses retinal image motion to generate tracking eye movements. Simple models of the pursuit system possess a fixed sensitivity to retinal velocity errors (RVEs). We have found, however, that the pursuit system has a separate response to retinal acceleration errors (RAEs) and that the sensitivity to RVEs changes dynamically during the 300-400 ms required to foveate a moving target.

Eye movements were monitored using the scleral search coil technique in two Rhesus monkeys. The monkey was seated with head immobilized 3.7 feet from a screen onto which targets were projected. Trials began when the monkey fixated a stationary spot at straight-ahead gaze. At a random time, this spot was extinguished and a second spot appeared at an eccentric position and moved horizontally with a specified velocity or acceleration. One set of experiments examined the initiation of pursuit. Known RVEs and RAEs were presented by taking advantage of the fact that target motion equals retinal image motion during the 90 ms prior to the initiation of pursuit. Other experiments imposed known errors in open loop conditions during pursuit. The target was driven with a signal composed of the current eye position plus the desired error signal.

Constant RAEs of 45-400 °/s^2 and constant RVEs of 2-25 °/s produced smooth eye accelerations. The averaged data were subjected to a quantitative analysis to determine whether the responses to constant RAEs were actually due to RVE sensitivity. Using observed eye accelerations to constant RVEs, we predicted on a millisecond time scale the eye velocity response expected from the sequence of velocity errors contained within a smooth acceleration. The actual eye velocity increased at an initial rate that was greater than that predicted from RVEs alone. We conclude that the pursuit system possesses a sensitivity to RAEs *per se*.

We examined changes in sensitivity to RVEs as a function of time by imposing RVEs under open loop conditions at various times, from just before to 600 ms after the onset of pursuit. The magnitude of eye acceleration for a given RVE depended on when the RVE was imposed and on whether the RVE was in the same (*onward*) or opposite (*backward*) direction relative to target velocity. Eye accelerations for onward RVEs were largest when presented within the first 50-150 ms of eye motion and then decreased. Eye accelerations for backward RVEs increased from initiation to 600 ms. For example, in one monkey, eye acceleration was 331 °/s^2 to an onward RVE of 25 °/s imposed at 100 ms after pursuit initiation, but 156 °/s^2 when imposed at 200 ms. Eye acceleration was 93 °/s^2 to a backward RVE of 25 °/s imposed at initiation, but was 235 °/s^2 when the error was imposed 200 ms later. Thus, the pursuit system is initially much more sensitive to onward RVEs. This bias reverses at 200-300 ms after initiation of pursuit, when the pursuit system becomes more sensitive to backward RVEs.

We conclude that pursuit eye movements are not driven exclusively by a neural analogue of target velocity and that sensitivity to visual feedback is dynamically regulated. Sensitivity to RAEs may improve the response characteristics of the pursuit system. Changes in RVE sensitivity may reflect a strategic gating of visual information that improves the ability of the pursuit system to extract relevant feedback signals. (Supported by NIH grant EY03878)

49.2 EVIDENCE THAT VISUAL INPUTS DRIVE OSCILLATIONS IN EYE VELOCITY DURING SMOOTH PURSUIT EYE MOVEMENTS IN THE MONKEY. D. Goldreich* and S.G. Lisberger (SPON: J. Bixby). Dept. of Physiology, Div. of Neurobiology, University of California, San Francisco, CA 94143

When primates use smooth pursuit eye movements to track constant-velocity target motion, their eye velocity oscillates about the target velocity. The oscillations are sinusoidal and undamped, with a peak-to-peak amplitude of about 5 deg/sec when the target moves at 30 deg/sec. The goal of our study was to determine whether the oscillation frequency changes when the delay around the visual feedback loop is altered. Variation of oscillation frequency as a function of delay would imply that the oscillations are visually driven. Invariance of the oscillation frequency would imply that the oscillations result from an internal oscillatory mechanism.

We monitored horizontal and vertical eye position using the magnetic search coil technique in two Rhesus monkeys. During experiments, the monkey was seated with head immobilized 3.7 ft from a screen onto which targets were projected. The monkey was required to fixate a stationary target at straight-ahead gaze. At a random time, this target was removed and a second, eccentric, target was moved horizontally at 30 deg/sec for 900 msec. The monkey was required to track the moving target in order to receive a water reward.

In one set of experiments, pursuit latencies ranging from 65 to 104 msec were obtained by varying the size and brightness of the projected target. The oscillation frequency decreased monotonically as the latency was increased. When the latency was 65 msec, the oscillation frequency was 6 Hz; when the latency was 104 msec, the oscillation frequency was 4 Hz. In another set of experiments, we artificially imposed extra delay in the visual feedback loop. The target was driven by a signal that was equal to desired target velocity (T = 30 deg/s) plus the difference between current eye velocity (E(t)) and eye velocity at a previous time (E(t - Δt)). At time t, this procedure produces a retinal velocity error of T minus E(t - Δt) instead of T minus E(t). The loop delay is therefore increased by time Δt. The oscillation frequency decreased monotonically as artificial delays up to 100 msec were imposed. In one experiment, for instance, as the imposed delay was increased from 0 to 100 msec the frequency fell from 6 to 2 Hz. Our two methods for increasing the delay - naturally by decreasing target size and brightness or artificially by delaying feedback - appear to be equivalent procedures. A frequency of approximately 4 Hz, for example, resulted from either (1) a 104 msec latency without added delay or (2) a 65 msec latency with 40 msec added delay. In both cases, the total delay around the loop, equal to the sum of latency and added delay, was approximately 105 msec.

Our results show that the frequency of pursuit oscillations depends on the total delay around the visual feedback loop. A delay-dependent oscillation frequency is incompatible with models in which the oscillations are driven solely by internal oscillatory mechanisms. We conclude that the oscillations in smooth pursuit eye movements are visually driven. (Supported by NIH grant EY03878).

49.3 ANTICIPATORY SLOW EYE MOVEMENTS DURING SMOOTH PURSUIT. Duane K. Boman and John R. Hotson. Institute for Medical Research-Santa Clara Valley Medical Center, San Jose, and Stanford University School of Medicine, Stanford, CA 94305.

Anticipatory slow eye movements are highly preditive, low velocity, smooth eye movements that precede both ramp and step target motions. The utility of these predictive responses is unclear. They are restricted by visual fixation targets and add little toward synchronizing smooth pursuit with the onset of target motions unless the fixation target is extinguished for a short period of time. Predictive, low velocity, smooth eye movements also precede terminations and direction changes of ramp stimuli. All of these predictive responses are similar in that they move the fovea away from the target. These observation make it attractive to suggest that these predictive responses share common mechanisms and are part of the predictive component of smooth pursuit. Therefore, a model is proposed in which the predictive responses produced during smooth pursuit are the sum of the anticipatory deceleration produced prior to the termination of ramp motion and the anticipatory acceleration produced prior to the initiation of ramp motion (when visual fixation is removed by a gap in the target presentation).

This model was tested by presenting subjects with highly predictable double ramp stimuli. The second ramp of the pair changed the direction of motion by either 90 or 180 degrees. With 180 degree direction changes, horizontal ramp speeds of 2, 6, and 10 deg/sec were presented, thus producing nine conditions. With 90 degree direction changes, the horizontal ramp speed was 6 deg/sec and the vertical ramp speed was either 6 or 10 deg/sec. Under each condition the stimulus was extinguished for 600 msec prior to the initiation of the first ramp. Eye movements were recorded from three subjects with a Dual Purkinje Image eyetracker. Average slow eye velocities were determined before and after the initiation of the first ramp, the termination of the second ramp, and the change in the direction of ramp motion.

Under each condition, eye velocity decreased prior to the change in ramp direction and was subsequently followed by a rapid acceleration that synchronized the eye and target velocities. The time course, velocities and direction of these 180 and 90 degree predictive turns in smooth pursuit were closely reproduced by summing the anticipatory velocities that were produced prior to the initiation and termination of unidirectional ramps of comparable speeds. Therefore, it is suggested that anticipatory slow eye movements are both active and useful during smooth pursuit, that they show directional specificity and are produced by the predictive component of smooth pursuit.

49.4 PRIMATE OCULOMOTOR PURSUIT OF A HAND CONTROLLED VISUAL TARGET: SMOOTH PURSUIT LATENCY DECREASES TO ZERO DURING ACTIVE HAND MOVEMENTS.

R. Domann* and R. Eckmiller (SPON: J.-P. Ewert).
Division of Biocybernetics, University of Düsseldorf, FRG.

Initiation of foveal pursuit has a latency T of about T=120 ms between the onset of target movement and eye movement. This latency was used here as an indicator to study possible synchronization and coupling of the neural control of eye and hand movements in primates.

Two monkeys (Macaca fascicularis) sitting in an upright position with their heads firmly attached to the upper portion of a primate chair, had been trained to pursue a horizontally moving (on a semi-circle with 15 cm radius) visual target (0.8 deg diameter). One hand (invisible to the animal) held a pointer, which could be moved along the semicircular path of the visual target between 20 deg left and right. Target movements were generated under three conditions: a) external control unrelated to hand movement; b) target position coupled with hand-held pointer position during spontaneous hand movements; c) as in b) but target and hand move in opposite rather than same directions.

Results

1. Under condition a), statistical analysis of the latency T yielded mean values of T=120 ms in agreement with the literature.
2. Under condition b), T decreased within several days of training from initial mean values of T=120 ms to T=0 ms.
3. Under condition c), too, T decreased within several days of training this condition from initial values of T=120 ms to T=0 ms.

Conclusions

Motor control signals for active hand movements as under conditions b) and c) can be used to generate synchronized oculomotor control signals for initiation of foveal pursuit eye movements. This finding supports the hypothesis that the motor program generators for both hand movement and pursuit eye movement can be initiated by the same pre-motor signal.

The neural pathways connecting the two motor program generators for hand and eye movements (presumably by means of efference copy signals) are the topic of a subsequent study using chemical lesions.

49.5 TORSIONAL EYE MOVEMENTS IN THE MONKEY DURING HORIZONTAL FOVEAL PURSUIT: BEHAVIORAL AND NEUROPHYSIOLOGICAL EVIDENCE.
R.Eckmiller and D.Ott*, University of Düsseldorf, FRG.

The existence of rapid and slow torsional eye movements (Collewijn et al., Exp.Brain Res. 59, 185-196, 1985; Fender, Brit.J.Ophthal. 39, 65-72, 1955) is ignored and not detectable by most oculomotor recording systems and seems particularly unlikely during foveal pursuit of horizontally moving small targets. A detailed analysis of the transformation of retinal events into pursuit eye movements, however, yielded two lines of evidence for additional torsional components.

Java monkeys (Macaca fascicularis) sitting in an upright position had been trained to pursue a small (8 min. of arc) target against a homogeneous background at 1.5 m distance in the lower photopic range. Sinusoidal target movement (0.3 - 1.2 Hz at 10 deg amplitude) was confined to a line on the screen in the horizontal plane of the eye balls. Movements of the fundus pattern of the left eye were monitored by means of TV-ophthalmoscopy (ophthalmoscope combined with a light-sensitive TV camera and video tape attached to the primate chair), while vertical and horizontal eye movements of the pursuing right eye were recorded with an infrared oculometer(Bouis).

Single unit recordings from ocular motoneurons were obtained in a related study by one of the authors (R.E.).

Results

1. During spontaneous fixations close to the primary position, small rapid torsional movements (below 1 deg of rotation about the line of gaze) often accompanied spontaneous saccades, although a systematic correlation between torsion and eye position could not be detected.
2. During horizontal foveal pursuit both rapid and smooth torsional movements (below 1 deg of rotation) were clearly superimposed on the horizontal (and occasionally small vertical) eye movements of the left eye. A systematic correlation between the smooth torsional components and horizontal eye position is presently being studied.
3. The instantaneous impulse rate of ocular motoneurons for control of vertical and/or torsional eye movements (musculus r.s., r.i., o.s., o.i.) was often found to be systematically slightly modulated (range of ± 5 Imp./s at 100 Imp./s) during horizontal pursuit but not during fixation along the pursuit track. While the line of gaze passed the primary position (with maximum eye velocity) during horizontal pursuit, the impulse rate typically reached its maximum or minimum in the absence of any measurable vertical movements.

It is concluded that: A) the observed torsional movements generate afferent visual signals of target rotation during horizontal pursuit and B) the emerging finding of a systematic correlation between torsion and eye position implies that the four vertical eye muscles are not kept in a 'fixation mode' during horizontal pursuit but receive small dynamic neural control signals.

49.6 OCULAR PURSUIT DURING YAW ROTATION IN HUMANS. X.N. Sahyouni*, V. Matsuo, and B.W. Peterson. Dept. of Physiology, Northwestern Univ. Med. Sch. and Sensory Motor Performance Program, Rehab. Inst. of Chicago, Chicago, IL 60611.

While it has been shown that smooth pursuit and suppression of the vestibulo-ocular reflex (VOR) are not the same process (McKinley and Peterson, Exp. Brain Res. 60:454) the interaction between the two has not been carefully studied. We examined this interaction by requiring a subject (S) to pursue a horizontally moving target while he was rotating in the horizontal plane.

We used five normal Ss who sat in a servo-controlled rotating chair (Neurokinetics) with the head held in a chair-mounted head restraint. The pursuit target was a 0.25 degree spot produced by a servo-controlled laser projection system. Eye movements were recorded using D.C. electro-oculography. Vestibular stimuli consisted of 40 deg/sec ramps. Pursuit stimuli were ramp target motions that initially moved with the chair at 40 deg/sec and then either moved in the same direction at 80 deg/sec, or in the opposite direction at 40 deg/sec. We also measured smooth pursuit of 40 and 80 deg/sec targets with S stationary (SP40, SP80) and baseline VOR with S relaxed (VORr) or attempting to follow an earth-stationary or chair-fixed target (VORe, VORs).

In the condition where the target moved in the direction of chair rotation at 80 deg/sec (40 deg/sec relative to S), Ss' smooth eye velocities averaged 22 deg/sec, which was not different from the sum of VORr + SP40. It was lower than the sum of VORs + SP40, which averaged 32 deg/sec. Thus Ss cannot effectively combine suppression of the VOR and pursuit to enhance the tracking of a target moving with the chair.

In the condition where the target moved opposite to the chair at 40 deg/sec (80 deg/sec relative to S), Ss' smooth eye velocities averaged 52 deg/sec. This was lower than the sum of the predicted smooth pursuit contribution + either VORr (66 deg/sec) or VORe (72 deg/sec). Thus not only were Ss unable to combine pursuit and VOR enhancement, they also could not combine pursuit and baseline VOR when tracking the target. This suggests that Ss may suppress their VOR when pursuing moving targets while rotating.

These findings suggest that interactions occur between smooth pursuit and the VOR whenever both the subject and the target are in motion.

49.7 SMOOTH PURSUIT AND SACCADIC EYE MOVEMENTS IN PATIENTS WITH ALZHEIMER'S DEMENTIA AND SCHIZOPHRENIA. Daniel Hommer, Trey Sunderland*, Thomas Clem*, GRECC, Rm. 182B, Seattle VAMC, 1660 S. Columbian Way, Seattle WA, 98108, Laboratory of Clinical Science, NIMH, Biomedical Engineering Branch, NIH

Eye movements of patients with schizophrenia, Alzheimer's dementia (DAT) and age matched controls were examined using an infra-red reflection technique. Eye position data was collected at 1000 hz and stored, displayed and analyzed using a specially developed microcomputer system. Recording was done in a quiet, darkened room. A small square on a video monitor was used as the target.

Patients with DAT showed a marked impairment in their smooth pursuit which correlated with the severity of their cognitive impairment. The more severely affected individuals with DAT had nearly complete replacement of smooth pursuit by saccadic eye movements. Patients with DAT also showed a prolonged saccadic latency and failure to learn a step-gap task which required the ability to predict a simple, repetitive pattern of target movements.

As a group schizophrenics also had worse smooth pursuit than cotrols but the magnitude of their dysfunction was much less than that of the patients with DAT. Over half of the schizophrenics had smooth pursuit which was indistinguishable from that of controls. Schizophrenics had normal saccadic latency, but patients receiving chronic neuroleptic treatment had marked dysmetria (undershot) on a step-gap task. This dysmetria was present to a much less extent in drug free schizophrenics. Dysmetric saccades to a remembered target may be secondary to chronic dopamine blockade. A small group of schizophrenics who also showed the worse smooth pursuit tracking failed to learn to predict target behavior in the step-gap task. These patients may represent a subpopulation of schizophrenics with cortical dysfunction.

49.8 EFFECTS OF KETAMINE ON OCULOMOTOR FUNCTION IN THE MONKEY. Charles J. Bruce and Gary S. Russo*. Section of Neuroanatomy, Yale Univ. School of Medicine, New Haven CT 06510.

The effects of the dissociative tranquilizer ketamine hydrochloride on the oculomotor system of macaque monkeys were investigated using a search coil to monitor eye movements. The primary effect of ketamine, especially in the absence of sensory stimulation, was to suppress all manner of eye movements. A few min after giving the ketamine (5-10 mg/kg IM) the gaze came to rest near the primary position (PP) in the orbit and did not move appreciably for 15-30 min thereafter. This severely fixed gaze is in marked contrast to the spontaneous saccades characteristic of awake monkeys and the slow, wandering eye movements characteristic of light sleep and sedation. We have analyzed the effects of ketamine on the different classes of conjugate eye movements.

All types of slow eye movements were strongly affected by ketamine. Optokinetic nystagmus (OKN) was virtually abolished; large (~50° square) drifting gratings no longer elicited OKN even though the eyes remained open. Similarly, the vestibular ocular reflex (VOR) was effectively eliminated; during passive sinusoidal head rotation the eyes were fixed in the orbit, at least to the accuracy of our measurements in this situation. We further investigated the effects of ketamine on the VOR via caloric stimulation of the canals. Instead of nystagmus, the gaze quickly drifted 2-6° ipsilateral to the ear that was irrigated with cold water, stayed there, and then slowly drifted back to the PP shortly after the irrigation ceased. Two monkeys with pathological constant-velocity nystagmus were tested; one had an omnipresent nystagmus accidentally caused by an experimental surgery, the other had nystagmus in the dark, probably caused by antibiotic therapy. For both monkeys ketamine completely eliminated the nystagmus and their gaze quickly came to rest near the PP.

Ketamine also had several effects on saccadic eye movements. (1) The gaze immediately drifted exponentially back to the PP after saccades in any direction. (2) Very few saccades ocurred during the acute intoxication, especially in the absence of sensory inputs (e.g. in the dark) . (3) More frequent saccades, predominantly upwardly directed, ocurred during the recovery from ketamine, especially in an illuminated environment. Epochs of these rapid upward movements and slow downward drifts comprised a gaze-dependent vertical nystagmus. Nystagmus is a prominent clinical sign of intoxication by ketamine or by the closely-related substance phencyclidine (PCP). (4) Threshold currents for evoking saccades with electrical stimulation of the frontal eye fields were raised by ketamine, and oblique elicited saccades became more vertical.

An hypothesis that explains many of these effects is that ketamine temporarily disables the "neural integrators" in the brain stem that are postulated as the mechanism for converting eye velocity commands into tonic eye position signals for the oculomotor neurons. Thus movement caused by the saccadic "pulse" are not maintained because the saccadic "step" that usually accompanies the pulse is eliminated. Similarly, feed-through of a tonic head velocity signal from caloric stimulation of the canals can effect a small static shift via direct connections between the vestibular and oculomotor nuclei, but the absence of ongoing integration of that velocity signal precludes true ocular tracking. If this neural integration hypothesis proves correct, then ketamine should provide a usefull tool for dissecting the basic mechanisms of the oculomotor system.

49.9 THE DEVELOPMENT OF NYSTAGMUS IN INFANT MONKEYS FOLLOWING VISUAL DEPRIVATION. R.J. Tusa, C.B. Smith and S.J. Herdman, Johns Hopkins University, Baltimore, Md. 21205, and Lab of Cerebral Metabolism and Lab of Neuropsychology, NIMH, Bethesda Md. 20892.

Monkeys monocularly deprived of vision by tarsorrhaphy at birth and then reverse sutured 25 days later (opening the closed eye and closing the other) developed nystagmus 2-3 days after the reversal. This nystagmus was not due to blindness; the monkeys visually-tracked small moving objects and their reflection in a moving mirror. In contrast, monkeys monocularly or binocularly deprived of vision for 25 days did not develop nystagmus that could be detected by visual observation.

In 2 monkeys eye movements were recorded with scleral search coils that were implanted at the time of the reverse suture. A conjugate jerk nystagmus with slow phases directed up and nasally with respect to the opened eye developed 2-3 days after the reversal. The slow phases appeared linear and the peak velocity reached a maximum of 10deg/sec. During the second week, the nystagmus waveform became more variable. Jerk nystagmus in all directions, pendular nystagmus, and combinations of pendular and jerk nystagmus were all observed. The slow phase components of the jerk nystagmus were often of increasing velocity peaking at 30deg/sec. By the third week, peak velocity of slow phases reached values as high as 100deg/sec. The nystagmus did not change when the monkeys were placed in the dark, although the nystagmus was markedly attenuated during eye closure and drowsiness (slow phase eye velocities <3deg/sec). In one monkey, both eyes were opened 3 weeks after the reverse suture. In this animal the nystagmus remained unchanged for the duration of the study (90 days).

The waveform of the nystagmus induced by reverse eye lid suture in infant monkeys resembles congenital nystagmus in human beings. Further studies are underway to determine the effects of reverse suture on visual acuity and eye tracking ability.

49.10 VESTIBULAR OCULAR ORGANIZATION IN VERTEBRATES IS A LARGELY CONSERVED PHYLOGENETIC PLAN. R. Baker, J.M. Delgado-Garcia*, W. Graf and R.F. Spencer. Dept. of Physiol. & Biophys., NYU Med. Ctr., New York, N.Y., Fac. Biol., Seville, Spain., Rockefeller Univ., New York, N.Y. and MCV, Richmond, Va.

Teleosts are uniquely different from other vertebrates in that the abducens nucleus exhibits two separate subdivisions and is located ventral in the medulla. In previous intracellular recording, HRP injection and light/electron microscopy of oculomotor motoneurons in the goldfish, Carassius auratus, we described the characteristic synaptic profiles producing excitation and inhibition. Herein we compare those findings with morphological, physiological and immunohistochemical studies of the goldfish abducens nucleus. Electron microscopy of HRP labeled abducens motoneurons showed numerous axo-somatic/dendritic synaptic endings containing spheroidal synaptic vesicles establishing both chemical (asymmetrical pre-/postsynaptic specialization) and extensive electrotonic (apposed membranes exhibiting gap junctions) synaptic contacts. Intracellular recording from antidromically identified abducens motoneurons revealed robust short latency electrotonic EPSPs (0.5 msec latency) followed by chemical depolarizations (1.3 msec) evoked by electrical stimulation of the contralateral vestibular nerve. Other axosomatic synaptic endings containing pleiomorphic vesicles established only chemical synaptic specializations. As expected, stimulation of the ipsilateral vestibular nerve revealed IPSPs (1.4 msec) that were reversed following injection of current and/or chloride ions. Like the mammalian abducens nucleus, efficacy of inhibition was demonstrated by blockade of the antidromic field potential following isolated electrical stimulation of the horizontal canal nerve. Immunohistochemical labeling in both the goldfish oculomotor and abducens nucleus was consistent with our findings in mammals demonstrating glycine and GABA to be the inhibitory neurotransmitter of second order vestibular neurons related to the horizontal and vertical vestibulo-ocular reflex, respectively. Collectively these data from the abducens and oculomotor nuclei demonstrate a common arrangement of vestibular inhibition and excitation across diverse vertebrate species. Although our detailed comparisons reveal quantitative differences in density of presumed inhibitory and excitatory contacts including gap junctions, it is the overall similarity of vertebrate vestibular ocular organization that is most striking. Viewed on an evolutionary scale these observations are noteworthy, because each of the many species studied to date are far removed, in divergent directions, from the 'truly primitive' vestibular ocular plan. Supported by NEI 02007, 04613 and 02191.

49.11 THE SOMA-DENDRITIC ORGANIZATION OF PHYSIOLOGICALLY CHARACTERIZED AVIAN EXTRAOCULAR MOTONEURONS. Juan Carlos Letelier*, Craig Evinger, and Josh Wallman. Dept. of Biology, City College, CUNY, New York, NY 10031 and Dept. Neurobiology & Behavior, SUNY, Stony Brook, NY 11794.

The physiological organization of the avian oculomotor system differs from that of mammals in that two separate types of motoneurons within a nucleus control tonic eye position ("tonic" neurons) and saccadic trajectory ("phasic" neurons). The tonic motoneurons are involved in positional control and, between saccades, fire at a steady rate correlated with eye position. All tonic motoneurons pause for every saccadic eye movement, regardless of direction. In contrast, the phasic motoneurons are completely silent except during saccadic eye movements, when they discharge with the 25 Hz oscillations typical of avian saccades. Trochlear motoneurons of this type exhibit a brief burst of spikes just prior to and during the beginning of each intorsional phase of the oscillatory eye movement.

To investigate the anatomical organization of these two classes of motoneurons, physiologically characterized neurons from the trochlear and oculomotor nuclei of alert chickens were intracellularly impaled and injected with horseradish peroxidase. Eye position was monitored with eye coils so that neurons could be classified as phasic or tonic.

Chicken extraocular motoneurons are similar in appearance to those of other species. Both trochlear and oculomotor motoneurons had five to seven primary dendrites. Although often beaded, the dendrites were rarely spiny. The dendrites of each motoneuron extended throughout the entire subdivision corresponding to the muscle that they innervate. Except for medial rectus motoneurons, the dendrites also extended outside of the nucleus into the medial longitudinal fasiculus (MLF) and adjacent reticular formation. In following motoneuron axons until they exited the brain, we never found any collaterals. While the overall appearance of "phasic" and "tonic" motoneurons was similar, phasic motoneurons tended to have thicker primary dendrites than tonic motoneurons. In addition to motoneurons, we stained axons within the MLF which exhibited phasic activity indistinguishable from that of phasic motoneurons. These axons terminated profusely within specific subdivisions of the oculomotor nucleus. They could be internuclear neurons involved in the synchonization of the different extrinsic oculorotary muscles during oscillations. In any event, this is indirect evidence that the bursts of activity of the phasic motoneurons are not the consequence of some biophysical property of their membrane, but rather that this oscillatory behavior is actively induced by their neuronal input.

49.12 SOME ANTERIOR ECTOSYLVIAN CORTICOFUGAL PROJECTIONS IN CATS R.L. Segal and R.M. Beckstead. Dept. of Rehab. Med., Emory Univ. School of Med., Atlanta, GA 30322, and Dept. of Anatomy and Cell Biology, Med. Univ. of South Carolina, Charleston, SC 29425.

Several studies have focused on the physiological organization of the cortex surrounding the anterior ectosylvian sulcus (AES) of the cat. Neurons responding to visual, auditory and somatosensory stimuli have been identified. Thus, the AES must be considered a multimodal cortical region. Little information is available concerning the anatomical connections between AES and the multimodal deep layers of the superior colliculus.

In a previous report (Segal and Beckstead)[1] we observed retrogradely labeled neurons all along the banks of AES, but with the greatest density along the fundus and ventral bank. We recently examined the projection from the caudal two-thirds of the fundus and ventral bank of AES to the colliculus and thalamus using anterograde tracers [WGA-HRP or L-(2,3,4,5)-^{3}H-proline].

Anterogradely labeled axons are observed ipsilaterally in the following thalamic nuclei : interadjacent division of the lateral posterior complex, posterior complex, posterior nuclear group and in the magnocellular, dorsal and ventral divisions of the medial geniculate complex. In the colliculus, labeled axons are observed throughout the rostrocaudal extent, but are concentrated in the medial one-half. In the rostral colliculus labeled axons pass through the deep gray layer to apparently terminate in the dorsal intermediate gray layer. More caudally (reaching the mid-colliculus), dorsal and ventral tiers of axon-labeling are observed within the intermediate gray and stratum opticum. From the mid-colliculus and caudal, a single bank of labeled axons encompasses the intermediate gray layer ventrally and extends dorsally into the stratum opticum. Examination of the colliculus contralateral to the cortical injection reveals labeled axons primarily in the intermediate gray layer and stratum opticum of the medial portion of the rostral one-half.

The results indicate that neurons in the caudal two-thirds of the ventral bank and fundus of AES, the so called anterior ectosylvian visual area (Mucke et al., '82)[2], project to the superior colliculus. In addition, the pattern of axonal labeling is different than from injections in the rostal two-thirds of the dorsal bank of AES (Stein et al., '83)[3].

49.13 THE NIGROTECTAL PROJECTION IN MAN. B.M. Johnson*, A.A. Sadun*, H. Chui#, and J.A. Mortimer@. *Dept. of Ophthalmology and #Alzheimer's Disease Center, USC School of Medicine, Los Angeles, CA 90033; and @Veterans Administration Medical Center, Minneapolis, MN 55417.

Several studies have documented the crucial role of the superior colliculus (SC) in the control of eye movements (Robinson, Vis. Res., 12:1795, 1972; Wurtz and Goldberg, Invest. Ophthalmol., 11:441, 1972). It has been shown in cat and monkey that one source of input to the superior colliculus is the substantia nigra (Graybiel, Brain Res., 143:139, 1978; Jayaraman et al., Brain Res., 135:147, 1977). There has been a dearth of investigations on a putative projection from the substantia nigra (SN) to the SC in humans, because of a previous absence of any techniques suitable for tracing this pathway. Recently, the paraphenylene-diamine staining technique (PPD) has been used to successfully trace degenerated human visual pathways, and has shown that degenerated axonal fibers persist in humans, even following lesions of long duration (Sadun et al., J. Neuropath. exp. Neurol., 42:200, 1983). Employing the PPD technique, examination of specimens from post-mortem brains has revealed eight retinofugal projections.

Parkinson's disease is a well-described syndrome in which the most characteristic pathological feature is degeneration in the SN. This would permit degeneration to be traced from the SN to any target nucleus. We therefore collected tissue from two Parkinson's disease patients at autopsy, both of whom had an otherwise normal ophthalmological history and lesion-free visual system. Blocks containing the entire mesencephalon in coronal section were processed for both paraffin and epoxy resin sectioning, and examined using both standard and special stains. Using the PPD method, degenerated axons were traced from the SN in a mid-lateral arc to the deep layers, but not to the superficial layers, of the superior colliculus. The degenerated fibers appear to arise from dorso-lateral areas in the SN pars compacta, and project in an arch laterally, bypassing the medial lemniscus, and terminate in the deep layers of the SC.

The presence of a nigrotectal projection in man establishes an anatomical substrate which allows us to speculate further on the role of the superior colliculus in eye movements. The termination of a nigral projection in the SC could provide a relatively direct route to elements of the oculomotor mechanism, including elements involved in visuo-motor control. The substantia nigra serves a site of projection for the basal ganglia (Wurtz and Hikosaka, Prog. Brain Res., 64:175, 1986), which in turn may serve as a 'primer' for eye movements (Denny-Brown and Yanasawa, Assoc. Res. Nervous and Mental Dis., 55:115, 1976). In view of such evidence, the nigrotectal pathway in man may contribute to the generation of signals in the initiation of eye movements. Injury to this projection might be the anatomical basis for abnormal eye movements (apraxia, cogwheel pursuits, etc.) commonly seen in Parkinson's disease patients.

49.14 ORIGIN OF CEREBELLAR PROJECTIONS TO THE REGION OF THE OCULOMOTOR COMPLEX, MEDIAL PONTINE RETICULAR FORMATION, AND SUPERIOR COLLICULUS IN CEBUS MONKEYS. G.R. Leichnetz and A. Gonzalo-Ruiz*, Dept. of Anatomy, Med. Coll. of Virginia, Virginia Commonwealth Univ., Richmond, VA 23298.

Horseradish peroxidase (HRP) microinjections, or transcannular HRP gel implants were made into the oculomotor complex (OMC), superior colliculus (SC), or medial pontine tegmentum of 16 adult capuchin monkeys (Cebus apella) to determine the origin of their afferents from the deep cerebellar nuclei. Some of the monkeys had been used in previous studies of cortical input to the same oculomotor-related structures (Leichnetz et al JCN 228:359-408, 1986).

Injections confined to the OMC only retrogradely-labeled a few cells in the dentate nucleus (DN). Larger injections that involved adjacent paraoculomotor nuclei, like the nucleus of Darkschewitsch (ND) and medial accessory nucleus of Bechterew (MAB), resulted in labeling within the anterior (AIN) and posterior (PIN) interpositus nuclei. When OMC injections involved the ventral periaqueductal gray (PAG), there was increased labeling of the fastigial nucleus (FN). A supratrochlear ventral PAG OMC-projecting cell group was found that received a significant projection from the FN. All of the OMC cases produced retrograde labeling in cell group Y, but not in the basal interstitial nucleus (BIN) as described by Langer ('85).

Injections into the caudal medial pontine reticular formation (mPRF) or pontine raphe resulted in large numbers of retrogradely-labeled cells in the FN. Only when the injection was in the more rostral mPRF, involving the nucleus reticularis tegmenti pontis (NRTP), did significant numbers of labeled cells occur in the DN. Such cases also contained labeling in the AIN, which was attributed to uptake of HRP by axons traversing the NRTP enroute to more caudal targets (eg. inferior olive).

The principal source of cerebellar input to the deep SC was from the PIN, although the ventrolateral FN also contained labeled cells.

The results are discussed in terms of the possible convergence of cerebellar projections with those of the frontal eye field to paraoculomotor and preoculomotor nuclei, and their interaction in the control of eye movement.

This study was partially supported by NSF Grant BNS 8113387 and VCU Grant-in-Aid to Faculty to G.R.L., and the U.S.-Spanish Joint Committee Grant IPB85-04059 to A.G.-R.

49.15 THE CELLS OF ORIGIN OF EFFERENT PATHWAYS FROM THE DEEP LAYERS OF THE SUPERIOR COLLICULUS IN THE RAT. M. E. Bickford* and W. C. Hall (SPON: B. R. Schofield) Dept. Anatomy, Duke Univ. Medical Center, Durham, N.C. 27710

These experiments address the question of whether the multiple efferent pathways which arise in the deep layers of the superior colliculus originate from different cell populations. The efferent pathways which have been studied include: (1) the tectothalamic pathway to the mediodorsal and intralaminar nuclei (2) the tectotectal pathway (3) the contralateral tectobulbar pathway and (4) the tectospinal pathway. The cells of origin of these pathways were compared by injecting fluorescent dyes into two structures in single brains. One structure was injected with Fluoro-Gold and the other with rhodamine labeled microspheres, and the neurons in the superior colliculus were examined to determine the distributions of cells with one or both labels.

Three of the pathways studied, the tectospinal, the contralateral tectobulbar and the tectothalamic, arise primarily from the intermediate grey layer (for nomenclature, see Weiner, S. I., J. Comp. Neurol. 244:137, 1986). The remaining pathway, the tectotectal, arises from cells distributed throughout the layers below the stratum griseum superficiale, with the majority located below the stratum griseum intermedium. Following injections of different labels in the contralateral brainstem and the ipsilateral thalamus, many cells containing both labels were found. In contrast, very few double-labeled cells were present when an injection in the contralateral superior colliculus was paired with an injection in either the contralateral brainstem or spinal cord.

The results obtained thus far suggest two main conclusions. First, the mediodorsal-intralaminar nuclear region of the thalamus may receive input from the same cells of the intermediate grey layer that project to premotor areas of the contralateral brainstem and spinal cord. Second, the tectotoectal pathway arises primarily from cells which are distinct from the cells of origin of the crossed descending pathways. (supported by NSF grant #BNS-86-07060).

49.16 THE AVIAN EDINGER-WESTPHAL NUCLEUS: SOURCES OF INPUT CONTROLLING ACCOMMODATION, PUPILLOCONSTRICTION, AND CHOROIDAL BLOOD FLOW. P.D.R. Gamlin and A. Reiner. Dept. of Physiological Optics, Univ. Alabama at Birmingham, Birmingham, AL 35294 and Dept. Anatomy and Cell Biology, Univ. of Michigan, Ann Arbor, MI 48109

The Edinger-Westphal nucleus (EW) is the source of preganglionic fibers to the ciliary ganglion. In the bird, cells in the medial EW (EWm) project to cells in the ciliary ganglion that innervate choroidal blood vessels. Thus the EWm may modulate retinal blood flow. Cells in the lateral EW (EWl) project to neurons in the ciliary ganglion that innervate the sphincter pupillae muscle and the ciliary body. The EWl therefore appears to mediate pupilloconstriction and accommodation. Previously, we have shown in the pigeon that the suprachiasmatic nucleus has a predominantly contralateral projection to the EWm (Gamlin et al., PNAS 79:3891-3895, 1982). We have also shown that a projection from a single retinorecipient pretectal nucleus to the caudolateral EWl mediates the pupillary light reflex. We have therefore inferred that cells in the caudolateral EWl mediate pupilloconstriction and that cells in the rostral EWl mediate accommodation (Reiner et al., TINS 6:140-145, 1983).

In this report, we describe two further sources of input to the EW. In our previous studies, HRP injections that included EW labeled a number of regions that might be sources of afferents. We have examined some of these regions by injecting them with 0.04-0.1 µl of tritiated proline/leucine (S.A. 200 µCi/µl). We have found that cells in a portion of the caudal mesencephalon ventrolateral to the oculomotor nucleus project to all subdivisions of the contralateral EW. This input may contain 5-HT and enkephalin since our immunohistochemical studies show that many neurons in this region contain 5-HT or enkephalin and that many fibers and terminals throughout EW contain these substances. In addition to this input to the entire EW, we have found an input to EWl (and not EWm) that arises from cells in a localized area of the rostral lateral reticular formation (FRL) dorsolateral to nucleus subpretectalis. This projection is predominantly contralateral and includes the accommodative subdivision of the EWl.

These studies suggest that cells in the rostral FRL and dorsolateral raphe may be components of separate pathways to EW, with the former influencing accommodation and the latter influencing all three ocular functions controlled by EW.

49.17 AN INEXPENSIVE ULTRASONIC CONTACT LENS TO MEASURE ACCOMMODATION
R.S. Remmel, J. Feeny*, M. Khodadoust*, C. Paulino*, and R. Sims*. Biomedical Engineering Dept., Boston Univ., Boston, MA 02215

Assessment of accommodation usually involves asking the patient to read at various distances--assuming he/she can read. Ultrasound probes usually obstruct vision. Refractometers costing >$10,000 involve measuring how light is focused upon the retina. An invalid output occurs if the patient blinks or moves.

We are trying to overcome these restrictions by placing upon a contact lens two piezoelectric crystals, a transmitter and a receiver, one on either side of the pupil. Vision is unaffected. The time delay between echoes from both eye lens surfaces yields lens thickness. For a 3.5 mm thick lens with a 1610 m/s speed of sound, the time difference is ≈4.3 μs (2*3.5 mm/1610 m/s).

The lead metaniobate crystals (EBL Co.) are 0.117 mm thick disks of 1 mm radius. A crystal is excited by a 50 V step, producing a wave. This is repeated at 2.8 KHz. When the echo exceeds a set threshold, a pulse is produced, which turns a clock on for the first echo and off for the second. A time-to-voltage converter outputs accommodation in diopters.

Echoes have been detected from objects immersed in water. The received signal was a 1 MHz sinusoid with a rise time of 2 μs and a fall time of 5 μs. The crystal rings. This 5 μs decay interferred with detection of a subsequent echo.

When the disk lies in the plane θ = 90 deg, the pressure $P(r,\theta,\phi,t)$ is calculated from the wave equation:

$$c^2 \nabla^2 P = \partial^2 P/\partial t^2$$

A solution for P involves the spherical harmonic $Y_{20}(\theta,\phi)$:

$$B[3\cos^2(\theta) - 1] [(3/k^3 - 1/k)\sin(k) - 3\cos(k)/k^2] \sin \omega t,$$

where $k=\omega r/c$, c=1497 m/s in water, $\omega=2\pi F$, and F=1 MHz, the measured resonance freq. B is a constant. This wave has a node at r=1.25 mm, which is approx. the crystal radius. This equation predicts that reducing the radius to 0.25 mm will increase the resonant freq. to 4 MHz--in accord with experiment. The damping time can thus be reduced if r is decreased.

A silicon-rubber annular lens with a hole over the pupil is being tested. The crystals can be glued on with silicon rubber glue, which is approved for use on the eye. A coil of wire can also be glued to the lens so that eye movements can be measured. Clinical evaluation of patient tolerance is planned.

Accommodation should be measurable with a device costing $300.

Supported by grant NIH, NEI RO1 EY05514.

49.18 **RETROGRADE TRANSNEURONAL LABELING OF SYMPATHETIC PREGANGLIONIC NEURONS FOLLOWING INJECTION OF TETANUS TOXIN C FRAGMENT INTO MUELLER'S EYELID MUSCLE.**
K.A. Manning, C. Evinger, and J.T. Erichsen. Dept. Neurobiology & Behavior, SUNY at Stony Brook, Stony Brook, NY 11794.

Mueller's muscle is a smooth muscle of the upper and lower eyelid that aids in lid opening. The muscle is innervated by cells in the superior cervical ganglion (SCG) and damage to the SCG produces lid ptosis. Although the preganglionic sympathetic neurons are situated in the spinal cord, it has not been possible to identify those cells which innervate specific targets via the SCG. We injected the atoxic C fragment of tetanus toxin (TTC) into the rat eyelid to localize: (1) the postganglionic SCG neurons that project to Mueller's muscle, and (2) the preganglionic spinal neurons that project specifically to these SCG neurons.

The eyelid of adult Sprague-Dawley rats was injected with 10ul of 15% TTC. After survival times of 5 to 55 hrs, the tissue was processed for immunohistochemistry and the TTC localized with a monoclonal antibody to TTC.

The data reveal a diffuse organization for the ganglionic and preganglionic innervation of Mueller's muscle. Retrogradely labeled cells are scattered throughout the SCG. At shorter survival times, the granular label appears to fill the cytoplasm. With longer survival times, the cell labeling diminishes except for the large grains that appear to outline the cell membranes. Although a majority of SCG cells remain unlabeled, light label is scattered throughout the ganglion, which may be the stained terminals of preganglionic fibers. Fibers of the SCG are poorly labeled. Lower cervical and upper thoracic spinal cord contain transneuronally labeled neurons. The majority of neurons are clustered in the intermediolateral nucleus. Others are scattered through the intercalated region and the lateral funiculus, although a few labeled cells lie in the central autonomic area. These regions have been previously reported to contain the neurons preganglionic to the SCG. Our data provide the first demonstration that preganglionic neurons for a specific motor target can be labeled transneuronally. The retrograde transneuronal labeling capabilities of TTC may help to eludicate the anatomical pathways of a wide variety of autonomic systems.

49.19 CELLULAR INVESTIGATION OF THE ADAPTIVE GAIN CONTROL OF THE BLINK REFLEX: MODULATION OF ORBICULARIS OCULIS MOTONEURONS.
C. Evinger and K.A. Manning. Dept. Neurobiology & Behavior, SUNY Stony Brook, Stony Brook, NY 11794.

The blink reflex of mammals exhibits adaptive gain changes. The activity of the orbicularis oculis (OO) muscle (the lid closing muscle) increases when the eyelid experiences an opposition to lid closure. Likewise, OO activity decreases with facilitation of eyelid closure. As an initial step toward understanding the neural mechanisms underlying adaptive processes of the blink reflex, we have recorded the discharge of OO motoneurons before, during and after adaptation of the eyelid.

The blink reflex was evoked by electrical stimulation of the cornea in decerebrate rats. Electromyographic (EMG) electrodes in the eyelid provided a measure of OO muscle activity while microelectrodes in the facial nucleus recorded the activity of individual OO motoneurons.

Rats exhibited rapid and robust adaptation to restraint of the upper eyelid. Fewer than 20 consecutive blinks (mean interstimulus interval of 12 sec) during eyelid restraint resulted in an increase in the magnitude of the OO EMG. Within 30 trials the OO EMG reached its maximum increase of 50% over preadaptation levels. Upon freeing the eyelid, the OO EMG activity returned to preadaptation levels in 5 to 10 trials. The adapted OO EMG had a slightly shorter latency to corneal stimulation, but the primary change was the addition of longer latency bursts of activity. Individual OO motoneurons showed parallel changes during adaptation. The latency in response to corneal stimulation fell from 12-15 ms before lid restraint to a latency of 8-12 ms in the adapted state. The motoneurons also exhibited longer latency bursts of action potentials so that the overall level of discharge in response to corneal stimulation increased approximately 30-50% over preadaptation levels. Upon freeing the eyelid, motoneuron discharge returned to preadaptation levels in 5-10 trials. Thus, the OO EMG accurately reflects the discharge patterns of individual OO motoneurons. The rapid gain changes and the mechanical and neuronal simplicity of the blink reflex make this preparation ideal for investigating the cellular mechanisms of adaptation. Moreover, since the adaptive gain changes seen in this rat preparation match those occurring in alert rabbits and humans, similar processes may underly blink adaptation in all mammals.

49.20 BILATERALITY OF THE SENSORY AND MOTOR PATHWAYS UNDERLYING BLINKING.
P.J. May and R. Baker. Dept. of Anatomy, Univ. of Mississippi Med. Ctr., Jackson, M.S. and Dept. of Physiology and Biophysics, New York Univ. Med. Ctr., New York, N.Y.

Blinking is most often a conjugate motor response requiring synchronous inhibitory control of both levator palpebrae muscles. The basis for this conjugacy was investigated in the cat. We previously described a population of cells lining the rostral and ventral aspects of the sensory trigeminal nucleus that were retrogradely labelled following injection of HRP into the caudal oculomotor nucleus. This pathway crossed the midline, traveled with the medial lemniscus to the level of the trochlear nucleus, turned dorsally and extended to terminate bilaterally, with a contralateral predominance, in and above the caudal pole of the oculomotor nucleus. Electrophysiological investigation revealed that antidromically activated levator palpebrae motoneurons were characterized by long latency (3.0-7.0 ms), small amplitude (<2.5 mV) hyperpolarizing synaptic potentials following electrical stimulation of either the ipsi- or contralateral orbital trigeminal nerves. EPSP-IPSP sequences (1.5 ms latency) were recorded following stimulation of either vestibular nerve. The latency of IPSPs evoked in levator motoneurons following bipolar central stimulation of the sensory trigeminal nucleus were shorter (1.8-3.0 ms). This IPSP was unaffected by acute transverse section (>3 mm deep) of the pons, including the MLF. Elimination of ipsilateral vestibular IPSPs in superior rectus motoneurons established the adequacy of the lesion, thereby indicating inhibition of the levator motoneurons was not the result of current spread to the ipsilateral vestibular nucleus, MLF or predorsal bundle fibers. Axons recorded within the levator subdivision displayed multiple action potentials, characteristic of trigeminal sensory division cells, and were activated from one set of orbital and central trigeminal electrodes with latencies of 3.0 and 1.5 ms, respectively. Intra-axonal HRP injection revealed that these axons terminated extensively within the levator subdivision and the adjacent supraoculomotor area. Intracellularly HRP injected levator motoneurons possessed ten or more primary dendrites that radiated to form a dendritic field (1.4 mm across) filling the levator subdivision and adjacent supraoculomotor area bilaterally. We conclude that the trigeminal sensory input from both sides reaches all levator motoneurons. More surprising, levator motoneurons were encountered that could be antidromically activated from both IIIrd nerves, demonstrating axon branches innervate both levator muscles. Thus the entire neuronal circuitry is organized to produce conjugate blinking.

51 WORKSHOP. COCAINE: MODULATION OF MONOAMINE FUNCTION. J.M. Lakoski, Univ. Texas Med. Br., (Chairperson); D.C.S. Roberts, Carleton Univ., J.E. Smith, Louisiana State Univ; F.J. White, Univ. Illinois; K.A. Cunningham, Univ. Texas Med. Br.; T.V. Dunwiddie, Univ. Colorado Health Sci. Center; M.P. Galloway, Wayne State Univ.; J.T. Williams, Oregon Health Sci. Univ.; and R.A. Wise, Concordia University.

A resurgence of interest in the neuropharmacology of cocaine has been prompted by the widespread abuse of this drug. Neuropharmacological effects of cocaine have recently been expanded with regard to interactions of cocaine with monoaminergic neurons. This workshop will provide a forum for discussion of current research to define the role of monoamine neurotransmitters in the potent pharmacologic effects of cocaine. Results obtained from behavioral, neurochemical, and electrophysiological approaches will be presented to provide new insights into the specific interactions of cocaine with monoaminergic neurons.

The workshop will first address the modulatory role of cocaine on monoaminergic function from a behavioral perspective. Studies identifying the neural substrates that underlie cocaine self-administration behavior, particularly with respect to dopamine, will be presented by David C.S. Roberts. Studies of the behavioral factors involved in the reinforcing properties of cocaine, with respect to monoaminergic function, will be presented by James E. Smith. These behavioral approaches will then be complemented by both in vivo and in vitro electrophysiological studies of cocaine's modulatory effects on monoamine function. Francis J. White will present electrophysiological data on the actions of cocaine on the mesoaccumbens dopamine system as related to cocaine's reward properties. Cocaine's specific interactions with serotonergic neuronal systems, as assessed by electrophysiological techniques, will be presented by Kathryn A. Cunningham. The modulatory effects of cocaine in the hippocampus and ventral tegmental area, utilizing both in vitro electrophysiological and neurochemical approaches, will be addressed by Thomas V. Dunwiddie. In addition, Matthew P. Galloway will discuss modulation of mesocortical and striatal dopamine synthesis following acute and chronic cocaine administration. These multidisciplinary approaches will provide state-of-the-art evaluations of the modulatory actions of cocaine on monoaminergic function.

An added feature of this workshop will be an open panel discussion of issues raised during the sessions which will be led by John T. Williams and Roy A. Wise. Major issues relevant towards understanding how cocaine produces its complex pharmacological profile will be addressed.

52 SYMPOSIUM. THE BASICS OF MOLECULAR BIOLOGY. J.L. Roberts, Stanford University; R. Goodman*, Tufts University; J. Brosius*, Columbia University.

This symposium will review many of the basic concepts and methodology involved in the understanding of and the use of molecular biological techniques to study questions of interest to neurobiologists. The first speaker, Dr. Scheller, will discuss how genes are organized in the chromosome and what technologies are used to isolate specific genes. There will be discussion of multiple gene families and some of the difficulties of deciphering their structures and functions. The next speaker, Dr. Richard Goodman will give a general description on how genes are transcribed by RNA polymerases, and how this transcription is regulated during development and after hormonal or environmental manipulation. Particular emphasis will be given to using molecular biological techniques to dissect the structure of the promotor regions of several important neuropeptide genes. Dr. Roberts, the third speaker, will discuss a later area of gene regulation, that of stability of cytoplasmic mRNA and efficiency of translation of those RNAs. This talk will cover how these post-transcriptional events become very important in determining exactly how much protein is synthesized from any specific gene product. Finally, Dr. Brosius, will speak on the use of eurkaryotic gene expression systems for the production of specific eukaryotic gene products. With the current ability to isolate intact genes and express them in heterologous cells, this approach has proved very advantageous to producing large quantities of a specific protein for subsequent biological studies to elucidate the function of these proteins. This series of talks should give the audience a brief overview of the events in the production of a specific gene product as well as an understanding of how the modern techniques of molecular biology are used in characterizing these gene products.

ACTION POTENTIALS AND ION CHANNELS V

53.1 A NEW TYPE OF K CHANNEL THAT CONTROLS THE RESTING POTENTIAL OF THE NERVE AXON. D.C. Chang. Department of Physiology and Molecular Biophysics, Baylor College of Medicine, Houston, TX 77030.

Unlike the case of the action potential, the membrane pathways responsible for the generation of the resting potential of a nerve cell have not been well understood. It is unclear whether the resting current passes mainly through a small number of excitable K and Na channels that stay open in the resting state, or, as some investigators have suggested, the pathway for resting current may simply be a "leakage" conductance. Using the internally perfused squid axon as a biological model, we studied the effects of various cations on the membrane potential, membrane conductance, and isotopé-labelled efflux in the resting state. We found evidence that the semi-permeable property of the resting membrane is controlled by a new class of K channel. This resting K channel has a slight tendency of inward rectification and is activated at a voltage below the normal resting potential. It's ion-selectivity sequence, as determined from our V-clamp studies, $K^+ > Rb^+ > NH_4^+ > Cs^+ > Na^+ \geq Li^+$, is similar to that of the resting membrane. The pharmacological properties of this resting channel seem to differ from those of the delayed rectifier K channel. For example, this resting channel is less sensitive to TEA^+ (tetraethylammonium) but is affected by internal Rb^+. Furthermore, the K efflux through this resting channel responds to a change of the external ionic environment in a manner different from that of the delayed rectifier. When the external concentration of K^+ increases, the K^+ efflux is actually elevated. These findings suggests that this new class of K channel may be structurally different from the delayed rectifier K channel. (Supported by ONF Contract N00014-85-K-0424 and NSF grant BNS-84-06932.)

53.2 CHARACTERISTICS OF 4-AP, TEA AND CA^{2+} INSENSITIVE VOLTAGE-DEPENDENT SLOW OUTWARD CURRENT IN STATOCYST HAIR CELLS OF HERMISSENDA CRASSICORNIS. L.M. Grover & J. Farley. Prog. Neurosci. & Behav., Dept. Psychol., Princeton Univ., Princeton, NJ 08544.

Voltage-clamp analysis of ionic currents in statocyst hair cells of Hermissenda has revealed the presence of three distinct components of outward current. Two appear to be identical to currents observed in a number of other preparations. These are: (1) A fast, transient, 4-AP sensitive potassium current (I_A). Activation of this current is steeply voltage dependent at potentials positive to -40 mV. At a steady-state membrane potential of -45 mV I_A is half-inactivated. (2) A delayed, TEA sensitive outward current (I_K), that shows substantial activation only at potentials above 0 mV.

We have also observed a third outward current which resists block by 5-10 mM 4-AP and 100 mM TEA. Although the kinetics of this current are similar to a calcium-activated potassium current seen in other central neurons of Hermissenda, this current is not calcium dependent. Removal of calcium ions from the bath does not reduce the magnitude of this current, although an inward calcium current is markedly reduced by this treatment. Elevation of extracellular calcium (from normal 10 mM to 100 mM) does not enhance the outward current, although I_{Ca} is increased. Calcium channel blockers (5 mM cadmium or 10 mM cobalt) which suppress the calcium current do not reduce the 4-AP and TEA resistant current. Intracellular injections of EGTA also do not reduce this current. Finally, the current-voltage relationship of the 4-AP and TEA resistant current does not display the characteristic "N" shape expected of a calcium-dependent current. Measurements of the reversal potential of this delayed current (made in 5 mM 4-AP, 100 mM TEA and 10 mM Co^{2+}) indicate that this is a potassium current, since it reverses near -70 mV, and varies in the expected direction with changes in $[K^+]_o$. This current shows no sign of inactivation, even with maintained depolarizations (5-15 sec) to relatively positive potentials (0 to +20 mV).

In preliminary patch-clamp experiments (cell attatched) we have recorded a 35 pS channel that may underlie this delayed outward current. As one would expect from the macroscopic current, the channel is open a large fraction of the time (steady-state) at potentials more positive than +20 mV.

It is likely that this current contributes in important ways to the integrative properties of the hair cell, since the other outward currents present in the soma membrane are either largely inactivated (in the case of I_A) or insufficiently activated (in the case of I_K) at the normal resting potential of these cells (-35 to -50 mV). Supported by NASA grant NAG2-397.

53.3 POTASSIUM CURRENTS UNDERLYING AFTERHYPERPOLARIZATIONS (AHPs) AND SPIKE REPOLARIZATION IN RAT HIPPOCAMPAL PYRAMIDAL CELLS (CA1).
J.F.Storm, Dept.Neurobiology & Behavior, SUNY Stony Brook, NY11794.

Action potentials in CA1 cells are followed by three AHPs: a fast (fAHP), a medium (mAHP), and a slow one (sAHP). The sAHP is due to a slow Ca-activated K-current, I_{AHP} [Lancaster & Adams, J.Neurophys. 55:1268]. Spike repolarization (s.r.) and the fAHP involve a fast Ca-activated K-current which is sensitive to 1mM tetraethylammonium (TEA) [Storm,J.Physiol.385:733]. Here, two questions are addressed: (1) Which currents underlie the mAHP ? (2) Is the Ca-dependent TEA-sensitive current underlying s.r./fAHP, transient [Zbicz & Weight,J.Neurophys.54:1034] or persistent (I_C [L.&A.]) ? These problems were studied in slices (28-33°C) using current clamp and single electrode voltage clamp (v.c.).

The mAHP, following trains of 2-8 spikes elicited by current injection, was (a) apparently less voltage sensitive than sAHP; (b) resistant to 0.2mM Cd or 4mM Mn, but reduced by 0.5-2mM Ba; (c) reduced 40-80% by 40µM carbachol (reversed by atropine) when the membrane potential was close to -60mV, but not at -80mV; (d) abolished by 2mM Cs at -80mV but not at -60mV. The mAHP seems also to be TEA-sensitive. This suggests that three currents contribute to the mAHP: I_M (a slow K-current blocked by carbachol or Ba [Halliwell & Adams,Brain Res.250:71]), I_Q (a Cs-sensitive inward current activated at hyperpolarized potentials, and deactivated by depolarization [H.&A.]), and I_K ("delayed rectifier" [Segal & Barker,J.Neurophys.51:1409], blocked by TEA, but not by carbachol). The contribution of each may vary with the membrane potential: I_M seems to dominate around -60mV (c.f. carbachol effect), whereas I_Q dominates at -80mV (c.f. Cs effect). The recruitment of I_Q may explain why mAHP was not reversed by hyperpolarization (a).

Under v.c. (V_h=-60mV), the fast tail current (τ~50ms) following 0.1-0.5s commands to -10 to -40mV (which should activate I_C [L.&A.]), showed (a) surprisingly little Ca-dependence (0-15% reduced by Mn/low Ca); (b) was reduced 40-60% by 40uM carbachol (reversed by atropine); and (c) was reduced 20-70% by 1-10mM TEA. Thus, this fast tail seems to correspond to the Ca-independent mAHP (rather than s.r./fAHP), and may represent a mixture of a carbachol-sensitive (I_M ?) and a carbachol-resistant current (I_K?). On the other hand, a Ca-dependent, TEA-sensitive (1mM) transient (lasting 5-20ms) current [Z.&W.], here called I_{CT}, was observed during v.c. commands positive to -45mV. I_{CT} may be the current involved in s.r./fAHP. Finally, a Ca-independent, carbachol-resistant, TEA-sensitive (10mM) outward current (I_K?) activated (τ~130ms) and subsequently decayed (τ~1.7s at -35mV) during commands positive to -40mV. The M-current also appeared to be TEA-sensitive.

Conclusions: (1) I_M, I_Q and I_K may underlie the medium AHP; (2) a transient Ca-dependent TEA-sensitive K current may underlie spike repolarization and the fast AHP. (Supported by NIH grant NS18579.)

53.4 SMALL CONDUCTANCE Ca^{2+}-ACTIVATED K^+ CHANNELS IN HIPPOCAMPAL NEURONS.
B. Lancaster, D.J. Perkel* and R.A. Nicoll, Depts. of Pharmacol. and Physiol., Univ. of Calif., San Francisco, CA 94143.

Single-channel recordings were made from inside out patches of membrane obtained from hippocampal neurons in primary culture. Patches were positioned in a continuous flow system which allowed exchange of solution at the cytoplasmic face of the patch. Except where noted, solutions bathing the patch were symmetrical, containing (mM) 140 KCl, 10 NaCl, 1 $MgCl_2$, 10 HEPES, 80 µM EGTA.

When 1 µM free Ca^{2+} was perfused across the cytoplasmic surface, two channel types were activated. 1. Large conductance channels (~200 pS) which opened for longer periods at depolarized potentials (Brett and Lancaster, Soc. Neurosci. Abstr., 11:954, '86). 2. Channels with slope conductance~19 pS. This second channel could be observed at hyperpolarized potentials, where the larger channel is closed due to its voltage sensitivity. At membrane potentials between -40 and -110 mV, 1 µM $[Ca^{2+}]_i$ caused the small conductance channel to remain open most of the time. Both channel types were observed if KCl was replaced by $KMeSO_4$ and are thus likely to be Ca^{2+}-activated K^+ channels (Blatz and Magleby, Nature, 323:718, '86; Lang and Ritchie, Soc. Neurosci. Abstr., 12:560, '86). Neither channel type was sensitive to apamin (25 nM) in the pipette.

Under normal conditions, the small conductance channel displayed inward rectification, i.e. no clear outward currents were observed positive to 0 mV. This rectification was not affected if Na^+ was removed from either side of the membrane. When Mg^{2+} was removed from the cytoplasmic face of the patch, Ca^{2+}-activated outward currents could be observed at the depolarized potentials. Under these conditions addition of 1 mM Mg^{2+} induced channel flickering. The observations are consistent with a small conductance Ca^{2+}-activated K^+ channel, lacking the voltage dependence of the large channel and which displays inward rectification due to Mg^{2+} block from the intracellular face (Vandenberg, Biophys. J., 51:366a, '87).

Cultured hippocampal neurons can display a long-lasting slow afterhyperpolarization (AHP) following a burst of spikes. As in the slice preparation, this can be abolished by 8-Br cAMP (2 mM final bath concentration). Cell-attached patches have revealed long-lasting activation of a K^+ channel following a burst of spikes. Activation of this channel parallels the time course of the AHP and the conductance is estimated to be no greater than 15 pS (pipette contained 140 NaCl, 10 HEPES, 4 $MgCl_2$, 1.3 KCl). The relation between channel activation and the AHP is being investigated.

53.5 CALMODULIN METHYLATION AND CALCIUM-DEPENDENT CURRENTS IN PARAMECIUM,
M.A. Wallen-Friedman, Y. Saimi*, D.-Z. Lu*, J.E. Colquhoun*, D.L. Nelson*, C. Kung*, Neuroscience Training Program, Department of Molecular Biology and Department of Biochemistry, University of Wisconsin, Madison, Wisconsin, 53706.

We used the eukaryotic unicell Paramecium tetraurelia as a model for excitable cells to study ion-channel function and regulation. It has been shown that a mutant, pntA, with a defect in calmodulin (CaM), has a greatly reduced current through the Ca^{++}-dependent K^+ channel. Normal current and behavior is restored when wild-type CaM is microinjected into pntA (Hinrichsen et al, 1986, Science 232, 503-506). pntA CaM has a single substitution of phenylalanine for serine at residue 101 of the wild-type CaM (Schaefer et al, 1987, PNAS, in press).

We have isolated a mutant, pntD, which also has a greatly reduced Ca^{++}-dependent K^+ current, but unlike pntA, has an increased Ca^{++}-dependent Na^+ current as well. The CaM from pntD differs from wild-type CaM and from pntA CaM in its migration pattern on native, on acid-urea and on isoelectric-focusing gel electrophoresis. Cytoplasmic fractions containing either pntD or wild-type CaM, when microinjected into pntA, restore equally wild-type behavior in pntA. Thus, it appears that the pntD lesion differs from and complements the pntA defect. Microinjection of wild-type CaM into pntD does not restore normal behavior to the pntD mutant.

CaM from wild-type Paramecium has 2 sites of post-translational lysine-N-methylation. Both of these sites are almost fully methylated in vivo; thus wild-type CaM is a poor substrate for N-methylation in vitro. In contrast, pntD CaM is heavily N-methylated in vitro, suggesting that the mutant CaM is undermethylated in vivo. Methylating activities in pntD and wild-type supernatant fractions appear to be similar. Experiments are underway to compare demethylating activity in wild type and pntD.

Ion channel regulation by cytoplasmic proteins is important in many neurophysiological processes, e.g. short-term memory. How CaM mediates or modulates the Ca^{++}-dependent K^+ current and the Ca^{++}-dependent Na^+ current may be addressed using this unique combination of mutations, functional restoration, biochemical analysis and electrophysiological measurements. 53.6 QUANTITATIVE CALCIUM-DEPENDENCE OF WHOLE-CELL NONSPECIFIC CATION AND POTASSIUM CURRENTS ACTIVATED BY INTRACELLULAR CALCIUM RELEASED FROM CAGED CALCIUM (NITR) CHELATORS.
R. S. Zucker and L. Landò. Dept. of Physiology-Anatomy, Univ. of California, Berkeley, CA 94720.

The relationship between whole-cell membrane current and intracellular calcium concentration was measured for two calcium-activated currents in large neurons in the abdominal ganglion of Aplysia californica. We used new tetracarboxylate 2-nitrobenzhydrol chelators, which are converted in 2 msec from a high affinity form (K_D = 630 nM for NITR-5, 215 nM for NITR-7, at 300 mM ionic strength) to a low affinity nitrosobenzophenone (K_D = 18 µM and 7.7 µM respectively) on exposure to a 0.5 ms flash of about 0.2 J/cm^2 of ultraviolet light between 340 and 380 nm. Computer simulations were developed to predict the average changes in free calcium concentration, depending on the average light intensity after absorption in a spherical cell, the concentrations of NITR and total calcium, and the rate of extrusion of calcium by active pumps. The simulated effects of successive flashes of light were confirmed by in vitro and in vivo spectrophotometric calibrations of 5-30 mM NITR, 60-90% bound to calcium, mixed with 0.25 mM arsenazo. The arsenazo absorbance changes at several visual wavelengths were used to detect calcium concentration change. We also measured the change in calcium concentration as a function of incident light-flash intensity.

Calcium-activated potassium currents were recorded from neurons voltage-clamped to the reversal potential for the nonspecific cation current (about -25 mV), or in which the nonspecific current was blocked in sodium- and calcium-free sea water. Calcium-activated nonspecific cation currents were isolated with 50 mM tetraethylammonium to block the calcium-dependent potassium current. The magnitudes of both currents were linearly related to calcium concentration changes over the range 0.1-20 µM, using different degrees of calcium loading of NITR-5 and NITR-7. This first-order stoichiometry was independent of membrane potential between -10 and -40 mV.

A computer model of the redistribution of calcium and free and bound nitrobenzhydrol, nitrosobenzophenone, and native buffer following a flash replicated the time course of decay of calcium-dependent currents from their peak after a flash to a steady-state level about one minute later. This decay is sensitive to the stoichiometry of calcium activation, and again indicated first-order calcium-dependence for both currents at all potentials between -10 and -40 mV. Sodium/calcium exchange hastened the decay of the currents slightly. Our diffusion model also predicted the slower decay of currents following a weak continuous light, due to the diffusional equilibration taking place during the light exposure.

The results suggest that different decay rates of these currents following a burst or depolarizing pulse in bursting pacemaker neurons are not due to differences in calcium stoichiometry, but perhaps to differences in voltage-dependent relaxations. Supported by NIH Grant NS 15114.

53.7 CO-LOCALIZATION OF Ca CHANNELS WITH Ca-ACTIVATED K CHANNELS IN HAIR CELLS OF THE BULLFROG'S SACCULUS. W. M. Roberts and A. J. Hudspeth. Department of Physiology, University of California School of Medicine, San Francisco, CA 94143-0444.

Hair cells from the bullfrog's inner ear exhibit electrical resonance that contributes to their frequency selectivity. The resonance arises from an interaction among calcium (Ca) channels, calcium-activated potassium (K_{Ca}) channels, and membrane capacitance; it occurs at a frequency that is largely determined by the time course of the K_{Ca} current. The K_{Ca} current is activated very rapidly in these cells by step depolarizations, rising to half its peak value in 1-4 ms. During this time, the Ca^{2+} concentration at a K_{Ca} channel is probably influenced by the number of Ca channels within a radius of less than 1 μm. The spatial distributions of these two channel types may therefore play an important role in determining the activation rate of the K_{Ca} current.

Using loose-seal pipettes to record ionic currents through small patches (10-50 μm^2) of membrane, we mapped the distributions of Ca channels and K_{Ca} channels on the basolateral surfaces of enzymatically isolated hair cells. Voltage-clamp steps were applied intracellularly through a separate tight-seal pipette, which was also used to measure the whole-cell current. A collagen plug at the tip of each loose-seal pipette prevented damage to the membrane when suction was applied to maintain an adequate seal resistance.

Ca-current density varied more than ten-fold among patches, with as much as 20% of a cell's current sometimes confined to a single patch. All patches that displayed Ca current also showed K_{Ca} current in a ratio similar to that observed in the whole-cell current; the two types of channels are thus highly co-localized.

To test the possibility that K_{Ca} channels are present in patches devoid of Ca channels, but cannot be activated due to a lack of local Ca^{2+} influx, we perfused cells internally with solutions in which the free Ca^{2+} concentrations were buffered at 10-100 μM with 60-100 mM HEDTA. Under these conditions, depolarizing voltage steps from a holding level of -70 mV elicited a K_{Ca} current with an exponential, rather than the usual sigmoidal, time course. This result confirms that the Ca^{2+} concentration at K_{Ca} channels was effectively elevated. Even with high intracellular concentrations of free Ca^{2+}, which should have activated all of the K_{Ca} channels in a cell, depolarizing voltage steps nevertheless elicited a K_{Ca} current of an amplitude similar to that seen with normal intracellular solution. Most K_{Ca} channels are therefore located close enough to Ca channels to be activated by the influx of Ca^{2+}. The clustering of Ca and K_{Ca} channels is expected to result in a more rapid rise in intracellular Ca concentration at the K_{Ca} channels, and hence a more rapid activation of the K_{Ca} current, than would occur if the channels were uniformly distributed across the cellular surface.

Supported by NIH grants NS22389 and NS07904.

53.8 **MESSENGER RNA SYNTHESIS DEPENDENCE OF POTASSIUM CURRENTS AND A CRITICAL PERIOD FOR MATURATION OF THE ACTION POTENTIAL.** Angeles B. Ribera and Nicholas C. Spitzer. Department of Biology, University of California, San Diego, La Jolla, CA 92093.

The action potential of embryonic *Xenopus* spinal neurons matures from a long duration, largely calcium dependent impulse to a brief sodium dependent spike during the first day of development in culture (Spitzer and Lamborghini, 1976). Whole-cell voltage clamp analysis shows that changes in outward potassium current are more substantial than those in inward sodium and calcium currents (O'Dowd, 1983a; Ribera et al., 1986) and suggests that potassium currents play a major role in the maturation of the action potential. The development of the Na dependent spikes is blocked by chronic inhibition of RNA synthesis begun before the end of a sensitive period (3-18 hr in culture), but not at later times (O'Dowd, 1983b); the development of inward currents is largely unaffected (O'Dowd, 1985). We have determined whether mRNA synthesis is required for development of outward currents. In addition, we have examined whether there is a critical period for the mRNA synthesis required for development of the action potential.

The reversible inhibitor of mRNA synthesis, 5,6-dichloro-1-β-D-ribobenzamidazole (DRB; 50 μM), was added to cultures 3 hr after plating. Continued presence of the drug from the time of plating prevented extension of neurites; when the drug was removed within a few hr, however, neurite extension was delayed by a comparable interval, suggesting that the action of the drug is reversible in these neurons.

Whole-cell voltage clamp methods were used to record voltage dependent potassium current. Chronic inhibition of mRNA synthesis blocked the developmental 3.5X increase in current density and doubling of activation rate previously reported for potassium current (Ribera et al., 1986). Intracellular recording under current clamp was used to elicit and record action potentials. The duration of the impulse, providing an index of its ionic dependence and maturity, was 1.6±0.2 ms ($n \geq 10$, mean±SEM) after 1 day in culture. In young neurons (6-9 hr), the action potential lasted 34±9 ms. Neurons that were subjected to chronic mRNA synthesis inhibition for 1 day had impulse durations of 72±16 ms, probably since transcription was arrested 3-6 hr before the time at which young neurons were examined. This value declined to 33±11 during the second day but is unlikely to reflect renewal of mRNA synthesis, since controls show that the drug is stable over this period. When DRB was applied acutely for 15 hr and the cells examined 1 day after washing out the inhibitor, the action potential lasted 23±8 ms.

These results indicate that chronic inhibition of mRNA synthesis blocks maturation of potassium currents, consistent with a major role for these currents in determining the mature form of the action potential. Furthermore, acute inhibition is sufficient to prevent the shortening of the impulse during neuronal differentiation, suggesting that a critical period of mRNA synthesis is associated with the development of the action potential.

53.9 EXPRESSION OF mRNA FOR THE CHICK BRAIN EARLY K CURRENT IN FROG OOCYTES; A BIOASSAY FOR cDNA CLONING OF THIS mRNA. I. Lotan*, A. Volterra, P. Dash*, S.A. Siegelbaum and P. Goelet*. HHMI, Ctr. for Neurobiol. & Behav., Columbia Univ., and NYS Psych. Inst., NY, NY 10032.

To clone the early potassium channel gene (A channel), for which there is no sequence information, we are developing a genetic approach based on hybrid arrest of translation of mRNAs microinjected into Xenopus oocytes.

Poly-A^+ RNA from chick embryo brain was injected into Xenopus oocytes (50-100 ng mRNA per oocyte). Four days later, the oocytes were assayed for ionic currents using a two microelectrode voltage clamp. The oocytes consistently expressed, in a concentration-dependent manner, both transmitter and voltage activated ionic currents, including GABA and kainate induced currents as well as fast TTX sensitive sodium current and early (A) K^+ current.

The early K^+ current was blocked by 4 mM 4-AP but was insensitive to 30 mM TEA, 4 mM Co^{2+}, and the calcium chelator BAPTA. The current activated following depolarizations positive to -50 mV, reached a peak outward value within 10-20 msec, depending on the donor, and then rapidly inactivated. Steady-state inactivation showed an S-shaped dependence on membrane voltage, with half-inactivation occurring at a holding potential of -77 ± 1.28 mV, and a slope factor for inactivation of -4.9 ± 0.5 mV (mean ± S.D., n = 4). These properties are very similar to the properties of the A current measured in both invertebrate and vertebrate neurons. The early K currents were never observed in control oocytes or in oocytes injected with liver mRNA (at up to 100-fold higher concentrations).

We have used chick ovalbumin and rabbit globin mRNAs to determine appropriate conditions for hybrid arrest in the Xenopus oocyte. Although both complementary RNA and DNA sequences to these mRNAs, generated from pKSM13 cDNA recombinants, selectively and quantitatively block in vitro translation of ovalbumin and globin mRNAs in reticulocyte lysates, in vivo translation of these mRNAs in the Xenopus oocytes was quantitatively arrested only by complementary DNA sequences.

To generate antisense DNA from chick brain mRNA that could be screened for the arrest of the expression of the early K^+ current, we have constructed an orientation-specific cDNA library from chick brain mRNA in pKSM13. This plasmid vector permits the preparation of strand-selected, single-stranded cloned DNAs. We are currently testing the ability of single-stranded DNA prepared from this cDNA library to arrest expression of the mRNA in Xenopus oocytes. By testing successively smaller subpools of recombinant cDNA from this library, we hope to isolate a cloned sequence, which by hybrid arrest blocks the translation of potassium A current mRNA in the oocyte.

53.10 DIVERSITY OF VOLTAGE DEPENDENT POTASSIUM CHANNELS INDUCED IN XENOPUS OOCYTES BY TOTAL AND FRACTIONATED RAT BRAIN mRNA. J.H.Hoger*, I.Ahmed*, N. Davidson*, H.Lester, & B. Rudy. Divs. of Biology & Chemistry, Caltech, Pasadena, CA 91125. and Dept. of Physiology & Biophysics N.Y.U. Med. Ctr., N.Y., N.Y.. 10016.

K channels show a high degree of diversity, varying in voltage dependence, kinetics, pharmacology, and single-channel properties. The types of K channels present in the brain are incompletely characterized due to the difficulties of applying present electrophysiological techniques to many cell types and regions of the cell. In order to characterize brain voltage-dependent K channels we have prepared poly(A) RNA from rat brains by a LiCl-urea procedure. This poly(A) RNA was injected into prepared Xenopus oocytes and expression of voltage dependent K channels was measured by two micro-electrode voltage clamping. This technique may allow the study of the source of diversity of K channels, because all the different channels are expressed in the same system. The K currents observed include a fast transient component with very similar characteristics to the "A" current and a "delayed rectifying" current. The delayed rectifying current may be composed of more than one component as determined by inactivation properties, activation and deactivation kinetics, and sensitivity to externally applied 4-aminopyridine(4AP), tetraethylammonium(TEA), and toxin I from Black Mamba. We have fractionated the mRNA by centrifugation on linear sucrose gradients (6-20%). A delayed rectifier type current was expressed by mRNA comigrating with the sodium channel alpha subunit mRNA(7.5-9.5Kb). This delayed rectifier type current may still contain more than one component; it is not completely blocked by TEA and it still contains different deactivating components. However, the "A" current is not expressed or greatly reduced in this fraction. A fraction of smaller size (6-8Kb), in contrast, expresses an "A" current and a "delayed rectifier" component. These results indicate that different voltage-dependent K channels are encoded by different mRNAs and are therefore composed of different polypeptides which may in part account for the diversity of voltage dependent potassium channels. Supported by NIH GM-26976, GM-10991, GM-29836, and Fellowships from American Cancer Society and NIH.

53.11 EXPRESSION OF DIFFERENT "A" CURRENTS IN XENOPUS OOCYTES INJECTED WITH TOTAL OR FRACTIONATED RAT BRAIN mRNA. B. Rudy, J.H. Hoger*, N.Davidson* & H. Lester.(SPON:J.Pollock) Dept. of Physiology & Biophysics New York Univ. Med. Ctr., N.Y.,N.Y. 10016. and Divs. of Biology & Chemistry, Caltech, Pasadena, CA. Xenopus oocytes injected with rat brain mRNA express a fast transient K current with very similar properties to the "A" currents observed in molluscan and mammalian neurons. The current has a relatively low threshold, activating at around -60 mV before there is significant activation of delayed rectifying type current. The rate of activation of this current is voltage dependent and often it can only be resolved properly for small depolarizations, where the time constants are of the order of 5 msec at room temperature. The activation time constant decreases as the depolarization is increased. The current inactivated with a relatively voltage-independent time constant of about 30-40 msec at room temperature. Steady-state inactivation by long prepulses is complete at -50 mV and half inactivation occurs at around -65 mV. The current is completely blocked by 5 mM 4-AP and half blocked at 2 mM. The degree of block at a given 4-AP concentration decreases with increasing depolarization, and decays during sequential pulses at frequencies higher than 0.5 sec $^{-1}$. The "A" current is insensitive to external TEA at concentrations of up to 40 mM.We have observed the expression of this current to be of variable magnitude with the same RNA, suggesting that other factors probably related to oocyte variability are important for its expression. Oocytes injected with sucrose gradient fractionated RNA express a fast transient K current when injected with a fraction of 6-8 kB. This current differs from the current observed when total mRNA is injected in that; (a)its activation and inactivation kinetics are faster and; (b)it is less sensitive to 4-AP. 5 mM 4-AP blocks the current for small depolarizations only. Even 10 mM 4-AP does not completely block the current. However, 4-AP block of this current shows the same type of voltage and frequency dependence as that of the current observed in oocytes injected with total mRNA. Furthermore, steady-state inactivation of this current by prepulses remains unchanged. We propose that the altered pharmacology is the result of the change in kinetics, as can be expected for a state-dependent block. Several explanations for these results will be considered. For example, this current may represent a distinct, fast transient K current or its altered kinetics may result from the fact that the channel contains more than one polypeptide. We will report on experiments attempting to reconstitute the original kinetics and pharmacology. Supported by NIH GM-26976, GM-10991, GM-29836, and a Fellowship from American Cancer Society.

53.12 COMPUTER SIMULATION OF THE EFFECT OF NON-INACTIVATING SODIUM CHANNELS ON EXCITABILITY. I.Z. Steinberg* (SPON: U.Z. Littauer). Chemical Physics Dept., Weizmann Institute of Science, Rehovot 76100 Israel.

Non-inactivating sodium channels (NI-NaC) have been discovered in various cell types, like Purkinje cells (Llinas & Sugimori, J. Physiol., 305:171,1980), the Squid axon (Shoukimas & French, Biophys. J., 32:857,1980; Rakowski, De Weer & Gadsby, Biophys.J., 47:31a, 1985), and frog oocytes (L.C.Schlichter, Dev.Biol., 98:47,1983; Baud, Kado & Marcher, Proc.Natl.Acad.Sci.,USA, 79:3188,1982). Additionally, normal voltage-gated sodium channels lose their inactivation capabilities following treatment with pronase (Armstrong, Bezanilla & Rojas, J.Gen.Physiol.,62:375, 1973) or certain chemicals and toxins. The presence of NI-NaC in a cell membrane profoundly modifies the electrical properties of the cell, since opening of these channels and cell depolarization reinforce each other without intrinsic control. Computer simulations were performed to systematically explore the pattern of behavior of excitable cells which have NI-NaC in their membranes. The Hodgkin and Huxley (H&H) equations for space-clamped cells were used to describe the changes in electric potential, except that the sodium currents were represented by the sum of two terms:
$FI \cdot g_{Na} \cdot m^3 \cdot h \cdot (V-E_{Na}) + (1-FI) \cdot g_{Na} \cdot m^3 (V-E_{Na})$, where $FI (0 \leq FI \leq 1)$ is the fraction of sodium channels which inactivate normally, and the other symbols have their usual definition. The simulations thus quantitatively apply to pronase-treated squid axons, but may serve to qualitatively illustrate patterns of electrical activity introduced by NI-NaC generally.

A rich repertoire of possible types of electrical behavior is obtained: Normal behavior, including capability of firing action potentials, requires values of FI which are not far from unity, the permissible range depending on g_K. Bistability, at which the cell may exist in one of two stable states of different resting potential, occurs when the value of FI is lowered. Transitions from the polarized to the depolarized resting states, and vice versa, may be brought about by depolarizing and hyperpolarizing triggers, respectively. Such behavior is like that of memory storage devices. Monostability at depolarized potentials is favored by low FI values and can occur if g_K is less than the H&H value. Repetitive firing is obtained for values of g_K which are appreciably lower than the H&H value and for values of FI which are close to unity. Note, however, that it may occur also with the H&H values of the ionic conductivities if the deactivation kinetics of the NI-NaC is slowed down. Inverse action potentials, following a hyperpolarizing trigger when the cell is in the depolarized resting state, are favored by FI values which are in the vicinity of the transition between monostability at depolarized potentials and bistability.

EXCITATORY AMINO ACIDS: PHARMACOLOGY I

54.1 PERTUSSIS TOXIN INHIBITS THE STIMULATION OF INOSITOL PHOSPHOLIPID HYDROLYSIS BY GLUTAMATE IN PRIMARY CULTURES OF CEREBELLAR NEURONS J.T. Wroblewski*, F. Nicoletti*, E. Fadda*, J. Mazzetta* and E. Costa (SPON: W.J. Wojcik). Fidia-Georgetown Institute for the Neurosciences, Georgetown Univ. Med. Sch., Washington, DC 20007.

In cerebellar granule cells the hydrolysis of membrane phosphatidylinositol (PI) is coupled to two subtypes of metabolotropic glutamate receptors. The G_{P1} receptor is activated by glutamate, aspartate and N-methyl-D-aspartate (NMDA), is inhibited by 2-amino-5-phosphonovaleric acid (APV), Mg^{2+} and negatively modulated by phencyclidine. The G_{P2} receptor is insensitive to the above inhibitory actions and is activated selectively by glutamate and quisqualate.

The incubation of cultured granule cells with pertussis toxin (PTX, 2 ug/ml, 16 h) results in a selective depression of the signal transduction at the G_{P2} receptor. After this treatment the stimulation of PI hydrolysis by quisqualate is reduced by 65%, while the stimulatory action of NMDA remains unaffected. PI hydrolysis stimulated by glutamate is reduced by only 30%, due to the action of glutamate at both PI-coupled receptors. When the action of glutamate at the G_{P1} receptor is eliminated by the addition of 1 mM APV, the remaining PI hydrolysis is inhibited by 70% by PTX treatment.

In cultured granule cells, PI hydrolysis is also stimulated by the cholinergic muscarinic agonist carbachol. However, treatment with PTX fails to affect this stimulation. Two ionotropic excitatory amino acid receptors are present in cultured granule cells, G_{C1} and G_{C2}, and are coupled to increased Ca^{2+} influx and cyclic GMP formation. PTX treatment does not reduce the signal transduction at these glutamatergic receptors.

The possible involvement of a GTP-binding protein in the signal transduction mechanism of the G_{P2} receptor was studied additionally in preparations of membranes obtained from cultured granule cells. Although membrane preparations did not preserve the stimulation of PI hydrolysis by transmitter receptor agonists, they responded with increased PI hydrolysis to the application of GTP-γ-S (stable GTP analogue). The same membrane preparations were used to study the effect of GTP on the specific binding of [^{3}H]glutamate. Additions of 50 uM GTP-γ-S resulted in a decrease of specific glutamate binding, reducing by 30% the number of binding sites, while not affecting the affinity.

These data indicate the presence in cultured granule cells of a PTX-sensitive GTP-binding protein which participates in signal transduction at G_{P2} receptors. This protein is not involved in the mechanisms of PI hydrolysis stimulated by other receptors present in the granule cells, nor in ionotropic signal transducing systems activated by excitatory amino acids.

54.2 SELECTIVE POTENTIATION OF EXCITATORY AMINO ACID RECEPTOR-STIMULATED PHOSPHATIDYLINOSITOL HYDROLYSIS BY LOW CONCENTRATIONS OF COBALT AND NICKEL. E. Fadda*, F. Nicoletti*, J.T. Wroblewski*, J. Mazzetta* and E. Costa (SPON: J.L. Meek). Fidia-Georgetown Institute for the Neurosciences, Georgetown University Med. Sch., Washington, D.C. 20007.

In primary cultures of cerebellar granule cells, excitatory amino acid recognition sites are coupled to ionotropic and metabolotropic signal transducing mechanisms. These include the hydrolysis of membrane phosphoinositides (PI) (G_P receptors) and the activation of receptor-operated Ca^{2+} influx with a consequent increase in cyclic GMP formation (G_C receptors). The two receptors coupled to PI hydrolysis differ by the pharmacology of their recognition sites and the molecular characteristics of their coupling mechanism. Thus, G_{P1} is activated by N-methyl-D-aspartate (NMDA), glutamate and aspartate, is antagonized by 2-amino-5-phosphonovaleric acid (APV), is sensitive to Mg^{2+} and allosterically modulated by phencyclidine (PCP). In contrast, G_{P2} is not sensitive to the above agents and is selectively stimulated by quisqualate and glutamate. The G_{C1} has a pharmacology similar to the G_{P1} receptor; however, is coupled to a Ca^{2+} influx

In the present work, we have demonstrated that micromolar concentrations of Co^{2+} and Ni^{2+} selectively potentiate signal transduction at the G_{P1} receptor. The dose-response curve for this potentiation was biphasic, reaching the maximal effect at 50 uM, while above 100 uM an inhibition could be seen, similar to that produced by Mg^{2+}. Among other divalent cations tested Mn^{2+}, Cu^{2+}, Fe^{2+}, La^{2+}, Zn^{2+} and Cd^{2+} shared the properties of Mg^{2+} but not those of Co^{2+} and Ni^{2+}.

The potentiation by Co^{2+} and Ni^{2+} was selective for PI hydrolysis stimulated by glutamate, NMDA and aspartate (G_{P1}), but not for that stimulated by quisqualate (G_{P2}) or the muscarinic cholinergic agonist carbachol. Moreover, it was inhibited by APV, Mg^{2+} and PCP, which act at the G_{P1} receptor. Despite large similarities in the pharmacological profiles of the G_{P1} and G_{C1} recognition sites, Co^{2+} and Ni^{2+} failed to affect Ca^{2+} influx and cyclic GMP formation mediated by the G_{C1} receptor.

These results indicate that in primary cultures of cerebellar granule cells Co^{2+} and Ni^{2+} show a selectivity of action which is restricted not only to a specific signal transducing mechanism (PI hydrolysis), but also to a specific subtype of excitatory amino acid receptors (G_{P1}). The results will be discussed in relation to the possibility that the supramolecular structure of the G_{P1} receptor may include two cation-dependent modulatory sites, one negative - sensitive to Mg^{2+}, the other positive - sensitive to Co^{2+} and Ni^{2+}.

54.3 PROTEIN KINASE C TRANSLOCATION AND ACTIVATION IN PRIMARY CULTURES OF NEURONS: REGULATIONS BY GLUTAMATE AND BY SPHINGOGLYCOLIPIDS. F. Vaccarino, A. Guidotti and E. Costa. FIDIA-Georgetown Institute for the Neurosciences, Washington D.C. 20007.

The amino acid glutamate and NMDA are ligands for receptor-operated cation channels that allow a substained increase in the influx of Ca^{2+} in neurons. One possible consequence of such an intracellular Ca^{2+} increase might be the stimulation of Ca^{2+}-dependent kinases such as protein kinase C (PKC). PKC stimulation involves two separate steps: translocation or priming, by which the enzyme becomes membrane-bound, and activation by membrane diacylglycerols (DAGs). In rat cerebellar granule cells in primary culture, glutamate activates PI turnover and increases Ca^{2+} influx (Nicoletti et al., 1986; Wroblewski et al., 1985). Using this model, we investigated whether such glutamate-activated signal transduction results in PKC translocation from the cytosol to the neuronal membrane with subsequent PKC activation. Treatment of intact granule cells with excitatory amino acids such as glutamate and NMDA increases the number of binding sites (Bmax) for ^{3}H-beta-phorbol-12,13-dibutyrate (PDBu) (a specific ligand for PKC). This increase was blocked by phencyclidine and by aminophosphonovaleric acid (APV), was not mimicked by cGMP or by carbachol, and was dependent upon the extracellular Ca^{2+}. These data suggest that glutamate elicits a Ca^{2+} influx thereby triggering PKC translocation from the cytoplasm to the membrane compartment. Moreover, if granule cell homogenates are preincubated with Ca^{2+} and centrifuged, a redistribution of ^{3}H-PDBu binding sites is observed from the cytoplasmic (supernatant) to the membrane (pellet) fractions. In parallel, the PKC-mediated phosphorylation of endogenous substrates disappears from the cytoplasmic fraction, while PKC-mediated phosphorylation of membrane proteins of approximately 55, 66, 76 and 84-kDa is stimulated in the membrane fraction after Ca^{2+} preincubation. Similar proteins were found to be phosphorylated after glutamate stimulation of intact granule cells and this increase was antagonized by APV. The action of glutamate was mimicked by the phorbol ester tetradecanoylphorbolacetate (TPA) and by DAG. The ganglioside G_{T1b} does not affect basal ^{3}H-PDBu binding to intact granule cells but it antagonizes the increase in Bmax induced by glutamate. This trisialoganglioside also inhibits the phosphorylation of the membrane substrates induced by glutamate. Gangliosides are normal components of neuronal membranes and in particular G_{T1b} is enriched in cerebellar granule cells but is absent in cerebellar astrocytes. The inhibitory action on PKC translocation and activation exerted by G_{T1b} in intact cells may imply an important role of these glycolipids in the physiological down regulation of PKC.

54.4 ACTIVATION OF GLUTAMATE RECEPTORS INDUCES THE EXPRESSION OF C-FOS PROTO-ONCOGENE IN PRIMARY CULTURE OF RAT CEREBELLAR GRANULE CELLS. A.M. Szekely, M.L. Barbaccia and E. Costa (SPON: E. Adler-Graschinsky). FIDIA-Georgetown Institute for the Neurosciences, Georgetown Univ. Med. Sch., Washington DC 20007.

Proto-oncogenes, whose altered retroviral counterparts cause tumorigenic transformation, are thought to regulate normal processes of growth and differentiation in many cell types, including neurons. C-fos belongs to a large class of oncogenes, whose protein products are present in the cell nucleus and presumably participate in the regulation of expression of other genes. This effect might induce modifications that have a time dimension outlasting the duration of the initializing stimulus. Since hippocampal signal transduction of excitatory amino acids has been implicated in memory processes, it became of interest to us to investigate the possible linkage between activation of excitatory amino acid receptor(s) and induction of proto-oncogenes using primary culture of cerebellar granule cells. These cells contain ionotropic (GC_1) and metabotropic (GP_1) receptors transducing the transmitter signal via Ca^{2+} influx or activation of phosphatidylinositol (PI) metabolism, respectively, in a Mg^{2+} sensitive manner (Wroblewski, J., Proc. Natl. Acad. Sci., in press). N-methyl-D-aspartate (NMDA) is the synthetic agonist of GC_1 and GP_1, kainate and quisqualate are the synthetic agonists for GC_2 and GP_2 receptors, respectively. We analyzed the change of c-fos specific mRNA level following selective stimulation of granule cells via GP_1, GP_2, GC_1 and GC_2 receptors. Total cellular RNA was isolated, poly (A^+) RNA was purified and analysed by Northern blotting using ^{32}P nick translated mouse c-fos cDNA probe. The c-fos mRNA level was expressed using as a reference β-Actin cDNA probe. The GP_1 and GC_1 receptor agonists glutamate (10^{-5} M) and NMDA ($5x10^{-5}$ M) increased c-fos mRNA level. Kainate (GC_2) and quisqualate (GP_2) ($5x10^{-5}$M) failed to modify the basal expression. While activation of protein kinase C by tetradecanoylphorbolacetate (TPA) (10^{-7}M) resulted in a dramatic increase of c-fos mRNA level, the increase of cytosolic Ca^{2+} concentration by the ionophore A23187 ($5x10^{-7}$M) failed to elicit a change of the basal signal. Our results indicate that the increase in PI turnover (GP_1) and/or activation of Ca^{2+} influx (GC_1) can increase c-fos mRNA level, while depolarization due to kainate receptor (GC_2) stimulation fails to change this mRNA signal. These inferences are consistent with a c-fos mRNA increase elicited by the phorbol ester-induced activation of protein kinase C.

54.5 EFFECTS OF APV, KETAMINE, PHENCYCLIDINE AND KYNURENIC ACID ON HIPPOCAMPAL SLICES BATHED WITH PENICILLIN OR Mg^{++}-FREE MEDIUM. J.H. Schneiderman and J.F. MacDonald. University of Toronto, Toronto, Ontario, Canada.

In order to examine the role of excitatory amino acid (EAA) receptors in generating epileptiform discharge, we compared the effects of specific NMDA blockers (APV, ketamine and phencyclidine) and a non-specific EAA blocker (kynurenic acid) on penicillin and Mg^{++}-free bursts in the same hippocampal slices.

APV (50 uM), ketamine (10 uM), PCP (1 uM) and kynurenic acid (1 mM) reduced the amplitude and duration of spontaneous bursts in Mg^{++}-free medium and usually blocked them. The burst rate tended to decrease when the bursts became small. These effects were identical to increasing magnesium above 500 uM. The actions of all the drugs were reversible; however, recovery from PCP required several hours of drug-free rinse. Kynurenic acid prolonged the interval between penicillin bursts without significantly reducing their amplitude, whereas the other drugs had little effect. Ketamine 200 uM reduced the amplitude and frequency of penicillin bursts but did not block them.

Therefore, it appears that the NMDA mechanism is activated in Mg^{++}-free medium but not in the presence of the GABA-blocker, penicillin. The ability of kynurenic acid to selectively decrease penicillin burst frequency without reducing burst amplitude suggests that a non-NMDA EAA receptor may be involved in generating the spontaneous rhythmic synaptic activity which triggers the bursts but not in the PDS itself.

54.6 EXTRACELLULAR STRIATAL CONCENTRATIONS OF GLUTAMATE AND ASPARTATE DURING STIMULATION OF FRONTAL CORTEX, IN VIVO. H. Perschak* and M. Cuénod (SPON: M.-C. Hepp-Reymond). Brain Research Institute, Zürich University, CH-8029 Zürich, Switzerland.

Corticostriate neurons are thought to use excitatory amino acids (eAA) such as glutamate (Glu) or aspartate (Asp) as transmitters. In vitro, eAA are being released from depolarized striatal tissue in dependence of intact corticostriate terminals. In preliminary in vivo experiments, however, striatal extracellular concentration of Asp was unchanged and Glu showed a significant decrease by 16% during a four min activation of frontal cortex. Under physiological conditions eAA are being inactivated by reuptake; thus, release and uptake are principal determinants of extracellular concentrations of eAA in vivo. In the present experiments activity dependent changes in extracellular levels of eAA were further investigated by shortening sampling time and/or stimulation duration.

Striata of anesthetized rats were perfused with a Ringer solution by means of a push-pull cannula. One min effluent fractions were collected before, during and after four min or one min electrical stimulation periods of frontal cortex. Endogenous Glu and Asp were measured using glass-capillary/mass-fragmentography.

The fraction collected during the first min of a four min stimulation period contained elevated levels of Glu and especially Asp. During the following three min concentrations of Glu and Asp decreased and dropped, in the case of Glu significantly, to a level below pre-stimulation conditions. The increase of Glu and Asp during one min stimulation compared to the resting situation was 58% and 56% respectively and was significant for the latter.

These observations are consistent with the following hypothesis: Stimulation dependent release of Glu and Asp, detectable during the first min, is later overcompensated by activity induced enhancement of eAA uptake. Such stimulation dependent uptake has been proposed by Nieoullon et al. (Neurosci Lett, 43:191, 1983).

54.7 EVIDENCE THAT GLUTAMATE IS A NEUROTRANSMITTER IN AVIAN RETINAL GANGLION CELLS. S.E. Raiguel* and R.E.Marc Dept. of Sensory Sciences, U.T. Health Sci. Ctr. at Houston, Houston, TX. 77030

Glutamate has been previously proposed as a neurotransmitter of retinal ganglion cells (GC's). In the present study, three approaches have been used to demonstrate an association between avian GC's and the receptors and high-affinity transport mechanism for glutamate.

(1) High-affinity uptake/autoradiography (HAU/ARG) of ^{3}[H]-L-Glutamate or ^{3}[H]-L-Aspartate in the optic tecta (OT) of normal birds showed a concentration of activity in the superficial layers of the OT in which the axons of the GC's terminate. Enucleation reduced both the thickness of these laminae and the density of silver grains over them. Conversely, in a developmental study using chick embryos, we found that Glutamate HAU first appeared in these layers at the time of GC axon arrival.

(2) Receptor binding/contact ARG of ^{3}[H]-L-Glutamate in the OT showed that Na^+-independent binding of this ligand was highest in the layers of the tectal SGFS which receive visual afferents, and in the nucleus of the basal optic root, which has been shown to the target of the axons of displaced ganglion cells in the pigeon and chick. Glutamate binding was displacable either with unlabeled Glutamate or with quisqualate. ^{3}[H]-Kainate showed identical patterns of radioactivity in the OT.

(3) Anti-glutamate peroxidase-antiperoxidase immunocytochemistry showed a pattern of immunoreactivity in the OT of normal birds similar to the silver grain distribution in glutamate HAU/ARG experiments, with activity concentrated in the visual layers of the fibrous gray layer (SGFS). Enucleation resulted in a decrease in the thickness of those layers with a loss of immunoreactivity throughout the SGFS. Moreover most of the cells of the ganglion cell layer of the retina, and a population of large cells in the amacrine cell layer, presumably displaced ganglion cells, were strongly immunoreactive.

Our data support the hypothesis that ganglion cells, both conventional and displaced, use glutamate as their neurotransmitter.

54.8 DIFFERENTIAL BLOCKADE OF SYNAPTIC INPUT TO NUCLEUS TRACTUS SOLITARIUS (NTS) NEURONS BY SELECTIVE EXCITATORY AMINO ACID ANTAGONISTS. B.D. Miller*, T.S. Donta*, and R.B. Felder. Department of Medicine and CV Center, University of Iowa Hospitals, Iowa City, Iowa 52242.

We recently demonstrated that selective antagonists for l-glutamate (l-glu) receptor subtypes blocked synaptic transmission in NTS in an in vitro rat brain slice preparation. We pursued this observation further in the present study by determining the effective blocking bath concentrations of these agents and by testing the effects of blocking concentrations of each antagonist on synaptic input to single NTS neurons activated by two different afferent pathways.

Single units evoked by stimulating the tractus solitarius (TS) (1 Hz, 0.3 ms) with ultrafine concentric bipolar electrodes were recorded from medial NTS using glass microelectrodes filled with 2 M NaCl (impedance 4-15 mohm). The ability of selective excitatory amino acid antagonists to block synaptic input to these units was then tested. Dose response relationships for 2-amino-5-phosphonovaleric acid (APV), kynurenic acid (KY) and glutamate diethylester (GDEE) were obtained by infusing increasing concentrations of each antagonist into the recording chamber. Maximum inhibition of the single unit response to APV (NMDA antagonist) was 94±4% at a calculated bath concentration of 40 μM, (n=6); KY (NMDA and kainate antagonist) caused a 90±6% inhibition at 290 μM (n=5) bath concentration, and GDEE (quisqualate antagonist) caused an 80±10% inhibition at a 240 μM (n=6) bath concentration.

Numerous cells in medial NTS responded to bilateral TS stimulation. Four units have been studied to determine the effects of more than one antagonist on synaptic input evoked by stimulation of each TS. Complete data for all three antagonists at blocking concentrations are available for two such units. The response of one cell to ipsilateral TS stimulation was inhibited by APV but not KY or KA while the response to contralateral TS stimulation was inhibited by KY and GDEE but not APV. The response of the second cell to ipsilateral TS stimulation was inhibited by KY but not APV or GDEE; contralateral input was not significantly inhibited by any of the antagonists studied.

These data suggest that more than one l-glutamate receptor subtype may be intrinsic to synaptic mechanisms in the NTS and that the presence of multiple l-glutamate receptor subtypes on single NTS neurons may provide a mechanism for selective activation by different neural pathways.

54.9 MEDIATION OF DIFFERENTIAL GLUTAMATE RESPONSES BY NMDA AND KAINATE RECEPTORS ASSOCIATED WITH DEGLUTITIVE NEURAL SUBSTRATES WITHIN THE RAT SOLITARIUS COMPLEX. M. A. Hashim* and D. Bieger. Faculty of Medicine, Division of Basic Medical Sciences, Memorial University of Newfoundland, St. John's, Nfld. A1B 3V6 Canada.

The complex motor act of swallowing comprises three subsynergies, viz., the linguopalatal, the pharyngeal and the oesophageal stages, governed by at least two closely linked central pattern generators associated with the nucleus tractus solitarii (NTS). As shown in previous studies (Bieger, D., Neuropharmacol., 23(12A): 1451-1464, 1984; Hashim, M. A. & D. Bieger, Brain Res.Bull., 18: 355-363, 1987), S-glutamate (Glu), applied pneumophoretically to the NTS, will elicit either complete deglutitive sequences (CDS) or the component subsynergies, depending upon the site of stimulation, muscarine, on the other hand, is selective in its action, producing primarily rhythmic oesophageal contractions at Glu-responsive NTS subnucleus centralis loci. In the present study, the involvement of different Glu receptor subtypes was investigated in urethane-anaesthetised rats with respect to their possible association with the individual subsynergies. For the microstimulation of deglutitive neurons, multibarrelled glass micropipettes (tip diameter 2-5 μm) were stereotaxically positioned in the NTS via an occipital craniotomy. Drugs contained in the micropipettes were pressure-ejected (400-500 kPa; 50-300 ms) by means of a nitrogen-pressured pneumophoresis pump. The three Glu-receptor agonists, N-methyl-D,L-aspartate (NMA), quisqualate (QA) and kainate (KA) were applied 0.1-10 pmol in pulses of 20-100 pL at NTS loci yielding pharyngeal and/or oesophageal responses. At pharyngeal sites, the rank order of agonist potency was KA>>NMA>QA; and the rank order of efficacy, KA>NMA>>QA, as indicated by repetitive swallowing frequency. However, at oesophageal sites, agonist potency followed the order NMA>QA=KA The specific NMDA-receptor blocker, 2-amino-5-phosphonovaleric acid (APV) selectively and reversibly antagonised the Glu-evoked oesophageal responses with no corresponding effect on rhythmic oesophageal responses elicited by muscarine; at CDS sites, APV spared the pharyngeal component while selectively blocking the oesophageal components. Unlike APV, the nonselective Glu-receptor antagonist, gamma-D-glutamylglycine failed to discriminate between Glu-evoked pharyngeal and oesophageal responses. In contrast to both the muscarine-evoked rhythmic oesophageal contractions and Glu-evoked pharyngeal swallows, Glu-evoked oesophageal responses displayed a typical self-sensitization. Application of equal volumes of the vehicle was ineffective. It is concluded that within the NTS, KA receptors are associated with the pharyngeal premotor elements whereas NMDA-receptors are linked to the oesophageal pattern generator. Both the KA- and the NMDA-mediated deglutitive mechanisms can operate under physiological conditions.

54.10 NMDA INDUCED FREQUENCY-DEPENDENT POTENTIATION OF CORTICALLY EVOKED EPSPs IN CAT CAUDATE. P. L. Herrling. Sandoz Research Institute Bern Ltd., P.O. Box 2173, CH-3001 Bern, Switzerland.

Previous work had shown that iontophoretically applied NMDA agonists can strongly potentiate EPSPs evoked by electrical stimulation of the prefrontal cortex in caudate neurons of halothane anaesthetised cats. (Do et. al.,J. Neurosci. 6:2226, 1986). This potentiation was defined as occurrence of EPSP amplitudes, -durations and number of synaptically evoked action potentials that were significantly larger during application of NMDA agonists than during equal depolarizations elicited by applications of non-NMDA excitatory amino acid receptor agonists such as quisqualate.

In subsequent experiments it became apparent that the probability for the occurrence of potentiated EPSPs varied with different stimulation frequencies. At 0.5Hz about 57% of cells (N=14) displayed potentiation. At 2Hz only 22% (N=9) of cells showed potentiation, however, at this stimulation frequency the cortical stimulus occurred in 89% of cells during a NMDA elicited depolarization plateau (for description of plateaus, see: Herrling et al., J. Physiol. 339:207, 1983). In these cases the depolarizations were abruptly terminated at a constant latency from the stimulation, independent of the previous duration of the plateaus. This phenomenon was called plateau cut-off. At 5 and 10 Hz potentiation probability increased to 100% (N=6 and 5, respectively) while plateau cutoff probability sank to 30 and 20%, respectively. At 20Hz, NMDA induced plateaus and EPSP potentiation disappeared and only regular firing occurred.

Measures on the time sequence of synaptic events triggered by cortical stimulation indicate that the frequency dependency of EPSP potentiation by NMDA might be a consequence of circuit properties of the caudate nucleus.

54.11 EXCITATORY AMINO ACID ANTAGONISTS DEPRESS ACOUSTIC STARTLE AFTER INFUSION INTO THE VENTRAL NUCLEUS OF THE LATERAL LEMNISCUS OR PARALEMNISCAL ZONE. R.F. Spiera* and M. Davis (Spon. C.A. Sorenson), Dept. of Psychiaty, Yale Univ. Sch. Med , 34 Park Street, New Haven, CT 06508.

The startle reflex is a simple behavior which has proven useful for examining the neural mechanisms underlying behavioral plasticity. The neural pathway that mediates this short latency response consists of the ventral cochlear nucleus, the paralemniscal zone (an area just medial to the ventral nucleus of the lateral lemniscus - VLL), nucleus reticularis pontis caudalis (RPC) and spinal motor neurons. The startle reflex can be modulated by neurotransmitters such as serotonin, dopamine, norepinephrine, glycine, GABA, acetylcholine, and various peptides. However, none of these substances appear to actually mediate startle (i.e., released by one neuron within the startle pathway onto the next neuron within the pathway) since depletion or antagonists of these transmitters do not eliminate startle. The present study begins to define possible neurotransmitters that might actually mediate the acoustic startle reflex.

The role of excitatory amino acid transmitters in acoustic startle was chosen for study. The startle reflex has an extremely short latency so that rapidly acting transmitters such as amino acid transmitters might mediate this very fast reflex. Moreover, excitatory amino acid transmitters appear to to be released by the auditory nerve, indicating that they mediate auditory transmission at the cochlear nucleus. The present study sought to evaluate the role of excitatory amino acid transmitters at the VLL since this auditory nucleus may be somewhat specific for startle.

Male albino rats were implanted with bilateral cannulas into the VLL under chloral hydrate anesthesia. After one week recovery, animals were tested for acoustic startle response by presenting noise bursts (100-115 dB) every 20 sec before and after bilateral infusion of either 0, 2.5, 5.0 or 10.0 μg/side of either λ-glutamylglycine (DGG), λ-D-glutamyl-aminomethyl sulfonate (GAMS) or 2-5-phosphonovalerate (APV). Infusions of DGG, APV, and GAMS produced a rapid, marked, dose-dependent depression of the acoustic startle response. All three drugs had similar potency and efficacy over this dose range. These effects only occurred in animals in which the cannulas were found histologically to be located in the VLL or paralemniscal zone. Moreover, these depressant effects were very specific to blocking the startle reflex, since drug infusions into the VLL did not produce any other obvious behavioral changes and an auditory lick-suppression technique demonstrated that infusions into the VLL did not eliminate hearing.

These results indicate that excitatory amino acid transmitters may play an important role in either modulating or mediating startle at the level of the VLL and paralemniscal zone.

54.12 DUAL-COMPONENT SYNAPTIC POTENTIALS IN XENOPUS EMBRYO INTERNEURONES: SPONTANEOUS AND EVOKED RELEASE OF EXCITATORY AMINO ACID TRANSMITTER FROM CUTANEOUS AFFERENT FIBRES. K.T.Sillar* and A.Roberts* (SPON: W.J.Heitler). Dept. of Zoology, Univ. of Bristol, Bristol BS8 1UG, U.K.

The trunk and tail skin of Xenopus laevis embryos near the time of hatching is innervated by the unmyelinated and free nerve endings of Rohon-Beard neurones. These have somata in the dorsal spinal cord and longitudinal axons in spinal marginal zones, where they make monosynaptic contacts with dorsolateral sensory interneurones. Transient indentation, or electrical stimulation of the skin with short current pulses evokes impulses in Rohon-Beard neurones and short latency EPSPs in dorsolateral interneurones (Clarke et al, J.Physiol. 348:511-525 (1984); Clarke & Roberts, J.Physiol. 354:345-362 (1984)). We now show that the EPSPs are dual-component, consisting of separate fast and slow potentials (cf. Dale & Roberts, J.Physiol. 363:35-59 (1985)), which are both blocked by 1-2 mM kynurenic acid. The dual-component EPSPs are therefore mediated by an excitatory amino acid neurotransmitter. The slow components, but not the fast are specifically blocked by the NMDA receptor antagonists APV and magnesium indicating that the dual-component EPSPs result from the simultaneous activation of NMDA and kainate/quisqualate receptors.

Dorsolateral interneurones also receive spontaneous depolarizing and hyperpolarizing potentials. The hyperpolarizing potentials are abolished by 1 uM strychnine, while the depolarizing ones are resistant to both 1 uM strychnine and 1 uM TTX. The depolarizing spontaneous potentials are abolished by 1-2 mM kynurenic acid and are therefore excitatory amino acid-mediated. Like the evoked EPSPs, they have fast and slow components. Unlike evoked EPSPs in which fast and slow potentials are usually evoked simultaneously, the spontaneous events are predominantly fast. However, a significant proportion (ca. 30%) are either slow or dual-component. The spontaneous EPSPs show the same pharmacological properties as the evoked EPSPs and they therefore result from a transmitter action at both NMDA and kainate/quisqualate receptors.

The major source of excitatory input to the dorsolateral interneurones is from the Rohon-Beard neurones. Given the similarities in timecourse and pharmacological sensitivity we suggest that the spontaneous EPSPs, like those evoked following skin stimulation derive from the presynaptic release of excitatory amino acid transmitter from Rohon-Beard neurones.

CELL LINEAGE AND DIFFERENTIATION I

55.1 DIFFERENTIATION OF CHOLINE ACETYLTRANSFERASE-IMMUNOREACTIVE CELLS IN QUAIL NEURAL CREST CULTURES. G. G. Leblanc* and M. E. Bronner-Fraser. (SPON: L. Smith-Thomas) Developmental Biology Center, University of California, Irvine, CA 92717.

When quail neural crest cells are grown in vitro, they differentiate into several of their normal in vivo derivatives, including melanocytes, adrenergic cells, and cells which resemble sensory neurons. Choline acetyltransferase (CAT) activity and acetylcholine synthesis have also been detected in these cultures, suggesting the presence of cholinergic cells. However, until recently there have been no histochemical markers for cholinergic cells. Hence, nothing is known about the distribution and morphology of cholinergic cells in neural crest cultures.

We have examined the differentiation of cholinergic cells in cultures of quail cranial and trunk neural crest using two different antibodies to CAT: a polyclonal antibody raised against CAT purified from chicken brain by Johnson and Epstein (J. Neurochem. 46, 968), and the monoclonal antibody 4D7, which was raised against CAT purified from rat brain by Crawford et al. (Proc. Natl. Acad. Sci. 79, 7031). Similar staining patterns were observed with both antibodies, consistent with the conclusion that the immunoreactive material present in cultured neural crest cells is genuine CAT.

The time course of appearance of CAT-immunoreactivity was similar to that previously reported for CAT catalytic activity in neural crest cells cultured under conditions identical to those used in the present study (Howard and Bronner-Fraser, Dev. Biol. 117, 45). Low levels of CAT-immunoreactivity were observed in some neural crest cells by 5 days in vitro. Seven day old cultures of both cranial and trunk neural crest contained numerous CAT-immunoreactive cells. These cells tended to occur in large clusters. Most of the CAT-immunoreactive cells seen in 7 day cultures appeared morphologically undifferentiated: they were ovoid or polygonal in shape and lacked processes. However, some of the cells had neuronal morphology: they had round cell bodies, formed ganglion-like aggregates, and extended long processes which contacted other aggregates of CAT-immunoreactive cells. The number of CAT-immunoreactive cells decreased substantially by 14 days, but extensive plexuses of CAT-immunoreactive fibers were seen at this time. Experiments are now in progress to determine whether the CAT-immunoreactive cells exhibit neuronal markers such as neurofilament immunoreactivity. We are also interested in examining what other neurotransmitters may be coexpressed with acetylcholine in cultured neural crest cells.

55.2 A MONOCLONAL ANTIBODY AGAINST A LAMININ-HEPARAN SULFATE PROTEOGLYCAN COMPLEX PERTURBS CRANIAL NEURAL CREST MIGRATION IN VIVO. Marianne Bronner-Fraser and Thomas Lallier, Developmental Biology Center, University of California, Irvine, Ca. 92717.

INO is a monoclonal antibody that blocks neurite outgrowth, probably by functionally blocking a laminin-heparan sulfate proteoglycan complex (Chiu, A.Y., Matthew, W.D. and Patterson, P.H., J. Cell Biol. 103: 1383, 1986). In the present study, we examined the effect of this antibody on avian neural crest migration by microinjecting INO into the pathways of cranial neural crest migration. After injection lateral to the mesencephalic neural tube, the injected antibody had a primarily unilateral distribution. INO was observed in the basal laminae surrounding the neural tube, ectoderm, and endoderm, as well as within the cranial mesenchyme on the injected side of the embryo. The INO distribution pattern was indistinguishable from staining patterns observed after injection of antibodies against laminin or heparan sulfate proteoglycan. The injected antibody remained detectible for eighteen hours after injection, with the intensity of immunoreactivity decreasing with time.

Embryos ranging from the neural fold stage to the 9-somite stage were injected with INO and subsequently allowed to survive for up to twenty-four hours after injection. Of the 64 embryos injected, 74% demonstrated severe abnormalities in cranial neural crest migration. The predominant defects were: 1. ectopic neural crest cells external to the neural tube (observed in 39% of the injected embryos); 2. neural crest cells within the lumen of the neural tube (observed in 20% of the injected embryos); and 3. neural tube deformities (observed in 36% of the injected embryos). In contrast, embryos injected with antibodies against laminin or heparan sulfate proteoglycan were unaffected. No effects were noted when embryos with greater than ten somites were injected with INO, suggesting that embryos are sensitive for only a limited time during their development. These results indicate that functional blockage of a laminin-heparan sulfate proteoglycan perturbs cranial neural crest migration. This is the first evidence that laminin is involved in aspects of neural crest migration in vivo.

Supported by RO1 HD15527-07 and a Basic Research Grant from the March of Dimes. M.B.-F. is a Sloan Fellow.

55.3 CHANGES IN THE HOMING BEHAVIOR OF NEURAL CREST CELLS OF AVIAN EMBRYOS AS THE RESULT OF TREATMENT WITH A PHORBOL ESTER DRUG. Gary Ciment, Rosalie Sears* and Lisa Hess* (SPON: M. Forte). Dept. of Cell Biology & Anatomy, Oregon Health Sciences University, Portland, OR 97201

The neural crest is a transient structure seen during early vertebrate embryogenesis. Neural crest cells originate within the neural tube, but leave the tube and migrate along characteristic pathways in the embryo, eventually giving rise to a wide variety of different cell types in the adult, including neurons and glial cells of the peripheral nervous system, as well as pigment cells of the integument.

In earlier studies, we found that neural crest-derived cells of early quail embryos change some of their developmental properties in response to the phorbol ester drug 12-O-tetradecanoylphorbol-13-acetate (TPA) [Ciment et al., Develop.Biol.118:392, 1987]. That is, organ cultures of either sympathetic ganglia, sensory ganglia, or peripheral nerves were found to contain pigmented cells when the medium contained 1.0 uM TPA, but never in the absence of this drug. These pigmented cells were judged to be true melanocytes by their ability to invade the integument and produce normal-appearing pigmented feather primordia in vivo. We interpret these and other results to mean that TPA reverses the developmental restriction of melanogenesis that normally occurs in neural crest-derived cells that migrate to sites in avian embryos where melanogenesis does not occur.

In order to determine whether TPA affected other properties of neural crest cells, we performed a series of heterospecific grafting experiments. In this studies, either dorsal root ganglia or peripheral nerves were dissected from 5-10 day quail embryos, cultured in the presence or absence of 1.0 uM TPA, and then grafted in ovo into the neural crest migratory space of 2.0 day embryonic chicken hosts. These chimeric hosts were allowed to develop for an additional 5 days, and then were fixed, embedded in parafin, sectioned, and stained according to the Feulgen-Rosenbeck procedure in order to differentiate between graft (i.e., quail) and host (i.e., chicken) cells.

We report here that TPA has dramatic effects on the homing behavior of quail neural crest-derived cells. Whereas cells cultured in the ABSENCE of TPA localized to sites characteristic of non-cultured crest cells, cells cultured in the PRESENCE of TPA localized to specific sites in which neural crest cells are normally never seen. These ectopic sites, for example, include regions of the central nervous system. These changes in the homing behavior are NOT simply the result of cell crowding or overflow, etc., since TPA-treated crest cells were not seen at sites to which untreated or non-cultured neural crest-derived cells normally homed.

55.4 RECONSTITUTED BASEMENT MEMBRANE COMPONENTS STIMULATE ADRENERGIC DIFFERENTIATION IN NEURAL CREST CULTURES. G.D. Maxwell and M.E. Forbes*. Dept. of Anatomy, Univ. of Connecticut Health Center, Farmington, CT 06032.

Considerable evidence indicates that neural crest cell development is affected by environmental cues during embryogenesis. In the course of their development some neural crest cells encounter basement membranes which line several epithelial structures in the embryo. We have examined the effect of a reconstituted basement membrane (RBM) preparation derived from the EHS tumor on the differentiation of quail trunk neural crest cells in tissue culture.

Secondary cultures were prepared from primary neural crest outgrowths after 2 days in vitro and grown in the presence or absence of an overlay of RBM gel. After one week the cultures were analyzed for the number of catecholamine-positive (CA+) cells that were present. Cultures grown in the presence of the RBM gel showed a 25-50 fold greater number of CA+ cells than sister control cultures without RBM gel. The morphology of the CA+ cells was similar in both conditions. Total cell number was not dramatically altered by the presence of the RBM gel, indicating that the effect was selective for the CA+ phenotype and not the result of the production of increased numbers of all cell types. Melanocytes were present with and without the RBM gel, although the amount of pigmentation in the cultures was somewhat reduced in the presence of the RBM gel.

The effect of the RBM gel was specific as shown by experiments in which type I collagen gels, type I collagen gels plus laminin, and laminin alone failed to mimic the effect of the RBM gel. Also, the timecourse of CA+ cell development was similar in the presence and the absence of the RBM gel, indicating that the effect was not one of simply increasing the rate at which CA+ cells develop.

When secondary cultures were prepared using a range of initial plating densities, all in the presence of RBM gel overlays, it was found that the development of CA+ cells was dependent on initial plating density. At initial densities below 20 cells/mm^2 no CA+ cells were observed (although melanocytes and unpigmented cells developed) while at initial densities of 80-320 cells/mm^2 the number of CA+ cells which developed was proportional to the initial plating density.

These results indicate that the presence of reconstituted basement membrane components results in a dramatic and selective stimulation of the differentiation of the CA+ phenotype by neural crest cells in tissue culture. This work was supported by NIH grants NS 16115 and RCDA NS 00696 to GDM.

55.5 A ROLE FOR THE EXTRACELLULAR MATRIX IN CNS NEUROGENESIS IN VITRO. T.A. Reh and K. Radke*. Dept. Med. Physiol., Univ. Calgary, Alta. Calgary, Alta. T2N 1N4.

Virtually nothing is known concerning regulation of proliferation of the germinal neuroepithelial cells (GNCs) that give rise to the vertebrate CNS. Among the reasons for the current lack of information about GNCs is that the cells do not remain mitotically active in vitro for any length of time. It is not clear why GNCs do not continue to proliferate in vitro. These cells may be programmed for terminal differentiation after a certain number of cell divisions since in the chick and rodent embryonic CNS, neuroepithelial proliferation only occurs in vivo for short periods. Alternatively, dissociation may promote terminal differentiation, by disrupting cellular associations or contacts with the extracellular matrix normally present in GNCs. In frogs, development of the CNS proceeds much more slowly than in homeothermic vertebrates. Frog retina retains a specialized zone of GNCs at the margin throughout the animal's life; therefore, this system might enable us to determine why GNCs don't normally prolierate in vitro and provide a source for a GNC line.

Midlarval staged Rana pipiens tadpoles were anaesthetized, the eyes removed, and the retinas, with RPE still attached, were embedded in low melting point agarose, quickly chilled at 4°C and sectioned at 100 to 200 µm. Retinal slices were cultured in media consisting of L-15, 1-10% fetal bovine serum, glucose, and antibiotics. To identify dividing cells in the cultures, [H^3]-thymidine was added to the media at concentrations of 1 µCi/ml. We found that GNCs in the proliferative zone of these retina slice cultures continued to incorporate [H^3]-thy and undergo mitosis in vitro for up to three weeks at the levels observed in vivo. Throughout this period the germinal cells retain their pseudostratified columnar epithelial morphology. Using neuron-specific and glial-specific monoclonal antibodies, we were able to determine that most of the new cells generated by the GNCs in culture were neurons.

Since these slice cultures preserve the normal cellular and matrix associations present in vivo, we were able to determine if proliferation of GNCs requires contact with the external basement membrane that surrounds the developing CNS by removing this matrix with collagenase. In the cultures labelled with H^3-thy one day after the removal of the external basement membrane, germinal cells still incorporate the label at near normal rates; however, by three days, the collagenase treated cultures have a significantly reduced level of H^3-thy uptake. In addition, this zone is beginning to differentiate to give a laminated pattern of cell distribution. By five days after removal of the basement membrane, virtually all GNC proliferation has stopped; no signs of degeneration were observed in this region following the enzyme treatment, but rather the germinal cells have apparently terminally differentiated. This suggests that the contacts of the germinal cells with their normal basement membrane may be important in keeping them in a proliferative state.

55.6 IMMORTAL NEUROPEITHELIAL PRECURSOR CELL LINES. K. Frederiksen, P-J. Jat, N. Valtz, D. Levy, R. McKay. Depts. Brain and Cognitive Science, Biology, MIT, Cambridge, MA 02139.

It is now clear that the functional ability of the adult brain is achieved by mechanisms which require many molecularly distinct neuronal types. As a consequence the methods of molecular biology are increasing applied to the outstanding problems in neuroscience. In vertebrates traditional genetic methods are tedious but as recent advances in cancer biology proove the tools of recombinant DNA based genetic manipulation can be applied powerfully to vertebrate cells in tissue culture. The precursor cells of the embryonic brain become specialized before neurons differentiate setting in motion a cascade of events which generate specific numbers and types of neurons. If precursor cell lines were available it would be possible to apply recombinant genetic methods to study the molecular basis of neuronal specificity.

We have used retroviruses carrying oncogenes to establish immortal cell lines with the properties of neuroepithelial precursor cells. Using hybridoma technology we have generated an antibody, Rat 401, which recognizes neuroepithelial precursor cells in vivo (Frederiksen and McKay, J. Neurosci. in press, 1987). The large SV 40 T antigen, v-myc and neu oncogenes establish stable cell lines expressing the Rat 401 antigen. These cell lines are clonal by Southern blot analysis of the integrated oncogene. The SV40 T antigen used was a temperature sensitive variant which can be inactivated by growing the cells at 39°C. When these cell lines are induced to differentiate by growth at the elevated temperature or by providing other differentiating signals some of these cell lines loose the precursor marker and express either neuronal or glial properies. The same clonal cell line can give rise to differentiated products which express antigens characteristic of neurons, astrocytes or oligodendrocytes. This data suggests that Rat 401 marks a multipotential precursor cell type in the developing cerebellum.

Our results suggest that functionally competent precursor cell lines can be obtained with conditional oncogenes. The differentiation potential of these cell lines can be rigorously assessed by transplantation into the developing rat brain. Our preliminary data shows that we can detect the transplanted cells upto six months after injection. There is no indication of tumors and the injected cells are found in large numbers in the gray matter. These data raise the exciting prospect of using genetically manipulated cell lines to identify the molecular bases of neuronal specificity both in tissue culture and in vivo.

55.7 CELL LINEAGE IN MOUSE CEREBRAL CORTEX STUDIED WITH A RETROVIRAL MARKER. M.B. Luskin, A.L. Pearlman, and J.R. Sanes. Departments of Anatomy & Neurobiology, Cell Biology, and Neurology, Washington University School of Medicine, St. Louis, MO 63110.

We recently began using a recombinant retrovirus to study postimplantation cell lineage in mouse embryos. The virus, LZ1, integrates into a chromosome but is defective in replication; it is therefore confined to the progeny of the initially infected cell. LZ1 contains the E. coli β-galactosidase (lacZ) gene, expression of which is detectable histochemically or immunohistochemically. By analyzing the clonal progeny of single infected cells, lineage relationships in yolk sac and skin were determined (Sanes et al., EMBO J. 5: 3133, 1986). Here, we report extension of this approach to the cerebral cortex.

To ask which cortical cell types can be infected by LZ1, we used primary cultures. Cells were dissociated from cerebral hemispheres of E12-13 mice (during the peak of neurogenesis) and virus was added ~6h after cells were plated; 3-8d later, cultures were doubly stained with antibodies to lacZ and to one of a group of cell type-specific proteins: neurofilaments (NF), neural cell adhesion molecule (NCAM), the cell adhesion molecule L1, glial fibrillary acidic protein (GFAP), or fibronectin (FN). Four types of homogeneous clones, each with 2-20 lacZ-positive cells, were identified: neurons (small, round, process-bearing, $NCAM^+$, $L1^+$, NF^+, $GFAP^-$, FN^-), flat astrocytes (medium sized, process-poor, NCAM-poor, $L1^-$, NF^-, $GFAP^+$, FN^-), star-shaped astrocytes (small, process-bearing, NCAM-poor, $L1^-$, NF^-, $GFAP^+$, FN^-), and fibroblasts (large, flat lamellipodia-bearing, $NCAM^-$, $L1^-$, NF^-, $GFAP^-$, FN^+). In addition, some clones were heterogeneous; these are being characterized to seek evidence for bipotential precursor cells. We conclude: 1) that an exogenous gene introduced by a retrovirus can be expressed in several brain cell types, and 2) that E12-13 cortex contains separate populations of neuroblasts and glioblasts.

In parallel experiments, we injected viral concentrate directly into the telencephalon of E12 or 13 embryos in utero, then fixed and stained intact brains for lacZ pre- or postnatally. Pieces of cerebral cortex (as well as of olfactory bulb, diencephalon, striatum, and cerebellum) containing clones of lacZ-positive cells were subsequently embedded and serially sectioned. Clones in cortex contained 2-10 cells, often arranged in interrupted columns that spanned several laminae, and comprising cells of several distinctive sizes and morphologies. We are analyzing these clones with cell type-specific markers, and comparing results obtained in vivo and in vitro, to document lineage relationships in the cerebral cortex. (Supported by NIH.)

55.8 PATTERNS OF NEUROGENESIS IN CHICK OPTIC TECTUM STUDIED WITH A RETROVIRAL MARKER. J.C. Glover, G.E. Gray* and J.R. Sanes (Spon: M.B. Luskin). Department of Anatomy and Neurobiology, Washington University School of Medicine, St. Louis, MO 63110

We are using a recombinant retrovirus as a lineage marker to analyze the fates of clonally-related cells in the chick optic tectum. The virus inserts a β-galactosidase (lacZ) gene into the genome of an infected cell; that cell's lacZ-positive progeny are detected histochemically in whole mounts and characterized in sections (Sanes et al., EMBO J 5: 3133, 1986, and preceding abstract). For use in chickens, the host range of the virus was extended by passage through an amphitrophic helper cell line (Miller and Buttimore, Mol. Cell Biol. 6: 2895, 1986). The optic tectum was chosen because of its prominent laminar and columnar organization, well-characterized inputs and outputs, and accessibility in ovo. By infecting cells and analyzing clones at appropriate times, we hope to learn the spatial and phenotypic fates of lineally related cells.

As a first step, we injected viral concentrate into the tectal ventricle during the period of active cell proliferation (Stages 10-24 or E2-4), and then analyzed clones when proliferation is nearly over but before laminae form (Stages 30-34 or E7-8; LaVail and Cowan, Brain Res. 28: 421, 1971). The 60 clones examined so far are comprised of isolated clusters of 2-100 morphologically similar, closely spaced, lacZ-positive cells. The number and arrangement of cells within clones varies systematically with the time at which LZ1 was injected: Clones resulting from injections at Stages 10-13 contain multiple closely-spaced vertical arrays of cells extending the full thickness of the tectum. Clones resulting from injections at Stages 15-20 generally consist of 1 or 2 vertical arrays of cells extending the full thickness of the tectum. Clones resulting from injections at Stages 22-25 consist of vertical arrays that do not extend the full thickness of the tectum. Thus, clones marked progressively later are spatial subsets of clones resulting from earlier injections.

From these results, we draw 2 conclusions: 1) During the period of neural proliferation, clonally related cells mingle little. 2) An orderly temporal progression exists, such that early-born progeny are displaced laterally (giving rise to multiple vertical arrays) while later-born progeny are displaced vertically (giving rise to single or partial vertical arrays). We are now analyzing older embryos, to learn the extent to which migration and differentiation lead cells in a near-coherent clone to diversify during later stages of tectal ontogenesis. (Supported by NIH.)

55.9 THE CELLULAR SOURCE OF PERINEURIUM DETERMINED WITH A RETROVIRAL MARKER. M.B. Bunge, J.R. Sanes, P.M. Wood*, L.B. Tynan*, and M.L. Bates*. Department of Anatomy and Neurobiology, Washington University School of Medicine, St. Louis, Missouri 63110.

In peripheral nerves, fascicles of axons and Schwann cells are ensheathed by a layer of cells and extracellular matrix called the perineurium. The cellular source of perineurium in vivo remains in question, although fibroblasts (Fbs) are leading candidates (Scaravilli, J. Anat. 139: 411, 1984). In culture, perineurium forms when pure populations of Fbs and Schwann cells (SCs) are added to cultured nerve cells (NCs) (Williams, Bunge and Wood, J. Cell Biol. 95: 2a, 1982). Since perineurial cells exhibit characteristics of both SCs and Fbs, but are distinct from either, perineurial cells could arise from either Fbs or SCs. To distinguish these alternatives, we have used a technique in which a heritable marker (the lacZ gene) is introduced into the genome by means of a defective recombinant retroviral vector; the product of this gene, β-galactosidase, is then detected histochemically (Sanes et al., EMBO J. 5: 3133, 1986; and see preceding abstracts by Luskin et al. and Glover et al.).

Our strategy was to prepare NC + SC + Fb cultures containing either virus-infected Fbs or virus-infected SCs, and then to ask which combination would give rise to lacZ-positive perineurium. Because the retrovirus infects only dividing cells, SCs were exposed to virus as they proliferated following addition to NCs; proliferating Fbs were infected in isolation and then added to NC + SC cultures. Following 6 weeks in differentiation-supporting medium, cultures were fixed, reacted for lacZ, and processed for electron microscopy (EM). Fascicles with labeled cells were located by light microscopy, then sectioned for EM. In NC + infected SC + Fb cultures, marked SCs were found along axons and throughout fascicles. EM showed that the lacZ histochemical reaction product is electron dense and readily detectable in SC cytoplasm around axons; however, reaction product was absent from perineurium. In NC + SC + infected Fb cultures, some marked Fbs appeared at fascicle perimeters; EM demonstrated the presence of reaction product in typical perineurial cells. We conclude that perineurial cells differentiate from fibroblasts in culture and, by implication, in vivo as well. (Supported by NIH Javits Award NS 09923.)

55.10 **RE-EXPRESSION OF TYROSINE HYDROXYLASE DURING SENESCENCE AND ONCOGENIC TRANSFORMATION OF MURINE PANCREATIC BETA CELLS.** G. Teitelman, S. Alpert* and D. Hanahan*, Division of Neurobiology, Cornell Univ. Med. Coll., New York, NY and Cold Spring Harbor Lab, Cold Spring Harbor, NY.

The catecholamine enzyme tyrosine hydroxylase (TH) is transiently expressed by pancreatic insulin (β) cells during development and reappears in some β cells of postnatal and adult mice. In this study we used immunocytochemical and autoradiographic techniques to characterize the adult TH-insulin cells during islet growth in pregnant mice, mutant obese (ob/ob) mice, and transgenic mice that develop beta cell tumors. The latter group contains a hybrid gene comprised of the 5' flanking region of the rat insulin II gene linked to the protein coding information for the Simian virus 40 large T antigen (Tag). The number of TH-insulin cells increased during normal pregnancy (from 1.5±0.2 per islet at gestation day 10 (G-10) to 3.3±0.3 per islet at G-18; $n \geq 20$) and as hyperplasia developed in ob/ob mice (from 1.2±0.2 per islet at 3 months to 3.9±0.5 per islet at 7 months; $n \geq 20$; controls 3 mo: 0.7±0.1 and 7 mo: 0.1±0.02). However, the TH-insulin cells of postnatal mice did not incorporate radiolabeled thymidine (^{3}H-tdR) into their nuclei indicating that they did not divide. In contrast, the insulin "only" cells proliferated and, thus, were responsible for the increase in beta cell numbers. This indicates that (a) islet growth was produced by proliferation of insulin only cells; (b) insulin cells underwent a limited number of cell divisions, then withdrew from the cell cycle, and re-expressed an embryonic marker (TH). To determine the fate of postnatal TH-insulin cells, ^{3}H-thymidine was injected into pregnant mice at G-17 and the pancreas of the progeny examined 7 days after birth. At this time, the nuclei of some TH cells were heavily labeled with the isotope. However, at 14 days these heavily labeled cells had vanished. Since postnatal TH-insulin cells do not divide, the disappearance of these cells cannot be due to dilution of the label. Thus, it seems likely that insulin cells that re-express TH are senescent cells destined to die.

In transgenic mice, the TH-insulin cells proliferated and their number increased dramatically during the pre-neoplastic period (from 9.3±1.2 per islet at 4 weeks postnatal to 50.7±5.2 per islet at 9 weeks, $n \geq 20$). In the neoplastic period, the TH-insulin cells did not die but increased their rate of proliferation. Thus, in the presence of an oncogene, the TH-insulin cells are apparently unable to complete terminal differentiation to a postmitotic state and instead escape from the senescence pathway to produce immortal tumor cells.

We conclude that TH is expressed in three different conditions of pancreatic beta cells: during maturation in embryos, in a terminal differentiation pathway to cellular senescence and elimination and during malignant transformation. The mechanism that mediates the number of times the beta cell divides before re-expressing TH and then determines their fate remains to be elucidated.

56.1 NGF SYNTHESIS IN VIVO AND IN VITRO. R.H. Edwards[1], M.J. Selby[1]*, S. Weinrich[2]*, D. Hruby[2]* and W.J. Rutter[1]*. [1]Hormone Research Institute, University of California, San Francisco, CA 94143 and [2]Dept of Microbiology, Oregon State University, Corvallis, Oregon 97331

We have used a recombinant vaccinia virus system to express NGF in a variety of cell lines. Two recombinant viruses were constructed, corresponding to the two major NGF transcripts: one (A) predicts a 34 kd precursor with mature NGF at the C-terminus and the sole hydrophobic domain internal; the other (B) predicts a 27 kd precursor lacking the N-terminal 7 kd of A, and consequently having the hydrophobic region at the N-terminus. Infection of a permissive cell line (BSC-40) with the recombinants showed substantial accumulation of NGF mRNA. Infection of this and other cell lines, including L929, G8, PC12, HIT, AtT20, MDCK and primary Schwann and fibroblast cultures, shows that all secrete mature NGF into the medium as indicated by immunoprecipitation of metabolically labeled protein. Furthermore, the medium induces sprouting from PC12 cells.

Using the recombinant viruses, we have studied the processing of NGF in infected cells. Both recombinants produce an NGF precursor of ~35 kd, in all the cell lines tested. Pulse-chase experiments show processing of the prohormone within the cell to mature NGF, followed by secretion ($T_{\frac{1}{2}}$ ~2 hr); and both recombinants show roughly the same kinetics. A 22 kd intermediate can occasionally but inconsistently be detected for A and B. The precursors appear to have substantial glycosylation, with N-glycanase digestion reducing both in size to ~30 kd on Laemmli gels. Tunicamycin at doses not affecting protein synthesis reduces the amount of NGF secreted and the precursor becomes undetectable within cells. Immunofluorescence shows NGF localized to the region of the Golgi apparatus.

We have used precursor from infected cells as a substrate for putative NGF-processing enzymes. γ-NGF is found as part of a complex with mature β-NGF in the mouse salivary gland, and has proteolytic activity on artificial substrates. NGF precursor synthesized in vitro using SP6-generated NGF RNA and a cell free translation system has previously been shown to be improperly cleaved by γ-NGF, resulting in the destruction of the mature hormone. A coupled translation-translocation system also failed to yield an adequate substrate. Precursor obtained from infected cells can, however, be cleaved to mature β-NGF by γ-NGF. Presumably, the precursor generated inside the cell but not in vitro has the conformation required for correct processing. Sequencing of precursor metabolically labeled with ^{3}H-valine from infected cells is consistent with prior cleavage of the signal peptide.

56.2 **REGULATION OF NGF GENE EXPRESSION IN A MOUSE CELL LINE.** **R. Houlgatte, D.Wion, N.Barbot, E.Dicou and P.Brachet. INSERM U.298, CHR, 49033 ANGERS Cx, FRANCE.**

Mouse L-929 cells are known to synthetize and secrete nerve growth factor (NGF), and these cells provide a simple model system suitable for the search and characterization of extracellular effector molecules able to influence the level of expression of the NGF gene.

L-cell proliferation can be obtained in serum-containing medium as well as in serum-free medium. Hybridization experiments performed with a cDNA probe have previously shown that serum itself contains some factor(s) which increase specifically the cellular levels of NGF mRNA (1). Correspondingly, serum induces an enhancement of the amounts of NGF secreted by the cells, as was evidenced by a double site ELISA assay (2). Recent experimental data indicated that the positive effect of serum was dose-dependant. It was elicited by sera from various vertebrate species, such as foetal calf, horse, rat or human. Although the modulatory activity was distroyed after a heat treatment of 5 min at 100°C at neutral pH, about 80% of the activity was recovered when heating was performed on serum samples previously adjusted to pH4. This heat and acid-resistant effector displayed an apparent MW of 100-130 k Da, as observed by gel filtration chromatography.

L cells were also cultured in a serum-free medium supplemented with human α,β or γ globulins, or serum albumin. α globulins exerted a marked effect on the biosynthesis of NGF. The compound responsible for this stimulation appeared heat-stable at pH4 and heat-sensitive at neutrality. β globulins exerted some stimulation too but the effector was heat-sensitive at either pH value. γ globulins and albumin were depleted of effect.

Serum appears to act in a very different way than another positive effector studied in this laboratory, retinoic acid. This analogue of vitamin A also enhances the cellular levels of NGF mRNA and NGF protein in L-cells cultured in serum-free medium. Relative levels NGF mRNA are increased by a factor of 3 in cells exposed to micromolar amounts of retinoic acid. However, the time course of this increase is long, since maximal stimulation is obtained after 3 days of treatment, while the effect elicited by serum is already detected 4h after its addition to the medium, and reaches maximal values after 24h or less. Both effectors, therefore, seem to differ in their mode of action.

56.3 SYNTHESIS AND RELEASE OF NERVE GROWTH FACTOR BY RAT MACROPHAGES U. Otten, G. Weskamp*, M. Hardung* and D. K. Meyer*
Dept. of Pharmacology, Biocenter of the University, Basel, Switzerland and Dept. of Pharmacology, University of Freiburg, Freiburg, FRG

Nerve growth factor (NGF) is a polypeptide known to regulate the development and function of peripheral sympathetic and sensory nerve cells and of cholinergic neurons of the basal forebrain. Recent studies indicate that NGF in addition to its neurotrophic effects may also be involved in the physiological modulation of inflammatory responses. The present study aimed to further investigate the latter NGF effects. We used a sensitive enzyme-linked immunosorbent assay for determination of NGF protein and an optimized Northern blot technique for quantification of NGF mRNA to characterize the regulatory mechanisms involved in NGF production and to identify the cell types synthesizing NGF.

1.) Nanomolar concentrations of immunoreactive NGF (irNGF) were found in inflamed tissues and in inflammatory pleural and peritoneal exudates induced by carrageenin or sterile paraffin-oil in adult rats.

2.) IrNGF released in inflammatory exudates is biologically active as monitored by the neurite outgrowth response in PC 12 cells and sensory neurons.

3.) The increase in irNGF-content in the peritoneal exudate after paraffin-oil injection reached peak values (16fold as compared to controls) after 4 days correlating with the accumulation of mononuclear cells.

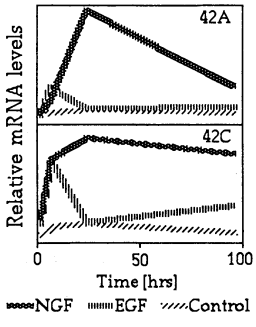
4.) Approximately 90 % of irNGF was found in the macrophages after separating them from the remaining inflammatory cells by their ability to bind to plastic surfaces.

5.) NGF mRNA content in peritoneal macrophages revealed a 4 - 5 fold increase over basal values as early as 24 h after onset of inflammation and decreased to basal levels within 7 days.

Thus, upon inflammatory stimuli peripheral macrophages enhance the synthesis and release of NGF. These results suggest that NGF may play an important role in various functions of macrophages including those in inflammatory and neuronal regeneration.

56.4 NERVE GROWTH FACTOR INDUCES IN PC12 CELLS TWO GENES CODING FOR S100-RELATED PROTEINS. P. Masiakowski* and E. M. Shooter. Dept. of Neurobiology, Stanford Univ. Sch. of Med., Stanford, CA 94305

The molecular mechanisms involved in NGF-induced neuronal differentiation can be conveniently studied in rat pheochromocytoma-derived PC12 cells. To identify genes which may be involved in this process, we have screened PC12 cDNA library with cDNA probes from PC12 cells grown for 7 days in presence or absence of NGF. Two of the clones, 42A and 42C, hybridize on Northern blots to short (700-800 nucleotides) RNA bands whose intensities increase within few hours of NGF addition and remain high for several days. EGF causes only brief increase in the levels of 42A and 42C mRNAs (see figure).



DNA sequence analysis allowed us to deduce the amino acid sequences of the putative proteins coded for by these mRNAs. Computer search of NBRF Protein Database revealed a strong homology of both peptides to the subunits of S100, a calcium-binding, nervous tissue specific protein. In addition, our peptides are highly homologous to porcine p11 (regulatory subunit associated with p36, a major target of tyrosine protein kinases) and human 2A9 (peptide deduced from a message inducible by factors stimulating fibroblast proliferation). All these proteins constitute a closely related family, as they are all about 100 amino acid long, with identical residues in 16 positions and conservative substitutions in 17 positions. Furthermore, in the predicted secondary structure, they all share a characteristic strongly hydrophilic region with turns in the part of sequence homologous to the calcium-binding site of well characterized calcium-binding proteins. This region is immediately followed by a strongly hydrophobic, possibly membrane-interacting, domain. To test the hypothesis that these conserved features reflect an important cellular role played by proteins corresponding to our clones, we are now transfecting PC12 cells with the copies of 42A and 42C recloned from a library constructed in an eukaryotic expression vector.

56.5 HIGH LEVELS OF NERVE GROWTH FACTOR mRNA IN THE CHICKEN EMBRYO COINCIDE WITH MAXIMAL RESPONSIVENESS TO RECOMBINANT NGF PROTEIN.

F. Hallböök[1]*, T. Ebendal[2]* and H. Persson[1]*.
(SPON: W. J. Friedman). Depts. of Medical Genetics[1] and Zoology[2], Uppsala University, S-752 23 Uppsala, Sweden.

Nerve growth factor (NGF) is a well characterized trophic protein necessary for the maintenance of sensory and sympathetic neurons in the peripheral nervous system, as well as a subset of cholinergic neurons in the central nervous system. We have used the eucaryotic expression vector p91023(B) to produce both a rat and a chicken recombinant NGF. The constructs were transfected into a monkey cell line (COS-cells) and NGF expression was analyzed by: Northern-blot analysis; immuno-precipitation with affinity purified anti-mouse NGF antibodies; and the ability of COS-conditioned medium to stimulate neurite outgrowth in a bio-assay using cultured sympathetic ganglia from 9 day old chick embryos. The transfected COS-cells produced NGF transcripts of predicted size and secreted a protein with the mol wt of 14k which was precipitated with anti-NGF antibodies. Transfection with both the rat and the chicken NGF constructs stimulated neurite outgrowth in the NGF assay.

Using a DNA probe from the cloned chicken NGF gene (Ebendal et al., 1986, EMBO J. 5:1483-1487) NGF mRNA was detected in the chicken as early as embryonic day 3.5 . The level of NGF mRNA increased fourfold from day E3.5 to day E8, remained high until day E12 and decreased subsequently. The transient rise in expression of NGF mRNA paralleled the fiber outgrowth response in sympathetic and neural crest-derived sensory neurons to the recombinant chicken NGF. The high NGF mRNA levels of embryonic day 8 were mainly derived from NGF mRNA expression in the skin and eye, possibly serving a trophic function for sensory neurons.

56.6 CHANGES IN BETA-NERVE GROWTH FACTOR mRNA AND PROTEIN LEVELS IN HIPPOCAMPUS FOLLOWING LESIONS OF THE SEPTOHIPPOCAMPAL PATHWAY IN RATS.

M. Hardung*, H. P. Lorez*, P. Erhard*, D. K. Meyer* and U. Otten (SPON: W. J. Fischli)
Dept. of Pharmacology, University of Freiburg Med. Fac., D-7800 Freiburg, FRG, Pharmaceut. Res. Dept. Hoffmann-LaRoche & Co. Ltd., Basel and Dept. of Pharmacology, Biocenter of the University, CH-4056 Basel, Switzerland.

According to recent evidence nerve growth factor (NGF) acts as a neurotrophic agent for cholinergic neurons of the basal forebrain: it is synthesized in target fields of cholinergic neurons such as hippocampus and retrogradely transported to the respective perikarya in the septum.
We investigated whether NGF gene expression in adult rat hippocampus is regulated by innervating cholinergic axons, the major part of the septohippocampal pathway.
4 and 15 days after bilateral surgical transection of the septo-hippocampal pathway, immunoreactive NGF protein (irNGF) and NGF mRNA levels were determined.
As compared to controls, the lesion decreased choline acetyl-transferase activity to 8 % and 30 % respectively in dorsal and ventral hippocampus after 4 days. At this time, irNGF content was increased by 50 % in dorsal and by 30 % in ventral hippocampus as compared to sham operated animals. In contrast, NGF mRNA levels declined to 50 and 75 %.
15 days after lesioning significant changes in irNGF and NGF mRNA in both dorsal and ventral halves of the hippocampus were no longer observed.
In summary, we found a good correlation between the lesion-induced decrease in cholinergic innervation and changes in NGF mRNA and irNGF in adult rat hippocampus. Thus, we conclude that NGF gene expression in adult rat hippocampus is modulated by cholinergic innervation. Whether increase in NGF protein concentration is due to a regulation at the posttranscriptional level or to accumulation of NGF following lesion-induced blockade of retrograde transport is being currently investigated.

56.7 **Transplants of NGF-rich tissue facilitate survival and regeneration of axotomized cholinergic neurons in the medial septum and diagonal band.**

J.E. Springer, T.J. Collier, M.F.D. Notter, J.R. Sladek, Jr., and R. Loy
Department of Neurobiology and Anatomy, University of Rochester Medical Center, Rochester, New York, 14642.

Transections of the fimbria-fornix (F/FX) result in a loss or shrinkage of cholinergic neurons in the medial septum/and vertical limb of the diagonal band (MS/VDB), possibly due to the deprivation of a retrogradely transported, target-derived trophic factor(s) in the hippocampal formation. From recent evidence reported in this and other labs, it is suggested that one of these trophic factors may be nerve growth factor (NGF). To provide axotomized MS/VDB neurons with a constant source of NGF we have utilized a transplantation model using intraventricular grafts of male mouse submaxillary glands (a rich source of NGF). Animals received unilateral transections of the F/FX, followed by intraventricular grafts of male mouse submaxillary gland. At 1-6 weeks following transection, a time at which axotomized MS/VDB neurons would normally have degenerated, animals with grafted submaxillary gland tissue exhibit marked survival of MS/VDB neurons which stain positive for acetylcholinesterase (AChE) and are immunoreactive for the NGF receptor (antibody provided by E. Johnson). In addition, fibers which are positive for both markers appear to course from the medial septum into the lateral septum. In some instances, AChE- and NGF receptor-positive fibers were found to penetrate the graft adjacent to the lateral septum. To determine the presence of NGF-like trophic activity in the graft at 3-4 weeks following transplantation, the graft was removed from the host brain and placed in a culture of PC12 cells, which are known to be responsive to NGF. Within 36 hours following attachment of the graft onto the cell layer, PC12 cells were observed to differentiate and extend neurites towards the direction of the submaxillary gland. NGF treatment is also known to increase choline acetyltransferase (ChAT) activity in the basal forebrain of neonate rats and in adult rats that have sustained F/FX damage. The MS/VDB was dissected from the host brain and the effect of the submaxillary gland on ChAT activity in the MS/VDB was determined 3-4 weeks following surgery. As reported by others, we found a recovery of ChAT activity in the MS/VDB of those animals that received only F/FX transections. However, in those animals that also received submaxillary gland grafts, ChAT activity in the MS/VDB was increased 40% above the recovery levels observed in animals receiving transections alone. From these results it is suggested that submaxillary gland transplants are able to i) survive for extended periods of time (3-4 weeks) in a cross-species grafting procedure ii) influence the survival and regeneration of axotomized MS/VDB cholinergic neurons, and iii) increase the biochemical activity of these basal forebrain neurons which are thought to be sensitive to NGF.

56.8 NGF STIMULATES GROWTH OF CHOLINERGIC FIBERS INTO THE HIPPOCAMPUS OF RATS WITH PARTIAL FIMBRIAL TRANSECTIONS.

C.N. Montero* and F. Hefti. Dept. of Neurology, University of Miami, Miami FL 33101.

NGF acts as a neurotrophic factor for cholinergic neurons of the basal forebrain. We earlier reported that NGF prevents the lesion-induced degeneration of these neurons after transection of the septo-hippocampal pathway (Hefti, J. Neurosci. 6:2155,1986; Montero, Proc. Soc. Neurosci. 12:1099,1986). We also studied the requirements for the NGF treatment to be effective and found that one month of treatment does not result in permanent surival of the cholinergic neurons. In addition, delayed onset of NGF treatment failed to rescue these cells. The effect of NGF was specific for cholinergic neurons, inasmuch as GABAergic neurons, which represent the majority of non-cholinergic septo-hippocampal neurons, did not respond.

The fimbrial transection performed in our studies destroys part of the septo-hippocampal pathway, leaving the most medial fibers intact. We earlier reported that NGF treatment during 10 weeks did not stimulate the growth of cholinergic fibers into the partially lesioned hippocampus (Hefti et al., Brain Res. 293:305, 1984). We now tested whether NGF treatment for up to 22 weeks promotes cholinergic fiber growth under these conditions.

Female adult rats with a unilateral partial transection of the the septo-hippocampal pathway were implanted with a cannula ipsilateral to the lesion. The animals were injected intraventricularly twice a week with 2.5S NGF (2.5ug in 5ul) or an equal ammount of cytochrome c. They were treated for up to 22 weeks and were then taken for histochemical visualization of AChE-positive fibers in the hippocampus. (AChE is a reliable marker for cholinergic fibers in the hippocampus). Control animals showed a marked loss of AChE-positive fibers in the CA3 area of the hippocampus ipsilateral to the lesion. In NGF-treated animals the density of hippocampal AChE-positive fibers on lesioned sides was higher than that of control animals in the same area which were treated for equal intervals of time. Furthermore, the fiber density on the lesioned side increased with the duration of NGF treatment.

These results suggest that intraventricular injections of NGF stimulate fiber growth of septo-hippocampal cholinergic neurons into the partially denervated hippocampus.

56.9 ACQUIRED DEPENDENCE OF BASAL FOREBRAIN NEURONS ON NGF. J.N. Barrett, D. Nonner* J. Hartikka*and F. Hefti (SPON: D.C. Mash). Depts. of Physiology and Biophysics and of Neurology, Univ. of Miami School of Medicine, Miami, FL 33101.

Neurons from fetal rat basal forebrain and/or septal area were cultured in a medium which supports long-term neuronal survival without glial proliferation (Kaufman and Barrett, Science, 220: 1394, 1983). Addition of 100 biological units/ml of Nerve Growth Factor (NGF) to this medium enhanced the cholineacetyl-transferase (ChAT) activity of the cultures by 2 to 10 times after growth periods of 1 to 6 weeks. A substantial increase (2 to 5 times) in ChAT activity was observed even when the cultures were first maintained in the presence of anti-NGF for 2-4 weeks prior to exposure to NGF. However, if the neurons were grown in medium containing NGF for 4 weeks or more and after washing out the NGF, were then exposed to anti-NGF, then ChAT levels fell to less than 50% of the levels found in control cultures never exposed to NGF. Later treatment of these cultures with NGF (after removal of anti-NGF) did not enhance ChAT activity. Treatment of cultures which had previously been exposed to NGF for 4 weeks with anti-NGF greatly reduced the number of neurons stained with ChAT immunocytochemistry. Damaged ChAT-positive neurons were observed in these cultures after exposure to anti-NGF for 2 days. Withdrawal of NGF, without addition of anti-NGF, did not usually reduce the number of ChAT-positive neurons or their ability to respond to later NGF treatment.

It is unlikely that the damage to cholinergic neurons observed in cultures treated with anti-NGF was complement-mediated, since complement was inactivated or removed from the antibody preparation. The findings therefore suggest that basal forebrain and septal cholinergic neurons exposed to NGF in culture for 4 weeks or more become dependent upon the presence of NGF and degenerate when this factor is removed. The finding that cholinergic neurons degenerated only after the addition of anti-NGF, but not after simple removal of NGF, suggests that other cells in the cultures produced sufficient amounts of NGF to keep these neurons alive without inducing maximal levels of ChAT activity. It seems likely that NGF was produced by astrocytes (Assouline et al., Proc. Soc. Neurosci. 11:933, 1985). Supported by NIH grant NS 12207 and the National Parkinson Foundation.

56.10 EXPRESSION OF NERVE GROWTH FACTOR RECEPTORS BY BASAL FOREBRAIN CHOLINERGIC NEURONS. J. Hartikka, W. Strauss and F. Hefti. Depts. of Neurology and Pharmacology, University of Miami School of Medicine, Miami FL 33101.

Nerve growth factor (NGF) acts as a neurotrophic factor for the cholinergic neurons of the mammalian basal forebrain. The effects of NGF are mediated through specific receptors located on the cell membrane. We have studied the expression of NGF receptors (NGFR) using immunocytochemical and molecular biological techniques.

Primary cultures of dissociated cells were prepared from fetal (E 17) rat septum. Cells were plated at high density (300,000 cells per sq cm) on poly-lysine coated dishes and grown in a modified L-15 medium. We earlier showed that NGF increases the activity of choline acetyltransferase (ChAT) in these cultures without affecting the survival of cholinergic neurons. After ten days cultures were fixed and taken for immunocytochemical visualization of NGF receptors using monoclonal antibody 192-IgG. In untreated septal cultures, only weakly stained neurons were visible. In NGF treated cultures, however, a large number of strongly stained neurons were found.

To further characterize the NGFR positive cells, cultures taken for immunocytochemical visualization of NGFR were co-stained for acetylcholinesterase (AChE). AChE has been shown to co-localize with ChAT and, therefore, to be a reliable marker for cholinergic neurons in our cultures. Double staining for NGFR and AChE was assessed by comparing photographs from the same visual fields. All of the 146 NGFR positive cells were also positively stained for AChE. Thirty-eight of the 184 AChE-positive neurons (i.e. 21% of the total) were not labeled by the NGF receptor antibody.

Co-staining for NGF receptors and AChE indicates that NGF receptors are exclusively located in cholinergic neurons in cultures prepared from rat basal forebrain. The finding that NGF treatment increases the staining intensity of neurons by NGFR immunocytochemistry suggests that NGF either increases the synthesis or decreases the degradation of its own receptor. Currently, we are studying the expression of the NGF receptor gene by measuring the level of NGFR mRNA in septal cultures using a cDNA clone for the rat NGF receptor (Radeke et al., Nature 325:593, 1987).

56.11 LOCALIZATION OF NGF RECEPTORS ON SPECIFIC CELL TYPES IN RAT BASAL FOREBRAIN CULTURES. C.F. Dreyfus, H.J. Martínez,* S.J. Rubin,* P. Bernd and I.B. Black. Div. Devel. Neurol., Cornell Univ. Med. Coll., New York, N.Y. 10021 and Dept. Anat., Mt. Sinai Sch. of Med. of C.U.N.Y., New York, N.Y. 10029.

Previous work has indicated that nerve growth factor (NGF) specifically and selectively increases choline acetyltransferase (CAT) and acetylcholinesterase in cultures of rat basal forebrain-medial septal area (BF-MS). To determine whether these actions are potentially receptor-mediated, and to identify cells expressing receptors, dissociated BF-MS cultures were examined. Two independent methods, radioautography following ^{125}I-NGF binding and immunocytochemistry with a monoclonal NGF receptor antibody (192-IgG, generously provided by Dr. E. Johnson, Jr.) detected specific receptors. The NGF receptors were localized to two different cellular populations, flat, large (70 µm), non-neuronal-like cells, and small, round, process-bearing neuron-like cells.

To define and localize receptor subtypes present in the cultures, dissociation studies were performed. Taking advantage of the dissimilar K_ds exhibited by low- and high-affinity receptor subtypes, cultures were incubated with ^{125}I-NGF (5ng/ml) followed by non-labelled NGF (5 µg/ml, 4°C, 10 min). Only the neuron-like cells exhibited silver grains following this procedure, suggesting that high-affinity receptors were localized to the neuron-like population, while only low-affinity receptors were localized to the non-neuron-like cells.

The BF-MS area is composed of a heterogeneous population of neuron-like cells. To define the individual cell types that express receptor, we examined cultures for co-localization of receptor and transmitter traits. Initially, cholinergic cells were identified immunocytochemically using a specific monoclonal antibody to CAT (kindly provided by Crawford and Salvaterra). Simultaneous radioautography detected ^{125}I-NGF binding sites on the CAT-positive cells. However, only a subset of CAT-positive cells exhibited NGF binding sites in these cultures, suggesting that CAT positive cells may comprise several populations. We tentatively conclude that NGF may elicit cholinergic effects by directly binding to high-affinity receptors on neurons, quite possibly cholinergic. However, future studies will be required to further identify populations expressing NGF receptors. 56.12 NERVE GROWTH FACTOR STIMULATES PRION PROTEIN GENE EXPRESSION IN DEVELOPING BRAIN. W. C. Mobley, S. J. DeArmond*, S. B. Prusiner, M. V. Johnston and M. P. McKinley*. Depts. of Neurology and Pathology, University of California, San Francisco, CA 94143; Dept. of Neurology, University of Michigan, Ann Arbor, MI 48109.

Rodents manifesting clinical signs of scrapie, a neurodegenerative disorder, demonstrate deficits in forebrain cholinergic presynaptic markers (McDermott et al., *Lancet* II:318, 1978). Nerve growth factor (NGF) exerts prominent, dose-dependent effects on developing cholinergic neurons of the rodent forebrain and may serve as a trophic factor for these cells (Mobley et al., *Mol. Brain Res.* 1:53, 1986). Because trophic factors have been suggested to participate in the pathogenesis of some neurodegenerative disorders, we undertook a study of NGF in scrapie. Considerable evidence indicates that a protein encoded by a cellular gene, designated scrapie prion protein (PrP^{SC}), plays a central role in the pathogenesis of scrapie. *In situ* hybridization studies indicate that most CNS neurons contain PrP mRNA (Kretzschmar et al., *Am. J. Pathol.* 122:1, 1986). Recent studies show that PrP mRNA levels are regulated in a regionally specific fashion in neonatal hamster brain. Interestingly, we found that developmental increases in PrP mRNA levels in hamster brain septum were almost coincident with those in ChAT activity, raising the possibility of coordinate control of these markers in basal forebrain cholinergic neurons. Since ChAT activity in neonatal rat brain had been shown to be stimulated by NGF (Mobley et al., op. cit.), we examined the possibility that PrP gene transcription might also be regulated by NGF. Neonatal hamsters were injected intraventricularly with NGF (30 ug) or vehicle on postnatal days (PD) 3, 5 and 7 and septum was assayed on PD9. ChAT activity was increased by 160% (NGF = 52+3 nmol ACh/hr/mg protein; vehicle = 20+2). In three separate experiments the level of PrP mRNA was increased approximately 14-fold, rising 40% above adult values. NGF effects on ChAT activity and PrP mRNA were both apparent within 48 hr of injection. Septal PrP mRNA was increased 7.5-fold following a single NGF injection at PD7. A lesser (70%) but significant increase in PrP mRNA was also found in caudate-putamen. No effect of NGF was registered in the thalamus, brainstem or cortex. ChAT activity was increased by 100% in septum and 45% in caudate-putamen in the same experiments. Although the magnitude of ChAT activity and PrP mRNA increases induced by NGF are different, the regional specificity and kinetics of these changes in developing forebrain are similar and raise the possibility that both changes are occurring in cholinergic neurons. *In situ* hybridization studies in progress may help to define the locus of NGF actions. It will be interesting to determine if NGF levels change during scrapie infection and whether exogenously administered NGF alters the course of disease.

57.1 AN ELECTRON MICROSCOPIC ANALYSIS OF THE MORPHOLOGY AND CONNECTIVITY OF INDIVIDUAL RAT VIBRISSA PRIMARY AFFERENT CENTRAL TERMINAL ARBORS LABELLED WITH INTRA-AXONAL HRP. W.E. Renehan, R.D. McCall*, R.W. Rhoades and M.F. Jacquin. Dept. of Anatomy, Univ. of Louisville Sch. of Medicine, Louisville, KY 40292; Dept. of Neuroscience, NY Inst. of Tech., Old Westbury, NY 11568; Dept. of Anatomy, Univ. of Med. and Dent. of NJ, Piscataway, NJ 08854.

In a previous light microscopic investigation of the morphology of the brainstem projections of individual physiologically identified trigeminal primary afferent neurons, we found that vibrissa, guard hair, nociceptive, hairy skin and mucosal afferents could be distinguished from each other on the basis of their central terminal arbor morphology (Jacquin, et al., 1986, J. Neurophys. 55:1153-1186). It was not possible, however, to differentiate the various types (e.g. rapidly adapting, slowly adapting, nociceptive-biased) of vibrissa-associated afferents from each other using that technique. The present study extends this analysis to the electron microscopic level in an attempt to increase our understanding of information processing and vibrissa connectivity in the rat trigeminal brainstem nuclear complex.

Individual physiologically characterized vibrissa primary afferent neurons were impaled with beveled glass microelectrodes (Microstar, R= 70-120 MΩ), filled with 6% HRP in 0.05 M Tris and 0.3 M KCl (pH 8.3) and processed for electron microscopy according to the method of Semba et al. (JCN, 1983, 221:466-481). To date, we have examined serially sectioned terminals from a slowly adapting type IIb afferent which supplied the E1 vibrissa and a D7 slowly adapting type I neuron. In both cases, all the HRP labelled boutons contained predominantly round, clear vesicles approximately 20-60 nm in diameter. We have observed terminals synapsing with dendritic spines (characterized by smooth endoplasmic reticulum but no microtubules) and dendritic shafts (containing parallel arrays of microtubules and neurofibrils, mitochondria, ribosomes and occasionally rough ER). The two slowly adapting afferents examined thus far were rarely postsynaptic to unlabelled axons or dendrites, a feature consistent with slowly adapting axons in the spinal cord (Ralston, et al., 1984, J. Neurophys., 51:777-792). It is also interesting that virtually every spinal cord or trigeminal intra-axonally labelled primary afferent investigated thus far, including those examined in the present study, has contained only clear round vesicles (see Semba et al., 1983, JCN:466-481 for review). Whether or not these axons represent some subpopulation of primary afferents awaits further analysis and an increase in our sample size. (Supported in part by DE-07734, DE-06528, NRSA NS-07444 and DE-07662).

57.2 TRIGEMINAL PRIMARY AFFERENT PROJECTION TO CONTRALATERAL DORSAL HORN: CENTRAL EXTENT, PERIPHERAL ORIGIN, AND PLASTICITY. M. Barcia*, N.L. Chiaia, R.W. Rhoades & M.F. Jacquin (SPON: L.C. Massopust). Dept. of Neuroscience, N.Y. Coll. of Osteo. Med., Old Westbury, NY 11568 & Dept. of Anatomy, N.J. School of Osteo. Med., Piscataway, NJ 08854.

Prior studies have documented a trigeminal (V) mandibular primary afferent (PA) projection to contralateral caudal medullary and cervical dorsal horns in cat, hamster and rat. We now report the existence of a much more substantial V ophthalmic PA projection to the extreme ventrolateral portion of contralateral caudal medullary and cervical dorsal horns in rat. Unilateral HRP injections, into the V ganglion or spinal tract (TrV), anterogradely labeled a large number of PA's exiting the caudal ventrolateral TrV to form a rostrocaudally continuous, transversely oriented, V PA decussation. These fibers terminated in each of laminae I-V along the ventrolateral border of the dorsal horn in contralateral caudal medulla, C1, and C2, though terminal label was heaviest in laminae III-V. Unilateral HRP injections, into medullary and cervical dorsal horns, also retrogradely labeled V PA collaterals contralateral to the injection site. Decussating V PA parent fibers (mean diameter ± SD: 1.49±0.85um, range: 0.43-3.91um) gave off collaterals in corresponding regions of dorsal horn, and in ventromedial subnuclei interpolaris, oralis, and principalis, rostral to their decussation. Thus, a given axon terminated both ipsi- and contralateral to its cell of origin. V ganglion cells were also labeled in dorsomedial (ophthalmic) portions of the contralateral V ganglion. 40.4±13.0 HRP-labeled cells were counted (N=5, corrected for split soma). Their average diameter was 29.9±3.3um, vs 26.3±5.4um for a spatially equivalent sample of ipsilaterally labeled ganglion cells. Double labeling studies were carried out to determine the ophthalmic receptor surface innervated by centrally crossing PA's. Diamidino yellow (DY) was injected into right medullary and cervical dorsal horns, and HRP was applied to the left cornea, ethmoid nerve, or the dura overlying cerebral cortex. The latter 3 structures are known to be represented in portions of ipsilateral dorsal horn receiving the crossed PA projection. Though DY labeled from 75-125 left ganglion cells per animal, no cells were double labeled. In conjunction with the relatively large ganglion cells and axons giving rise to this projection, and their central terminations, these data suggest that nociceptive-biased ophthalmic nerves are not the source of the crossed ophthalmic PA projection.

We have previously shown that ipsilaterally projecting mandibular and ophthalmic PA's maintain normal topography subsequent to neonatal infraorbital nerve damage. In adult rats subjected to left infraorbital nerve section at birth, HRP injections into right V ganglion or TrV labeled decussating ophthalmic PA's which were of normal density and terminal distribution in all left V brainstem subnuclei, C1 and 2. These data provide further evidence of an absence of central sprouting in spared V PA's following neonatal V deafferentation.

57.3 THE CAPACITY OF HUMAN SUBJECTS AND PRIMATE S-I CORTICAL NEURONS TO PROCESS DIRECTIONAL INFORMATION PROVIDED AT TWO SKIN SITES. G.K. Essick* and B.L. Whitsel (SPON: A. Stuart). Dept. of Physiol. and Dent. Res. Cntr., UNC, Chapel Hill, NC 27514.

The ability of 6 human subjects to discriminate direction of tactile stimulus motion on the dorsum of the hand was determined (i) in the absence and (ii) in the presence of a temporally overlapping moving stimulus delivered to a second skin site on the ipsi- or contra-lateral forelimb. Similarly, the activity evoked from 16 single primate (Mac. fas.) directionally selective S-I neurons by two moving stimuli applied to different parts of their receptive fields was examined. The effects on directional sensitivity of stimuli moving in both the same and in opposite directions over the two skin sites was assessed.

It was found that when the two brushing stimuli move in the same direction, the directional sensitivity of the human observer is typically below that predicted for a hypothetical subject who can independently process information provided at each of the two skin sites. Moreover, the directional information provided at each skin site is often completely lost when the temporal order of site stimulation (ie, the long-range motion cues) provides conflicting directional information. In contrast, the directional sensitivity of invariant neurons was found to approximate that predicted for independent processing even when conflicting directional information was provided by delivering the two stimuli non-simultaneously.

In both the psychophysical and neurophysiological experiments, linear summation of the directional information provided by the two stimuli was observed only when the two stimuli were timed and positioned so that they approximated one continuous movement across the skin. Moreover, directional information was lost when the two stimuli moved in opposite directions.

The differences and similarities between the human and single neuron data lead us to suggest that while the S-I neurons cannot be solely responsible for the global motion processing capacity of human subjects, the behavior of the directionally selective cells of the primate S-I cortex is consistent with the idea that they may subserve an early, local, short-range process in tactile motion perception.

Supported by NIH grants #DE02668 and #DE07509.

57.4 FOUR CHANNELS MEDIATE THE SENSE OF TOUCH. S.J. Bolanowski, Jr., G.A. Gescheider, R.T. Verrillo and C.M. Checkosky*, Institute for Sensory Research, Syracuse University, Syracuse, NY 13210, Center for Brain Research, University of Rochester Medical School, Rochester, NY 14642 and Department of Psychology, Hamilton College, Clinton, NY 13323.

Previous physiological experiments have identified four groups of afferent fibers in glabrous skin of the human somatosensory periphery that are capable of signaling tactile stimuli: Pacinian (P), Rapidly adapting (RA), Slowly adapting type I (SA I) and Slowly adapting type II (SA II). Psychophysical studies, however, have shown that only two (P and non-Pacinian I or NP I), or perhaps three (P, NP I and NP II) channels participate in the perceptual process. This fact has been corroborated in microneurographic studies in which one of the fiber types (SA II) fails to evoke a sensation, even when electrically excited at high rates. By using stimuli to selectively mask the previously determined psychophysical channels, we now demonstrate that a fourth channel does, indeed, exist. The fourth channel responds to vibrations over a frequency range between 0.4 and 100 Hz and is unaffected by changes in skin-surface temperature (15 to 40° C), stimulus size (0.008 to 2.9 cm^2) and stimulus duration (700 to 2500 ms). Adhering to previous psychophysical nomenclature, we call the fourth channel NP III. The four channels combine, at threshold, to create an operating range for the perception of vibration which extends from 0.4 to greater than 500 Hz. Each channel mediates a specific portion of the overall threshold-frequency characteristic, although the sensitivities of the channels partially overlap. Thus, suprathreshold stimuli may activate several channels simultaneously, suggesting that the perceptual qualities of touch may be determined by the combined inputs from all four channels. Since the exact neural code used by each afferent fiber group is not presently known, it is possible that the failure to evoke a sensation from SA II fibers may be explained by inappropriate electrical stimulation.

57.5 ANTI- AND ORTHODROMIC SPONTANEOUS ACTIVITY IN RAT SAPHENOUS NERVE
Lisa C. Russell, Ph.D. & Kim J. Burchiel, M.D. Dept. Neurological Surgery, University of Washington & Veterans Administration Medical Center, Seattle, Washington

Spontaneous centrifugal activity was recorded in both acutely cut and chronically axotomized rat saphenous nerve. In 34 male Sprague-Dawley rats, a modification of the microfilament recording method was used to conduct surveys of spontaneous activity in saphenous nerve. Under deep pentobarbital anesthesia, six rats underwent L3 cordotomy, then unilateral saphenous axotomy. The proximal stump was then dissected into 30-50 small microfilaments and surveyed for spontaneous activity. Afterward, the nerve was cut back; gallamine (20 mg) was administered; and the nerve was once again surveyed in the same fashion. Twenty-eight rats underwent unilateral saphenous axotomy 1-8 weeks prior to similar recordings, and the neuroma was excised just before microfilament dissection. Spontaneous discharges originated from three foci: (1) the in-continuity dorsal root ganglia (DRG); (2) sympathetic vasoconstrictor neurons; and (3) dichotomizing afferent axons in peripheral nerve. There was significantly more antidromic activity from DRG in rats with prior axotomies than in control animals ($t=2.38$; $p < .025$), and gallamine produced a significant increase in DRG activity in chronically lesioned rats ($t=2.43$; $p < .025$) but not in acutely lesioned controls. However, 90% of the spontaneous activity in these recordings appears to be from sympathetic efferents. This activity was not increased by chronic neurotomy ($t=1.9$; $p > .05$), nor was it affected by gallamine administration ($t=.957$; $p > .1$). Usually 4-6 C-fibers exhibited synchronous firing at approximately 2 Hz each, and was coupled with the respiratory rhythm. Body cooling or hyperventilation induced a delayed increase in discharge rate. This activity was temporarily abolished by a sympathetic ganglion blocker (trimethaphan, 1 mg I.V.). These data correspond to sympathetic efferent activity recorded in human and cat cutaneous (sensory) nerve fascicles.

In only 2 microfilaments were spontaneous antidromic action potentials observed with receptive fields on blood vessels in the nearby fascia. Both branched axons were in acutely cut nerve thus were not the result of retrograde sprouting from a neuroma.

Conclusions: (1) Chronic axotomy of sensory afferents produced ectopic activity in their in-continuity DRG. (2) Potassium channel-blocking agents increased spontaneous activity from DRG in chronically axotomized rats. (3) On-going sympathetic efferent activity in rat saphenous nerve was not affected by distal axotomy for up to 8 weeks. (4) Rare branched sensory afferents in peripheral nerve occasionally exhibit spontaneous activity.

57.6 HYPOALGESIA AND DECREASES IN SPINAL CORD SUBSTANCE P AND CALCITONIN GENE-RELATED PEPTIDE ASSOCIATED WITH CAPSAICIN DESENSITIZATION IN ADULT RATS.
M.J. Iadarola, C.M. Flores* and R. Dubner, Neurobiology and Anesthesiology Branch, NIDR, NIH, Bethesda, MD 20892.

Recently, calcitonin gene-related peptide (CGRP) has been colocalized with substance P (SP) in primary afferent neurons. Treatment of adult rats with capsaicin, unlike neonatal treatment, does not destroy the primary afferent neuron but does deplete spinal cord SP content. The present experiments examine the effect of adult capsaicin treatment on the content of spinal cord CGRP and SP and the relationship to behavioral hypoalgesia.

CGRP was measured with a c-terminally directed antibody that does not crossreact with cholecystokinin or FMRFamide. HPLC analysis of acidic extracts of rat spinal cord indicated that the major immunoreactive species coeluted with authentic rat CGRP. SP was measured in parallel with a second RIA. Capsaicin was administered by two routes: (1) s.c. in ascending daily doses of 30, 60, 60, 100 and 150 mg/kg or (2) direct application of a 1.5% solution to the sciatic nerve for 15 min. Nociceptive responses, paw withdrawal latencies (PWL), were assessed by application of a radiant heat source to the plantar surface of the foot.

Systemic administration of capsaicin produced a pronounced hypoalgesia (PWL: 14.0 vs 9.3 sec) as early as 24 hr after the first injection of capsaicin and lasting throughout the injection series. PWL returned to control levels over the ensuing 16 days. Depletion of CGRP (55%) occurred within 3 days of the first injection and was maintained at approximately this level for at least 3 weeks. SP was depleted in a precisely parallel fashion, but the decrease (36%) was less than that of CGRP. Thus, peptide depletion is concommitant to but outlasts the behavioral hypoalgesia. Application of capsaicin directly to the sciatic nerve produced a profound hypoalgesia (PWL reached the 25 sec cut-off) which lasted at least one week; peptide depletion did not exceed 35% for either CGRP or SP in spinal cord or lumbar dorsal root ganglia.

Our experiments show that treatment with capsaicin produces parallel effects on both CGRP and SP levels in dorsal spinal cord. Depletion with single nerve application was less robust than with systemic treatment. With systemic treatment, depletion is prolonged and exceeds the duration of hypoalgesia. This recovery of thermal sensitivity suggests that adaptive changes may occur to restore noxious sensitivity and that under certain conditions, there exists a dissociation between peptide depletion and the behavioral hypoalgesia seen after capsaicin treatment.

57.7 MULTIPLE RESPONSE CLASSES OF PERIPHERAL AFFERENT UNITS TO INTRA-ARTERIAL INJECTION OF BRADYKININ AND T-KININ.
R.H.Cohen, T.E. Paulson* and E.R. Perl. Dept. of Physiology, Univ. of North Carolina, Chapel Hill, NC 27514.

Kinins are potent pain-producing peptides formed as a consequence of the tissue injury. T-kinin (Ile-Ser-bradykinin) is the primary kinin formed in rats 24 hrs. after injection of carrageenin into an air pouch[1]. We examined and compared the afferent response elicited by bradykinin and T-kinin by recording from small fiber bundles teased from the great auricular nerve of an isolated rabbit ear preparation maintained *in vitro* by perfusion with an oxygenated Krebs-Henseleit solution. Typically, the threshold neural response to kinin, a gradual increase in spontaneous activity beginning more than 180 sec. after injection of 1 to 3 ηgms of kinin, occurred only once in multifiber recordings. At subsequent higher doses a shorter latency (<30 sec.) response appeared. Threshold sensitivity to bradykinin varied in multifiber recordings from 3 ηgms to 1000 ηgms. T-kinin was approximately 1/3 as potent. All C-polymodal nociceptors responded to the kinins in a similar fashion with a characteristic 20 to 30 sec. latency in onset and a low frequency discharge which reached a peak rate of less then 3 spikes per second at 1 - 2 minutes post injection. We could not demonstrate consistent changes in sensitivity to mechanical and thermal stimuli following each series of kinin presentations. Some unidentified units had a short latency response that began within seconds following injection and terminated within 1 minute post injection. In several multifiber recordings, units responded to the kinins with irregular bursting that lasted for many minutes post injection. Others responded with a maintained high frequency (>20/sec.) discharge that lasted up to 10 seconds or with trains of bursts that lasted many seconds. This multiplicity of response types and wide range of sensitivity to kinins indicates the need to reexamine categories of nociceptive afferent units with regard to chemoreceptive properties.
Supported by NINCDS grant NS10321 with computer facilities supplied by NS14899; RHC was the recipient of a NINCDS fellowship NS07788.

57.8 CORNEAL MECHANORECEPTOR RESPONSES TO REPETITIVE STIMULI.
H.W. Thompson,* B.M. Dupuy,* and R.W. Beuerman. LSU Eye Center, New Orleans, LA 70112.

The cornea is covered by an epithelial sheet containing free nerve endings originating from the ophthalmic branch of the trigeminal nerve. Many of these free nerve endings are mechanically sensitive, but have not been examined with stimuli of reproducible micron range displacements.

In anesthetized New Zealand rabbits, ciliary nerve branches were dissected free at the back of the globe of the eye, and single unit activity was obtained via conventional extracellular recording techniques. The eye was held firmly by tying the conjunctiva to a stainless steel ring. Mechanical stimuli of known force, displacement, rate of onset, and frequency were applied to the cornea by a piezoelectric stimulator driven by a function generator. Displacements were between 10 and 60 microns. In some experiments, the cornea was preloaded by probes of different areas and shapes (cylinders, spheres, and monofilament fibers) applied to different locations within a receptive field.

Two classes of mechanoreceptors were distinguished. The first class responded with bursts, or a single action potential, to the onset of only a few cycles of repeated stimulation before fatiguing. The second class, which did not fatigue rapidly, responded with bursts of potentials to the onset or offset of preloading displacements of 100 microns or more, and with single action potentials to each stimulus cycle of repeated stimuli. Single action potential responses were seen at frequencies up to 50 Hz, in response to displacements as small as 10 microns, and followed reliably for up to 10 minutes. Conduction velocities (1.5-4.0 m/s) for both groups were in the A-delta range. The two unit classes were often observed to have overlapping receptive fields, since a series of repeated small displacement pulses to the cornea frequently evoked two units (distinguishable by waveform and latency), one of which fatigued rapidly, and the other of which was nonfatiguing. Units of both types were highly sensitive to the rate of stimulus onset. Ramps or sinusoidal waveforms of fibers (0.13 mm dia.) were more effective stimuli than the larger spheres (1.7, 1.2, 0.7 mm dia.) or cylinders (1, 2, or 3 mm dia.). Sensitivity to rapid stimulus onset and the more effective nature of punctate stimuli for the two classes of corneal mechanoreceptors suggest that both may be involved in the perception of foreign bodies introduced into the eye. Comparison of the brainstem response to the output of rapidly fatiguing and nonfatiguing mechanoreceptors may be useful in understanding the processing of corneal pain information in the trigeminal nervous system.

57.9 EVIDENCE THAT THE DISTRIBUTION OF POLYMODAL NOCICEPTORS DOES NOT DETERMINE BOTH THERMAL AND MECHANICAL PAIN THRESHOLDS OF HUMAN GLABROUS AND HAIRY SKIN. Casey, K.L., Butler, J.*, Lewis, K.G.* and Morrow, T.J., V.A. Medical Center, Ann Arbor, MI 48105

Polymodal nociceptors (PMNs) innervating mammalian skin respond to both mechanical and thermal noxious stimuli. If the distribution of PMNs is the major determinant of both mechanical and thermal pain threshold in humans, then both types of pain threshold should show the same relative difference among different sites on the cutaneous surface.

We measured mechanical and thermal pain thresholds in normal volunteers of both sexes aged 18 to 75. Mechanical skin pinch stimuli were delivered with a modified hemostat to 10 points within each of 6 body sites of 38 subjects. Pinch force was increased over a measured area at a rate of 3.7 $N \cdot sec^{-1}$ until the subject signaled the onset of pain. Average mechanical pain thresholds (N/mm^2) were computed for each body site. Thermal stimuli were delivered wtih an infrared CO_2 laser (45 msec, 5mm beam diameter) to 10 points within each of 6 body sites, 5 of which were identical to those tested with mechanical stimuli. The thermal pain threshold (watts) for each body site of 39 subjects was estimated by successive incremental adjustment of stimulus intensity from point to point.

For mechanically induced pain, the rank order of sensitivity (N/mm^2 ± SE) was: upper lip (0.19 ± .004), dorsal forearm (0.31 ± .007), ventral forearm (0.33 ± .004), finger pads (0.37 ± .009), dorsal foot (0.39 ± 0.14), and palm (0.50 ± .009). For laser-induced thermal pain, the rank order of sensitivity (watts ± SE) was: lower back (3.36 ± .21), ventral forearm (4.18 ± .31), dorsal foot (4.28 ± .21), dorsal forearm (4.66 ± .37), palm (9.28 ± .49), and finger pads (10.57 ± .50). This rank order of sensitivity and inter-site threshold differences for thermal pain agrees with previous results obtained using radiant heat (Hardy et al, Proc. Soc. Exp. Biol. Med. 80:425-427, 1952) except that we find glabrous skin thresholds higher relative to the minimum (lower back).

Mechanical and thermal pain thresholds are similar in showing no differences among the hairy skin sites of the forearms and dorsal foot, and in being significantly higher on the glabrous skin of the palm than on hairy skin. The thermal pain threshold of the finger pads, however, was even higher than that of the palm, while the mechanical pain threshold was the same as that of hairy skin. We conclude that the distribution of PMNs is not the major determinant of both mechanical and thermal pain threshold in hairy and glabrous skin and that other central and/or peripheral mechanisms determine the thresholds for each of these different types of pain.

57.10 NEURAL MECHANISMS OF CUTANEOUS HYPERALGESIA IN HUMANS: PERIPHERAL OR CENTRAL? R.H. LaMotte, E. Torebjörk*, and L. Lundberg*. Dept. of Anesthesiology, Yale University Sch. of Med., New Haven, CT 06510 and *Dept. of Clin. Neurophysiol., University Hosp., Uppsala, Sweden.

Does intensely painful activation of cutaneous nociceptive peripheral nerve fibers sensitize (lower the thresholds and enhance the responses of) peripheral nociceptors or the central neurons to which they project? Either mechanism might account for hyperalgesia after cutaneous injury. To test for central sensitization without the complications of changes in response sensitivities of receptors, we delivered electrical test stimuli (TS) through a recording microelectrode inserted into the common peroneal nerve in awake humans and elicited pain sensations referred to a localized region (the projection field, PF) on the dorsum of the foot. Subjects judged the magnitude of pain sensation produced by each of 5-10 moderately painful TS (3 sec pulse trains of 10 Hz every 5 minutes). The TS were delivered before and after either of two intensely painful conditioning stimuli (CS). One CS was capsaicin (CAP) (100 ug in 10 ul tween-saline) injected intradermally within or adjacent to the PF; it produced intense pain and a wide area of hyperalgesia characterized by tenderness or pain to lightly stroking the skin. The alternative CS was an intensely painful, barely tolerable, intraneural electrical pulse train (1 Hz) delivered continuously for durations from 20 sec to 10 minutes. The magnitude estimates of evoked pain were not significantly different for TS given before and after either CS. Thus, an intensely painful CS, which presumably produced vigorous nociceptive input, failed to sensitize higher order neurons.

To test for peripheral mechanisms of hyperalgesia, evoked responses in 11 single C-fiber polymodal nociceptive afferent fibers (CPNs) were recorded from the common peroneal nerve in humans before and after intradermal injection of CAP. Injection of CAP 9-20 mm away from the CPN receptive field (RF) produced tenderness to skin stroking in an area encompassing the RF but did not sensitize the CPN. CPNs injected within or close to ($\leq$ 8 mm) their RFs were not sensitized although they typically did respond weakly to CAP, but ceased responding well before the termination of CAP pain. Injections within the RF desensitized responses to all cutaneous stimuli. Thus, activity of these CPNs could not account for CAP pain or hyperalgesia. Despite evidence that intense pain of peripheral origin can produce cutaneous hyperalgesia without "central sensitization," the peripheral nociceptors responsive for CAP pain and hyperalgesia have yet to be identified. 57.11 OPIATES INCREASE REACTION TIME LATENCY TO FIRST AND SECOND PAIN SENSATIONS. R.H. Gracely*, R. Dubner, D. Walther*, P.J. Wolskee* and L. Lota*. Clinical Pain Section, Neurobiology and Anesthesiology Branch, NIDR, NIH, Bethesda, MD 20892.

Two experiments assessed the influence of IV opiates on thermally-evoked first and second pain sensations. A contact thermode delivered trains of six 1.4 sec 51°C pulses (baseline 39°C) at 3 sec intervals. Subjects pressed a button to the first pain felt for each pulse in the train. Previous studies showed that for pulses 1 and 2, the first pain felt is a pricking, A-delta mediated, first pain sensation. This activity is suppressed after 4 pulses, and pulses 5 and 6 evoke only a diffuse, C-fiber mediated second pain sensation. Reaction time latencies to pulses 1 & 2 and 5 & 6 provided a relative measure of A-delta and C-fiber functioning. Reaction time latencies to auditory stimuli presented at the same intervals served as a motoric control.

In exp I, 24 pain-free subjects received 16 thermal and 10 auditory trains before and after double-blind IV infusion of either 1.1 ug/kg fentanyl (n = 9) or saline placebo (n = 15). In comparison to placebo, fentanyl increased reaction time to both first (132 msec, $t(22) = 2.42$, $p < 0.05$) and second (154 msec, $t(22) = 2.27$, $p < 0.05$) pain sensations while corresponding auditory latencies (pulses 1 and 2, 26 msec; pulses 5 and 6, 22 msec) were nonsignificantly increased.

In exp II, 21 chronic low back pain patients received 18 thermal (and 14 received 10 auditory) trains before, after and between sequential double-blind infusions of either morphine then 0.4 mg naloxone, or saline then morphine, presented on counterbalanced alternate days. Individually-determined morphine doses averaged 12 mg. In comparison to saline and naloxone, morphine increased latency to both first (291 msec, $t(21) = 3.69$, $p < 0.01$) and second (180 msec, $t(21) = 3.10$, $p < 0.01$) pain sensations, and decreased the detection frequencies of second pain sensations (2.57, $t(21) = 4.34$, $p < 0.001$). Auditory latencies (pulses 1 and 2, 38 msec increase; pulses 5 and 6, 70 msec increase) and detection frequency (pulses 5 and 6, 0.07 increase) were unaltered by morphine.

The present results suggest that opioid modification of both A-delta and C-fiber mediated pain sensation can be demonstrated in controlled studies of normal and chronic pain populations, and implicate these mechanisms in clinical analgesia.

57.12 PAINFUL SYNDROME NEWLY RECOGNIZED: POLYMODAL HYPERALGESIA WITH CROSS MODALITY THRESHOLD MODULATION AND RUBOR. ITS BASIS: 1 SENSITIZED NOCICEPTORS, 2 PLUS ANTIDROMIC VASODILITATION. [1]J.Ochoa, [1]M.Cline, [1]W.Comstock,* [2]W.J.Culp,* [1]R.Dotson, [3]P.Marchettini,* [4]H.E.Torebjork.* [1]Portland, OR, USA, [2]Dartmouth, NH, USA, [3]Milano, Italy, [4]Uppsala, Sweden.

Combined application to patients and volunteers of microneurography, intraneural microstimulation, thermography, quantitative sensory tests, sympathetic monitoring, differential nerve blocks, and capsaicin experiments, have allowed to define a specific neuropathic pain entity (Ochoa, 1986).

Key symptom is Stimulus-induced pain from weak stimulation of symptomatic skin. Spontaneous pain often occurs. Both mechanical and thermal stimulus modalities induce pain: Polymodal Hyperalgesia (PH). Cooling abolishes spontaneous and induced pains. Warming aggravates both.

Influence of one stimulus energy (thermal) upon perception threshold for pain elicited by another energy (mechanical) (Cross-modality Threshold Modulation: XTM) is explained at primary receptor level rather than through central gating. The possibility that specific thermal (cold) afferents may shut CNS gates is negated by persistence of XTM during selective afferent blockade (A-block resistent XTM). It is assumed that different energies alternatively excite or depress specific transducers within the same polysensitive ending in polymodal nociceptors (PNs). Sensitization of such units is suggested by PH and is endorsed by results of A-fiber blocks: when C fibers alone are conducting, PH persists. C nociceptor sensitization is proven by microrecording of single C-fiber PNs (Cline and Ochoa, 1986).

Key sign is skin warming from vasodilatation: it can occur in absence of sympathetic vasoconstrictor failure and probably reflects antidromic release by PNs of vasoactive transmitters. The same chemicals can lead to sensitization of nociceptors.

Symptoms and signs are similar to capsaicin-induced vasodilatation and sensitization of PNs via axon-reflex neurosecretion.

Symptoms up-modulated by warming may aggravate during sympathetic blocks due to the thermal increase.

58.1 THE DISTRIBUTIONS OF DOPAMINE D1 AND D2 RECEPTORS ARE PARTIALLY COMPLEMENTARY IN THE CAT BASAL GANGLIA. R.M. Beckstead. Department of Anatomy and Cell Biology, Medical University of South Carolina, Charleston, SC 29425.

The patterns of dopamine D1 and D2 receptors were examined in the basal ganglia of the cat brain by quantitative autoradiography after in vitro radioligand binding with [^{3}H]SCH23390 and [^{3}H]spiperone, respectively. Highly specific binding for both radioligands occurs in striatal, pallidal and nigral components. However, the density of binding varies from one structure to another, and the density distribution in some striatal regions is heterogeneous. Both D1 and D2 radioligand binding occurs in irregular high and low density zones in the caudate nucleus and putamen. Such patches of high density D2 radioligand binding appear mainly in the dorsolateral half of the caudate head. For the D1 radioligand, the high density patches are more widespread throughout the caudate nucleus, nucleus accumbens and putamen. Low density zones of D2 radioligand binding occur at more caudal levels of the caudate nucleus. These low density D2 zones are often in register with, and matched in size and shape by the high density zones of D1 radioligand binding. These observations are consonant with the concept of neurochemical and connectional compartmentation in the striatum.

Pallidal and nigral structures show marked disparities in binding of the two different radioligands. The D2 radioligand binding in the globus pallidus is about twice that in the entopeduncular nucleus and pars reticulata of the substantia nigra, the latter two having approximately equal levels. No measurable binding of the D2 radioligand occurs in the ventral pallidum. In contrast, D1 radioligand binding is highest in the entopeduncular nucleus and in the pars reticulata of the substantia nigra, and moderate in the ventral pallidum, but no binding of D1 radioligand occurs in the globus pallidus. The binding density of D1 radioligand is comparable in both subdivisions of the substantia nigra, but a pronounced difference is apparent between the two subdivisions regarding the D2 radioligand binding: that in the pars compacta greatly exceeds that in the pars reticulata. Thus, the pattern of receptor binding conforms to the notion of duality in the striatifugal system.

Lesions of the nigral dopamine neurons with 6-OHDA or lesions of the striatum or entopeduncular nucleus with ibotenic acid indicate that the pars compacta D2 receptors are autoreceptors, whereas the nigral and entopeduncular D1 receptors are mainly in the membranes of striatonigral axons.

58.2 **RECEPTOR BINDING PROPERTIES OF [I-125] LABELED IODOBENZAMIDE (IBZM): A SPECIFIC D2 DOPAMINE RECEPTOR LIGAND FOR SPECT.** T. Bruecke*, Y.F. Tsai*, W. Singhaniyom*, C. McLellan*, H.F. Kung*, R.M. Cohen* and C.C. Chiueh, (SPON: J.G. Kenimer), NIMH, Bethesda, Md, 20892 and Univ. of Pennsylvania, Pa, 19104.

Currently, several positron emitting ligands are in use to label and visualize dopamine (DA) receptors in the living human brain by using positron emission tomographic (PET) procedures. Because PET research is expensive and limited to a relatively small number of research centers, the search for ligands suitable for use in single photon emission computerized tomography (SPECT), a more readily available scan modality, seems advantageous. Benzamide derivatives appear to be specific ligands for D2 DA receptors while their reversibility permits receptor kinetic determinations within a convenient scanning time frame. In the present study we evaluated an I-125 labeled benzamide by investigating its binding properties in vitro.

I-125 labeled S(-)-N-(1-ethyl-2-pyrrolidinyl)methyl-2-hydroxy-3-iodo-6-methoxybenzamide (IBZM; sp.act. 600 Ci/mmol) was synthesized and purified by Kung et al (1986). In vitro binding experiments were performed using bovine and mouse caudate nucleus membrane preparations. I-125-IBZM binding is shown to be highly specific for D2 DA sites, since IC50 values for the D2 receptor antagonists, YM-09151-2 and spiperone, were in the nM range, which was 4 orders of magnitude lower than the IC50 value for the D1 antagonist SCH-23390. The S(-)-IBZM isomer was 10 times more potent than the R(+)-isomer in competing for the I-125-IBZM binding. The dissociation constant Kd of I-125-IBZM was 2.1 nM as measured by saturation analyses and calculated by Scatchard plots. DA agonists also competed with the I-125-IBZM binding. The IC50 values for DA, 6-F-DA and LY-171555 (DA agonist) were in the μM range and for Terguride (partial DA agonist) 10^{-8} M. 10^{-5} M clonidine and yohimbine (α-2 receptor ligands) displaced 15% and 40% of I-125-IBZM binding, respectively. A low affinity of S(-)-IBZM for the serotonin S2 receptors in frontal cortex was observed which was 2 orders of magnitude lower than the affinity of S(-)-IBZM for D2 sites in the striatum.

These results indicate that I-125-IBZM binding is highly specific for D2 DA receptors with a low affinity for D1, S2 and α2 binding sites. Furthermore, this ligand has been used successfully for in vivo imaging of denervation-induced increase in Bmax of D2 DA receptors in rat striatum (Kung et al., 1986; 1987). S(-)-IBZM, when labeled with a short half-life isotope, such as I-123, may prove to be a useful tracer for in vivo imaging of D2 DA receptors by SPECT procedures.

58.3 NONSTEADY-STATE MEASUREMENT OF RADIOLIGAND-RECEPTOR BINDING IN VIVO USING PET AND 18F-SPIPERONE: IMPLEMENTATION IN HUMANS. JS Perlmutter*, J Markham*, M Kilbourn*, M Welch*, ME Raichle (SPON: T Videen). Washington Univ Sch of Med, St. Louis, MO 63110

We have developed a method using positron emission tomography (PET) and ^{18}F-spiperone (SP) for the measurement of radioligand-receptor binding in vivo. We now describe the implementation of this method in normal human subjects.

We studied 10 normal volunteers (8 male and 2 female) with a mean age of 26 years (range, 20 to 38). In each, we measured regional blood flow and blood volume with PET and rapidly administered ^{15}O-labeled radiotracers. The fraction of ^{18}F-SP bound in arterial blood, f_1, was determined with ultracentrifugal microfiltration. Following these measurements, up to 5 mCi of no-carrier-added ^{18}F-SP (containing < 2 to 4 ug of SP) was injected IV. Thirty-nine sequential PET scans and measurements of arterial-blood radioactivity due to ^{18}F-SP and its labeled metabolites continued for 3 hr. Regional measurements of radioactivity from the PET scans were obtained using a stereotactic localization method that is independent of the appearance of the images.

A 3-compartment model describing the in vivo behavior of ^{18}F-SP and a parameter estimation technique were used to analyze the PET and arterial-blood data. This enables us to calculate 4 parameters: (1) the combined forward-rate constant, k_1', (equal to the product of an association rate and the maximum number of available binding sites; (2) the binding-site dissociation rate constant, k_{-1}; (3) the free fraction of ^{18}F-SP not specifically bound in tissue, f_2; (4) the regional permeability-surface-area product, PS, of the blood-brain barrier for SP.

We calculated the following data (mean ± SD) for the 10 subjects: f_1 = .047 ± .014 and f_2 = .0065 ± .0021. For left caudate, PS = .047 cc/sec ± .022; k_1' = .140 sec^{-1} ± .056; and k_{-1} = .00034 sec^{-1} ± .00074 and for the right caudate, PS = .045 ± .021; k_1' = .191 ± .054; k_{-1} = .00053 ± .00074. Repeated studies in selected subjects yielded similar results.

This nonsteady state method for estimating radioligand-receptor binding in vivo can be implemented in human subjects and, with careful attention to technical details, yields reproducible results.

58.4 DOPAMINE D_2 RECEPTOR LIGAND BINDING SUBUNIT DETECTED BY PHOTOAFFINITY LABELING. D.E. Grigoriadis, H.B. Niznik and P. Seeman. Dept. Pharmacology, University of Toronto, Toronto, Ontario, M5S 1A8.

The ligand binding subunit of the dopamine D_2 receptor from canine striatal membrane homogenates has been identified by a novel photoaffinity label. The compound [^{3}H]azido-N-methylspiperone ([^{3}H]AMS) was derived from the potent neuroleptic spiperone and developed as a specific D_2 photoaffinity probe. In the absence of light, [^{3}H]AMS bound reversibly and with high affinity (K_D = 70 pM) to sites which could be competitively inhibited by agonists and antagonists with the appropriate pharmacologic dopaminergic rank order profile and stereospecificity. The dissociation constants of all agonists and antagonists correlated well with those obtained with other [^{3}H]dopaminergic ligands. Pre-exposure of [^{3}H]AMS to UV light did not affect its ability to bind to D_2 dopamine receptors in a reversible and saturable manner with high affinity. Upon photolysis by direct irradiation under UV light, [^{3}H]AMS was found to covalently incorporate into a peptide of Mr 92,000 as assessed by SDS-PAGE. Minor peptides of 70,000 - 50,000 Da were observed under some conditions and were the result of proteolytic breakdown of the 92,000 Da protein. The presence of protease inhibitors decreased the occurrence of these minor labeled peptides. The incorporation of [^{3}H]AMS into canine striatal membranes was inhibited by the proper pharmacologic rank order of potencies for both agonists and antagonists identifying the major labeled peptide at 92,000 Da as the dopamine D_2 receptor.

The alkylating agent N-ethylmaleimide or the reducing agent dithiothreitol did not have any effect on the mobility of the 92,000 Da protein suggesting that the ligand binding subunit is composed of a single polypeptide chain. The photolabeled receptor could be deglycosylated by the enzyme neuraminidase suggesting that the glycoprotein nature of the D_2 receptor contains terminal sialic acid residues. Cleavage of the photolabeled protein at terminal sialic acid residues altered the mobility of the 92,000 Da peptide to 55,000 Da. The specificity of [^{3}H]AMS labeling of the 92,000 Da peptide suggests that this peptide is the ligand binding subunit of the canine striatal D_2 dopamine receptor. This ligand should prove to be a useful tool in the further elucidation of the molecular structure of dopamine receptors.

58.5 **ANTI-AMINOSPIROPERIDOL ANTIBODIES WITH HIGH AFFINITY FOR SPIROPERIDOL.** **R. R. Luedtke*, M. Korner*, K. Neve, F. Rahhal* and P.B. Molinoff. Department of Pharmacology, University of Pennsylvania School of Medicine, Philadelphia, PA 19104-6084.**

Spiroperidol (SPD), a member of a structural class of neuroleptics called butyrophenones, is a high-affinity antagonist for the D2 subtype of dopamine receptor. An N-bromoacetyl derivative of aminospiroperidol (ASPD) was used to covalently couple ASPD to keyhole limpet hemocyanin. The hapten-protein conjugate was used to immunize white New Zealand rabbits. Rabbit antisera bound ^{3}H-SPD at nanomolar concentrations (10 to 30 nM), indicating that high-affinity antibodies for SPD had been elicited. Scatchard plots of the data from direct binding experiments were curved, indicating that a heterogeneous population of anti-ASPD antibodies had been elicited. BALB/c mice were also immunized and a panel of 16 monoclonal antibodies was selected based on the ability to bind ^{3}H-SPD with high affinity (K_d values from 10 to 100 nM). The majority of antibodies were IgG_1 although the IgM, IgG_3 and IgG_{2a} isotypes were also expressed. Each of the anti-ASPD antibodies had a kappa light chain. The binding site of each monoclonal antibody was characterized by inhibiting the binding of ^{3}H-SPD with ligands that are either structurally related to SPD (anilinoperidol, nitroperidol, haloperidol and pipamperone) or are selective antagonists for D2 receptors structurally different from the butyrophenones (domperidone, sulpiride and clebopride). Seven different reactivity patterns were observed. Several anti-ASPD antibodies bound only SPD with high affinity, while others bound only butyrophenones (SPD, haloperidol and pipamperone). One antibody (APSD 4-7) bound the D2 antagonists SPD and domperidone with high affinity (K_d values of 13.5 nM and 24.5 nM, respectively). However, the affinity of ASPD 4-7 for pipamperone (K_d of 3000 nM), a butyrophenone that is an antagonist for the S2 subtype of serotonin receptors, was 100- to 200-fold lower than for SPD or domperidone. ASPD 4-7 has been purified by affinity chromatography using a p-fluorophenethylamine-epoxy Sepharose column. The purified ASPD 4-7 antibody will be used to prepare anti-idiotypic antibodies that will be tested for cross-reactivity with membrane-associated D2 receptors. (Supported by U.S.P.H.S Grant No. NS 18591 and the Scottish Rite Schizophrenia Research Program.)

58.6 D-1 AND D-2 DOPAMINE RECEPTOR MECHANISM IN DOPAMINERGIC BEHAVIOR. W. C. Koller, R. O'Donnell* and G. Herbster*. Deparment of Neurology, Loyola Medical Center, Maywood, IL 60153

Dopamine (DA) receptors are classified into D-1 and D-2 subtypes. Most dopaminergic behaviors are thought to be mediated by D-2 DA receptors. We have investigated the selective D-1 DA agonist, SKF 38393 (SKF), alone and in combination with dopaminergic agonists to define the role of D-1 agonism in these behaviors. The administration of SKF (1 to 64 mg/kg) to rats resulted in occasional non-stereotypic sniffing and grooming which was also observed in placebo treated animals. SKF potentiated apomorphine (0.25 mg/kg) induced stereotypy in a dose-dependent manner (1-40 mg/kg) when the drugs were given concomitantly. SKF (1-20 mg/kg) enhanced and altered the behaviors of ciladopa (20 mg/kg), a partial DA agonist. Full agonist behaviors i.e. gnawing, were observed when 20 mg/kg of SKF was combined with ciladopa. In unilateral 6-OH DA substantia nigra lesioned rats SKF (1-10 mg/kg) with mixed D-2 agonists, PHNO or quinpirole, or mixed D-1/D-2 agonist, pergolide or levodopa, resulted in a potentiation of the number of contralateral rotations induced by these drugs. SKF (1-40 mg/kg) produced no change in locomotion, as measured by a Columbus Varimax Activity Monitor. Apomorphine produced a biphasic response with inhibition at low doses. SKF (10 mg/kg) in combination with apomorphine did not alter the inhibititory response but markedly enhanced the stimulatory effect. No changes in behavior were observed in rats challenged with apomorphine after being treated 21 days with SKF, PHNO, SKF plus PHNO, and placebo.

It is concluded that D-1 agonism is capable of augmenting dopaminergic behavior of both D-2 agonists and DA drugs with mixed D-1/D-2 activity. A combination of D-1 and D-2 agonism may represent optimal drug treatment for Parkinson's disease.

58.7 PHARMACOLOGICAL PROPERTIES OF THE PARTIAL DOPAMINE D-2 RECEPTOR AGONIST SDZ 208-912. M. Karobath, Preclinical Research, Sandoz Ltd., CH-4002 Basle, Switzerland.

SDZ 208-912 is an ergoline which interacts in binding assays in vitro with dopamine D-2 receptors (pKi 8.35), alpha-1 receptors (pKi 8.0), 5HT-1A receptors (pKi 8.09), alpha-2 receptors (pKi 7.72), 5HT-2 receptors (pKi 7.2), and dopamine D-1 receptors (pKi 7.0) with an affinity similar to that of haloperidol. The pharmacological actions of SDZ 208-912 in vivo are characterized by a predominance of simultaneous agonistic and antagonistic effects at dopamine D-2 receptors. Thus SDZ 208-912 is equipotent to haloperidol as antagonist of apomorphine (1 mg/kg s.c.) induced climbing behaviour in the mouse (ED 0.5 mg/kg p.o.) and of apomorphine (2 mg/kg i.v.) induced gnawing in the rat (100% inhibition at 0.02 mg/kg p.o.). SDZ 208-912 like classical neuroleptics strongly elevates dopamine turnover in striatum, and it induces the neuroleptic-like alterations in the rates of regional glucose utilization in several brain areas like the lateral habenula. In high doses SDZ 208-912 even induces catalepsy in rats (threshold dose 2 mg/kg p.o.). SDZ 208-912 has also potent dopamine D-2 agonistic actions in vivo. Thus orally administered SDZ 208-912 causes a long-lasting suppression of plasma prolactin in rats at dose levels similar to those blocking apomorphine effects in this species. In the same species after s.c. administration it is equipotent to bromocriptine as prolactine inhibitor. In rats with unilateral lesions of the S. nigra SDZ 208-912 induces contralateral circling behaviour at 1.0 mg/kg p.o. with immediate onset and long duration of action. These pharmacodynamic effects are compatible with the notion that SDZ 208-912 is a partial agonist with low intrinsic activity at dopamine D-2 receptors and that the thresholds for agonistic effects differ for dopamine D-2 receptors in different brain areas.

58.8 DOPAMINE (DA) D_2 RECEPTORS AND GUANINE NUCLEOTIDE BINDING (G) PROTEINS IN BENIGN AND MALIGNANT PROLACTIN (PRL)-SECRETING RAT PITUITARY TUMORS. R. Collu, C. Bouvier*, G. Lagacé*, Res. Unit Reprod. Devel. Biol., Pediat. Res. Center, Hôp. Ste-Justine and Univ. de Montréal, Montréal, Québec H3T 1C5.

Previous studies performed with an estrogen-induced PRL-secreting rat pituitary adenoma have allowed us to conclude that the minimal size for the binding site of normal D_2 receptors present in adenomatous mammotrophs is approximately 100,000 daltons when evaluated by radiation inactivation (RI), and that association with a GTP-binding subunit of a G protein increases the receptor size to 145,000 daltons and decreases its affinity for DA agonists (Bouvier et al., J. Neurochem., 47:1653, 1986). More recently, we have found that D_2 receptors present in high affinity form in two malignant PRL-secreting rat pituitary tumors, 7315a and MtTW15, which are resistant to the inhibitory actions of DA, are insensitive to guanine nucleotides but have similar minimal binding site sizes as normal D_2 receptors as evaluated by photoaffinity labeling. To further evaluate the structural differences existing between normal and tumoral D_2 receptors we have determined the target size (TS) of receptorial proteins present in adenomatous and malignant mammotrophs and we have looked for the presence of G proteins in the three types of preparations. For TS analysis, receptors were labeled by photoaffinity using [^{125}I]-N_3-NAPS. Labeled receptors were then exposed to increasing amounts of gamma rays using the Gammacell 220, and were then subjected to SDS-PAGE followed by autoradiography. The intensity of radioactivity bands was measured by scanning and found to decrease linearly with increased radiation exposure. TS was determined by calibration with proteins of known Mr. The presence of G proteins was evaluated by immunoblot using antibodies raised against Gi-alpha, Go-alpha and G-beta, and purified G proteins provided by Dr A.M. Spiegel. TS was found to be 93,000 for normal, 96,000 for 7315a and 163,000 for MtTW15 receptors. Gi-alpha was found to be present in all three preparations (ug/mg protein. Normal: 0.6; 7315a: 0.4; MtTW15: 0.2). Go-alpha was present in normal and MtTW15 but not in 7315a cells (Normal: 1.55; MtTW15: 0.48). G-beta was found in all three preparations (Normal: 1.43; 7315a: 1.71; MtTW15: 2.74). These results suggest the presence of an anomaly in the D_2 receptorial protein of MtTW15 cells (dimer?). They show furthermore the presence in a pituitary adenoma of the alpha subunits of Gi and Go as well as the common beta subunit which may be involved in the transduction of the DA inhibitory message controlling PRL release. The absence of the Go-alpha subunit in 7315a cells is an interesting finding and may indicate that DA-resistance in the two malignant PRL-secreting tumors is due to different molecular anomalies.

58.9 DOPAMINE INHIBITS PROLACTIN RELEASE AND cAMP GENERATION IN THE MMQ CELL, A HOMOGENEOUS PROLACTIN-SECRETING CELL LINE. A.M. Judd*, I.S. Login* and R.M. MacLeod. Departments of Internal Medicine and Neurology, University of Virginia School of Medicine, Charlottesville, VA 22908.

Dopamine inhibits prolactin release from normal anterior pituitary cells. However, the pituitary cell population is heterogeneous and presently established prolactin-secreting cell lines do not express functional dopamine receptors, thus making the study of control mechanisms difficult. We determined that the prolactin and ACTH-secreting 7315a tumor has functional dopamine receptors and undertook to isolate from this tumor a homogeneous prolactin-secreting cell line possessing these receptors. The solid tumor was dispersed with collagenase and cultured in RPMI-1640 containing normal horse and calf serum. After 12 days in culture, two cell populations--one adherent, one nonadherent to plasticware--were obtained. In the nonadherent cells, but not in the adherent ones, dopamine inhibited prolactin release that was stimulated by maitotoxin, a calcium channel activator. A clonal cell line, MMQ, was derived from the nonadherent cells which secretes prolactin, but no detectable amounts of ACTH nor other pituitary hormones. Dopamine was found to inhibit (50-80%) maitotoxin-induced prolactin release from these cells. We studied cAMP levels in the MMQ cells. Vasoactive intestinal peptide (VIP), forskolin and cholera toxin each increased cellular cAMP levels, and dopamine (50-1000 nM) inhibited each response in a concentration-dependent manner as it does in normal pituitary cells. Haloperidol, a dopamine receptor antagonist, blocked these dopaminergic effects as did pretreatment of the cells with pertussis toxin, an inactivator of a receptor-associated GTP binding protein. Somatostatin (SRIF, 100 nM) also significantly attenuated (30%) forskolin- and VIP-stimulated cAMP generation, but to a lesser extent than the attenuation caused by 1 uM dopamine (50%). MMQ cells grow rapidly (dividing time less than 24 hours), and after more than a year in culture the effect of dopamine on prolactin release has not been altered. In conclusion, the MMQ cell line secretes only prolactin and contains dopamine receptors that are negatively coupled to adenylate cyclase by a GTP-binding protein. These cells also possess functional SRIF and VIP receptors. This homogeneous cell line appears to be a valuable tool for determining the mechanism(s) through which dopamine, VIP and SRIF regulate cellular function. [Supported by NIH Research Grants CA-07535 and CA-38228, and grants from the American Parkinson Disease Association.]

58.10 CHRONIC TREATMENT WITH FLUNARIZINE AND NIMODIPINE AFFECTS STRIATAL DOPAMINE RECOGNITION SITES. S. Govoni, M.R. Moresco*, S. Di Giovine*, A.Leggio* and M. Trabucchi^. Institute of Pharmacological Sciences, University of Milan and ^Chair of Toxicology, 2nd University of Rome, Italy.

Clinical and experimental observations suggest an interaction of calcium antagonists with dopaminergic transmission. In particular, the chronic treatment with flunarizine, a diphenylalkylamine calcium antagonist, induces extrapyramidal disturbances in old patients.

In addition, in in vitro experiments, flunarizine decreases dopamine release from rat striatal slices (Battaini et al., Naunyn Schmiedeberg's Arch. Pharmacol. 332:267-270, 1986). Moreover nimodipine, another calcium antagonist, belonging to a different chemical class (i.e. dihydropyridines), may reduce the synthesis of striatal dopamine when acutely injected in rats. On the basis of these data we have investigated whether these drugs may present direct actions on dopamine recognition sites either in vitro or after in vivo repeated treatment. Tritiated spiroperidol and tritiated SCH 23390 were used as selective dopaminergic ligands. Tritiated spiroperidol is displaced by flunarizine and verapamil with different potency (IC50 0.7 micromolar and 10 micromolar, respectively) whereas nimodipine and nitrendipine have no effect.

In contrast, the binding of tritiated SCH 23390, a selective D1 antagonist, is displaced by 36% and 52% by nimodipine and flunarizine (10 micromolar). The displacement by nimodipine can be observed at very low concentrations, it is maximal at 10 nM, then not increasing over 40% of the specific binding even at concentrations as high as 100 micromolar. The in vivo data further support the concept of an interaction of these drugs with dopaminergic transmission. In fact, the chronic treatment with flunarizine and nimodipine induces complex adaptative changes of dopamine receptors which differ in D1 and D2 receptors.

In particular both flunarizine and nimodipine produce an increase in the Bmax of haloperidol displaceable spiroperidol binding (+24% and +22% respectively) without effect on Kd. In contrast flunarizine, but not nimodipine, decreases the Bmax of tritiated SCH 23390 binding.

These data may explain, at least in part, the extrapyramidal side effects of flunarizine. In addition the results indicate that nimodipine may interact with dopaminergic transmission although with a mechanism different from that of flunarizine. Whether the two compounds alter also the functional state of other neurotransmitters remains to be determined.

58.11 EVIDENCE THAT TERMINAL DA-AUTORECEPTORS INHIBIT DA-RELEASE IN VIVO. A. Imperato* and G. Di Chiara. Inst. of Exp. Pharmacology and Toxicology, University of Cagliari, Italy.

Dopamine (DA) autoreceptors located on DA-terminals are believed to control in an inhibitory manner the release of transmitter DA. In spite of the number of studies devoted to clarifying this mechanism its actual significance for the control of DA-transmission in vivo remains uncertain. We have tested this possibility by studying the effects of DA-agonists and antagonists locally applied in the caudate on the in vivo release of DA estimated by brain dialysis in freely moving rats. Various DA-agonists active on D-2 receptors such as LY 171555, BHT 920, pergolide and apomorphine (0.1-10 /uM) reduced DA-release in a concentration dependent manner; DOPAC and HVA output was reduced only by high concentrations of the agonists. These effects were prevented by systemic administration of clebopride (0.5 mg/kg s.c.) a specific antagonist of D-2 receptors. (-)3PPP applied at concentration of 10 /uM stimulated DA-release and metabolism. Local application of DA-receptor antagonists (-) sulpiride and haloperidol (0.1-10 /uM) stimulated DA-release in a concentration dependent/manner. (+)Sulpiride, the isomer inactive on DA-receptors, failed to modifie DA-release up to concentrations of 10 /uM. The results are consistent with the possibility that DA-autoreceptors located on DA-terminals are operative in controlling DA-release also in vivo.

58.12 DO AUTORECEPTORS CONTROL DOPAMINE SYNTHESIS IN RAT FOREBRAIN? EFFECTS OF APORPHINE ANALOGS OF DOPAMINE. R.J. Baldessarini, J.L. Neumeyer, M.H. Teicher, N.S. Kula,* A. Campbell,* and E. Marsh.* Harvard Medical School; *Mailman Research Center, McLean Hospital, Belmont, MA 02178.

The significance of putative presynaptic autoreceptors at dopamine (DA) containing nerve terminals remains unclear. There is good evidence for the ability of such a mechanism to diminish neuronal release of DA. However, evidence for autoreceptor mediated control of tyrosine hydroxylation, the rate-limiting step in DA synthesis, is less secure. We prepared and evaluated several rigid, hydroxylated aporphine analogs of DA to assess stereoisomeric and hydroxy-substituent effects on DA receptors. Compounds assessed included the R(-) and S(+) enantiomers of N-n-propylnor-apomorphine (NPA, a catechol), and their 11-monohydroxy congener. The R(-) and S(+) isomers of these agents, respectively, showed behavioral evidence of enantiomerically selective agonism or antagonism of DA receptors in the intact rat. The R(-) agonist isomer of NPA appeared to diminish turnover of DA in rat forebrain in vivo (diminished HVA:DA ratio or decreased accumulation of DOPA after inhibiting its decarboxylation), based on liquid chromatographic assays with amperometric detection. These effects were not stereoselective, however, and the antagonist (+)NPA also inhibited turnover. Also, the effects of (-) and (+) N-propyl-11-hydroxynoraporphine to decrease or increase DA turnover, respectively, were not strong or consistently dose-dependent. However, after pretreatment with gamma-butyrolactone to diminish neurophysiological activity in DA neuronal projections, the agonist isomers inhibited the rise of DOPA after inhibiting its decarboxylation with NSD-1015. The latter effect was stereoselective and was inhibited by haloperidol. In in vitro studies of tyrosine hydroxylase activity (by production of $^{14}CO_2$ from 1-^{14}C-L-tyrosine) with a synaptosomal fraction of corpus striatum, the NPA isomers inhibited DA synthesis by a process that was neither stereoselective nor inhibited by D-1 or D-2 dopaminergic antagonists. The monohydroxyaporphines produced a weak and reserpine-sensitive effect that also was not influenced by neuroleptic agents. The effects of exogenous DA on synthesis in synaptosomes were not inhibited by DA receptor antagonists but were blocked by potent antagonists of DA transport. These results taken together suggest that end-product and postsynaptically mediated inhibition of tyrosine hydroxylation can be demonstrated readily, but that demonstration of effects mediated by putative presynaptic DA autoreceptors at DA nerve terminals depends on the experimental methods employed.

59.1 IN THE GUINEA PIG, HORSE, AND MONKEY ASTROCYTES ARE RESTRICTED TO VASCULARIZED PARTS OF THE RETINA. Jutta Schnitzer* (SPON: A.C. Rusoff). MPI für Hirnforschung, D-6000 Frankfurt/M. 71, F.R.G.

Until recently, it was generally believed that astrocytes occurred ubiquitously in the nerve fiber layer (NFL) of mammalian retinae. However, the rabbit retina has been shown to have a distribution of astrocytes restricted to the medullary rays (Schnitzer, J., J. Comp. Neurol. 240:128, 1985). Interestingly, this region is the only part of the rabbit retina that is vascularized.

In the present study the distribution of astrocytes has been investigated in the sparsely vascularized guinea pig and horse retina, and in the richly vascularized monkey retina. The guinea pig retina and optic nerve head lacked glial fibrillary acidic protein (GFAP) immunoreactivity; but GFAP-positive astrocytes were detectable in the myelinated part of the guinea pig optic nerve. However, the optic nerve head and adjacent regions of the retina contained vimentin-positive astrocytes. The restriction of astrocytes to the small vascularized retinal region immediately adjacent to the optic nerve head was confirmed in semithin sections. In the whole-mounted horse retina, GFAP-positive astrocytes were restricted to a narrow zone close to the optic nerve head. This is also the only region of the horse retina that is vascularized. Thus, as in the rabbit, in the guinea pig and horse retina astrocytes and blood vessels coexist in the NFL.

In the whole-mounted Old World Monkey (Cercopithecus aethiops) retina, GFAP-positive astrocytes were found ubiquitously in the NFL. The avascular foveal region and a small vascularized rim which only contains capillaries in the inner nuclear layer, lacked astrocytes. The cessation of blood vessels close to the fovea coincides with a reduction in astroglial cell density; and supports the hypothesis of a co-occurrence of astrocytes and intraretinal blood vessels, a feature which may be common to all mammals.

59.2 ASTROCYTES IN RAT OPTIC NERVE ARE GENERATED IN A SINGLE WAVE BEFORE OLIGODENDROCYTES. R.P. Skoff and C. Brown*. Dept. of Anatomy and Cell Biology, Wayne State Univ. Sch. of Med., Detroit, MI 48201.

To determine whether astrocytes (AS) in the rat optic nerve (ON) are generated in a single wave before oligodendrocytes (OLS) are formed or whether a second wave of AS formation also occurs after OLS, a series of ^{3}H-thymidine autoradiographic studies were undertaken. Our previous studies of gliogenesis in ON (Skoff,R.P., J. Comp. Neurol., 169: 291 & 313, 1976) indicated that OL formation tapers off sharply by 15 days postnatal (DPN). One set of animals was given daily injections of thymidine from 15 to 19 DPN and sacrificed at 26 DPN, one rat was injected daily from 15 to 19 DPN, 22 and 24 DPN, and another set injected every other daily beginning at 19 DPN and ending at 28 DPN. The rats were perfused, ONs embedded in Araldite and sectioned at 1um for autoradiography. Adjacent thin-thick sections were also prepared so that the type of labelled cells could be definitively determined at the ultrastructural level. Both the orbital and intracranial segments of the ON were examined. Approximately 40 sections were quantitated/animal. Most sections were exposed for 1 month. In ONs from 2 animals, adjacent sections were exposed for either 1 or 2 months.

In the rats injected at 15 DPN, the average no. of labelled cells per section is 7.8. In the rats injected at 19 DPN, the average is 1.1. This change in number indicates that proliferation drops off sharply between 15 and 19 DPN. Since the total no. of glia/section is a little over 300, the low no. of labelled cells shows that only a few percent of glia are generated after 15 DPN. No signifcant differences in the no. of labelled cells were found in the different regions of the nerve nor in the no. of labelled cells exposed for 1 vs 2 months.

At the light level, the vast majority (>90%) of the labelled cells appear to be OLS in different degrees of differentiation. A few labelled AS are present. Ultrastructurally, 30 labelled cells have been identified so far. With the exception of 1 cell, the labelled cells all appear to be OLS. The vast majority have the characteristic features of OLS including stacks of ER, clusters of ribosomes, an eccentric nucleus, etc. Our results indicate that glial proliferation after 15 DPN is minor and that a second wave of astrocytes are not generated after OL formation. In a recent study from Raff's group (Miller, R.H. etal, Dev. Biol., 111:35, 1985), the investigators claimed that type-2 astrocytes, which are akin to fibrous astrocytes, are generated after OLS in a second wave in rat ON. Since the injection schedules in both studies were the same, the discrepancy in results between these two studies might be explained by the method of fixation. Raff's group used mostly frozen sections at the light level while we utilized embedded tissue at light and em level. It is easy to confuse many OLS with AS at the light level, especially OLS which are differentiating at later stages of development, as they often exhibit a moderate density, modest cytoplasm and may be surrounded by AS processes, giving the impression that they may be AS. Indeed, some of the labelled cells we tentatively idetified as AS at the light level have turned out to be OLS at the em level in the adjacent thin section. This and our previous studies of gliogenesis showing AS are generated mostly before OLS has significant implications regarding the time of appearance and lineage of AS in postnatal ON.

59.3 **DEVELOPMENT OF A RAPID BIOLOGICAL ASSAY FOR THE CELL-SURFACE LIGAND, ASTROTACTIN.** T. N. Stitt and M. E. Hatten, Dept. of Pharmacology, New York University Medical School, 550 First Avenue, New York, N. Y. 10016.

In the early postnatal mouse cerebellum, granule neurons migrate along Bergmann glia from the pial surface to their final position in the cortex. Use of an in vitro microculture system in which purified populations of granule neurons and cerebellar astroglia are co-cultured has allowed direct observation of glial-guided neuronal migration and has been used to identify an immune activity, named anti-astrotactin, which blocks neuron-glia interactions in culture (Edmondson et al., J. Cell Biol., in press). An initial step in the further purification and characterization of the astrotactin antigen has been the establishment of a simple and rapid biological assay based on such neuron-glial interactions. As the astrotactin activity is localized to the plasma membrane, granule neuron membranes were used as a probe to monitor astrotactin-dependent binding to a glioma cell line, G26-24, which has previously been shown to bind and differentiate in response to granule neurons.

Purified granule neurons from P7 mouse cerebellum were obtained following a step-gradient centrifugation in Percoll and preplating on polylysine-coated substrata. The granule cells were metabolically labelled with 35S-methionine (100 µCi/ml) for 4 hr and collected. Following incubation in 1 mM zinc chloride for 12 hr at 4°C, the cells were homogenized and a plasma membrane fraction was prepared by centrifugation in a two-phase Dextran-polyethylene glycol gradient. Labelled granule neuron membranes in Ca, Mg-free PBS were added to confluent monolayer cultures of G26-24 glioma cells in 24-well plates and incubated at 37°C. At time points of five minutes to 2 hr later, the wells were shaken vigorously on a rotary platform to remove non-adherent material. The medium and the cell layer were separately harvested and assayed for radioactivity by scintillation counting. By 1 hr of incubation, approximately 70% of the radiolabelled material was found in the cell layer fraction, indicating that the membranes had bound to the glioma monolayer. When the neuron membrane fraction had been pre-incubated in a 1:50 dilution of anti-astrotactin serum raised against cerebellar cells, however, the membrane binding was blocked and nearly all of the labelled material remained in the medium.

The binding of the granule neuron membranes is apparently not due to cell-cell interactions mediated by the adhesion molecules N-CAM or Ng-CAM. Absorption of the astrotactin antiserum with intact PC12 cells, which express both N-CAM and Ng-CAM on their cell surface, did not remove the blocking activity of the serum. The neuron membrane-glioma interaction, then, is dependent on a ligand neutralized specifically by anti-astrotactin. Studies are now being done to tailor this system for use as a blocking assay for other candidate antisera and as a competition assay for astrotactin-like activity in biochemical fractions of cerebellar cells.

These studies have been supported by NIH grant 15429.

59.4 TRANSFERRIN IN OLIGODENDROCYTES OF THE HUMAN CNS. E.S. Wargotz* and J.R. Connor. (SPON: R. Bohn) Depts. of Pathology and Physiology, Geo. Washington Univ. Sch. of Med. Washington DC 20037

Transferrin is an 80,000 MW glycoprotein. It is mainly synthesized in the liver, but an mRNA for transferrin (Tf) is found in a number of organs including the brain. In the brain, the mRNA for Tf is reportedly located in oligodendrocytes [Block et al., (1985) PNAS 88:6706]. Recently, we have reported that Tf is present in oligodendroyctes in the rat and mouse central nervous system. The purpose of this study is to extend our investigation of the cellular localization and distribution of CNS Tf to the human. Human CNS material was obtained at autopsy within 12 hrs post-mortem. Samples of tissue were taken from the precentral gyrus, cerebellum and upper cervical spinal cord and placed into a 10% buffered formalin overnight. The next day the tissue was either cut at 30µM thickness on a Vibratome or processed through 10% and 30% sucrose solution (in Tris buffered saline) and cut at 8 µm on a cryostat. The antisera in this study was either rabbit anti-human Tf (Polysciences) or goat-antihuman Tf (E-Y Labs). Both antisera had an optimal dilution range of 1:750-1:1000. Both the sections cut on the Vibratome and those from the cryostat were processed as follows: 3% H_2O_2, 5% DMSO, serum block, overnight incubation in primary antisera. The immunohistochemistry was accomplished using the Vectastain ABC kit with 3-3'diaminobenzidine as the chromogen. The results of the study demonstrate that oligodendrocytes in both gray and white matter of the human CNS contain Tf. The Tf-positive cells in the gray matter had small, round somata. The reaction product was confined to one area of the soma giving the immunolabeled cells a "cap-like" appearance similar to that seen in rats and mice. White matter immunoreactive cells generally had rectangular somata. The Tf-positive cells rarely had immunoreactive processes. This study extends our finding that Tf is present in oligodendrocytes to the human CNS. Furthermore, these data support the hypotheses that iron and Tf may play a major role in the maintenance of myelin and that oligodendrocytes are involved in regulating iron in the CNS.

59.5 EXTRACELLULAR MATRIX PRODUCTION BY ASTROCYTES AND ITS RELATION TO NEURITE GROWTH. M.D. Ard and R.P. Bunge. Dept. Anatomy & Neurobiology, Washington Univ. Sch. Med., St. Louis, MO 63110.

Astrocytes have previously been shown to produce the extracellular matrix (ECM) molecules heparan sulfate proteoglycan (HSPG) and laminin in vitro (Ard and Bunge, Soc. Neurosci. Abstr. 1986 12:394). Because certain components of ECM are promoters of neurite growth, and astrocytes provide a terrain for neurite growth within the developing CNS, we have asked whether there is a correlation between ECM production by astrocytes and their ability to influence neurite growth. Production of laminin and HSPG by astrocytes was studied by light microscopic (LM) immunocytochemistry and electron microscopy (EM) and was found to be regulated by culture conditions. Astrocytes grown on rat tail collagen in medium with serum for 5 days to 2 weeks exhibited ECM visible by LM and EM. On the other hand, astrocytes grown in defined medium produced no ECM detectable by these methods, and the amount of ECM in serum-containing cultures decreased rapidly upon conversion to defined medium. Long-term (4-6 weeks) growth in serum-containing medium also resulted in a decrease in the amount of HSPG and laminin. In all conditions studied, morphology of the cells changed from flat to stellate in parallel with the decline in HSPG and laminin.

The importance of serum in up-regulating ECM production may not be attributable to the fibronectin content of serum, since addition of 20 ug/ml of purified fibronectin to defined medium did not result in deposition of detectable HSPG or laminin, or change in morphology of the astrocytes.

When fetal rat dorsal root ganglion neurons were cultured on astrocytes, neurite growth was not correlated with ECM production by astrocytes nor with changes in their morphology. Neurites grew on astrocyte surfaces in preference to the rat tail collagen substratum. In serum-containing cultures at 5 days, the few layers of astrocytes present exhibited a small amount of ECM deposited on the substratum and between the cellular processes. Intercellular spaces were small. Neurites were found on the upper surface and between layers of astrocytic processes. After 11 days of culture with serum, there were several layers of astrocyte processes separated by large intercellular spaces or channels containing ECM. Neurites grew within these channels, though not apparently in relation to the ECM. In older (4-6 weeks) cultures in serum, neurites grew both on the upper surface of the astrocytes and between the many layers of astrocytic processes; little ECM was visible between astrocytic processes. In defined medium astrocytes were sparse, but their processes were seen to partially enclose bundles of neurites. Thus the capacity of astrocytes to interact with growing sensory ganglion neurites is not regulated in tandem with production of ECM components as examined in this study. (Supported by NIH NS09923 and a National Multiple Sclerosis Society Fellowship.)

59.6 CEREBELLAR ASTROGLIA SYNTHESIZE BASIC FIBROBLAST GROWTH FACTOR, A PROMOTER OF NEURITE EXTENSION BY GRANULE NEURONS IN VITRO. M.E. Hatten, M. Lynch*, J. Joseph-Silverstein*, D. Moscatelli* and D.B. Rifkin*. Departments of Pharmacology and Cell Biology and the Kaplan Cancer Center, New York University School of Medicine, New York, NY 10016.

When grown in the absence of astroglial cells, purified mouse cerebellar granule neurons survive less than 16 hours and do not differentiate. We have found that basic fibroblast growth factor (bFGF) at low doses 1-25 ng/ml maintains the viability and promotes the differentiation of granule neurons grown under these conditions. This maintenance and differentive activity of bFGF was blocked by antibodies prepared against bFGF.

In mixed microcultures of cerebellar neurons and astroglial cells, the presence of bFGF (1-4 ng/ml) markedly increased the density of granule cell neurites. When affinity-purified antibodies against bFGF were added to these cultures, the amount of process extension by granule neurons was severely impaired. No differences in the pattern of the association of neurons with astroglial cells was seen; granule neurons were located along the arms of the astroglial cells in the microcultures. The inhibition of neurite outgrowth in the presence of anti-FGF antibodies was reversed by the addition of 20 ng/ml of exogenous bFGF.

Immunoprecipitation of ^{35}S-labeled cerebellar astroglial cells with affinity-purified anti-FGF antibodies revealed a single band at 18,000 daltons, the molecular weight of bFGF. These results indicated that glial cells synthesize bFGF and may be an endogenous source of bFGF in cerebellar cultures. Thus, astroglial cells may provide soluble factors needed for neuronal differentiation.

59.7 SCHWANN CELL MITOGEN IN MYELIN STIMULATED MACROPHAGE CONDITIONED MEDIUM MAY BE RELATED TO MYELIN BASIC PROTEIN Baichwal, R.R., Bigbee, J.W., DeVries G.H., Dept. of Biochem. and Mol. Biophys. and Anatomy, Virginia Commomwealth Univ., Richmond, VA 23298

Myelin phagocytosis by infiltrating macrophages during Wallerian degeneration may correlate with Schwann cell proliferation observed in the distal stumps of degenerating nerves. We have previously shown that exogenously added myelin-enriched fraction (MEF) and myelin stimulated macrophage conditioned medium (MCM) are mitogenic to cultured Schwann cells (SCs) (Baichwal et al, Soc. Neurosci. Abstr., Vol 12, p394, 1986). MEF from rat, bovine and human CNS were equally potent in stimulating the production of the mitogenic supernatant indicating a lack of species specificity. Supernatants obtained by the addition of CNS MEF were 2-3 times more mitogenic than those obtained from autologous PNS fractions. Sensitivity of MCM to heat and trypsin suggested that the mitogenic factor may be a polypeptide. CNS-derived supernatants are two to three fold more mitogenic than PNS-derived MCM which is similar to the ratio of myelin basic protein (MBP) in myelin of CNS and PNS. To further test the possibility that the mitogenic factor may be related to MBP, membrane fractions from the mutant mouse shiverer which lacks MBP and proteolipid protein (PLP) were used to produce MCM. Shiverer brain white matter was homogenized and fractionated on a 10-40% linear sucrose gradient to obtain axolemma-enriched fraction (AEF) and MEF as described previously (DeVries et al, J. Neurochem. 40, 1983). Membrane fractions from 29-31% sucrose region which showed highest specific activity for acetylcholinesterase were pooled as AEF. Fractions from 17-19% sucrose region of the gradient were pooled as MEF and lacked MBP and PLP but did contain the Wolfgram proteins when analyzed by SDS PAGE. Direct stimulation of SCs with AEF gave a labelling index (LI) of twenty fold over background while MEF produced only a two fold stimulation. However, SC cultures showed a LI of 0.86% (±0.23%) in response to AEF conditioned medium and 0.30% (±0.06%) in response to MCM, with background levels of stimulation being 0.62% (±0.37%). The lack of SC response to MCM derived from shiverer myelin may indicate that the mitogenic factor may be derived from MEF and may be related to MBP. (Supported by NS15408 and NS10821).

59.8 A NEUROBLASTOMA-DERIVED GROWTH FACTOR FOR OLIGODENDROCYTE PRECURSORS. S.F. Hunter*, M.F. Seidel* and J.E. Bottenstein, Dept. of Pharmacology, Marine Biomedical Institute and Dept. of Human Biological Chemistry & Genetics, University of Texas Medical Branch, Galveston, TX 77550.

There is evidence that neurons and/or axons are influential in the appearance and development of oligodendrocytes (ODC) in vivo, although they have not been shown to be required for development of galactocerebroside-positive (GC^+) ODC in vitro. Chemically defined N4 medium which has been conditioned (CM) for 4 days by B104 rat CNS neuroblastoma cells possesses activity which promotes the proliferation of A2B5-positive ($A2B5^+$) ODC precursor cells in mechanically dissociated neonatal rat brain cultures. Cells are inoculated at 500,000 cells/mm^2 in chemically defined O3 medium on poly-D-lysine and fibronectin-modified culture dishes. O3 medium consists of Dulbecco's modified Eagle's medium (DME) supplemented with 15 μg/ml insulin, 1 μg/ml transferrin, 30 nM sodium selenite, and 10 ng/ml biotin. The activity in the CM is soluble in nature, lyophilizable, sensitive to 100°C or trypsin treatment, and is not ether-extractable. Increases in both $A2B5^+$ and GC^+ cells are observed at 4, 8, 12, and 20 days in vitro (DIV) when 33% B104 CM is added to O3 medium. At 8 DIV the mean densities of $A2B5^+$ cells are increased 4-fold and of GC^+ cells are increased 10-fold. These increases are even greater when compared to DME with 15% calf serum rather than our usual control: O3 medium with 33% unconditioned N4 medium. When considering all of the glial phenotypes present, the percentage of $A2B5^+$ and GC^+ cells in B104 CM treated cultures is about 3.5 times that of control cultures, and the percentage of glial fibrillary acidic protein-positive (GFA^+) Type I astrocytes is about half that of controls. Autoradiography (24 hr ^3H-thymidine pulse) combined with indirect immunofluorescence for these cell surface antigens reveals that 28% of $A2B5^+$ cells and 10% of GC^+ cells are labelled at 4 DIV while 7% and 0% respectively are labelled in control cultures. Mature, morphologically well-differentiated ODC are generally unlabelled, while the less differentiated $A2B5^+$ cells are labelled. Treatment of cells with CM factor partially purified by gel filtration chromatography also results in dose-dependent increases in the densities of $A2B5^+$ and GC^+ cells in O3 medium. Our results are consistent with the hypothesis that the major target of the growth factor is the ODC precursor cell. A similar CNS neuron-derived endogenous factor might be a signal involved in gliogenesis, glial turnover, and/or recovery from demyelinating injury. (Supported by NIH grant NS20375)

59.9 OLIGODENDROGLIAL STEM CELLS ARE INDUCED TO PROLIFERATE ON A "VELATE PROTOPLASMIC" LIKE CEREBELLAR ASTROGLIAL CELL CLONE. N. Delhaye-Bouchaud, F. Alliot and B. Pessac. Centre de Biologie Cellulaire CNRS, 94200 Ivry-sur-Seine, France.

We have previously reported the derivation from 8 PN day mouse cerebella of permanent clonal cell lines with astroglial properties which might be the in vitro counterparts of the Golgi-Bergmann epithelial cells and of the velate protoplasmic astrocytes (Alliot, F. and Pessac, B., Brain Res., 306:283-291, 1984). When neuronal cells from 15 embryonic day cerebella are seeded at low density on monolayers of these astroglial cell lines, 60-80 % survive after 5 days of coculture (Pessac, B. and Alliot, F., Soc. Neurosci. Abstr., vol. 12, Part 1, p. 397, 1986). To investigate whether the Golgi-Bergmann and the velate protoplasmic lines could support the survival of other cell types, single cells were dissociated from the ventral part of 18 embryonic day mouse medulla and were plated on layers of these astroglial clones. A few round cells could be seen on both layers during the first days of coculture. However, very rare foci of these cells appeared only on the velate protoplasmic layers after the 10th day of coculture. These cells proliferated very actively during 2-3 weeks, so that each focus had about 1.5×10^5 cells which were identified as oligodendrocytes by the presence of surface galactocerebrosides and cytoplasmic 2'-3' cyclic nucleotide 3' phosphodiesterase. Similar results were obtained when single cells from embryonic cerebella were plated on the velate protoplasmic astroglial layers. In contrast, when single cells from embryonic mouse medulla or cerebellum were plated on astrocyte-enriched passaged cultures from medulla, cerebellum or cerebral hemispheres, many foci of round cells rapidly appeared, which were composed of about 10^5 oligodendroglial cells.

Taken together, these data show that the ventral medulla and the cerebellum contain very rare stem cells that can actively proliferate in vitro for 15-20 generations with a doubling time of less than 18 hrs and which acquire markers specific for oligodendrocytes. The mitogenic signal responsible for the proliferation of this subset of very rare oligodendroglial stem cells is present in the cerebellar velate protoplasmic astroglial clone but apparently not in astrocyte-enriched cultures from various regions of the CNS.

59.10 EXPRESSION OF PROTO-ONCOGENES *fos* AND *myc* INCREASES AFTER INJURY TO THE FISH OPTIC NERVE: IN VITRO AND IN SITU STUDIES. C. Stein-Izsak, I. Cohen*, M.-F. Chesselet, M. Murray, and M. Schwartz. The Weizmann Institute of Science, Rehovot, Israel and Medical College of Pennsylvania, Philadelphia, Pennsylvania, USA.

CNS injury in a species capable of regeneration causes proliferation and differentiation of the surrounding non-neuronal cells, including the production of factors that appear to stimulate regeneration in mammalian and non-mammalian axons (Schwartz, M. et al., Science 228: 600, 1985). This supports the idea that activated non-neuronal cells might contribute to successful regeneration. Previously, we have shown that mRNA from non-neuronal cells of carp (Cyprimus carpio) optic nerve contains sequences homologous to the oncogenes, *fos* and *myc* (Stein-Izsak, C. et al., Proc. 16th Meet. Soc. Neurosci. 12:12, 1986). We now show that crush injury to the carp optic nerve results in increased proto-oncogene mRNA levels in the non-neuronal cells, evident 1 and 8 days post-operatively. RNA slot blot hybridizations with nick-translated *fos* and *myc* probes showed 2-4 fold increases in *myc* expression 8 days after nerve crush and up to 10-fold increases in *fos* expression, as measured by scanning densitometry of the slot-blot autoradiograms. This increase in proto-oncogene expression in the non-neuronal cells seems not to reflect a general increase in all mRNA species, as hybridization with a tubulin probe showed no increases at the same times.

We used in situ hybridization with single-stranded RNA probes to visualize cells expressing *fos* and *myc* mRNA in the fish optic nerve. The hybridization signal, indicated by silver grains, was much greater in nerve 1 and 8 days post-crush than in intact nerves. More grains were distributed over the distal than over the proximal stump. The cellular distribution of *fos* and *myc* mRNA also appeared to be different, providing a hint as to their possible role in the non-neuronal cell response to injury.

59.11 EFFECTS OF L-GLUTAMATE ON ION TRANSPORT PROCESSES AND SWELLING IN PRIMARY ASTROCYTE CULTURES. H.K. Kimelberg and S. Pang*, Div. of Neurosurgery, Albany Medical College, Albany, N.Y. 12208.

L-glutamate is known to be taken up avidly by astrocytes both in situ and in vitro, and in vitro such uptake is known to be Na^+, and perhaps Cl^- dependent. Application of L-glutamate is also known to cause astroglial swelling in situ and is released during pathological states when astroglial swelling also occurs. Such swelling may have deleterious consequences. The effects of L-glutamate on volume and ion transport in astrocytes is thus of importance and we are studying these processes in primary astrocyte cultures from neonatal rat brain to elucidate potential mechanisms. 10^{-5} to 10^{-4} M L-glutamate directly causes Na^+ dependent depolarization of cells in such cultures (Bowman & Kimelberg, Nature 311:656-659, 1984) and we have found that, in the presence of ouabain, L-glutamate causes cell swelling and increased uptake of $^{22}Na^+$ and $^{36}Cl^-$. In the absence of ouabain L-glutamate causes increased uptake of $^{86}Rb^+$ (used as a K^+ analog), which is also Na^+ dependent as well as being completely ouabain-sensitive. The initial uptake of 10^{-4}M [^{3}H] L-glutamate is not blocked by 1mM ouabain added at the same time as [^{3}H] L-glutamate, but when measured over 10 min. the uptake of 10^{-4}M [^{3}H] glutamate is inhibited by about 50%. We ascribe this to dissipation of the inwardly directed transmembrane Na^+ gradient. Na^+ dependent uptake (95-97% of total [^{3}H] glutamate uptake) of 10^{-4}M [^{3}H] L-glutamate is inhibited by SITS (46%), DL aspartic acid β hydroxamate (63%), β-methyl DL aspartate (77%), DL threo β hydroxy aspartic acid (86%) (values in parentheses refer to % inhibition and concentrations of all inhibitors was 1mM). 1mM DL threo β hydroxy aspartic acid also inhibited 10^{-4}M L-glutamate-stimulated $^{22}Na^+$ uptake. These data are consistent with electrogenic uptake of L-glutamate due to a Na:glutamate ratio of > 1 and that, in the presence of ouabain, intracellular accumulation of Na^+ and Cl^-, which is presumably being co-transported, leads to cell swelling. We have attempted to directly estimate the ratio of increased $^{22}Na^+$ uptake to [^{3}H] L-glutamate taken up. At 10^{-5} to 10^{-4}M L-glutamate we have found ^{22}Na:[^{3}H] glutamate ratios of 2 to 3. These studies were done in the presence of ouabain to eliminate outward pumping of Na^+ but considerable error in the estimation of $^{22}Na^+$ uptake led to some variation in this ratio which appeared to be at least 2. In the absence of ouabain there is clearly stimulation of (Na+K) pump activity as evidenced by increased uptake of $^{86}Rb^+$. Under some pathological conditions we propose that the (Na+K) pump is inhibited and that uptake of Na^+ and Cl^- associated with glutamate uptake and the lessened capacity to pump out accumulated Na^+ is partly responsible for the astroglial swelling observed. (Supported by grant NS23750 from NINCDS).

59.12 EFFECTS OF PENTYLENETETRAZOL (PTZ) ON ION TRANSPORT PROCESSES OF ASTROCYTES IN PRIMARY CULTURE. H. Steve White*, Sandra Reinhold*, Sien Yao Chow* and Dixon M. Woodbury. Dept. of Pharmacology and Toxicology, College of Pharmacy, Univ. of Utah, S.L.C., UT 84112.

In view of the role that has been implicated for astrocytes in regulating extracellular fluid potassium concentration ($[K^+]_o$) during increased neuronal firing and the fact that PTZ increases K^+ flux across epithelial cell types, the aims of the present study were to identify and characterize the effects of PTZ on astrocyte ion transport processes. The effect of PTZ on radioiodide ($^{125}I^-$) and radio-chloride ($^{36}Cl^-$) distribution, Na^+/K^+-ATPase activity and total cell K^+ was determined in mature primary astrocyte cultures derived from the cortices of newborn rats and mice.
