Six male Sprague-Dawley rats received transauricular electroconvulsive shock (ECS group) once daily for a period of one week. Control rats (n=6)(CON) received no ECS. All animals were decaptiated 24h following the time of the last ECS; brains were removed and rapidly frozen in isopentane. Hypothalamic blocks were sectioned at 10 um on a Bright cryostat. ^{35}S-UTP labelled probe complimentary to AVP was prepared with an Sp6 Riboprobe transcription system and hybridized to tissue sections for 48h. Specific activity of probes and hybridization time were calculated to insure that time mRNA-cRNA binding was saturated. Following the hybridization reaction, slides were dipped in Kodak NTB2 emulsion for autoradiography. Emulsion-dipped sections (at 50 um intervals) were coverslipped, digitized and grain density over the PVN, SON and SCN subsequently quantified using Loats Associates RAS 1000 image analysis software.

Analysis revealed an 80% increase in AVP mRNA in the SON of ECS rats relative to the CON group ($p<.01$, ECS vs. CON). Quite surprisingly, no differences were evident in the magnocellular subdivisions of the PVN, whose cells are believed to subserve functions similar to those of SON neurons. In addition, there were no changes in AVP mRNA content in the medial parvocellular subdivisions of the PVN, a region where AVP gene expression is known to be induced following perturbations of the pituitary-adrenal axis. No changes were observed in the SCN. These data suggest that ECS promotes AVP gene expression in a subset of magnocellular AVP neuronal populations, and therefore that magnocellular AVP neurons may be a more physiologically heterogeneous population of neurons than had been heretofore believed. Whether the up-regulation of AVP mRNA in the SON is the result of altered adenohypophysial and/or neurohypophysial function remains to be determined.

165.6 SUBSTANCE P GENE EXPRESSION IN VENTROMEDIAL HYPOTHALAMIC NEURONS OF ESTROGEN-TREATED AND CONTROL RATS ANALYZED BY IN SITU HYBRIDIZATION. G.J. Romano, T.I. Bonner*[1] and D.W. Pfaff. The Rockefeller University, New York, N.Y. 10021 and [1]Laboratory of Cell Biology, NIMH, Bethesda MD 20892.

Neurons in the ventrolateral aspect of the ventromedial nucleus of the hypothalamus (VLVM) mediate some of estrogen's effects on reproductive behavior in the female rat. Approximately 40% of these neurons contain estrogen receptors (Morrell, et al. Exp.Br.Res.,86). Substance P (SP) is present in VLVM neurons and has been shown to facilitate lordosis (Dornan et al., NSci.Abs.,84). Since SP and estrogen receptors are colocalized in the same neurons in the VLVM (Akesson et al., NSci.Abs.,86) we hypothesized that estrogen might regulate the synthesis of SP in this nucleus. To investigate this, we employed in situ hybridization to determine whether estrogen regulates the levels of SP mRNA in the VLVM.

The probe used for in situ hybridization was a [3H] cRNA complementary to nucleotides 1-468 of exon 7 of the rat SP gene. This probe hybridizes to all three SP mRNA species. Hydrolysis of the cRNA resulted in fragments of 50-150 nucleotides. Female rats were ovariectomized, implanted s.c. with 5mm silastic capsules which were either blank (n=3) or filled with 17β-estradiol (E2)(n=3), decapitated 2 weeks later and the brains were frozen on dry ice. Cryostat sections (10 μm) were postfixed in paraformaldehyde, and in situ hybridization was carried out according to the method of Shivers et al. (Meth.Enz.,124,1986). The sections were dipped in emulsion, and exposed at 4°C for 60 days. For analysis, the mediobasal hypothalamus was scanned for labelled cells and the autoradiographic signal was cuantitated in VLVM neurons by grain counting. No labelled neurons were observed in control sections which were RNase digested prior to hybridization or hybridized with probe diluent alone.

While numerous SP mRNA-containing neurons were observed in and adjacent to the VLVM, no significant differences in grain density or in the number of labelled neurons were observed in the VLVM between the E2-treated rats and the ovariectomized controls. Surprisingly, this suggests that estrogen does not directly regulate SP mRNA levels in the VLVM neurons known to contain both SP and estrogen receptors. Although quantification was restricted to the VLVM, we have observed SP mRNA-containing neurons throughout the mediobasal hypothalamus, notably in the dorsal aspect of the ventromedial nucleus, dorsomedial nucleus, lateral hypothalamus and arcuate nucleus. Therefore, these results do not preclude an effect of estrogen on the other populations of SP mRNA-containing neurons in the MBH. The apparent lack of an estrogen effect on SP mRNA in the VLVM is especially interesting in light of our demonstration that estrogen greatly increases proenkephalin mRNA in this nucleus (Romano, et al., NSci.Abs.,86).

165.7 DIFFERENTIAL REGULATON OF PHENYLETHANOLAMINE-N-METHYL TRANSFERASE (PNMT), TYROSINE HYDROXYLASE (TH), AND PROENKEPHALIN (pEK) mRNA LEVELS IN CULTURED BOVINE CHROMAFFIN CELLS BY ACETYLCHOLINE (ACH), DEXAMETHASONE (DEX), FORSKOLINE (FSK), AND TETRABENAZINE (TBZ). M.K. Stachowiak*, R. Slepetis*, J.-S. Hong, O.H. Viveros. (SPON: G. Pollard). LBNT, NIEHS, NIH, P.O. Box 12233, Wellcome Research Laboratories, Research Triangle Park, NC 27709.

Adrenal medullary chromaffin cells contain multiple hormonal substances. In addition to epinephrine and norepinephrine, large amounts of pEK A derived peptides are costored and coreleased with catecholamines (CA). Recently we began to investigate the mechanisms which determine hormonal output from adrenomedullary cells. We have previously shown that the adaptations of the adrenomedullary cells to alterations in transmitter release involve changes in mRNA levels, synthesis, and postranslational processing of CA synthetizing enzymes and pEK. The present studies were undertaken to elucidate the role of ACH, glucocorticoids, cAMP, and CA in the regulation of these processes. Bovine adrenal chromaffin cells were exposed for 3 days to defined medium containing 2 mM Ca++ with FSK (50 uM), TBZ (100 uM), DEX (1 uM) or to ACH (50 uM) with 10 uM physostigmine. Control cultures were supplemented with ethanol (0.05%) and HCl (100 uM). The relative abundances of specific mRNAs were determined by dot blot hybridization and northern analysis using cloned TH, PNMT, and pEK cDNA probes. DEX and ACH treatments increased relative abundance of all 3 mRNAs studied. A 50% increase in PNMT mRNA occured after 24 hours of DEX treatment, whereas the effects of ACH were smaller (+30%) and became apparent at 48 hours. TH and pEK mRNA levels increased by 20-40% after DEX, while changes produced by ACH were 2-3 times larger. Striking dissociations in responses of individual mRNAs to TBZ and FSK were observed. FSK produced over 2 fold increase in both TH and pEK mRNA levels. Decrease in the cell CA content after TBZ was accompanied by a 100% increase in pEK mRNA, and relatively small (+30%) elevation of TH mRNA levels. Most interestingly relative abundance of PNMT mRNA was dramatically reduced by both treatments; over 80% decrease was observed in the presence of TBZ and a 55% decrease in the presence of FSK. Changes after TBZ occured already after 1 day treatment, 24 hours earlier than with FSK, suggesting different mechanisms may be operative for these two agents. These results are consistent with the hypothesis that the effects of ACH on PNMT mRNA levels are not mediated by cAMP or intracellular CA. In conclusion, PNMT, TH, and pEK mRNA levels are differentially controlled by extracellular and intracellular factors. Such differential regulation may provide bases for selective control of the hormonal output from adrenal chromaffin cells.

165.8 EXCESS CORTICOSTERONE INCREASES PREPROENKEPHALIN mRNA LEVELS IN THE RAT HIPPOCAMPUS. R.E. Harlan and M.M. Garcia*. Departments of Anatomy and Pharmacology, Tulane University School of Medicine, New Orleans, LA 70112

A fundamental aspect of the response to stress is secretion of glucocorticoids from the adrenal gland. Glucocorticoids act on a variety of tissues, including the brain. A primary target site for glucocorticoid action in the brain is the hippocampus. We have begun to evaluate the effects of exposure of rats to excess glucocorticoid by determining specific mRNA levels in different brain regions. In an attempt to mimic the glucocorticoid response to chronic stress, we injected 10 mg of corticosterone (N=6), or vehicle (N=5), daily for two weeks. The rats were then decapitated, and the brains were removed rapidly and dissected into caudate-putamen, hippocampus, amygdala and hypothalamus. Samples were frozen on dry ice and stored at -80°C until use. Total RNA was extracted from each sample by the guanidinium isothiocyanate-cesium chloride method. One or 0.5 μg of each sample was dotted onto nitrocellulose by vacuum filtration, then baked in a vacuum oven. The RNA on the nitrocellulose filter was hybridized to a ^{32}P-labeled cDNA complementary to rat preproenkephalin (PPE) mRNA (gift of R. Howells). Hybrids were detected autoradiographically and quantitated by a scanning densitometer.

Results indicate that corticosterone treatment significantly increased PPE mRNA levels in the hippocampus (79% increase, $p < .01$). There was no significant effect of corticosterone on PPE mRNA levels in the amygdala, mediobasal hypothalamus or caudate-putamen. Corticosterone treatment also significantly ($p < .01$) decreased body weights. Dissected brain sample weights did not differ according to treatment group.

These results may implicate peptides derived from proenkephalin in the negative feedback regulation of corticosterone secretion mediated by the hippocampus. In addition, the results may provide insight into altered neuronal responses during stress. Supported by NS24148

165.9 TRANSCRIPTIONAL CONTROL OF ADRENAL CATECHOLAMINE AND OPIATE PEPTIDE TRANSMITTER GENES. E.F. La Gamma, & I.B. Black, SUNY at Stony Brook, 11794 and Cornell University Medical Center, NY, 10021.

In the rat, decreasing transsynaptic activity through adrenal denervation, nicotinic receptor blockade, or explantation is associated with an increase in preproenkephalin mRNA, enkephalin prohormone and peptide. In contrast, catecholamine pathways remain unchanged under similar conditions. Conversely, membrane depolarization, increased sodium or calcium ion flux, or increased intracellular levels of cAMP, all serve to inhibit enkephalin biosynthesis, lowering levels of preproenkephalin mRNA, prohormone, and peptide (see La Gamma et al., Annals NY Acad. Sci., 1987). It is not known whether changes in messenger RNA result from stabilization or increased synthesis. To begin to resolve this issue, we exploited transcription "run-off" assays to measure the rate of transmitter gene read out. Tyrosine hydroxylase message (TH-mRNA) was found to be the most abundantlty produced transcript in the unmanipulated control rat adrenal medulla. TH-mRNA was produced in excess of twice the rate of transcription of the structural gene actin. In contrast, preproenkephalin transcription occurred at a much lower rate (60% of the actin gene and only 25% of tyrosine hydroxylase gene transcription). All transcripts were inhibted by the polymerase II inhibitor, alpha-amanitin. After two days in explant culture, the rate of enkphalin transcription increased approximately 2-fold (to the same level as actin transcription); while tyrosine hydroxylase transcriptional activity fell to 30% of actin levels. Then, to analyze cellular mechanisms, explants were depolarized with potassium chloride. Enkephalin gene transcription was observed to be 2.5-fold less when grown under depolarizing conditions than in control explants. On the otherhand, tyrosine hydroxylase gene read-out was unchanged, similar to results obtained when TH catalytic activity was measured. These data indicate that membrane depolarization can selectively regulate expression of a transmitter gene product and are consistent with a proposed transsynaptic regulatory mechanism controlling biosynthesis of adrenal opiate peptides. Additionally, these observations represent a molecular mechanism through which physiologically relevant stimuli can modify transmitter expression to alter neurohumoral function or transmitter pheontypic plasticity.

165.10 REVERSE TRANSCRIPTION OF MESSENGER RNA IN FIXED TISSUE SECTIONS. L.H. Tecott, J.D. Barchas and J.H. Eberwine. Nancy Pritzker Laboratory, Department of Psychiatry and Behavioral Sciences, Stanford University, Stanford, California 94305.

A method is under development in which the synthesis of DNA complementary to a specific mRNA is achieved in fixed tissue sections. The in situ transcription (IST) procedure is an extension of in situ hybridization (ISH) technology. An oligonucleotide complementary to an mRNA of interest is hybridized in situ and serves as a primer for the polymerase activity of the enzyme reverse transcriptase. Using the mRNA as a template, a complementary radiolabeled DNA strand may be synthesized. This strand will remain hybridized to the mRNA and may thus enhance the ISH signals obtainable with oligonucleotide probes. In addition, the IST procedure may provide information regarding the translational state of mRNA.

A 36-mer was synthesized complementary to the sequence coding for amino acids 100-111 of rat proopiomelanocortin (POMC). The unlabeled oligonucleotide was hybridized in situ to 10 micron paraformaldehyde-postfixed cryostat sections of rat pituitary. Following hybridization and washes, transcription was performed on the tissue sections in reverse transcriptase buffer in the presence of radiolabeled deoxynucleotides. Following reverse transcription, sections were washed, dehydrated through an ethanol series and exposed to X-ray film.

The IST procedure resulted in intense hybridization signals in the intermediate lobe, requiring very brief film exposures (10 min). Heat inactivation of the reverse transcriptase enzyme prior to the reaction eliminated the signal. The signal was also eliminated by omission of the oligonucleotide primer and by substitution of a heterologous oligonucleotide of similar length and base composition. Prior treatment of rats with 4 daily i.p. doses of 3 mg/kg haloperidol resulted in increased intermediate lobe signals relative to controls, consistent with known effects of the drug on POMC mRNA levels.

The above results indicate that the IST signal is enzyme-dependent and primer-specific. The regional pattern of signal and its haloperidol-induced increase provide support for the specificity of the method. The signal intensity produced by the method suggests its potential usefulness for the detection of low-abundance messages. We are currently investigating the utility of the method as a means for the nonisotopic detection of in situ hybrids. (NIDA 01207 and NIMH 23861.)

165.11 REGULATION OF G-PROTEIN mRNA LEVELS IN ACTH/ENDORPHIN-PRODUCING PITUITARY CELLS. E.A. Thiele*, R.R. Reed* & B.A. Eipper. Dept. of Neuroscience, Johns Hopkins Univ. Sch. of Med., Baltimore, MD 21205

Guanine nucleotide-binding proteins (G proteins) are essential components of various signal transduction systems, including the adenylate cyclase/cAMP system. We find significant alterations in G protein mRNA levels in AtT-20 cells and rat neurointermediate pituitary lobes in response to agents affecting secretion, suggesting that regulation of G protein levels may be an important mechanism in determining the responsiveness of a cell to stimuli.

In AtT-20/D16v mouse corticotrope tumor cells, corticotropin releasing factor (CRF), vasoactive intestinal peptide (VIP) and β-adrenergic agonists stimulate the synthesis and secretion of pro-ACTH/endorphin (PAE) by increasing adenylate cyclase activity. Pretreatment of AtT-20 cells with dexamethasone (DEX), a synthetic glucocorticoid, suppresses this stimulation. In intermediate pituitary melanotropes the synthesis and secretion of PAE are inhibited by dopamine via inhibition of adenylate cyclase.

The cDNAs corresponding to $G\alpha_s$, $G\alpha_i$, and $G\beta$ were obtained from a rat olfactory bulb cDNA library (D. Jones and R.R. Reed, manuscript submitted) and used to probe total cellular RNA on Northern blots. AtT-20 cells contained RNA species hybridizing with cDNA for $G\alpha_s$, $G\alpha_i$, $G\beta$. Rat neurointermediate pituitary contained RNA species hybridizing with cDNAs for $G\alpha_s$ and $G\alpha_i$; $G\beta$ mRNA was not detected in the rat neurointermediate pituitary.

AtT-20 cells were treated with 100 nM CRF for 4 hours, or with 1 μM DEX for 2 days. CRF treated cells exhibited a 1.5-fold increase in secretory rate of PAE-derived peptides and DEX treated cells exhibited a 3-fold decrease. Northern analysis indicated parallel changes in PAE mRNA. $G\alpha_s$ and $G\alpha_i$ mRNA levels increased several-fold in the CRF treated cells. The increase in $G\beta$ mRNA levels was smaller but still significant. In DEX treated cells, there were similar, although less dramatic, increases in the levels of all three G protein mRNA levels. Cholera toxin and pertussis toxin treatment of AtT-20 cells both decreased G protein mRNA levels.

To investigate possible regulation of G protein mRNA levels in the neurointermediate pituitary lobe, adult male rats were treated for 3 weeks with bromocriptine (1 mg/kg/day) or haloperidol (2 mg/kg/day). Neurointermediate lobes were removed, and extracted for peptides or total cellular RNA. Radioimmunoassay indicated a 5.3-fold decrease in PAE content following bromocriptine treatment and a 2.3-fold increase following haloperidol treatment. PAE mRNA levels showed parallel changes. Following bromocriptine treatment there was a decrease in levels of $G\alpha_s$ mRNA, and no apparent change in levels of $G\alpha_i$ mRNA. Following haloperidol treatment there was a significant increase in $G\alpha_s$ mRNA levels and a decrease in $G\alpha_i$ mRNA levels.

165.12 HORMONAL MODULATIONS OF VIP GENE TRANSCRIPTS: I. Gozes and F. Baldino, Jr. Department of Hormone Research, The Weizmann Institute of Science Rehovot 76100, Israel and Neurobiology Group, Medical Products Department E.I. du Pont de Nemours and Co., Wilmington, Delaware 19898, U.S.A

VIP-vasoactive intestinal peptide is a widely distributed multifunctional neuromodulator. As a neurohormone VIP has been proposed as an inducer of prolactin release. A sensitive RNA detection assay which utilizes in vitro transcribed RNA probes corresponding to specific exons of the VIP gene identified a 2,000-base long RNA encoding VIP. This RNA also contains the coding sequences for the VIP-related peptide PHM/I (peptide histidine methionine amide or isoleucine amide). During lactation a two fold increase in the hypothalamic VIP mRNA was demonstrated (Gozes, I. and Shani, Y. Endocrinology 119, 2497, 1986. To precisely localize the hypothalamic areas involved and more particularly the cells associated with the changes in VIP-PHM/I gene activity an in situ hybridization histochemical procedure was adapted which employs either radioiodinated or ^{35}S-labeled synthetic oligodeoxynucleotide probes (Card, J.P., Fitzpatrick-McElligott, S., Gozes, I. and Baldino, F. Jr., submitted for publication). Our in situ hybridization results show a most pronounced increase in VIP and PHM/I transcripts during lactation in the suprachiasmatic nucleus as well as in the thalamus areas not directly involved in the regulation of pituitary hormone secretion. Thus, an indirect role for VIP gene products additional to the prolactin releasing activity is suggested. The modulation of VIP gene transcripts during lactation may be associated with alteration of steroid levels at this period which in turn may interact directly with steroid binding sites on the VIP gene (Gozes, I., Giladi, E., Shani, Y., Chao, H.M., McEwen, B.S. and Rostène, W.H., submitted for publication, Gozes, I., Werner, H., Fawzi, M., Shani, Y. and Koch, Y., in preparation, and Gozes, I. (1987) In: Krieger - Brain Peptides Update, Martin & Brownstein, eds., Chapter 10).

166.1 FASTING INCREASES AND REFEEDING REINSTATES NEUROPEPTIDE Y (NPY) CONCENTRATIONS IN THE PARAVENTRICULAR NUCLEUS (PVN). A. Sahu*, S.P. Kalra and P.S. Kalra, Dept. OB-Gyn, Univ. Fla., Col. Med., Gainesville, FL 32610

We have shown that a bolus intraventricular injection of NPY elicits a robust feeding response lasting 120 min and continuous NPY infusion provokes an episodic feeding pattern in satiated rats in a manner seen during the night when rats normally eat. To demonstrate further that NPY may be a physiological neurochemical signal that normally activates feeding, we have studied the effects on NPY concentrations in various brain sites either of fasting (F) for 2, 3 or 4 days to increase appetite or in rats fasted for 4 days and allowed ad libitum (FA) access to rat chow for one day to reinstate satiety. Male rats were decapitated and various hypothalamic sites were microdissected by the technique of Palkovits and processed for measurement of NPY immunoreactivity by RIA. The hypothalamic sites selected were those shown previously to be innervated by NPY neurons and implicated in the control of feeding behavior. Water was available ad libitum throughout the experiment. Body weight decreased as a function of time of fasting by 26% and regained 12% after 1 day of free access to rat chow. The arcuate nucleus, rich in NPY perikarya, showed a progressive increase in NPY concentrations during food deprivation (Control (C): 103 ± 9; F2d: 114 ± 4; F3d: 184 ± 26; F4d: 221 ± 18; pg/µg protein, F = 13.542, ANOVA) and the levels remained elevated even in the FA group (243 ± 15). However, two types of responses in NPY concentrations were seen in those regions that are either sparsely or richly innervated by projections of NPY perikarya located in the arcuate nucleus. NPY concentrations in the median eminence and dorso- and ventromedial nucleus remained unchanged in response to either food deprivation or followed by free access to rat chow. Likewise, fasting failed to change NPY levels in the medial preoptic area, but surprisingly, availability of rat chow for one day after 4 days of fasting significantly increased NPY levels (C: 45 ± 2.7; FA: 82 ± 6.4, $p < 0.05$). In contrast, in the PVN, a site implicated in the control of feeding behavior and richly innervated by NPY neurons, NPY levels increased significantly in response to food deprivation. The NPY increments were apparent within two days and continued to rise in a time-related fashion for 4 days of fasting (C: 63 ± 12; F2d: 97 ± 21; F3d: 137 ± 18; F4d: 169 ± 17; pg/µg protein, F = 4.736, ANOVA) and fell precipitously in FA rats (86 ± 16, $p < 0.05$) and returned to the range found in satiated control rats. Thus, these results show for the first time that hunger and satiety evoke regionally specific reciprocal changes in the secretory function of NPY innervations in a site implicated in control of feeding behavior. Consequently, these findings strongly imply that NPY may be a physiological neurochemical signal that normally evokes the eating response. (Supported by NIH DK 37273).

166.2 CONTINUOUS INTRAVENTRICULAR INFUSION OF NEUROPEPTIDE Y (NPY) EVOKES EPISODIC FOOD INTAKE IN SATIATED FEMALE RATS: EFFECTS OF ADRENALECTOMY AND CHOLECYSTOKININ (CCK). S.P. Kalra, M.G. Dube* and P.S. Kalra, Dept. OB-Gyn, Univ. Fla. Col. Med., Gainesville, FL 32610

We have reported that a bolus intraventricular injection of NPY stimulated components of feeding behavior in male and female rats. We have now studied the effects on feeding behavior of continuous intraventricular infusion of 117, 470 or 1175 pmol/h for 4 h and for 2 h postinfusion in satiated female rats. The components of feeding behavior analyzed were: cumulative food intake, number of feeding episodes, mean episode length, total time eating, eating rate (g/min) and interepisode interval. Rats were implanted with permanent cannulae in the third ventricle of the brain and 6-14 days later they were connected to an infusion assembly on the morning of the experiment. Saline (18 µl/h) or various concentrations of NPY in saline were infused for 4 h. Only 1 of the 6 saline-infused control rats displayed some feeding (0.7 g) which consisted of 4 episodes of an average 33 sec duration, and 2.2 min total feeding time. In contrast, a dose-dependent stimulation of all components of feeding behavior monitored was seen with 117 and 470 pmol/h NPY infusion rates; at 1175 pmol/h rate, NPY produced a plateau effect. In addition, despite continuous NPY receptor activation, these rats displayed discrete episodes of feeding, the duration of which varied from a mean of 50 sec to 170 sec/rat. The episodes were interrupted mostly by grooming, drinking and exploratory behavior and to a lesser extent by restful postures and sleeping. Moreover, the elicitation of feeding episodes was dose-dependent as from a mere 4 episodes seen in saline-infused or 117 pmol/h NPY-infused rats, they increased characteristically to 40 after 1175 pmol/h NPY infusion. Remarkably, the incremental pattern of food intake was sustained during the 2 h post-NPY infusion period. CCK (1175 pmol/h) infused concurrently with NPY (470 or 1175 pmol/h) failed to block the NPY stimulation of any parameters of feeding monitored. In contrast, adrenalectomy dramatically attenuated ($p < 0.05$) the cumulative food intake by 50% in rats receiving NPY at the hourly rate of 470 pmol, this attenuation was apparent only during the 3rd and 4th h of NPY infusion. Further analysis showed that the reduction in food consumption was due to a dramatic increase in the interepisode interval ($p < 0.05$) resulting in significant decrease (> 50%) in the number of feeding episodes and in time spent feeding. Therefore, these studies show for the first time that continuous central NPY receptor activation can evoke episodic pattern of feeding behavior which is not blocked by the putative satiety influence of CCK. Adrenalectomy attenuated, but did not eliminate food consumption and affected the inter episode intervals and related feeding parameters. In summary, our findings of episodic feeding behavior in response to continuous NPY infusion taken together with the observations (reported elsewhere) of changes in NPY levels occurring specifically in the paraventricular nucleus in response to food deprivation, and augmentation of ongoing feeding response by NPY administration during the night, support the hypothesis that NPY may be a physiological neurochemical signal that normally activates the feeding response. (Supported by NIH DK 37273).

166.3 INTRAVENTRICULAR (IVT) ADMINISTRATION OF NEUROPEPTIDE Y BOTH INCREASES FOOD INTAKE AND CAUSES CONDITIONED TASTE AVERSIONS. A. J. Sipols*, D. J. Brief, K. Ginter*, S. Saghafi*, and S. C. Woods. Department of Psychology, University of Washington, Seattle, WA 98195.

Neuropeptide Y (NPY), a 41-amino acid peptide found in the brain and the gut, elicits rapid and large increases of food intake when administered in microgram quantities into either the cerebrospinal fluid or the paraventricular nuclei in rats. Preliminary work in our lab revealed that as the dose of IVT NPY is increased, food intake may actually decrease. The purpose of this experiment, therefore, was to determine if NPY might cause the formation of food aversions in addition to enhancing meal size. Male Long-Evans rats (N=8) were surgically implanted with cannulas aimed at the third cerebral ventricle. Patency and location within the ventricle were assured when each subject consumed at least 10 ml of water within 2 hours following IVT administration of carbachol. Rats were food-deprived 6 hours daily. Food was then presented and intake recorded over the subsequent hour. Following stabilization of intake after IVT saline, all animals were administered 9.5 µg NPY. Food intake increased 44.9 +/- 8.6% ($p<.01$, paired t-test) over the previous saline day. The animals were then adapted to a schedule of ad lib food. Water was available only 20 min/day. Following water intake stabilization (11 days), a novel aqueous solution of non-caloric lime-flavored Koolaid was offered instead of water. After 20 minutes, half the rats were injected with saline IVT and half with 9.5 µg NPY. On the subsequent day, all subjects were presented with a two-bottle choice of lime Koolaid vs. water. Animals receiving NPY drank significantly ($p<.01$, t-test) less Koolaid (12.4 +/- 3.1% of total intake as Koolaid) than animals receiving saline on the previous day (50.0 +/- 4.7%), with no reliable difference of total intake between the two groups. These results indicate that NPY causes at least two consequences associated with ingestion. Through one IVT cannula, it both stimulates food intake and causes the formation of a flavor aversion depending upon the paradigm.

166.4 INTRAVENTRICULAR NEUROPEPTIDE Y INJECTIONS STIMULATE FOOD INTAKE IN LEAN, BUT NOT OBESE ZUCKER RATS. D.J. Brief ,A. Sipols*, K. Ginter*,D. Amend*,& S.C. Woods. U. of Washington, Dept. of Psychology, NI-25, Seattle WA 98195.

Intraventricular and intrahypothalamic injections of neuropeptide Y (NPY) increase food and water intake in satiated rats. Because NPY receptors exist in many areas of the brain containing insulin receptors, and because obese Zucker rats have relatively few insulin receptors in the brain and do not alter food intake in response to intraventricular insulin administration, we injected either saline or NPY (.95, 3.0, 9.5, & 30.0 µg/rat) into the third ventricle of satiated homozygous fat (fa/fa), heterozygous lean (Fa/fa), and homozygous lean (Fa/Fa) Zucker rats and measured food and water intake at 1, 4, and 22 hours postinjection.

Neither .95 nor 30.0 µg NPY had any effect on food or water intake in any group. However, a significant ($p \leq .05$) increase of food intake was observed in Fa/Fa rats at 1 and 4 hours after 3.0 µg NPY and at 1, 4, and 22 hours after 9.5 µg NPY. Both 3.0 and 9.5 µg injections of NPY also increased 1 and 4 hour food intake in Fa/fa rats above intake following saline, but this increase was only significant ($p \leq .05$) 4 hours after 3.0 µg NPY. In constrast, there was no effect on food intake of fa/fa rats at any dose of NPY.

The only significant increases in water intake occurred in Fa/fa rats 1 hour after a 3.0 µg injection ($p \leq .05$) and in Fa/Fa rats 4 hours after a 3.0 µg injection ($p \leq .05$).

Lean Zucker rats, like rats of other strains, have elevated food intake following intraventricular injections of NPY. Obese Zucker rats, however, show a similar lack of response to the effects of centrally administered insulin and NPY on food intake. These results are consistent with the hypothesis that NPY and insulin receptors may interact to influence food intake.

166.5 CCK RECEPTOR BINDING IN THE PYLORUS OF GENETICALLY OBESE MICE (ob/ob). A. J. Strohmayer, D. Greenberg, T. Moran, and P. McHugh. Depts. of Psychiatry, Cornell Univ. Med. Coll., Manhasset, NY 11030 and Johns Hopkins School of Med., Baltimore, MD 21205

The hyperphagia of the genetically obese mouse (ob/ob) has been characterized as increased meal size and abnormal satiety behavior (Strohmayer & Smith, Physiol. & Behav. 22:1157-62, 1979). Cholecystokinin (CCK) has been shown to be a satiety peptide which reduces meal size and stimulates behavioral satiety (Smith & Gibbs, Ann. NY Acad. Sci. 448:417-423, 1985). An attractive hypothesis is that ob/ob mice either do not make or release active CCK in response to food stimuli or that receptor or effector mechanisms are dysfunctional. Strohmayer & Smith, (Brain Res. Bull. 17:571-73, 1986) have demonstrated that exogenous CCK administration was effective in reducing meal size and restoring some satiety behavior with appropriate equal sensitivity between obese and lean mice (2 ug. kg). However, this dose may be supra-physiological. Moran and McHugh (AJP, 242: R 491-97, 1982) have suggested a possible mechanism for CCK satiety is stimulation of pyloric constriction via CCK receptors increasing gastric distension. In order to determine if these receptors were intact in ob/ob mice, we compared the specific binding of CCK-33 in the pylorus of obese and lean mice. Specimens of the pyloric junction were obtained from 3 obese and 4 lean male mice frozen in methyl butane and 25 micron tissue sections were prepared with I^{125} labelled CCK-33 with or without 1u molar cold CCK-8, (Brain Research, 362:175-179, 1986). Autoradiographic images were quantified using a computer microdensitometry system. Specific binding (the difference between images with or without cold CCK-8) is reported as units of relative optical density.

The median specific binding for obese mice was .478 (range .406-.648) vs .229 (range .147-.343) for lean mice. Thus there was greater binding for the obese mice ($p = .028$ by Mann-Whitney U Test). We can conclude CCK receptors are present and bind CCK in obese mice. The increase in specific binding is consistent with an up regulation suggesting lower endogenous levels of active CCK in the obese mouse. Further experiments will attempt to measure endogenous CCK release.

166.6 TOTAL ABDOMINAL VAGOTOMY, BUT NOT GASTRIC OR HEPATIC VAGOTOMY, BLOCKS THE SYNERGISTIC SATIETY EFFECT OF SIMULTANEOUS INJECTION OF PANCREATIC GLUCAGON AND CHOLECYSTOKININ ON SHAM FEEDING. J. LeSauter* Z. Pap* M.K. Albertson* & N. Geary. Dep't. Psychology, Columbia Univ., New York, NY 10027.

Simultaneous intraperitoneal injection of pancreatic glucagon (PG) and cholecystokinin (CCK) inhibits rats' sham intake of milk more than the sum of the inhibitions elicited by the peptides individually (LeSauter et al., Soc. Neurosci. Abstr. 11: 38, 1985). To investigate the peripheral neural mechanism of this synergism, we tested the effects of PG and CCK alone and in combination after selective hepatic or gastric vagotomy or total abdominal vagotomy. Rats with chronic gastric cannulas were maintained on Purina chow ad lib and sham fed condensed milk. Simultaneous injection of CCK and PG still elicited large inhibitions of sham feeding after either selective vagotomy:

Mean ± SEM % Inhibition of 30 min Sham Intake

	PG 400 µg/kg	CCK 0.3 µg/kg	PG + CCK
Surg. Control (n=8)	7 ± 10	34 ± 13*	74 ± 13*
Hepatic Vagox (n=8)	-2 ± 6	44 ± 10*	73 ± 6*
Surg. Control (n=6)	12 ± 3	25 ± 15	53 ± 11*
Gastric Vagox (n=7)	7 ± 5	25 ± 17	75 ± 15*

*Inhibition of sham feeding, $p < .01$, Tukey's test after ANOVA.

In contrast, total abdominal vagotomy greatly attenuated, but did not entirely block, the inhibitory effect of simultaneous PG and CCK:

Mean ± SEM % Inhibition of 30 min Sham Intake

	PG 400	CCK 0.15	CCK 0.30	PG + .15 CCK	PG + .3 CCK
Surg. Contr (n=7)	7 ± 5	32 ± 8	58 ± 10*	65 ± 13*#	73 ±12*
Total Vagox (n=5)	15 ± 18	-5 ± 6	-5 ± 7¢	19 ± 10¢	29 ±13*¢

*Inhibition of sham feeding, $p < .05$, Tukey's test after ANOVA.
#$p < .08$ vs. sum of PG alone and CCK alone.
¢Smaller inhibition than surgical controls, $p < .01$.

These results suggest that subdiaphragmatic vagal neural traffic is necessary for the synergistic inhibition of sham feeding elicited by PG and CCK, but that neither the hepatic branch nor the gastric branch alone is necessary. Two possibilities are that coeliac vagal fibers mediate the synergism or that the hepatic and gastric branches provide redundant contributions that are each sufficient to mediate the synergism. This contrasts with the reported dependence of the satiety effect on real feeding of CCK on the gastric branch (Smith et al., Science 213: 1036, 1981) and of PG on the hepatic branch (Geary and Smith, Physiol. Behav. 31: 391, 1983).

166.7 DIFFERENTIAL POTENCY OF FOUR ANTAGONISTS OF CHOLECYSTOKININ (CCK) FOR THE PYLORIC, PANCREATIC, AND SATIATING EFFECTS OF CCK-8. R.B. Murphy, G. Haraminian#, L.H. Schneider, and G.P. Smith. Department of Psychiatry, New York Hospital-Cornell Medical Center, White Plains, NY 10605, and Department of Chemistry, New York University, New York, NY 10003

Receptors for CCK in the pyloric sphincter, abdominal vagus, and hindbrain are candidates for mediating the satiating potency of peripherally administered CCK. In order to identify which of these candidate populations are involved, we have examined the potency of 4 CCK antagonists to inhibit contraction induced by CCK-8 at a half-maximal dose (8×10^{-10} M) in the isolated rat pyloric sphincter (Murphy et al Peptides 8: 127, 1987), and compared the results to the reported potency of these compounds to reverse the inhibition of CCK-8-induced satiety in the rat (Schneider et al, in press) and to antagonize the effect of CCK-8 on pancreatic acinar cells (Niederau et al, Am. J. Physiol. 251:G856, 1986; Jensen et al, Am. J. Physiol. 249:G214, 1985; Chang and Lotti, P.N.A.S. 83:4923, 1986).

Results

Drug	Pyloric IC_{50} (M)	Relative Potencies: Pylorus	Acinar Cell	Satiety
Proglumide	1×10^{-3}	1	1	1
PGDPA	$4 \pm 0.5 \times 10^{-6}$	250	133	1000
CR-1409	$5 \pm 1 \times 10^{-7}$	2000	4000	1000
L-364,718	$4 \pm 2 \times 10^{-9}$	250,000	800,000	100,000

Discussion. Pyloric and pancreatic acinar cell receptor populations have very similar absolute and rank-ordered potencies for the 4 antagonists. These potencies are also similar to those found for the inhibition of CCK-8-induced satiety, except for that of PGDPA which is considerably more potent for antagoninizing CCK-8-induced satiety than it is in the pyloric sphincter or on the pancreatic acinar cell. The differential potency of PGDPA suggests that although CCK receptors in the rat pyloric sphincter and/or pancreatic acinar cells could contribute to CCK-8-induced satiety, additional receptor populations or control mechanisms are also involved. Supported in part by RSA MH00149, MH40010.

166.8 L-364,718 ABOLISHES THE INHIBITION OF FOOD INTAKE INDUCED BY CCK-8 IN RATS. L.H. Schneider, R.B. Murphy, P.M. Perez# and G.P. Smith. Dept. of Psychiatry, Eating Disorders Inst. and Bourne Lab, NY Hospital-Cornell Med. Ctr., White Plains, NY 10605 and Dept. of Chemistry, New York University, NY, NY 10003.

L-364,718 is presently the most potent antagonist of cholecystokinin octapeptide (CCK-8) in vitro (Chang & Lotti, 1986). We investigated L-364,718 for its potency to antagonize the inhibition of food intake produced by exogenous CCK-8.

Methods. 44 male Sprague-Dawley rats were adapted to 30-min access to sweet milk after an 18h food deprivation and ip injections at -15 and -5 min. They were tested with vehicle + saline on Mondays, Tuesdays, and Thursdays, and with vehicle + CCK-8 (8 mcg/kg) on Wednesday. The purpose of the Wednesday test was to assure that the inhibitory effect of CCK-8 on food intake was balanced across the Friday test groups. On Fridays, 4 groups of 11 rats each received CCK-8 (8 mcg/kg)and one of the following doses of L-364,718: 0 (the control group); 2, 20, 200 pg/kg; 2, 20, 200 ng/kg; 2, 20, 200 mcg/kg. We also tested the effect of 200 mcg/kg of L-364,718 on the inhibition of food intake produced by bombesin (12 mcg/kg; n=11).

Results. L-364,718 antagonized the inhibition of food intake produced by CCK-8 in a dose-related manner [$F(9,90)=10.56$; $p<.01$]. Doses of L-364,718 of 2, 20, and 200 mcg/kg completely reversed the effect of CCK-8; mean (±SE)% inhibition of baseline intake (vehicle + saline, ip) was 3.4 (6.2), 4.9 (6.0) and -13.7 (5.7), respectively, as compared with 55.9 (3.3) in the control group. The lowest dose that produced a reliable partial reversal of the effect of CCK-8 was 200 ng/kg (28.0±7.3% inhibition; $p<.05$ Dunnett's t-test, 2-tailed). The highest dose of L-364,718 did not antagonize (42.8±5.8%) the inhibitory effect of bombesin (12 mcg/kg) on food intake (49.7±9.8%).

Conclusions. L-364,718 is the most potent antagonist of the inhibition of food intake produced by exogenous CCK-8 we have tested, being about 100,000 times more potent than proglumide and about 100 times more potent than the two proglumide analogues PGDPA and CR-1409 (Schneider et al, 1986, 1987) under our experimental conditions. We confirmed that L-364,718 is selective for reversing CCK-8, but not bombesin, induced satiety. Our results indicate a much higher potency than that reported in a recent abstract (Hanson and Strouse, 1987) that L-364,718 administered p.o. (ED50=334 mcg/kg) antagonized CCK-8 induced satiety (12 mcg/kg), in rats, even when taking account of several differences in experimental conditions.

Given its behavioral potency and selectivity, we conclude that L-364,718 will be a valuable probe into further investigations of a role of endogenous CCK in normal satiety mechanisms.

166.9 SOMATOSTATIN AND GLUCAGON BLOCK THE INHIBITORY EFFECT OF CCK8 ON FOOD INTAKE IN DOGS. T.J. Kalogeris*, R.D. Reidelberger*, T.E. Solomon* and V.E. Mendel (SPON: V.V. St. Omer). Depts. of Medicine and Physiology, University of Missouri Medical School and Truman V.A. Hospital, Columbia, MO 65201.

We studied the dose-response effects of somatostatin and glucagon alone and in combination with CCK8 on food intake in dogs. Seven pure-bred beagles were adapted to ad libitum access to solid food for 18 h followed by a 4 h food deprivation prior to a one hour test session. In one feeding study dogs received intravenous infusions of somatostatin (0, 40, 400, 4000 pmol/kg-h, one dose per day) for 15 min prior to presentation of the test meal and during the subsequent 45 min feeding period. No effect on feeding was observed except at 4000 pmol/kg-h which increased 45 min meal size by 21%. In a second study, a similar dose range of somatostatin was tested in combination with each of three doses of CCK8 (0, 50, 400 pmol/kg-h). In the absence of somatostatin, CCK8 at 50 pmol/kg-h did not affect food intake, whereas CCK8 at 400 pmol/kg-h depressed food intake by 55%. This inhibition was blocked at all doses of somatostatin tested. Combination of a physiologic dose of CCK8 (50 pmol/kg-h, which alone is subthreshold for inhibition of feeding) with any dose of somatostatin did not affect food intake. Somatostatin alone at 4000 pmol/kg-h increased food intake by 60%. In a third study the effects of glucagon (0, 50, 500, 5000 pmol/kg-h) in combination with each of three doses of CCK8 (0, 50, 400 pmol/kg-h) on food intake were tested. Infusions were given for 25 min prior to and during the subsequent 35 min feeding period. When glucagon was given in combination with 0 and 50 pmol/kg-h of CCK8, food intake was not affected. At 400 pmol/kg-h, CCK8 alone depressed food intake by 53%; glucagon produced a dose-dependent attenuation of this effect. Insofar as a potential endocrine role for these peptides in the control of food intake in dogs is concerned, these results demonstrate: 1. physiologic intravenous doses of CCK8, somatostatin and glucagon alone, and combinations of CCK8 and somatostatin or CCK8 and glucagon do not inhibit food intake; 2. somatostatin and glucagon each block the inhibition of food intake caused by a supraphysiologic dose of CCK8; and 3. somatostatin alone increases food intake at a supraphysiologic dose.

166.10 **INHIBITORY EFFECTS OF CHOLECYSTOKININ DEVELOP THROUGH INTERACTION WITH ABDOMINAL SIGNALS.** **J.E. Cox & M.J. Smith*, Dept. Psychology, Univ. Alabama at Birmingham, Birmingham, AL 35294.**

We sought to further specify the nature of the interaction between cholecystokinin (CCK) and feeding-contingent signals in decreasing feeding motivation. Our previous research revealed large decrements in runway performance if tests were preceded by the combination of 0.25 - 1.0 ug/kg CCK-8 and prefeeding of 30% sucrose (Cox, Behav. Brain Res., 21, 29, 1986). We have subsequently assessed the effectiveness of sham feeding (SF) and intragastric feeding (GF) for reproducing the capacity of normal prefeeding to interact with CCK-8.

Male Sprague-Dawley rats underwent surgery for gastric implantation of stainless steel cannulas for SF (N=7) and silastic catheters for GF (N=5). All test protocols included 21 h food deprivation, a prefeeding interval, an i.p. injection of 1 ug/kg CCK-8 (Sincalide, Squibb) or 0.9% saline 2 min later, and 6 runway trials for 0.3 ml of 30% sucrose beginning 10 min after the injection. For the GF group there were 4 prefeeding conditions: 9 ml of 30% sucrose consumed normally (F), gastric infusion of 9 ml of 30% sucrose (GF), infusion of 9 ml of 0.9% saline (GS), and no prefeeding (NF). Performance after CCK-8 was similar on NF (7% decrease compared to saline injections) and GS tests (5% decrease). Intragastric sucrose was, by contrast, as effective as normal prefeeding in interacting with CCK-8. The impairment produced by the drug was 39% on F tests and 46% on GF tests. For the SF group, there were 3 prefeeding conditions: normal prefeeding, of 30% sucrose (F), sham feeding (SF), and no prefeeding (NF). On NF tests CCK-8 produced a small decrease in running speed (9%), whereas in the F condition, rats ran 43% slower after CCK-8 than after 0.9% saline. SF failed to mimic normal prefeeding. CCK-8 produced very little reduction in running speed (2%) after sham feeding. These results suggest abdominal origin of the critical feeding-contingent signals; signals generated by intragastric sucrose were as effective as normal prefeeding, and signals from the oropharynx were without apparent effect. Subsequent experiments will more specifically examine the contribution of the stomach.

We should add the proviso that the above conclusions apply most clearly to tests using relatively small doses of CCK-8. In subsequent tests, we found evidence of synergism between SF and CCK-8 with larger doses. After SF, 2 and 4 ug/kg CCK-8 decreased running speed by 29% and 41%, respectively, though these doses produced little inhibition (5% and 12%) without prefeeding. Thus, increasing doses of CCK-8 appear to engage additional inhibitory mechanisms involving signals from the oropharynx.

This research was supported by NSF grant BNS-8606768.

166.11 COMPARISON OF POSTPRANDIAL PLASMA LEVELS OF CCK WITH PLASMA LEVELS OF CCK ANALOGS THAT INHIBIT FOOD INTAKE IN DOGS. R.D. Reidelberger*, T.J. Kalogeris*, C.M. Turkelson*, and T.E. Solomon* (SPON: R.C. McClure). Depts. of Medicine and Physiology, University of Missouri Medical School and Truman V.A. Hospital, Columbia, MO 65201.

Cholecystokinin (CCK) is postulated to be a satiety hormone. While peripheral administration of large doses of CCK inhibits feeding, it is not known whether physiological doses produce satiety. We used specific, sensitive radioimmunoassays of CCK to compare postprandial blood levels of CCK with plasma levels of CCK analogs that inhibit food intake. Eight pure-bred beagles were adapted to ad libitum access to solid food for 18 h followed by 4 h food deprivation and a 1 h test session. Dogs received intravenous infusions of CCK8, cerulein, or Thr(28),Nle(31)-CCK9 (0, 25, 50, 100, 200, 400, and 800 pmol/kg-h, one dose per day) for 15 min prior to presentation of the test meal and during the subsequent 45 min feeding period. Each peptide produced a similar dose-dependent inhibition of food intake. The minimal effective dose for each analog was the same (200 pmol/kg-h). At this dose food intake was suppressed 36, 41, and 55 % by CCK8, Thr(28),Nle(31)-CCK9, and cerulein, respectively. In a second study the same dogs received scalar doses of CCK8 or Thr(28),Nle(31)-CCK9 (0, 25, 50, 100, 200, and 400 pmol/kg-h), or cerulein (0, 16.7, 50, and 150 pmol/kg-h), each dose for 30 min, and each peptide given on different days. Blood samples were collected at the end of each dose for determination of plasma peptide concentrations. Peptide levels were highly correlated with dose: correlation coefficients were 0.94, 0.95, and 0.87 for CCK8, Thr(28),Nle(31)-CCK9, and cerulein, respectively. Peptide levels produced by the minimal effective dose for inhibition of food intake were 67, 72, and 55 pM, respectively. In a third study, blood samples were collected before food presentation and at 15, 45, and 90 min after access to food, and plasma CCK concentrations were determined. CCK levels increased significantly from 2.7 $\pm$ 0.2 pM before food intake to a peak of 5.0 $\pm$ 0.7 pM at 45 min. These results do not support a role for CCK as a satiety hormone, since plasma levels of CCK analogs required to inhibit feeding in dogs were 10 to 14 times larger than physiological levels of plasma CCK produced by food intake.

166.12 SUPPRESSION OF SHAM FEEDING BY INTRAINTESTINAL OLEATE IS ATTENUATED BY A SPECIFIC CCK RECEPTOR ANTAGONIST. D Yox, H Stokesberry*, RC Ritter. Department of VCAPP, College of Veterinary Medicine, Washington State University, Pullman, WA 99164 and WOI Regional Program in Veterinary Medical Education, University of Idaho, Moscow, ID 83843

Suppression of food intake following systemic administration of exogenous cholecystokinin (CCK) is well-documented. Recently, specific and potent CCK receptor antagonists have become available. Using these antagonists, several laboratories have attempted to assign a role in the termination of feeding to endogenous CCK. Nevertheless, attempts to increase the size of meals utilizing CCK antagonists have met with very limited success. It is likely, however, that CCK is involved in mediating only a subset of multiple postingestive signals involved in control of food intake. Consequently, the role of endogenous CCK in ingestive control may be more easily appreciated if its participation in the suppression of intake by individual gastrointestinal stimuli can be established. Therefore, we have examined the effect of the potent CCK antagonist, CR1409 (Rotal), on the suppression of feeding by intraintestinal sodium oleate infusions. The effect of CR1409 on suppression of sham feeding by intraintestinal oleate infusion (0.65 kcal/min) is shown in the table below.

INJECTION	INFUSATE	% SUPPRESSION[a]
saline	saline	---
saline	oleate	36.4 $\pm$ 4.9
CR1409 (300 ug/kg)	oleate	22.7 $\pm$ 3.8[b]
CR1409 (600 ug/kg)	oleate	5.5 $\pm$ 4.9[c]
CR1409 (300 ug/kg)	saline	-3.5 $\pm$ 2.1
CR1409 (600 ug/kg)	saline	0.5 $\pm$ 4.8

a $\frac{[(\text{saline \& saline}) - (\text{experimental treatment})]\ [100]}{[\text{saline \& saline}]}$

b, c Differs from saline/oleate, b=$p<0.05$, c=$p<0.001$

CR1409 (300 ug/kg) attenuated oleate-induced suppression of sham feeding while a dose of 600 ug/kg abolished the suppression entirely. Neither dose of the antagonist altered sham feeding in the absence of oleate. As a test of CR1409's specificity for attenuating suppression of intake by CCK, we examined the effect of CR1409 on feeding following systemic treatment with exogenous CCK-8 or bombesin. CR1409 failed to attenuate the suppression of intake induced by bombesin but completely abolished suppression of intake induced by 2 ug/kg of CCK-8. These results suggest that endogenous CCK may participate in the mediation of suppression of ingestion by intestinal chemical signals such as long chain fatty acids. Supported by NIH grant R01 NS20561.

167.1 MECHANISMS OF FORMATION OF THE RETINAL GANGLION CELL AND OPTIC FIBER LAYERS. M. Watanabe*, U. Rutishauser, and J. Silver (SPON: A.L. Acheson). Neuroscience Program, Department of Developmental Genetics and Anatomy, Case Western Reserve University School of Medicine, Cleveland, Ohio 44106

The neural retina is an example of nervous tissue which begins as a simple neuroepithelium and differentiates into a multi-stratified structure with alternating cell body and neurite domains. In order to begin to understand the mechanism by which such layers form, the early development of the retinal ganglion cells was examined using EM immunohistochemical techniques. The row of ganglion cells with its associated fiber layer are the first two layers to form within the retinal anlage.

A newly characterized monoclonal antibody directed to a neuron-specific cytoskeletal component was used to specifically mark retinal ganglion cells that have left the mitotic cycle and have elaborated an axon. Wedges of E4-6 chicken neural retina were immunostained after permeabilization of the tissue in PLP fixative (McClean and Nakane, 1974, J. of Histochem and Cytochem. 29, 775) and prepared for observation by light and electron microscopy. In retina of 4-6 day chicken embryos, most of the retinal ganglion cells which were stained with the neuron-specific antibody had already migrated to the vitreal surface. However approximately 3% of the stained cells at E4 and E6 had cell bodies and processes in the middle or ventricular zone of the retinal neuroepithelium and of these several had radial processes connected to vitreal endfeet. Ultrastructural observations of the vitreal margin revealed that several endfeet were stained with the ganglion cell specific antibody. Furthermore, stained axons were observed protruding directly from stained and as well as unstained vesicle-filled vitreal attachments. Such primitive appearing ganglion cells that possess simultaneously axons and vitreal endfeet were described at the light microscope level in Golgi stained material by Morest (1970, Z. Anat. Entwickl.-Gesch. 131, 45-67). We have identified and examined at the ultrastructural level cells with the morphology which fit into his proposed sequence of ganglion cell differentiation. According to Morest, the axonogenic retinal ganglion cell is anatomically bipolar with both a ventricular and vitreal attachment (vitreal endfoot). It first releases only the ventricular attachment, generates its axon directly from the vitreal endfoot, translocates its cell body to the vitreal position while maintaining the vitreal attachment and finally, without ever freely migrating, eliminates the vitreal endfoot once translocation is complete. Our results provide evidence that this is a viable mechanism for the formation of the first 2 layers in the retina of the chick embryo.

167.2 REMODELLING OF CAT RETINAL GANGLION CELLS DURING FETAL AND POSTNATAL DEVELOPMENT. A.S. Ramoa, G. Campbell* and C.J. Shatz. Dept. Neurobiology, Stanford U. Sch. of Med., Stanford, CA 94305.

The retina of the adult cat contains a variety of morphologically distinct ganglion cell types. Among these, alpha cells have the largest somata and long, sparsely branched dendrites while beta cells have medium sized somata and very small extensively branched dendritic trees. Here we have examined when the adult cell classes first can be recognized in development and whether the acquisition of adult form is simply the result of progressive growth or whether morphological remodelling is also involved.

Retinae were dissected from cats aged between embryonic day 35 (E35; gestation is 65 days) and adult and maintained alive in a tissue-slice chamber. To distinguish retinal ganglion cells from other cell types early in development, they were identified by the retrograde transport of rhodamine labeled microspheres (Katz et al, Nature 310,498,1984) injected 48 hours earlier into central retinal targets (superior colliculus and lateral geniculate nucleus). The fine morphology of 283 ganglion cells was then revealed by intracellular filling with Lucifer Yellow (LY). Between E35 and E45 (gestation=65 days), LY filled ganglion cells are morphogically immature, with a few simple dendrites often aligned parallel to the trajectory taken by axons en route to the optic disc. From E52 onwards a much more elaborate pattern of dendritic branching is present. At this age some of the LY-filled cells resemble the alpha and beta classes of the adult based on comparisons of the soma size and dendritic spread of cells located at a similar eccentricity. By E57 cells resembling the gamma class could also be recognized. In other respects, however, the fetal and neonatal ganglion cells display several morphological features not present in the adult including 1) an enormous number of dendritic and somatic spines, 2) more highly branched dendrites, 3) short sidebranches along the intraretinal course of axons, and 4) axons that (for about 10% of the cells) bifurcate, giving rise to one or more collaterals. Quantification of these transient morphological features indicates that they are all especially evident between E57 and P7, mostly gone by P31 and not found in the adult cat.

These results show that some retinal ganglion cells can be assigned to classes analogous to those present in the adult as early as two weeks before birth. However, the transient expression of excessive dendritic, axonal and somatic protrusions implies that a great deal of remodelling occurs in the retina before the final adult morphology is established. Thus basic ganglion cell form may be laid down even before photoreceptor outer segments are present, but final maturation may require visual experience. (Supported by NSF grant BNS 8616798 and the March of Dimes.)

167.3 DO AMACRINE CELLS EXTEND, THEN RETRACT A CENTRALLY-PROJECTING AXON? G.Campbell*, A.S.Ramoa and C.J.Shatz (SPON: M.W. Siegel). Dept. of Neurobiology, Stanford Univ. Sch. of Medicine, CA 94305.

We have investigated the possibility that amacrine cells of the mammalian retina derive from ganglion cell precursors that lose a centrally-projecting axon (Hinds and Hinds, J.Comp.Neurol. 213, 1, 1983). We examined whether, during fetal development in the cat, amacrine cells project an axon beyond the optic chiasm.

To test whether amacrine cells transiently project to central targets, large injections of rhodamine labeled microspheres were made in vivo into the optic tract, diencephalon and midbrain in order to retrogradely label any retinal cells with centrally-projecting axons at the time of injection. In one set of experiments, microspheres were injected at embryonic day 56 (E56; 9 days before birth) or older (up to postnatal day 32) and 24-48 hrs later the retinae were removed and placed as living wholemounts in vitro. Somata containing retrogradely transported microspheres were intracellularly injected with Lucifer Yellow (LY) to reveal their morphology. Almost every cell double-labeled with LY and rhodamine microspheres could be morphologically identified as a ganglion cell and had an axon in the optic fiber layer. Moreover, no double-labeled cells, even those with the smallest somata, resembled adult amacrine cell types. Amacrine cells could only be injected when the microelectrode was advanced into cells devoid of microspheres, in which case by E62 many narrow-, small-, medium- and wide-field types of cat amacrine cell (Kolb, Vis. Res. 21: 1081, 1981) could be identified and distinguished from ganglion cells. Moreover at this age and thereafter, none of these cell types had axons in the optic fiber layer. Thus amacrine cell types resembling those in the adult may be present as early as E62, but at this age, they do not send an axon into the optic tract or beyond.

In a second set of experiments, the microspheres were injected at E35-E38 but the retinae from injected animals were not removed for the LY injections in vitro until E62 or older in order to examine whether amacrine cells have axons in the optic tract early that are retracted by E56. E35-38 was selected because many retinofugal axons have just arrived at their central targets and very few growth cones are left in the optic nerve. Again no double-labeled cells resembling amacrine cells were found at E62 or older, while 227/237 double-labeled cells were identified as ganglion cells.

These results firstly show that many amacrine cells acquire their basic form prenatally, at least by E62. Secondly, while it is possible that during development amacrine cells extend an axon for short distances, it is unlikely that amacrine cells derive from ganglion cell precursors that shed a centrally-projecting axon. Supported by NSF grant BNS 8616798, and the March of Dimes.

167.4 CLUSTER ANALYSIS OF CAT RETINAL GANGLION CELLS DURING POSTNATAL DEVELOPMENT. J.S. Tootle and M.J. Friedlander Neurobiology Research Center and Dept. of Physiology & Biophysics, Univ. of Alabama at Birmingham, Birmingham, AL 35294.

Despite the enormous volume of data supporting the division of adult cat retinal ganglion cells (RGCs) into the three (X-, Y- and W-) functional classes, the recognition of functional cell classes in the neonate remains controversial. In order to identify the appropriate number and nature of the functional groups present during development, we have applied cluster analysis to electrophysiological data acquired from retinal ganglion cells. Action potentials in response to visual and electrical stimulation were recorded from single retinal ganglion cell axons within the optic tract just beneath the lateral geniculate nucleus. Recordings were made from RGC axons at 3 postnatal ages (4½ weeks n=40; 6½ weeks n=33; adult n=36). The spatial resolution, temporal resolution, latency of response to electrical stimulation of the optic chiasm (OX) and degree of linearity of spatial summation of each cell were quantified. The scores on each variable were standardized to a mean of zero and unit variance and were used with Ward's hiearchical clustering method (SAS, Inc.) to form from 1 to 5 clusters at each age. R-Squared and pseudo-F statistics were plotted as a function of the number of clusters formed and indicated that two groups (clusters) were present at all ages tested. The cells in one cluster had on average low spatial and high temporal resolution, short response latencies to OX stimulation and nonlinear spatial summation. Cells in the other cluster had on average high spatial and low temporal resolution, long response latencies to OX stimulation and linear spatial summation. In the adult the two clusters corresponded closely to X- and Y- cells (cluster 1: 13/14 X-cells; cluster 2: 15/18 Y-cells). The direction of differences on the clustering variables were the same for the kitten and adult, but many kitten cells did not reach adult criteria for X- or Y- classification on some variables. The results demonstrate that 1) two groups of cells, which correspond closely to X- and Y- cells, are identified by the application of cluster analysis to data acquired from retinal ganglion cell axons in adult cats and 2) two functional classes of retinal ganglion cells which show the same relative differences on the clustering variables as adult X- and Y- cells can be recognized in the neonatal kittens as young as 4 to 5 postnatal weeks.

167.5 CHANGES IN THE BASIS OF THE RETINAL SPECIALIZATION AS THE GOLDFISH RETINA MATURES. A.D. Springer and A.S. Mednick. Dept. of Anatomy, New York Medical College, Valhalla, NY 10595.

The goldfish has a retinal specialization (RS) that is situated along the temporal boundary between the dorsal and ventral retina. This RS was observed in retinae that varied in size from 10-50 mm^2. Retinal ganglion cell density was at least 500% higher in the RS as compared to the surrounding retina. Similarly, the inner nuclear and cone mosaic layers of the RS also had a high density of cells as compared to the surrounding retina.

The ganglion cell layer contains cells that do not backfill when cobaltous-lysine is applied to the cut optic nerve. Many of these unfilled, hematoxylin stained, cells appear to be morphologically similar to the amacrine cells of the inner nuclear layer. Ganglion cells range in size from 10-310 um^2, and most are 40-50 um^2. Presumptive displaced amacrine cells are 10-60 um^2 in size, and most are 30 um^2. Since there is appreciable overlap in the soma area distributions for ganglion and displaced amacrine cells, many cells would be misclassified unless the various cell types were distinguished by backfilling the ganglion cells with cobaltous-lysine.

In small retinae, the percentage of neuronal cells in the ganglion cell layer that are ganglion cells (95%) or displaced amacrine cells is constant across the retina. However, neuronal cell density is 25% higher in the RS. In large retinae, the RS, where ganglion cells are numerous, has a low density of displaced amacrine cells. The density of displaced amacrine cells is greater in the region that surrounds the RS. Adding the displaced amacrine cells to the ganglion cells results in a homogeneous distribution of cells across the ganglion cell layer of large retinae. Therefore, unlike the small retinae, the RS in large retinae contains a disproportionately higher percentage of ganglion cells relative to the surrounding retina. Furthermore, although ganglion cell density diminishes as retinal area increases, displaced amacrine cell density increases as retinal area increases. The data suggest that several mechanisms (e.g., differential cell death, differential cell transformation) may serve to maintain the RS as the retina grows. Supported by NEI 03552.

167.6 A POSITIONAL MARKER FOR THE EMBRYONIC MOUSE RETINA. S. A. Rabacchi* and U. C. Drager. Harvard Medical School, Dept. Neurobiology, Boston MA 02115.

We are trying to identify molecular mechanisms involved in the establishment of topographical maps in the visual system of the mammalian embryo. As work on cold-blooded vertebrates indicates that hypothetical specification events for the topographical coordinates of the retina take place just before the first retinal ganglion cells start to differentiate, we generated monoclonal antibodies to the corresponding stage of the mouse embryo at embryonic day 11 (E11). One of our monoclonal antibodies, "Jula", labels the early embryonic retina in a position- but not maturation-dependent fashion. At late E10 or early E11, when antibodies to differentiation antigens--neurofilaments and HNK-1 epitope--do not yet label the eye, the Jula antigen appears in the dorsal retina opposite to the optic fissure; it first covers about one third of the extent of the retina, where it appears to distribute diffusely in the cytoplasm of all cells. As maturational processes, starting at E11.5, advance from the center to the periphery, the Jula antigen becomes gradually pushed toward the dorsal edge; as soon as cells turn positive for neurofilaments or HNK-1, they lose the Jula antigen. By E16 the Jula antigen has practically disappeared from the neural retina, but occupies only a small sector on the dorsal rim of the eye cup which sprouts to form the iris.

The Jula antigen is not restricted to the retina, but it appears transiently also in central locations: at E13 in the optic nerve, at E14 in the diencephalon in the region of the lateral geniculate body and in the internal capsule of the forebrain.

Two other antigens with initially similar distribution, but which persist in differentiated regions of the embryonic eye, have been identified with monoclonal antibodies: "TOP" (Trisler et al.) detects a cell-surface glycoprotein, and "JONES" (Constantine-Paton et al.) a ganglioside in the dorsal retina. To test whether the Jula antigen corresponds to one of these, we are trying to determine its biochemical nature. So far we have found that Jula immunoreactivity is destroyed by SDS, high temperature, low pH, alcohols, pronase and chymotrypsin; it is partially affected by periodate; and it is resistant to lipid solvents (Triton, ether, chloroform, xylene, acetone) and a large number of enzymes including neuraminidase.

These preliminary biochemical observations and the apparent cytoplasmic labeling pattern suggest that the Jula antigen may be a novel cytoplasmic protein, and its topographical distribution suggests that it may be relevant for the setting-up of the dorso-ventral axis in the embryonic eye. 167.7 CLASS SPECIFIC CELL DEATH DURING DEVELOPMENT SHAPES THE DISTRIBUTION AND PATTERN OF CENTRAL PROJECTION OF CAT RETINAL GANGLION CELLS. A.G. Leventhal, J.D. Schall, S.J. Ault, J.M. Provis, D.J. Vitek. Anatomy Dept., University of Utah School of Medicine, Salt Lake City, Ut. 84132; Dept. of Brain and Cognitive Science, E25-634, MIT, Cambridge, MA 02139; and Dept. of Clinical Ophthalmology, Sydney Eye Hospital, Sydney, Australia 2011.

The development of the nasotemporal division in cat retina was studied. We find that in the normally pigmented neonatal cat many of the ganglion cells in temporal retina project to the contralateral dorsal lateral geniculate nucleus (LGNd). Since very few cells in temporal retina project contralaterally to the LGNd in the adult, most of these cells must be eliminated during development.

Experimental interruption of one optic tract in the neonate results in the retrograde degeneration of the ipsilaterally projecting ganglion cells in the temporal retina ipsilateral to the lesion. Consequent to the loss of the ipsilaterally projecting cells in this hemiretina, many of the ganglion cells projecting to the intact contralateral LGNd survive and grow to be abnormally large (Ault et al, Soc. Neurosci. Abstr., 11:15, 1985). All classes of retinal ganglion cells comprise this "stabilized exuberant" projection. Contralaterally projecting alpha cells extend up to four mm into temporal retina; contralaterally projecting beta cells extend up to two mm into temporal retina and contralaterally projecting epsilon and other ganglion cell types extend to the temporal margin. Also, unlike in the normal cat in which very few of the small ganglion cells in temporal retina project to the LGNd, in optic tract lesioned cats many of the smallest ganglion cells in the temporal retina ipsilateral to the lesion project contralaterally to the intact LGNd.

A quantitative analysis of ganglion cell density in the temporal retina contralateral to the lesion (ipsilateral to the intact hemisphere) indicates that there is a reduction in the population of ipsilaterally projecting ganglion cells which is complementary to the abnormally large number of contralaterally projecting cells which survive in the temporal retina ipsilateral to the lesion. A loss of alpha cells is evident as far as 4 millimeters from the nasotemporal division; a loss of beta cells is evident within 2 millimeters of the nasotemporal division. As a result of this complementary loss, the intact LGNd receives inputs from normal numbers of alpha and beta cells. These results suggest that class specific cell death during development helps to shape to the retinal distribution and pattern of central projections of the different classes of ganglion cells in the mature cat retina. 167.8 EVIDENCE FOR EARLY SPECIFICITY OF THE RETINOGENICULATE X CELL PATHWAY. M.Sur, A.W.Roe* and P.E.Garraghty. Dept. of Brain and Cognitive Sciences, M.I.T., Cambridge, MA 02139.

The development of the retinogeniculate pathway in cats and ferrets involves specific connections between retinal X and Y afferents and their target geniculate neurons within eye-specific laminae. How early in development is the specificity of retinal X and Y axons for their target cells laid down?

In cats, retinogeniculate axons have segregated into eye-specific laminae by birth (E64); ablating area 17 (the target of A-laminae X cells) as well as area 18 at birth causes degeneration and loss of LGN X cells (McCall et al., '86) and transneuronal loss of retinal X cells (Tong et al., '82). In ferrets, the temporal order of retinogeniculate development matches almost exactly that in cats (Linden et al., '81; Shatz '83), yet ferrets are born much earlier (E42) and axons from the two eyes overlap extensively in the LGN at birth. In the present experiments, we ablated areas 17, 18 and parts of 19 in newborn ferrets, and asked whether this would still cause a reduction in the X cell retinogeniculate pathway.

In ablated animals reared to adulthood, the LGN was only about half its normal size but eye-specific laminae were well-formed. Physiologically, while only 20% of cells in the normal LGN can be classified as Y cells (Esguerra et al., '86), we recorded almost exclusively Y cells in the LGN of ablated animals. Receptive field properties of these cells were similar to normal Y cells. Though there was some clustering of On and Off cells, On/Off sublaminae seen in the A-laminae of normal animals did not form clearly. This is consistent with a reduction in the retinogeniculate X cell pathway; in normal ferrets, retinogeniculate X arbors closely follow the On/Off sublaminar segregation while Y axons do not (Roe et al., '86). Finally, retrograde labeling of retinal ganglion cells following small injections into the surviving LGN and comparison with normal animals indicated a substantial reduction in backfilled medium-sized (200-350 um2) ganglion cells.

While ablation of cortex can have other effects, these data suggest that early removal of target neurons, even before retinogeniculate axons from either eye have segregated or most axons have elaborated a recognizable terminal arbor (eg., Sretavan and Shatz '86), still causes a loss of the retinogeniculate X cell pathway. Therefore, at least the X retinal axons must have a high degree of specificity for their LGN targets by E42.

Finally, contrary to the cat LGN (Murphy and Kalil '79), surviving cells in the A-laminae were smaller than normal. These cells are contacted by Y axons; the smaller size of these cells is consistent with a role for geniculocortical factors in controlling cell structure independent of the retinogeniculate pathway.

167.9 LAMINAR SEGREGATION OF BINOCULAR AFFERENTS TO THE RAT TECTUM INDUCED BY NEONATAL LESIONS OF THE OPTIC TRACT. C.A. Serfaty* & R. Linden, Instituto de Biofísica da UFRJ, Rio de Janeiro, Brazil.

The normal retinotectal projections of rodents show no segregation of crossed and uncrossed components, although this can occur after induction of recrossed projections in hamsters (Mooney et al., Dev. Brain Res., 19: 297, 1985). We report a form of aberrant laminar segregation in the superior colliculus (SC) of rats following neonatal lesions of the opposite optic tract. Tectopretectal lesions (Linden & Perry, Neurosci., 7: 2813, 1982) were made on the left side of the brain of newborn rats, and the retinal projections to the right SC were traced with HRP or ^{3}H-proline injected in the eye. In operated rats the uncrossed retinotectal projection formed an aberrant subpial lamina of terminal labeling, in addition to the puffs of termination normally placed at the lower edge of the superficial gray layer. The subpial lamina varied in size but was consistently found at the rostral 2/3 of the SC, especially in its lateral half. The lamina tended to form at the expense of the deep puffs, but the total volume of uncrossed projection was greatly increased. In 6 out of 9 rats tested the crossed retinotectal projection retracted from the surface of the SC, forming holes similarly located as but smaller than the subpial uncrossed lamina. Double labeling showed that the crossed and uncrossed projections segregated only where the density of the ipsilateral lamina was the highest. The uncrossed retinotectal projection normally develops along a rostrolateral to caudomedial gradient, as shown by the progressive condensation of the deep terminal zones. In operated rats the condensation of the subpial uncrossed lamina was apparent at 3 days after birth, and developed along a gradient similar to normal rats, cotemporal with natural neuronal death among retinal ganglion cells. The results indicate that segregation of binocular afferents to the rodent tectum is critically dependent on the relative densities of projection from each eye. The data are also consistent with the interpretation that the anomalous retinotectal projection induced by neonatal optic tract damage in rats is due to a change in the course of developmental neuronal death in the retina.

167.10 Prenatal Development of Retinogeniculate Axon Arbors in the Presence of Tetrodotoxin - D.W. Sretavan[1], C.J. Shatz[1] & M.P. Stryker[2]. [1]Dept. of Neurobiology, Stanford Univ. Sch. Med., CA. 94305 & [2]Dept. of Physiology, Univ. Calif. San Francisco, CA. 94143

During the cat's prenatal development, retinal ganglion cell (RGC) axons from both eyes are initially intermixed within the lateral geniculate nucleus (LGN) and are morphologically simple, consisting of one main axon with a few side branches. Between embryonic days 43 and 58 (E43-E58) (birth=E65), axons from the two eyes sort out from each other by losing side-branches in parts of the nucleus destined to belong to axons from the other eye while simultaneously forming terminal arbors in parts of the LGN appropriate to eye of origin. By E58, axons are like those in the adult consisting of a smooth main trunk and a narrow cylindrical arbors strictly localized to an eye-specific layer (Sretavan & Shatz, J. Neurosci. 6:234, 1986).

To examine whether action potential activity is involved in shaping RGC axon terminal arbors during this period of fetal development, we have used tetrodotoxin (TTX), a Na^{+} channel blocker that eliminates action potentials and is known to prevent the formation of the eye-specific layers (Shatz & Stryker, Soc. Neurosci. Abstr. 12:589,1986). TTX (0.3mM) in citrate buffer (0.32 mM) was infused intracranially via osmotic minipumps starting at E42. (Infusion of citrate vehicle alone does not affect formation of the layers.) At E57 or E58, fetuses were delivered and RGC arbors were filled with horseradish peroxidase using an in vitro method. Preliminary saxitoxin competition binding assays of CSF samples at E57/58 showed 160-720 nM of TTX, within the range of the level needed to block action potentials in neonatal rat optic nerves (Foster et.al. Dev. Br. Res.3:371, 1982).

RGC axon arbors (n=27) in fetuses treated with TTX from E42-58 were highly abnormal, branching widely along their entire traverse across the LGN. TTX axons at E58 formed broader terminal arbors (TTX:253um ± 88um, n=14; Normal:90um ± 33um, n=28) and in addition elaborated more total axon length within the LGN (TTX:3910um ± 1116um, n=14; Normal:2520um ± 810um, n=28). Eye injections of ^{3}H-leucine in these same fetuses showed that the pattern of eye-specific layers, normally present at this age, was missing.

Our results show that in the presence of TTX, retinal axons fail to elaborate the restricted axon arbors that form the basis of the eye-specific LGN layers. In addition TTX-treated axons are not slowed in their axonal growth nor do they resemble normal axons arrested at earlier stages of arbor development. These observations imply that during fetal development, activity dependent mechanisms are likely to be important in directing the formation of axon terminal arbors that are both of the appropriate morphology and in the correct location within CNS targets.

167.11 **LAMINATION OF GLIAL CELL MARKERS PRECEDES THE FORMATION OF NEURONAL LAMINATION IN THE LATERAL GENICULATE NUCLEUS (LGN).** **James B. Hutchins and Vivien A. Casagrande**, Dept. of Cell Biology, Vanderbilt Univ. School of Medicine, Nashville, TN 37232.

The development of cell layers in the lateral geniculate nucleus (LGN) occurs after LGN cells are born and have migrated from the third ventricle to the lateral edge of the thalamus. At present, it is unclear what mechanisms are involved in producing LGN layers from an apparently homogeneous mass of cells. We have been examining this issue using the tree shrew (*Tupaia belangeri*) as a model system. In this species, retinal afferents segregate into layers prior to birth (at postnatal day zero, or P0) within the cytoarchitecturally-homogeneous nucleus. Six cell layers gradually emerge during the first postnatal week. Several investigators have proposed that glial cells play a role in trophic and/or mechanical guidance of neurons to their final locations. We have used antisera against glial fibrillary acidic protein (GFAP) and vimentin (Vim), two intermediate filament proteins known to be expressed in glia during different times in development. Both antigens were localized using either peroxidase/antiperoxidase or avidin/biotin-complex immunocytochemical methods. At P0, prior to the formation of cell layers, there is a laminar pattern of GFAP+ astrocyte-like cells and a shadow-like staining of very fine processes. The GFAP+ LGN laminar pattern at P0 resembles the retinal afferent lamination pattern more closely than it does the cell layer pattern that will form later. At P0, Vim+ radial glia are seen in the midbrain, thalamus and cortex. Radial glia still traverse the dorsal-most segment of the LGN; they are absent from the main body of the LGN where astrocyte-like cells prevail. GFAP+ and Vim+ fibers are also seen within the optic tract and radiations at P0. During the period of LGN cell layer formation, a GFAP+ laminar pattern is still apparent. However, by P9, it has come to more closely resemble the cellular pattern of lamination. Faint bands of Vim+ LGN lamina are also apparent during the first postnatal week. At the end of this period, Vim+ radial glia are no longer apparent in any part of the LGN and have begun to disappear elsewhere. In the adult, GFAP+ and Vim+ LGN lamination is no longer evident. Fine, perivascular GFAP+ processes, and evenly-distributed Vim+ cells and fibers, are seen in the LGN. Since glial-like elements are laminated within the LGN early in development, they are potentially in a position to guide the process of cell layer formation. However, it remains to be demonstrated whether the neuronal cellular lamination is dependent upon glial lamination, and whether glial lamination follows or precedes the lamination of retinal terminals.

167.12 A GOLGI STUDY OF DENDRITIC DEVELOPMENT IN THE DORSAL LATERAL GENICULATE NUCLEUS (dLGN) OF FERRETS. J. Keith Sutton, Darrell A. Agee*, and Judy K. Brunso-Bechtold. Department of Anatomy, Bowman Gray School of Medicine of Wake Forest University, Winston-Salem, NC 27103

The dLGN of ferrets, Mustela putorious, is anatomically similar to that in cats, having 2 distinct layers (A and A1) and 4 narrow, unseparated layers (collectively called C layers). Prior studies have documented several morphological classes of neurons within the adult dLGN of various species. We have employed the Riley modification of the Golgi-Kopsch technique (Riley, Brain Res. Bull., 4: 127, 1979) to demonstrate the dendritic arbors of neurons within the dLGN of ferrets aged P0 (first postnatal day) to adults. Our main focus has been to study the postnatal maturation of dendritic arbors in an effort to begin an examination of possible correlations between changes in these dendrites and other developmental events. In adult ferrets, cells of the dLGN were similar to those described previously in cats (Guillery, J. Comp. Neurol., 128: 21, 1966). Large multipolar neurons (35-45 µm somata) with highly-branched dendrites arranged in a spherical array were seen as well as medium multipolar neurons (20-30 µm somata) with tufts of dendritic appendages clustered at regular intervals. Both of these cell classes were found throughout the dLGN except for the outer C layers. Some medium neurons (20-30 µm somata) with dendrites oriented perpendicular to the axes of the cell layers were found in layers A and A1. Within the C layers, other neurons (20-25 µm somata) were found oriented parallel to the axes of the cell layers. In immature animals, all neurons examined were from layers A or A1 due to increased overlap of filled cells and increased artifact in the C layers. At P0, neurons were small (10-15 µm somata) and had few dendrites with occasional branches. At subsequent ages, dendrites increased in number and in extent of branching. At P0, some neurons appeared more immature with thick dendrites and many appendages while other neurons appeared more mature with thin dendrites and short, less frequent appendages. Long (4-5 µm), thin-stalked appendages were also seen arising from neuronal somata between P0 and P21. Somatal appendages were not seen at P56 although, at that age, dendritic appendages were still more apparent than in adults. Cell classes could first be distinguished at P21, when dendritic arbors first began to resemble those of adults and when increases in size (15-25 µm somata) were apparent. (Supported by NIH grant EY05028).

167.13 POSTNATAL DEVELOPMENT OF GABAERGIC SYNAPSES IN THE LATERAL GENICULATE NUCLEUS OF NORMAL AND DEPRIVED CATS: AN ELECTRON MICROSCOPIC IMMUNOCYTOCHEMICAL STUDY. R.E. Kalil and A.N. Lies*. Dept. of Ophthalmology and Neurosciences Training Program. University of Wisconsin, Madison, WI 53706

There are several reasons to believe that cells in the lateral geniculate nucleus (LGN) of the cat that contain gamma-aminobutyric acid (GABA) are probable interneurons. Specifically, GABA containing cells are uniformly small in size, they cannot be labeled retrogradely from visual cortex with horseradish peroxidase, and they have synaptic endings that frequently contain pleomorphic vesicles. Light microscopic evidence suggests that the development of GABA-positive cells in the LGN is completed during the third postnatal month, but no information is available regarding the maturation of terminals in the LGN that may release GABA as a neurotransmitter. We have therefore combined electron microscopy with immunocytochemistry to study the development of GABAergic synapses directly.

Antibodies made in rabbits against GABA conjugated to bovine serum albumin were affinity purified, and their specificity confirmed by immunoblotting. Following incubation in the primary antibodies, immunoreactive terminals in the LGN were stained with the biotin-avidin method. Normally reared cats that ranged in age from newborn to adult were examined, as were animals that had been raised to adulthood with monocular or binocular eyelid suture.

In thin sections from newborn animals, GABA-positive cell bodies and dendrites can be recognized easily, but very few immunoreactive profiles can be found that also contain synaptic vesicles. Immunostained terminals increase in number slightly during the first three postnatal weeks, but they are not prominent in the LGN until the fourth week. In the second postnatal month GABAergic terminals enlarge in size and occur frequently in complex synaptic zones, in association with retinogeniculate boutons and LGN cell dendrites. This configuration is characteristic of the mature pattern. GABA containing terminals in adult cats raised with monocular or binocular visual deprivation do not appear qualitatively different from those in normal animals of the same age.

These results indicate that GABAergic synaptic profiles in the LGN, which probably derive from interneurons and presumably are inhibitory, develop chiefly between the third and eighth postnatal weeks. During the first month, these synaptic terminals are not common in the LGN. This suggests that many of the GABA-positive "puncta" seen with the light microscope at early ages represent sections through immunostained dendrites and axons, and therefore do not reflect synaptic endings reliably.

167.14 DIFFERENTIATION BETWEEN DISUSE AND BINOCULAR COMPETITION EFFECTS IN VISUAL CORTEX CELLS OF MONOCULARLY DEPRIVED SPLIT BRAIN KITTENS. U.Yinon* and M.Chen (SPON: Z.Elazar). Physiol. Lab., Goldschleger Eye Inst., Tel-Aviv Univ. Faculty of Medicine, Sheba Med. Ctr., Tel-Hashomer, 52621, Israel.

To differentiate between the effect of disuse developmentally induced in visual cortex cells by deprivation and the effect of the resulting interocular competition , visual split brain was surgically produced in kittens concurrently with monocular deprivation. Unit recording was made in cortical areas 17,18 and their boundary, >4 months after the surgical procedures. In all cats in which split brain was induced, a full separation was found between the two hemispheres as reflected in the absolute ipsilateral eye dominance. In the monocularly deprived split brain cats the relation between the visually responsive cells in the visually experienced hemisphere (ipsilaterally to the nondeprived eye) and the responsive cells in the inexperienced hemisphere (ipsilaterally to the deprived eye) was 2:1. In comparison, a relation of nearly 3:1 was found between cells driven by the nondeprived and the deprived eye in the monocularly deprived control cats. It has been concluded that visual disuse resulting from monocular deprivation has an effect on visual cortex cells independently of binocular competition. The binocular competition in our experimental condition enhances the effect of disuse on cortical cells by a factor of 1.5; this competition-factor however, is age dependent.

DEVELOPMENT OF INVERTEBRATES I

168.1 CHANGES IN TRANSMITTER PHENOTYPE DURING DEVELOPMENT IN IDENTIFIABLE NEURONS IN THE AMERICAN LOBSTER. *Barbara S. Beltz.* Biology Dept., Wellesley College, Wellesley, MA 02181, and *Edward A. Kravitz* (SPON: R. Tuttle). Neurobiology Dept., Harvard Med. Sch., Boston, MA 02115.

Within a 2-4 week period, newly hatched larval lobsters undergo a dramatic anatomical and behavioral metamorphosis. We want to identify neuronal changes during this period, in order to understand the cellular bases for the development of behavior. Specifically, we have been examining the timing of appearance and disappearance of amines and peptides in the nervous system using immunocytochemical methods.

We see distinct patterns in the timing of transmitter acquisition for a variety of amines and peptides. The earliest embryos studied (at 50% development) already show immunoreactivity for serotonin. The stained neurons and processes are similar in most ways to those seen in adults. We believe that the function of one unpaired medial neuron in the first abdominal ganglion may change during development: it reaches full adult size and stains densely for serotonin during embryonic life, while staining only faintly in adults. In contrast to early staining for serotonin, immunocytochemical studies of proctolin show only a few hundred cell bodies staining in embryos, while the full complement of adult neurons (1500) does not stain until the fifth larval stage. The acquisition of proctolin immunoreactivity generally follows an anterior - posterior gradient, with the largest increase in numbers of cells staining at the third and fourth larval stages. Of particular interest is a large unpaired anterior, medial cell in the second abdominal ganglion that stains strongly for proctolin during embryonic and early larval life, but loses the peptide phenotype by the fifth larval stage. Immunostaining for FMRFamide-like peptides during development shows a pattern distinct from the other substances examined. FMRFamide immunoreactivity first appears in mid-embryonic life and the development of staining does *not* follow an anterior-posterior gradient. The first cells to stain are paired medial abdominal neurons and anterior subesophageal cells, while thoracic cells acquire the FMRFamide phenotype only during late larval stages. Many cells that stain prominently in embryonic and larval life stain weakly, or show no FMRFamide immunoreactivity in juvenile animals. Future studies will focus on (1) anatomical and physiological characterization of the neurons showing transmitter plasticity during development, to see what properties of these cells are changing, and (2) developmental immunocytochemical studies of additional peptides and amines, to further explore the possible guiding principles in the expression of transmitter phenotype in neurons. (Supported by NIMH and NINCDS.)

168.2 **DISTRIBUTION OF PEPTIDE NEUROMUSCULAR JUNCTIONS IN WILD-TYPE AND HOMEOTIC MUTANT *DROSOPHILA*** . M.E. Halpern*, M.-D. S. Anderson, J. Johansen and H. Keshishian. Dept. of Biology, Yale University, New Haven, CT 06511.

On the basis of transmitter phenotypes specific neuronal populations in the *Drosophila* CNS can be identified. Similarly, patterns of peripheral synaptic connections made by motoneurons expressing a given transmitter can be described. We have recovered the peptide neurotransmitter proctolin from the CNS, hindgut and segmental bodywall musculature of *Drosophila melanogaster* third instar larvae by reverse phase HPLC. The peptide is expressed in segmentally iterated clusters of dorsal and ventral neurons in the larval ganglion as shown by immunocytochemistry (M.E. Halpern *et al. Soc. Neurosci. Abstr.*, 1986). We propose that some of these cells are motoneurons that project to the bodywall musculature, which accounts for the high level of proctolin associated with it. The larval segmental musculature consists of internal, external and superficial fibers arranged in a highly stereotypic pattern of from 7 to 30 fibers per hemisegment. Since each muscle fiber is uniquely identifiable, this is an ideal preparation for studying the development and organization of specific neuromuscular junctions.

Immunocytochemistry of whole-mount larval bodywalls with a proctolin antiserum reveals that the peptide is present in nerve terminals on a subset of the oblique and longitudinal muscle fibers (muscles 4, 12, 13 and 19). Proctolin innervation is found on these fibers in the third abdominal segment and all segments posterior to it. The stained endings are less than 0.5 um in diameter and contain regularly spaced varicosities ranging between 1 and 3 um in size. Proctolinergic endings rarely extend the full length of a muscle fiber, in contrast to the glutamate and aspartate immunoreactive nerve terminals described by J. Johansen *et al.*, this volume. Experiments are in progress to discover whether other transmitters are co-localized with the proctolin endings.

Since the peptide innervation is arranged in a muscle fiber and segment-specific pattern, it can be examined in *Drosophila* homeotic mutants where segmental identities are altered. We began the analysis using third instar larvae bearing viable mutations at the Bithorax Complex (BX-C). The BX-C is responsible for specifying thoracic and abdominal segmental identity in ectodermal and mesodermal derivatives (E.B. Lewis, *Nature*, 1978). Haplo-insufficient BX-C gene function (*i.e.* a wild-type/deficiency larvae) results in the regular appearance of proctolinergic endings on muscles of A2, one segment anterior to the wild-type innervation. The novel endings in the second abdominal segment are found on the expected muscle homologs, indicating that overall fiber specific patterns are retained. However, there is also evidence for the innervation of muscle fibers that do not usually receive proctolinergic input in wild-type larvae. Using appropriate genotypes, we can rearrange patterns of neuromuscular endings as defined by transmitter phenotype. We plan to determine whether these changes are due to novel axonal projections or switches in transmitter expression.

We thank C. Bishop and M. O'Shea for the proctolin antisera.

168.3 FATE OF MOTOR AXONS LACKING TARGET MUSCLES IN THE DROSOPHILA TS MUTANT SHIBIRE. M.R. Hummon and W.J. Costello, Dept. Zool. & Biomed. Sci./Col. Osteo. Med., Ohio Univ., Athens, OH 45701.

Insect flight muscle requires innervation for survival and function; however, insect motor axons may survive in the absence of targets. In an adult flightless grasshopper, certain muscle fibers are reduced or absent, but motor axons from earlier instars persist and maintain presynaptic terminals (Arbas & Tolbert, 1986). In the Drosophila mutant sr/df(3), certain target muscles are eliminated, and motor axons form neuromas with numerous presynaptic terminals (hemisynapses) (Costello & Wyman, 1986). We are investigating the development of the giant fiber pathway in the Drosophila mutant shi, in which we can generate adults with some but not all flight muscle fibers absent. shi flies have largely normal development, morphology and behavior at 22C, but continuous exposure at 30C is lethal. A 6h heat pulse (HP) during pupal development results in adults with predictable, time-dependent anomalies in adult morphology and function.

In wild-type and non-HP shi flies, DLM (wing depressor) has 6 fibers, each singly innervated. The 5 motor axons exit the thoracic ganglion in a peripheral nerve (PDMN). In shi exposed to 6h HP starting at 30h of pupal development at 22C (at 25C ≅ 20h; eclosion at 96h), adult DLM fiber number is only 1 or 2, not 6 (3 flies, 6 sides). The extant fibers retain their normal anterior - posterior orientation. The fibers can be activated by the giant fiber pathway, contain synaptic profiles, and have the normal 3:1 thin:thick filament ratio.

The 5 DLM motor axons are within the PDMN (confirmed by TEM, 4 sides), which extends dorsally as normal. However, in all cases, the PDMN divides before the expected level of the ventral-most DLM fiber. Typically, 2 motor axons (confirmed by TEM, 2 sides) continue dorsally toward the targets. The remaining motor axons extend for about 50 um and terminate in a tangled neural mass, or neuroma, always located posterior to the PDMN. The neuroma contains numerous smaller axon profiles and many presynaptic terminals (hemisynapses) facing other axons, glia, or space.

The regularity in the altered pattern of muscle and motor axons is striking, and suggests that the greater apparent autonomy of invertebrate motor axon survival can be mediated by target muscle survival. This regularity should allow us to follow the development of the final pattern, to learn more of the interaction of nerve and muscle during formation of the motor system which mediates escape in Drosophila. 168.4 TRANSFORMATION OF IDENTIFIED MUSCLE AND ITS MOTORNEURON IN BITHORAX DROSOPHILA. A.M. Schneiderman, M.L. Tao* and R.J. Wyman, Dept. Biology, Yale University, New Haven CT 06511.

Although the cuticular transformations caused by mutant bithorax-complex (BX-C) genes of Drosophila have been well characterized, the effects of these genes on neurons and muscles are less well understood. Not all tissues are transformed: most striking is that the mutant metathorax (T3) is virtually devoid of flight muscle [Ferrus & Kankel, Dev. Biol. 85:485, 1981; Costello & Wyman, Roux's Arch. 194:373, 1985]. Not all classes of sensory cells appear to be transformed [Palka & Ghysen, Trends Neurosci.5:382, 1982], and the extent of transformation of adult cuticle and of underlying central nervous system do not correspond [Teugels & Ghysen, Nature 304:440, 1983]. We are using identified cells in the pathway for the jump response to recognize transformation of neurons and muscles in mutant abx bx^3 pbx/Df(3R)P2 flies, in which the T3 (metathoracic) cuticle is transformed to T2 (mesothoracic).

In wildtype flies, the T2 tergotrochanteral muscles (TTMs) provide the thrust for the escape jump, which is elicited by extracellular stimulation of the giant fiber (GF), the command neuron for the response [Tanouye & Wyman, J. Neurophys. 44:405, 1980]. Within the T2 neuromere, the GF axon makes a characteristic tuft and lateral bend where it synapses with the TTMn, the motorneuron innervating the T2 TTM [Koto et al., Brain Res. 221: 213, 1981]. Developmental studies show that the GF never enters T3. Thomas and Wyman [Devel. Biol. 102: 531, 1984] observed that in mutant flies the GF, which as a head segment (brain) cell should not be affected by the BX-C genes, enters T3 where it makes a supernumerary tuft and lateral bend. They suggested that transformed neurons in T3 induced the extra GF branches, but did not directly study cells intrinsic to T2 and T3.

We have found that the mutant T2 TTM is anatomically similar to its wildtype form. In T3, although the flight muscles are greatly reduced or absent, there is a TTM-like muscle, approximately half the volume of a T2 TTM, but larger than any muscle found in wildtype T3. It has points of insertion in the transformed cuticle similar to those of the T2 TTM. The motorneurons to both the T2 and T3 muscles have dendritic branching patterns that closely resemble that of the wildtype T2 TTMn, and are similarly driven at fast latency and frequency by GF stimulation. We thus suspect that the cells we identify as the T3 TTM and TTMn are transformed, either from homologous cells normally in T3 or as cells totally new to T3. Supported by NSF BNS-85-10678 and Helen Hay Whitney Foundation.

168.5 *FACET-GLOSSY*, A *NOTCH* MUTANT, AFFECTS *DROSOPHILA* PUPAL EYE DEVELOPMENT. Ross L. Cagan* and Donald F. Ready. Dept. of Biology, Princeton University, Princeton, New Jersey 08540

We have taken advantage of the simplicity and accessibility of the retina of *Drosophila melanogaster* to study an allele of *Notch*, *facet-glossy*. In flies without normal *Notch* product, neuroblasts proliferate at the apparent expense of epidermis; loss of *Notch* product in adult tissue is lethal, with a variety of defects observed (Deitrich and Campos-Ortega, 1984). Models of *Notch*'s role in development would benefit from studying mutant alleles in a system in which each cell's developmental history was known. We have undertaken an electron and light microscope analyses of the development of the pigment and bristle cells. We compared normal development with that of *facet-glossy*, and find that *facet-glossy* fails to develop normal primary pigment cells. This in turn appears to lead to a cascade of later defects.

The fly's compound eye contains 700-800 unit eyes, or ommatidia. Towards the end of larval development, eight photoreceptor cells and four cone cells group into prospective ommatidia. Development of these twelve cells uses local cell contacts to cue each cell to its fate (Tomlinson and Ready, 1987). At about 10% of pupal development, eight to ten undifferentiated cells surround each maturing ommatidium. Two cells, one contacting the anterior cone cell, the other contacting the posterior cone cell, stretch around the ommatidium in both directions, displacing cells in their path. These cells will ultimately touch each other at both ends, encircling the ommatidium. They will become the primary pigment cells. The displaced cells are pushed out between ommatidia, and appear to compete to become the remaining secondary and tertiary pigment cells; excess cells die to leave nine pigment cells shared between clusters. Later, the primary pigment cells will accumulate brown pigment; the secondary and tertiary pigment cells accumulate red pigment.

In the *Notch* allele *facet-glossy*, eye development in the larva is essentially normal. During early pupal stages, two cells touching the anterior and posterior cone cells begin to stretch around the ommatidium, displacing cells much as in wild type. However, these cells fail to fully encircle the ommatidium, leaving not two but generally four cells surrounding the ommatidium. Most of the displaced cells remain between the clusters and excess cells fail to die. Furthermore, cells that should become primary pigment do not synthesize brown pigment, but accumulate the red pigment characteristic of secondary pigment cells.

168.6 OCTOPOD, A HOMEOTIC MUTATION OF THE MOTH MANDUCA SEXTA, INFLUENCES THE FATE OF PATTERN ELEMENTS WITHIN THE CNS. R. Booker* and J.W. Truman (Spon. J. Palka). Dept. of Zoology, Univ. of Washington, Seattle, WA 98195

In insects much progress has been made in understanding the process of segmental determination, primarily due to the existence of homeotic mutations, which result in the transformation of one body part to another. While it has been firmly established that the homeotic mutations transform epidermal structures, there is less certainty about their role in establishing the segmental specificity observed within the CNS. Recently we isolated the first homeotic mutation of the moth Manduca sexta. It is an autosomal dominant mutation resulting in the appearance of ectopic thorax-like legs on the first and less often the second abdominal segments. We have named this mutant Octopod. This mutation also influences the fate of pattern elements within the CNS.

During adult development new neurons are added to all of Manduca's segmental ganglia. These new neurons are generated during larval life by an array of individually identifiable stem cells (neuroblasts (NBs)). The number of NBs found within a ganglion varies in a segment specific manner. The third thoracic ganglion contains 45 NBs while in the first abdominal ganglion a homologous but reduced array of 24 NBs are found. There are also regional differences in the numbers of progeny generated by homologous NBs, with those in the thorax generating substantially more progeny than their abdominal homologs.

An examination of the first abdominal ganglia of Octopod moths revealed that they were partially transformed with the appearance of from 3 to 9 ectopic NBs. These Nbs were homologous to Nbs found in the thoracic ganglia based upon morphological criteria and the number of progeny they generated. The distribution of the ectopic neuroblasts was not uniform, as they were found only in the anterior half of the ganglion. In addition, the fate of some of the NBs normally present in the first abdominal ganglion was transformed. By the end of the larval stage some of the NBs in the first abdominal ganglion had generated the number of progeny typical of their thoracic homologs. Our analysis demonstrates that the fate of pattern elements within the segmental ganglia of insects can be influenced by homeotic mutations. (supported by NIH grant # NS-13079)

168.7 EMBRYONIC ASSEMBLY OF A MUSCLE LAYER IS ORGANIZED BY A SINGLE COMPLEX CELL IN THE LEECH. J. Jellies and W.B. Kristan, Jr. Department of Biology, B-022, UCSD, La Jolla, CA 92093.

We have found a single cell in the leech (Hirudo medicinalis) that serves as a necessary organizer for one of the three muscle layers in the body wall. These layers consist of an inner layer of longitudinal muscle, an outer layer of circumferential muscle, and an orthogonal grid of obliquely oriented muscle fascicles between them. The oblique muscle grid first appears at about embryonic day 12, after the rudiments of longitudinal and circular muscle layers have assembled.

Intracellular dye-filling revealed a bilaterally represented cell in each segment of the embryonic leech that had a complex morphology reminiscent of the oblique muscle layer. Each such cell ("centipede", or C-cell) has a longitudinally oriented spindle containing a single nucleus. Each spindle projects 35 thin, parallel processes toward the ventral midline at a posteriorly directed angle of 45-60° and an oppositely directed set of 35 processes toward the edge of the germinal plate, the future dorsal midline. The processes of bilaterally homologous C-cells cross perpendicular to one another, forming an orthogonal grid that is coincident with the grid of oblique muscle. By filling C-cells and individual muscle fibers with different fluorescent probes we found that individual muscle cells align themselves with C-cell processes during development, forming the oblique muscles.

The necessity of the C-cell for oblique muscle formation was tested by photoablating it in living embryos before oblique muscle assembly began. Each of 36 such animals exhibited a complete loss of the oblique muscle fascicles corresponding to the predicted location of the missing C-cell and its processes when examined 6-10 days after the ablation. The fact that a single cell organizes such an extensive array of muscle bands makes the C-cell quite different from the "muscle pioneers" found in insects.

The striking morphology of the C-cell makes it interesting to us not only because of its role in organizing muscle assembly, but also as a "model" cell for examining how its many processes navigate long distances in a highly ordered fashion in vivo. It appears that the 70 or so individual "growth cones" of a single C-cell interact with each other and with other cells in the embryonic environment to accomplish this task.

168.8 **PERIPHERAL TARGET CHOICE BY IDENTIFIED NEURONS DURING EMBRYOGENESIS OF THE LEECH.** C.M. Loer and W.B. Kristan, Jr. Dept. of Biol., Univ. of Calif., San Diego, La Jolla, CA 92093.

The acquisition of a unique phenotype by a neuron during embryogenesis is under the direction of both internal instructions and external influences. We have been investigating the importance of target interactions in the development of differences between segmentally homologous neurons in the leech, *Hirudo medicinalis*. A pair of large serotonergic Retzius (Rz) cells is found in each segment of the CNS. In most segments, Rz cells diffusely innervate the body wall of their own and each adjacent segment. Rz cells in segments 5 and 6 [Rz(5,6)] instead heavily innervate the reproductive tissue. During embryogenesis, Rz(5,6) initially have the same pattern of outgrowth as their segmental homologues, but their processes stop growing into the body wall and interganglionic connectives following apparent contact with the reproductive primordia. Rz(5,6) subsequently become different from their segmental homologues in a variety of morphological and physiological characteristics. These observations suggest that some interaction between Rz(5,6) and the reproductive primordia causes these neurons to assume their segment-specific phenotype. We have shown previously that when their normal target is ablated, Rz(5,6) develop more like standard Rz cells. For example, they frequently extend axons into the connectives and body wall. Here we ask whether standard Rz cells are capable of developing like Rz(5,6) when given the opportunity to innervate reproductive tissue.

Reproductive primordia were transplanted into standard midbody segments at a time before Rz cell processes have exited the CNS. Body wall not containing reproductive primordia was transplanted into control embryos. Almost all embryos survived the operation and ectopic reproductive tissue was incorporated into standard segments in more than half of the experimental embryos. 6 to 7 days later, embryos were dissected and assayed either with a serotonin antiserum which marks all Rz cell processes or by injection of HRP into individual Rz cells.

Transplanted male reproductive tissue in experimental embryos was almost as heavily innervated by standard Rz cell processes as it would normally be by Rz(5,6). Furthermore, the tissue was sometimes innervated through additional nerve branches similar to the sex nerves normally found only in segments 5 and 6. In control embryos, transplanted body wall was innervated similarly to normal body wall. Injecting HRP into individual standard Rz cells revealed that the neurons innervate ectopic reproductive tissue more densely than body wall; however, they also appeared to retain other morphological characteristics of standard Rz cells. These results could mean that standard Rz cells differ intrinsically from Rz(5,6) in their ability to be modified by interaction with the reproductive tissue. Another possibility is that we have not yet provided the conditions necessary for standard Rz cells to interact appropriately with reproductive tissue and thereby express the Rz(5,6) phenotype. Further experiments are being performed to distinguish between these possibilities.

This work was supported by an NIH Traineeship, GM07313 (CML) and an NIH grant, NS20746 (WBK).

168.9 **PERIPHERAL CELLULAR CONTACTS THAT MAY REGULATE THE CENTRAL MORPHOLOGY OF DEVELOPING IDENTIFIED LEECH (*Hirudo medicinalis*) NEURONS.** K.A. French, S.M. Furgal* and W.B. Kristan, Jr. Department of Biology, B-022, UCSD, La Jolla, CA 92093.

A set of identified neurons, the Retzius (Rz) neurons, in the leech central nervous system assume during embryonic development essentially the same morphology in every segment of the ventral nerve cord, except in the two segments that contain the reproductive structures. Rz cells in segment 5 (the male segment) and segment 6 (the female segment) possess unique central and peripheral morphology. The results of previous experiments have shown that their distinctive morphology arises only after peripheral processes of these Rz cells - Rz(5,6) - have reached the vicinity of the primordial reproductive tissue in the two segments, an event that occurs on the 10th day of development. Furthermore, when the primordial reproductive tissue is ablated before this time, the morphology of Rz(5,6) develops much more similarly to that of Rz neurons in standard, non-reproductive segments (Loer, Jellies, and Kristan, *J. Neurosci.*, in press).

When Rz(5) were filled with horseradish peroxidase (HRP) on the 10th day of development and their peripheral processes were examined with EM, the filled growth cones and processes were observed to be in contact with cells that surrounded the definitive reproductive primordium, but were not integrated into it. The cells contacted could be identified by two distinctive features in sections; they had irregular and often tortuous boundaries, suggesting active extension and ruffling of the plasma membrane, and many of the cells contained one or more large (approximately 1 μm across), electron-lucent vesicles. We have named these cells V cells, for their distinctive intracellular inclusions. Filled profiles contacted V cells in two regions in which Rz processes possess large growth cones, structures that suggest that the processes are actively choosing a pathway: the near-vicinity of the primordial male reproductive duct and the region between the duct and the as-yet-undifferentiated genital pore, which eventually becomes heavily innervated by Rz(5).

As a step toward identifying the function of V cells, we wished to learn whether the vesicles were pinocyotic. A solution of 6% HRP and 0.1% fast green in leech saline was injected into whole embryos on the 9th day of development. After 24 hours, the embryos were dissected, fixed, reacted for HRP, and observed with the EM. In all 4 embryos examined in this way, most cells with the characteristics of V cells contained one or more typical large vesicles filled with HRP reaction product. Few such vesicles were observed that were not filled with HRP. From their irregular external shape and the HRP-filled vesicles, we conclude that V cells share many characteristics with cells in other systems that have been activated by exposure to growth factors or by transformation by oncogenes. Future work will focus on identifying the developmental fate of V cells and characterizing the nature of the interactions between these cells and Rz(5).

168.10 MALE SPECIFIC NEURONS ARE STAINED IN THE NEMATODE CAENORHABDITIS ELEGANS WITH ANTIBODIES AGAINST MOUSE NEURAL CELL ADHESION MOLECULE (N-CAM). S. Siddiqui. Laboratory of Molecular Biology, Toyohashi University of Technology, Toyohashi 440, Japan and Department of Biochemistry, Molec. Biology and Cell Biology, Northwestern University, Evanston, IL 60201.

The nematode Caenorhabditis elegans exists in two sexual forms, hermaphrodites, the self fertilizing with two X chromosomes, and males with one sex chromosome. Using polyclonal antibodies raised against mouse neural cell adhesion molecule(N-CAM), we have shown that N-CAM like antigen is limited to the male specific neurons in C. elegans. Anti-N-CAM antibodies(kindly provided by Dr. U. Rutishauser, Case Western Reserve U.) stain four cephalic neurons in the male head, when wholemount animal squashes are stained. In addition, a small number of neurons are stained in the male tail. We have identified the neurons stained in the head as male specific CEMDL, CEMDR, CEMVL, and CEMVR neurons. This identification was confirmed by staining mutants of ced-3 and ced-4(in these hermaphrodite animals CEM cells survive due to a block in programmed cell death, H. R. Horvitz and others, MIT Cambridge, Mass.). The male tail neurons, we have tentatively identified as ray neurons B. Among the non-neural tissues stained in both sexes are pharyngeal gland cells, excretory H-cell and sperm. The immunoreactivity is observed from the early embryonic development and it continues during the entire growth through larval phases to adulthood. This is consistent with immunoblot analysis of embryonic, larval and adult tissues which show a large number of smeary bands from 200 k daltons to 16 k daltons in both sexes. We have also stained tra-1, tra-2, and tra-3(transformer mutants in which XX animals are transformed into males, J. Hodgkin, MRC, Cambridge, England) animals, and found that the transformed animals stain like wild type males.

We have recently screened a genomic library of the C. elegans DNA with a 600 b.p. probe of NCAM cDNA (coding region), given by Dr. C. Goridis(CNRS-CIML,Marseille, France) and found many positive clones on hybridization. Currently we are trying to characterize these putative clones of the C. elegans NCAM like gene. Work in Evanston was done in the labs of Prof. J. Culotti (cytochemistry) and Prof. R. Holmgren (Molecular genetics), their support is appreciated. Ms T. Orenic helped in teaching the cloning work, for which I am grateful.

168.11 NEURONAL CHANGES DURING THE METAMORPHOSIS OF THE GENITAL SEGMENTS IN A HOLOMETABOLOUS INSECT. R.S. Thorn* and J.W. Truman. Dept. of Zoology, Univ. of Washington, Seattle, WA 98195

In the tobacco hornworm moth, Manduca sexta, metamorphosis triggers a sex-specific differentiation of the genital segments of the abdomen into the male or female genitalia of the adult. Giebultowicz and Truman (1984, J.Comp.Neurol. 226: 87-95) demonstrated that this transformation is accompanied by an extensive bout of sex-specific motorneuron death that sculpts the different adult neuronal complements from an identical set of larval neurons. We have carried this analysis further by asking, first, whether this sex-specific neuron death correlates with a sex-specific loss of target muscles, and, secondly, how does the adult nervous system then accomodate the production of new targets in these segments, namely the muscles associated with the reproductive tract(s).

By dissection and cobalt backfilling, we have followed the fates of specific nerve muscle pairs in the genital segments through metamorphosis. We find that all of the muscles degenerate during the early stages of metamorphosis in both sexes. After this decline, there is a sex-specific regrowth of specific muscle remnants to generate the two adult muscle patterns. Reuse of a larval muscle remnant is invariably accompanied by retention of its larval motorneuron in the adult, while loss of a remnant is always paralleled by loss of the motorneuron. This pattern is inviolate for skeletal muscle motorneurons.

Visceral muscle motorneurons show greater plasticity. Larval visceral motorneurons of the genital segments can survive or perish along with their targets, but some appear to be able to switch targets during metamorphosis. This usually involves switching from a purely larval structure, such as the rectal cryptonephridium, to the adult reproductive tract. The adult reproductive tract also receives innervation from several classes of post-embryonic cells specific to the adult which first differentiate during metamorphosis.

168.12 INDUCTION OF A NEURONAL ARBORIZATION BY NON-TARGET TISSUE IN C. ELEGANS: C. Li and M. Chalfie, Department of Biological Sciences, Columbia University, New York, New York 10027

We are assessing the role of target cells and surrounding tissues on the innervation of the vulva in Caenorhabditis elegans. Two cell types, the VC and PVT neurons, arborize extensively at the vulva where they synapse onto the vulval muscles and a pair of neurons, the HSN cells. The extent of this arborization can be seen immunocytochemically with an antibody raised against the neuropeptide FMRFamide (kindly donated by R.L. Calabrese). In mutants in which the vulva and target vulval muscles are displaced anteriorly, the arborization is similarly displaced, suggesting that external factors are influencing the VC and PVT projections.

The region around the vulva contains the muscle and neuronal targets, vulval and non-vulval hypodermal cells, and gonadal cells. By examining mutants affecting the development of these cell types, we have found that the vulval hypodermal cells and not the muscle or neuronal targets cells are necessary for the induction of the vulval arborization. Specifically, perturbations of the target cells, such as displacement of the vulval muscles in egl-15 mutants or removal of the HSN neurons in egl-1 mutants, had no effect on the pattern or position of the arborization. By contrast, mutants in which the vulval hypodermal cells are absent but the target cells are present, for example in lin-2, lin-3, lin-7, and lin-10 mutants, have no detectable arborization.

Examination of cell lineage mutants that have ectopic clusters of hypodermal cells revealed that vulval hypodermal cells, irrespective of their positions, can induce neuronal branching. Specifically, when the clusters are composed of vulval hypodermal cells, immunoreactive processes are observed projecting into the clusters. When the clusters are composed of non-vulval hypodermal cells, however, no processes are observed.

These experiments suggest that vulval hypodermal cells are necessary for the induction of vulval branches by the VC and PVT neurons. The target cells have no inductive capacity, but may serve a role in the final shaping of the vulval arborization.

PRESYNAPTIC MECHANISMS II

169.1 POTASSIUM-EVOKED ATP SECRETION FROM A HIGHLY PURIFIED PREPARATION OF MOUSE BRAIN SYNAPTOSOMES. J. A. Bitran*, H. B. Pollard and E. Rojas*. Laboratory of Cell Biology and Genetics, NIDDK/NIH, Bethesda, MD. 20892

Secretion of neurotransmitters from presynaptic terminals, in synaptosomal preparations, occurs by a very fast process. For this reason it has been difficult to study the kinetics of synaptosomal secretion in a quantitative manner and the mechanisms involved remain to be elucidated. To resolve the time course of transmitter secretion from mouse brain presynaptic terminals, we have measured the stimulated secretion of ATP from synaptosomes using a luciferin-luciferase mixture and monitoring the light emitted by the reaction. ATP is not only a transmitter itself, but is also co-stored and co-secreted with transmitters from synaptic vesicles. From the crude synaptosomal preparation (P2), we obtained a highly purified fraction using an isotonic continuous metrizamide/sucrose gradient. The use of biochemical markers and electronmicroscopy indicates that this fraction is highly enriched in synaptic endings and the luciferin-luciferase method shows that this fraction has the highest ATP content. Depolarizing the synaptosomes with elevated K^+ causes the synaptosomes to secrete ATP, and the time course could be fit to a single exponential, thus indicating a first order reaction. Two different processes could be detected, however, depending on whether depolarization occurred in the presence or absence of calcium in the medium. In the presence of Ca^{2+}, secretion was rapid, having a time constant in the range of c. 1 sec. However, in the absence of Ca^{2+} secretion was much slower, having a time constant of c. 7 sec. In the presence of $[Ca^{2+}]_o$, increasing $[K^+]_o$ induced a moderate decrease in the time constant. In the absence of Ca^{2+} similar changes in $[K^+]_o$ did not significantly affect the time constant of release. At each $[K^+]_o$ the extent of the secretory response was evaluated. Taken together, the data showed that an e-fold change in the extent of secretion could be obtained over a 2-fold smaller range of voltage for Ca^{2+}-dependent than Ca^{2+}-independent secretion. At each $[K^+]_o$, decreasing $[Ca^{2+}]_o$ from 1 to 0 mM induced c. a 4-fold increase in the time constant required to fit the time course of release. The results suggest that, in addition to the Ca^{2+}-dependent mechanism for the release of neurotransmitters from presynaptic terminals, synaptosomes are also equipped with another mechanism that does not require extracellular Ca^{2+}. It is possible that this latter mechanism might involve the activation of voltage-dependent Na^+-channels and/or the activation of intracellular messengers to induce Ca^{2+} release from intracellular stores.

169.2 DIFFERENTIAL ION DEPENDENCY OF GLUTAMATE INDUCED ^{3}H-GABA RELEASE FROM OLFACTORY BULB in vitro. E.H. Jaffé*, M. L. Vaello* and N.H. Hernández* (SPON: J.A. González V.). Laboratorio de Neuroquímica, IVIC, Caracas, Venezuela.

It is well established that GABA is the neurotransmitter of a population of granule cells of the olfactory bulb of the rat. These cells establish dendro-dendritic reciprocal synapses with the mitral cells which is apparently of glutaminergic nature. These dendrites project densily to the external plexiform layer (EPL) of the olfactory bulb making it possible in this way to microdissect these neuronal elements. Previously we could show that the glutamate (Glu) agonist, kainic acid (KA) is able to release ^{3}H-GABA from EPL but not other Glu agonists as NMDA or aspartic acid. Glu itself was only effective when the tissue was preconditioned with 25 mM K^+, 12 minutes before adding 5 mM Glu. This effect on the ^{3}H-GABA release was apparently receptor mediated since specific Glu antagonists could block it (Jaffé, E.H., Vaello, M.L., submitted to Neuroscience). We were interested to characterize the ion dependency of the ^{3}H-GABA release from rat EPL using 25 mM K^+, 0.5 mM KA and 25 mM K^+ - 5 mM Glu stimulation. The microdissected tissue was incubated in 0.1 µM ^{3}H-GABA and superfused with Krebs bicarbonate under continuous oxygenation. Fractions were collected every 2 minutes and radioactivity measured using a liquid scintillation counter. The K^+ stimulated ^{3}H-GABA release was completely inhibited when the tissue was superfused with $0Ca^{++}$/EGTA, 2 mM Co^{++} and partially inhibited by 25 mM Mg^{++}. In a similar way, KA induced ^{3}H-GABA release was completely inhibited by 2 mM Co^{++}. However, no Ca^{++} dependency of the K^+ - Glu stimulated ^{3}H-GABA release could be observed in the presence of $0Ca^{++}$/EGTA, 2 mM Co^{++} or 25 mM Mg^{++}. This was not an unspecific effect of the K^+ prestimulation since the same treatment of the KA induced ^{3}H-GABA release was completely blocked by 2 mM Co^{++}. The Ca^{++} dependency of the KA induced release was not at the receptor level since 5 mM Mg^{++} which completely blocked the K^+ - Glu release did not inhibit the KA one. To study the Na^+ dependency of this ^{3}H-GABA release mechanism from the EPL, the tissue was superfused with 300 nM TTX or with $0Na^+$ solution. A complete inhibition of the K^+ - Glu as well as the KA induced ^{3}H-GABA release was observed with no effect on the K^+ induced release. Our results suggest the presence of two different release mechanisms of ^{3}H-GABA with a different Ca^{++} dependency when stimulated with two different glutamate agonists. Interestingly, no Na^{++} dependency of the K^+ stimulate ^{3}H-GABA release was observed, however, the complete Na^+ dependency of glutamate and KA stimulation brings further evidence for a Na^+ dependent depolarization mechanism for this two glutamate receptor agonists.

169.3 ELECTRICALLY EVOKED RELEASE OF TRANSMITTER FROM CULTURED SYMPATHETIC NEURONS IS FACILITATED BY FORSKOLIN AND VASOACTIVE INTESTINAL POLYPEPTIDE - ROLE OF cAMP AND Ca. T.D. Wakade,* S.V. Bhave,* R.K. Malhotra* and Arun R. Wakade. (SPON: J. Jakway) Dept. of Pharmacol., SUNY Health Science Center at Brooklyn, Brooklyn, NY 11203.

A number of compounds facilitate stimulation-evoked release oftransmitter from sympathetic neuroeffector organs. However, the mechanism of such a facilitation has remained unresolved, the major reason being that measurements of key substances involved in release process can not be made in sympathetic neuroeffector organs. For this reason, we have used a homogenous population of cultured sympathetic neurons to determine the effects of forskolin and vasoactive intestinal polypeptide (VIP) on electrically evoked release of ^{3}H-norepinephrine (^{3}H-NE). The major aim was to know if these agents influence the release by altering intracellular messengers such as cAMP and Ca. Sympathetic neurons derived from peripheral ganglia of 10- to 12-day-old chick embryos were cultured in serum-free medium. After 2 to 3 days, cultures were loaded with ^{3}H-NE to study the release of tritium in the absence and presence of electrical stimulation (1 Hz for 15 sec). We show here that VIP or forskolin in the presence of the phosphodiesterase inhibitor, 3-isobutyl-1-methylxanthine (IBMX), enhanced neuronal cAMP by about 7- to 10-fold without affecting Ca^{45} uptake and the release of ^{3}H-NE. Electrical stimulation of sympathetic neurons (1 Hz for 15 sec) evoked a marked increase in ^{3}H-NE release over the spontaneous release, without altering cAMP levels but enhancing the net uptake of Ca^{45}. Stimulation in the presence of forskolin or VIP caused a pronounced facilitation of ^{3}H-NE release without an additional increase in Ca^{45} uptake. If 10 nM phorbol 12, 13-dibutyrate, an activator of protein kinase C, was added along with forskolin and IBMX, the evoked release was even further potentiated, and it was associated with an almost 10-fold increase in the net uptake of Ca^{45} but cAMP content was not further enhanced. It is concluded that facilitation of sympathetic transmitter release is a result of either an increase in intracellular concentrations of cAMP, Ca, or both; the major role of cAMP appears to be in the utilization rather than mobilization of Ca ions.

169.4 A ROLE FOR BOTH cAMP AND PHOSPHATIDYL INOSITOL IN SEROTONIN FACILITATION IN CRAYFISH. D. Dixon* and H.L. Atwood. Dept. of Physiology, University of Toronto, Toronto, Ontario M5S 1A8.

Facilitation of synaptic transmission by serotonin at the crayfish neuromuscular junction has been shown to have two phases of decay after induction (Dixon and Atwood, J. Neurobiol. 16:6, 1985), as in lobster (Glusman and Kravitz, J. Physiol. 325, 1982). The second long lasting phase was shown to involve cAMP as a second messenger in the lobster. We report here that the second phase of facilitation in the crayfish is cAMP mediated, while the first phase involves phosphatidyl inositol metabolism.

Brief applications of activators of adenylate cyclase (e.g. Forskolin) or inhibitors of phosphodiesterase (eg. IBMX) can facilitate transmitter release (as recorded intracellularly) at a relatively low level (100%) for long periods of time (1+ hr.), as in the second phase of serotonin facilitation. Presynaptic injection (while recording intracellularly) of Protein Kinase Inhibitor (PKI) or SQ 22,536 (a cyclase inhibitor) blocks the development of the second phase of facilitation. Only a brief, high level of facilitation remained after serotonin application. The spread of PKI in the pre-synaptic region was monitored using a Rhodamine tag on the protein. Post-synaptic sites were selected, one within the region of PKI influence, one distant from the injection site. Normal facilitation developed at the distant site, whereas the second phase of facilitation was absent at the site near the point of injection.

The injection of RA 233 (a phospholipase C inhibitor) blocked the development of both phases of serotonin facilitation. Release of intracellular calcium induced by inositol tri-phosphate may be responsible for the early, high level facilitation. In calcium-free medium, some release is restored during serotonin application; this is indicative of increased intracellular free calcium. C kinase activation may lead to stimulation of the adenylate cyclase since both phases of facilitation are blocked by RA 233.

169.5 **PAIRING PRE- AND POSTSYNAPTIC NEURONS LOCALIZES FACTORS AFFECTING EFFICACY AND VARIABILITY OF SYNAPTIC CURRENTS.** Daniel Gardner. Department of Physiology, Cornell University Medical College, New York NY 10021.

At these meetings last year, I reported (*Soc. Neurosci. Abstr.* 12: 740, 1986) that both duration and amplitude of synaptic currents vary, that each may be altered over the short term by manipulating presynaptic activity, and that these variations affect synaptic efficacy. In order to localize the sites of variability as either pre- or postsynaptic, I now report results from analyzing variations recorded in identified three-cell networks of *Aplysia* buccal ganglia. Two protocols were used: either a single identified postsynaptic neuron innervated by paired presynaptic neurons B4 and B5, or else a single presynaptic cell innervating two similar postsynaptic neurons. In either case, peak amplitude g_{peak} and time constant of decay τ of inhibitory postsynaptic currents (PSCs) could be recorded with low noise. All PSC were evoked by intracellular stimulation of specific presynaptic neurons. Time constants of digitized PSCs were measured using least-squares fits to semilog plots. For this population, as before, coefficients of variation CV (σ/mean) were uncorrelated with g_{peak} or τ ($r < 0.15$).

PAIRED PRESYNAPTIC INPUTS TO SINGLE POSTSYNAPTIC NEURONS: The similarity of paired inputs on common followers itself differed from cell to cell. To determine if the postsynaptic neuron constrained variability, paired presynaptic inputs on single postsynaptic cells were compared to those for the unpaired population. Fractional differences between paired g_{peak} (0.30 ± 0.08) were as large as those for the population (0.43 ± 0.04). Similarly, ANOVA for g_{peak} showed paired variance equal to unpaired. In contrast, fractional differences between τ produced by paired inputs (0.11 ± 0.03) were significantly ($p < 0.05$) smaller than those of the population (0.27 ± 0.02).

Tetanization or DC polarization of a single presynaptic interneuron modulated input from that neuron alone, producing a significant ($p < 0.01$) change in both g_{peak} and its CV for PSCs evoked from the modulated neuron, without any effect on any parameter of input from from the unmodulated neuron. This result is consistent with a presynaptic locus for short-term variability.

SINGLE PRESYNAPTIC CELLS INNERVATING PAIRED POSTSYNAPTIC NEURONS: In complementary protocols, two postsynaptic neurons innervated by a common presynaptic cell were simultaneously voltage-clamped and PSCs recorded synchronously in both neurons. As before, values for parameters determining synaptic efficacy and variability resembled those of the unpaired population. Following tetanic stimuli of the presynaptic neuron, PSCs in both postsynaptic cells showed post-tetanic potentiation, usually of similar amplitude and time course.

I conclude, on the basis of differences in variability seen in three-cell networks, that both presynaptic and postsynaptically determined factors contribute to short-term plastic changes affecting PSC amplitude and duration, and therefore efficacy. Additionally, synapse-to-synapse variability of some parameters is greater than similarity introduced by a common pre- or postsynaptic element.

169.6 IS LONG-TERM POTENTIATION IN HIPPOCAMPUS ASSOCIATED WITH AN INCREASE IN TRANSMITTER RELEASE? S. S. Chirwa* and B. R. Sastry. Neuroscience Research Laboratory, Department of Pharmacology & Therapeutics, Faculty of Medicine, University of British Columbia, Vancouver, B.C., Canada, V6T 1W5.

Tetanic stimulation of stratum radiatum in the hippocampus results in a subsequent long-term potentiation (LTP) of the excitatory postsynaptic potential (EPSP) in the CA_1 neurons. Whether this LTP is pre- or postsynaptic is unclear. At the skeletal neuromuscular junction it is known that in the presence of extracellular Ba^{2+}, stimulation of the motor nerve terminals result in not only the synchronous end-plate potential (EPP) but also a tail of miniature EPPs (Silinsky, E. M., J. Physiol. (Lond.), 274: 157, 1978). In the present investigation, we examined whether Ba^{2+} has similar effects at the synapses between stratum radiatum and CA_1 neurons in the guinea pig hippocampal slices; and if it did, determined if the number of miniature EPSPs in the tail was increased during LTP.

Intracellular recordings were made from CA_1 neurons with CH_3COOK filled electrodes while the slices (the CA_2, CA_3 and CA_4 somata were dissected out) were in the normal medium. After obtaining controls (stable membrane potential above -60 mV, input resistance greater than 25 M ohms), the slices were exposed for 2 min to a medium containing 3.5 mM Ba^{2+}, 0.5 mM Ca^{2+} and 0.1 mM picrotoxin. Stimulation of stratum radiatum (1-5 pulses at 50 Hz, stimulation strength was enough to evoke an action potential in the CA_1 neuron) at 0.02-0.2 Hz resulted in a tail of miniature EPSPs that followed the evoked action potential for at least 3 s (24 of 31 neurons). After obtaining adequate control records of the tails of miniature EPSPs, slices were reexposed to normal medium for 15 min. LTP could then be induced (in 18 of the above 24 cells) by tetanizing stratum radiatum (400 Hz, 200 pulses). When slices were reexposed to Ba^{2+}-containing medium 15 min after the tetanic stimulation, the number of miniature EPSPs in the tail was at least doubled (in 14 of the above 18 cells). In control experiments, if Ba^{2+}-containing medium was applied twice with a 30 min interval in between, the tails were not significantly different. During Ba^{2+} application the input resistance was increased, spikes were broadened, membrane potential depolarized and the after-spike hyperpolarization decreased. The passive electrical properties of the neurons during the control tails and post-tetanic tails were similar.

The size of the miniature EPSPs was small (less than 2 mV). It was, therefore, not possible to do further quantal analysis to determine that the increase in the number of miniature EPSPs in the tail during LTP does in fact reflect an increase in transmitter release. We, therefore, tentatively conclude that LTP is associated with what appears to be an increase in transmitter release. Experiments are currently underway at mossy fiber - CA_3 synapses, where an analysis of size distribution of the miniature EPSPs is feasible.

169.7 PRESYNAPTIC, VOLTAGE-DEPENDENT CONTROL OF LONG-TERM FACILITATION (LTF) AT THE CRAYFISH NEUROMUSCULAR SYNAPSE. J.M. Wojtowicz, H. L. Atwood, Department of Physiology, University of Toronto, Toronto, Ontario M5S 1A8.

Crustacean neuromuscular synapses can be facilitated for periods of several hours when subjected to bouts of intense activity lasting a few minutes. LTF was studied in a crayfish opener muscle by means of pre- and post-synaptic electrophysiological recordings. A presynaptic microelectrode was used to measure membrane potential and to pass depolarizing and hyperpolarizing current pulses via a standard bridge circuit. A postsynaptic electrode recorded quantal release of neurotransmitter. Preparations were perfused with crayfish saline at 13°C with the addition of 0.1 mM 4-AP to reduce potassium conductance in the nerve terminal and 0.1 μM TTX to abolish voltage sensitive sodium conductance. In such a medium a bout of stimulation delivered to the terminal (3-5 msec depolarizing pulses, 30-60 mV in amplitude, repeated at 20Hz for a period of 10 minutes) resulted in 81% enhancement (range 30-117%, s.d. = 33, n=5) of post-synaptic response 40 minutes after the tetanus. It was determined that the induction of this long-lasting effect was not critically dependent on the influx of sodium ions into the terminals since TTX together with replacement of 90% of sodium ions with either choline or N-methyl-D-glucamine had only a small effect on the magnitude of LTF (mean = 62%, range 20-91%, s.d. = 37, n=3,). Similarly omission of calcium ions and their replacement by either 6 mM manganese or 30 mM magnesium did not reduce LTF significantly (mean = 67%, range 0-171%, s.d. = 55, n=7). Thus it appeared that repeated depolarizations and not ionic fluxes were primarily responsible for the establishment of LTF. We can be less certain as to the exact alteration produced by the depolarization. Two mechanisms proposed for other types of long-lasting plastic changes, viz, reduction in input conductance of the terminals and accumulation of calcium ions, have been ruled out: no change in the slope of the synaptic transfer curves or synaptic delays was observed and there was no increase in the rate of occurrence of spontaneous release. We propose that LTF is produced by a direct structural (or conformational) change in the presynaptic membrane which in turn alters release of transmitter substance. Alternatively a second messenger system, triggered by membrane depolarization, may be involved. Experiments are in progress to identify the exact mechanism.

169.8 MATHEMATICAL MODEL OF TWO CELLULAR MECHANISMS CONTRIBUTING TO DISHABITUATION AND SENSITIZATION IN APLYSIA. K.J. Gingrich and J.H. Byrne, Albany Medical College, Albany, NY and University of Texas Medical School, Houston, TX. 77225.

Presynaptic facilitation contributing to dishabituation and sensitization in Aplysia appears to be mediated by two mechanisms, broadening of the presynaptic spike and mobilization of transmitter (Gingrich & Byrne, 1985; Hochner et al, 1986; Rankin & Carew, 1986). While spike broadening can be observed directly, mobilization has been inferred from mathematical models and from changes in kinetics (shape) of the EPSP. Using a modification of a model of transmitter release developed previously (Gingrich & Byrne, 1985), we were interested in determining if mobilization in conjunction with spike broadening could account for the electrophysiological results obtained by Hochner et al (1986).

The model includes a description of membrane Ca^{2+} influx, diffusion of Ca^{2+} away from the plasma membrane, transmitter release proportional to the product of a depletable Ca^{2+} pool of transmitter and the square of the concentration of Ca^{2+} in the submembrane compartment (5 nm deep), and a postsynaptic membrane modeled by an RC circuit.

In normal (undepressed) cells, the PSP amplitude is a steep function of the duration of presynaptic voltage clamp pulses. In contrast, this function is relatively flat in depressed cells (Hochner et al, 1986). The model simulates changes in PSP amplitude produced by spike broadening. Broadening the pulse duration without modulating the releasable pool enhanced release in normal cells. In depressed cells, the releasable pool is depleted, and increasing pulse duration alone does little to enhance the PSP. In order to restore the effectiveness of pulse widening, the size of the releasable pool must be increased (i.e. mobilization).

The model also supports the hypothesis that the shape of the PSP can be used to gain insight into the relative contribution of spike broadening and mobilization to facilitation. We found that mobilization alone is associated with enhanced PSPs with constant time-to-peak and increased rate-of-rise, while pulse broadening alone is associated with enhanced PSPs with a reduced rate-of-rise and increased time-to-peak. To simulate dishabituation, we approximated spikes from Hochner et al (1986) with pulses and adjusted the size of the releasable pool. The model simulated the experimentally observed complex changes in the amplitude and shape of the PSPs (Hochner et al, 1986).

Our model demonstrates that mobilization of neurotransmitter in conjunction with spike broadening can account for the physiological changes in PSPs produced by presynaptic facilitation and can be used to gain insights into the relative contribution of these mechanisms in experimental studies.

169.9 EVIDENCE THAT THE ARACHIDONIC ACID CASCADE GENERATES SECOND MESSENGERS THAT MEDIATE PRESYNAPTIC INHIBITION IN AN IDENTIFIED CELL CIRCUIT OF APLYSIA. E. Shapiro, D. Piomelli* and J.H. Schwartz. Howard Hughes Med. Inst., Columbia Univ. Col. of Phys. & Surg., New York, NY 10032.

In the abdominal ganglion of Aplysia, the transmitter output of cell L10 can be reduced by stimulating L32 neurons. Histamine, the putative transmitter of L32, mimics the synaptic actions of L32 and reduces the transmitter output of L10 (Kretz et al., J. Neurophysiol. 55:113 and 131, 1986). It also stimulates the formation of metabolites of arachidonic acid in Aplysia neurons (Piomelli, Shapiro, Feinmark & Schwartz, Soc. Neurosci. Abst. 12:1340, 1986), and this prompted us to examine the role of the arachidonic acid cascade in the L32 circuit.

In ganglia prelabeled with [^{3}H]arachidonic acid, physiological intracellular stimulation of L32 neurons generated labeled metabolites of arachidonic acid including 12-hydroxyeicosatetraenoic acid (12-HETE) and prostaglandin E_2. Application of arachidonic acid onto L10 (0.1 mM puffed from a broken micropipette) reversibly hyperpolarized L10 through an apparent increased conductance mechanism, and reduced its transmitter output by 26%, mimicking both the stimulation of L32 and the application of histamine. Application of seawater or eicosamonoenoic acid had no effect.

The responses of L10 to histamine are blocked with the phospholipase inhibitor 4-bromophenacyl bromide (BPB), providing further indication for the involvement of arachidonic acid. Histamine (10^{-4} M) was puffed onto L10 to elicit hyperpolarizing responses; BPB (20 uM in 0.1% DMSO) within 30 min inhibited this response by more than 90%. Using 50 uM BPB we were also able to reduce the L32-L10 IPSP. Histamine and L32 responses were stable for over 1 h in 0.1% DMSO alone.

We suggest that presynaptic inhibition in L10 is produced by a cascade initiated by a histamine receptor which activates a phospholipase to liberate arachidonic acid from membrane phospholipids. Cell-specific metabolism of arachidonic acid might generate a variety of second messengers that affect characteristic membrane conductances and thereby reduce transmitter release. FMRFamide has also been found to produce inhibition by a similar mechanism in sensory neurons (Piomelli et al., Nature, submitted). We are now attempting to identify the active metabolites and are examining the conductance pathways that they modulate in L10.

169.10 PERTUSSIS TOXIN-SENSITIVE G PROTEIN TRANSDUCES THE RESPONSE TO HISTAMINE THAT PRODUCES PRESYNAPTIC INHIBITION IN L10, AN IDENTIFIED APLYSIA INTERNEURON. S.S. Vogel*, E. Shapiro, G.J. Chin and J.H. Schwartz (SPON: M.E. Swanson). Howard Hughes Med. Inst., Columbia Univ. Col. of Phys. & Surg., New York, NY 10032.

A M_r 40,000 protein, labeled by pertussis toxin (IAP)-catalyzed [^{32}P]ADP-ribosylation (Critz et al., Neur. Lett. 64:145, 1986), is also recognized by antibodies raised against bovine G protein synthetic peptide sequences (G.J. Chin et al., These Abstracts) in 100,000 x g Aplysia neural membrane fractions; it is not present in the supernatant. In both neural and muscle membranes a single component on SDS-PAGE appears to be labeled with IAP. An identical component was labeled in pooled isolated cell bodies. Western blots on the cell bodies with an antibody that recognizes the IAP substrate revealed that the G protein is present in L10 (Chin et al., ibid.). Partial proteolysis of these substrates from neural and muscle membranes with V8 protease and chymotrypsin reveal similar peptide patterns, suggesting that the proteins from both tissues are alike. In contrast, rat brain and squid optic lobe contain two components that are labeled with IAP; these are likely to be G_o and G_i.

Transmitter output from the Aplysia cholinergic interneuron L10 is reduced by application of histamine, which causes slow hyperpolarization mediated by a decreased Ca^{++} current and an increased K^+ current (Kretz et al., J. Neurophysiol. 55:131, 1986). Intracellular injection of IAP (0.2 mg/ml) within 50 min reduces the peak response to histamine more than 90% without affecting L10's resting potential or input resistance. Inhibition was dose-dependent: injection of 0.1 mg/ml decreased the histamine response by 75%. Injection of heat-inactivated IAP (80°C, 30 min) had no effect. Application of arachidonic acid mimics the histamine response in L10; this suggests that histamine acts as a neurotransmitter and liberates arachidonic acid from L10's membrane through a receptor-linked phospholipase (E. Shapiro et al., These Abstracts). We saw no significant decrease in the arachidonic acid-induced hyperpolarization after the histamine response had first been blocked by injecting IAP; this suggests that the histamine receptor is linked to a phospholipase through an IAP-sensitive G protein.

169.11 12-HYDROPEROXYEICOSATETRAENOIC ACID (12-HPETE), A LIPOXYGENASE METABOLITE OF ARACHIDONIC ACID THAT PRODUCES PRESYNAPTIC INHIBITION IN APLYSIA, IS METABOLIZED TO THE HEPOXILINS A AND B IN NEURAL TISSUE . D. Piomelli*, S.J. Feinmark* and J.H. Schwartz. Depts. of Pharmacology, Medicine, and Howard Hughes Med. Inst., Columbia Univ. Col. of Phys. & Surg., New York, NY 10032.

Several inhibitory responses in Aplysia are mediated through release and metabolism of arachidonic acid. Histamine and FMRFamide, two transmitters that cause presynaptic inhibition, stimulate the formation of the lipoxygenase metabolite, 12-hydroxy eicosatetraenoic acid (12-HETE). Application of 12-HPETE, the short-lived precursor of 12-HETE, mimics these responses in the appropriate identified neurons (Piomelli et al., J. Neurosci., in press, 1987; Piomelli et al., Nature, submitted, 1987; E. Shapiro et al., These Abstracts). 12-HETE, a major metabolic end product of 12-HPETE, was found to be inactive. Does 12-HPETE act as the actual second messenger, or, rather, must it be transformed to another product to be active? To answer this question, we are examining the metabolism of 12-HPETE in Aplysia neurons.

In mammalian tissues, 12-HPETE is converted to other products beside 12-HETE: these include two epoxy alcohols, the hepoxilins A and B (Pace-Asciak et al., J. Biol. Chem. 258:6835, 1983). In Aplysia, we find that [^{3}H] arachidonic acid can be transformed in substantial yields to products with the chromatographic properties of the hepoxilins, as assessed by normal phase HPLC and by thin layer chromatography (after HPLC purification). The identity of these compounds was confirmed using gas-chromatography/mass spectrometry. These products were isolated after incubation of neural components dissected from Aplysia ganglia with either 12-HPETE (50 uM for 10 min) or arachidonic acid (50 uM for 30 min). After they were purified by HPLC, the metabolites were converted to the corresponding methyl esters trimethylsilyl ethers. Hepoxilin A eluted from the GC with an equivalent chain length (ECL) of 23.3 as expected (Pace-Asciak et al., ibid.); characteristic ion fragments for hepoxilin A were generated from this material (m/z 407, 391, 311, 281 and 255). Hepoxilin B had the expected ECL of 22.1, and yielded characteristic ions (m/z 311, 282 and 269). Pace-Asciak et al. (ibid.) has provided evidence that the hepoxilins participate in modulating glucose-stimulated insulin secretion in pancreatic islets. We are testing whether these products are active in Aplysia neurons that are inhibited by histamine and 12-HPETE.

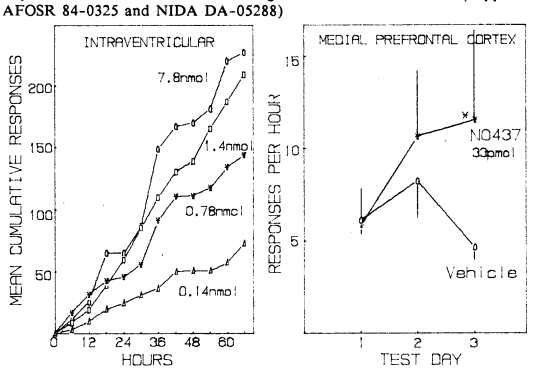
169.12 STIMULATION OF STRIATAL PRESYNAPTIC DOPAMINE D-2 AUTORECEPTORS DIFFERENTIALLY AFFECTS THE ACTIVATION OF TYROSINE HYDROXYLASE BY 2-CHLOROADENOSINE AND PHORBOL DIESTERS. P.Onali, B.Bunse* and M.C.Olianas. Department of Neurosciences, University of Cagliari, via Porcell 4, 09100 Cagliari, Italy.

In striatal dopaminergic terminals tyrosine hydroxylase (TH) activity is under inhibitory control by dopamine (DA) acting on presynaptic D-2 autoreceptors. Previous studies have shown that stimulation of D-2 sites is associated with inhibition of either adenylate cyclase activity or phospholipase C-induced hydrolysis of inositol phospholipids. We have investigated the possible involvement of these second messenger systems in the presynaptic control of TH by examining the effect of the D-2 agonist quinpirole on the stimulation of TH by 2-chloroadenosine (2-CADO), which increases cyclic AMP levels via adenosine A-2 receptors, and by phorbol diesters, which are potent activators of protein kinase C. Striatal synaptosomes were incubated in the presence of the various agents, pelleted by centrifugation and lysed by sonication. TH activity was assayed in the supernatant fraction of lysed synaptosomes using 0.1mM L-(1^{14}C) tyrosine in the presence of pterin cofactor 6-methyl-5,6,7,8-tetrahydropterin (6-MePH4). Exposure of synaptosomes to quinpirole produced an inhibition of TH activity which was maximal (40% decrease of control activity) at 1μM quinpirole, whereas preincubation of tissue with 2-CADO (from 10 to 3000μM) maximally increased TH activity by fourfold. The inhibitory effect of quinpirole was associated with an increase in the Km of TH for 6-MePH4, whereas the enzyme activation by 2-CADO was accompanied by a decrease in the Km for 6-MePH4. Quinpirole reduced by approx. 50% the enzyme stimulation produced by 2-CADO. This effect was antagonized by l-sulpiride but not by d-sulpiride. On the other hand, quinpirole failed to inhibit the activation of TH (50% increase) produced by 1μM phorbol 12-mystrate 13-acetate (PMA). Indeed, in the presence of the phorbol diester the inhibitory effect of quinpirole was significantly smaller than that observed under basal conditions. These results strengthen the idea that inhibition of a presynaptic adenylate cyclase activity is involved in the negative feedback on TH activity mediated by D-2 autoreceptors. Moreover the antagonistic action exerted by PMA on D-2 inhibition of TH activity suggests that the diacylglycerol-protein kinase C pathway may also be operative in the autoreceptor mediated control of striatal DA synthesis.

BEHAVIORAL PHARMACOLOGY: DOPAMINE AND NEUROLEPTICS

170.1 **DOPAMINE D2 "REWARD" RECEPTORS IN MEDIAL PREFRONTAL CORTEX.** K.E. Stevens, N. Nourbakhsh*, J.D. Belluzzi and L. Stein. Department of Pharmacology, College of Medicine, University of California, Irvine CA 92717

Brain self-stimulation studies are contradictory in assessing the relative importance of dopamine D1 and D2 receptors in behavioral reinforcement; some studies implicate the D2 receptor (Gallistel & Davis, 1983), while others implicate the D1 receptor (Nakajima, 1986). In the conditioned place preference test, we found that the specific dopamine D2 receptor agonist N0437 exerted a rewarding effect, whereas the specific D1 receptor agonist SKF38393 did not (Gilbert et al. 1986). Here we used our intraventricular self-administration method (Belluzzi & Stein, 1977) to determine whether rats would learn to work for N0437 solutions delivered directly into the lateral ventricle. A bar-press response delivered one of the indicated doses of N0437 (1μl in 0.9 sec). Rates of self-administration in the 66-hr test were monotonically related to dose (left graph). We also used the cortical self-administration method of Goeders and Smith (1983) to determine whether rats would self-administer N0437 directly in the medial prefrontal cortex. Each bar press delivered 100nl of N0437 (33pmol) or vehicle in 5 sec. On the third test day, hourly self-administration rates of N0437 significantly ($p<0.05$) exceeded that of the vehicle control (right graph). This effect of N0437 was blocked when the D2 antagonist sulpiride (33pmol) was added to the reinforcing solution (not shown). The results support the suggestion of Goeders and Smith (1986) that the medial prefrontal cortex contains reinforcement-relevant dopamine D2 receptors that may be important sites for the reinforcing actions of cocaine. (Supported by AFOSR 84-0325 and NIDA DA-05288)



170.2 BEHAVIORAL SUPPRESSANT EFFECTS OF NEUROLEPTICS IN MONKEYS:RELATION TO DOPAMINE D_2 RECEPTOR BINDING. J. Bergman*, B.K. Madras, D. Canfield*, R.D. Spealman*. Harvard Medical School, New England Regional Primate Research Center, Southborough, MA 01772.

The potencies of a series of neuroleptics for altering schedule controlled behavior were compared with their potencies for binding to dopamine D_1 and D_2 receptors in monkeys. Behavioral experiments were conducted in squirrel monkeys trained to respond under a fixed-interval (FI) schedule of reinforcement. Binding studies were conducted in striatal membranes derived from both fresh and stored (-85°C) brains of cynomolgus monkeys. Dopamine D_1 receptors were labelled with tritiated ^{3}H-SCH 23390 using cis-flupentixol to determine non-specific binding; dopamine D_2 receptors were labelled with ^{3}H-spiperone using S-butaclamol as the baseline drug.

All drugs produced dose-related decreases in response rate under the FI schedule; dose-response curves were approximately parallel for all drugs. The rank order of potency for suppression of schedule-controlled behavior was: cis-YM-09151-2 (YM) > raclopride (RAC) ≈ haloperidol (HAL) > clozapine (CLZ) ≈ remoxipride (REM). All drugs also produced concentration-dependent inhibition of ^{3}H-spiperone or ^{3}H-SCH 23390 binding with pseudo-Hill slopes close to unity. The rank order of potency for displacing ^{3}H-spiperone from D_2 binding sites was similar to the rank order for suppressing schedule-controlled behavior (YM > RAC ≈ HAL > CLZ ≈ REM). However, the rank order of potency for displacing ^{3}H-SCH 23390 from D_1 binding sites differed considerably from the rank order for suppression of behavior (HAL > CLZ > YM > RAC > REM).

These results are consistent with the view that the behavioral suppressant effects of neuroleptics in monkeys are more closely linked to their antagonistic actions at D_2 than D_1 receptors. (Supported by USPHS Grants RR 00168, DA 03773, DA 00499.)

170.3 **EFFECT OF MEDIAL PREFRONTAL CORTEX LESIONS ON DOPAMINE TURNOVER AND DOPAMINE AGONIST INDUCED BEHAVIORS.** G.E. Jaskiw*, F. Karoum, W.J. Freed, J.E. Kleinman, and D.R. Weinberger. Clinical Brain Disorders Branch, NIMH, St. Elizabeths Hospital, Washington, D.C. 20032

Indices of augmented dopaminergic transmission at subcortical sites in the rat have been demonstrated after various lesions of the medial prefrontal cortex (MPFC) and frontal cortex (FC). While it has been suggested that FC and particularly MPFC tonically inhibit subcortical dopamine (DA) systems, it is still not clear how destruction of MPFC neurons alone affects these systems.

Bilateral MPFC lesions were made in male rats (Sprague-Dawley 200-250 gr) using stereotactic injections of ibotenic acid (IA) (5 μg in 0.5 μl), an excitotoxin which preferentiallly affects neuronal bodies while sparing axons of passage. The lesions were confirmed histologically and neurochemically. Behavioral sensitivity to apomorphine was tested using a cumulative dose response schedule (.05, .25, .5 and 1.0 mg/kg) on post-lesion days 7, 14 and 21. Responses to d-amphetamine (2.5 mg/kg) on day 28 were also tested. After a 30 min. habituation phase, locomotion (photocell apparatus) as well as stereotypy (observational rating) scores were recorded for 90 min. following injections of saline and drug. Rats were killed on day 42. Quick frozen brains were sectioned on a cryostat (150 μm thickness) and punch biopsies taken of MPFC, nucleus accumbens, striatum, olfactory tubercle, substantia nigra and ventral tegmental area, for analysis of DA and its metabolites using HPLC. There were no significant differences between sham and IA lesioned animals in stereotypy or locomotion scores at any point during the testing. Behavioral results were also compared to results from biochemical analysis. Our findings are different from those reported following MPFC electrolytic lesions (Carter, C.J. et al. Br. J. Pcl., 62:402, 1978), and FC aspiration lesions (Scatton, B. et al. Brain Res., 232:331, 1982). Selective destruction of MPFC cell bodies may produce different effects than lesions which also affect axons of passage. These data also suggest that the influence of MPFC on subcortical DA systems is not one of simple tonic inhibition.

170.4 ATYPICAL ANTIPSYCHOTICS, LIKE D-1 ANTAGONISTS, INCREASE DOPAMINE METABOLISM BUT NOT RELEASE AT BEHAVIORALLY EFFECTIVE DOSES. C. A. Altar, W. C. Boyar, A. M. Wasley*, S. Gerhardt, J. M. Liebman and P. L. Wood. Neuroscience/Cardiovascular Res. , Pharmaceuticals Div., CIBA-GEIGY Corp., Summit, NJ 07901.

Behaviorally effective doses of clozapine (Wood et al, Prog. Neuropscyhopharm. Biol. Psych. 7:765, 1983) and CGS 10746B (Altar et al, Life Sci. 39:699, 1986) decrease or do not change 3-methoxytyramine (3-MT) levels and increase dihydroxyphenylacetic acid (DOPAC) and homovanillic acid (HVA) concentrations. Because D-1 antagonists also increase dopamine metabolism but not release (Boyar and Altar, J. Neurochem. 48:824, 1987), the neurochemical activity of some antipsychotics may depend upon a D-1 mechanism, as suggested for clozapine and fluperlapine (Anderson and Braestrup, J. Neurochem. 47:1822, 1986). Using GC/MS analysis, 3-MT, DOPAC, HVA, and dopamine levels were measured in the caudate-putamen 60 min after the oral administration of 14 experimental or clinically effective antipsychotic drugs.

Male Swiss-Webster mice (18-26 g; Mbf:(SW)) received either the cornstarch vehicle (10 ml/kg) or a dose equal to or 6 times the ED_{50} dose for the inhibition of cage climbing induced by a subcutaneous injection of 2.0 mg/kg apomorphine.

DOPAC and HVA were increased by at least one dose of every drug tested. The drugs could, however, be readily categorized by their effects on 3-MT. Among the "atypical" antipsychotics (those relatively free of motor system side effects) or atypical antipsychotic candidates, clozapine and CGS 10746B decreased 3-MT at doses that increased or did not alter DOPAC and HVA. Fluperlapine, flumezapine, CL 77,328, BW 234U and RMI 81582 did not change 3-MT levels at doses that increased DOPAC and HVA levels. Thioridazine and mesoridazine increased 3-MT at the higher dose and increased DOPAC and HVA at each dose. Melperone and perlapine consistently increased 3-MT, DOPAC, and HVA, as did the "typical" (side-effect prone) antipsychotics haloperidol, chlorpromazine, and metoclopramide.

In summary, drugs associated with a low incidence of extrapyramidal side effects in humans or animal models increase dopamine metabolism but not release at doses effective in the apomorphine climbing test. Thus, antagonism of a cyclase-linked population of D-1 receptors may be a mechanism that contributes to the atypical profile on dopamine release identified here.

170.5 BLOOD LEVELS OF NEUROLEPTICS AND METABOLITES AND CLINICAL RESPONSE IN SCHIZOPHRENICS. Robert D. Edkins*, Thomas Mattio*, Samuel D. Shillcutt* and Douglas W. Hoffman (SPON: B. Manyam). Neurochemistry Lab., SIU Sch. of Med., Springfield, IL 62708.

There are both clinical and basic scientific difficulties in the current methods of neuroleptic quantification. Radioreceptor assays (RRA), relative to high performance liquid chromatography (HPLC), have the advantages of greater sensitivity combined with a measure of biological activity, but they cannot distinguish active metabolites or nonspecific interference from parent drug, as can HPLC. To resolve these problems, we are performing HPLC of neuroleptic drugs and metabolites in patient plasma followed directly by RRA of all the HPLC fractions, which provides the sensitivity of detection of the RRA coupled with the selectivity and resolution of HPLC.

Receptor binding assays for D_2, $alpha_1$ and sigma receptors are performed, as neuroleptic drugs and their metabolites have been shown to be pharmacologically active at several classes of neurotransmitter receptors. The antagonism of D_2 receptors by neuroleptic drugs is central to the dopamine theory of schizophrenia, but the activities of neuroleptics and their metabolites at other receptor sites may play a significant role in both their therapeutic and toxic actions, and so raise questions regarding an exclusive role for D_2 receptors in schizophrenia and neuroleptic activity.

Up to 50% of patients respond poorly to these medications or experience serious toxicity or severely disabling or discomforting side effects. We are using our method to compare the plasma levels of phenothiazine and metabolites in patients who are clinically defined as responders or non-responders to drug therapy, and in patients in whom side-effects develop. We have identified several different patterns of metabolism in patients with positive response to neuroleptic medication.

170.6 MOTOR AND POSTURAL EFFECTS OF HALOPERIDOL AND OTHER SIGMA LIGANDS AT A NON-DOPAMINERGIC RECEPTOR SITE. R. R. Matsumoto, W. D. Bowen, D. L. Gans*, K. D. Jones*, F. O. Walker*, J. M. Walker. Brown University, Providence, RI 02912 and Wake Forest University, Winston-Salem, NC 27103.

It has been suggested that the motor side effects of haloperidol and other antipsychotic drugs are mediated by dopamine systems. However, many antipsychotic drugs, including haloperidol, have been shown to bind to a non-dopaminergic subclass of sigma receptors. The possible involvement of this haloperidol-sensitive sigma receptor in posture and movement was tested in rats. Di-ortho-tolylguanidine (DTG), a selective ligand for the haloperidol-sensitive sigma receptor, and two other sigma ligands (haloperidol and +SKF10,047) were unilaterally microinjected into the red nucleus and substantia nigra pars reticulata, two areas rich in sigma receptors and known to be involved in posture and movement.

Unilateral microinjections of haloperidol hydrochloride and DTG acetate (9.3, 3.72, and 1.49 nmol) into the red nucleus produced dose-dependent torsional head angles that resembled the abnormal postures of clinical torticollis, a motor side effect that can be precipitated by antipsychotic drug treatment. +SKF10,047, a sigma ligand that is less potent than haloperidol and DTG in binding assays for the sigma receptor, also produced torticollis, but to a lesser degree than haloperidol and DTG. In addition to the abnormal postures, a noticeable reduction in spontaneous movement was observed in the animals. Although the actions of haloperidol, DTG, and +SKF10,047 in the red nucleus resemble some side effects of antipsychotic drug treatment, the effects are thought to be mediated by sigma receptors and not dopamine receptors since: (1) DTG binds sigma, but not dopamine receptors, and (2) the red nucleus is virtually devoid of any other type of receptor that may interact with either haloperidol or +SKF10,047 (i.e. the red nucleus contains almost no dopamine, norepinephrine, PCP, opiate, or 5-HT2 receptors).

A second group of animals received unilateral microinjections of one of five doses (5.0, 1.25, 0.31, 0.078, or 0.019 ug) of DTG acetate in the substantia nigra pars reticulata. Significant dose-dependent contralateral rotations were produced at doses as low as 0.078 ug. These activating effects of DTG in the pars reticulata are among the most potent effects ever reported in the nigra and suggests that an endogenous ligand for sigma receptors may be involved in movement. Haloperidol and +SKF10,047 were not tested in the pars reticulata since they cross-react with other non-sigma receptors that are also present in the nigra.

The findings suggest that sigma receptors may be involved in movement and posture. It also appears that at least some of the motor effects of antipsychotic drug therapy that are normally attributed to dopaminergic systems may in fact be mediated by haloperidol-sensitive sigma receptors.

170.7 ROLE OF THE A10 DOPAMINE NEURONS IN SENSITIZATION TO COCAINE AND AMPHETAMINE, P.W. Kalivas*, and B. Weber, Department of Veterinary and Comparative Anatomy, Pharmacology and Physiology, Washington State University, Pullman, WA.

It is known that daily treatment with cocaine or amphetamine produces a progressive increase in the motor stimulant effects of these drugs. Since both of these drugs produce an acute psychostimulant effect by augmenting dopamine (DA) neurotransmission, it is generally presumed that an enhancement in the capacity of cocaine or amphetamine to augment DA neurotransmission may underlie the behavioral sensitization following daily administration. However, in one study it was found that daily microinjection of amphetamine into the nucleus accumbens (a DA terminal field) did not augment the behavioral response to subsequent peripheral amphetamine administration (Life Sci., 1981). Since it is now known that behavioral sensitization to peripheral opioid administration results primarily from an action in the A10 DA region (J. Pharmacol. Exp. Ther., 1987), we designed experiments to determine if amphetamine and cocaine may be acting in the A10 DA region to produce behavioral sensitization.

Male S.D. rats were implanted with chronic injection cannulae into the A10 or A9 DA region, or into the nucleus accumbens, striatum or lateral ventricles. Amphetamine (0.5-15.0 µg/brain) was bilaterally injected into the implanted brain region once a day for two days. One to two weeks later the rats were adapted to a photocell cage for 60 min, followed by injection of saline, ip. The next day following a 60 min adaptation the rats were injected with cocaine (15 mg/kg, ip) or amphetamine (1.0 mg/kg, ip) and motor behavior monitored for 120 min. It was found that rats pretreated with amphetamine in the A10 or A9 regions demonstrated a greater motor stimulant response to amphetamine and cocaine. However, the threshold dose for the A10 region was 0.5 to 1.5 µg of amphetamine, while it was 1.5 to 5.0 µg for the A9 region. In contrast, pretreatment with 15 µg amphetamine into the nucleus accumbens, striatum or lateral ventricles did not alter the motor stimulant effect of subsequent peripheral administration of cocaine or amphetamine. These data argue that the capacity of daily amphetamine or cocaine administration to produce behavioral sensitization may result from an action on the A10 and perhaps A9 DA perikarya. Since behavioral sensitization to these psychostimulants in humans can produce paranoid psychotic symptoms, these data argue that a drug-induced change in the function of DA perikarya, not terminal fields, may mediate this action.

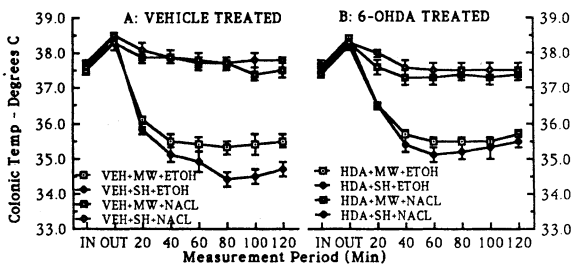
170.8 STRESS-INDUCED INSOMNIA: OPIOID-DOPAMINE INTERACTIONS W.Fratta, M.Collu*, M.C.Martellotta*, M.Pichiri*, G.L.Gessa*. Department of Neurosciences-University of Cagliari - Via Porcell,4 09124 Cagliari; Italy.

Platform technique of REM deprivation (REMD) in rats involves several factors such as isolation, immobilization, falling into the water, soaking and others which cause a heavy stress. A peculiar feature of this model is that the period of REMD is immediately followed by a constant period of wakefulness characterized by a high degree of motor activity, exploratory behaviour, increased alertness and reactivity toward enviromental stimuli. At the end of this period the rats fall asleep and show the first episode of REM sleep whithin few minutes. For the above reasons we have regarded this particular feature as a model of stress-induced insomnia. In order to understand the possible biochemical mechanisms involved in this phenomenon, we have investigated whether different treatments, known to affect opiatergic, dopaminergic and gabaergic neurotransmission, could specifically interfere whith this behaviour. The results obtained indicate that this peculiar phenomenon of excitement and insomnia is related to an hyperactivity of opiatergic and dopaminergic systems. In fact, excitement and sleep latency were significantly reduced by Naloxone while Morphine, β-Endorphin and DADLE have an opposite effect. Neither Diazepam nor the benzodiazepine antagonist Ro 15-1788 had any effect, suggesting that GABA systems do not play a specific role in this situation. A dopaminergic control, specifically mediated through D1 type receptors seems to be evident. Thus, while Sulpiride was ineffective, the selective D1 antagonist SCH 23390 was extremely potent in reducing the sleep latency and excitement following REMD. On the contrary, the administration of the specific D1 agonist SKF 38393 induced a marked opposite effect. These data do not exclude the possibility that other neurotransmitter systems might actively interact in this situation. However, these results indicate that opioid and dopaminergic systems, the latter specifically through D1 receptors, play a crucial role in this experimental model of stress-induced insomnia.

170.9 6-HYDROXYDOPAMINE BLOCKS 2.45 GHz MICROWAVE ATTENUATION OF ETHANOL-INDUCED HYPOTHERMIA IN RATS. D.L. Hjeresen and J.M. O'Donnell. Biophysics/Neurobiology Group, Los Alamos National Laboratory, Los Alamos, NM 87545

Recent work in our laboratory has focused on the possible interaction between low-level microwave irradiation and central neurotransmitter systems. Specifically, we have confirmed the report by Lai et al. (Bioelectromagnetics 5:213, 1984) that low-level microwave energy (Specific Absorption Rate = 0.3 to 0.6 W/kg, 2.45 GHz, CW) attenuates the hypothermic effects of ethanol (EtOH). Additional studies suggest that this effect is mediated in part by an interaction between microwave energy and beta-adrenergic neurotransmitter systems. That is, the microwave attenuation can be blocked by pretreatment with propranalol or sufficient doses of CGP-12177, both beta-adrenergic antagonists. The present study was conducted to determine if pretreatment with the noradrenergic neurotoxin 6-hydroxydopamine (6-OHDA) would also block the microwave attenuation of EtOH-induced hypothermia.

Ninety-six male and female Long-Evans rats were injected with 6-OHDA or vehicle (1 mg/kg, s.c.) at four days of age. At 60 days of age (mean body weight = 242.6 ± 24.2 g) rats were tested in a 2 X 2 X 2 design comparing pretreatment (6-OHDA/vehicle), microwave or sham irradiation (0.3 W/kg, 45 min, CW irradiation in circularly polarized waveguides), and ethanol (3.5 g/kg, 20% v/v, i.p.) or saline injection. Colonic temperature was monitored before and after irradiation and at 20 min intervals for 2 hr. Panel A of the figure demonstrates that microwave irradiation significantly attenuated the EtOH-induced hypothermia of vehicle treated rats. Panel B illustrates that neonatal pretreatment with 6-OHDA attenuated this microwave effect. No differences were noted on the basis of the sex of the animals. Analysis of central and peripheral tissues indicates nearly complete depletion of NE in 6-OHDA treated animals. The results support our hypothesis of a microwave interaction with noradrenergic systems. Supported by the U.S. Air Force School of Aerospace Medicine.



170.10 THE SITE OF THE ANTIEMETIC ACTION OF METOCLOPRAMIDE ON GASTRIC IRRITATION INDUCED EMESIS IN THE FERRET. J. D. Naylor* and G. E. Lucier (SPON: A. G. M. Bulloch). Department of Medical Physiology, Faculty of Medicine, University of Calgary, Calgary, Alberta, Canada T2N 4N1.

Metoclopramide is an antiemetic which is currently used to alleviate emesis due to antineoplastic drugs. The site of the antiemetic action of metoclopramide has not been clearly defined, although central and peripheral locations have been suggested. This drug is thought to block apomorphine induced emesis centrally by binding dopamine receptors in the chemoreceptor trigger zone (CTZ). Metoclopramide also blocks the visceromotor correlates of emesis, gastric relaxation and reverse peristalsis, and coordinates the aborad peristaltic activity of the gastroduodenum. This action on the efferent limb of the emetic reflex is dependent on the intramural release of acetylcholine (ACh) and possibly the antagonism of the intrinsic non-adrenergic non-cholinergic (NANC) inhibitory neurotransmitter. The purpose of this study was to identify the site of action of metoclopramide during electrical and gastric irritation induced emesis in the ferret.

Adult male ferrets, (0.7 to 1.3 kg) were anesthetized and maintained with a halothane/oxygen mixture. Emesis was elicited by electrical stimulation of the supradiaphragmatic vagal communicating branch as previously reported (Naylor and Lucier, IUPS Proc. 26:P261.12, 1986) and by intragastric administration of hypertonic saline (1.5 M). Each emetic episode was documented by recording tongue, diaphragm and abdominal muscle EMG, thoracic venous pressure and arterial pressure.

In order to show that electrical stimulation and gastric irritation were dependent on a common vagal afferent pathway, the right and left cervical vagal trunks were cooled. This resulted in failure to produce emesis with either stimuli. Following control elicitation of emesis by both electrical and gastrointestinal stimuli, metoclopramide (5 mg/kg IV) blocked vomiting produced by hypertonic saline but failed to have any effect on electrically induced emesis. The persistence of the response to electrical stimulation eliminates the possibility that metoclopramide is acting centrally at a medullary vomiting center, or indirectly through dopamine antagonism in the CTZ. The selective blockade of vomiting due to gastric irritation suggests that metoclopramide exerts this antiemetic effect by acting at the level of the gut, on the afferent limb of the emetic reflex. (Supported by the Alberta Cancer Board)

170.11 SPECIFIC D-1 AND D-2 DOPAMINE AGONISTS AND ANTAGONISTS HAVE SYNERGISTIC EFFECTS IN THE RAT 6-OHDA CIRCLING MODEL. C. Rouillard and P.J. Bédard, Lab. Neurobiology, Laval Univ., Québec, CANADA, G1J 1Z4.

The possibility of a functional interaction between D-1 and D-2 dopamine receptor subtypes has arisen from the recent use of highly selective D-1 and D-2 agonists and antagonists in biochemical, physiological and behavioral studies. In the present study, we have studied the effects of specific D-1 and D-2 agonists (SKF 38393 (2.5 mg/kg i.p.) and RU 24213 (30 mg/kg i.p.)) alone and the synergistic effects of a combination of half-doses of both drugs on circling behavior in rats with a unilateral 6-OHDA lesion of the nigrostriatal pathway. We have also studied the ability of SCH 23390 and sulpiride to antagonize these synergistic effects. Finally, we have investigated the ability of these specific antagonists to block the circling induced by two non-specific dopamine agonists (apomorphine and amphetamine). The results show that some animals responded to only one of the selective dopamine agonists alone, some responded to both but all responded to apomorphine and to the combination of half-doses of SKF 38393 and RU 24213. A powerful synergistic effect was demonstrated when specific dopamine agonists were given in combination. The circling response was greatly enhanced. The increase was 300% when compared to the circling response to SKF 38393 alone and 376% when compared to that of RU 24213 alone. Sulpiride (100 mg/kg i.p.) almost completely blocked the circling response (decrease of 78%) induced by the combination of these drugs. However, the D-1 antagonist SCH 23390 even at a dose of 3.0 mg/kg i.p. was totally inefficient. The blocking capacity of SCH 23390 and sulpiride was highly diminished in the apomorphine-induced circling model compared to the amphetamine-induced circling model where normosensitive dopamine receptors are involved. Amphetamine-induced ipsiversive circling was almost completely suppressed by prior administration of sulpiride (100 mg/kg, decrease of 91%) or SCH 23390 (3 mg/kg, decrease of 96%) while the same doses of antagonists were unable to block more than 65% of the apomorphine-induced contraversive circling. However, when we combined D-1 and D-2 antagonists, a more powerful blockade of the action of apomorphine was achieved (decrease of 83%). These data suggest an heterogeneous responsiveness to D-1, D-2, D-1 plus D-2 and mixed D-1/D-2 dopamine agonists and a strong synergistic effect of the combination of SKF 38393 and RU 24213. In our study, only the D-2 antagonist sulpiride was a potent blocker of that synergy. Denervation also induced some changes in the ability of specific dopamine antagonists to block the behavioral response after the administration of non-specific dopamine agonists. (Supported by MRC and Parkinson Foundation of Canada).

170.12 DIFFERENTIATION OF THE DIRECTLY ELICITED BEHAVIORAL EFFECTS OF TWO HALOPERIDOL-SENSITIVE SIGMA SITE LIGANDS, 1,3-DI-ORTHO-TOLYL-GUANIDINE (DTG) AND (+)3-(3-HYDROXY-PHENYL) N-(1-PROPYL) PIPERIDINE ((+)3-PPP). W.D. Essman[1]*, W. Koek[2]*, J.H. Woods[1,2], E. Weber[3]. Depts. of Psychology[1] and Pharmacology[2], Univ. Michigan, Ann Arbor, Michigan, 48109 and Dept. of Biochemistry[3], Oregon Health Sciences University, Portland, Oregon, 97201.

Two classes of phencyclidine (PCP) binding sites have been proposed; a PCP site associated with an NMDA-antagonist binding site, and a "sigma" site, characterized by high affinity binding of certain neuroleptics (e.g., haloperidol) and two new drugs, (+)3-PPP and DTG (Weber et al., 1986, Proc. Nat'l. Acad. Sci. USA 83: 8784-8788). The purpose of the present study was to evaluate the directly elicited behavioral effects of the two purported selective haloperidol-sensitive sigma ligands, DTG and (+)3-PPP, in rats. Upon intraperitoneal administration, (+)3-PPP produced a dose-dependent increase in elicited behaviors, e.g., increased locomotion (10.0 mg/kg), rearing (18.0 mg/kg), sniffing (18.0 mg/kg), and locomotion with the head held close to the floor (56.0 mg/kg), with clonic convulsions and death produced by doses between 100.0 and 320.0 mg/kg. Increased locomotion, rearing, and sniffing were elicited following administration of 10.0-32.0 µg of (+)3- PPP directly into the lateral ventricle; doses up to 560.0 µg icv did not produce the clonic convulsions and death observed after high doses administered ip. As reported previously, ip injections of DTG did not induce a PCP-like behavioral syndrome (Woods et al., 1987, Fed. Proc. 46: 951); 10.0 mg/kg elicited a still posture with the head resting directly on the floor of the observation chamber, while 32.0 mg/kg induced labored breathing, gaping, and death. DTG administered icv induced a distinct set of behaviors; 32.0 µg elicited an increase in forelimb extension and backward-walking and/or circling (pivoting backward around one hind limb). The percentage of rats displaying these effects increased dose-dependently to 100% at a dose of 100 µg. A dose of 320.0 µg icv induced gaping, loss of righting, and falling, but not death. It is not known what mechanisms or pharmacological factors mediate the different behavioral syndromes observed after administration of these two haloperidol-sensitive sigma ligands. Supported in part by USPHS Grant DA-00154.

MOTOR SYSTEMS AND SENSORIMOTOR INTEGRATION: CEREBELLUM II

171.1 SOMATIC AFFERENT TERMINATION PATTERNS IN THE CAT INFERIOR OLIVE. H.H. Molinari and R.N. Sluyters*. Department of Anatomy, Albany Medical College, Albany, N.Y. 12208.

The gracile nucleus and lumbosacral spinal cord relay most of the somatic information from the hindlimb that reaches the inferior olive. These somatic afferents terminate in three distinct olivary subdivisions, the rostral dorsal accessory olive (rDAO), caudal dorsal accessory olive (cDAO), and caudal medial accessory olive (cMAO). A recent ultrastructural study (Molinari, 1987) demonstrated that in rDAO, gracile axons terminate primarily in dendritic thickets. The present study addressed the question of whether all somatic afferents to the different parts of the inferior olive terminate in a similar fashion.

Gracile terminals in cMAO and spinal cord terminals in rDAO and cDAO were labeled, as in Molinari (1987), by anterograde transport of wheat germ agglutinin-horseradish peroxidase and visualized with tetramethylbenzidine. The tissue was prepared for EM using a modification of Lemann et al. (1985). The postsynaptic elements receiving input from the labeled somatic afferents were classified as isolated, if they did not directly contact any other dendritic element, or part of a complex, if they did. The complexes were called dendritic thickets if the majority of postsynaptic elements were dendritic shafts (Sotelo et al., 1974); and called spine clusters, if the majority were spines.

Gracile and spinal cord terminals in all parts of the inferior olive contained round synaptic vesicles and formed asymmetric synapses and were presumably excitatory. In rDAO, the majority of spinal cord axons, like gracile axons, terminated in dendritic thickets. Synapses in dendritic thickets were seven times more common than were those on spine clusters. The majority of somatic afferents in cDAO and cMAO also terminated in complexes. In marked contrast, however, in these two regions synapses in spine clusters were as common as synapses within dendritic thickets. Thus, the dendritic thicket is the major target of somatic afferents in rDAO but not in either cDAO or cMAO.

Serial reconstructions of the spine clusters that received somatic input revealed that these spines arose from one or two dendritic shafts which were themselves generally part of a dendritic thicket. It is therefore possible that spine clusters develop from dendritic thickets and that the major difference between somatic afferents in rDAO and in cDAO and cMAO is the proximity of their synapses to the spines that arise from groups of olivary dendrites.

Supported by NSF Grant BNS-8506475.

171.2 **ORGANIZATION OF OLIVARY PROJECTIONS TO THE ANTERIOR LOBE OF THE CEREBELLUM IN THE RAT** S.A. Azizi, A. J. Painchaud, and D. J. Woodward *University of Texas Health Science Center at Dallas, Dallas Texas 75235*

As part of an ongoing study of the organization of the olivo-cerbellar system, in this series of experiments we have determined the detailed projections of the olivary neurons to the anterior lobe of the cerebellum in the rat. Small quantities (.01 to .2 µl) of *HRP-WGA* were pressure-injected into discrete areas of the anterior lobe of the cerebellar cortex in 38 rats. The sensitive chromogen tetramethyl benzidine was used to visualize the labeled neurons.

In previous studies we have divided the inferior olivary complex into seven lamellae (*JCN 1987*). Results of the present investigation demonstrated that three of these lamellae project to three distinct sagittal zones in the anterior lobe of the cerebellum. Clusters of cells located in the horizontal lamella (groups *a* and *b*) of the medial accessory olive project to a sagittal zone in the midvermal region of lobules I - V. Cells that constitute the dorsal fold of the dorsal accessory olive (caudal region of *DAO*) project to a sagittal zone located laterally to the above. Cells located in the ventral fold of the dorsal accessory olive project to a third sagittal zone in the cerebellum. In addition, a small group of neurons in the principal olive projects to a lateral zone of lobules IV and V, and a few scattered neurons in nucleus beta and *c* project to lobule I.

A microorganization was noted within the lamellae. Cells located in the lateral aspect of the horizontal lamella (group *a*) project to lobule III, while neurons located in medial aspect of this lamella (group *b*) project to lobules I and II. Similarly, neurons in the caudal lateral regions of the dorsal fold project to lobule III, while the more medial and rostral neurons project to I and II.

In summary, we have studied the organization of the olivary prjections to the anterior lobe of the cerebellum. Three slabs of olivary cells (lamellae) project to three sagittal zones in the anterior lobe of the cerebellum. The horizontal lamella of the *MAO* projects to a midvermal sagittal zone, while the two lamellae that form the *DAO* project to two sagittal zones located more laterally. A microorganization was discovered such that small clusters of cells within each lamella project to small patches within each sagittal zone These patches collectively form the sagittal strips.

Supported by DA-2338 and Biological Humanics Foundation

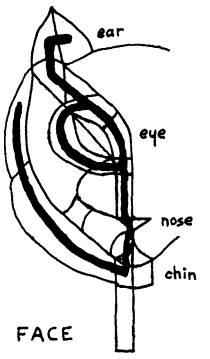
171.3 THE INFLUENCE OF GRANULE CELLS ON PURKINJE CELLS IN TACTILE REGIONS OF THE RAT CEREBELLAR CORTEX: AN IN VITRO INTRACELLULAR AND IN VIVO MULTI-SINGLE UNIT EXTRACELLULAR APPROACH. M. Rao, B. Rasnow, M. Nelson, and J. Bower. Divisions of Biology and Physics, Caltech, Pasadena, CA 91125.

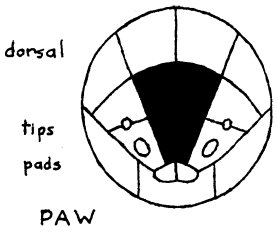
The overall objective of this is to understand input output relationships within cerebellar cortex. Specifically, tactile, mossy fiber inputs to the granule cell layers of the cerebellar hemispheres of the rat are organized in a patchy somatotopic fashion (Shambes et al., BBE 15: 94, 1978). Examination of the output of Purkinje cells (and thus the cortex) overlying these patchy projection patterns has revealed two somewhat surprising results (Bower and Woolston, J. Neurophysiol. 49: 745, 1983): first, no parallel fiber beam-like pattern of activity is evoked following activation of restricted granule cell layer loci, instead activated Purkinje cells are only found directly over active regions of granule cell layer; and second, in activated cells, short duration (5 msec) tactile stimuli result in rate changes in simple spike activity lasting hundreds of msecs.

We have pursued both results using two different physiological techniques. First, we have developed multi-single unit extracellular recording methods to sample activity in numerous Purkinje cells and their underlying granule cell layer locations at the same time. These techniques have allowed us to use tactile stimuli to restrictively activate small regions of the granule cell layer and explore subtle influences of parallel fibers on distant Purkinje cells. Second, we have used intracellular in vitro brain slice techniques to examine in detail the influence of granule cell layer activation of Purkinje cells. For example, using a slice cut parallel to the plane of the Purkinje cell dendrite and multiple stimulating electrodes positioned under the cell, we have found that brief (100 μsec) activation of the granule cell layer evokes a prolonged (200-300 msec) plateau potential that is graded with respect to stimulus intensity, and sums with stimuli delivered simultaneously at different underlying granule cell layer locations. The additional fact that this potential often induces prolonged increases in simple spike activity suggests that it may underlie the long duration responses of Purkinje cells to short tactile stimulation seen in vivo. Supported by NS 22205 and the Joseph Drown Foundation.

171.4 AGGREGATION OF COMPARTMENTS TO FORM CAT CLIMBING FIBER TACTILE RECEPTIVE FIELDS. Gin McCollum and Lee T. Robertson, Neurological Sciences Institute, Good Samaritan Hospital and Medical Center, 1120 NW 20th Ave., Portland, Oregon 97212.

In sets of cells with intersecting receptive fields, the composition of the receptive fields is related both to the type of information they can encode and to the ensembles of cells that work together to encode it. Receptive fields are unions of compartments, the smallest units of skin surface that can be resolved by groups of climbing fibers in the anterior lobe. Analysis of 291 receptive fields shows that both face and paw receptive fields are usually unions of compartments that are neighbors on the skin. However, two neighboring toe tips or toe pads can constitute a receptive field, even though they are separated by intervening skin. On the other hand, two compartments which are neighbors on the skin can fail to behave as contiguous in receptive fields. For example, face receptive fields do not cross the jawline. Rather, they form lines of compartments, as indicated by the heavy line: from nose to ear above the eye, around the eye, and under the jawline. Receptive fields along the nosebridge and the jawline intersect at the chin. Paw receptive fields form medial-to-lateral lines among toe tips and toe pads, but in general their shape is more rectangular: when more than one toe is included, the same surfaces are included in all toes, as in the paw receptive field shown.





Cells with intersecting receptive fields are activated when the intersection of their receptive fields is stimulated. Groups of cells with few pairwise intersections can be separated according to the area of the skin they encode. This is true of cells with face receptive fields. On the other hand, cells with paw receptive fields are not easily separated into groups; information from all areas of the paw must be processed together.

171.5 FEATURES OF SOMATOTOPIC ORDER IN THE REPRESENTATION OF CUTANEOUS MECHANORECEPTOR INPUTS IN THE CEREBELLUM. K. L. Johanson and J. T. Wall. Department of Psychology, Vanderbilt University, Nashville, TN 37240.

Ascending circuits from mechanoreceptors in the skin to primary somatosensory cortex have been extensively studied, and are known to be somatotopically organized. The somatotopy of other circuits which process tactile information has received less attention. The present study characterized the somatotopic organization of low threshold cutaneous inputs to the cerebellum in folium 9a of the uvula in rats.

Normal adult rats were anesthetized with ketamine hydrochloride. The caudal cerebellum was exposed, covered with silicone fluid, and photographed. A tungsten microelectrode was angled perpendicular to the folium surface and multiple unit receptive fields to tactile stimuli were defined over a systematic array of penetrations. As indicated by depth readings and by locations of microlesions made during recordings, cutaneous responses were recorded from the granule cell layer.

Cutaneous mechanoreceptor inputs to folium 9a are characterized by the following features. (1) The receptive field location of neurons at any given recording site remains relatively constant throughout the depth of the granule cell layer. (2) Receptive fields are primarily located on the head, and involve the vibrissae pad, upper lip, caudal face, nose, scalp, and neck. Occasional forearm and forepaw receptive fields are also encountered. (3) All receptive fields are ipsilateral. The midline of the folium represents the junction between the two head representations. (4) Receptive fields are relatively large; e.g., vibrissae fields typically involve convergence of several vibrissae onto neurons at a single recording site. (5) Although there is some "between animal" and "between side" variability, each hemifolium consistently has a large mediolaterally oriented strip representing the vibrissae, which is adjacent to two relatively large, but split representations of the upper lip. (6) Within the representation of the vibrissae, inputs from each row diverge widely across the folium. Vibrissae in rows D and E activate neurons at more penetrations than vibrissae in other rows.

These results indicate that folium 9a contains an organized map of the head. The multi-vibrissae receptive fields, wide divergence of inputs from each vibrissae row, and split upper lip representation indicate this map is not as tightly somatotopic as the primary somatosensory cortical map of the comparable skin area. (Supported by Grant NS21105).

171.6 **INTERACTION OF VISUAL AND AUDITORY RESPONSES IN RAT CEREBELLAR PARAFLOCCULUS** Brian N. Maddux, S.A. Azizi, and D.J. Woodward *Dept of Cell Biology and Anatomy, University of Texas Health Science Center at Dallas. Dallas, Texas 75235.*

As part of ongoing studies of sensory inputs to the cerebellum, we have previously demonstrated anatomic connections from regions in secondary visual and auditory cortices via dorsolateral pons to the paraflocculus. In addition, we have demonstrated that parafloccular neurons are responsive to both physiologic auditory and visual stimuli. The goal of the current study was to understand the nature of temporal and spatial interactions among signals incoming to the cerebellar cortex via these sensory modalities. In the initial phase of this project, we report results of interactions of responses to pure tones with electrical stimulation in visual cortex.

Long-Evans female rats were anesthetized with halothane in oxygen. Bipolar concentric tungsten stimulating electrodes were implanted in area 18 of visual cortex. Unit recording in paraflocculus was accomplished with glass micropipettes and conventional unit recording apparatus. Real time computer software (UnitLab) was used for collection and analysis of data. Suprathreshold electrical stimuli consisted of double cathodal pulses (0.1 ms duration spaced 2 ms apart, intensities of 100-500 microamperes), and auditory stimuli were 10 kHz tones (200 ms duration at 85 dB). Preliminary results were obtained from 15 units which responded to electrical and/or auditory stimuli. Each unit recorded was subjected systematically to electrical, auditory, and combined stimulation.

Inspection of post-stimulus time histograms (PSTHs) revealed that the majority of cells responded to electrical stimulation with an excitatory peak at about 8-12 ms, followed by an inhibitory trough of variable duration. The peak of excitation ranged from 40% to 2300% over background activity. Each unit was also tested with auditory stimulation. Two units exhibited a relatively large (65% and 116%) sustained increase in activity during the tone. In four other cells, slight (15-20%) increases were recorded during the entire tone. The remainder of cells did not respond to auditory stimuli.

In the combined stimulus protocol, the electrical stimulus was delivered up to 50 ms after the onset of the tone. In seven cells, the excitatory response to electrical stimulation was accentuated in the presence of the tone. Two of these seven cells had not exhibited any response to auditory stimuli alone, and four others had shown only weak (15-20%) response to the tone. Inhibitory responses to electrical stimulation were slightly reduced in three cells during the tone, two of which displayed enhanced excitatory response. A reduction of both excitatory and inhibitory responses was seen in one cell.

In these studies, the alteration in the activity of a cell in the cerebellar cortex to a stimulus is dependent both on parameters of that stimulus and on the convergence of other inputs. It is clear that nonlinear summation of excitatory and inhibitory influences can occur. Also, significant interactions occur between inputs subthreshold for causing direct changes in Purkinje cell activity. We have particular interest in such subthreshold phenomena in view of recent suggestions that auditory processing in cerebellum may trigger, after a delay, learned motor responses which involve cerebellar circuitry. *Supported by grant DA-02338 to DJW and the Biological Humanics Foundation.*

171.7 CLIMBING FIBER REPRESENTATION OF CRUS I OF THE CAT CEREBELLUM. Stephen A. Elias* and Lee T. Robertson. Neurological Sciences Institute, Portland, OR 97209

This study examines the climbing fiber organization of crus I as part of a long term project to determine the representation of the body surface in the cerebellar cortex. This region of the cat cerebellar cortex has been shown using electrical stimulation, to receive both mossy fiber and climbing fiber input from the face and forelimb. Welker and associates have reported that in the rat, the mossy fiber face representation is restricted to a buried folium of crus I and organized in a patchy fashion. However, little information is available on the corresponding climbing fiber representation to tactile stimulation.

The data were obtained from 7 cats anesthetized with sodium pentobarbital. Individual Purkinje cells were isolated with extracellular recording. The climbing fiber responses were elicited by cutaneous (i.e., light mechanical taps with a force of less than 2.0g) and deep stimulation of the body surface. The receptive fields were delineated with von Frey hairs. Reconstructions of the electrode tracks and locations of the isolated Purkinje cells were made from histological sections.

In crus I, 15% (36/209) of the isolated Purkinje cells had climbing fiber responses evoked by tactile stimulation. The proportion of responsive units was similar for both crus Ia and crus Ip. Of the responsive units, 50% represented the forelimb, 11% the hindlimb, 11% the trunk, and 8% the face. The remaining 20% of the responsive units had split receptive fields, either trunk/forelimb, trunk/hindlimb, trunk/face or forelimb/hindlimb. About 65% of the receptive fields were classified as deep.

Climbing fiber responses representing the body surface were located mainly near the medial border with the vermal lobule VII and the border of crus IIp. Some of the responsive units were arranged in patches with similar receptive fields and modalities. Most of the unresponsive units were in the rostral half of crus I, and appear to be a continuation of the unresponsive area previously reported in crus IIa. In contrast to previous reports, no distinct face region for the climbing fiber system in crus I was observed.

Crus I contains a climbing fiber representation from a variety of body areas, most of which required stimulus forces higher than required for cutaneous activation. Nearly all of the responsive climbing fibers were located in the caudal part of crus I, with little or no body representation in the rostral region. (Supported by NIH grant NS 18242)

171.8 **IDENTIFICATION OF GRANULAR LAYER UNITS IN CEREBELLAR CORTEX.** P.L.E. van Kan*, W.G. Kruberg* and J.C. Houk. Dept. of Physiology, Northwestern University Medical School, Chicago, IL 60611.

A previous report described the information content of presumed mossy fiber afferents as determined by single unit recording in the intermediate cerebellar cortex of alert monkeys (Van Kan, Houk & Gibson, Soc Neurosci Abstr 12: 578, 1986). To interpret information flow along the mossy fiber-granule cell-parallel fiber-Purkinje cell path, granular layer neural elements must be identified by adequate and reliable criteria. In the present study we have evaluated the applicability of a method that could be valuable for the identification of mossy fiber afferents in conscious animals. This method is based on the waveshapes of extracellularly recorded action potentials and has been used previously to identify granular layer neural elements in the turtle cerebellum (Walsh, Houk and Mugnaini, J. Neurophysiol. 37: 30, 1974).

10 Cats were anaesthetized with sodium pentobarbital. An array of 3 stimulating electrodes was inserted in the inferior cerebellar peduncle (ICP) for orthodromic activation of mossy fiber afferents. Stimuli consisted of single 50 μs pulses applied between different combinations of electrode pairs. Unitary potentials were recorded with tungsten microelectrodes (1.0-2.5 MΩ) in the anterior lobe of the intermediate cerebellar cortex. Determining the boundaries of the granular layer was aided by the characteristic features of the simple and complex action potentials of Purkinje cells and the shape of the field potential generated by ICP stimulation. Recording sites of single units were histologically verified by electrolytic lesions made at selected sites along each penetration.

Granular layer units were classified on the basis of waveshape. The most frequently encountered types were biphasic (positive/negative) or triphasic (positive/negative/positive) potentials that lacked an IS-SD break. They were of small amplitude (200-300 μV) and had a fast rise time (less than 100 μs). Many of these units were briskly activated from peripheral receptive fields. A subset was asynaptically activated by ICP stimulation. Orthodromic latencies of these units did not vary by more than 0.2 ms over a wide range of stimulus intensities. We attribute these potentials to mossy fiber afferents. Less frequently, we recorded units with larger amplitude waveshapes (1.0-1.5 mV) and more regular firing rates. These units were not activated by ICP stimulation and often receptive fields were not found. We attribute the latter potentials to Golgi cells.

Classification on the basis of waveshape in combination with multiple tests to associate these waveshapes with specific neural structures is potentially of great value because this method can be used to identify all mossy fiber afferents, regardless of their origin. This technique is especially promising for identification of mossy fiber afferents in chronic recording studies since identification under these conditions presents a dilemma for the experimenter: conclusive identification requires chronically implanted electrodes that, over the extended recording periods required, destroy afferent pathways and thus are threatening to the functional integrity of the cerebellum.

171.9 SIMULTANEOUS RECORDINGS FROM PURKINJE CELLS OF DIFFERENT FOLIA IN THE RAT CEREBELLUM AND THEIR RELATION TO MOVEMENT. M. Fukuda*, T. Yamamoto* and R. Llinás (SPON: J. Ransohoff). Dept. Physiol. & Biophys., New York Univ. Med. Ctr., 550 First Ave., New York, NY 10016.

Presently our multiple electrode recording technique has been increased from 64 (Yamamoto, Fukuda & Llinás: Soc. Nsci. Abst., 1986) to 96 simultaneously recorded Purkinje cells from various folia, in rats anesthetized with ketamine (100 mg/kg initial dose and 30 mg/kg every 2 hrs). The recordings include Crus 1 bilaterally, Crus 2 bilaterally, and Crus 2 plus a vermal folium. Climbing-fiber evoked complex spike crosscorrelations could be determined for any particular neuron with respect to any of the other 95 cells. As in previous reports, it was found that spontaneous activation of Purkinje cells via the climbing fiber system occurs in rostrocaudal bands in a close to simultaneous fashion (a time interval of less than one millisecond). A study of the onset of spontaneous firing within this rostrocaudal band of activity suggests that the inferior olive generates such patterns by a very rapid electrotonic conduction within the nucleus. However, in the mediolateral direction the degree of electrotonic coupling is variable due to synaptic shunting. Thus, only a mean value for electrotonic spread can be evaluated. This "mean conduction spread" may be expressed as an average conduction velocity of 25-50 cm/sec in the cerebellar cortex. In agreement with the above, mechanical stimulation of the perioral area induced climbing fiber activation in Crus 2 that may spread in either the mediolateral or lateromedial direction. This suggests that sensory input can serve as a pacemaker for electrotonic spread among inferior olivary neurons and that, as indicated above, the actual direction of electrotonic spread between cells in the mediolateral direction in the cortex may vary from one moment to the next, probably reflecting on-going electrical activity at the olive. Finally, the onset of spontaneous movement of the mouth and lips correlates well with the onset of synchronous climbing fiber activation. Recordings from Crus 2 indicate that the onset of movement, whether spontaneous or generated by harmaline, is preceded by a synchronous climbing fiber volley of the order of 5 to 10 msec. [Supported by NS-13742 from NINCDS.]

171.10 **COMPARISON OF DISCHARGE PATTERNS BETWEEN CEREBELLAR AND MOTOR CORTICAL NEURONS DURING WHOLE-ARM REACHING: ONSET LATENCIES, DIRECTIONAL PROPERTIES AND RESPONSES TO LOADS.** Pierre A. Fortier, John F. Kalaska and Allan M. Smith. Centre de Recherche en Sciences Neurologiques, Département de Physiologie, Université de Montréal, Montréal, Québec, Canada, H3C-3J7.

Cerebellar and motor cortex neurons were recorded from monkeys trained to make whole-arm reaching movements from a common central starting position toward 8 radially oriented targets spaced at 45 degree intervals. The time of first change in firing frequency was calculated for neurons showing a significant activity change during the reaction time. The results of this analysis showed that there was no significant difference among the onset latencies of Purkinje cells, interpositus neurons, dentate units, and motor cortex cells. In general, the onset latencies were 132 ± 85 ms (mean ± SD) prior to the onset of movement in the cerebellar population and 120 ± 37 ms in the population of motor cortex cells. The direction related activities formed bell-shaped curves for both the motor cortical and cerebellar populations. However, statistical analysis of their directionality (sector width) revealed that the motor cortex discharge was more narrowly tuned for movement direction. The spontaneous discharge of the cerebellar population was 3 times greater than that of the motor cortex population. Since the sector width analysis takes into account the spontaneous discharge level, we recalculated the sector widths based on only the changes in activity during movement rather than absolute discharge frequencies. This correction reduced the difference between the motor cortex and cerebellar populations, but the motor cortex was still more directional ($p < 0.05$). The effects of loads pulling the arm in any of 8 directions were tested on the discharge frequency of 222 motor cortex cells and 58 cerebellar units. The loads produced relatively similar changes in absolute discharge frequency in the two structures: 26.4 ± 9.8 spikes/sec in the motor cortex and 36.6 ± 15.7 spikes/sec in the cerebellum. However, when expressed as a ratio of the no-load discharge rate of each cell, the relative load effect was much weaker in the cerebellum (load ratio 2.4 ± 1.6) than in the motor cortex (4.6 ± 6.8), due to the higher cerebellar spontaneous firing rates. In conclusion, the time course of activation of cerebellar and and motor cortex cells was very similar prior to movement onset. Cerebellar cells appeared less directional and less sensitive to loads than motor cortex, but this was partly due to their higher overall spontaneous discharge rates.

171.11 CORRELATION BETWEEN PURKINJE CELL SIMPLE SPIKE ACTIVITY AND MOVEMENT KINEMATICS DURING CLOSED-LOOP, VISUALLY GUIDED MULTI-JOINT MOVEMENT WITH ALTERED GAIN AND DELAY FEEDBACK. D.C. Tam, T.J. Ebner, and C.K. Knox. Departments of Neurosurgery and Physiology, Univ. of MN, Mpls., MN 55455.

The present study investigated the role of Purkinje cells in the feedback control of visually guided voluntary arm movements. Two Rhesus monkeys were trained to perform movement tasks requiring moving a two-joint manipulandum in a horizontal plane. The monkey was required to position a cross-shaped cursor in an initial box, and then move to a second target box displayed on a horizontal video monitor. Cursor position with respect to the manipulandum (hand) position was adjusted by a gain and/or an addition of a time delay to elicit corrective hand movements. The movements were unconstrained point-to-point movements without tracking requirements on the trajectory kinematics. Also the altered feedback conditions were randomly presented, preventing adaptation to the movement task. Two orthogonally placed targets were presented in random order to prevent anticipation. Various combinations of gain factors of 0.8, 1.0, and 1.2, and time delays of 0, 50, and 100 msec were tested.

Chronic extracellular recordings of 124 identified Purkinje cells in the intermediate zone of the anterior lobe showed that the simple spike discharge was modulated with movement in at least one movement direction (97/124). In 92% of the cells simple spike discharge increased (89/97) and 16% decreased (16/97) at the initial phase (onset) of movement for at least one movement direction. The patterns of discharge from the histograms aligned on either movement or target onset were sometimes different for movements orthogonal to each other, either with a latency difference between the onsets of discharge or with different discharge profiles. Following the initial change in simple spike firing, the firing pattern sometimes reversed sign (from an increase to decrease or vice versa) (19/97) in one movement direction. Spike triggered averaging techniques demonstrated that the simple spike discharge was correlated with the hand velocity (and/or acceleration) throughout the movement in the two-dimensional movement space. The correlation profiles to a target were similar independent of the feedback gain or time delays imposed, that is, independent of the corrective movements. Furthermore, the correlation profiles were similar for orthogonal movements except for a time lag in some cases. The patterns of EMG activity of arm and shoulder muscles were coupled to the onset of simple spike activity only. These results suggest the discharge of this population of Purkinje cells is correlated with hand kinematics independent of the imposed feedback alterations. Supported by NIH grant NS-18338.

171.12 ACTIVITY OF CEREBELLAR-RECEIVING THALAMIC NEURONS IN THE AWAKE MONKEY. M.E. Anderson and R.S. Turner* Depts. of Physiology and Biophysics and Rehab. Med. and Regional Primate Research Center, Univ. of Washington, Seattle, WA 98195.

Cerebellar information destined for the cerebral cortex relays in the thalamus. Although past studies have described the activity of thalamic neurons during active arm movements, the particular system in which they participated was not identified.

In three awake monkeys, we have identified 65 thalamic neurons that were shown to be excited at short latencies by stimuli applied through electrodes implanted in the contralateral cerebellar nuclei. These cerebellar-receiving (CR) thalamic neurons were further characterized by (1) their response during spontaneous active movements or passive joint manipulation, (2) their discharge pattern as the animal held the arm stationary prior to a visual target cue, and (3) their discharge during a visually-triggered arm reaching task.

The discharge of 28 of the CR neurons changed with respect to active or passive movement of specific body parts (driven cells). Eighteen of these were "arm-related" neurons, and of these, half were driven by manipulation or movement around the shoulder. Four cells changed their firing during movement of the hip or lower leg, and the discharge of the rest was related to eye or head movements.

CR cells tend to have relatively low, irregular "resting" discharge rates, usually less than 20 spikes/sec, in the absence of limb movements. In our sample, "driven cells" with changes in discharge related to proximal limb joints (shoulder, hip) had the highest "resting" rates, with the lowest variability.

Fifty-six of the CR cells, including all of the "arm-related" neurons, showed a task-related change in discharge during the arm-reaching task. Of these, 43 had an initial increase in discharge, and 13, an initial decrease. Of the 28 "driven cells" with task-related changes in discharge, 7 out of 8 of those with initial decreases in firing were driven by movements around the proximal joints (shoulder, hip) or by active eye movements. Of the "arm-related neurons, the earliest changes in firing occurred in "wrist" neurons (180 msec prior to movement initiation), followed by those related to the elbow and then the shoulder.

Thalamic neurons that receive excitatory input from the cerebellum can be identified, and their task-related changes in discharge can be related to parameters of the task and to the internal organization of muscles during task performance.

Supported in part by NS 15017-09.

BIOLOGICAL RHYTHMS IV

172.1 DIURNALLY INCREASED CELL FIRING IN THE ARCUATE AREA OF THE HYPOTHALAMIC SLICE DUE TO ESTRADIOL AND PROGESTERONE. R.R. Yeoman, A.J. Jenkins, L.E. White, J.N. Miller. Departments of Obstetrics-Gynecology, Neurology, Anesthesia, University of South Alabama, Mobile, Alabama 36688.

Previous studies have demonstrated a predictable afternoon luteinizing hormone rise in the ovariectomized estradiol-primed rat. We set out to record the firing rate of arcuate neurons in vitro to test the hypothesis that their electrical activity is responsive to estradiol (E) and progesterone (P) treatment and correlates in time with luteinizing hormone levels normally observed in vivo.

Female Sprague Dawley rats were raised in a 12:12 light dark cycle with lights on from 0500 to 1700h. At 27-29 days of age the animals were ovariectomized and implanted with capsules of E or cholesterol crystals. Two days later they were sacrificed, the hypothalamus sliced at 400 um and placed in a chamber perfused with oxygenated artificial cerebral spinal fluid alone or plus P (2ng/ml). Single neurons were recorded consecutively for 5 minute sampling times as the microelectrode was advanced during the experiments. Adequate E priming was confirmed by examination of uterine fluid content. In 10 experiments with E pretreatment alone (N=250 cells), units recorded from 1100-1500h had a slow discharge rate with hourly mean ranging from 0.7 to 0.86 spikes/sec. However, in the next hour, a significant increase in firing rate was observed (1.96 ± 0.19 spikes/sec, $P < 0.01$). In 5 additional experiments the rats were sacrificed 2 hours later, and 40 cells were recorded from 1400h through 1700h. An increase in firing rate was also noted after 1500h, suggesting a diurnal mechanism rather than a technical artifact responsible for the timing of activity increase. In 7 steroid control experiments with cholesterol capsules electrical activity was higher than with E before 1500h and did not have a diurnal pattern.

P was added to the superfusate at noon in 8 other experiments with E pretreatment (N=250 cells). A significant increase in firing rate was found from 1300 to 1400, compared to levels before P (0.8 ± 0.1 vs 1.7 ± 0.2 spikes/sec, $P < 0.025$) and compared to firing levels at the same time of day with estradiol pretreatment alone ($P < 0.01$). Activity peaked from 1400 to 1500h at 2.7 ± 0.3 spikes/sec, still earlier than an increase observed with E pretreatment alone. These changes correlated to the time of day that luteinizing hormone rises are seen in the intact animals. We conclude that the arcuate area appears to contain an intrinsic clock mechanism which is revealed by E pretreatment and modulated by P administration. This electrical activity most likely represents interneurons which may project to luteinizing hormone releasing hormone axonal endings and stimulate release of this hormone into the portal circulation.

172.2 **TWO MECHANISMS OF PHOTOENDOCRINE TRANSDUCTION IN CULTURED CHICK PINEAL CELLS**

M. Zatz and D.A. Mullen* Lab. of Cell Biology, NIMH, Bethesda, MD 20892.

Primary cultures of chick pineal cells, maintained under constant red light, display a circadian rhythm of production and release of the hormone melatonin. Single 4 hour pulses of white light caused an acute fall in melatonin release, independent of the phase of the melatonin cycle. These effects indicate a pathway from the photopigment to the melatonin synthesising system. Such light pulses also caused phase-dependent phase shifts in the melatonin rhythm. These latter effects indicate a pathway from the photopigment to the pacemaker generating the melatonin rhythm. Norepinephrine, acting through an α_2-adrenoceptor, also caused phase-independent acute falls in melatonin release but, unlike light, did not cause phase shifts.

Pertussis toxin, which can block the function of certain GTP-binding ('G') proteins, including G_i and transducin, blocked the acute effects of light or norepinephrine on melatonin release. It did not, however, block the ability of light to cause phase-dependent phase shifts. These results suggest the involvement of pertussis toxin-sensitive G proteins in the acute regulation of melatonin, but not in the pathway from the photopigment to the pacemaker. They imply the existence of two mechanistic pathways in the regulation of melatonin production by light.

172.3 **VOLTAGE-DEPENDENT CALCIUM CHANNELS REGULATE MELATONIN OUTPUT FROM CHICK PINEAL CELLS**

N. L. Harrison*, J. L. Barker and M. Zatz (SPON: T.G.Smith Jr.)
Lab. of Neurophysiology, NINCDS, NIH and Lab. of Cell Biology, NIMH, Bethesda, MD 20892.

Chick pineal cells in primary culture display a circadian rhythm of melatonin production and release. The nocturnal increase in melatonin output is suppressed both by inorganic calcium channel blockers (Co or Mn) and by dihydropyridine antagonists; conversely, melatonin output is enhanced by the calcium channel 'agonist' BAY K 8644. These data suggest the existence of 'L-type' Ca channels in the plasma membrane of these cells. Electrophysiological recordings were made at 22°C from individual chick pineal cells after 2-3 days in culture, using the whole-cell patch-clamp technique. In initial studies, the pipette solution contained 145mM K gluconate, 0.1mM $CaCl_2$ and 1.1 EGTA; the extracellular medium was a HEPES-buffered physiological saline containing 1.5mM Ca and 1mM Mg. The cells are of high input resistance (>1 Gohm), and do not generate TTX-sensitive action potentials. No transient outward current was observed, but all cells exhibit a TEA-sensitive sustained outward current. In the presence of TEA, presumed Ca-dependent action potentials are evoked by depolarizing current injection.

To isolate Ca currents, cells were bathed in a K-free solution containing 10mM Ca (or 20mM Ba) and 1mM Mg. The pipette solution contained 110mM N-methyl D-glucamine (NMG) methanesulphonate and 10mM NMG hydrochloride, plus 5mM BAPTA, 5mM ATP, 20mM phosphocreatine and 20U/ml creatine kinase. Cells were voltage-clamped at potentials between -100 and -40mV. From a holding potential of -100mV, a biphasic inward current was activated by steps to potentials positive to -40mV. The peak inward current during a step to 0mV was often 2-5 times greater than the steady-state inward current, indicating the existence of a rapidly-inactivating component. Both components of inward current declined at test potentials positive to +10mV and were abolished by 2mM Co. When the holding potential was -40mV, only a sustained inward current was activated during depolarizing commands. This was enhanced by BAY K 8644 and blocked by nifedipine. The inactivating current was insensitive to dihydropyridines. These two Ca currents are similar to those previously designated L-type (sustained) and N-type (transient) by Nowycky, Fox and Tsien (*Nature*, 316, 440-443, 1985). The above results indicate that voltage-dependent Ca channels are important in controlling the entry of Ca into, and the regulation of melatonin output from, chick pineal cells.

172.4 FMRF-AMIDE AND SEROTONIN HAVE OPPOSITE MEMBRANE EFFECTS ON CIRCADIAN PACEMAKER NEURONS IN Bulla. Jon. W. Jacklet. Dept. Biology, Neurobiology Research Center, SUNY Albany, Albany, NY 12222.

The pacemaker neurons in the basal retina of the eye of Bulla are responsible for generation of the circadian rhythm of autogenous CAP (compound action potential) activity recorded from the ON (optic nerve) of an isolated eye. It has been shown (Jacklet et al., J. Neurobiology, in press) that FMRF-amide immunoreactive efferent axons of brain neurons terminate in the retinal neuropil adjacent to the pacemaker neurons and in position to form synaptic contacts with the pacemaker neuron dendrites. Exogenous FMRF-amide suppresses CAP Activity, suggesting that the efferent axons are capable of suppressing CAP activity also. Now we show by intracellular recording from retinal pacemaker neurons as recording are also made from the ON that FMRF-amide hyperpolarizes the membrane potential and decreases the membrane resistance, suggesting a K conductance increase. The membrane potential of ca. -65 mV hyperpolarizes to -75 mV and membrane resistance decreases to 75% in 1 μM FMRF-amide as autogenous and light-evoked action potentials (ca. 80 mV) and 1:1 correlated ON Caps are suppressed. After FMRF-amide removal, the CAP rate and amplitude increase briefly as the membrane potential depolarizes, action potentials occur and membrane resistance increases, before returning to normal. Serotonin (1 μM) depolarizes the membrane potential and increases the membrane resistance resulting in a burst of action potentials and ON CAPs, suggesting a K conductance decrease. The serotonin effect is mimicked by 1 mM dibutyryl cyclic AMP. FMRF-amide reverses the effects of serotonin. CAP excitability and amplitude increase in serotonin and decrease in FMRF-amide apparently as a consequence of the membrane resistance changes. An increase in membrane resistance should increase the electrotonic coupling among the pacemaker neurons by shunting a greater proportion of current through the electrotonic junctions among the pacemaker neurons and decrease in membrane resistance should have the opposite effect. Changes in CAP amplitude should reflect changes in the number of pacemaker neurons contributing an action potential to each CAP. FMRF-amide and serotonin may produce these effects by acting on the s potassium channel. Supported by NSF BNS 8510626.

172.5 **DEPOLARIZING AND HYPERPOLARIZING IONIC TREATMENTS GENERATE PHASE SHIFTS IN BULLA OCULAR PACEMAKER THROUGH A CALCIUM DEPENDENT MECHANISM.** **G.D. Block and S.B.S. Khalsa. Department of Biology, University of Virginia, Charlottesville, VA 22901.**

The eye of the marine mollusc Bulla gouldiana contains a circadian pacemaker. Previous studies in our laboratory have implicated membrane potential and a calcium flux in the entrainment process since injection of depolarizing current into basal retinal neurons (BRNs) generates phase advances or delays and lowering extracellular calcium (10^{-7}M) blocks phase delays to light pulses (McMahon & Block, Neurosci. Abstr. 11:1138; 12:596).

The present experiments were undertaken to test the generality of these results with other treatments which alter membrane potential and to explore further the role of a calcium flux in phase shifting. We first tested whether elevated potassium pulses (50mM), a treatment which depolarizes BRNs, can phase shift the pacemaker. Eyes were removed from Bulla, recorded for one cycle, treated, and any resultant phase shift calculated as the phase difference in the time of midrise on the second cycle following the experimental treatment. We found that three hr pulses of Hi-K^+ at CT 13-16 generated a phase delay of -1.3 hr (±1.2 = 95% Confidence Interval, N=8) and a phase advance of +1.0 hr(±0.8, N=7) at CT 21-24. Two hr Hi-K pulses likewise generated significant shifts: -1.1 hr (±0.8, N=7) at CT 14-16 and +0.7 hr(±0.4, N=4) at CT 22-24. Similar to light-induced phase shifts, Hi-K^+ phase shifts were blocked in EGTA seawater ($Ca^{++}=10^{-7}$M). Hi-K^+ + EGTA at CT 13-16 resulted in a 0.0 hr shift (±0.5, N=6). Three hr EGTA pulses alone at this phase did not generate phase shifts (0.1hr ±0.5, N=3).

Lowered Na^+ solution (12mM), a hyperpolarizing agent for BRNs, also generated advances and delays but at different phases than depolarizing treatments. Lo-Na^+ pulses at CT 21-1 produced a phase delay of -1hr (±0.6, N=7), an advance of +0.7 hr (±0.5, N=8) at CT 8-11, and no phase shift between CT 10 - 13 (+0.2hr ±0.7, N=3). If hyperpolarizing treatments phase shift by reducing a Ca^{++} flux, EGTA pulses should mimic the action of Lo-Na^+. This appears to be the case since EGTA pulses generated phase delays during the late subjective night/early subjective day (CT 21-3, -1.2 hr ±1.0, N=5) and phase advances during the late subjective day (CT 8-14, +0.6hr ±0.5, N=4).

These results confirm prior observations that changes in membrane potential can phase shift the ocular pacemaker, provide new evidence that phase shifts to depolarizing treatments other than light are blocked by EGTA, and lend support to the proposition that depolarizing phase shifts are effected through increases in a calcium flux and hyperpolarizing phase shifts through a decreased flux. 172.6 LIGHT-INDUCED PHASE SHIFTS OF THE BULLA OCULAR CIRCADIAN PACEMAKER ARE NOT BLOCKED BY CALMODULIN ANTAGONISTS. S.B.S. KHALSA and G.D. BLOCK. Department of Biology, Gilmer Hall, University of Virginia, Charlottesville, VA., 22901.

A population of retinal cells in the eye of the mollusc Bulla gouldiana functions as a competent in vitro circadian pacemaker. The circadian rhythm of compound action potentials recorded from the optic nerve can be phase shifted by light pulses. A light pulse (22 lux) applied at circadian time (CT) 13-16 yields a phase delay of 1.7 hr. (n = 9, 95% C.I. = 0.5), whereas a light pulse applied from CT 21-24 yields a phase advance of 1.1 hr. (n = 9, 95% C.I. = 0.7 hr.).

McMahon & Block (Neurosci. Abstr. 12, pg. 596, 1986) have shown that light-induced phase shifts can be blocked by reducing the extracellular calcium concentration, suggesting that a transmembrane calcium flux may be essential in the phase shifting mechanism. Since calcium is known to often serve as a second messenger via calmodulin, we have evaluated the hypothesis that calmodulin is directly involved in the mechanism of light-induced phase shifts by applying calmodulin antagonists in an attempt to block these shifts.

Light pulses were applied at CT 13-16 in the presence of calmidazolium, a highly specific calmodulin antagonist, at 10 uM with 0.1% DMSO. The observed shifts were not significantly different from shifts to light alone for delaying pulses (1.9 hr., n = 5, 95% C.I. = 1.0) or advancing pulses (0.7 hr., n = 6, 95% C.I. = 0.5). Calmidazolium alone, applied at the same or similar phases, was ineffective in perturbing the phase of the rhythm. Higher concentrations of calmidazolium were toxic and resulted in fewer expressed cycles, nevertheless, with 100 uM calmidazolium a typical phase delay was present on the first cycle of activity following the pulse (1.3 hr., n = 2). Furthermore, 10 uM calmidazolium was equally ineffective at blocking light-induced phase shifts at CT 13-16 when the light intensity was reduced to < 1 lux (low light + calmidazolium phase delay = 1.4 hr., n = 2; low light phase delay = 1.0 hr., n = 4, 95% C.I. = 0.9).

Trifluoperazine applied with light at CT 13-16 at 10 uM in 0.1% DMSO, against a control of trifluoperazine alone, was also ineffective at blocking light-induced phase shifts (2.2 hr., n = 4, 95% C.I. = 1.5). Variable results were obtained with the antagonist W7, although it appeared that phase shifts were not affected.

These data suggest that calmodulin is not involved in the light-induced phase-shifting mechanism of the Bulla pacemaker, at least not under our experimental conditions.

172.7 **CIRCADIAN RHYTHM REGULATION AND TWO DIMENSIONAL GEL ANALYSIS OF PROTEIN PHOSPHORYLATION IN THE APLYSIA EYE.** R. Zwartjes* and A. Eskin. Biol. Dept., Univ. of Houston, Houston, TX 77004.

Serotonin (5-HT) shifts the phase of the circadian rhythm of compound action potentials recorded from the isolated eye of Aplysia. 5-HT appears to act on the pacemaker through activation of adenylate cyclase and the resultant intracellular increase in cyclic adenosine-3',5'-monophosphate (cAMP). Forskolin, an activator of adenylate cyclase, mimics the effect of 5-HT on the rhythm.

In other systems the primary effect of cAMP is to activate cAMP-dependent protein kinase. Thus it is likely that the pathway through which 5-HT acts on the pacemaker includes the phosphorylation of at least one protein. To explore that possibility we have used two dimensional polyacrylamide gel electrophoresis (2D-PAGE) to examine the phosphoproteins of the eye.

One eye from each animal was placed into an experimental group, the other into a control group. Eyes were kept in darkness and incubated in $^{32}P_i$ for 16 hours before treatment. Shorter incubations resulted in variable incorporation of label. After treatment the eyes were rinsed and homogenized, then loaded on urea-acrylamide isoelectric focusing gels. The IEF gels were then run on SDS-PAGE gels which were subsequently autoradiographed. About 80 endogenously phosphorylated proteins are discernible on each gel.

Incorporation of ^{32}P into one protein consistently increased after 25 minute and 6 hour treatments with 5-HT ($5x10^{-6}$M) when eyes were treated at the phase when 5-HT produces its largest advance phase shift. The protein has an apparent molecular weight of 57,000 Daltons and a pI of 7.2. An increase in incorporation into this protein is also seen with a six hour treatment of forskolin ($1x10^{-6}$M).

As a test of the specificity of phosphorylation of the 57kD protein, eyes were treated with phorbol 12-myristate 13-acetate (TPA) ($1x10^{-6}$M) for six hours. TPA, an activator of protein kinase C, does not appear to shift the rhythm at the above phase. The phosphorylation of the 57kD protein was not changed by TPA.

From this evidence, the 57kD protein is worthy of further study as a component of the pathway through which 5-HT shifts the rhythm.

172.8 CHRONIC CLORGYLINE ALTERS FORMAL PROPERTIES OF THE CIRCADIAN PACEMAKER IN SYRIAN HAMSTERS W.C. Duncan*, P.G. Sokolove, L. Tamarkin*, and T.A. Wehr*(SPON:M. Altstein)Clinical Psychobiology Branch NIMH Bethesda MD 20892 and the Department of Biological Sciences, University of Maryland Baltimore County, Catonsville MD 21228

Clorgyline(CLG), a type A monoamine oxidase inhibitor (MAOI) exhibiting antidepressant properties in humans was evaluated with respect to its capacity to alter a) the intrinsic period of wheel running (Experiment 1) and b) the phase-shift response to brief light pulses (Experiment 2). In Experiment 1, male hamsters, 13-16 wks old with ad lib access to food, water and running-wheels were housed in LD14.5:9.5 for 1 week and then DD for the next 8 weeks. After 3-4 weeks in DD, animals were implanted s.c. with Alzet minipumps (Model 2002) containing clorgyline (2 mg $kg^{-1} \cdot day^{-1}$; N=17) or saline (N=12); at two week intervals, empty pumps were replaced with fresh pumps. Periodogram analysis of wheel-running activity indicated clorgyline increased the intrinsic period of wheel-running compared to clorgyline pretreatment ($p<.005$) or compared to saline treatment ($p<.05$). This change in period was not associated with a change in phase due to the implantation of the clorgyline mini-pumps since extrapolation of activity onsets following treatment back to activity onsets prior to treatment did not indicate a significant change in phase. Chronic treatment with this MAOI increased the amount of wheel-running activity late in the active phase. In a similar experiment, we observed that bilateral enucleation did not prevent chronic clorgyline's capacity to increase the circadian period of wheel-running.

In Experiment 2, group-housed hamsters were pretreated for four weeks with clorgyline using Alzet minipumps. Animals were then placed in isolated cages containing running wheels. Following 7 days in LD 14.5:9.5, hamsters were 1) released into DD for seven days, 2) on day 8 received a 15' pulse of 250-300L fluorescent light and 3)monitored for the next 2 weeks in DD. Phase change was measured by calculating the linear regression to activity onsets prior to, and following the light pulse, and determining the phase change between the two regressions on the day after the pulse. Phase responses were pooled into twelve groups according to the phase of the light pulse relative to the onset of running activity. Two-way ANOVA indicated a significant treatment (CLG vs saline) by circadian phase interaction ($p< .03$). Compared to saline, CLG significantly increased the magnitude of phase delays at CT 14 ($p< .03$) and CT 16 ($p<.04$). CLG affected the phase($p< .032$) but not the slope of the crossover between phase delays and advances. We conclude that in the Syrian hamster clorgyline a) increases the period of the circadian pacemaker, b) this effect does not require an intact retina, and c) alters the response of the circadian pacemaker to brief light pulses. These results support the hypothesis that chemical antidepressants alter formal properties of the mammalian circadian pacemaker.

172.9 SUPRACHIASMATIC NUCLEI SEROTONERGIC FIBERS DO NOT MEDIATE THE EFFECT OF MONOAMINE OXIDASE INHIBITORS ON HAMSTER CIRCADIAN RHYTHMS J.S. Kruse Center for Brain Research, University of Rochester School of Medicine, Rochester, New York 14642.

LY51641, a type A monoamine oxidase inhibitor (MAO-I), delays the onset of wheel running in hamsters entrained to a light-dark cycle. These delays in entrainment of circadian rhythms are similar to results in other laboratories with a variety of antidepressant drugs, including tricyclics, MAO-Is, and lithium (Wirz-Justice 1983). All of these drugs disrupt serotonin neurotransmission. Chronic, peripheral administration of LY516141 inhibits serotonin catabolism in the suprachiasmatic nuclei (SCN), as measured by HPLC with electrochemical detection. The following experiment was conducted to determine whether the serotonergic raphe-SCN pathway mediates the delay induced by LY51641 in the circadian rhythm of wheel running.

Male golden hamsters weighing 100-120 grams were kept in L:D 14:10 with constant access to running wheels. After two weeks of baseline running, the serotonergic neurotoxin, 5,7-dihydroxytryptamine, was injected stereotaxically (bilaterally, 0.3 µl, 10 mg/ml) with the needle aimed at the dorsocaudal end ofthe SCN. Running wheel data were collected for two weeks following surgery; all hamsters remained entrained to the L:D cycle. Osmotic minipumps were then implanted subcutaneously to deliver 10 mg/kg/day LY51641 for two weeks. All hamsters (15/15) demonstrated a delay in running wheel onset during drug treatment. The delay (34 +/- 14 minutes) was comparable to the delay (44 +/- 19 minutes) induced by identical LY51641 treatment in hamsters that had not received stereotaxic injections of the toxin. Immunocytochemistry for serotonin (ABC method) was used to ascertain the accuracy and specificity of neurotoxic lesions. Since hamsters with no detectable serotonin in the SCN region still delayed the onset of their wheel running in response to LY51641, serotonergic fibers are not essential for this drug to effect the circadian clock.

172.10 THE EFFECTS OF THYROPARATHYRIODECTOMY (TPX) AND CALCIUM DIETS (Ca) ON ACTIVITY RHYTHMS AND LEVELS IN MALE AND FEMALE RATS. J. Schull*, J. Cooper*, L. Hillivirta*, K. Fitzgerald*, D. McEachron, J. Ruckdeschel*, D. Schumacher*, D. Stanger*, and J. Walker*, Dept. of Psychology, Haverford College, Haverford, PA 19041

Considerable clinical research has been reported linking affective disorders with abnormal circadian rhythms and with thyroid and parathyroid disfunction. The question remains as to whether these 2 biological phemonena, both of which are linked to affective disease, are somehow linked to each other.

To investigate this question, fourty-eight rats were divided into 4 equal groups: 1. male controls; 2. female controls; 3. male TPXs; and 4. female TPXs. Each animal was placed into an individual running wheel cage where activity was monitored by microswitches attached to a computer. There were 4 phases to the experiment: entrainment (LD 12/12), free-run, free-run on normal dietary Ca, and free-run on a low Ca diet. After the initial free-run period, 1/2 the animals in each group were placed on the low Ca diet while the other half were fed the normal diet. After 10 days, these conditions were reversed and continued for a second 10 days. Period (tau) estimates were determined on computer-generated activity plots by blind rating.

In the free-run phase, females displayed significantly shorter taus than males ($p<0.01$), and TPXs showed shorter taus compared to controls ($p<0.01$). There was an interaction between sex and surgery-female TPXs displayed shorter taus than did male TPXs ($p<0.03$).

Also in the free-run phase, females were significantly more active than males ($p<0.01$) and TPXs were more active than controls ($p<0.01$). Again, there was a significant interaction-male TPXs displayed a great-er increase in activity over controls than did female TPXs ($p<0.01$).

The low Ca diet reduced blood calcium in TPXs by 40% but no significant effects on activity were observed. An apparent shortening of tau with low Ca in female TPXs is presently being investigated.

In summary, thyroid/parathyroid function does appear linked to circadian rhythms and this linkage is influenced by an animal's sex.

172.11 CIRCADIAN RHYTHMS AND ESCAPE LEARNING IN RATS EXPOSED TO SHOCK. K.T. Stewart*, A.M. Rosenwasser, J.R. Volpicelli*, H. Hauser*, and N.T. Adler. Department of Psychology, University of Pennsylvania, Philadelphia, PA 19104.

Although disturbances in biological rhythmicity have been implicated in the affective disorders, their role has not been established. We have attempted to develop a paradigm based on a well-known animal model of depression in order to explore the relationship between behavioral pathology and changes in circadian rhythmicity.

It has been established that 60-80% of rats given inescapable, but not escapable shock, exhibit several motivational, associative, physiological, and neurochemical deficits which are similar to those seen in many depressed patients. In addition, these animals fail to learn to escape shock even when it is possible to do so. This phenomenon has been described as "learned helplessness", and it can be reversed by the administration of anti-depressant drugs. We employed this animal model in order to examine the relationship between pathological behavior and changes in circadian period.

Free-running circadian rhythmicity was monitored in wheel-running cages for several weeks before and after four sessions of inescapable footshock administered halfway through the animals' "subjective day". We reported last year that several rats showed increases in the free-running period of wheel-running rhythms following shock.

We now report on the relationship between period change and escape learning. We conducted several studies showing that animals which did not show impaired escape learning when tested with escapable shock exhibited increases in period. On the other hand, those animals which did show impairments in escape learning showed no change in the period of activity rhythms.

Thus, inescapable shock resulted in lengthening of period only in animals which did not exhibit deficits in escape learning. These results suggest that changes in the circadian system may be a mechanism involved in adaptive responses to environmental stressors. Others have shown that animals may alter the temporal pattern of behavior in response to stressors such as the presence of a dominant conspecific. It has also been demonstrated that administration of anti-depressant medications and lithium results in increases in free-running period of circadian rhythms; these effects on the circadian system may underlie their therapeutic efficacy.

172.12 EFFECTS OF COMPLETE AND PARTIAL SCN LESIONS ON ULTRADIAN AND CIRCADIAN LOCOMOTOR ACTIVITY RHYTHMS IN LEW/ZTM RATS. F. Wollnik and F.W. Turek. Dept. Neurobiology and Physiology, Northwestern University, Evanston, IL 60201.

Both circadian and ultradian rhythms in locomotor activity have been observed in laboratory rats. However, while the neural pacemaker involved in the regulation of the circadian activity rhythm (as well as many other rodent circadian rhythms) appears to be located in the suprachiasmatic nuclei (SCN), the neural basis for the generation of behavioral ultradian rhythms remains unclear. Complete and partial lesions of the SCN were used to determine if the same neural substitute may underlie both circadian and ultradian rhythms in the wheel-running activity of LEW/Ztm rats. This inbred strain of laboratory rats exhibits very precise and reproducible ultradian rhythms with periods of 4 and 4.8 h in locomotor activity (Büttner & Wollnik, Behav. Genet., 14:137, 1984) as well as in heart rate and body temperature.

Male and female rats of this strain were maintained under light-dark entrainment (LD 12:12) and under free-running conditions (blinded animals). They received complete or partial SCN lesions between days 35 and 50 after initially being housed in running-wheel cages. Wheel-running activity was recorded for a total of 90 days using an on-line microcomputer system. To detect rhythmic components, activity records were subject to chi-square periodogram and harmonic spectral analyses.

While sham lesions had little or no effect on the wheel-running activity pattern, complete SCN lesions resulted in a complete loss of ultradian and circadian rhythms in both male and female animals. The absence of ultradian and circadian rhythms was observed in blinded, free-running animals as well as in those maintained under LD 12:12 conditions. Under both free-running or entrained conditions, ultradian and circadian rhythms were still present after partial SCN lesions, with their amplitude dependent on the size of the lesion. Periodogram analysis for any given animal revealed that the period of the ultradian rhythm was always a submultiple of the entrained or free-running circadian period. Furthermore, a close relationship between ultradian and circadian rhythms was suggested by a high correlation between the amplitudes of their spectral estimates.

The present results indicate that the SCN contributes to the control of both ultradian and circadian rhythms in wheel-running behavior of LEW/Ztm rats. However, it is not clear if ultradian rhythms are caused by an ultradian pacemaker within the SCN or if they are the result of desynchronization among a population of circadian oscillators. Further examination of the LEW/Ztm strain might be useful in developing a better understanding of the origin and function of behavioral ultradian rhythms.

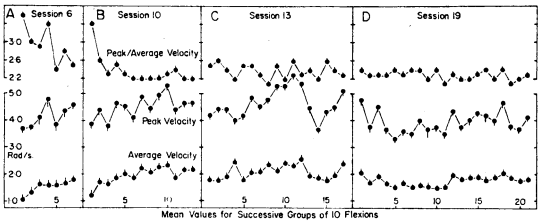
LEARNING AND MEMORY: PHYSIOLOGY I

173.1 PERMANENT LEARNING OF TEMPORARY MOVEMENT ADAPTATIONS BY MONKEYS. V.B. Brooks and S. Watts*. Dept. Physiology, Univ. of Western Ontario, London, Ont. N6A 5C1, Canada.

Adaptations of "continuous" elbow movements (single-peaked velocity profiles) were studied during motor learning of two monkeys. The animals were rewarded for what they did, namely to carry out a step-tracking task with an elbow movement followed by prolonged holding of the arm in the target; but not for how they did it, that is, for any particular mode of movement execution. Rewarding task-related behavior (what to do) by making holding periods long in relation to move-times, so that shortening move-times could not increase rewards significantly. Yet, both animals developed the use of continuous, i.e. programmed, movements with short move-times when they began to understand the behavioral task requirements [cf Brooks, Kennedy, Ross 1983, Physiol Behav 31: 561-563].

Two kinematic movement adaptations of continuous movements were noted, namely increases of (1) peak velocities and (2) average velocities such that their ratio remained steady or decreased. These non-rewarded, adaptive changes tend to optimize movement performance, although our data could not indicate which parameter was being optimized because most continuous movements were not time-symmetrical [cf. Hogan 1984, J Neurosci 4: 2745-2754].

The adaptations occurred again and again in successive daily training sessions, covering the same range of values. Only after about 2 weeks, when the animals approached their best performance proficiencies, were the adaptations learned, that is incorporated into movement programs that were remembered from one session to the next. The change from nonremembered adaptation to remembered learning occurred in one, transitional session [Brooks, Watts 1987 Exp Brain Res. in press]. These simple kinematic observations present new opportunities for future studies of neural actions in memory formation of behaviorally active animals. (MRC of Canada)



173.2 ASSOCIATIVE LTP OF SELECTIVE SPINAL REFLEXES. R.G. Durkovic. Department of Physiology, SUNY Health Science Center, Syracuse, NY 13210.

Potentiation of certain spinal reflexes has been shown to develop as a consequence of cutaneous nerve stimulation presented in an associative conditioning paradigm (Neurosci. Lett. 39:155). The purpose of the present study was to examine the persistence of this conditioned reflex facilitation. Changes in the magnitude of reflexes evoked in semitendinosus (ST), tibialis anterior (TA) and extensor digitorum longus (EDL) muscles of the spinal cat were examined. The CS was 10 Hz electrical stimulation of the saphenous nerve for 1.5 sec (random intertrial intervals averaged 3 min) for both experimental and control animals. The US was 30 Hz stimulation of the superficial peroneal nerve for 0.5 sec. Nerve recordings assured constant afferent inputs which involved all A-alpha and A-delta fibers of both cutaneous nerves. Experimental animals received 30 paired trials of CS and US with a 1.0 sec interstimulus interval. Control animals received the same stimuli, but the US was delivered in the middle of the CS intertrial interval. Following acquisition all animals received 30 additional CS alone trials at 5 min intervals. Low intensity probe CS alone trials, subthreshold for A-delta cutaneous fibers, were presented intermittently throughout the experiment in order to monitor excitability of the "A-alpha spinal circuitry".

During acquisition the response to the CS increased over trials for ST and TA muscles in experimental animals, while those of controls decreased. Little change in EDL responses was observed in either experimental or controls. During the subsequent 2.5 hr (CS alone) period differences between experimental and control animals' ST and TA muscle responses were maintained while the EDL responses of the two groups did not differ. The probe CS responses of the two groups did not differ for any of the muscles. The results show that the classically conditioned reflex potentiation is long-lasting and specific to certain flexor muscle reflexes. Furthermore, changes in cutaneous primary afferent output and generalized increases in motoneuron excitability may be eliminated as mechanisms underlying the associative LTP effects. This spinal cat preparation exhibits the major characteristics of intact mammalian learning and memory behavior, is representative of a complete behaving system (peripheral afferents, central processor, motor efferents), and has the potential for definition of the neural circuitry and the causal events underlying the response plasticity.

Supported by NSF grant BNS 8415917.

173.3 The coding of spatial information by neurons in the primate hippocampal formation.

J. Feigenbaum*,P.M.B.Cahusac*, and E.T. Rolls. University of Oxford, Dept. of Experimental Psychology, South Parks Road, Oxford OX1 3UD, England.

Damage to the primate hippocampus is known to disrupt the learning of some spatial tasks (see Gaffan, 1987). In order to analyse how spatial information might be processed in the hippocampus we have analysed the activity of 245 single neurons in the hippocampal formation (hippocampus and adjacent gyrus) in the rhesus monkey performing spatial tasks. These tasks included object and place memory tasks, for the performance of which the hippocampus is required (Rolls, 1987). 26.7% of the neurons had spatial response properties, in that they responded when stimuli were in one position but not in another on the test screen or in the laboratory. (These 'space' cells are different from the 'place' cells described in the rat by O'Keefe (1983) and others, which fire when the animal is in a particular place in the room.) For 6% of neurons, the responses remained in the same position relative to the monkey's body axis when the screen was moved or the monkey was rotated or moved to a different position in the laboratory. These neurons thus represented space in egocentric coordinates. For 17% of neurons, the responses remained in the same position on the screen or in the room when the monkey was rotated or moved to a different position in the laboratory. These neurons thus represented space in allocentric coordinates. These results provide evidence that in addition to neurons with egocentric spatial fields, which have also been found in other parts of the brain, there are neurons in the primate hippocampal formation which encode space in allocentric coordinates.

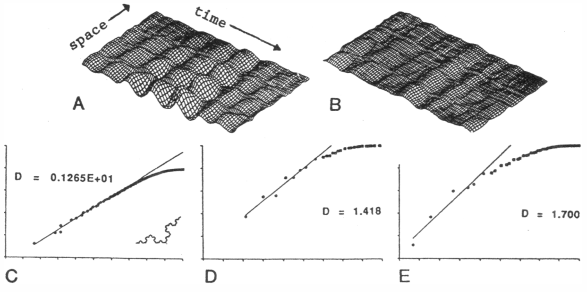
173.4 **FRACTAL DIMENSIONALITY-INCREASE OF THE 40-80 Hz SURFACE POTENTIALS ON THE RABBIT OLFACTORY BULB FOLLOWING PRESENTATION OF A NOVEL ODOR.** **J.E. Skinner, B. Saltzberg*, J.E. Cunningham*, W. Burton*, C.E. Landisman*, and M. Mitra*. Neurophysiology Section, Neurology Department & Neuroscience Program, Baylor College of Medicine, Houston, TX 77030 (Spon. P. Kellaway)**

As in the neocortex, an event-related slow potential (ERSP) is evoked on the surface of the olfactory bulb by presenting a novel odor. Concurrent with the ERSP are spatial (Gray, Freeman & Skinner, Behav.Neurosci.,1986) as well as temporal changes in the bulbar surface activity (Fig. 1A,B). These changes in the two domains are rapid, suggesting a fractal process. Babloyantz & Destexhe (Proc. Natl. Acad. Sci., 1986) described a new method for determining fractal dimensionality of synchronous EEG potentials; they found that when a human subject shifted from waking to a less attentive state (e.g., drowsiness or petit-mal absance), the fractal dimensionality coefficient reduced.

We modified their method and estimated the dimensionality coefficient, in the time domain, by the slope of: (x-axis) log R/Ro (normalized range of differences between zero-crossing intervals) vs (y-axis) accumulated log N/No (accumulative sum of normalized number of cases). First we determined that our method is valid by calculating the dimensionality for a known fractal function (Koch-triangle function); our value (Fig 1C) was the same as that calculated by another method (D = 0.126) by Mandelbrodt (Fractal Geometries of Nature, 1986). Then, we found that the dimensionality increased, from 1.4 during the 1/3-sec of quiet wakefulness just before a novel odor (Fig 1D) to 1.7 during the more attentive 1/3-sec after the odor (Fig 1E).

An explanation for bulbar fractal dimensionality changes is that the underlying molecular activities are themselves fractal. Hess & Markus (TIBS, 1987) demonstrated fractal processes for some biochemical reactions and Liebovitch et al. (Biophys. J., 1987) showed that single-channel ion-kinetics are best modeled by fractal functions.

Our finding (i.e., that an increase in processing state is associated with an increase in fractal dimensionality) is consistent with that of Babloyantz and Destexhe. Thus the two studies together demonstrate that fractal dimensionality may be a useful measure along a spectrum of cognitive processing-states in a cortical or model-cortical system.



173.5 SELECTIVE PICTORIAL INFORMATION IS RETAINED BY NEURONS IN THE VENTRAL TEMPORAL CORTEX OF THE MONKEY DURING THE DELAY PERIOD OF A MATCHING-TO-SAMPLE TASK. Y. Miyashita*, K. Cho* and K. Mori* (SPON: M. Ito) Dept. Physiol., Fac. Medicine, Tokyo Univ., Tokyo, Japan.

Visual delayed matching-to-sample (DMS) tasks have been used widely for testing memory functions in behavioral studies. However, single-unit recordings have been unsuccessful in revealing the neuronal correlates for the retention of visual memory during the delay period of the task, except for the sustained neuronal discharge reported in a delayed color-matching task (Fuster & Jervey, 1982). No neurons have been known to retain shape information during such a delay. We report here that neurons in the ventral temporal cortex of monkeys (Macaca fuscata) exhibit sustained activity during the delay period of a visual DMS task, and that the activity is highly selective to pictorial or configurational information contained in cue signals.

In a trial of our DMS task, sample and match stimuli were successively presented on a video monitor, each for 0.2sec with an interval of 16sec. The stimuli were newly selected for every trial among 100 computer-generated colored fractal patterns and 100 pseudo-colored images of scenery. The monkey was to choose a "go" or "no-go" response, according to a match or non-match combination.

Of the 144 single neurons recorded in the anterior ventral temporal cortex (areas TE and 35), 95 neurons showed an increased or decreased discharge frequency during the delay period, compared to that during the inter-trial period. In 77 of these 95 cells, discharge frequency during the delay was selective to certain cue stimuli, while in the remaining cells, there was no such selectivity. A substantial number of the 77 cells showed especially high selectivity; only a few pictures (sometimes just one) produced strong excitation or inhibition during the delay, whereas other pictures were ineffective. The optimal picture differed from cell to cell. Since the stimulus-selective discharge during the delay was not necessarily preceded by firing changes during the sample period, it did not simply represent sensory afterdischarge.

To further analyze stimulus-selective properties of the delay discharge, 1) stimulus size was reduced by half, 2) stimulus was rotated by 90 degrees in a clockwise direction, 3) colored stimulus was transformed into monochrome by referring to a pseudo-color look-up table, and 4) stimulus position was changed on the video monitor (a 0.2sec stimulus presentation time is short enough to exclude a contribution of saccadic eye movement). These manipulations did not alter stimulus-selectivity during the delay in many of the tested neurons. Thus, it is most likely that the discharge during the delay reflects a mnemonic process which is related to identification or extraction of configurational information in the picture. We propose a hypothesis that these neuronal activities are associated with a pictorial working memory.

173.6 DIRECTION CONTINGENT FIRING OF HIPPOCAMPAL PLACE CELLS C.R.Breese*, R.E.Hampson*, and S.A.Deadwyler. Department of Physiology and Pharmacology, Bowman Gray School of Medicine, Wake Forest University, Winston-Salem, NC 27103

Hippocampal place cells tend to fire rapidly when a freely-moving rat enters a particular portion of its environment. Theoretical attempts to explain the firing patterns of these cells include: location in absolute vs relative space; distance from the center of the place field; and difference between the present and future location of the animal (demonstrated by shifting the cell firing along the time and location dimension; Muller & Kubie, Soc. Neurosci. Abs. 141.8, 1986). Place cell firing was analyzed with respect to the above theories in an attempt to explain the nature of cell firing within the place field, and its possible relation to exploratory behavior.

The experimental apparatus consisted of an elevated platform (56 sq cm) with small water cups in the middle and at each corner. Complex spike (CS) cells from CA1 and CA3 hippocampal fields (Christian & Deadwyler, J. Neurophys. 55:331-348, 1986) were isolated and tested for place field firing, as indicated by rotations of prominent sensory stimuli. Results indicated a strong place specificity for all complex spike cells ($CS=6.52\pm1.10$, $p<0.01$), and a correlation of increased cell firing as the animal moved toward the center of the field ($t(260)= -5.89$, $p<0.01$). This trend, however, was nonlinear ($r=-0.34$), indicating that firing rate was not totally dependent on distance to the center of the field. Subsequent analyses revealed that maximum firing occurred when animals entered or exited a particular location (place field) on the platform, suggesting a strong "boundary" of the place field. The increased firing upon entering the place field corresponds to Muller & Kubie's observation of convergence of the place field with the animals' anticipated move to a new location. The observed increase in firing rate upon exiting the field has not been previously reported and indicates that place cells also code for exiting as well as entering the place field. A further analysis of the animals' traversal within a particular place field revealed that the cells tended to fire in relation to specific movement trajectories (vectors) as the animal moved into and out of the place field. Analysis of firing-dependent trajectories indicated that cells in 20 out of 22 fields (all $X^2>20$, $p<0.05$) fired maximally on only two of twelve possible trajectories, indicating traversal patterns into and out of the place field were controlling cell discharge. Thus, within a place field, the traversal pattern of the animal is an important behavioral determinant of place cell firing within the environment.

173.7 AN ANIMAL MODEL OF ENDOGENOUS EARLY NEGATIVITY AND P300 EVOKED POTENTIAL CORRELATES OF HUMAN SELECTIVE ATTENTION. G.F. Steinfels[1], K. A. Helmstadter*[1], G. P. Albericí*[1], and D. S. Ruchkin[2]; [1]DuPont Pharmaceuticals, Wilmington, DE 19898; [2]Univ. Maryland School of Medicine, Dept. Psyiology, Baltimore, MD.

Human cognitive processing and endogenous components of evoked potentials recorded from human scalp have been studied extensively over the last 20 years. A number of relatively early endogenous negative components and late positive components such as P300 have been linked with specific information processing operations. Using male New Zealand rabbits, the present study examined 2 of these components, P300 and an earlier negative peak, in relation to variation of stimulus probability, stimulus discriminability, and pharmacological manipulations. The recording electrodes were located over the midline region of the frontal, somatosensory, and cingulate cortices referenced to a neck electrode. An "oddball" tone paradigm was used with target and nontarget tones. Training sessions were conducted in the morning and test sessions in the afternoon. Training sessions were comprised of 120 trials with a 0.5 probability for the target tone. During training sessions only, a very mild shock (current adjusted to be 20% below that necessary to evoke a muscle twitch) was applied to the temporalis muscles 750 msec following the target tone. There was no presentation of shock during the test session (400 trials). When target probability was 0.1 during a test, the averaged evoked response displayed an early negative peak at 90 msec followed by a late positive component (P300) at 325 msec. Both the negative and P300 components varied inversely in amplitude with stimulus probability. Similar evoked responses were observed during test sessions if a brief visual flash was substituted for tone during training. A second experiment examined the effects of varying the discriminability between target and nontarget tones. The probability of the target tone was 0.1. Decreasing the frequency separation between the target and nontarget tones decreased the amplitude of the early negativity and P300 elicited by the target tone. Preliminary pharmacological evidence indicates that both the early negative and P300 peaks are sensitive to manipulation of the cholinergic system. Prior studies with animals have demonstrated a P300 analogue which is similar to the human P300 in that the amplitude varies inversely with stimulus probability. The present study supports these data and further adds the finding that variations in discriminability modulate P300 amplitude, which also has been reported for human P300. Recent human studies have identified negative components (N1, N2, Na, Nd) which are associated with different modes of information processing. Latency analysis indicates that the rabbit early negativity appears analogous to N1, however the amplitude variation as a function of stimulus probability is also consistent with an N2 interpretation.

173.8 LEARNING ABILITY OF YOUNG RATS UNAFFECTED BY CHRONIC EXPOSURE TO A STATIC ELECTROMAGNETIC FIELD IN EARLY LIFE. R. Thompson, C-Z. Hong and J. Yu. Department of Physical Medicine and Rehabilitation, University of California, Irvine Medical Center, Orange, CA 92668.

The influence of static magnetic field on cognitive function is still unclear. In this study, infant Sprague-Dawley albino rats were exposed to a static electromagnetic field of 0.0 Tesla (control) or 0.5 Tesla (experimental) for 15 min daily over the first 14 postnatal days. Following a one-month rest period, the experimental (13 males and 10 females) and control (11 males and 14 females) rats were trained on four successive reversals of a position habit in a single unit enclosed T-maze adapted for the use of escape-avoidance of mild foot shock as a motive. There was no significant difference in learning ability between the experimental and control groups in terms of total (initial combined with repetitive) errors committed over the four reversal problems. While the females tended to make more errors than the males, this difference was likewise insignificant.

173.9 IN-VIVO EFFECTS OF PAVLOVIAN CONDITIONING ON CURRENTS MEASURED IN NEURONS OF THE MOTOR CORTEX OF AWAKE CATS WITH SINGLE ELECTRODE VOLTAGE CLAMP TECHNIQUES. C.D. Woody, D. Birt and E. Gruen*. Mental Retardation Res. Ctr., Brain Res. Inst., Depts. of Anatomy and Psychiatry, UCLA Med. Ctr., Los Angeles, CA 90024.

Net currents were measured intracellularly in neurons of the pericruciate cortex of awake cats with single electrode voltage clamp techniques described previously (Woody et al., Soc. Neurosci. Abstr., 1985). Holding currents ranged from -70 to -80 mV with command steps of ± 10 to 40 mV. During Pavlovian conditioning, 14 of 16 cells that developed CRs showed decreases in a net outward current that was activated rapidly by depolarization. None of five cells that failed to develop CRs showed such decreases. The CS (click) and US (glabella tap) employed were similar to those used previously to produce associative behavioral conditioning. Cells of this region are necessary and (with their projections) sufficient for the development of this type of conditioning (Woody et al., J. Neurophysiol., 1972, 1974), and changes in their activity have been shown previously to control initiation of the short latency blink CR (Woody and Engel, J. Neurophysiol., 1972; Sakai and Woody, J. Neurophysiol., 1980). The present studies used unit discharge in response to the CS as an index of conditioning. To speed rates of acquisition of the CR, local iontophoretic application of glutamate (GLUT) was given with the US. Rapid conditioning was not produced when saline was substituted for GLUT. Iontophoresis of saline (n = 13 cells) produced small increases in net outward current in seven cells, small decreases in four cells, and no change in two cells. As in previous studies, conditioning depended on the order of CS + US + GLUT presentation as did the development of the changes in activity and conductance. The increase in unit activity in response to the CS resembled that found after behavioral conditioning. The decrease in net outward current after conditioning resembled that found after local application of acetylcholine or cyclic GMP dependent protein kinase (Woody and Gruen, Soc. Neurosci. Abstr., 1986). Changes in other, sustained currents were also seen in some cells. This is the first direct demonstration of a decrease in conductance in a mammalian cell linked to associative conditioning. The finding was predicted by earlier electrophysiologic studies of behavioral conditioning (Woody and Black-Cleworth, J. Neurophysiol., 1973). We suggest that these changes constitute one of the cortical engrams needed for this type of learned behavior. (Supported in part by AFOSR F49620-85-C-0100 and HD 05958.)

173.10 **LONG-TERM TRANSLOCATION OF PROTEIN KINASE C BY *IN VIVO* AND *IN VITRO* CONDITIONING.** B. Bank*, J.J. LoTurco and D.L. Alkon. (SPON: D.L. Chute) Section on Neural Systems, Laboratory of Cellular & Molecular Neurobiology, NIH-NINCDS, Rockville, MD.

Recent work in our laboratory has shed light on neural substrates of associative learning in mammals by employing classical conditioning of the rabbit's eyeblink as a model. Two important biophysical correlates of eyelid conditioning obtained *in vitro* in hippocampal CA1 pyramidal cells are long-term reduction in the amplitude and duration of the slow after-hyperpolarization (AHP) (Disterhoft et al., PNAS, 83: 2733, 1986), and an increase in the summation of synaptic potentials (LoTurco et al., this volume). Both effects are mimicked by bath application of phorbol esters. We hypothesized that long-term activation of protein kinase C (PKC) mediated the biophysical effects of conditioning. Accordingly, we found that 24 h after conditioning there was a redistribution of PKC activity in hippocampal CA1 cells so that in condition animals 63.3% (± 4.1, n=10) of the PKC was membrane-bound versus 42.0% (± 5.0, n=9) in pseudoconditioned animals and 44.7% (± 5.1, n=10) in naive animals ($p<0.01$, ANOVA). Total PKC activity was the same for all groups, implying that conditioning induced a translocation of PKC activity from cytosol to membrane. We proposed that this was due to a concominant activation of pyramidal cells by glutamate induced diacylglycerol (and hence PKC) activation (CS-pathway) and depolarization induced Ca^{++} influx (US-pathway). We tested this proposal by exposing hippocampal slices to either 1 mM glutamate, 15 mM K^+, 1 mM glutamate + 15mM K^+, or normal ACSF. Immediately after 1 h exposure, all three treatments induced PKC translocation, with the glutamate + K^+ group being twice as much as either the glutamate or K^+ alone. One h following treatment, only the glutamate + K^+ group still exhibited PKC translocation. These results support the hypothesis that conditioning causes an alteration in PKC or its membrane anchoring proteins via activation of PKC by diacylglycerol in conjunction with Ca^{++} influx so that it remains stably attached to the membrane.

173.11 **ENHANCED SUMMATION OF SYNAPTIC POTENTIALS: A CORRELATE OF ASSOCIATIVE LEARNING IN RABBIT HIPPOCAMPAL CA1 NEURONS MIMICKED BY KINASE C ACTIVATION.** J. J. LoTurco, D. A. Coulter, B. Bank*, & D. L. Alkon. Laboratory of Cellular and Molecular Neurobiology, NIH-NINCDS, Rockville, MD.

A novel synaptic correlate of associative learning has been identified by studying hippocampal slices that were isolated from rabbits 24 hours following eyeblink classical conditioning training, explicitly unpaired training, or no training. Previous experiments have revealed a biophysical record, reduction in the after-hyperpolarization (Disterhoft et al., PNAS, 83: 2733, 1986), similar to that of *Hermissenda* classical conditioning (Alkon, *Science*, 226: 1037, 1984). Both records involve persistent reductions of calcium dependent potassium currents. We now report that in addition to a reduction in the AHP there is a conditioning-specific enhancement of the summation of synaptic potentials. This synaptic difference, not apparent for single psps, is characterized by increased depolarization during 50 hz, 300 msec stimulation of the Schaffer collaterals in cells from conditioned (10.2±SEM 0.8mV) relative to control (unpaired, 5.2±SEM 0.6mV; naive 4.4±SEM 0.5mV; p<.001) animals. This enhanced summation correlates with AHP reduction and may involve NMDA receptors as it is blocked by bath application of APV (50 µM).

We propose that, in CA1 pyramidal neurons, stable association of kinase C with the plasma membrane leads to an array of learning-related biophysical changes. In support of this proposal, i) classical conditioning induces stable attachment of kinase C to the plasma membrane of cells in area CA1 of the hippocampus (Bank et al., this volume), and ii) phorbol ester (DPBA, 250 nM), a kinase C activator, induces properties in CA1 neurons that parrallel conditioning-specific properties: reduced AHP and enhanced summation of synaptic potentials. Thus, both learning-specific properties may be mechanistically linked and are likely to work in concert to contribute to the functional role of hippocampal CA1 pyramidal neurons in classical conditioning.

173.12 C-KINASE ACTIVATION MEDIATES PROTEASE REGULATION OF VOLTAGE-DEPENDENT K^+ CURRENTS. D.L. Alkon, C. Chen* & P.E. Gallant (SPON: H. Pant). Lab of Cellular and Molecular Neurobiology, NINCDS-NIH, Bethesda, MD 20982.

Activation of C-kinase by phorbol esters such as DPBA (12-deoxyphorbol 13-isobutyrate 20-acetate) depends on translocation of this enzyme from the cytosolic to the membrane compartment. Recent evidence (Bank et al., Nature, 1987) indicates that similar translocation in CA1 hippocampal neurons persists at least one day after classical conditioning of the rabbit. This conditioning-specific translocation can account for biophysical changes measured under the same in vitro (slice) conditions. Conditioning-induced reduction of voltage-dependent K^+ currents (I_A and I_C) underlies both the biophysical changes of CA1 cells as well as long-lasting excitability changes (of Type B cells) causally implicated in classical conditioning of the mollusc Hermissenda (Alkon, Science, 226:1037-1045, 1984). C-kinase activation by DPBA together with Ca^{2+}-loading conditions also reduces Hermissenda I_A and I_C and a protein substrate for C-kinase undergoes conditioning-specific changes in phosphorylation (Neary et al., Nature 293:658-660, 1981). In the present study two microelectrode-voltage-clamp (at -60 mV) of isolated Type B somata was used to measure I_A and I_C. The simple presence of concentrated (250 µg/µl) leupeptin, a protease inhibitor, in the voltage-recording microelectrode (also containing 0.95 MKAc pH 7.4) caused marked reduction at 0 mV of I_A (14.8 ± 7.7 S.D., nA, N=6) and I_C (7.7 ± 4.3, N=6) as compared to values obtained without leupeptin: I_A (62.4 ± 11.7, N=10, p<.001) and I_C (21.0 ± 8.8, N=10, p<.001). By contrast, the simple presence of concentrated trypsin (8 µg/µl), a leupeptin-sensitive protease, in the microelectrode caused enhancement of I_A (84.0 ± 1.7, N=3, p<.005) and I_C (30.0 ± 6.2, N=3, p<.03). After a ten-fold reduction of leupeptin concentration, little current differences were observed with impalement alone, but injection (+2.0 nA, 2 min) caused marked reduction of I_A (Δ: -16.4 ± 6.5, N=7, p<.001) and I_C (Δ: -5.4 ± 6.7, N=7, p<.001). This reduction did not occur in the absence of leupeptin and was greatly reduced by pre-exposing the cells to the phorbol ester DPBA 500 nM: I_A (-5.33 nA, N=3) and I_C (-1.33 nA, N=3). DPBA eliminated I_A and I_C reduction by injection of smaller currents (-1.0 nA, 2') through the leupeptin-containing microelectrode: I_A: -4.5 ± 1.7 nA, N=4 vs. -0.4 nA (with DPBA), N=4; I_C: -2.5 ± 2.6, N=4 vs. -0.12 nA (with DPBA). These results suggest that: 1) endogenous cytoplasmic protease degrades C-kinase in the cytoplasm on an ongoing basis and thereby increases the amplitude of I_A and I_C; and 2) translocation of C-kinase (e.g., with classical conditioning) achieves persistence, at least in part, because of membrane-associated C-kinase's relative invulnerability to degradation by Ca^{2+}-independent, cytoplasmic protease.

173.13 CHANGES IN REGIONAL OXIDATIVE METABOLISM INDUCED BY TACTILE LEARNING AND TACTILE RECOGNITION IN MAN. P.E. Roland, L. Eriksson*, L. Widén* and S. Stone-Elander*. Department of Clinical Neurophysiology, Karolinska Hospital, S-104 01 Stockholm, Sweden

There are two important questions with regard to how the brain stores and retrieves memorized information about the outside world: 1) are the anatomical structures which participate in the storage the same as those participating in the analysis of the sensory information? 2) Are the anatomical structures which store the information the same as those participating in the retrieval of the stored information? We measured the regional cerebral oxidative metabolism (rCMRO2) in normal healthy volunteers in three different stages: rest, tactile learning and tactile recognition. During tactile learning blindfolded subjects had to learn 10 complicated geometrical objects they manipulated in their hand. In tactile recognition these objects were mixed with similar, but previously unknown objects. The frequency of manipulatory movements during tactile recognition was twice that of tactile learning. Tactile recognition with the right hand increased rCMRO2 in six prefrontal cortical areas, bilaterally in the supplementary motor areas, the premotor areas and supplementary sensory areas, in the left primary motor and primary sensory area, in the anterior superior parietal lobule, the secondary somatosensory area, the anterior insula, lingual gyri, hippocampus. basal ganglia, anterior parasagittal cerebellum, and lobus post. cerebelli. Except for the anterior insular cortex, the posterior intermediate prefrontal cortex and the lateral cerebellum - all these structures have in earlier experiments been found to participate in manipulatory movements and analysis of somatosensory information. Tactile learning increased rCMRO2 in the same structures as tactile recognition did. Thus we found no differences in the anatomical structures participating in storage and retrieval. However the rCMRO2 increases in the left premotor cortex, supplementary motor area and left somatosensory hand area were larger during tactile recognition in accordance with the higher frequency of manipulatory movements and higher flux of somatosensory information from the periphery during recognition. Despite this the rCMRO2 was significantly higher in the neocerebellar cortex during tactile learning. The extra rCMRO2 in the posterior lobe appeared during the learning interval but disappared when the stored information about the objects was retrieved during the recognition. This extra energy demand in the posterior lobe could not be related to motor learning, because there were no learning effect on the manipulatory movements. Therefore the metabolic activity in the posterior lobe of cerebellum was attributed to energy demanding processes necessary for the storage of somatosensory information.

174.1 CENTRAL INJECTIONS OF NEUROTENSIN INDUCE POLYDIPSIA IN THE RAT. J.D. Baker*, M.F. Hawkins, and A.A. Baumeister. Department of Psychology, Louisiana State University, Baton Rouge, LA 70803.

Microinjections of neurotensin (NT) into various brain loci have been reported to decrease food intake in food-deprived rats (e.g., Hawkins, M.F. et al., Physiol. & Behav., 36:1, 1986; Hawkins, M.F., Life Sci., 38:2383, 1986). Little is known, however, about the effect of this peptide on water intake. The present study investigated the effects of central injections of NT on water intake in male, Sprague-Dawley rats (280-320g) under 16 hours of water deprivation. Guide cannulae (22 gauge) were implanted unilaterally in the lateral ventricle (LV), and bilaterally in the lateral hypothalamus (LH), preoptic area (POA), and ventral tegmental area (VTA) under Ketamine HCl anesthesia (0.2mg/g, im). After water intake had stabilized (approximately 9 days) the animals were injected with NT (0.1, 1.0, & 5.0µg; Sigma) or saline vehicle and water intake was monitored at 15, 30, 60, 90, and 120 minutes post-injection. A within-subject design was used so that every animal served as its own control. Injection volume was 5.0µl in the LV and 1.0µl in the LH, POA, and VTA. The data were analyzed with an analysis of variance for repeated measures and the Newman-Keuls procedure. NT produced a dose-related increase in drinking when injected into the LV (see table below). This effect was brief, with no statistical differences occurring after 15 minutes post-injection. The peptide had no effect on water intake when injected into the other loci investigated. The data suggest that central NT may be involved in the regulation of water intake and that the LH, POA, and VTA may not mediate this effect.

LV Injection*	15 Minutes Post-Injection Mean	SE	30 Minutes Post-Injection Mean	SE
Saline	8.8	±2.0	1.3	±0.7
0.1µg NT	11.5	±2.2	3.2	±0.2
1.0µg NT	16.5[a,b]	±3.6	3.2	±0.8
5.0µg NT	23.5[a,b]	±2.2	2.8	±1.0

*There were 6 animals in the group. a = p<.05 compared to saline; b = p<.05 compared to all other means

174.2 EFFECT OF OSMOTIC DEHYDRATION ON FOOD INTAKE, GASTRIC FUNCTION AND OXYTOCIN SECRETION IN RATS. L.M. Flanagan*, J.G. Verbalis, and E.M. Stricker. Departments of Behavioral Neuroscience and Medicine, University of Pittsburgh, Pittsburgh, PA 15260

Previous studies in this laboratory have shown that LiCl and CCK, agents known to decrease food intake, each cause a dose-related inhibition of gastric emptying in rats. Because these agents also have been found to stimulate neurohypophyseal secretion of oxytocin (OT), we examined the effect of hypertonic saline, which also stimulates OT secretion, on these other variables.

In the first experiment, rats with indwelling gastric catheters were food-deprived overnight, then allowed to eat chow for one hour the next afternoon. After this meal, gastric pressures were recorded for a 20-min baseline period. Rats then were injected with 2 M NaCl (0.5-2 ml), LiCl (0.75-3.0 mEq/kg) or CCK (0.5-10 ug/kg). Whereas the rats showed large and frequent stomach contractions before the injections, each of the three agents abruptly and markedly reduced gastric motility. In the second experiment, gastric emptying of a 10% glucose load was measured in rats with indwelling catheters, pretreated with 2 ml 2 M NaCl, 3.0 mEq/kg LiCl or 10 ug/kg CCK. Gastric emptying was inhibited by all three agents. The third experiment compared the effects of 2 M NaCl and LiCl on food intake and OT secretion. Rats were maintained on a regimen of two daily feedings, with access to chow but not water for 20 min in the morning and chow with water for 2 hr in the afternoon. On the morning of the test day, they were pretreated with 2 M NaCl or LiCl. Both agents produced a dose-related inhibition of food intake, over the same range of doses that inhibited gastric motility. At the end of the 20-min feeding period, rats were decapitated and trunk blood was collected and assayed for OT. In both groups, the decrease in food intake was significantly correlated with increased plasma levels of OT.

Our results demonstrate that hypertonic saline resembles LiCl and CCK in its effects on food intake, gastric function and OT secretion. Because the latter effects are known to be mediated by oxytocinergic neurons projecting from the paraventricular nucleus (PVN) of the hypothalamus, these data therefore add further support to the notion that changes in gastric motility and pituitary OT secretion reflect activation of PVN pathways that mediate the central inhibition of food intake.

174.3 INCREASED FEEDING BEHAVIOR AND REDUCED PLASMA LH LEVELS IN RING DOVES FOLLOWING INTRACRANIAL INJECTIONS OF PROLACTIN: DOSE-RESPONSE AND SPECIFICITY PROPERTIES. J.D. Buntin*, R.W. Lea* and G.R. Figge* (SPON: R. Quock). Dept. of Biological Sciences, Univ. of Wisconsin-Milwaukee, Milwaukee WI 53201 and Dept. of Applied Biology, Lancashire Polytechnic, Preston PR1 2TQ England

Food intake is markedly increased and gonadal weight is significantly reduced in male and female ring doves given intracerebroventricular (ICV) injections of ovine prolactin (oPRL; Buntin & Tesch, Horm. Behav., 19:188, 1985). The present study examined the dose-response relationships and hormone specificity characteristics for these centrally mediated effects. Daily food intake was monitored and post-treatment plasma LH levels were measured by RIA in 10 groups (n=8-10/grp) of male doves given 5 daily ICV injections of oPRL at 0.1, 0.5, 1.0, or 2.0 ug/day, turkey PRL (tPRL), turkey growth hormone (tGH), human GH (hGH), or ovine GH (oGH) at 1.0 ug/day, ovine luteinizing hormone (oLH) at 10 ug/day, or saline vehicle (2 ul/day). A significant ($p < .05$), dose-dependent increase in food intake was observed with all doses of oPRL (mean ± sem % increase over baseline levels = 28.4±4.5, 57.2±6.4, 78.3±6.2, & 91.4±2.7 for 0.1, 0.5, 1.0, & 2.0 ug oPRL, respectively; saline = 9.1±5.7). The three GH preparations also increased feeding significantly (56.4±4.7, 60.1±5.6, & 70.1±6.4 for oGH, tGH, and hGH, respectively), but only hGH was as effective as 1.0 ug oPRL. Turkey PRL and oLH failed to stimulate feeding. LH levels were significantly reduced by tPRL (3.6±0.7 ng/ml vs. 6.2±1.1 for saline) and by 0.5, 1.0, & 2.0 ug oPRL (2.3±0.6, 1.2±0.2, & 1.7±0.4 ng/ml, respectively), but not by 0.1 ug oPRL (6.6±0.8). Plasma LH levels were also decreased significantly by the three GH preparations (2.3±0.7, 1.7±0.6, & 0.8±0.1 ng/ml for oGH, tGH, & hGH, respectively). Data from oLH injected birds were inconclusive due to difficulties in blood collection. Testis weight differences between groups generally paralleled differences in LH levels. Crop sac analyses provided no indication of significant systemic effects of ICV injected PRL.

These results suggest that PRL and GH can act centrally to alter feeding behavior and pituitary gonadotropin secretion. Moreover, the dose-response relationship between feeding and oPRL and the hormone specificity characteristics for this response are similar to those observed for LH changes. However, hormones from ovine, turkey, and human sources vary markedly in their effectiveness. Future studies will attempt to identify the nature and location of the binding site(s) responsible for mediating these effects, to determine whether these effects are causally related, and to assess the degree to which PRL or GH promote these changes under normal physiological conditions. (Supported by NIMH grant 41447 and NSF grant DCB 8303026 to JB)

174.4 INSULIN-LIKE GROWTH FACTOR II (IGF-II) IN RAT BRAIN: DISTRIBUTION OF IGF-II NEURONS AND FIBERS AND PEPTIDE CONCENTRATION CHANGES WITH FED STATE. T.J. Lauterio*, L. Marson, M.A. Della-Fera and C.A. Baile Washington University School of Medicine, St. Louis, MO 63110 and University of Kentucky, Lexington, KY 40511.

The peroxidase-antiperoxidase method of immunohistochemical detection was used to localize IGF-II containing neurons and fibers in brain. Colchicine treatment (24-48 hours, 100 µg/rat) was employed to enhance the visualization of IGF-II containing neurons prior to immunohistochemistry. IGF-II fiber staining was conducted in untreated rats. Rats were then anesthetized with equithesin and perfused with isotonic saline followed by 10% paraformaldehyde, in preparation for sectioning. Frozen brain sections (40 µ) were then incubated with a 1:500 dilution of a monoclonal antibody raised against human IGF-II which is cross-reactive with rat IGF-II. Slides were then serially incubated with mouse IgG, PAP (1:50) and diaminobenzedine (15 min) to visualize immunoreactive areas and examined with a light microscope. Prominent staining for IGF-II was seen in the ventral hypothalamus, dorsal to the optic tract. Greatest immunoreactive staining was observed in the median eminence, with dense staining of fiber bundles occurring in the arcuate nucleus and retrochiasmatic areas of the hypothalamus. In a separate study, brain tissue concentrations of IGF-II in fasted rats were compared to IGF-II concentrations in meal fed rats. Animals were acclimated to an overnight fast followed by presentation of food. After rats consistently ate meals of 3 grams or greater within 30 minutes of food presentation, they were randomly assigned fed or fasted treatments and either sacrificed the following morning without a meal (fasted) or sacrificed upon completion of their meal (fed). Brains were immediately removed and frozen on dry ice. Punches were then made from brain slices and sonified tissue was assayed for protein and IGF-II content. Greater tissue concentrations of IGF-II were observed in meal fed rats compared to fasted rats in the suprachiasmatic nucleus, paraventricular nucleus and dorsomedial hypothalamus. The physiological and immunohistochemical data accumulated in these studies suggest a role for the suprachiasmatic region and dorsal hypothalamus in the IGF-II regulation of food intake in the rat. The finding of dense IGF-II fiber staining in the median eminence and arcuate nucleus also support the hypothesis that IGF-II is important in neuromodulation of pituitary function. Supported by NIH grant # 20000 and a grant from the Monsanto Company.

174.5 BEHAVIORAL CHARACTERIZATION OF THE INCREASED FOOD INTAKE BY RATS MICROINJECTED WITH RAT HYPOTHALAMIC GROWTH HORMONE-RELEASING FACTOR (rhGRF) INTO THE SUPRACHIASMATIC NUCLEUS/MEDIAL PREOPTIC AREA (SCN/MPOA). P. Dickson, and F.J.Vaccarino. University of Toronto, Canada, M5S 1A1.

Intracerebroventricular injections of rhGRF have been shown to cause a significant increase in food intake in food deprived and sated rats. This effect is believed to be independent of the growth hormone releasing properties, since further work has shown the feeding effect when rhGRF is microinjected into the SCN/MPOA. The present study was designed to replicate the SCN/MPOA finding, and to determine how this feeding effect is behaviorally expressed.

Food (Purina Rat Chow) and water intake of adult male Wistar rats with cannula implants aimed at the SCN/MPOA was measured for a 90 min period on 6 consecutive days following 90 min exposure to fresh food. On subsequent test days, consumption was measured for the 90 min period following an intracranial rhGRF injection. Observations of the feeding behavior profile were also carried out. The following doses were tested in random order: 0.0, 0.01, 0.1, and 1.0 picomoles. rhGRF was dissolved in a 0.1% ascorbic acid vehicle and administered in a 0.5 ul volume over 1 min. A minimum of 2 no-treatment days separated drug tests.

The results demonstrate that microinjections of rhGRF into the SCN/MPOA significantly increased food intake in sated rats. Behavioral observations suggest that at lower doses the rhGRF effect is expressed through significantly longer meals. At the highest dose the increased intake is condensed into normal meal lengths, resulting in a faster rate of eating. Since both water intake and latency to onset of eating are unaffected, it is suggested that rhGRF has a specific effect on maintenance of eating behavior, rather than on initiation of food intake.

This research was supported by NSERC grant U0443 to FJV. We thank Drs. J. Rivier and W. Vale for their generous gift of rhGRF.

174.6 VTA MICROINFUSIONS OF (S)-CHOLECYSTOKININ OCTAPEPTIDE POTENTIATE AMPHETAMINE CONDITIONED PLACE PREFERENCES. H.O. Pettit and K. Mueller, Department of Psychology, Texas Christian University, Fort Worth, Texas 76129.

Cholecystokinin (CCK) and dopamine (DA) have been shown to coexist in both cell body and terminal areas of an A10 mesolimbic pathway which projects from the ventral tegmental area (VTA) to the nucleus accumbens (N ACC). Autoradiographical studies report extensive CCK binding sites in the N ACC, but not in the VTA. However, iontophoresis of CCK into the VTA results in activation and/or deactivation of DA firing rates and bursting activity (depending upon dose). CCK could have neuromodulatory effects upon VTA-DA neurons. In two studies, behavioral effects from VTA infusions of CCK were examined in the conditioned place preference (CPP) paradigm. In the CPP paradigm the effects of a drug are paired with one environment and effects of the drug vehicle are paired with another environment. If a drug has reinforcing properties, then animals, when given a choice, will spend more time in a drug-paired than in a vehicle-paired environment. In the first experiment, 40 rats received permanent cannula implants aimed at the VTA. Rats were conditioned to associate the effects of CCK infusions into the VTA (0.0, 0.04, 0.4 and 4.0 ng/cannula) with one novel environment, and the effects of a CCK saline vehicle with another environment. Significant CPPs were not produced by any dose tested. Although some tendency towards reinforcing effects was observed, the effects were not significant. Thus, quantifiable reinforcing effects were not induced by the three CCK doses which were infused into the VTA. In the second experiment, 50 animals received bilateral cannula implants aimed at the VTA. In four groups of subjects (N=10/group) the effects of amphetamine (1.0mg/kg, S.C.) combined with effects of VTA infusions of CCK (0.0, 0.04, 0.4 or 4.0 ng/cannula) were examined in the CPP paradigm. The 10 remaining animals received amphetamine vehicle and CCK vehicle as a procedural control. Amphetamine CPPs were potentiated by CCK infusions. Furthermore, the effects were dose-dependent and linear in form. Results demonstrate that CCK infusions in the VTA can potentiate the reinforcing effects of amphetamine. A possible peptide neuromodulatory role in drug-abuse, and VTA mechanisms of action for CCK are implicated.

174.7 VASOPRESSIN (VP) IMMUNOREACTIVITY IN THE HYPOTHALAMUS OF CASTRATED, TESTOSTERONE-TREATED DOMINANT HAMSTERS AS COMPARED TO THEIR CASTRATED, UNTREATED SUBORDINATE PARTNERS. C.F. Ferris and J.K. George* (SPON: P. Grigg). Department of Physiology, University of Massachusetts Medical Center, Worcester MA 01605.

The Golden hamster communicates dominance status by rubbing specialized scent glands located on its flanks against objects in the environment. This behavior, called flank marking, is dependent upon VP-sensitive neurons in the anterior hypothalamus. The present study was undertaken to determine dominant/subordinate (D/S) behavior in pairs of castrated hamsters when one member of the pair was treated with testosterone proprionate (TP) while its partner was untreated, and to subsequently compare the VP immunoreactivity in the hypothalamus of these D/S hamsters. Male hamsters (n=20) were anesthetized, castrated and implanted with silastic capsules (2.2 cm) containing TP or with empty capsules. Animals were individually housed and maintained on a 14:10, L:D cycle for 3 wks. On the 4th wk TP-treated hamsters were paired with untreated animals for a 15 min period in a neutral cage. The same animals were paired for 5 consecutive days of testing. During each of the 5 test periods the number of attacks, bites, retreats and flank marks made by each hamster was scored. A hamster was considered dominant if it had a higher aggressive index (attacks, plus bites, minus retreats) than its partner in three out of the five test periods. Nine out of 10 pairs of hamsters established D/S relationships. In each of the 9 cases the TP-treated hamster was dominant over its untreated partner. The TP-treated hamsters had a significantly higher ($p<0.001$) mean aggression index (25.3±5) and mean frequency of flank marks (21.4±5) than their subordinate partners (3.0±2 and 3.3±1, respectively). The brains from three of the nine pairs were fixed, sectioned (50μm) on a vibratome and prepared for ICC using PAP with DAB. The anti-VP (Immunonuclear) was used at a dilution of 1:1000, and preabsorption controls showed the antibody to be specific for VP. The number of VP-immunoreactive perikarya in the nucleus circularis was significantly greater ($p<0.05$) in the dominant hamsters (64±15) than in their subordinate partners (15±5). The number of VP neurons in the bed nucleus of the stria terminalis (21±2 vs 23±1), paraventricular nucleus (210±28 vs 202±22) supraoptic nucleus (1105±121 vs 1184±78) were not significantly different between D/S hamsters. It should be noted that the VP neurons of nucleus circularis are located in an area of the anterior hypothalamus known to be involved in the organization and expression of flank marking behavior. Hence the pronounced difference in flank marking behavior between D/S hamsters may be correlated to the difference in VP-immunoreactivity in this site of the hypothalamus. (This work was supported by NIH grant NS-23557)

174.8 INJECTIONS OF CCK-8 INTO THE VENTROMEDIAL NUCLEUS OF THE HYPOTHALAMUS INHIBITS LORDOSIS BEHAVIOR IN THE FEMALE RAT. A.M. Babcock,* G.J. Bloch,* R.A. Gorski and P.E. Micevych (SPON: M. Hines). Dept. of Anatomy and Lab. of Neuroendocrinology, Brain Res. Inst., UCLA School of Medicine, Los Angeles, CA 90024.

We have reported that i.p. injections of CCK-8 will stimulate and inhibit lordosis behavior in female rats (Physiol. Behav., 39: 217, '87). Since the tissue content and binding sites of CCK-8 within the ventromedial nucleus of the hypothalamus (VMH), a region critical for the expression of lordosis, are sexually dimorphic and sensitive to the steroid environment, we investigated the effects of CCK-8 on lordosis behavior following injection into the VMH. Two weeks following ovariectomy, unilateral guide cannulae were implanted into the VMH of 30 adult female Long-Evans rats. One week following surgery, each rat was injected with 5 μg estradiol benzoate and tested 53 hrs later during the dark phase of the photoperiod. Ten minutes prior to testing, 0.5 μl injections of CSF (vehicle) or CCK-8 (5, 50, 100 ng) into the VMN were made. Lordosis behavior, expressed as lordosis quotient (LQ), was assessed by recording the number of lordotic responses to 10 mounts by a stimulus male. Receptivity increases with repeated steroid administration; therefore rats were retested using the identical procedure every 10-12 days for a total of 5 behavioral tests with treatment groups randomly assigned for each test. Data were evaluated by ANOVA and Newman-Keuls post hoc tests.

Injections of CCK-8 failed to alter LQ in tests 1-4 (CSF-LQs were 17, 58, 48, 88, respectively); however, CCK-8 significantly inhibited LQ in test 5 (CSF-LQ was 95). Post hoc analysis revealed a significant inhibition of LQ, as compared to CSF controls, for the 5, 50, 100 ng doses in test 5 (CCK-LQs 40, 58, 23, respectively). In our previous study, peripheral injections of CCK-8 facilitated LQ when receptivity was low and attenuated LQ when receptivity was high. CCK-8 injections into the VMH inhibited LQ when receptivity was high; however, these VMH injections of CCK-8 did not facilitate LQ when receptivity was low. The present experiment indicates that VMH CCK-8 may participate in the CNS regulation of lordosis behavior. The inability of VMH injections of CCK-8 to significantly increase lordosis behavior suggests that CCK-8 may interact with some other CNS region to produce a facilitation of lordosis.

174.9 EFFECT OF 5α-DIHYDROTESTOSTERONE ON THE FACILITATION OF FEMININE SEXUAL BEHAVIOR BY NEUROACTIVE PEPTIDES. Erskine, M.S. & E. Kornberg*. Dept. Biology, Boston University, Boston, MA 02215.

In female rats, the 5α-reduced androgen, 5α-dihydrotestotserone (DHT), exerts strong inhibitory effects on the display of estradiol (E_2)-induced sexual behavior (lordosis) and gonadotropin release. In the past several years, we have attempted to determine the mechanism(s) by which DHT is having its behavioral effects; evidence suggests that DHT does not prevent the priming action of E_2 in inducing hypothalamic cytoplasmic progestin receptors, nor can large doses of estradiol benzoate (EB) overcome its inhibitory effects. The present experiments were carried out to determine whether DHT acts by preventing the known ability of LHRH to facilitate lordosis. Naloxone (Nal) and Substance P (Sub P), two peptides known to increase LHRH activity in brain, were also tested. Seven days after ovariectomy and 3-4 days after implantation of intracerebral guide cannulae aimed at the lateral ventricle, two injections (pulses) of E_2 (1 μg/injection s.c. in 10% ethanol given 8 hrs apart) were given/day for three consecutive days. Experimental substances were given on the following day through internal infusion cannulae in 4 μl over 1 min and the behavioral response observed. Females were tested for lordosis with sexually active males approximately 30 min prior to (pretest), and at 30, 60, 90, and 180 min after infusion. Seven days after the initial E_2 injection, another 3 days of pulsed E_2 began, with DHT (2.5 mg/rat, s.c.) being given at the time of the first E_2 injection on day 3. As before, infusion and testing was carried out on the day following the third day of E_2 injections. All animals received the same infusate on this second test as on the first. After the E2-only injections, animals receiving LHRH (500 ng) and Nal (1 μg) showed significant increases in lordosis by 30 min after infusion and remained highly receptive until 180 min. Lordosis did not increase in Sal-treated animals. Unexpectedly, Sub P (1 μg) induced no increase in lordosis over levels seen in vehicle (Veh, 0.01 N acetic saline) control levels. DHT treatment in the second week had no effect on pretest levels of lordosis; however, this androgen completely prevented the stimulatory actions of LHRH and Nal seen the previous week. DHT did not reduce the level of receptivity seen in Sub P or Veh animals. These data are inconsistent with previous findings in which LHRH was able to reinstate receptivity in EB + DHT-treated mice (Luttge, 1977). The present results demonstrate that DHT does not inhibit lordosis by preventing the facilitatory effects of LHRH, and raise the question of whether DHT acts in a specific manner on E_2- or E_2 + progesterone-induced sexual receptivity or whether this steroid acts through a more general mechanism to inhibit behavior. Support: HD 21802 to MSE.

174.10 THE EFFECTS OF MEDIAL PREOPTIC AREA INJECTIONS OF SUBSTANCE P AND CHOLECYSTOKININ ON MALE RAT SEXUAL BEHAVIOR. W.A. Dornan*, C.W. Malsbury (SPON: G.Carre). Department of Psychology, Memorial University of Newfoundland, St. John's, Newfoundland, Canada A1B 3X9

The critical importance of the medial preoptic-anterior hypothalamic continuum (MPOA-AH) for male rat sexual behavior has been clearly demonstrated in studies using a variety of experimental approaches. Recently, the MPOA-AH has been shown to contain numerous neuropeptides. At this point, however, little is known about the role of peptidergic afferents/efferents of the MPOA-AH in the regulation of male sexual behavior. Two peptides found within the MPOA-AH that are perhaps most relevant are substance P (SP) and cholecystokinin octapeptide (CCK-8). For example, both CCK-8 and SP concentrations within certain areas of the CNS previously implicated in male rat sexual behavior have been shown to be dependent on gonadal hormones. This suggests that SP and CCK-8 may play a role in the neural regulation of male rat sexual behavior. The following series of experiments was designed to explore this possibility.

Sexually experienced Sprague Dawley male rats each received a pair of stereotaxically implanted stainless steel guide cannulae aimed at either the MPOA-AH, lateral ventricles (LV), or the dorsal caudate/putamen (CP). Each animal received two post-operative tests with a receptive female. On the second test, different groups of males were injected bilaterally with either SP (10 ng, 100 ng, or 200 ng/0.3 ul per cannula), CCK-8 (same doses), or the acidified saline vehicle into the MPOA-AH. Two additional groups were bilaterally injected with SP (10 ng/0.3 ul per cannula) into the LV or CP.

Injections of all three doses of SP into the MPOA-AH significantly reduced the latency to initiate copulation, while the two lower doses also reduced ejaculation latencies. In contrast to the MPOA-AH, bilateral injections of SP into the CP had no appreciable effect on male copulatory behavior. Injections of SP into the LV significantly reduced the number of intromissions to ejaculation and the post ejaculatory interval. Interestingly, a reduction in the number of intromissions prior to ejaculation was not observed following the same (10 ng) dose of SP injected into the MPOA-AH. CCK-8 injections into the MPOA-AH had no significant effect on any of the parameters of copulatory behavior, although there was a non-significant trend for reduced latencies following the larger doses of CCK-8 compared to the saline controls.

174.11 ARE GASTROENTEROPANCREATIC PEPTIDES INVOLVED IN REM SLEEP MODULATION? O. Prospéro-García,* R. Pérez-Montfort,* M.T.Pacheco* and R. Drucker-Colín. Depto. de Neurociencias, Instituto de Fisiología Celular, UNAM. Apartado Postal 70-600, México, D.F. 04510. México.

Recently, we have shown that the intraventricular (IVT) injection of either cerebrospinal fluid of sleep deprived cats (CSF SD), Vasoactive Intestinal Polypeptide (VIP) and Cholecystokinin (CCK-8) induces REM sleep in the parachlorophenylalanine (PCPA) pre-treated insomniac cats. These results additionally showed that while CSF SD and VIP increased the frequency of REM epochs, CCK-8 increased their duration. On the basis of such observations, these experiments were designed to determine the effects of IVT administration of CSF SD incubated with antibodies antiVIP on PCPA-insomniac cats, in order to test whether the antibodies can inhibit CSF SD hypnogenic properties. We additionally tested the effects of combining VIP and CCK-8 . A complementary study was done in order to determine whether VIP is able to restore REM sleep in Basal Forebrain Area (BFA) lesioned cats. A total of 50 cats were used in this study. Ten of these cats were used as donors of CSF and 40 were recipients of either CSF or other substances. All cats were implanted with a stainless steel cannula into the 4th ventricle. Recipients cats were additionally implanted with electrodes for standard recording of the sleep-wake cycle. Seven days after surgery, donors were sleep deprived during 24 h using the water tank method. The total volume of CSF was divided into 2 parts. One of them was incubated with antibodies antiVIP during 12 h (CSF VIPab), the other portion was not treated (CSF SD). Thirty PCPA pre-treated recipients cats were divided into 6 groups (n=5). Twenty four h after the second injection of PCPA, cats belonging to a given group were IVT injected with either CSF SD, CSF VIPab, VIP (200 ng) CCK-8 (100 ng), VIP + CCK-8 and saline. The last ten cats were BFA electrolytically lesioned and then divided into 2 groups (n=5). Ten days after the lesion, cats belonging to a given group received VIP (200 ng) or saline. In all cases, the injected volume was 100 ul. Results showed that, first antibodies antiVIP were able to inhibit the CSF SD hypnogenic effect. Second, the administration of VIP + CCK-8 had additive effects. Finally, VIP was able to restore REM sleep in the BFA lesioned cats. In conclusion, we can suggest that CSF SD has an antigenically VIP-like substance which is involved in the observed CSF SD hypnogenic properties. We can also suggest that VIP and CCK-8 are sinergistic and that the effect observed in the BFA lesioned cats gives additional evidence supporting VIP's involvement in REM sleep modulation.

174.12 DIFFERENTIAL BEHAVIORAL AND ENDOCRINE EFFECTS PRODUCED BY INTRA-RAPHE ADMINISTRATION OF THE NEUROKININ AGONIST, DiMe-C7, AND THE $GABA_A$ AGONIST, MUSCIMOL. J. Lee*, H. Mitsushio*, J.M. Paris and S.A. Lorens. Behavioral Pharmacology Laboratory (Bldg. 135), Loyola Univ. Med. Ctr., Maywood, IL 60153; and, J. Ritchie and C. Nemeroff. Dept. of Psychiatry, Duke Univ. Sch. of Med., Durham, NC 27710.

We have shown previously (Pharm. Biochem. Behav. 18:407, 1983; Behav. Brain Res. 1987, in press) that intra-raphe injections of muscimol and DiMe-C7 produce dose-dependent increases in the locomotor activity (LMA) of male Sprague-Dawley rats. The increase in LMA induced by DiMe-C7, in contrast to that produced by muscimol, depends on intact midbrain raphe serotonin (5HT) neurons, and is blocked by the dopamine (DA) antagonist, haloperidol (200 μg/kg, i.p.). These observations suggest that two distinct neuronal systems, which originate in the midbrain raphe, play a role in the regulation of behavioral arousal as measured by changes in activity level. One system involves a neurokinin - 5HT - DA circuit, whereas the other involves a $GABA_A$ - non-5HT - non-DA circuit. The objective of the present series of experiments was to determine whether these distinct "arousal modulating systems" are functionally linked to different neuropsychological processes.

A conditioned place preference paradigm was used to determine whether intra-raphe injections of muscimol (25 - 100 ng in 0.5 μl vehicle) and DiMe-C7 (30 ng - 1.0 μg in 0.5 μl vehicle) produce dose-dependent rewarding effects. Neither drug induced consistent or robust alterations in place preference. The data suggested, however, that intra-raphe infusion of muscimol may produce a mildly aversive effect, whereas DiMe-C7 may induce a rewarding effect. This possibility currently is being examined using an intra-raphe drug self-administration paradigm.

In a separate series of experiments, it was demonstrated that intra-raphe muscimol (25 - 100 ng) administration, but not DiMe-C7 injections, dose-dependently elevated plasma ACTH and corticosterone levels. In addition, it was shown that the muscimol induced increases in plasma ACTH and corticosterone levels are not dependent on intact midbrain raphe 5HT cells.

In a third series of experiments (still in progress), evidence has been obtained which indicates that intra-raphe infusion of muscimol, but not DiMe-C7, induces eating and drinking behavior in non-deprived animals.

Overall, the data suggest that two distinct neuronal systems emanating from the midbrain raphe modulate behavioral arousal but differentially affect endocrine and motivational processes. Only one of these systems depends on the integrity of mesencephalic raphe 5HT neurons.

174.13 INHIBITORY EFFECTS OF NEUROTENSIN ON BEHAVIORS INDUCED BY PHYSOSTIGMINE AND A SMALL DOSE OF THE DOPAMINE AGONIST N-PROPYLNORAPOMORPHINE. R. Rivest, M.A. Gagne*, S. St-Pierre* and F. B. Jolicoeur. Department of Psychiatry Faculty of Medicine, University of Sherbrooke, Sherbrook, Quebec, Canada J1H 5N4. We have shown previously that intraventricular (IVT) administration of neurotensin (NT) inhibits both yawning and penile erections induced by a small dose of apomorphine, a drug thought to stimulate dopaminergic presynaptic inhibitory receptors (autoreceptors). (Jolicoeur et al Soc. Neurosci. Abstr. Vol II, Part 1 p. 618, 1985). In order to verify the specificity of these findings we first examined the effects of IVT administration of various doses of NT (0.025-3.75 µg) on the same behaviors elicited by subcutaneous administration of 1.9 µg/kg of N-propylnorapomorphine (NPA), a dopamine (DA) agonist whose binding affinity in subcortical limbic structures has been reported to be markedly decreased by NT (Agnati et al. Acta Physiol. Scand. 119: 459,1983). Both number of yawns and penile erections were found to be significantly decreased by 1.875 µg and totally suppressed by larger doses of the peptide. These dose related effects of NT are identical to those we previously described for apomorphine. In another series of experiments the effects of the same doses of NT on yawning induced by 100 µg/kg of the anticholinesterase, physostigmine, were studied. Interestingly, 0.05 µg IVT injection of NT was sufficient to significantly reduce the number of yawns induced by this drug, pointing to a prominent anticholinergic effect of NT. Since yawning behavior is generally considered to implicate a DA-cholinergic link, our observed inhibitory effects of NT on yawning and penile erections produced by small doses of DA agonists could be attributed to anticholinergic effects of the peptide. However, although yawning induced by the dopamine agonist was significantly decreased by 1.0 mg/kg atropine, doses up to 10 mg/kg of this well-known direct anticholinergic agent failed to affect number of penile erections. Together these results suggest that NT exerts both anticholinergic effects and an inhibitory action on dopamine autoreceptors.
Supported by Medical Research Council of Canada (Grant No. DG-284).

174.14 EFFECTS OF DIRECT ADMINISTRATION OF NEUROTENSIN INTO DISCRETE BRAIN REGIONS ON BOTH SPONTANEOUS AND ADTN INDUCED MOTOR ACTIVITY. D. Gaudin*, R. Rivest, A. Drumheller and F.B. Jolicoeur. Department of Psychiatry, Faculty of Medicine, University of Sherbrooke, Sherbrooke, Quebec, Canada J1H 5N4.
Intraventricular administration of the tridecapeptide neurotensin (NT) has been shown to significantly reduce, in rats, both spontaneous locomotor activity and the strong and persistent hyperactivity produced by intra-accumbens injections of ADTN, a potent and long acting dopamine receptor agonist (F.B. Jolicoeur et al., Handbk. Neurochem. 8:93 1985; Neuropeptides 6:143, 1985). The purpose of the present study was to delineate the neuroanatomical sites where the peptide exerts its prominent inhibitory actions on both spontaneous activity and on the hyperactivity produced by bilateral intra-accumbens administration of 12.5 µg ADTN. Selection of brain regions was based on known output efferents of the accumbens and/or sites where high immunoreactive concentrations of the peptide are found. For each region, NT (0.0 to 3 µg) was administered bilaterally in a volume of 0.5 µl NaCl.

Results indicate that none of the doses of NT significantly affected spontaneous locomotor activity when injected into either substantia nigra, accumbens or striatum. However, injections of 0.375 and 1.5 µg NT into the central amygdaloid nucleus and substantia innominata, respectively, significantly attenuated spontaneous activity of animals. Injection of the peptide into the striatum was also ineffective in reducing ADTN induced hyperactivity. On the other hand, hyperactivity was markedly reduced with bilateral injection of NT into the central amygdaloid nucleus (0.187 µg), substantia innominata (0.375 µg), nucleus accumbens (1.8 µg) and substantia nigra (3.0 µg). These data indicate that certain brain regions are more sensitive to the inhibitory action of NT on motor activity. Furthermore, our data demonstrate that the peptide's actions are more prominent on activity stimulated by pharmacological activation of the mesolimbic dopaminergic pathway. In order to further characterize the influence of NT on activity, we are presently examining the effects of the peptide administered into the globus pallidus, stria terminalis and the "mesencephalic locomotor regions". Supported by MRCC Grant No. DG-284.

174.15 SPINAL EXCITATORY MODULATION OF THE STARTLE REFLEX BY SUBSTANCE P AND SEROTONIN (5-HT$_{1A}$) RECEPTORS. D.S. Simmons*, J.H. Kehne, and M. Davis (*SPON: T. Baker), Dept. Psychiat., Yale Univ. Sch. Med., 34 Park St., New Haven CT 06508

In the ventral horn of the spinal cord, the neuropeptide substance P is colocalized with serotonin (5-HT) in descending terminals (Gilbert et al., 1982; Neurosci., 7, 69-87). Furthermore, both 5-HT and substance P exert excitatory neuromodulation on motor neurons (White, 1985; Brain Res., 335, 63-70). Previous studies indicated that spinal 5-HT receptors exert an excitatory modulation on startle reflexes elicited by auditory stimuli (Davis et al., 1986, Psychopharm. Bull., 22, 837-843). The first purpose of the present study was to further characterize the 5-HT receptor subtype that mediates this excitatory modulation of the startle reflex and to assess its possible linkage to pertussis toxin sensitive G-proteins. The second purpose was to assess the role of spinal cord substance P in the modulation of the startle reflex, and to evaluate some possible interactions between substance P and descending 5-HT neurons.

Previous work demonstrated that intrathecal infusion of the selective 5-HT$_{1A}$ agonist 8-hydroxy-2-(di-n-propylamino) tetralin (8-OH-DPAT) increased startle following systemic or intrathecal, but not following supraspinal infusion (Davis et al., ibid.). In the present study, the excitatory effect of intrathecal infusion of 25 µg 8-OH-DPAT was blocked by 200 µg of the 5-HT$_1$ antagonist pindolol. Intrathecal pindolol did not attenuate the excitation produced by intrathecal infusion of the phosphodiesterase inhibitor rolipram (25 µg). Finally, pretreatment with pertussis toxin (2 µg; 2-3 days before testing) which inactivates G$_i$ as well as other membrane-bound G proteins, failed to attenuate the excitatory effect of 25 µg of intrathecally administered 8-OH-DPAT.

Intrathecal infusion of the stable substance P analogue (pGlu^{5}MePhe^{8}Sar^9) substance P (5-11) ("DiMe-C7"; 6.25 - 50 µg) produced a dose-related increase in startle amplitude. In contrast to 8-OH-DPAT, the excitatory effect of 25 µg DiMe-C7 was not blocked by intrathecal pindolol (200 µg). The excitatory effect of intrathecal infusion of 8-OH-DPAT or DiMe-C7 was not attenuated by destruction of spinal 5-HT terminals by prior pretreatment with the 5-HT neurotoxin 5,6-dihydroxytryptamine (3 x 20 µg, injections 24 hr apart; testing 3 wks after final infusion).

These data indicate that: (1) Serotonin exerts an excitatory modulation of the startle reflex through spinal 5-HT$_{1A}$ receptors that are not linked to pertussis-toxin sensitive G-proteins; and (2) Stimulation of spinal substance P or 5-HT$_{1A}$ receptors increases startle amplitude by a mechanism that does not involve intact 5-HT terminals in the cord.

174.16 DECREASED MONONUCLEAR LEUKOCYTE TSH SECRETION IN PATIENTS WITH MAJOR DEPRESSION. D. Harbour*, A. Anderson*, J. Farrington*, A. Wassef*, E. Smith* and W.J. Meyer, III* (SPON: R. M. Rose). Dept. of Psychiatry & Behavioral Sciences, The University of Texas Medical Branch, Galveston, TX 77550.

A subgroup of individuals with major depressive disorder have an impaired thyrotropin (TSH) response to thyrotropin releasing hormone (TRH) (Loosen, Psychoneuroendocrinology 10:237, 1985). The possible causal relationship and mechanism of this "blunted" TSH response in depression is unknown. Numerous, recent studies have characterized similarities and interactions between the immune and neuroendocrine systems. The immune system both produces (Smith et al, PNAS 80:6010, 1983) and responds to TSH (Kruger et al, J Immunol 137: 197, 1986). Our studies indicate that the major cell type producing ir-TSH is the T lymphocyte. We utilized a peripheral blood leukocyte system to compare immunoreactive (ir)-TSH responsiveness in 11 adult patients (2M, 9F) with Research Diagnostic Criteria for major depressive disorder to that of 10 normal controls. All subjects had normal baseline serum TSH concentrations. Isolated mononuclear leukocytes were treated in vitro with 0.5 µg/ml Staphlococcal enterotoxin A (SEA), 50 µg/ml TRH or no stimulant. After incubation, the cells were monitored for ir-TSH production by indirect immunofluorescence and reverse hemolytic plaque assay using antisera to TSH-β. The culture supernates were analyzed by TSH-RIA. SEA and TRH treated cell cultures from depressed individuals had significantly fewer immunofluorescent positive cells as well as significantly fewer number and size of plaques than did similarly treated normal leukocytes. The increase in supernatant ir-TSH was significantly less in TRH treated cultures from depressed patients as compared to normals ($P < .05$). These results suggest that examination of leukocyte TSH production may reflect the state of neuroendocrine function and thus be a useful marker for major depressive disorder. In addition, the leukocyte system may serve as a tool to elucidate the mechanism of TSH hyporesponsiveness to TRH observed in patients with major depression.

175.1 MODIFICATION OF A MECHANORECEPTOR CHANNEL PRODUCES HABITUATION IN THE PROTOZOAN, STENTOR. D.C. WOOD. Department of Behavioral Neuroscience, University of Pittsburgh, Pittsburgh, PA 15260

The contractile protozoan, Stentor coeruleus, habituates during repetition of the mechanical stimulus used to elicit the initial contractions. This decrement in response probability is highly correlated with a reduction in receptor potential amplitude while the amplitude of the action potentials, which trigger the contractions, does not change.

Three lines of evidence indicate this receptor potential reduction is due to an alteration in the voltage-dependence of the mechanoreceptor Ca++ channel conductance:

1) The I-V plots of mechanoreceptor currents elicited from cells before and after habituation have a voltage-dependent region between -60 and -20 mV and a linear voltage-independent region between -20 and 20 mV with a reversal potential near 20 mV. The slope of the linear region did not change as a result of habituation indicating that the maximum mechanoreceptor channel conductance and hence the total number of mechanoreceptor channels was the same in control and habituated cells. The mechanoreceptor reversal potential was changed by only a few millivolts, from 21.6 to 17.2 mV, leaving the driving force term for the mechanoreceptor current at resting potential relatively unchanged. On the other hand, the voltage dependence of the mechanoreceptor channel conductance became significantly steeper after habituation (9.6 mV/e-fold change) compared with its value before habituation (12.6 mV/e-fold change).

2) The amplitude of receptor potentials elicited from cells depolarized by current pulses habituated to only a very limited degree while receptor potentials elicited at resting potential underwent marked habituation.

3) Radioactively labeled (+)-tubocurarine (TC*) binds selectively to that conformation of the mechanoreceptor channel which predominates at resting and hyperpolarized potentials and binds only weakly to that conformation which predominates at depolarized potentials (Wood, 1985). TC* binding was significantly increased in habituated animals relative to controls when both were at normal resting potential, but this difference disappeared as both types of cells were depolarized by increased extracellular concentrations of K+. Thus, the voltage-dependent characteristic of TC* binding was effected by the habituation process.

Taken collectively, these data suggest that the voltage gate of the mechanoreceptor channel has a larger charge after habituation than before it.

175.2 PLASTICITY IN THE SHORTENING REFLEX OF THE SEMI-INTACT LEECH: BEHAVIORAL AND CELLULAR ANALYSIS. J.MAZER*, N.BOULIS*, C.SAHLEY, BIOLOGY DEPT, YALE UNIVERSITY, CT.

Habituation, sensitization, and classical conditioning have been demonstrated in the leech, Hirudo medicinalis (Lockery et al, 1985; Henderson & Strong, 1972; Sahley & Ready, 1985). To begin the cellular analysis we developed a semi-intact preparation that allows simultaneous behavioral and physiological observations. We show here that this preparation exhibits plasticity similar to that of the intact leech. Also, this preparation was used to study the role of the fast conducting system (FCS) in plasticity.

FCS activity elicited by tactile stimulation is often accompanied by whole body shortening (Magni & Pellegrino, 1978), and FCS activity mimics behavioral changes seen during simple learning (Belardetti et al, 1982). To further study the role of the FCS in reflex plasticity, we simultaneously recorded behavioral and FCS changes during habituation, sensitization, and dishabituation of the shortening reflex in a semi-intact preparation consisting of the first 9 segments and 3 exposed ganglia. FCS activity was recorded extracellularly. Shortening was measured through a force transducer attached to the sucker. Stimuli were low voltage shocks delivered to the anterior portion of the leech's back.

In Exp 1 behavioral and FCS changes were recorded during 20 repeated stimulus presentations at a 2 min ISI, and for 4 trials following dishabituating stimuli. Behavioral decrement as a result of the repeated stimulus (habituation) and a recovery from this decrement following the dishabituating stimulus were observed. In contrast, spiking showed no significant change. In Exp 2 identical protocols were used as in Exp 1, except that three ISIs were tested (10 sec, 45 sec, 5 min). Spiking showed a decrement over trials, but did not correlate with behavioral changes. Behavior showed significant decrement at the 45 sec and 5 min but not the 10 sec ISI. In Exp 3 presentation of a noxious stimulus prior to habituation training (sensitization) was studied. No increase in responding was observed, but subsequent habituation was prevented. The same stimulus, though not increasing initial responding, produced an increase from a habituated baseline.

The semi-intact preparation is, thus, a suitable means of studying the cellular basis of behavioral plasticity. Further, changes in FCS activity during training are not a simple source of the behavioral plasticity seen in whole body shortening.

175.3 DISHABITUATION AND SENSITIZATION OF THE TOUCH-ELICITED SHORTENING REFLEX IN THE LEECH, *HIRUDO MEDICINALIS*: THE FACILITATORY STIMULUS MODIFIES T AND P SENSORY NEURONS. C. L. SAHLEY, (SPON: C. STEVENS), DEPT. OF BIOLOGY, YALE UNIVERSITY, NEW HAVEN, CT.

The touch elicited shortening response of the leech can be modified by several types of learning including habituation, dishabituation, sensitization, and classical conditioning. We have recently begun to analyze the cellular and molecular changes mediating these learned changes in behavior. Since the same noxious stimulus, shock to the skin for the intact animal or shock to the connective for the semi-intact preparation, can be used to produce dishabituation and sensitization of the reflex as well as be used as the unconditioned stimulus (US) in conditioning experiments, we began our cellular analysis by examining the effects of this facilitating stimulus on identified cells within the neural circuit underlying the shortening reflex.

The touch sensitive (T) and pressure sensitive (P) mechanosensory cells are activated by the tactile stimulus used in our experiments and make monosynaptic connections on to the longitudinal (L) motorneuron. Contraction of the L motorneuron results in whole body shortening. Any changes in the intrinsic characteristics of the sensory cells such as increases or decreases in the width of the action potentials or increases or decreases in the level of excitability could be reflected as an enhancement or decrement in the reflex. For this reason we have looked at the effects of the facilitating stimulus on the T and P sensory cells.

Using semi-intact preparations or a chain of isolated ganglia we compared the effect of the facilitatory stimulus on the response of the T and P cells to a threshold intracellular current injection. The responce to three pulses was measured prior to the delivery of the facilitating stimulus and again following the stimulus at intervals of 2 min, 5min, 10 min, and 20 min. The results indicated that T and P cells were affected differently by the facilitating stimulus. T cells showed an increase in action potential duration while P cells changed from giving a single spike to firing multiple spikes to the test stimulus. Both of these results are consistent with the enhancement of the reflex seen in intact leeches following presentation of the facilitating stimulus.

175.4 FOOD AVERSION CONDITIONING OF A CARNIVOROUS LEECH. T. Karrer and C. L. Sahley, Psychology Dept, Yale University, New Haven, CT. 06520

Although the leech has proven useful in the study of the cellular basis of many behaviors including swimming (Brodfuehrer & Friesen, 1986) and feeding (Lent & Dickinson, 1984), it has rarely been the focus of classical conditioning studies (Henderson & Strong, 1972). For the most part leech studies have concentrated on the shortening reflex and employed only aversive reinforcers. Our goal is to expand our understanding of learning in the leech by studying both aversive and appetitive learning.

Feeding is modified by learning in a number invertebrates, including *Pleurobranchaea* (Mpitsos & Davis, 1973), *Limax* (Sahley et al, 1981), *Achatina* (Croll & Chase, 1980), *Lymnaea* (Audesirk et al, 1982), and *Drosophila* (Tully & Quinn, 1985). The study of feeding behavior is advantageous since it can be modified with both appetitive and aversive reinforcers (Sahley et al, 1982; Tempel et al, 1983). We have chosen to study plasticity of feeding in the carnivorous leech, *Haemopis marmorata*. Our initial studies employed a food avoidance protocol to test whether this leech could learn to associate a food taste with the aversive taste of quinidine, such that the leech would decrease its preference for the food paired with quinidine.

We employed discriminative training, in which there were two CS's: A CS+, which consisted of a food paired with a bitter chemical (US); and a CS-, a different, but equally attractive food, which was not paired. Counterbalanced groups of leeches were run simultaneously: A Chic+ group, which received CS+ trials of paired chicken (CS) + quinidine (US), and CS- trials of liver alone; and a Liv+ group, which received CS+ trials of paired liver (CS) + quinidine (US), and CS- trials of chicken alone. Training was conducted in randomly ordered CS+/CS- trial pairs, whose within-pair ITI = 20 min. Between each trial pair was a 1 hr interval. Tests were conducted either 1-3 hr after the last training trial or test, or 1-3 days later. Testing consisted of simultaneous presentation of both CSs, without the US; the leeches' preferences were tabulated.

The results suggested that learning had occurred. Comparing responses to a food that had been paired with quinidine to responses to that same food when it had been unpaired revealed that the food was chosen more often when it was unpaired than when it was paired. In other words, the leeches preferentially avoided the paired food.

175.5 ROTATION-INDUCED OPIOID ANALGESIA IN THE TERRESTRIAL SNAIL, CEPAEA NEMORALIS. F.S. Tepperman, M. Kavaliers and K.-P. Ossenkopp, Div. of Oral Biology and Dept. of Psychology, University of Western Ontario, London, Ontario, Canada.

There is evidence to suggest that endogenous opioids are involved in the regulation of the aversive behavioral and physiological responses of both vertebrates and invertebrates. Administration of morphine to the terrestrial gastropod mollusc, Cepaea nemoralis, elicits a naloxone-reversible increase in the latency of the avoidance behavior to a warmed surface. This response, which is analogous to the morphine-induced analgesic responses of mammals, appears as an increased latency in the lifting of the anterior portion of the fully extended foot from a warmed surface. In mammals, exposure to a variety of stressful stimuli has been shown to induce endogenous opioid-mediated analgesic responses that are analagous to the responses observed following administration of morphine. In the present study, we describe the effects of a commonly used laboratory stress, body rotation, on the aversive thermal responses of Cepaea.

Various groups of snails were held in moist, sealed containers and exposed to either continous (79 rpm) or intermittent (15, 30 sec, on,off) body rotation for varying periods of time (5-30 min). At specific times (0-60 min) after rotation, the latency of the foot-lifting response to a surface held at 40°C was determined for individual Cepaea. Snails exposed to either continuous or intermittent rotation were analgesic, displaying significantly greater thermal response latencies than sham-rotated or control animals. Pre-treatment with low doses of naloxone (1.0 mg/kg) blocked both the continuous and intermittent rotation-induced analgesia, while having no evident effects on the responses of control snails. These opioid-mediated analgesic responses were evident up to 60 min after continuous rotation, with longer rotation periods eliciting greater durations of analgesia. Intermittent rotation produced a relatively prolonged analgesia, whose duration was also dependent on the temporal parameters of the rotation. These results suggest that the stress of body rotation leads to the activation of endogenous opioid systems in Cepaea and the display of opioid-mediated analgesic responses that are similar to those observed in mammals.

175.6 LONG-TERM MEMORY OF LEARNING THAT FOOD IS INEDIBLE IN APLYSIA IS UNAFFECTED BY GUT DENERVATION. M. Schwarz* and A.J. Susswein, Dept. Life Sciences, Bar Ilan Univ., Ramat Gan, 52 100 ISRAEL.

Feeding in Aplysia is modulated by an associative learning task resembling operant conditioning (Susswein et al., J. Neurosci. 6: 1513-1527). When feeding is paired with internal stimuli arising from failure to consume food, animals learn that food is inedible, and stop responding. Successful feeding is a positive reinforcer. Memory of training is retained for at least 48 hours, as shown by decrease in time to retrain animals. Gut stimuli are necessary for producing reinforcement of feeding, as shown by an inability to learn when the esophageal nerves innervating the gut are bilaterally sectioned (Schwarz & Susswein, J. Neurosci. 6: 1528-1536).

The present study investigated whether memory of training is retained for longer than 48 hours, and whether gut stimuli are necessary for retention of training. We found that memory is retained for at least 3 weeks, and that denervation of the gut **after** learning does not affect retention of the learned change.

In experiments testing retention of memory for 3 weeks, Aplysia were fed the seaweed Ulva wrapped in plastic net. Animals responded to netted food, but were unable to consume it. As training proceded, animals made fewer successful feeding responses, and eventually ceased responding to food. Twenty-four hours later, Aplysia were retrained. Fewer successful feeding responses occurred, and time to stop responding was 48.0% ± 8.0 (SEM) of that on the previous day. Three weeks later animals were trained again to determine if memory was retained. Time to stop responding was 69% ± 11.7 (SEM) of that on the first training session. Thus, responsiveness was higher than during the second session, but still significantly less than during the first session.

We also tested memory a week following a single training session. Time to stop responding was 51% ± 7.6 (SEM) of that on the first session, indicating that memory is virtually intact from 1 to 7 days after training.

In experiments testing whether gut innervation is necessary for retention, as it is for the original training, Aplysia were trained as described above. One day after training animals were anesthetized, and the esophageal nerves innervating the gut were bilaterally sectioned. One week later animals were trained a second time in a blind procedure, along with naive, sham-operated and previously-trained unoperated animals as controls. All three groups showed similar decreases in time to stop responding upon retraining (Unoperated: 51% ± 7.6 (SEM); Sham Operated: 40.6 ± 10.8 (SEM); Esophageal Nerves Cut: 43% ± 5.8 (SEM)). These data show that gut inputs are **not** necessary for retention of learning, and that retention is due to changes occurring in the central nervous system.

175.7 MOLLUSCAN OLFACTORY INTERNEURONS: MEMBRANE RESPONSES AND CALCIUM TRANSIENTS A. Gelperin, D. W. Tank, J. A. Connor, and J. Flores*. Molecular Biophysics Research Department, AT&T Bell Laboratories, Murray Hill, NJ 07974.

The procerebrum (PC) of the terrestrial slug *Limax maximus* contains half a million interneurons which receive direct axonal projections from the superior and inferior noses. The extensive neuropil of the PC contains a dense matrix of connections between the intrinsic interneurons, input fibers from the noses and modulatory fibers containing serotonin, dopamine, SCP_B and FMRFamide. As part of an ongoing study of olfactory processing in the *Limax* PC, we have studied the membrane responses and intracellular calcium levels of isolated PC neurons in culture.

Procerebral lobes were isolated and completely freed of connective tissue by dissection. After a 1 hour incubation in Sigma type IX protease at 35°C, lobes were mechanically dissociated by stirring at 4°C for 1 hour. A 0.25 ml volume of cell suspension was plated onto a polylysine coated surface. After allowing 2 hours for cells to adhere to the substrate, additional medium was added. Cells were grown in *Limax* saline supplemented with 15 mg/ml bovine serum albumin (BSA). BSA was necessary to obtain extensive neurite outgrowth. Cells were studied after 1 - 8 days in culture. For studies of intracellular calcium levels cells were loaded with fura2/AM indicator by incubation for 20 min in saline containing 5 uM fura2 that had been dissolved in DMSO. Indicator readings were obtained by either dual wavelength (340/380 nm excitation) differential imaging (Connor, Proc. Natl. Acad. Sci. USA, 83:6179, 1987) or single photodiodes monitoring the intensified images of PC neurons. Membrane currents were monitored with whole-cell patch recording. Spontaneous action potentials were measured by loose and tight seal cell-attached patch recording.

Most isolated PC neurons display spontaneous action potentials and under whole cell voltage clamp display fast inward and slow outward currents which might underlie action potential production. Cells showed both regular and irregular bursting. Cultured PC neurons also display spontaneous fluctuations of intracellular calcium as determined from fluorescence measurements.

Isolated cells were challenged with 5X potassium saline and modulatory neurotransmitters known to be present in the PC lobe. Depolarization with 5X saline resulted in rapid but transient increases in intracellular calcium. Work is continuing on recordings aimed at measuring synaptic interactions between PC neurons in culture and immunocytochemical determination of additional neurotransmitters operating in the PC circuit.

175.8 IN APLYSIA OSMOREGULATION AND ITS NEURAL CORRELATES ARE AGE-SENSITIVE. T.L. Skinner* and B. Peretz. Dept. Physiology and Biophysics, Univ. of Kentucky, Lexington, KY 40536.

Osmoregulation in Aplysia is affected by age. When exposed to 90% artificial seawater (90%-ASW), old animals (244 days old) take signigicantly longer than mature animals (173 days old) to: 1) reestablish their original weight, 2) reestablish their original hemolymph osmolality and, 3) increase their metabolic activity. Yet, when exposed to 100%-ASW after being volume and osmotically stressed internally by injections of distilled water, old and mature animals reestablish their control weight and hemolymph osmolality at the same rate. The results suggest that the non-neural mechanisms involved in water balance are unaffected by age. This study examines the age effects in the neural pathway mediating osmoregulatory behavior (ORB) in response to 90%-ASW.

First, the effect of lesioning the osphradium was examined in 12 mature animals to determine the contribution of the osphradium to the ORB in response to 90%-ASW. The time course of osmoregulation in osphradial-lesioned mature animals was significantly slower than that of sham-lesioned mature animals, $F(9,90)=6.2$, $p<0.03$, but not significantly different from that of non-lesioned old animals, $F(9,126)=0.47$, $p<0.5$. The osphradium then is necessary for the mature response to 90%-ASW. The age effect seen in the ORB may be due to age-related changes in the osphradium.

R_{15} possibly mediates water balance (Kupfermann, I. and K.R. Wiess, J. Gen. Physiol., 67:113, 1976; Bablanian, G.N. and S.N. Triestman, J. Comp. Physiol. B, 155:297, 1985). Exposure of the osphradium to hypo-osmotic seawater evokes an hyperpolarization (hyperpol.) in R_{15} and inhibits it (Stinnakre, J. and L. Tauc, J. Exp. Biol., 51:347, 1969). Second, when the osphradium from mature preparations (n=3) was exposed to 80%-ASW, an hyperpol. of 21.4±6.8 mv was evoked in R_{15} which inhibited its bursting; but, in old ones (n=3) an hyperpol. of only 3.2±3.1 mv was evoked in R_{15} which did not change its bursting. Possibly, R_{15}'s decreased inhibition during old animal's exposure to 90%-ASW contributes to the age-dependent slowing of the ORB. Single pulses to the branchial nerve evoked in mature R_{15}s an hyperpol. of 24.6±8.1 mv while in old R_{15}s it evoked an hyperpol. of 13.1±3.4 mv. The input resistance of old R_{15}s is nearly half that of mature R_{15}s, i.e. 5.1±0.7 vs 9.3±1.2 M , which can explain the difference in the amplitude of the evoked hyperpol. But, the decreased hyperpol. of old R_{15}s to osphradial stimulation is not explained by this resistance change, because the hyperpol. is nearly 7x less than that in mature R_{15}s. Two sites in the ORB pathway in response to hypo-osmotic stress are affected by age: sensory activity and neuroeffector responsiveness.

175.9 THE APLYSIA GILL WITHDRAWAL REFLEX AND ITS NEURAL CORRELATES ARE AGE DEPENDENT. J.L. Ulmer* and B. Peretz (SPON: L. Boyarsky). Dept. Physiology and Biophysics, Univ. of Kentucky, Lexington, KY 40536.

Peretz et al. (P.N.A.S., 81:4232, 1984) showed that in old Aplysia there was a significant decrease of motor neuronal efficacy for L_7, but not for LDG_1. The present study was done to determine if L_7's age-sensitivity affected the gill withdrawal reflex, (GWR).

In preparations from 19 mature (152 days old) and 24 old animals (235 days old) with the CNS innervation to the gill, mantle, and siphon left intact, activity of motor neurons in the abdominal ganglion was recorded during the GWR, which was elicited by tactile stimuli of 0.2 to 5 g/mm^2 to the siphon. The GWR amplitude was significantly reduced in old as compared to mature animals, $F(1,32)=11.7$, $p<0.002$. The relationship between GWR amplitude and the range of stimulus intensities was significantly uncoupled in old animals as compared to that in mature ones, $F(4,128)=8.8$, $p<0.001$. To determine the neurons responsible for the GWR age-sensitivity, the contribution of each motor neuron was determined by comparing the GWR amplitude, with a neuron hyperpolarized, to that when it was allowed to spike. L_7 mediated on the average 56% of the GWR in the mature group (cf. Kupfermann, I., et al., J. Neurophysiol., 37:998,1974), but only 13% in the old group, $F(1,13)=12$, $p<0.005$. LDG_1's average contribution of 40% in mature animals was reduced to 2% in the old group, $F(1,10)=5.4$, $p<0.05$. Lg and LDG_2 mediated an average of 35% of the GWR in both age groups. The contributions of the 4 neurons being > 100% in the mature group shows that their effects are not simply additive. In old animals, L_7's and LDG_1's reduced role in the GWR may result partially from decreased effectiveness of afferent inputs to them, because fewer spikes were evoked in both old L_7s and old LDG_1s as compared to the mature groups, $F(1,15)=15.8$, $p<0.001$ and $F(1,13)=7.1$, $p<0.025$ respectively. Also, the relationship between the number of spikes evoked in old L_7s and stimulus intensity was reduced compared to that in mature L_7s, $F(4,60)=6.5$ $p<0.001$; this finding appears primarily a result of L_7's age-sensitivity. Unlike the reduced spiking evoked in LDG_1 by siphon stimulation, spiking evoked during gill respiratory movements was virtually unchanged with age. Hence, in addition to L_7's motor neuronal efficacy being reduced, the afferent input initiating the GWR appears to be age-sensitive, thus compromising both L_7's and LDG_1's ability to mediate the GWR.

175.10 PROPERTIES AND CHARACTERISTICS OF GILL GANGLION CELLS IN APLYSIA CALIFORNICA. Elaine Colebrook and Ken Lukowiak. Dept. of Medical Physiology, Univ. of Calgary, Calgary, Alberta, Canada, T2N 4N1.

Utilizing anatomical, electrophysiological, pharmacological and immunohistochemical techniques, various properties of the gill ganglion (gg) of Aplysia californica have been identified as a first step towards determining the role that this ganglion may play in the mediation of gill behavior.

Studies with LY have shown the cells to be monopolar, with many of their axons coarsing towards the gill. The axons of other neurons remain intrinsic to the ganglion. Dense bushy dendrites are seen directed towards the abdominal ganglion.

The neurons vary in their electrophysiological properties. Some cells are coupled, coupling ratios from 0.1 to 0.9 have been observed between different pairs of cells. Use of the semi-intact gill, siphon, mantle preparation has revealed that depolarization of some gg cells can induce gill withdrawals; suggesting that certain of these cells have similar properties to the gill motor neurons in the abdominal ganglion. Bursts of activity in the cells correlate with spontaneous gill withdrawals. Such bursting is evident even in the absence of the abdominal ganglion. This indicates a role for the gg cells in respiratory pumping movements of the gill. Hyperpolarizing responses are induced in certain cells by stimulation of the pedal nerves and tapping the gill or siphon causes depolarizing responses. Hence a likely role in defensive gill reflexes and, possibly, their plasticity.

Low concentrations of 5-HT (10^{-6}) inhibit the activity of spontaneously active gg cells. Higher concentrations of 5-HT (10^{-4}-10^{-5}) increase the rate of firing in spontaneously active cells. Bath application of SCP_B (10^{-5}-10^{-6}) induces regular bursting activity in gg cells. These effects are apparent with and without an intact branchial nerve, indicating a direct effect of these neurotransmitters on the gg cells.

5-HT antisera revealed fibres within the branchial nerve which pass by the gg. No cell bodies within the gg were revealed with the 5-HT antisera. There was no SCP_B immunoreactivity in or around the gg; suggesting that the excitatory effect of SCP_B may be mediated via the blood.

These findings together suggest that the heterogeneous neurones of the gill ganglion play a role in the mediation of gill behavior, and probably its plasticity.

(Supported by MRC of Canada and AHFMR).

175.11 TIME COURSE OF STRUCTURAL CHANGES AT IDENTIFIED SENSORY NEURON SYNAPSES DURING LONG-TERM SENSITIZATION IN APLYSIA. C.H. Bailey and M. Chen. Ctr. for Neurobiol. & Behav., Dept. of Anat. and Cell Biol., Neurol., & Psychiat., Columbia Univ., P&S, and NYS Psychiat. Instit., N.Y, NY 10032.

We have used the gill- and siphon-withdrawal reflex of Aplysia californica to explore the morphological basis of the synaptic plasticity that underlies simple forms of learning and memory. In earlier studies we described two classes of structural changes at identified sensory neuron synapses that occur following long-term sensitization. These structural alterations occur at different levels of biological organization and include increases in the number, size, and vesicle complement of active zones as well as an overall increase in the total number of synaptic varicosities per sensory neuron. In the present study we have begun to examine which of these anatomical changes might be necessary for the maintenance of long-term sensitization by exploring the time course over which they occur and in particular, their duration relative to the persistence of the memory assessed behaviorally.

Toward this end we have quantitated changes in the total number of varicosities of single horseradish peroxidase (HRP)-labeled sensory neurons taken from long-term sensitized and control animals at different intervals following training. Experimental animals were trained for long-term sensitization after the 4-day protocol of Pinsker et al. (1973); control animals were carried under identical conditions but without training. Experimental (N=15) and control (N=8) animals were then examined for retention of sensitization at 1-2 days, 1 week, or 3 weeks following the end of training. A single sensory neuron from each animal was intrasomatically pressure-injected with HRP, incubated for 2 hrs., fixed, histochemically processed and embedded in EPON. The neuropil arbor of each cell was completely reconstructed using serial 20 μm slab-thick sections and the total number of HRP-labeled varicosities for each sensory neuron was counted through a blind procedure. A total of 23 sensory neurons were analyzed in this fashion.

As reported in an earlier study, we have found that long-term sensitized animals examined within 48 hrs following the completion of training demonstrate an increase in the total number of varicosities per sensory neuron (2841 ± 372 S.E.M., N=6) compared to control animals (1521 ± 66 S.E.M., N=3). This increase persists unchanged for at least 1 week (3066 ± 554 S.E.M., N=4 vs. 1356 ± 154 S.E.M., N=3) and is only partially reversed at the end of 3 weeks (1878 ± 246 S.E.M., N=5 vs. 1232 ± 211 S.E.M., N=2). The duration of these changes in varicosity number parallels the behavioral time course for the retention of long-term sensitization. These similarities suggest that the timekeeping steps for a long-term memory trace may, in part, be specified by morphological change and strengthen the notion that alterations in the number of sensory neuron synapses may play a role in the maintenance of long-term sensitization.

175.12 INVOLVEMENT OF SEROTONIN IN SENSITIZATION OF APLYSIA GILL-WITHDRAWAL REFLEX. A.M. Dyke*, S.L. Mackey*, D.L. Glanzman and R.D. Hawkins (SPON: M. Segal). HHMI & Columbia P&S, NY, NY 10032.

Several lines of evidence suggest that serotonin (5-HT) plays a role in sensitization of the Aplysia gill-withdrawal reflex. 5-HT and tail shock both produce behavioral sensitization due in part to presynaptic facilitation of the siphon sensory neurons. Injecting animals with the serotonin neurotoxin 5,7-dihydroxytryptamine (5,7-DHT) reduces the facilitation produced by tail shock (Glanzman et al., 1986). Immunohistochemical studies (Kistler et al., 1985) indicate there are serotonergic endings on the sensory neurons. Finally, we have identified a pair of serotonergic neurons in the cerebral ganglia (LCB1 and RCB1), stimulation of which produces presynaptic facilitation of the sensory neurons (Hawkins, 1986; Mackey et al., 1986). Here we provide evidence that the CB1 neurons participate in behavioral sensitization of gill withdrawal. In addition, we report that treatment with 5,7-DHT reduces this behavioral sensitization.

To assess the role of the CB1 neurons in sensitization, we recorded their response to cutaneous stimulation in a semi-intact preparation. They respond with a phasic increase in firing to moderate tactile stimulation anywhere on the body surface, and respond with a very prolonged (in some cases greater than 15 minutes) increase in firing to noxious stimuli such as those used to produce behavioral sensitization. Intracellular stimulation of CB1 neurons with approximately this physiological pattern produces reliable broadening of action potentials in the siphon sensory neurons. We also injected CB1 neurons with Lucifer yellow and found that they 1) have 5-HT-like immunoreactivity, and 2) send axons to both cerebral-pleural connectives. The morphological appearance of these axons is consistent with serotonergic axons which Longley and Longley (1986) showed extend to the abdominal ganglion and branch extensively in the neuropile. These results support the idea that the CB1 neurons participate in mediating behavioral sensitization of gill withdrawal. Since their facilitatory effects are modest, however, other serotonergic cells may also participate in sensitization.

To assess the role of all serotonergic facilitatory neurons in behavioral sensitization, we injected Aplysia with 2 g/kg 5,7-DHT and then tested sensitization of gill withdrawal using a semi-intact preparation. The 5,7-DHT treatment reduced behavioral sensitization by over 90% with either tail shock (N=10, U=17.5, $p<.02$) or mantle shock (N=15, U=61, $p<.05$) as the sensitizing stimulus. In addition to sensitizing the evoked contractions, tail and mantle shocks produced an increase in the frequency of spontaneous contractions of the gill; this effect was also significantly reduced by 5,7-DHT treatment. There were no significant differences between the 5,7-DHT-treated and control preparations in either the pre-shock test scores or the direct responses to the shock.

Together, the results of these two sets of experiments provide additional evidence for the involvement of 5-HT in behavioral sensitization of the Aplysia gill-withdrawal reflex.

175.13 THE HELIX ASPERSA "LOVE DART" INJECTS A DIGITIFORM GLAND FACTOR(S) THAT SYNCHRONIZES MATING BEHAVIOUR. S.A. Adamo and R. Chase. Dept. Biology, McGill Univ., Montreal, Quebec, H3A 1B1, Canada.

In Helix aspersa, a simultaneously hermaphroditic terrestrial snail, copulation follows after eversion of the genital apparatus, which occurs during a courtship period lasting 45-125 min. We have identified 7 stages of genital eversion. Stage 5 includes the shooting of a calcareous dart. The dart carries mucous secreted by the digitiform glands into the hemocoel of the mating partner. Copulation follows within 2-20 min. of the second of the reciprocal dart shots.

It was recently reported (Chung, D., J. Exp. Zool. 238: 129-139, 1986) that injections of digitiform gland extract produce some genital eversion in animals that had none prior to injection. We have found that the duration of the response ($p<0.05$) and the percentage of animals responding to digitiform gland ($p<0.05$) is dependent on the extent of the animal's initial eversion. Control snails injected with either dart sac plus dart or with saline showed no increase in eversion at any preinjection eversion stage.

Preliminary results with dartless and digitiform glandless animals show that these animals have a larger range of courtship times than controls. The dartless and digitiform glandless animals differ most from controls when the courting partners are at very different genital eversion stages. In these cases, the time between dart shooting (or attempted dart shooting) and copulation is lengthened, and more pairs fail to reach copulation.

Our interpretation of these results assumes that the successive stages of genital eversion represent increasing levels of arousal and that the two courting snails must reach progressively higher levels of arousal in approximate synchrony for copulation to occur. The snail receiving the first dart is brought closer to the arousal level of the shooting snail. This increases the probability of copulation. Because the effect depends on the animal's initial state of arousal, the digitiform gland secretion material appears to work synergistically with other hormonal or neurohormonal agents.

175.14 SELF-LOATHING AND EVASIVENESS IN NOTASPID SNAILS: POSSIBLE REGULATION OF AVOIDANCE BEHAVIOR BY DEFENSIVE ACID SECRETION. Rhanor Gillette and Rong-Chi Huang. Department of Physiology & Biophysics, University of Illinois, Urbana, IL 61801.

Notaspidean opisthobranchs are notable for their ability to secrete sulfuric acid from their skin in response to noxious stimuli (Thompson and Colman, J. Moll. Stud. 50, 66). Because of this secretion, and perhaps other factors, these mollusks are rejected as food by most predators, including such markedly tasteless scavengers as crabs, herring gulls and starfish; aversion is specific to the skin, as internal organs are readily accepted. Indeed, skin contact frequently triggers stereotyped avoidance/escape responses in starfish, many species of snails and swimming anemones. Accidental observations arising from a mis-made solution while working on local notaspids at the Isle of Man led to demonstration that acid solutions elicit a stereotyped avoidance behavior similar across 5 species.

Solutions of seawater adjusted to pH 2-3 (10-100 times less acid than animals' defensive secretions) and pipetted slowly onto the oral veil cause stereotypic avoidance behavior consisting of local withdrawal, aversive turns and rapid escape locomotion in specimens of Pleurobranchus membranaceus, Berthella plumula, Berthella californica, Berthellina citrina and Pleurobranchaea californica. Pleurobranchus and occasional Pleurobranchaea showed swimming escape locomotion. Acid solutions were aversive at any part of the body, and caused local withdrawal when applied to isolated Pleurobranchaea skin resting in buffered seawater, suggesting a component of avoidance behavior mediated peripherally. The avoidance behavior of Pleurobranchaea is indistinguishable from that often shown to conspecifics, and that observed in associatively food-avoidance trained animals.

These data show that avoidance behavior in these species is intimately tied to defensive acid secretion, and they suggest further ties. The importance and potential contribution of acid secretion to protection from cannabalism and learned food-avoidance behavior in Pleurobranchaea is under investigation.

The hospitality of the University of Liverpool Marine Station at Port Erin, I. O. M., is gratefully acknowledged.

175.15 SHORT-TERM AND LONG-TERM CHANGES IN IDENTIFIED B-PHOTORECEPTORS OF HERMISSENDA PRODUCED BY LIGHT AND SEROTONIN. J. Forrester* and T. Crow (SPON: J. Horn). Dept. of Physiology, Univ. of Pittsburgh School of Medicine, Pittsburgh, PA 15261.

Positive phototactic behavior in Hermissenda undergoes a long-term reduction after repeated pairings of light with rotation. Associated with conditioning of Hermissenda are intrinsic changes in the primary sensory neurons (type B-photoreceptors) of the pathway mediating the conditioned stimulus (CS). We have been investigating the contribution of the neuromodulator 5-HT to conditioning in Hermissenda. Previous research demonstrated that light responses of Hermissenda B-photoreceptors were enhanced and prolonged by bath application of 5-HT (Crow & Bridge, 1985). Recently, it was shown that 5-HT immunoreactive fibers and varicosities terminate near the optic nerve and in the neuropil near photoreceptor synaptic terminals (Land & Crow, 1985). In addition, the reduction in normal positive phototactic behavior can be mimicked by pairing light with direct application of 5-HT to the exposed circumesophageal nervous system (Crow & Forrester, 1986, PNAS 83:7975). Collectively these results suggest a role for 5-HT in conditioning in Hermissenda. In order to determine if pairing light and 5-HT produces intrinsic changes in sensory neurons we have investigated changes in the light responses of identified B-photoreceptors at different times following the application of light and 5-HT.

Light responses (generator potentials) of surgically isolated medial and lateral B-photoreceptors were examined 1 hr and 24 hrs after one session of light paired with 5-HT. Controls received light and 5-HT unpaired. Both the paired group (N=23) and the unpaired group (N=25) exhibited a significant enhancement in the amplitude of the generator potential evoked by a 2 min light step 1 hr after training as compared to normal controls (N=10). The mean amplitude of the generator potential at the end of the light step was 28.9mV for medial B-photoreceptors from the unpaired group, 27.9mV for medial B-photoreceptors from the paired group, and 24.6mV for normal controls. Overall differences were statistically significant, $p<.05$. The mean amplitude of the generator potential of lateral B-photoreceptors from the paired group at the end of the light step was 27.8mV compared with 28.1mV for the unpaired group and 25.2mV for the normal controls ($p<.05$). The enhanced light responses of medial B-photoreceptors from the paired and unpaired groups, and lateral B-photoreceptors from the unpaired group were short-term. The light responses of isolated medial B-photoreceptors and lateral B-photoreceptors from both the paired (N=23) and unpaired groups (N=23) examined 24 hrs after the light-5-HT session revealed that only the lateral B-photoreceptors exhibited an enhanced response at the end of the light step (paired, $\bar{X}$=29.1mV; unpaired, $\bar{X}$=25.6mV, $p<.05$). These results indicate that paired light and 5-HT produce both short-term and long-term changes that are intrinsic to identified B-photoreceptors. Short-term enhancement of the generator potential is not pairing-specific. Long-term pairing-specific changes in the light response are detected in only the lateral B-photoreceptors and are expressed by changes in adaptation to sustained illumination.

175.16 CHARACTERIZATION OF A SUBSET OF PUTATIVE MOTOR NEURONS IN THE PEDAL GANGLIA OF HERMISSENDA WHOSE LIGHT RESPONSES ARE DUE TO SYNAPTIC INPUT FROM PHOTORECEPTORS. T.M. Hodgson* and T. Crow (SPON: O. Reinmuth). Dept. of Physiology, Univ. of Pittsburgh School of Medicine, Pittsburgh, PA 15261.

Suppression of the normal positive phototatic response in the marine mollusk Hermissenda is produced by a conditioning procedure which pairs stimulation of the visual system and gravity-detecting statocysts. The learning is expressed as a suppression of the initiation of locomotion in the presence of the CS (light). The neural circuitry underlying the conditioning has been well studied for the sensory systems involved in the CS and UCS (vestibular) pathways, but investigation into the neural circuitry underlying the expression of the behavior and its modification by conditioning has just begun.

As an initial step in this investigation intracellular recordings were made from putative motor neurons in the pedal ganglia. The responses of the pedal cells to light were tested with a 10 second light step. Four new types of light-responsive neurons were found. One cell type is an intermittent burster which hyperpolarizes at the onset of light; its return to baseline has a variable time course (from <1 sec up to the duration of the light step). The other three cell types show excitatory responses to light. Two of these are intermittent bursters, one of which shows a transient (<1 sec) burst of impulse activity at light onset followed by an immediate return to baseline activity. The other cell also exhibits this transient, plus a more prolonged (3-5 sec) increase in impulse activity. During spontaneous hyperpolarization or with the injection of extrinsic hyperpolarizing current to eliminate action potentials, the light response appears as an EPSP at light onset, accompanied by a slight depolarization whose time course extends 1-2 seconds past the duration of the light step. The third cell type with an excitatory light response shows considerable synaptic activity between action potentials and produces a transient burst of impulse activity at light onset followed by an immediate return to baseline activity.

To determine if the light responses were intrinsic to the pedal neurons or due to synaptic input from the photoreceptors, the cells' light responses were recorded before and after one of two manipulations. The first procedure involved cutting the optic nerve to isolate the photoreceptors from the rest of the nervous system. The second procedure was a bath application of the Ca^{2+} blocker $NiCl_2$ to a final concentration of 20 mM to block all synaptic activity. The light responses of all the cell types were abolished after either treatment, indicating that the responses were produced by synaptic activity originating in the photoreceptors.

These results show that a subset of putative motor neurons in the pedal ganglia of Hermissenda are light-responsive due to synaptic inputs from the photoreceptors. Further experiments are planned to determine which photoreceptor(s) provide input to these cells, and whether the light responses of these pedal cells can be modified by conditioning.

175.17 ELECTRICAL RESPONSE OF ABALONE LARVAE TO GABA; A SETTLEMENT-INDUCING MOLECULE. L. A. Barlow*. (SPON: M. L. Block). Dept. of Zoology, Univ. of Washington, Seattle, WA 98195.

The neurobiology of the veliger larvae of the red abalone, *Haliotis rufescens,* and of the pinto abalone, *H. kamtschatkana* , was investigated by making intracellular recordings from the ciliated cells of the larval swimming organ, the velum. Velar cells had resting potentials between -55 and -65 mV, which were independent of the age of the veliger. While these electrically coupled cells were at rest, the cilia of the velum beat metachronally. Each action potential recorded in a velar cell was correlated with a ciliary arrest. The action potentials of abalone velar cells were slow (lasting 250 msec) and overshooting with a total amplitude of ca 65 mV. Spike shape did not change with respect to veliger age.

The velar action potential was not blocked by .3 or 3 uM tetrodotoxin, but did show a variation in shape when the larva was perfused with low Na+ seawater (Na+ substituted with N-methyl-D-glucamine). Both Co++ and Ni++, when substituted for Ca++, blocked the action potential, indicating that the velar spike was carried primarily by Ca++.

The larvae of both red and pinto abalone are induced to settle and metamorphose when presented with a molecular component of the crustose coralline algae, *Lithothamnium* and *Lithophyllum* . GABA mimics the action of the coralline inducer substance. The electrophysiological response to GABA was used to examine an individual's ability to perceive the settlement cue. Spontaneous electrical activity consisted of random action potentials and slight fluctuations in membrane potential. When GABA was presented to the larva by perfusion, firing frequency in the velar cells increased abruptly. The ability of larvae to respond to GABA was both dose- and larval age-dependent. Precompetent larvae required larger doses of GABA to elicit a response than did older metamorphically competent larvae. Greater concentrations of GABA also induced higher rates of firing. These data suggest that larval abalone become increasingly sensitive to GABA as they approach metamorphic competency.

GABA did not appear to act directly on the velar cells, since no change in input resistance was observed at subthreshold concentrations. It is more likely that velar electrical activity represents integrated motor activity in response to GABA.

Since GABA arrests ciliary beat, and therefore swimming, perhaps this initial physiological and behavioral response is related to the phenomenon of induction of settlement by the GABA-like substance found in the natural inducer, crustose coralline algae.

175.18 A CLASS OF DROSOPHILA BEHAVIORAL MUTANTS THAT ARE SENSITIVE TO BOTH MECHANICAL VIBRATIONS AND TEMPERATURE CONDITIONS. M.G. Burg and C.-F. Wu, Dept. of Biology, Univ. of Iowa, Iowa City, Ia. 52242.

Several Drosophila behavioral mutations are known to affect basic neurophysiological processes, resulting in paralysis at high temperatures. A class of so called "bang-sensitive" mutations are characterized by paralysis after exposure to mechanical vibrations. These mutations have been mapped to different loci on the X chromosome: tko (technical-knock-out), kdn (knock-down), eas (easily-shocked), bas (bang-sensitive), and bss (bang-senseless) (Ganetzky and Wu, Genetics 100: 597, 1982).

We examined the responses of individual bang-sensitive (b.-s.) mutants to both mechanical vibration and temperature conditions. Surprisingly, all the b.-s. mutations exhibited temperature-induced paralysis. Of the 4 mutants analyzed, bss and eas were paralyzed by low temperatures, whereas bas and tko were paralyzed by high temperatures. In addition, responses of individual flies to mechanical vibrations demonstrated distinct differences between these mutations.

In Drosophila, mutations that alter related functional processes may interact, resulting in more severe phenotypes (Ganetzky and Wu, Ann. Rev. Genet. 20: 13, 1986). Viable b.-s. double mutants exhibited a more severe vibration-induced paralytic phenotype than single mutants, suggesting that a functional interaction may be occurring between mutant gene products. In addition, both individual mutant phenotypes were present in the double mutants, i.e. the bas bss double mutant being paralyzed by high and low temperatures.

Behavioral analysis of b.-s. genetic mosaics containing part mutant and part normal tissue suggests that different regions of the nervous system are responsible for the various mutant phenotypes exhibited. Together, the results from double-mutant and mosaic analyses suggest that the b.-s. mutations may affect different cellular processes. Alternatively, they may affect similar processes in separate discrete regions of the fly's nervous system. Physiological experiments are presently underway to investigate the affected neural regions and the underlying cellular defects. This work was supported by an NIH pre-doctoral training grant GM07091 to MGB and NIH grants NS00675, NS15350, and NS18500 to CFW.

175.19 TACTILE REFLEXES OF COCKROACH LEG. C.A. Meyer* and M.V.S. Siegler*, (SPON R.L. Calabrese). Dept. of Biol., Emory Univ., Atlanta, GA 30322.

Behavioral and developmental studies on several insect species indicate that epidermal cells, cuticular sensory receptors, and associated sensory neurons are specified according to their location on the body surface. In the locust, spatial information from tactile receptors on the surface of a leg is integrated in the CNS to organize avoidance reflexes that differ according to the location of the stimulated receptors (Siegler and Burrows, J.Neurosci., 6, 507, 1986). In the cockroach, excised cuticular structures are regenerated in a way that indicates there is a continuum of positional values along the length of a leg segment and around its circumference (French, Phil.Trans.R.Soc.B, 295, 601, 1981).

The present study was undertaken to test whether in the cockroach, as in the locust, this spatial information might be of some behavioral significance. We report that tactile sensilla on the metathoracic legs of the cockroach Periplaneta americana are organized into receptive fields. Touch to sensilla that lie within different receptive fields elicit different avoidance reflexes of a leg. These fields occur on the different segments of a leg, and are oriented either with respect to the dorsoventral or the anteroposterior axis of the leg. For example, touching the proximal, ventral femur elicits promotion of the coxa, levation of the trochanter, and extension of the tibia, whereas touching the proximal, dorsal femur elicits promotion of the coxa, depression of the trochanter, and flexion of the tibia. Touching sensilla on the anterior ventral ridge of the coxa elicits levation of the trochanter and extension of the tibia, whereas touching sensilla on the posterior surface of the coxa elicits depression of the trochanter and extension of the tibia. (The surfaces of a leg are described as if it is held at a right angle to to the longitudinal axis of the body, with all its joints fully extended (Snodgrass, Smith.Misc.Coll., 82, 1, 1929). Accordingly, the meron of the coxa is on the dorsal surface of the leg, whereas the femoral spines are on the ventral surface of the leg.) Some ten further reflexes are described that are likewise elicited by touching sensilla that are located on different regions of the metathoracic legs.

175.20 FMRFamide PREVENTS HABITUATION OF THE EVOKED GILL WITHDRAWAL RESPONSE IN THE ISOLATED GILL OF APLYSIA. D. Cavthorpe and K. Lukowiak (SPON: P. Hicks). Dept. of Medical Physiology, University of Calgary, Alberta, Canada, T2N4N1.

The evoked gill withdrawal response (GWR) of the isolated gill of Aplysia californica may exhibit simple forms of learning such as habituation or sensitization. The peptide, FMRFamide, when perfused through the isolated gill of Aplysia, elicits spontaneous contractions of the gill. As well, FMRFamide immunofluorescence has been localized to nerve terminals innervating the gill, (Weiss, et al. 1984). This study examined the effects of FMRFamide on the habituation of the evoked GWR.

The gill, siphon and mantle were pinned dorsal side down to the base of a Sylgard dish. The abdominal ganglion was removed. The gill was cannulated via the afferent vein and perfused at a rate of 5-10 ml/minute. The gill was attached to a Grass FT03C force transducer by a thread tied to a single pinnule of the gill. Gill movements and tension were recorded on a Grass 79D polygraph. The gill was stimulated with a mechanical tapper. Artificial sea water (ASW; Instant Ocean) was used as perfusate. FMRFamide, (Peninsula), was diluted in ASW to the desired concentration immediately prior to perfusion through the gill. Experiments were commenced once a steady perfusion was attained and the gill was allowed to rest for one hour. In all experiments two control GWR's were recorded with an ISI of 20 minutes. Measurements of increases or decreases in the amplitude of the evoked GWR are expressed as a percent of the second control response preceeding that experimental run.

FMRFamide induced gill contractions with a threshold of 1-3 nM. Perfusion of FMRFamide (10 nM) elicited maximal gill contractions whereupon, washout of FMRFamide was commenced. The GWR was evoked upon return of gill tone to the baseline tension. FMRFamide (10 nM) increased the amplitude of the evoked GWR to 142% (S.E.=20%) of control (n=10). For control habituation experiments, a standard stimulus was delivered with an ISI of 5 minutes. The evoked GWR amplitude was recorded. After ten such stimuli at this rate, the amplitude of the evoked GWR decreased to 38.1% (S.E.= 11.03%) of control (n=10). The viability of the gill was tested with a gill or siphon pinch, which generally resulted in dishabituation of the habituated GWR when evoked immediately following the pinch. For experimental habituation runs, FMRFamide (10 nM) was perfused for approximately 1-3 minutes during each ISI. Once spontaneous contractions began the perfusion of FMRFamide was terminated by switching to control ASW. When the gill became quiescent and the gill tension returned to baseline, the standard tactile stimulus was delivered and the evoked GWR amplitude recorded. This was repeated until ten stimuli had been delivered, as in the control run. When FMRFamide was perfused in this manner habituation of the evoked GWR did not occur.

In these experiments the perfusion of FMRFamide prevented habituation of the evoked GWR and increased the amplitude of the evoked GWR with respect to control. In addition to the induction of spontaneous gill movements, FMRFamide may also be involved in modulation of adaptive gill behaviors.

176.1 **CORRELATION OF SWIMMING BEHAVIOR WITH THE ACTIVITY OF IDENTIFIED GIANT RETICULOSPINAL NEURONS IN THE LAMPREY SPINAL CORD** Joseph Ayers and C. M. Rovainen, Marine Science Center, Northeastern University, East Point, Nahant, MA 01908

The lamprey spinal cord contains the largest number of re-identifiable neurons of any vertebrate, but, their function during normal behavior is unknown. We have developed techniques which allow us to record from reticulospinal axons at two sites in the spinal cord during swimming and then subsequently extract their activity by a signal processing algorithm. Recordings from axons of reticulospinal neurons are obtained from the spinal cords of freely behaving lampreys with silver electrodes inserted into the dorsal meningeal canal. The action potentials of identified neurons exhibit a unique triplet signature (rostral waveform, caudal waveform, inter-electrode latency) which can be distingushed from those of other reticulospinal axons. The spinal cord recordings survive reduction of the preparation to allow intracellular stimulation of identified cell bodies in the brain. The spinal recordings can be triggered off the intracellular spike to allow each triplet signature to be ascribed to a identified neuron. These identified triplets can then be extracted from the *in vivo* recordings by a template matching algorithm which relies on a product-sum correlation of the proximal and distal templates on a point by point basis with the digitized *in vivo* data. Synchronization of the behavioral analysis and electrophysiological recordings is based on a signal common to the two forms of data, a photoelectric LED. The behavioral analysis starts with the first movie frame where the LED is illuminated, and the analog digitization is triggered off the voltage pulse which illuminates the LED. The overall analysis results in a raster plot of identified neuron activity plotted over a graph of the locus of flexion waves as a function of time shown below *(Science 221:1312-1314)*, allowing the behavior to be related directly to the neuron activity. Supported by NSF Grant *BNS8406880*

176.2 AGGRESSIVE BEHAVIOR IN SIAMESE FIGHTING FISH, *BETTA SPLENDENS*; NEURAL PATHWAY FOR GILL-COVER ERECTION. D.L. Gorlick, Dept. Biol. Sci., Columbia Univ., New York, N.Y. 10027.

There are no complete descriptions of the neural pathway mediating any aggressive behavior patterns in fishes. The primary goal of this research is to describe the neural pathway controlling gill-cover erection in male *Betta splendens*. Gill-cover erection is a characteristic component of aggressive encounters in *Betta*. It occurs during frontal display and consists of extreme lateral movement of the opercula until they are at right angles to the body axis where they may be held for periods of a few seconds up to a minute or more.

Gill-cover erection is produced by a single muscle, the opercular dilator. This muscle is large in male *Betta* and may be primarily dedicated to the performance of gill-cover erection. HRP injections into the opercular dilator show that the motor neurons that innervate this muscle are located in the anterior medulla in the lateral and medial parts of the motor nucleus of cranial nerve VII. Work to date has concentrated on the lateral part of VII.

Iontophoretic injections of HRP into lateral VII (VII-L) label ipsilateral neurons in the adjacent medial reticular area (Rm), nucleus intermedius octavolateralis (Octavo), and nucleus vestibularis magnocellularis (Magno). Octavo and Magno may process lateral line inputs related to water movements produced by displaying fish. Afferent input to VII-L also comes from ipsilateral and contralateral cells in the anterior pole of the motor nucleus of cranial nerve X. This part of X also contains motor neurons that innervate muscles of the branchiostegal membrane that are involved in production of the other component of aggressive frontal display behavior in *Betta* (Augenbraun & Gorlick, Soc. Neurosci. Abstr., 1987).

Rm receives afferent input from contralateral and ipsilateral Magno, contralateral Rm, and from ipsilateral inferior reticular neurons (Ri) that are located medial to neurons in cranial nerve nuclei IX and X-XI. Magno receives afferent input from contralateral Magno and from ipsilateral Octavo. Magno also sends a strong efferent fiber projection anteriorly in the lateral lemniscus that terminates in the contralateral torus semicircularis. Octavo appears to receive input only from contralateral Octavo.

176.3 MOTOR NUCLEI RESPONSIBLE FOR BRANCHIOSTEGAL MEMBRANE EXTENSION DURING AGGRESSIVE DISPLAY IN *BETTA SPLENDENS*. E. Augenbraun* and D.L. Gorlick (SPON: Darcy B. Kelley), Dept. Biol. Sci., Columbia Univ., New York, NY 10027.

There are two components of aggressive display behavior in the Siamese fighting fish *Betta splendens:* frontal and lateral. During the frontal display the fish extends a highly developed branchiostegal membrane composed of thin sheets of muscle that run between the branchiostegal rays. Contraction of these muscles causes the branchiostegal membrane to fan out during frontal display. An adjacent pair of muscles, "*X*," also appears to contribute to frontal display as cutting them modifies the shape of the branchiostegal membrane. These muscles originate anteriorly in the angle of the lower jaw and appear to insert distally on the inside of the branchiostegal membrane. Left and right muscles cross at the midline forming an "*X*." Male fish have larger, thicker branchiostegal membranes and larger "*X*"- muscles than do females. The behavior is also sexually dimorphic in that males display more frequently and for longer periods of time.

We have used retrograde tracing with Horseradish peroxidase (HRP) to identify the motor nuclei controlling this behavior. Large neurons in cranial nerve nucleus n.IX and n.X-XI innervate the branchiostegal membrane in both males and females. In males most of the labeled n.X cells are in a prominent medial bulge at the anterior end of the nucleus. Neurons in this area send efferent projections to motor neurons that control gill-cover erection, the other component of frontal diplay in *Betta splendens* (Gorlick, Soc. Neurosci. Abstr., 1987). In females, however, the bulge appears to be less prominent and many labeled cells are found outside the bulge. Motor neurons that innervate the "*X*"- muscle are also located in n.X. However, they appear to be located just posteriorly to those that innervate the branchiostegal membrane.

176.4 THE NEUROETHOLOGY OF A VISUALLY MEDIATED BEHAVIOR: THE EYE-BAR RESPONSE. M.M. Hagedorn, R.D. Fernald. Institute of Neurosciences, Univ. of Oregon, Eugene, OR 97403

African male cichlid fish, Haplochromis burtoni, respond to threats from male conspecifics at the boundaries of their territories by facing one another and displaying a dark, pigmented eye-bar beneath each eye. Usually, both males possess eye-bars and ultimately, when the loser turns to flee, the eye-bar pales. The eye-bar response is largely a visually mediated behavior related to aggressive interactions between males and is effected by a darkening or paling of chromatophores in the scales below the eyes.

The anatomy and function underlying this behavior was investigated at two levels: 1) the signal input pathway from the retina; 2) the motor output pathway. Since visual information passes primarily to the tectum, tectal efferents were mapped using horseradish peroxidase (HRP). Tectal injections were made in adult males (n=5) by pressure injecting a 20% solution of HRP or a 1% solution of lectin conjugated peroxidase. The animals were allowed to survive for 2-3 days and then prepared for histology. The animals were anesthetized and perfused intracardially with saline followed by a 4% gluteraldehyde solution, post-fixed for 4 hours, cut at 60 μ and reacted with a heavy metal intensified diaminobenzidine reaction. Labelled tectal efferents were found in pretectal nuclei, the anterior nuclei, the posterior commissure, the glomerulus nuclei, the torus longitudinalis, the torus semicircularis, the valvula, the tectobulgar tracts, the vagal lobe, the medio longitudinal fasciculus and the fasciculus medialis tracti optici.

To analyze the function of the motor output, neural lesions were made in the trigeminal nerve. Previous studies have suggested that chromatophore nervous control is part of the sympathetic trigeminal system and that the chromatophores in the eye-bar are neurally controlled by a post-ganglionic nerve which follows the orbit of the eye and travels with a branch of the maxillary nerve along the jaw into the cranium. Stimulation of this post-ganglionic nerve results in a contraction of the chromatophores and a paling of the eye-bar, whereas, nerve lesions result in an expansion of the chromatophoes and a darkening of the eye-bar. Pre-ganglionic nerve lesions were made in the trigeminal nerve in 2 animals. These animals recovered and their behavior monitored for 4 hours, no expansion of the chromatophores or darkening of the eye-bar was observed. This suggests two functional possibilities for the eye-bar pathway; one, the preganglionic nerve is not part of the trigeminal nerve or two, a population of the post-ganglionic fibers are spontaneously active, thus maintaining the chromatophore in a contracted state despite the removal of the pre-ganglionic input. This is the first step in identifying the pathways required for the behaviorally significant eye-bar response.

176.5 A GOLGI STUDY OF THE SONIC MOTOR NUCLEUS OF THE OYSTER TOADFISH, P.J. MOSCA* AND M.L. FINE. Dept. of Biology, Virginia Commonwealth University, Richmond, Virginia 23234

The sonic motor nucleus (SMN) of the oyster toadfish Opsanus tau is sexually dimorphic: females have small neurons and males can have either large or small neurons. Golgi stains (Golgi Kopsch method) were performed on the SMNs of 50 toadfish. Five neuron types (fusiform, rostral, stellate, ventral and caudal) were separated on the basis of position, soma shape and size, and direction and pattern of dendritic branching. All neuron classes were present in both types of males and in females, and sexually dimorphism was manifest as differences in soma size. The ratio of mean area of small cells to large cells ranged from 0.56 to 0.87 for the different types. The SMN was organized into 3 layers with fusiform and rostral neurons forming a chain across the dorsal-dorsolateral surface, stellate cells in the middle and ventral cells below. Caudal neurons were localized in the caudal fifth of the nucleus, often lined up in rows. Fusiform, stellate and caudal neurons had similar soma areas ($\bar{x}$ = 1466 to 1560 um^2 in small-celled SMNs and 1803 to 1812 um^2 in large ones), ventral cells were smaller (1243 and 1789 um^2) and rostral cells smallest (780 and 1379 um^2). Fusiform neurons were ovoid in shape and characteristically sent a large-diameter dendrite ($\bar{x}$ = 9.3 um) toward the center of the SMN and 1-3 thinner dendrites ($\bar{x}$ = 3.8 um) in rostral and caudal directions. They had the smallest number of primary dendrites but the greatest amount of branching, starting within 50 um of the soma. Rostral cells had an average of 3.0 dendrites, which tended to project ventrally and caudally and share a similar branching pattern with fusiform neurons. Stellate cells had the roundest somas and the greatest number of primary dendrites ($\bar{x}$ = 4.8), which were distributed evenly. A small amount of branching was concentrated between 50 and 100 um from the soma. Ventral cells had rounded somas except on the dorsal surface where they were flat or concave between pairs of thick dendrites (4-7 um), which projected dorsolaterally and dorsomedially and exited the SMN. An intermediate amount of branching, was distributed uniformly to 200 um from the soma. Caudal cells were round or ovular in frontal and horizontal sections and more elongate in sagittal sections. Dendrites were polarized in the rostral and caudal directions, and caudal dendrites exited the SMN. A small amount of branching was distributed uniformly to 200 um in horizontal section. Retrograde transport of horseradish peroxidase from the sonic muscles indicated that all cell types were motoneurons. Ventral and caudal cells receive afferent information from higher centers. We suggest that rostral and fusiform neurons synchronize the SMN along its rostrocaudal axis, and that stellate cells provide a bridge between the other cell layers.

176.6 ELECTRIC CUES ELICIT SONIC COURTSHIP IN THE MORMYRID FISH Pollimyrus isidori. J. D. Crawford* and C. D. Hopkins (SPON: L. Nowak). Neurobiology and Behavior, Cornell University, Ithaca, NY 14853

The African electric fish, Pollimyrus isidori, uses both acoustic and electric social signals. The electric repertoire consists of a single highly stereotyped electric organ discharge (EOD; 100-200 µs duration) which can be produced in a wide range of temporal patterns. The acoustic repertoire consists of 5 distinct sounds. *Grunts* and *Growls* are pulsatile sounds with pulse repetition rates of 50 and 25 Hz respectively. The peak power of individual pulses for both sounds is 220 Hz. *Moans* are quasi-sinusoidal with a dominant fundamental at 220 Hz. All three sounds are probably produced through a common mechanism involving the swim bladder. The *Pop* is a single pulse with a broad power spectrum and the *Hoot* is tonal with a variable dominant frequency of about 100 Hz.

Three of the sounds are used during courtship and the other two during aggression. Territorial males concatenate *Grunts*, *Moans* and *Growls* to produce a song when they are approached by egg-bearing females. This sonic courtship can be elicited experimentally by placing a "test" fish, captive within a small perforated container, into the territory of a "resident" male. When a gravid female is introduced in this fashion, the resident sings acoustically for the duration of a 2-4 min trial. When another male is introduced, the resident produces *Hoots*, *Pops* and high frequency bursts of EODs, and relatively few *Grunts*, *Moans* or *Growls*.

An electric dipole was substituted for a real fish in the test container in order to investigate the possibility that electric signals emitted by test fishes determine the resident male's response. Trains of electric stimuli were presented using lists of interpulse intervals stored on a computer to trigger an arbitrary waveform generator loaded with EODs (digitized at a sampling frequency of 1.0 MHz). Males respond vigorously with acoustic courtship when the electric behavior of a conspecific is mimicked by playing-back EODs at species typical intervals. Natural female EODs played-back in a female typical pattern, male EODs in a male typical pattern , male and female EODs played back in a random pattern of species typical intervals, and 5 KHz sinusoidal waveforms presented in regular synthetic patterns all elicit sonic courtship. Electric stimuli are clearly potent releasers for male sonic courtship in Pollimyrus isidori. The basis of male-female discrimination is not yet clear, but the role of the EOD waveform and discharge repetition patterns are currently being investigated.

176.7 WHITE NOISE ANALYSIS PREDICTS TEMPORAL SPIKE PATTERN OF TUBEROUS ELECTRORECEPTORS IN MORMYRID ELECTRIC FISH.
C.D. Hopkins and G.D. Harned*. Section of Neurobiology and Behavior, Cornell University, Ithaca, New York. 14853.

Electric fish from the African family Mormyridae have tuberous Knollenorgan electroreceptors which have been identified as putative *communication sensors* for electric communication. They appear to be used for detecting electric organ discharges from other electric fish and for species- and sex-recognition.

Knollenorgans have a low threshold, are tuned to the power spectrum of the species-specific electric organ discharge (EOD), and are ideally suited for preserving timing information in electric stimuli. Knollenorgans can be studied electrophysiologically by applying electric stimuli through a bridge amplifier to the electroreceptor pore while simultaneously recording spike-like receptor potentials from the receptor organ.

We used Gaussian-distributed white noise, bandwidth limited to 10 kHz, as a stimulus and used the technique of reverse correlation (deBoer and Kuyper, . IEEE Trans. Bio. Med. Eng. 15:169) to determine the linear part of the transfer function of the spike generator in the Knollenorgan. We computed spike-triggered averages of stimulus waveforms from a minimum of 2000 spikes. These reverse averages are the linear part of the system impulse response.

The impulse responses determined in this way were highly consistent from one measurement to the next, over an 18 dB dynamic range of stimulus amplitudes.

Impulse responses were typically highly damped, showing an initial excitatory phase followed by a weaker, longer-lasting inhibitory or refractory phase. There is a very close resemblance between the impulse response of a receptor and the shape of the extracellularly-recorded receptor potential. Low-frequency Knollenorgans had longer duration impulse responses than did high frequency receptors.

The reverse-correlation generated impulse response was subjected to Fourier analysis. The power spectrum of the impulse response is the "gain" of the linear filter. The power spectrum was compared to the frequency tuning curve of the receptor. Best frequencies and quality (Q_{10}) were closely matched for the two methods. The overall shape of the tuning curve, although highly variable from unit to unit, was matched by the shape of the power spectrum.

We measured compound post-stimulus time histograms of spike density in response to a variety of complex stimulus waveforms , including: single period sine waves, repeated or static white noise. and EOD waveforms. We also compared the observed compound PSTH to the predicted output generated by calculating the convolution integral between the stimulus waveform and the impulse response of the system. There is a very close match between the predicted waveform and the observed compound post stimulus time histogram, indicating that the linear model of the receptor accounts for much of the observed output. At high stimulus intensities, the amplitude of observed responses differed from predicted, indicating the presence of amplitude nonlinearities.

The reverse-correlation computed impulse response was used to accurately predict the response times to arbitrary waveforms, like species-specific EODs and other signals.

176.8 GONADOTROPIN-INDUCED SHIFTS IN THE ELECTROSENSORY SYSTEM OF *STERNOPYGUS*. H. H. Zakon, H.-Y. Yan* and P. Thomas*. Dept. of Zoology and the Marine Sciences Institute, University of Texas, Austin TX, 78712.

The weakly electric fish Sternopygus macrurus emits a sinusoidal electric organ discharge (EOD) from an electric organ in its tail and detects its own EOD with tuberous electroreceptors distributed across its body. The duration of a single electric organ (EO) pulse, the frequency of firing of the EO, and the tuning of electroreceptors are highly coordinated in each individual and are sexually dimorphic. All three of these parameters have been shown to be influenced by the exogenous administration of the androgen hormones testosterone (T) and dihydrotestosterone. Only a single study has observed the effects of an exogenously-applied ovarian hormone, estradiol 17ß (E), on EOD frequency in this species (Meyer, 1983). The effect reported in this study was significant but small. We investigated the effects of gonadotropin on fish of both sexes in order to determine if a more robust effect might be induced in females by the release of endogenous ovarian hormone(s) and to estimate circulating levels of endogenous androgens and estrogens that are sufficient to induce changes in the electrosensory system.

Large juvenile or small adult fish of both sexes were used (~ 25-40 cm length). Blood samples were taken to determine baseline levels of circulating steroids. Baseline measures of EOD frequency and EO pulse duration were taken. Single unit recordings of electroreceptive afferent fibers were made (N = 20 per fish) to determine mean receptor best frequency (the frequency to which a receptor is most sensitive). Fish in the experimental group were then given 3 injections of human chorionic gonadotropin (HCG, 10 units/ gram body weight) spaced 5 days apart. Control groups of both sexes received saline injections. EOD frequency was tracked during this time, blood samples were taken at various intervals, and EO pulse duration and electroreceptor tuning were measured again 3-5 days following the last injection.

HCG caused increases from baseline levels of T (from < 1.0 ng/ml plasma to > 5.0 ng/ml) and 11-ketotestosterone (11-KT, the major androgen in fishes) (<1.0 to > 3.0 ng/ml) in males, and T (< 1.0 to >7.0 ng/ml) and E (<0.5 to > 1.0 ng/ml) in females. When compared to the saline control groups whose EOD frequencies were unchanged, EOD frequency was significantly lowered in HCG-primed males and increased in females ($p < 0.005$, Mann-Whitney U, for both sexes). In addition, preliminary analysis of EO pulse duration and receptor tuning show changes in the expected direction: EO pulse duration of males is increased and that of females is lessened, receptors of males are tuned to lower frequencies, while those of females are tuned to higher frequencies.

These data demonstrate that endogenously-released steroid hormones (in concentrations of a few nanograms/ ml plasma) are capable of effecting changes in the electrosensory system previously reported to occur after administration of exogenous steroids of comparable, or in some cases unknown, concentrations. In addition, HCG induces larger changes in EOD frequency than the exogenous application of E. Whether this is due to a difference in timing of release or average circulating levels of E by HCG and exogenous injection, co-release of other steroids from the ovary by HCG, or direct effects of HCG on the EOD generating circuitry is not known.

176.9 HORMONE-MEDIATED SHIFTS IN ELECTRORECEPTOR TUNING OCCUR IN FISH WITH MEDULLARY PACEMAKER LESIONS. M. B. Ferrari* and H. H. Zakon (SPON: G. Pollak). Dept. of Zoology, University of Texas at Austin, Austin, TX 78712

The weakly electric gymnotiform Sternopygus macrurus produces and detects a quasi-sinusoidal electric field; this field is generated by an electric organ in the tail and is detected by electroreceptors in the epidermis. The firing frequency of the electric organ is determined by a medullary pacemaker nucleus (PMN) and each fish has its own characteristic frequency, with a species range of 60-200Hz. Sternopygus also exhibits a sexual dimorphism; the males discharge at low frequencies and the females discharge at high frequencies. The discharge frequency of the PMN and frequency tuning of the electroreceptors are correlated such that the fish remains tuned to its characteristic frequency.

Previous studies have demonstrated that androgens, specifically DHT, lower both the frequency of discharge of the PMN and concomitantly lower the best frequency tuning of the electroreceptors. Recent studies have also demonstrated that the fish's electric field does not influence the hormone-mediated tuning shift of electroreceptors. Although it appears that the hormone directly affects electroreceptor tuning, the possibility remains that changes in the firing frequency of the pacemaker nucleus may affect the tuning of the electroreceptors, even though no known anatomical connection between the two has been demonstrated. Therefore, in the present studies we lesioned the PMN to examine if hormone-mediated shifts in electroreceptor tuning depend on PMN firing frequency.

Fish were curarized and recordings were made from electroreceptor afferents (n=20 per fish) to establish the baseline mean best frequency (xBF) of electroreceptor tuning. The PMN was located electrophysiologically with a large-bore (5-10um) micropipette and the nucleus was then lesioned with a pressure injection of $CoCl_2$. In no cases have the fish regained a normal discharge. After lesioning, a small silastic capsule filled with DHT was implanted in the peritoneal cavity. Control fish received empty capsules. Recordings from the same afferent populations two weeks post-implant showed significant decreases in xBF for experimental versus control fish ($p<0.01$, Mann-Whitney). The percentage change in xBF for experimentals ranged from -16.9% to -35.5% (mean= -25.4%) while that of control fish ranged from -2% to -14.2% (mean= -7.1%). Previous results from intact, DHT-implanted fish show a mean change of -23.4% indicating no significant difference between PMN- lesioned fish and normal animals ($p<0.29$, Mann-Whitney).

These results support the idea that hormone-mediated changes in PMN firing frequency and electroreceptor tuning occur independently but concomitantly in order to preserve the fish's ability to remain tuned to its own discharge. Supported by NSF Grant # BNS-8606744.

176.10 A MODEL FOR AGE-RELATED INCREASES IN SENSITIVITY OF ELECTRORECEPTIVE AFFERENTS. D.Y. Sanchez and H.H. Zakon Dept. of Zoology, The University of Texas, Austin TX 78712.

The weakly electric fish Sternopygus possesses in its skin electroreceptors which are specialized for sensing its own electric discharge as well as that of its conspecifics. The receptor cells are organized into clusters within epithelial capsules which are termed tuberous organs. The organs are innervated by afferents from the anterior lateral line nerve. Often, an afferent fiber innervates more than one organ. The afferent and all of the organs which it innervates is called a tuberous unit. These fish add new organs as they grow and tuberous units gradually develop into two distinct sub-populations: one adds organs while the other remains at only one or two organs per axon. Thus, fish relatively small in size show a single unit population of only a few receptor organs per axon, whereas those of relatively larger size show, in addition, a population of units which may have ten or more organs per axon.

In order to investigate how growth-related changes in morphology might affect the physiology of this system, recordings were made from individual electroreceptive afferents. Large sample sizes were collected; more than 30 units per fish. Threshold and best frequency (BF) were measured for each unit and the probability of firing to a stimulus at the unit's BF was calculated at various stimulus intensities. When probability of firing as a function of stimulus intensity (in dB) was plotted, sigmoidal curves resulted that were similar in shape from fish to fish and within individuals. The average threshold value for the most sensitive units in each fish, when plotted against fish length, shows an increase in sensitivity equivalent to about one order of magnitude as fish increase in size from 12 - 42 cm. Unit size increases from about two to over ten organs per axon in fish over this size range. We then designed a model to explain how increased convergence of receptor organs onto afferents might yield an increase in sensitivity.

The synaptic terminals beneath each receptor cell may be capable of generating spikes since, in a closely related fish, they stain for electrogenic membrane (potassium ferrocyanide stain; Saidel, personnal communication). If one assumes that there is a spike initiating zone beneath each receptor cell and that each receptor cell responds linearly with intensity, our model predicts the probability of recording a spike in the axon, P(axn), given an arbitrary probability for a spike under each receptor cell, x.

$$P(axn) = 1 - (1 - x)^{a\,b}$$ where x = probab of spike @ receptor
a = #cells per organ
b = #organs per axon

Plotting P(axn) as a function of log x generates sigmoidal curves which closely match the curves of probability of firing vs. stimulus intensity from actual data. Graphs of these curves demonstrate that increasing the number of organs per axon ten-fold would not affect the shape of the curve but would shift its position on the graph one log unit to lower "x" values (i.e. would make the unit an order of magnitude more sensitive). Thus, this model predicts, as our data demonstrate, that a ten-fold increase in unit size with growth correlates with an increase in sensitivity of approximately one order of magnitude.

176.11 DIVERSITY OF NEURONAL CELL TYPES IN THE ELECTROSENSORY LATERAL LINE LOBE OF STERNOPYGUS. B. Losier* and J. Matsubara, Dept. of Anatomy, Dalhousie University, Halifax, Nova Scotia, Canada.

The electrosensory lateral line lobe (ELLL) is an important medullary processing center for electric behaviors such as electrolocation and the jamming avoidance response (JAR). Evidence of the complexity of the ELLL is seen in its composition of 8 laminae, 11 cell types and three somatotopic maps of tuberous electroreceptors. It receives both primary electroreceptive afferents and descending signals from the dorsal praeementialis and lobus caudalis. As such, the ELLL is pivotal in its location within the electroreceptive pathway.

We have undertaken a detailed anatomical and immunocytochemical analysis of the cell types in the ELLL of Sternopygus since this species displays unique behaviors: It is the only wave-species whose electrolocation abilities are unimpaired by electrical noise and, accordingly, does not possess a JAR. Correlated to these differences, physiological studies revealed species-typical response properties of neurons in the ELLL (Matsubara, 1981) as well as the main target of the ELLL, the torus semicircularis (Rose and Heiligenberg, 1986). Using Golgi-Cox, Nissl, cytochrome-oxidase and calbindin immunocytochemistry we observed that the cell types in the ELLL of Sternopygus include the main types previously seen in other species and other cell types unique to Sternopygus (i.e. horizontal cells in the polymorphic layer and spindle cells intermixed between fiber bundles in the plexiform layer). In the deep neuropil layer (DNL), we identified a cell type which is distinguished from the spherical cell by its elongated, tapered soma and extensive dendritic bush. Analysis of perimeter form factor (FF), an index of the similarity between the shape of a cell and a circle, revealed that the cells in the DNL of Sternopygus (FF = 0.51, s.e. 0.02) differed considerably from spherical cells in Apteronotus (FF = 0.84, s.e. 0.01). Immunocytochemical differences exists: in Apteronotus, spherical cells stain intensely with antisera against calbindin, in agreement with previous reports (Maler et al, 1984). Cells in the DNL of Sternopygus and Gymnotus (a pulse-species with EOD frequencies of 50-60Hz) surprisingly, show no immunoreactivity when tested with the same antibody. Finally, levels of cytochrome-oxidase (CO), a long-term metabolic activity marker, were high in the ELLL of Sternopygus and Gymnotus, and less so in Apteronotus. Calbindin immunoreactivity and CO levels, thus, appear inversely related. Our results indicate that the anatomical and chemical make-up of the ELLL cells vary considerably among species and may provide the anatomical bases underlying observed species-typical behavioral differences.

(Antisera were kindly donated by C.Carr, Cal Tech and K.G. Baimbridge, UBC. This work funded by NSERC).

176.12 BICUCULLINE AFFECTS BOTH TEMPORAL AND RECEPTIVE FIELD PROPERTIES OF PYRAMIDAL CELLS IN THE ELECTROSENSORY LATERAL LINE LOBE. C.A. Shumway and L. Maler, Neurobiology Unit, Scripps Inst. of Oceanography, UCSD, La Jolla,CA 92093 and Dept. of Anatomy, Fac. of Health Sciences, Univ. of Ottawa, Ottawa, Canada K1H 8M5

The electrosensory lateral line lobe (ELL) of weakly electric fish is a laminated hindbrain structure which has been well characterized anatomically (Maler et al.,1981,JCN 195:87-139) and physiologically (see Bastian,1986, in Electroreception,Bullock and Heiligenberg, eds). Primary afferent input from electroreceptors encoding changes in EOD amplitude (P-type units) converges either directly or indirectly (via inhibitory granule cells) onto 2 types of ELL output neurons (basilar and nonbasilar pyramidal cells, respectively). Two physiological transformations that occur at the level of the ELL are 1) Pyramidal cells are phasic in response to a step change in EOD amplitude, showing a 25-100 fold increase in the rate of adaptation relative to the electroreceptors. 2) Pyramidal cells have center-surround receptive fields. Both transformations are mediated by local inhibitory neurons, primarily granule cells and polymorphic cells which are themselves strongly influenced by descending input (Bastian,1986,JN 6:553-562).

We investigated the effect of bicuculline (a GABA antagonist) on the physiological response properties of basilar pyramidal cells. GABAergic synapses are found predominately in 2 main regions of the ELL: 1) in the pyramidal cell layer and 2) in the granule cell and deep neuropil layer (Maler and Mugnaini, 1986,Soc.of Neurosci.Abstr.,312). We selectively iontophoresed bicuculline (1 mM, pH 3.5) in one or the other of these regions. Bicuculline applied to the pyramidal cell layer caused an overall increase in excitation and made the basilar pyramidal cells more tonic (n=10). The mean firing rate increased 68% and the mean time constant of adaptation increased 205% We believe the effect is due primarily to removal of granule cell inhibition of the basilar pyramidal cell. In preliminary experiments, bicuculline applied in the granule cell/deep neuropil layers caused a dramatic inhibition of the basilar pyramidal cell (n=1). Spontaneous activity decreased from 31.3 to 1.3 spikes/sec, and the response to a moving metal object decreased from 20.6 to 5.2 spikes/sec. We interpret this result to be due to removal of inhibition of granule cells (by polymorphic cells) which increases the granule cell inhibition of the basilar pyramidal cell. Thus the phasic properties, the receptive field properties, and the spontaneous activity of the basilar pyramidal neuron are shaped primarily by granule cells. The granule cells' influence on the basilar pyramidal cell is mediated by both excitatory descending input and inhibitory polymorphic cell input.

176.13 CENTRAL TERMINATION OF AFFERENTS FROM MORMYROMAST ELECTRORECEPTORS. C.Bell. Neurol. Sci. Inst., Portland, OR 97209.

Electric fish of the family Mormyridae use mormyromast electroreceptor organs in their skin for active electrolocation. Mormyromast electroreceptor organs have two types of sensory cells (types A and B of Szabo and Wersall, 1970), which are distinct in both morphology and location. The two sensory cells also have separate primary afferent innervation. Afferents from mormyromast electroreceptors terminate centrally within two distinct zones (medial and dorsolateral) of the electrosensory lateral line lobe (ELLL). The present experiments were designed to determine whether the afferents from the two types of sensory cells project to different ELLL zones, and if so, to determine which type projects to which zone.

Horseradish peroxidase (HRP) was iontophoretically injected into each of the two ELLL zones, in separate experimental animals. The injections were made into the termination regions of mormyromast afferents from the skin just anterior to the eye, using evoked potentials to local electrosensory stimuli to locate these regions centrally. The fish were then allowed to survive for 5 to 6 days before being sacrificed and perfused. The skin in front of the eye was removed, reacted for HRP as a whole mount, and embedded in plastic (soft Epon) for sectioning.

Examination of the skin sections showed that afferents from Type A sensory cells project exclusively to the medial zone of ELLL, whereas afferents from the Type B sensory cell project exclusively to the dorsolateral zone of ELLL.

Physiological studies combined with anatomical identification of the termination zone indicate that afferents to the medial zone of ELLL have a higher theshold and respond with a smaller number of spikes to a maximal stimulus than do afferents to the dorsolateral zone. There are some additional small differences between the two afferent types but the threshold difference is the most striking one. This threshold difference suggests that the two sensory cell types may serve to extend the dynamic range of the electrosensory system as a whole, without sacrificing incremental sensitivity.

176.14 A FEW CELLS WITHIN EIGENMANNIA'S DIENCEPHALIC ELECTROSENSORIUS COMPLEX WOULD BE SUFFICIENT TO DISCRIMINATE THE SIGN OF DIFFERENCE FREQUENCIES IN THE JAMMING AVOIDANCE RESPONSE. C H Keller and W Heiligenberg. Scripps Institution of Oceanography, UCSD, La Jolla, CA 92093.

The gymnotiform electric fish Eigenmannia shifts the frequency of its electric organ discharge (EOD) away from that of a neighboring fish, a behavior called the Jamming Avoidance Response (JAR). Determination of the proper direction in which to shift the EOD is dependent upon the analysis of phase and amplitude modulations contained within the mixed EODs of the two fish. Cell types responsible for processing this information have been found in the medulla and in the torus semicircularis and tectum opticum of the midbrain (for review: Heiligenberg 1986, Ch 20 in Electroreception, Bullock and Heiligenberg eds.). Carr et al. (1981, J Comp Neurol 203:649) demonstrated a projection from the electrosensory torus to a diencephalic area which they named "nucleus electrosensorius". Subsequently, Bastian and Yuthas (1984, J Comp Physiol 154:895) recorded extracellularly from this area and found cells whose response depended upon the sign and magnitude of the frequency difference (Df) between the jamming signal and the animal's own signal. Such "sign-selective" cells are considered important for the control of the JAR.

We here report the results of more extensive recordings from this area and provide intracellular lucifer-yellow fills of sign-selective cells that demonstrate their dendritic morphology. A variety of physiological cell types is found in this area. For at least some of these cells the response is independent of the orientation of the jamming signal with reference to the animal's own signal. Threshold of discrimination of the sign of Df in terms of the relative intensity of the jamming signal approaches that of the behavior in intact fish. In contrast, toral and tectal sign selective cells respond selectively to one particular orientation of the jamming signal and are an order of magnitude less sensitive. This sensorimotor interface is thus characterized by continual convergence to a smaller number of cells whose response properties more closely match those of the intact behavior.

176.15 INDIVIDUAL PREPACEMAKER NEURONS CAN MODULATE THE MEDULLARY PACEMAKER OF THE GYMNOTIFORM ELECTRIC FISH, EIGENMANNIA. M.Kawasaki and W. Heiligenberg. Neurobiology Unit, Scripps Institution of Oceanography, A-002, University of California at San Diego La Jolla, California 92093.

The prepacemaker nucleus (PPN) in the midbrain of the gymnotiform electric fish Eigenmannia provides the only known neuronal input to the medullary pacemaker nucleus, which triggers each electric organ discharge (EOD) cycle by a single command pulse. Electrical stimulation of the PPN elicited two distinct forms of modulations in the pacemaker frequency, abrupt and brief accelerations, hence referred to as 'chirps', and gradual frequency shifts with a time constant of approximately one second. The associated EOD modulations were indistinguishable from natural communication signals. Depending upon the site of stimulation, the two forms of modulation could be elicited alone or superimposed. Stimulation sites eliciting only chirps could be separated from sites eliciting only gradual shifts by as little as 60 µm. The magnitude of the elicited chirps depended upon the timing of the pulse stimulus with reference to the phase of the pacemaker cycle.

Extracellular and intracellular recordings of single PPN neurons revealed that an action potential from a single neuron generates a chirp, and that the magnitude of the chirp depends upon the timing of the action potential with reference to the phase of the pacemaker cycle. Depolarization of such neurons by current injection produced bursts of chirps, and intracellular injection of Lucifer Yellow labeled a large type of PPN neuron which could also be retrogradely labeled from the pacemaker with horseradish peroxidase (HRP). Although the jamming avoidance response, which consists of gradual frequency shifts in the EOD, was elicited during the unit recording, the spike activity of these neurons had no relation to the JAR. The abrupt and brief acceleration in a chirp triggered by an action potential of a PPN neuron is too large and too sudden compared to the gradual shifts in the JAR. These observation thus preclude a possible participation of chirp-related PPN neurons in the JAR.

177.1 LEARNING RECEPTIVE FIELDS FOR COLOR CONSTANCY. T. Poggio and A. Hurlbert*. Artificial Intelligence Laboratory, Mass. Institute of Technology, Cambridge, MA 02139.

Recent physiological, psychophysical and computational results suggest that color constancy is achieved by filtering the retinal signal in separate chromatic channels through a center-surround receptive field with a narrowly peaked center and a very large, shallow, inhibitory surround. Computational analyses of how to recover surface reflectance from the image intensity signal, in which reflectance is mixed with illumination, yield exactly that filter. In Land's most recent demonstration, a filter of this type acts on Mondrians under varying illumination to yield constant color designators that match human color perception. Physiological data suggest that color-coded cells in primate cortical area V4, thought to be involved in mechanisms underlying color constancy, have very large ("non-classical") receptive fields. We show that a simple algorithm can learn color constancy from a set of examples, and that what the algorithm learns is a filter of this type.

The examples are pairs of images: an input image of a Mondrian under smoothly varying (across space and spectrum) illumination, and an output image of the Mondrian as if under uniform, white illumination (the reflectance image). Given enough examples (the number depends on the Mondrian size), the algorithm synthesizes the optimal linear filter that, acting on each input image, would yield its correct output image. Computer simulations show that the learned filter has a sharp positive peak and a broad negative surround. Given new input images with either linear or logarithmic illumination gradients, the filter acts on them to yield the correct output images.

This simple algorithm learns how to achieve color constancy in a restricted Mondrian world. We have implemented it on a network of interconnected simple processors that may be interpreted as a biological network of neurons and synapses.

177.2 HUE, LUMINANCE, AND HUE/LUMINANCE CELLS IN FOVEAL V1, V2 AND V4 OF THE BEHAVING MACAQUE MONKEY. Takashi Yoshioka*, Bruce M. Dow and Robert G. Vautin*. (SPON: Roberta Pentney). Department of Physiology, School of Medicine, SUNY, Buffalo, NY 14226.

Color includes "hue" and "luminance" (or brightness) as attributes. Colors such as orange and brown have the same hue but different luminance (brightness, lightness) levels with respect to some common background. Previous neurophysiological studies of color vision have tended to ignore the luminance component in color perception. In the present study, through the use of a color video display (Chromatics) we have examined the responses of single cells and cell clusters in macaque visual cortex (the foveal portions of areas V1, V2 and V4) to a color set which includes such "dark" colors as black, brown, coffee, olive, maroon, indigo and gray, as well as more traditional "bright" colors like white, orange, yellow, green and red. Recordings are conducted in alert monkeys trained to hold their eyes on a fixation point for several seconds at a time. After careful receptive field mapping and selection of the preferred spatial stimulus (a bar or spot), each cell is tested with a set of 19 colors (8 bright, 8 dark, 3 achromatic) presented as a 500 msec pulse of light (or dark and/or color) on a gray background of intermediate luminance. Our present data sample includes 700 cells with mapped receptive fields, and 500 cells with complete color tuning curves, roughly 50% from V1, 25% from V2 and 25% from V4. The cells fall into 3 major groups which we refer to as hue (H), luminance (L) and hue/luminance (HL). H cells are sensitive to hue but insensitive to luminance (e.g., responsive to both orange and brown). L cells are sensitive to luminance but insensitive to hue. HL cells are sensitive to both hue and luminance, requiring either positive or negative luminance contrast for activation of their color sensitivity (e.g., responsive to either orange or brown but not both). L cells constitute 49% of the total, with about the same proportion in each of the 3 visual areas. H cells constitute 7% and HL cells 44% overall, with H cells more common in V4 than in V1, and HL cells more common in V1 than in V4.

The data suggest that hue and luminance are processed both separately, by H cells and L cells, and together, by HL cells. Three-dimensional reconstruction of the cytochrome oxidase stained tissue, including a number of microelectrode marking lesions, is currently in progress, with a view toward establishing correlations between physiology and anatomy. Supported by NIH grant EY02349.

177.3 **NEURONAL ACTIVITY IN V1, V2 AND V4 IN MACAQUE MONKEY PERFORMING A VISUAL MATCHING TASK.** N.K. Logothetis, R. Vogels and P.H. Schiller. Dept. of Brain and Cognitive Sciences, M.I.T., Cambridge, MA

Visual cortex in mammals consists of several distinct visual areas which are assumed to subserve different functions. In an effort to further clarify the differences among these areas, this study examined the extent to which single cells in V1, V2 and V4 exhibit modulated activity during the performance of a visual matching task.

A male rhesus monkey performed a matching task. The start of each trial was indicated by the appearance of a white fixation spot. After the monkey fixated it, four stimuli of different colors or orientations were presented peripherally, with one of them centered within the receptive field (RF) of the cell under study (which stimulus appeared at this location was randomized by trial). After 500 ms the fixation spot was replaced by a cue stimulus identical to one of the four peripheral stimuli. The monkey's task was to saccade to the matching (target) stimulus. In V1 81 cells, in V2 87 cells, and in V4 188 cells were examined during the performance of this task.

While in V1 and V2 cells could be activated by the appropriate visual stimuli used in the task, their activity was not modulated by the appearance of the cue stimulus. In contrast, in V4 such modulation was evident: in 5% of the cells activity was significantly elevated when the stimulus in the RF matched the cue; in 10% of the cells activity was elevated independent of which stimulus was present in the RF; in 3% of cells activity was related to the execution of saccades.

In addition a strong oblique effect was found with gratings as indicated by reduced accuracy and increased latency (Correct %: 55 for oblique, 95 for horizontal vertical; latency: 689 ms and 295 ms respectively). A uniform distribution of preferred orientations was found, however, in all three visual areas.

These results suggest that in the visual system V4 is one of the first stations at which extraretinal modulatory activity is evident using a matching paradigm.

Supported by EY00676.

177.4 SELECTIVE SUPPRESSION OF RESPONSES OF FOVEAL V1, V2 AND V4 CELLS IN THE MACAQUE DURING A COLOR MATCHING TASK. Bruce M. Dow, Takashi Yoshioka* and Robert G. Vautin*, Department of Physiology, School of Medicine, SUNY, Buffalo, NY 14226.

We have trained macaque monkeys to do 2 visual tasks, a dim task and a color task, on a color video (Chromatics) display screen. The dim task was the standard one introduced by Wurtz (1969). The color task was a new one which we designed. In this task the fixation point (FP) assumes one of 4 colors: red, yellow, green or blue. The "stimulus", which comes on 1 sec later and remains on for 500 msec, can likewise be red, yellow, green or blue. The color task requires the monkey to release his response lever within about 500 msec if the FP and stimulus colors are the same, but to hold and wait for a later dimming of the FP if the 2 colors are different. Following completion of training, single cell recordings are obtained using chronic techniques as previously reported (Vautin and Dow, J. Neurophysiol. 54:273, 1985). An implanted eye coil (CNC Inc., Seattle, WA) is used to monitor eye position. Each cell is tested with its preferred spatial stimulus (a bar or spot) established on the basis of careful receptive field mapping. The dim task is conducted with a set of 8 bright colors, 8 dark colors, and 3 achromatic colors. The color task consists of 16 separate conditions, 4 types of "same" trials (red-red, blue-blue, etc.) and 12 types of "different" trials (red-green, red-yellow, etc.). All testing is done with 8 interleaved repetitions of each stimulus condition.

We have obtained complete data, including color tuning curves under both control (dim task) and test (color task) conditions, from a total of 250 cells, approximately equally divided among the 3 visual cortical areas V1, V2 and V4 (foveal regions). The main finding, present in 61% of all tested cells, is selective suppression of responses. Enhancement is present in only 4% of all cells, with mixed suppression/enhancement in 16%, and no effect in 19%. Suppression tends to be selective for FP color, most commonly blue, least commonly yellow. Suppression typically lasts for the first 250 msec of the 500 msec stimulus ON period, approximately coinciding with the monkey's "same" trial reaction time. Suppression is stronger in V1 than in V4, stronger with decreasing receptive field eccentricity, stronger in cells with a distinct luminance threshold, and stronger in cells with orientation selectivity. A possible explanation for the results is that blue FP color causes a threshold elevation in a luminance-dependent, border-detecting system (which is known to lack blue cone input). Experiments are currently in progress to test this hypothesis, and to look for possible histochemical correlations. Supported by NIH grant EY02349.

177.5 CORTICAL AFFERENTS TO AREA V1 IN THE CEBUS MONKEY. A.P. B. Sousa*, R. Gattass*, M.C. Piñon* and M. G. P. Rosa* (SPON: C.G. Gross) Dept. Neurobiology, Inst. Biofísica Carlos Chagas Filho, Universidade Federal do Rio de Janeiro, Rio de Janeiro, Brazil.

The topographic organization of areas V1, V2 and MT, in the Cebus, have been previously described (Gattass et al., Soc. Neurosci. Abstr., 10: 474, 1984, and Soc. Neurosci., 12: 1366, 1986). Here we describe the cortical afferents to area V1 as revealed by injections of retrograde fluorescent tracers. In 5 Cebus we made combined injections of two fluorescent tracers placed at different eccentricities. Injections were placed in V1 in the regions of representation of both the superior and inferior visual quadrants, at eccentricities ranging from .6 to 54 deg. The portion of the visual field represented at the injection site in V1, was determined by concurrent electrophysiological recording.

The results showed that V1 receives homotopic projections from V2 and MT, as defined electrophysiologically. Following injections in the inferior quadrant we found labelled cells in the banks of the lunate sulcus, in the pre-lunate gyrus, in the posterior bank of the superior temporal sulcus, regions which may correspond to areas V3, V4 and V4t described in the macaque. After injections in the upper quadrant we found labelled cells in the ventral surface, in a strip of cortex anterior to V2, a region which may correspond to areas V3 and V4 as defined electrophysiologically (umpublished observations). In addition, following centrally located injections, both in the upper and lower quadrants, we found labelled cells in the banks of the occipito-temporal sulcus; while after peripherally located injections we found labelled cells in the calcarine sulcus, in a region corresponding to area prostriata, and in the parieto-occipital cleft, in the superior bank of the medial parieto-occipital sulcus and on the medial surface, an area which may correspond to area PO described in the macaque (Covey et al., Neurosci. Abstr., 8: 681, 1982). In all areas the labelled cells were located exclusively in the infragranular layers, while in V2 the cells were found both in the infragranular ans supragranular layers. (Research supported by CNPq, FINEP and CEPG/UFRJ)

177.6 **MULTIPLE VISUAL AREAS BETWEEN V2 AND MT IN THE OWL MONKEY.** M.I. Sereno, C.T. McDonald, and J.M. Allman. Division of Biology 216-76, California Institute of Technology, Pasadena, CA 91125.

Previous mapping experiments in owl monkey extrastriate cortex suggested that the region between the representation of central vision in V2 and area MT was occupied by a single visual area, DL (dorsolateral crescent). Degeneration and HRP studies of the interhemispheric connections of owl monkey visual areas (Newsome and Allman, J. Comp. Neurol., 194:209, 1980; Cusick, Gould, and Kaas, J. Comp. Neurol., 230:311, 1984), however, revealed a prominent labeled band located about halfway between V2 and MT. Since callosal connections in the initial stages of the hierarchy of visual areas are roughly correlated with vertical meridian representations, which usually define borders between areas, we decided to reexamine this region in detail.

The visuotopic organization of this region varies more from animal to animal than does the organization of V2, MT, and DM. An additional vertical meridian representation was usually found in the dorsal half of the region between V2 and MT, approximately at the location of the callosal band described above. It separates two strip-like, mirror-image representations of most of the lower field. The posterior area congruently adjoins the horizontal meridian of V2 and the anterior area congruently adjoins the horizontal meridian of DL proper. For a given dorsoventral level, receptive fields in the anterior area are more eccentric than receptive fields in the posterior area, which in turn are more eccentric than receptive fields in V2. Medially, both areas adjoin DI (dorsointermediate area). Thus, there are three representations of the lower visual field between V2 and MT. The most anterior area, DL proper, closely resembles V4t in macaque monkeys. The homologies of the other two areas are presently less clear.

The visuotopic organization of the ventral half of the region between central V2 and MT is more complex. There are multiple, small representations of parts of both upper and lower fields. The lower field representations are not continuous with the ones described above. The topography here does not seem consistent with the idea of there being thin, parallel, dorsoventrally continuous strip-like areas between V2 and MT, containing only dorsal lower fields and ventral upper fields.

177.7 ELECTRICAL STIMULATION OF AREA MT AND MST IN THE MONKEY CEREBRAL CORTEX: EFFECTS ON PURSUIT EYE MOVEMENTS. H. Komatsu and R. H. Wurtz Laboratory of Sensorimotor Research, National Eye Institute, NIH, Bethesda, MD 20892 USA.

Chemical lesion of the foveal representation within the superior temporal sulcus produces a directional pursuit deficit in monkeys (Dursteler, Newsome, and Wurtz 1987): a reduction in speed of pursuit for a target moving toward the side of the lesion. The area damaged includes the foveal representation of MT (MTf) and the adjacent lateral part of MST (MST1). To clarify the nature of the directional bias, the present experiments determined the effects of electrical stimulation applied to these areas during pursuit eye movements. We applied electrical stimulation (biphasic pulses, 0.2ms in width, 500Hz, 0.4s in duration with a current of 50-150 μA) through microelectrodes after pursuit had been initiated. At many sites in MTf and MST1, we observed a directional effect: clear deceleration with stimulation during pursuit away from the stimulated hemisphere and weak acceleration with pursuit towards it. The current threshold was about 50 μA, and the stronger the current, the greater the effects. The velocity of pursuit also influenced the effects of stimulation: the higher the velocity, the greater the effects. We compared the effects of electrical stimulation in conditions where retinal slip information was available (closed-loop) and removed (open-loop). There was little difference in the effects under the two conditions, suggesting a loss of retinal-slip information during stimulation. Electrical stimulation during fixation evoked slow eye movements toward the side of the stimulation, but the effects were much weaker than during pursuit.

Directional effects were observed only when the stimulation was applied in MTf and MST1. Stimulation applied to extrafoveal MT produced no effects, however, when the stimulation was applied before the monkey made a saccade to the target moving in the contralateral visual field, a marked reduction in the initial speed of pursuit occurred. This is reminiscent of the retinotopic deficit following chemical lesions in the extrafoveal MT. Weak transient decreases in eye velocity in either direction occurred with stimulation of the intermediate area of MST representing the peripheral visual field. No consistent effect was observed with stimulation of dorsal-medial MST (MSTd).

Our experiments indicate that the areas of MT and MST involved in the control of pursuit eye movements in a directionally selective manner are limited to subregions MTf and MST1. The dependency of the stimulation effects on eye velocity suggests that eye velocity information is modulating the visual motion information used for the maintenance of pursuit and is enhancing a directional bias toward the stimulated hemisphere.

177.8 RECOVERY OF FUNCTION FOLLOWING CHEMICAL LESIONS OF CORTICAL AREA MT. Dwayne S. G. Yamasaki and Robert H. Wurtz. Lab. Sensorimotor Res., National Eye Inst., Bethesda, MD 20892, USA.

Chemical lesions of area MT in the extrastriate cortex of the monkey produce deficits in the initiation of pursuit eye movements (Newsome et al., J. Neurosci., 1985), but this pursuit recovers within days to weeks. In the present experiments we investigated two aspects of this recovery process in the weeks following such a lesion: changes in the receptive fields of cells in the adjoining areas of MT, and the effects of visual experience.

Monkeys were trained in a step-ramp paradigm to pursue spots of light moving at 16°/sec. We then injected one to three microliters of a neurotoxin, AMPA, into an identified region of MT. We observed a deficit for initiation of pursuit to targets moving in any direction in a retinotopically localized region of the contralateral visual field.

In the single cell studies, we wanted to know if the receptive fields of MT cells might expand toward the area of the visual field damaged by the neurotoxin; such enlargement of receptive fields might compensate for loss of visual information in that part of the visual field. In two monkeys, we recorded cells through several guide tubes directed toward regions of MT adjacent to the future site of the chemical lesion, but far enough away to be spared any direct effect of the neurotoxin. In the days following the injection, we again sampled cells from these same guide tubes. We did not see selective expansion of the receptive fields toward the injection site. We continued to find cells with receptive fields comparable in size to those seen before the lesion, but in addition, we saw a scattering of cells with receptive fields larger than those seen before the injection. Receptive fields of these cells expanded in all directions. We do not know whether the field expansion is related to recovery from the lesion, or is a non-specific effect in cortex surrounding a damaged area.

In one monkey, we determined the effect of visual pursuit experience on the recovery process. The monkey was fitted with a mask attached to its implanted head holder that denied it visual motion experience. Control experiments had demonstrated no effect of wearing the mask for a week on the pursuit performance in two normal monkeys. Immediately following the chemical injection, the mask was placed on the monkey. The next day we verified that the monkey showed a deficit in a few tests of pursuit. Previous monkeys tested with comparably small lesions showed substantial recovery within a week of the lesion. In contrast, this monkey, denied visual motion and pursuit experience, showed little recovery within the same time period. We do not yet know the extent of the change in time course of this recovery.

177.10 CORTICAL CONNECTIONS OF A DORSAL VISUAL AREA IN SQUIRREL MONKEYS. R. E. Weller, G. Steele and C. G. Cusick. Dept. of Psychology, Univ. of Alabama at Birmingham, AL 35294 and Dept. of Anatomy, Tulane Univ., New Orleans, LA 70112.

Recent anatomical studies in squirrel monkeys identified a dorsal area of cortex, rostrally bordering Area 18, possessing strong connections with the rostral Dorsolateral Area, DL (Cusick, C. G., Anat. Rec., 218:30A, 1987). This dorsal region appeared to be a different area from DL, an area bordering lateral Area 18. We have investigated the cortical connections of this region of cortex, named the Dorsal Area (D). Injections of 0.15-0.2 µl of 1% wheat germ agglutinin conjugated to horseradish peroxidase (WGA-HRP), 3% Fast Blue, or 2% Fluoro-Gold were made in D in adult squirrel monkeys. After perfusion, a large part of surface cortex including D was removed, flattened, and sectioned parallel to the surface of cortex. The remainder of the brain was sectioned coronally. Sections were processed for HRP using tetramethylbenzidine or O-dianisidine as chromagens. Injection sites and patterns of connections were related to architectonic borders of areas visible in sections stained for cytochrome oxidase activity or myelin.

Most regions of cortex that had connections with D contained both retrogradely labeled cells and anterogradely labeled projections. The strongest connections of the Dorsal Area were with rostral DL. Connections were also present with cortex in both banks of the caudal Sylvian fissure and the caudal superior temporal sulcus, in the location of the Middle Temporal Area (MT). Two locations on the ventral surface of the hemisphere were labeled, both in the inferior temporal sulcus. The more caudal focus was approximately 5-6 mm rostral to the 17/18 border. The rostral focus was in ventral inferior temporal cortex. Injections in D also resulted in sparse connections with cortex in the region of the Frontal Eye Field, and weak and variable connections with caudal DL and lateral Area 18.

The connections of the Dorsal Area are distinct from those of the adjoining area, DL. These distinctions support designating D and DL as separate areas. Thus, as found in other primates, squirrel monkeys have multiple visual areas rostral to Area 18 or V2. The strong connections of D with cortex in the region of MT and in the posterior parietal lobe suggest that D is involved in the relay of visual information to posterior parietal cortex. Finally, similarities between the connections of D of squirrel monkeys and the Dorsointermediate and Dorsomedial Visual Areas of owl monkeys raise the possibility that D and one of these areas are homologous in these two New World primates.

177.11 **VISUAL AREA PIP: AN EXTRASTRIATE CORTICAL AREA IN THE POSTERIOR INTRA-PARIETAL SULCUS OF MACAQUE MONKEYS.** D. J. Felleman, A. Burkhalter and D. C. Van Essen. Biology Div., 216-76, California Institute of Technology, Pasadena, CA 91125.

We have identified PIP, the posterior intra-parietal area, as a visual cortical area that is located at the posterior end of the intra-parietal sulcus (IPS), extending from the floor of the sulcus near its junction with the parieto-occipital sulcus (POS), to dorso-medial portions of the prelunate gyrus. PIP is located within V3A as originally identified by Van Essen and Zeki (J. Physiol., 227:193,'78), but in a region they reported as having a complex topographic organization. PIP can be distinguished from V3A and other nearby areas on the basis of its topographic organization and laminar patterns of connections with several well defined visual cortical areas.

We studied some of the cortical connections of PIP by making injections of anatomical tracers (HRP, 3H-proline, and fluorescent dyes) into physiologically and anatomically identified sites in V3 (n=3), VP (n=3), and V4 (n=13). The locations of injection sites, transported label, the myeloarchitectonic borders of V3 and the pattern of interhemispheric connections were displayed on unfolded, two-dimensional maps of cortex.

Injections into V3, VP, and V4 each led to two distinct foci of labeling within a restricted region of the lunate sulcus and intra-parietal sulcus. Although this region is delineated by a single callosal-free zone surrounded by a callosal-recipient ring, the separation between foci is sufficiently large (2 to 10 mm) and consistent (16 of 19 cases) that there is a sound basis for considering these as distinct visual areas. The lateral focus, on the anterior bank of the lunate sulcus, corresponds to V3A, while the medial focus corresponds to PIP. Lower-field PIP is located medially, in the fundus of the IPS, while upper-field PIP is located dorsal and slightly lateral on the pre-lunate gyrus. PIP receives feedforward connections from areas V3 and VP that are reciprocated by cells primarily in infragranular layers of PIP. Upper and lower field V4 provide feedback projections to PIP that are reciprocated by cells in both the supragranular and infragranular layers of PIP.

Feedforward projections were found from all three areas to the ventral intra-parietal area (VIP), in and near the floor of the IPS, and from V4 to the lateral intra-parietal area (LIP) on the lateral bank of the IPS. We are unsure whether V3 and VP also project to LIP, owing to uncertainties as to how the border between VIP and LIP should be identified. No projections were seen medial to PIP to area PO, (Covey et al., SNS Abstr., 8:681, 82), possibly because our injection sites were in regions representing relatively central portions of the visual field.

177.12 RETROGRADE CONNECTIONS OF THE SULCAL REGION OF THE SUPERIOR PARIETAL LOBULE (AREA 5) IN THE MACAQUE. G.R. Stoner*, G.J. Blatt and R.A. Andersen (Sponsor: P. S. Churchland) The Salk Institute for Biological Studies, La Jolla, California 92] 38-92] 6.

Area 5 of the superior parietal lobule occupies four continuous regions in posterior parietal cortex: (]) a posterior region (PEc), (2) a medial region (PGm), (3) a rostral area which lies on the convexity of the superior parietal lobule (PE) and (4) a lateral region along the medial bank of the intraparietal sulcus (PEa). At the fundus of the intraparietal sulcus, area 5 adjoins the ventral intraparietal area (VIP) whereas posterior and medial to area 5 is the extrastriate visual area PO.

In the present study, retrograde fluorescent dyes, diamidino yellow (DY) and/or fast blue (FB) were placed in the sulcal region of area 5 (i.e., area PEa). Prior to delivery of the tracers, single unit recordings were made throughout various regions of area 5. The majority of cells tested were responsive to contralateral joint position and/or tactile stimulation. Many cells were responsive to multiple joint manipulation and also responded to touching the skin overlying the joint area. Some cells were responsive to bilateral or ipsilateral somatosensory stimulation and only a few cells responded to a visual stimulus.

Retrogradely labeled cells from injections in the sulcal region of area 5 (i.e., PEa) were mainly from other somatosensory cortical areas. Areas that had moderate-heavy label include area 7b, somatic sensory cortex area 2, second somatosensory cortex area SII and local connections with other regions of area 5: PE, PEc and PGm. Labeled cells were also seen in the medial bank of the Sylvian fissure and in various thalamic nuclei including the central-lateral nucleus (CL), lateral posterior nucleus (LP) and light label in some divisions of the pulvinar. In one case, heavily labeled cells were found in the anterior cingulate gyrus (area 24).

Two or three clusters of densely labeled cells were found in visual area PO. These labeled cells were seen in both the medial and lateral regions of PO, posterior to area 5. An additional cluster of labeled PO cells was observed from a dye injection made on the opposite bank of the intraparietal sulcus, (i.e., in area LIP or POa). Thus, area PO sends afferents to both the medial and lateral banks of the intraparietal sulcus (i.e., to area PEa and LIP respectively). From the area 5 injections, there was no obvious labeling of cells in any other extrastriate visual areas. In one case, however, there were a few labeled cells in LIP and area 7a, but this was probably due to leakage across the intraparietal sulcus. In other cases where the injection site was entirely restricted to area 5, no labeling in area LIP or 7a was observed.

These findings show that area PEa has extensive somatic input. In addition, though, area PEa also receives some visual information from extrastriate area PO. The significance of this visual input to the sulcal region of area 5 is not clear. A possibility is that input from the visual world may combine with other incoming sensory information (e.g., joint position) to enable area 5 cells to send appropriate signals to cells in motor and/or premotor cortex.

177.13 THE LATERAL INTRAPARIETAL AREA (LIP) IN THE MACAQUE: ASSOCIATIONAL CONNECTIONS AND VISUAL RECEPTIVE FIELD ORGANIZATION. G.J. Blatt, G.R. Stoner* and R.A. Andersen. The Salk Institute for Biological Studies, La Jolla, CA 92138-9216.

Area LIP, the lateral intraparietal area, is a cortical field in the caudal portion of the lateral bank of the intraparietal sulcus in the macaque. The present study consisted of two parts: 1) an anatomical tracing study using the methods of tritiated amino acid autoradiography and fluorescent dyes to map the anterograde and retrograde connections of area LIP and 2) an extracellular recording study to determine the receptive field organization of visually responsive LIP neurons.

The LIP injections were made on a 15 degree anterior-posterior angle through a recording chamber traversing area 5 in the superior parietal lobule which is primarily a somatosensory area (i.e., joint position, touch, etc.) This approach prevents the spread of tracers into visual area 7a.

A comparison of associational connections of area LIP with adjoining area 7a show some common connections but also important differences. Both LIP and 7a have connections with each other and to some extrastriate visual areas such as PO, dorsal prelunate (DP) and the medial superior temporal area (MST). However, area LIP and not 7a has a reciprocal projection with the medial temporal area (MT) and, has connections with areas V3A, V4 and the ventral intraparietal area (VIP). A previous study from our lab has shown that area 7a has strong connections with temporal lobe areas TF, TH, the caudal superior temporal sulcus (STS) and the cingulate gyrus. Area LIP, however, is connected with TF and TEO and lacks connections with the caudal STS and cingulate gyrus. Finally, only LIP and not 7a projects to the superior colliculus and anterior pretectal nuclei and LIP has stronger connections with the frontal eye fields than does area 7a.

Functionally, area LIP contains both visually responsive cells and an abundance of neurons responsive to saccadic eye movements. In the present studies, single unit recordings were made in anesthetized macaca fascicularis monkeys using an eye ring preparation to stabilze the eye. The receptive fields of visually responsive neurons in LIP revealed a local organization with neighboring cells tending to have partially overlapping receptive fields. An orderly progression of receptive field location was observed as the recording electrode moved tangentially relative to the cortical surface. However, discontinuities and/or duplications in the visual representation of the contralateral hemifield were observed. This suggests that within area LIP, the overall topographic representation was disorderly. Receptive fields of area LIP neurons were found to be smaller in size than those found in adjoining area 7a and unlike area 7a, were almost exclusively confined to the contralateral visual field.

These findings suggest that area LIP is an anatomically and functionally distinct visual area from area 7a. Area LIP has extensive connections with areas known to play a role in 1) saccadic eye movements and 2) processing of motion information suggesting that it is an important cortical area for visuomotor integration.

177.14 CORTICAL CONNECTIONS OF INTRAPARIETAL AND INFEROTEMPORAL VISUAL AREAS IN THE MACAQUE MONKEY: A DOUBLE-LABELLING STUDY. A. Morel* and J. Bullier. INSERM-Unité 94, 69500 Bron, France.

It is generally concluded from anatomical and behavioral studies that parietal and inferotemporal cortex process different aspects of visual information coming from the occipital cortex. The degree of separation between these two visual pathways was examined using multiple injections of retrograde and anterograde tracers (fluorescent dyes, WGA-HRP and tritiated amino acids) in cynomolgus monkeys. Following paired injections in the lateral bank of the intraparietal sulcus (area POa) and caudal inferotemporal cortex (area TEO) a large number of cortical areas were labelled and we focused on the connections with the prestriate, superior temporal sulcus(STS) and frontal cortex.

The results confirm that areas POa and TEO receive projections from largely separated areas of the occipital lobe, area POa from dorsal prestriate cortex (including dorsal V4) and TEO from ventral prestriate cortex (primarily ventral V4). However, some regions of the prestriate cortex, like area V3, project to both POa and TEO. Similarly, in the cortex of the STS rostral to the middle temporal area (MT), projections to POa and TEO are largely separated although some areas, particularly in rostral half of the STS, provide common projections to POa and TEO. In the prestriate as in the STS cortex, a small proportion of neurons (3-10%) send collateral projections to both parietal and inferotemporal areas.

Concerning the afferents from the frontal cortex, area POa receives extensive projections from cortex within both branches of the arcuate sulcus (AS) and the caudal half of the principal sulcus (PS) where several cyto- and myeloarchitectonic divisions could be recognized. The prefrontal projection to TEO arises from a small region located in the rostral bank and adjacent gyral surface of the descending branch of the AS. This region which falls within the zone of projection to POa contains only few neurons (less than 1%) with collaterals to POa and TEO.

In addition to their common connections with several regions of the prestriate, STS and frontal cortex, areas POa and TEO are also reciprocally connected. This suggests that these two parietal and inferotemporal areas are not part of completely separated cortical pathways, and that there are multiple cortical sites in which the two may interact.

177.15 CORTICAL AREAS PROJECTING TO ANTERIOR INFERIOR TEMPORAL GYRUS AS DEMONSTRATED BY RETROGRADELY TRANSPORTED WHEAT GERM AGGLUTININ CONJUGATED TO HORSERADISH PEROXIDASE IN THE MACAQUE. C.L. Martin-Elkins and J.A. Horel. (SPON: R.W. Stach) Dept. of Anatomy and Cell Biology, SUNY Health Science Center, Syracuse, NY 13210.

The inferotemporal cortex (IT) consists of the relatively ill-defined middle temporal (mtg) and the inferior temporal (itg) gyri which are partially separated by the anterior middle temporal sulcus in the macaque. IT plays an important role in the acquisition and retention of visual information. This cortex is exclusively visual in function, but does not receive projections directly from striate cortex, but rather indirectly through prestriate cortex. Although considered to be a single, homogenous visual area in the majority of studies on this pathway, functional subdivisions within IT are beginning to emerge. Recently, cooling studies in this laboratory have demonstrated impairments in performance of a delayed matching task (DMS) when anterior itg is cooled. Conversely, cooling mtg, posterior itg, or foveal prestriate cortex was without effect on DMS with delays of 45s.

Visual information is thought to chain down from striate cortex through the prestriate and then posterior IT to ultimately reach anterior IT. The fact that interrupting this putative pathway providing visual information to anterior itg does not result in deficits similar to those produced by direct suppression of itg, raises the question of how anterior itg receives the visual information necessary for performance of DMS.

As a preliminary step in determining the pattern of cortical connections between anterior itg and other visual cortical areas, wheat germ agglutinin conjugated to horseradish peroxidase (WGA-HRP) was injected into anterior itg. Retrogradely labeled cortical cells were mapped both contralaterally and ipsilaterally in the temporal pole, posterior itg and the parahippocampal gyrus. Labeled cells were particularly numerous in the ipsilateral parahippocampal gyrus in both infra- and supragranular layers. Ipsilaterally, cell bodies were mapped in orbitofrontal cortex, the lower bank of sts, the insula, and the subiculum. Few, if any, cells appear to be labeled in mtg consistent with evidence that itg may function independently of mtg in the performance of DMS. (Supported by NINCDS Grant NS 1829-05.)

177.16 THE INFERIOR TEMPORAL CORTEX OF THE MACAQUE MONKEY: I. REGIONAL DIFFERENCE IN RESPONSE PROPERTIES OF CELLS. K. Tanaka, Y. Fukada*#, M. Fukumoto*$ and H. Saito. NHK Sci. & Tech. Res. Labs., #Teikyo Univ. Facul. Arts, $Tokyo Univ. Facul. Med., Tokyo, Japan.

To learn the process of integration of pattern information, we have studied response properties of cells in the inferior temporal cortex (IT), which is assumed to be the center of the pattern vision. Since the previous lesion studies suggested regional difference of function within IT, a wide antero-posterior extent of the lateral surface of IT was explored, using semichronically prepared monkeys (M. fuscata). The monkeys were anesthetized with N_2O/O_2 and immobilized with gallamine triethiodide during the single-cell-recording. Responses of individual cells were initially tested with the whole range of the stimuli which included white, black, and colored rectangles and stripes of various sizes, photographs of various regular patterns as well as several tens of animal and plant 3-D models. For cells which were activated most effectively by the presentation of complex 3-D objects, we further tried to make clear which component or combination of components of the stimuli were crucial for the activation, by using 2-D models made of white, black and colored papers.

Of 503 IT cells so far studied, 333 showed clear responses (mainly excitatory for 319 and inhibitory for 14). There was a wide variety both in their stimulus selectivity and the size of the receptive fields. However, a large part of the variety is due to regional difference between the posterior and anterior parts of IT. Cells in the posterior part (P2-A5) had small (the root of area < 5 deg) receptive fields near the fovea, and most of them were activated by such simple patterns as a bar and a spot. For some cells, either orientation or color was not crucial. The other cells were selective only for the orientation or the color. Many of the nonoriented cells prefer small objects to long ones, and many of the noncolor cells prefer either light or dark contrast to the other. Cells with similar properties clustered in single penetrations.

Cells in the anterior part of IT (A5-A23) had large (7-30 deg) receptive fields which included the fovea or adjoined it at their medial margin. A majority of the responsive cells showed more integrated selectivity than the cells in the posterior IT. The essential feature for the activation was the shape more complex than oriented contours, a combination of shape and color, or that of shape and texture (see the accompanying paper for examples). There were also cells for which we failed to extract the trigger feature from the set of effective 3-D objects. The variety within single penetrations was generally large, although the clustering of cells with similar properties was seen in some penetrations.

From these results, we suggest that the coding of visual patterns of objects takes place in the anterior IT while more basic analyses of the central visual field are carried out in the posterior IT.

177.17 THE INFERIOR TEMPORAL CORTEX OF THE MACAQUE MONKEY: II. THE LEVEL OF COMPLEXITY IN THE INTEGRATION OF PATTERN INFORMATION. H. Saito, K. Tanaka, M. Fukumoto*# and Y. Fukada*$. NHK Sci. & Tech. Res. Labs., #Tokyo Univ. Facul. Med., $Teikyo Univ. Facul. Arts, Tokyo.

Recent studies have established the presence of cells responding specifically to faces in a small cortical region of the superior temporal sulcus. This may encourage the idea that the concepts of various objects are represented by the activity of respective gnostic cells. In this study, we tested this possibility by examining the response selectivities of cells in the inferior temporal cortex (IT) which is thought to be the center of the object recognition system.

Experiments were performed on anesthetized macaques prepared as described in the companion paper. Of cells recorded in the anterior part (A5-A23) of IT, 18% were well activated by simple patterns such as bars and spots. The vast majority (299, 82%) were unresponsive to such patterns, and therefore the responsiveness to various real objects was tested for them. The standard set of objects included realistic plastic models of vegetables and fluits (30 kinds), colored feather brushes (5 kinds), colorful miniature models of various animals made of wools or vinyl sheats (10 kinds), and realistic models of the human head and hand.

One hundred and forty seven cells (50%) showed reliable and selective responses to some particular real objects. To know the simplest essential features for the activation, we examined responses to 2-D patterns of various complexities which contained some of the components of the object's pattern. For 54 cells (37% of the 147 cells), the essential requirement for their activation was found to be a combination of spatial parameters (shape, texture), or of shape and color. For example, the trigger feature of a cell which responded selectively to a model of a zebra was found to be a pair of orthogonally oriented stripes placed within an elliptic frame, and that for a cell which specifically responded to a banana was found to be the combination of an elongated and tip-sharpened profile, yellowish color and short parallel lines on it. The trigger feature of a cell which responded selectively to an apple was found to be the combination of a circular disk and a short bar, and the stimulus requirements of cells which selectively responded to hands were reduced to the combinations of a circular disk and several bars extruding from it radially with special angles. For the rest (63%), we could not reduce the stimulus requirements to 2-D patterns. However, the vast majority responded to several different objects comparably, suggesting that these cells were activated by some common features shared by the objects.

Though there was a population of cells (20) which responded only to faces, we suggest that IT, as a whole, codes the visual patterns of objects not by gnostic units but by combinations of multiple cells each of which represents a feature of a moderate complexity.

177.18 **POTENTIALS EVOKED BY FACE STIMULI AND NON-FACE STIMULI IN THE HUMAN ELECTROENCEPHALOGRAM.** **O.-J. Grüsser, K. Bötzel* and B. Häussler*.** Dept. of Physiol., Freie Universität Berlin, Arnimallee 22, 1 Berlin 33, Germany-West.

Electroencephalographic responses evoked by changes in pictorial patterns were recorded in 43 adult human subjects (26 females, 17 males). The responses from electrodes T5, T6, Cz, Pz, Oz and the lower occipital region were quantitatively analyzed (international 10/20 recording scheme). The stimuli were projected to a 4 x 6 degree binocularly viewed field. The patterns changed within 6 ms every 2.5-4.5 sec according to a random program; average luminance of successive slides was the same. Average evoked potentials were obtained by means of a digital computer.

Paradigm(1): Schematic faces in normal and upside-down position and scrambled patterns changed in random order. The most prominent response differences between normal and upside-down faces and between faces and non-face stimuli were obtained at the electrodes Cz, T5 and T6 (with no significant left/right difference) with a positive peak at Cz at about 160-180 ms latency, followed by a small negative peak at about 200-250 ms and a slow positive deflection between 300 and 700 ms. Sex differences were most prominent at electrode Cz.

Paradigm(2): A very schematic round face, a deformed schematic face with the same outline and a circle with the same mouth, nose and eye signals, but randomly distributed (non-face), followed each other in random order as in paradigm (1). Category-dependent differences (face/non-face) were again obtained at electrode Cz, T5 and T6 with a significant side difference between T5 and T6 for a peak between 150 and 180 ms.

Paradigm(3): Identical black-on-white or white-on-black line drawings of a face, a tree or a chair were used, altogether 160 slides in semi-random order. At Cz and Pz a response characteristic for faces was found with three prominent peaks. Especially a P 150-maximum was very pronounced in the EEG responses to face stimuli but absent with chair or tree stimuli. Difference curves (face-chair, face-tree, chair-tree), auto- and cross-correlation functions between these difference curves supported the hypothesis of "face-specific" responses.

Paradigm(4): 4 x 6 degree slides (black and white photos) of 54 different human faces, 53 vases and 53 pairs of shoes were projected as in paradigm(3). Face-specific responses (N 140-160, P 210-240, N 300) were more marked in female than in male subjects and again most pronounced at electrode Cz.

Paradigm(5): A recognition task was included in paradigm(4); 9 out of 160 items were memorized 20 minutes before the recording session. Essentially the same evoked potentials were obtained with the unknown stimuli as in (4), but a late positive wave appeared in addition (450-600 ms) in the responses to all stimuli.

We assume that the "face-specific" responses do not originate in the temporo-occipital cortical face region but in deep limbic structures or in the basal parts of the temporal lobe.

177PO AREAS 7 AND 5 IN CAT: VISUAL AND SOMATOSENSORY RESPONSES OF SINGLE NEURONS AND AFFERENT SENSORY PATHWAYS. C.R. Olson, R.J. Krauzlis* and S.M. Lipkin*: Dept. of Psychology, Princeton University, Princeton, N.J. 08544.

The aim of these experiments was to map out visual and somatosensory divisions of parietal association cortex in the cat. Two approaches were employed. First, we characterized regional variations of sensory responsiveness by single-neuron recording in alert cats. Second, we analyzed regional variations of afferent connectivity by use of retrograde tracers. Convergent results obtained from the recording and connectional experiments suggest that in cat, as in primate, parietal association cortex consists of sharply distinct visual (area 7) and somatosensory (area 5) divisions.

Single-neuron recording in alert cats. We have analyzed neuronal sensory responsiveness by chronic recording in alert, head-restrained cats. Recording sites spanned a broad cortical strip encompassing the anterior lateral and middle suprasylvian gyri. Area 7. Throughout the middle suprasylvian gyrus, with the exception of a narrow anterior strip, neurons were responsive to visual stimulation and firing appeared frequently to be correlated with eye movements, gaze angle and fixation distance. Some neurons were responsive to somesthetic stimulation. These had very large bilateral receptive fields and their responses were markedly reduced during active fixation of a visual target. No obvious auditory responses occurred. Area 5. Within a cortical strip including the anterior part of the middle suprasylvian gyrus and the anterior lateral gyrus, neurons were responsive exclusively to somesthetic stimuli. They possessed comparatively small receptive fields and were arranged somatotopically. In a large central sector, neurons with receptive fields on the forelimb were encountered. Small medial and lateral aggregates of neurons were responsive, respectively, to hindlimb and head stimulation.

Connectional analysis. We have compared patterns of retrograde transport obtained following nine tracer injections in area 5 to patterns observed in a previous study from our laboratory following 14 injections in area 7. Sensory projections to area 5 derive from somesthetic cortical areas (SI, SII, SIV and two other zones bounding area 5 medially and laterally); sensory projections to area 7 derive from extrastriate visual cortex. Motor projections to area 5 derive from area MI and are somatotopically organized; motor projections to area 7 originate in the frontal eye fields. Areas 5 and 7 both receive projections from cingulate, insular and parahippocampal cortex, but the projections arise in each case from nonoverlapping groups of neurons.

178.1 A SYSTEM FOR MULTIPLE MICROELECTRODE RECORDING FROM THE NEOCORTEX OF WAKING MONKEYS. V.B. Mountcastle, G.F. Poggio, H.J. Reitbock*, A.P. Georgopoulos, K.O. Johnson, M.B. Longerbeam*, M.A. Steinmetz, J.R. Phillips, D.K. Brandt*, and C. G. Habbel*.Bard Laboratories of Neurophysiology, Dept. Neuroscience, The Johns Hopkins University School of Medicine, Baltimore, MD 21205.

We have modified and adapted for recording from the neocortex of waking Rhesus monkeys a method for multiple microelectrode recording originally devised by Reitbock, et al. (1,2). A common sliding drive allows micropositioning of 7 independent electrodes in steps of 2 um. Microelectrodes are quartz glass fibers (OD 80 um) with central metal cores (30 um) of Pt-Rh alloy drawn to the desired tip size and ground to the desired form. Electrodes of 2-5 um tips and 3-4 megohms impedance (at 1 Khz) penetrate the dura of 3-4 Kg monkeys, and record satisfactorily from neocortical neurons. The drive is held securely over the region to be explored; the electrodes pass through 300 um guide tubes grouped along their distal portion in a flexible bundle and held in any chosen spatial arrangement within a 5 mm stainless steel implant inserted with hydraulic seal in a small craniotomy opening.

Microprocessor controlled multiple channel processing systems have been designed and constructed for display and discrimination of single neuron impulse activity. Gain, noise filtering, and automatic impedance testing is provided for each electrode. Any electrode may be switched to any of eight processing channels. Each channel consists of a waveshaping filter and a differential amplitude discriminator. Bidirectional electrode movement, as well as signal switching, is obtained via the microprocessor which displays and updates on the console terminal the electrode depth, impedance, and selected channel assignment. A second, independent, microprocessor based system is used to collect, buffer, and encode in real time all event data which are transferred to an experiment-controlling minicomputer whenever convenient.

Exploratory recordings were made in the visual, parietal, and somatic sensory areas; they established the reliability of the method and the stability of recording. The first experiment in a trained macaque was made in the motor cortex of an animal working in a 3D reaching task. In 10 daily sessions, 59 of 66 attempted penetrations were successful; 355 cortical neurons were studied during execution of the reaching paradigm. Seven neurons were recorded simultaneously 15 times; 6 - 14x; 5 -16x; 4 - 11x; 3 - 10x; and 2 - 2x. Analyses of these and other results will be presented.

178.2 MASS CORRELOGRAMS OF VISUALLY RESPONSIVE NEURONS IN CORTICAL AREA 18 OF THE CAT. S. Reinis and D.S. Weiss*, Department of Psychology, University of Waterloo, Waterloo, Ontario, Canada, N2L 3G1.

The function of the central nervous system depends on multiple parallel interactions of large numbers of neurons which together form extremely complex networks where each unit is connected with hundreds of other cells. A meaningful study of brain function depends, therefore, on the analysis of the neuronal circuitry using both morphological and physiological methods. However, when complex interactions are investigated, existing methods for analysing neuronal relationships of neurons are hardly adequate. For this reason, we introduced the method of calculating "mass correlograms", where the frequency distribution of the intervals between the peaks of the mass firings of many neurons around the recording microelectrode are calculated and summarized.

These peaks usually do not represent a single neuronal spike, but are rather formed by several neurons firing simultaneously. In this study, we present mass correlograms recorded in the vicinity of functionally defined, complex cells in the area 18 of the cortex. When the cells respond to an adequate visual stimulus (a light bar moving at the optimal angle, speed and direction), the mass correlogram shows an early regular rhythmic activity with a repeated interval of about 3 ms. The rhythmic interactions may be traced to approximately 100 ms from the beginning of the correlogram. Then, between 500 and 2000 ms, the numbers of interspike intervals gradually increase, and far exceed the frequency of the early rhythmic interactions.

These findings suggest that the analysis of the moving visual stimuli in area 18 of the cortex depends on an early rhythmic interaction of large numbers of neurons, and on an even larger number of long-term interactions which last up to two seconds and possibly more. If we assume that the synaptic delay is about 1 ms, then the neuronal network for the detection of the moving visual stimulus is composed of thousands of successively activated neurons.

All experiments conformed to the guidelines approved by the Canadian Council of Animal Care.

178.3 QUANTITATIVE METHODS FOR THE STUDY OF DEPTH PERCEPTION. H. A. Mallot* and H. H. Bülthoff, Inst. f. Zool. III, Joh. Gutenberg-Univ., Saarstr. 21, D-6500 Mainz, FRG and Center for Biological Information Processing, MIT, E25-201, 45 Carlton St., Cambridge, MA 02139, USA.

Most studies on depth perception in neurophysiology have focused on binocular disparity and used artificial stimuli (bars or random dot stereograms). On the other hand, the importance of pictorial cues (e.g. shading and texture gradients), especially for monocular viewing and for distant scenes is well known in the psychophysics of depth perception. Interaction of different cues is used to disambiguate equivocal information. We have designed experiments to study different cues in human psychophysics which can be used in electrophysiological and behavioral experiments as well.

Computer graphics provide a powerful tool to generate natural images of simple objects (ellipsoids) that provide depth cues in a completely controllable way. Different shading models and ray-tracing were used to compute dull and shiny surfaces. Textured surfaces and texture gradients were generated by means of a solid modelling technique. In addition, stereo image pairs could be interlaced on the color CRT-monitor. The interlace signal of the monitor triggered shutter glasses such that the views of the stereo pair were displayed alternatingly to the corresponding eye.

Quantitative measurement of perceived depth was performed by a cross comparison between different depth cues. In a first series of experiments, a small local stereo probe had to be adjusted interactively to the perceived surface. By this procedure, a local (pointwise) depth map is measured. In a second experiment, we displayed two entire images on the screen one of which could be changed interactively in elongation. This experiment allows a cross comparison of any two cue-combinations at a higher level surface representation.

The following results on the psychophysics of depth perception have been obtained: (1) If no edges (discontinuities in image intensity) are present, stereo information can still be used ("intensity-based stereo"). (2) Perceived depth is greater when more information is available (accumulation). (3) Edge-based stereo vetoes intensity-based stereo in contradictory cases. (4) Shape from shading is a rather weak cue; it is vetoed by edge-based but not by intensity-based stereo. (5) Texture gradients by themselves are also weak but seem to improve the performance when combined with other cues such as shading. (6) Surface interpolation between sparse edges is significantly improved by shading and intensity-based stereo. In certain contradictory cases, the interpolated surface is perceived as "subjective surface".

Very little is known on the neurophysiological correlates of these results, since most of the discussed depth cues are missing in stimuli composed of light bars, edges, and gratings. In future work, we plan to adapt the experiments described here for studies with alert monkeys.

178.4 CAN GERBILS WITH LESIONS OF PRIMARY VISUAL CORTEX USE RETINAL IMAGE SIZE TO ESTIMATE DISTANCE IN A JUMPING TASK? D. P. Carey, L. A. Booth* and M. A. Goodale, Dept. of Psychology, The University of Western Ontario, London, Ont., N6A 5C2.

The Mongolian gerbil (Meriones unguiculatus) can be easily trained to jump accurately from one surface to another over a wide range of distances. Previous experiments in our laboratory have shown that gerbils use a number of different dynamic and static depth cues to calibrate the amplitude of their jump, and that the final estimate of the distance to be jumped is a weighted average of these different cues (Ellard, Goodale, & Timney, Beh. Brain Res., 14, 1985). Gerbils with lesions of area 17 and 18, in contrast to animals with lesions of the superior colliculus or pretectal nuclei, were found to be impaired on this task (Ellard, Goodale, Maclaren Scorfield, & Lawrence, Exp. Brain Res., 64, 1986). Nevertheless, they still showed some residual capacity to calibrate their jumps on the basis of visual cues. Unlike normal animals, gerbils with lesions of area 17 and 18 did not appear to use motion parallax cues to gauge the distance to be jumped. Since retinal image size has also been shown to be a powerful cue for normal gerbils in this situation (Goodale, Ellard, & Booth, unpublished observations), there was a possibility that this same learned cue to depth could be utilized by animals with lesions of area 17 and 18. To test this hypothesis, we first trained gerbils to jump over a gap between two platforms which varied randomly from 10 to 36 cm. Changing the size of the landing platforms on 'probe' trials resulted in systematic errors in the calibration of the jump, suggesting that retinal image size was being used to estimate the distance of the gap. In other words, the gerbils overjumped their usual landing position if the landing platform on probe trials was smaller than the one they were familiar with, and underjumped if it was larger. After large lesions of the posterior neocortex which included all of area 17 and much of the surrounding extrastriate cortex, the animals showed some difficulty with longer jumps but in general were surprisingly unaffected by the lesion. Moreover, the amplitude of their jumps on probe trials revealed that they were still sensitive to the retinal image size of the landing platform. These results suggest that an important learned cue to depth, retinal image size, may not depend entirely on the geniculostriate pathway and its cortical elaboration, but instead may involve other retinofugal systems which may be largely subcortical. (This work was supported by Grant #A6313 from the Natural Sciences and Engineering Research Council of Canada to M. A. Goodale).

178.5 CAN MARKOV ANALYSIS PROVIDE AN INDEX OF HUMAN INFORMATION PROCESSING DURING VISUAL SCANNING? M. Rizzo, R. Hurtig, Division of Behavioral Neurology and Dept. of Speech Pathology and Audiology, Univ. of Iowa, Iowa City, Iowa 52242

The parameters of eye movements typically associated with the scanning of complex images are the number, location, duration and sequence of fixations. Previous studies of scanpaths have emphasized the feature dependence of fixations and their spatial distribution and have neglected how the pictures were scanned. It is reasonable to speculate that the sequential dependence of fixations in a scanpath should vary depending on (a) the external stimulus features and their spatial arrangement, (b) the biological or personal significance of stimuli, and (c) the result of previous exposure.

We applied a standard mathematical technique to analyze the overall predictability of successive fixations in scanpaths in an attempt to develop a new index of human visual information processing. We obtained a quantitative measure of the sequential dependence of fixations in scanpaths by calculating the transitional probability of moving from one region of a stimulus to others. We applied this analysis to fixations extracted from the digitized scanpath data of 29 normal subjects recorded using standard electro-oculography with a minimum resolution of 0.5 degrees. They viewed complex images (including upright and inverted faces and picture scenes) under differing sets of instructions. The analysis was based on a division of the picture stimuli into cells defined by specific image features or by spatial locations. From the first order Markov matrix of the fixations defined by the cells it was possible to calculate a statistic known as the asymmetric lambda. The asymmetric lambda can be taken as an index of how constrained a scanpath is by external stimulus features or by internal cognitive processing factors.

Results showed a characteristic range of overall predictability for sequential fixations that varied for different classes of stimuli. Asymmetric lambdas for scanpaths were lower for processes requiring abstract judgments rather than for those requiring mere descriptions of physical stimulus characteristics. These data show that sequential properties of scanning like the spatial distribution of fixations may depend on stimulus type and goals of search. The sequential properties of scanning can be used as an index of higher neural processes associated with cognitive tasks such as learning, recognition and goal directed search of complex visual displays.

178.6 REDUCTION OF VISUAL CORTICAL PROCESSES TO A COMMON ALGORITHM. G. J. Carman. Division of Biology, Caltech, Pasadena, CA 91125.

Early visual processes, such as those for motion and stereo, make use of different retinal cues in order to derive information about the visual world, such as the presence of edges and the relative depths of surfaces. It may be useful to examine the similarities between such seemingly different visual processes in hopes of discovering whether they can be reduced to a common algorithm, with the goal of obtaining an understanding of how cortex functions as a network. Here I propose a general associative algorithm which makes use of a representation obtained from graph theory to solve the early visual problems of motion correspondence and binocular correspondence. In so doing, the algorithm derives representations of the boundaries of objects from monocular and binocular retinal information over time.

This algorithm accepts as input two sets of tokens, T1 and T2, with each token giving the attribute(s) for a position. For example, in motion or stereo correspondence the tokens could give the sign of the local luminance contrast as a function of position along local, 1-dimensional samples from the retinal image. The algorithm determines which token(s) i of T1 are associated with which token(s) j of T2 by an optimization of an objective function subject to applicable constraints. For example, the optimization could seek to minimize retinal displacement for motion, or retinal disparity for stereo. If there are N tokens in each set, then there are $2^{N \times N}$ possible distinct associations between two arbitrary sets of tokens, requiring on the order of N^2 neurons. In many cases, including motion and stereo, the constraints for a given process manifest themselves as restrictions on this large solution space, requiring only on the order of N neurons to obtain the optimal solution. This solution gives a new local set of tokens T3 which, together with an another set T3' produced in parallel, provide the input to the next level in this process of "folding together of dimensions" to produce progressively more abstract representations.

Simulations of this algorithm on random dot images demonstrate that it can solve the correspondence problem for motion and stereo, combining two samples over time or space, respectively, into a single representation of edges and surfaces with relative depth. A hypothetical implementation of this algorithm given the input to striate cortex leads to the formation of orientation selectivity and its loss at the center of hypercolumns. Iterative application of this algorithm can in principle generate a series of representations which lead to hierarchical, object-centered representations which are thought to be implemented within extrastriate cortex.

178.7 RECOVERING 3-D STRUCTURE FROM MOTION: SOME NEW CONSTRAINTS. V. S. Ramachandran*, S. Cobb*, D. Rogers* (SPON: R. M. Boynton). Psychology Department, C-009, University of California, San Diego, La Jolla, CA 92093

If a 2-D parallel projection of a rotating object is cast on the screen, viewers can recover its 3-D structure ("structure from motion" or SFM). How is this achieved? We find that the visual system derives SFM by using a wide repertoire of short-cuts and "rules-of-thumb." These rules include: (1) Velocity: We superimposed two coaxial opaque random dot cylinders of identical diameter spinning at two different speeds. What we saw was a single object even though no rigid interpretation was theoretically possible. The dots were seen to occupy two different depth planes rotating with identical angular velocities with the faster dots always being seen nearer (as though there was a small cylinder inside a larger one). Thus the brain derives SFM by responding directly to velocity cues rather than by using an algorithm that seeks rigid interpretations. In fact, the system is quite willing to discard rigidity in order to use velocity. Also, when the two cylinders were presented side by side, the faster one appeared much more convex. (2) Occlusion: We generated a single opaque rotating 3-D cylinder. Although this display could depict either the convex front surface or the concave back surface of a cylinder, it was always perceived as convex. When we did reverse it perceptually it looked non-rigid. The brain prefers the convex percept because otherwise it cannot "explain" the appearance and disappearance of dots at the borders. (3) Visual Inertia. A transparent 3-D cylinder was made to "oscillate" on its axis, i.e. it rotated by 30° and then reversed direction. The cycle was repeated continuously. Surprisingly, the cylinder appeared to rotate continuously instead of appearing to rock, an example of visual "inertia." 4) Reversal of Direction. Two superimposed transparent planes of dots moved in opposite directions at a constant linear velocity. As each dot reached the vertical border it reversed direction and retraced its path. Instead of two co-planar sheets of dots we perceived a "cylinder." The mere reversal of direction at the border generated a depth separation.

We conclude that velocity cues can profoundly influence the derivation of 3-D struture although we do not rule out the possibility of an additional rigidity-based algorithm. By the collective use of several crude short-cuts the system achieves the same biological goal as it could with a single sophisticated algorithm.

178.8 A PARALLEL DISTRIBUTED PROCESSING MODEL FOR THE ABILITY TO OBTAIN THREE-DIMENSIONAL STRUCTURE FROM VISUAL MOTION IN MONKEY AND MAN. R. M. Siegel. The Salk Institute for Biological Studies, La Jolla, CA 92037.

Rhesus monkeys and human subjects can both detect the change in three-dimensional structure of a cylinder using only motion cues. Two motion areas, the middle temporal area (MT) and the medial superior temporal area (MST) appear to be involved in this analysis based on single unit recordings and the effects of chemical lesions in the monkey. In order to understand how neurons in area MST might form receptive fields sensitive for structured motion from area MT input, a model has been constructed based on the known physiological and anatomical evidence.

The parallel distributed processing model consisted of three layers. The properties of the one hundred processing units in the input layer were chosen to be homologous to those of a set of area MT neurons. Each was broadly tuned for a given velocity at a retinotopic location and projected to all ten units of the middle layer. The middle layer units projected to an output layer consisting of a single unit. This last unit signaled whether the input display was structured or not and was modeled after a MST neuron. The output of a unit in the middle or output layer was given as a sigmoidal function of a weighted linear sum of the outputs from the units in the input or middle layer respectively. All the weights were initially chosen at random; the weights were then iteratively adjusted to minimize the difference between the model's output unit and the known structure of the input configuration. The input stimuli were a collection of velocity profiles of 10,000 structured and unstructured cylinders of 6^0 diameter. Each cylinder had 1-64 points on its surface and rotated at 1-10^0/sec.

The model rapidly "learned" to correctly identify whether or not the input velocity flow field was structured. Psychophysical analysis of the model using the same stimuli as in previous work (Andersen and Siegel, Soc. Neurosci. Abstr., 1986) demonstrated that it satisfied the biological constraints of fraction of structure, number of points, and global spatial analysis. The "receptive fields" of this representation in the middle layer were complex, yet symmetrical, functions in both the spatial and velocity domain. Given the designed similarities of this network to the motion analysis system in primates, it is predicted that similar fields will be found in areas MT and/or MST.

This model provides a solution to the problem of extracting structure from motion that is distributed among a number of units. It differs from previous models in that it uses the motion flow field, does not rely on algebraic formulations and can easily be mapped onto known cortical structures. Lastly, this model demonstrates that the use of parallel architectures that are closely modeled on the cortical representation is a computationally efficient means to solve problems in vision. (Funded by The Salk Institute, San Diego Supercomputing Center and PHS NS07457-02.)

178.9 **LOCALIZED RESPONSES TO LOW CONTRAST MOVING RANDOM DOT PATTERNS IN HUMAN VISUAL CORTEX MONITORED WITH POSITRON EMISSION TOMOGRAPHY.**
F M Miezin, P T Fox, M E Raichle & J M Allman Division of Biology, California Institute of Technology, Pasadena, CA 91125 and Washington University Medical School, St. Louis, MO. 63110

The magnocellular system of the visual pathway is characterized by its sensitivity to low contrast moving patterns. The ascending stages in the magnocellular system are the P-alpha retinal ganglion cells, the magnocellular laminae of the LGN, layer 4C-alpha and 4B of striate cortex, and the middle temporal area (MT). Neurons in the magnocellular laminae of the LGN are sensitive to stimulus contrast of less than 10% while the neurons in the parvocellular laminae are much less sensitive (Kaplan & Shapley J. Physiol. 330:125-143, 1982). In deoxyglucose experiments Tootell (J. Neurosci., 1987) found that low contrast stimuli selectively activated layers 4C-alpha and 4B of striate cortex and area MT with relatively little activation of adjacent cortical structures. We have used stimulus evoked changes in cerebral blood flow monitored with positron emission tomography (PET) to map the portions of the human visual cortex responsive to low contrast stimuli. Data were analyzed using the image subtraction technique (Fox et al. Nature 323:806-809, 1986). Subjects were instructed to fixate on a small dark fixation point in the center of a random pattern of dots with a local contrast of 8% and a 10% dot density. Data were generated by subtracting the response to a control stimulus condition from a test stimulus condition (see Fox et al. J. Neurosci. 7:913-922, 1987). In the control condition the dots were stationary; in the test condition the array of dots moved at 16 degrees per second with the direction of movement for the array changing every 2 seconds. Eight movement directions presented in pseudorandom order were used. In both the control and test conditions, data were collected over a 40 second period. There were a total of 17 test-control comparisons in 6 subjects. The data were combined using a stereotactic system (Fox et al. J. Comp. Asst. Tomog. 9:141-153, 1985) and averaged together to reduce the background noise level. The largest response was centered in striate cortex. The second largest response was located in the fundus of the temporal-occipital-parietal pit (TOPP) (Polyak The Vertebrate Visual System,1957; Talairach & Szikla Atlas D'Anatomie Stereotaxique du Telencephale, 1967). This region is included in a bilateral lesion found in a patient with a selective impairment of perception of motion (Zihl et al. Brain 106:313-340, 1983) and is a possible candidate for the location of area MT in human visual cortex. (Supported by NIH grants EY03851, RR 07003, NS-06833, HL-13851, NS-07025 and NS-0094 and grants from the Gordon Trust and the Sloan Foundation.)

178.10 PSYCHOPHYSICAL MEASURES FOR CHANGES IN DIRECTION OF MOTION.
B.J. Schwartz and L. Kaufman. Neuromagnetism Laboratory, Depts. of Physics and Psychology, New York University, 4 Washington Place, New York, NY 10003.

Dynamic random dot motion displays were used to measure sensitivity to changes in direction of motion. Motion sensitive units in striate cortex are thought to process motion for separate retinal directions of flow, while units found in higher centers, such as mediotemporal cortex, combine more than one simultaneous direction of flow. Thus far, there have been no reports of cells tuned to sequential changes in the direction of motion.

We obtained thresholds for changes in motion direction by adjusting the percentage of dots moving coherently on a random noise field. There is no translating pattern present. This presents the visual system with signal-to-noise task for motion. This ratio can be varied independently from dot speed, direction, and display brightness.

Sensitivity to changes in direction increases monotonically with the angle between the two directions. Over a wide range of velocities, detection thresholds for linear motion, expressed in terms of the signal-to-noise ratio, are lower than or nearly equal to changes in speed and/or direction. In no condition is threshold for change lower than that for simple direction.

Using above-threshold motions, a repeated sequence of alternating directions (a zigzag trajectory) is seen either as such ("component motion") or as an oscillation superimposed on a continuous mean direction of flow ("composite motion"). The latter is seen at faster rates of alternation (above 4 Hz), and with narrower angles separating the two component directions. At intermediate values of alternation (3-4 Hz), the percepts may change spontaneously. This is a temporal analog to earlier experiments with pairs of superimposed drifting gratings, in which percepts were either "composite" plaids or "component" gratings moving in separate directions.

The underlying mechanism for these percepts was explored with motion after effects (MAEs). After adapting to a zigzag stimulus sequence for more than 1 min, MAEs are seen with test fields of stationary dot patterns. There is no MAE specific to adaptation for changing directions as distinct from simple motion. Even for the slowest zigzag adapting fields, seen as "component motion," MAE is a steady drift in a direction opposite to the mean of the component directions. This holds true even for separations as wide as 130 deg, which argues for the existence of populations of cells broadly tuned for direction. A more central mechanism must be responsible for the sequential combination of these components into various perceived trajectories.

178.11 EVIDENCE OF AN INTRINSIC TEMPORAL CODE FOR PICTURES IN STRIATE CORTEX NEURONS.
Barry J. Richmond, Lance M. Optican*, and Timothy J. Gawne*, (SPON. M. Segraves). Laboratory of Neuropsychology, National Institute of Mental Health, and Laboratory of Sensorimotor Research, National Eye Institute, Bethesda, MD 20892.

In the preceding abstract we reported that information transmitted about pattern, duration, and luminance was greater when all three features were considered simultaneously rather than separately. This synergy requires a consistent, unconfounded, mapping from stimulus features to neuronal responses. However, information theory does not require that the neural code be interpretable in terms of these features. Nonetheless, we have identified an intrinsic coding scheme that would allow pattern, duration, and luminance to be extracted.

The responses of the 15 striate cortical neurons reported in the preceding abstract were analyzed further. The stimuli were 16 one-dimensional Walsh patterns, presented at each of 7 luminance combinations (112 stimulus conditions) for seven neurons, and for 4 luminances and 5 durations (320 stimulus conditions) for 8 others. For each neuron, the responses were decomposed into their principal components (PCs). These components are orthogonal patterns of temporal activity that define the axes of a multidimensional space. Responses with different temporal waveforms have different PC coefficients and map to different points in this PC space.

In a planar space defined by two PCs, no relation between stimulus features and neuronal responses was apparent. However, in a space defined by the first three PCs, the responses elicited by an individual Walsh pattern, irrespective of duration or luminance, appeared to lie near a plane. Thus, we approximated the responses to each of the 16 patterns by their best-fit planes. The average residual variance per plane was 4.6% $\pm$ 4.1 (SD, n = 112) for the 7 neurons tested with 7 luminances, and 12.0% $\pm$ 5.2 (n = 128) for the 8 neurons tested with 4 luminances and 5 durations. Since the coefficients of the PCs are uncorrelated, if the responses to a given pattern had not been well approximated by a plane, the residual variance would have been at most 33%.

In any one neuron's PC space many of the planes representing the 16 stimulus patterns appeared easily differentiable. This geometrical structure demonstrates that the generation of neuronal responses obeys certain rules, which form an intrinsic temporal neural code for visual features. A response is potentially decodable, to determine the stimulus pattern irrespective of duration or luminance, if the plane into which the response falls can be ascertained. Information about duration and luminance is then encoded relative to that plane. Since three points determine a plane, such a decoding scheme may require as few as three complementary neurons sharing related codes.

178.12 STRIATE CORTEX COMPLEX NEURONS DO NOT CONFOUND PATTERN, DURATION, AND LUMINANCE.
Timothy J. Gawne*, Barry J. Richmond, and Lance M. Optican*. Laboratory of Neuropsychology, National Institute of Mental Health, and the Laboratory of Sensorimotor Research, National Eye Institute, Bethesda, MD 20892.

We have used Shannon's information theory to show that temporal modulation of a neuron's response contains information about stimulus pattern. Other stimulus features, such as duration and luminance, can also modulate the response. Does the neuron transmit information about these features as well?

A rhesus monkey fixated while stimuli, 2.5 degrees wide, were flashed on the receptive fields of neurons located 2° eccentrically. The stimuli were 16 one-dimensional, optimally-oriented Walsh patterns. They were presented at one of four luminance combinations (luminance range: 0.004 - 5.0 ft-lamberts), and flashed on for one of five durations (32 - 256 ms). All 320 stimulus combinations were presented to eight cells. A continuous spike density function was obtained by convolving the spike train with a Gaussian pulse (σ = 3 ms). Then, principal components (PCs) were extracted from 320 ms segments of the densities (Richmond et al., J. Neurophysiol., 1987). The coefficients of the PCs form a multivariate measure of the temporal modulation of the responses.

Transmitted information measures the discriminability among inputs given an output for a pair of input and output codes. Information is low when inputs are confounded among outputs. We related four stimulus input codes to each of two response output codes. The input codes were: 1) the four luminances alone, 2) the five durations alone, 3) the 16 patterns alone, and 4) the 320 combinations of these features. The two output codes were: 1) the coefficients of the first three PCs (T3) and 2) the number of spikes in the response (Ts).

	all 320	pattern	duration	luminance
T3(bits)	1.07$\pm$.08(SE)	0.32$\pm$.04	0.20$\pm$.05	0.19$\pm$.02
Ts(bits)	0.46$\pm$.04	0.15$\pm$.02	0.06$\pm$.02	0.05$\pm$.01

T3 was two to four times greater than Ts for all input codes. Ts for pattern was much greater than that for duration or luminance, whereas T3 had approximately the same magnitude for all three features. Strikingly, the transmitted information based on the input code of all 320 stimulus combinations (1.07 bits) was substantially greater than that predicted by the sum of the information from the individual codes (0.71 bits).

The codes for the three stimulus features were synergistic: more was known about the stimulus when a code that simultaneously accounted for all three features was used. Similar synergy was also observed in another seven cells tested with 16 patterns and 7 luminances at one duration. This synergism implies that the different stimulus features were not confounded by the neuron.

178.13 CATS SEE SUBJECTIVE CONTOURS. M. Bravo* and R. Blake* (SPON: C. Enroth-Cugell). Cresap Neuroscience Lab., Northwestern University, Evasnton, IL 60201

The formation of subjective contours allows a parsimonious and usually accurate representation of object boundaries from complex and incomplete visual information. The human visual system presumably constructs these illusory contours at an early level of processing and uses them in subsequent stages. We now have evidence that cats see subjective contours.

Subjective contours were formed by a stimulus configuration in which four disks, each with a cut-out quadrant, are positioned to create a Kaniza illusory square. To prevent the cats from learning the particular configuration of disks that creates the square, we presented the cats with a movie of a subjective square undergoing apparent motion. The stimulus was devised such that if subjective contours are not seen, the disks forming the illusion appear to spin about their centers. If subjective contours are seen, then a square moving across the display is seen in addition to the local spinning motion.

Before presenting these displays to cats, we evaluated the saliency of the subjective square on naive humans. These observers could readily discriminate a movie with an embedded subjective square that moved over successive frames from one of randomly rotating disks. Performance remained accurate over a range of frame rates. Observers did not see global motion with disk configurations that did not produce subjective contours. At slow frame rates it was possible to find these other configurations as they moved across the screen, but as frame rate was increased these configurations eluded detection.

Using a forced choice procedure and food reinforcement for correct responses, we trained two cats on a number of displays that successively approximated the final display described above. The cats were then tested for twenty days on different versions of the final display and their performance was consistently above chance over this period. Performance was not impaired by increasing the frame rate, indicating that the cats were not relying on recognition of the disk configuration to discriminate between movies with and without the subjective square. Rather, these results strongly suggest that the cats were seeing the subjective contours. Evidence that non-primate mammals perceive subjective contours argues against the idea that subjective contours are cognitive in origin.

178.14 OSCILLATORY MOTION THRESHOLDS MEASURED BY THE VISUAL EVOKED POTENTIAL. A.M. Norcia* and W.W. Wesemann* (SPON: E. Keller). Smith-Kettlewell Eye Research Foundation, 2232 Webster St., San Francisco, CA 94115.

Visual evoked potentials were recorded in response to small periodic phase shifts of sinusoidal luminance gratings. The grating position was shifted back and forth in square wave steps at rates between 12 and 40 displacements per sec. Displacement amplitude was increased in a series of 19 linearly spaced steps over a period of 10 sec. The amplitude and phase of the evoked response ocurring at the direction reversal rate were determined by a Discrete Fourier Transform. The lower threshold for motion was determined by extrapolation of the function relating VEP amplitude to displacement amplitude. These thresholds were compared to psychophysically determined thresholds as a function of the spatial frequency and contrast of the grating as well as the temporal frequency of the motion.

The VEP amplitude versus displacement function consisted of an initial rising portion usually followed by a saturation of amplitude at displacements well short of 180 deg. The phase of the evoked response was nearly constant, although phase leads with increasing displacement were sometimes noted.

VEP and psychophysical thresholds were nearly constant over the range of spatial frequencies between about 1 and 16 c/deg and over the range of temporal frequencies between 15 and 40 direction reversals per sec. Best thresholds were in the range of 15 to 20 arc sec. The present results with the VEP replicate previously reported psychophysical results (Wright and Johnston, Vision Res., 25:187, 1985). The oscillatory motion threshold lies between the range of the visual hyperacuities such as vernier offset acuity and stereoacuity which have thresholds of under 10 arc sec and grating resolution which ranges between 40 and 60 arc sec. Oscillatory motion thresholds were found to be elevated in observers with strabismus/amblyopia.

178.15 VISUAL EVOKED POTENTIALS AND EEG ACTIVITY UNDER DIFFERENT LEVELS OF ANESTHESIA IN RAT. D.F. Sisson* and J. Siegel, Institute for Neuroscience and School of Life and Health Sciences, University of Delaware, Newark, DE 19716 and J.H. Lukas*, U.S. Army Human Engineering Lab., Aberdeen, MD 21005.

The use of EEG as a predictor of anesthesia induced changes in visual evoked potentials (VEP's) was examined in acute rat preparations. VEP's were generated in male, Wistar rats (500 - 750 g) by binocular, strobe-light flashes and recorded from Area 17 simultaneously by cortical screw (left) and micropipette (right). EEG activity was measured at the cortical screw, and its spectral composition was analyzed by Fourier transform. Anesthesia level was varied by chloral hydrate intravenously in 10 mg doses. Heart rate was used as a gross measure of anesthetic level, and throughout the experiment sufficient doses were administered to maintain heart rate between 250 and 350 bpm.

Within this gross range of anesthetic levels, two distinct forms of VEP's were observed. Some VEP's were similar to those reported from awake, chronic preparations. The major differences were increases in latency to peak of all components and attenuation of the late components P3 and N3 relative to those observed in chronic animals. In other VEP's N1 was either greatly attenuated or entirely absent, and the amplitude of the P1 component was concomitantly increased. During intervals when normal VEP's were observed, a major EEG frequency band between 4 and 5 hz was always present; a minor frequency band between 15 and 25 hz was often observed. During intervals when N1 was attenuated, most EEG frequencies were in a band from less than 1 hz to 3 hz with little contribution from frequencies higher than 10 hz. Heart rate was only weakly correlated to VEP shape and only at the extremes of the range allowed. Normal VEP's were obtained at 350 bpm while VEP's with attenuated N1 components were obtained at 250 bpm. Between these extremes either VEP type could be observed at any heart rate.

Laminar analysis of normal VEP's recorded from a micropipette show polarity reversal of P1 near cortical layer IV and of N1 and P2 in deeper layers. VEP's with attenuated N1 components show polarity reversal of most of the potential near layer IV with only minor alterations in deeper layers suggesting that N1 attenuation is a sign of cortical depression and that in this state, the reflection of direct geniculate input to cortex can be observed unobscured in the VEP.

The categorization of VEP's by EEG activity helps to control one source of variability in evoked potential data, and increases the reliability of comparisons of VEP's measured over long time periods.

178.16 VALIDATING CLUSTER ANALYSIS OF VISUAL EVOKED POTENTIALS BY Q-FACTOR ANALYSIS. D.S. Weiss* and S. Reinis (SPON: J. Landolt). Dept. of Psychology, University of Waterloo, Waterloo, Ont., Canada, N2L 3G1.

Given the inherently complex and variable nature of the EP waveform, there is little consensus among researchers as to the best approach for analysing EP datasets. Consequently, EP datasets are subjected to a wide variety of statistical procedures, usually with some loss of relevant information. One method of analysing EP waveforms is Euclidean distance cluster analysis (complete linkage). This technique is independent of score distribution, and incorporates latency, amplitude and symmetry information into the clustering solution. However, the cluster solution (dendrogram) does not actually describe the waveform features which separate the clusters, and statistical inferences drawn from the solution are difficult and problematic. Therefore, a method of analysing EPs is required which will independently verify the cluster solution without loss of information and which will allow statistical inferences to be drawn from the data.

Q-factor analysis with varimax rotation is a method for clustering objects according to attributes. When applied to EP data, the data matrix is transposed so that individual EPs are variables (columns) and voltages at successive time points are cases (rows). Before factoring, a correlation matrix is computed between EPs across time points, thus preserving information about EP amplitude and wave shape characteristics. Principal factor axes are then calculated and rotated, thereby organizing the original EP dataset into clusters according to the rotated factor loading matrix. The Q-factor solution can then be used to cross-validate the Euclidean distance dendrogram. Q-factor scores, calculated from the rotated factor loadings, represent "ideal" waveforms which model the characteristics of the original EPs within each cluster, adding the dimensions of wave shape and features analysis to the cluster solution.

Clustering solutions for 72 sets of eight visual EPs, recorded from four cats, were cross-validated by Q-factor analysis. The eight EPs in each dataset (responses to the onset and movement of a light bar stimulus presented at eight different angles) were represented by three principal factors, which typically accounted for approximately 94 percent of the variance within the dataset. Of the 273 clusters obtained from the Euclidean dendrograms, 244 were successfully replicated by the Q-factor loading matrix (89.4 percent).

All experiments conformed to guidelines approved by the Canadian Council of Animal Care.

178.17 VISUAL CALLOSAL PROJECTIONS IN THE FERRET. Rosemarie B.Rayos del Sol-Padua,* Joyce Brown* & E.Hazel Murphy. (SPON: A.J. Haroian). Department of Anatomy, Medical College of PA., Phila., PA., 19129.

The callosal projections between visual cortical areas in the adult pigmented ferret have been studied, using combined physiological and retrograde tracing techniques, in order to characterise the tangential and laminar organization of these projections. Three groups of animals were used. In one group, the corpus callosum (CC) was sectioned and gelfoam, soaked in 20% HRP, was inserted between the cut ends of the callosal axons. In a second group, multiple injections of 20% HRP were made unilaterally throughout the dorsal posterior surface of the cortex, encompassing much of areas 17 and 18. In the third group, the 17/18 border was identified by physiological mapping of the visual field and injections of 20% HRP were made in this location. Following a survival of 1-2 days, animals were perfused, the brain cut and alternate sections were processed for HRP reaction (TMB chromagen) to visualise callosal cells,for cytochrome oxidase (CO) to aid in identification of the 17/18 border, and for Nissl to aid in identification of laminar boundaries.

The HRP material was drawn and analysed, using light and darkfield optics and a camera lucida, to determine the tangential extent and laminar organization of the callosal cell zone at the 17/18 border. The callosal cell zone in area 17 had a mean width of 2.3mm. The width of the callosal cell zone in area 18 was more variable in width and in the density of callosal cells, but had a mean width of 5.3 mm. The 17/18 border was clearly distinguishable in CO and Nissl material, and analysis of HRP filled cells at this border indicated a clear distinction in the laminar organization of callosal cells in these 2 cytoarchitectonic areas. In area 17, virtually 100% of the callosal cells are in laminae II/III. In contrast, in area 18, approximately 60% of callosal cells are in laminae II/III, and most of the remainder are equally divided between laminae V and VI. Fewer than 5% are located in lamina IV. These differences in tangential extent and laminar organization of the callosal projections between areas 17 and 18 must reflect differences in their funtional contributions to these 2 cytoarchitectonic regions of cortex.

Supported by NIH grant EY02488.

178.18 PROPERTIES OF AREA 17/18 BORDER NEURONS CONTRIBUTING TO THE VISUAL TRANSCALLOSAL PATHWAY IN THE CAT. M.E. McCourt*, J. Boyapati* and G.H. Henry* (SPON: D.G. Albrecht). Dept. of Physiology, JCSMR, The Australian National University, Canberra, A.C.T. 2601 Australia

The response properties and laminar distribution of area 17/18 border neurons contributing to the visual callosal pathway in the cat were studied using single-unit recording, electrical stimulation and neuroanatomical labelling techniques. A total of 203 units driven either ortho- (O: N=165) or anti-dromically (A: N=38) from stimulating electrodes in either the corpus callosum (CC) or the area 17/18 border of the contralateral visual cortex (CH) were obtained from 7 anesthetized, paralyzed cats. Forty-three percent (87/203) of the callosally-recipient (O) or projecting (A) neurons were also activated from stimulation at the ipsilateral lateral geniculate nucleus. The laminar distribution of 144 callosal units (O=110; A=34) was determined from electrode track reconstruction. Seventy-five percent (109/144) resided in layers 2/3 and 4ab. The reconstructed distribution matched closely that derived from the injection of horseradish peroxidase at the site of the CH stimulating electrodes. Neurons in the complex family (C and B cells: Henry, G.H., Brain Res., 133:1, 1977) comprised 68% (81/119) of the cells which could be classified according to receptive field (RF) type. S-cells accounted for 30% (36/119); 2% were non-oriented. The ratio of O to A units was not significantly different across RF type. The ocular dominance (OD) distribution for 83 callosal units (O=67; A=16) was trimodal: 36% were monocular (OD classes 1 and 7) and 32% were binocular (OD=4). OD distribution was similar across RF types and across O and A units. Estimates of transcallosal conduction time (CT) and synaptic delay (SD) were derived for 132 units which could be driven from both the callosum and contralateral visual cortex. CT was obtained by subtracting spike latency from stimulation at CC (Lcc) from that resulting from stimulation at CH (Lch). Mean CT for all cells was 2.52 ms. Mean CT for 58 C-family units was 2.94 ms (≈11 m/s velocity), and was significantly longer than CT in 26 S-cells, which averaged 1.80 ms (≈18 m/s). Four percent of callosal units possessed CT's suggesting unmyelinated axonal conduction (≈2 m/s). CT's measured from O and A units were not significantly different. SD was computed as 2Lcc-Lch. For O cells, SD indexes synaptic delay plus spike initiation latency; for A cells the SD value indexes only spike initiation latency. For 22 A cells, mean SD was 0.26 ms, consistent with previous measures of spike initiation latency. In 101 O cells, the modal SD was 1.20 ms. Subtracting spike initiation latency and post-synaptic depolarization delay in the generation of the action potential yields an SD estimate for O cells of ≈0.8 ms. Most O cells are thus monosynaptically activated by callosal afferents. Mean SD values for both O and A units did not differ significantly as a function of RF type.

178.19 THE ORGANIZATION OF CALLOSAL CONNECTIONS IN THE OCCIPITAL VISUAL CORTEX OF THE PIGMENTED RABBIT. A.M. Grigonis. Department of Anatomy, Hahnemann University, Broad and Vine, Philadelphia, PA 19102-1192.

In the adult pigmented rabbit, the projection of the corpus callosum connecting the striate visual cortex of both hemispheres has been well documented. The cells which make up the callosal projection between the two visual hemispheres are localized around the border between striate and occipital cortices. The tangential extent of the distribution of callosal cells is limited to the lateral third of the mediolateral extent of the striate cortex. The radial distribution of callosal cells in the striate cortex consists of a majority of cells present in laminae II and III, with few cells in laminae IV and V. In the present study the tangential and radial organization of callosal cells were examined in the occipital visual cortex of the pigmented, Dutch-Belted rabbit. Normal adult rabbits received multiple injections of 20% HRP throughout both striate and occipital visual areas in one hemisphere (total injected amount, approx. 15μl). Retrogradely labelled cells were visualized by reacting coronal sections throughout the visual cortices of the opposite hemisphere with tetramethylbenzidine. One out of every four sections were stained with thionin in order to identify cytoarchitectonic patterns which were used to define the cortical regions. The organization of callosal cells in the occipital cortex of the rabbit forms a more complex pattern than in the striate cortex. The callosal cells found in the occipital cortex are distributed similarly to the striate callosal cells in the rostral half of the occipital cortex. More caudally, however, there is a wider distribution of callosal cells in the occipital cortex, and there are bands of cells which are present throughout the mediolateral extent of the occipital cortex, which are not found in the striate cortex. Also, there is a different radial distribution of callosal cells between the rostral and caudal portions of the occipital cortex. In rostral regions of the occipital cortex, the proportion of cells found in each of the laminae is similar to the proportion found in the striate cortex; however, in more caudal regions, there is an increased proportion of cells located in laminae II and III than in laminae IV and V. The results suggest that in the occipital cortex of the rabbit, the callosal projection consists of an uneven distribution of cells compared to the projection in the striate cortex, which may reflect functional differences between striate and extrastriate cortical regions.

Supported by NIH grants EY06986 and EY02488.

179.1 GABA AND ACETYLCHOLINE SYNTHESIS IN THE OFFSPRING'S VESTIBULE OF PROPYL-THIO-URACYL TREATED RATS. L. Cerón* and G. Meza. Dept. Neurociencias, I.F.C., UNAM. Apdo. Postal 70-600, 04510 México, D.F., México.

It is currently accepted that vestibular sensory cells have chemical synapses in which GABA and acetylcholine (Ach) function most probably as afferent and efferent neurotransmitters, respectively. To provide evidences in that respect, the enzymes of synthesis of both putative neuromediators (glutamate decarboxylase, GAD, for GABA and choline acetyltransferase, ChAT, for Ach) were measured in homogenates of vestibules of Long-Evans rats. To investigate GAD and ChAT localization, propyl-thio-uracyl (PTU) was administered to pregnant rats and GAD and ChAT were measured in the progeny's vestibule. PTU causes congenital hypothyroidism to offsprings of PTU-treated animals, preventing among other effects, the arrival of efferent connections to the vestibule, thus providing a model in which sensory cells are naturally isolated from their efferent synapses.

We found that GAD and ChAT activities were present in vestibular homogenates of normal Long-Evans rats, findings that provide evidence of GABA and Ach as neuromediators in the rat vestibule. When these enzymes were measured in the vestibule of 38-day-old congenitally hypothyroid rats (CHR) a 70% decreased ChAT with respect to normal rats was found; in contrast, GAD was not modified. When new-born CHR were treated with thyroxine hormone this PTU effect on ChAT was prevented.

These results provide evidence of the efferent bouton's localization of ChAT and that the sensory cell contains GAD being Ach and GABA their respective neurotransmitters.

179.2 MORPHOLOGY OF VESTIBULAR PRIMARY AFFERENTS IN JUVENILE TURTLES, *PSEUDEMYS SCRIPTA*. A.M. Brichta and E.H. Peterson. Dept. Zoological & Biomedical Sciences and College of Osteopathic Medicine, Ohio University, Athens, Ohio, 45701.

As part of a study aimed at understanding the sensory control of cervical musculature in *P. scripta* we are using the neuronal marker horseradish peroxidase (HRP) to characterize the functional architecture of primary vestibular afferents. Experiments were conducted *in vitro* and *in vivo* using juvenile turtles (2-3" carapace length) to minimize transport distances and the number of sections over which neurons must be reconstructed. We made injections into anterior or posterior branches of C.N.VIII or into individual ampullary nerves. In some cases we back-filled secondary vestibular cells by iontophoretically injecting HRP into the medial longitudinal fasciculus.

Peripheral nerve endings within the cristae, are of three morphological types; 1) calyceal - chalice-like endings with limited branching; 2) bouton - finely varicose endings with extensive branching; 3) dimorphic - having characteristics of both. Within the cristae, calyceal and dimorphic endings are located centrally while bouton endings are more peripheral. This sequestered arrangement corresponds to the known distribution of vestibular receptors in *Pseudemys* (Jorgensen, '74). Parent axons of each ending type differ significantly in diameter (calyx= 1.64±.04, dimorphic= 1.41±.03 and bouton= 0.75±.05 um). Diameters of these peripheral processes are correlated with the size of their somata and central processes. Thus vestibular primaries in *Pseudemys* form three size classes which also differ in their peripheral morphology and distribution.

Central processes of vestibular primaries enter the brainstem and bifurcate. The two daughter branches run longitudinally, lateral to the vestibular nuclei, and drop off multiple, finely beaded collaterals in the transverse plane. Collectively these collaterals form a three dimensional orthogonal lattice traversing the vestibular nuclei. Although each centrally projecting vestibular primary gives off collaterals throughout much of the vestibular complex, each appears to have a preferential site of termination. The presumed targets of these afferents, secondary vestibular neurons, are bipolar and are aligned transversely, parallel to incoming primaries. Thus individual collaterals can be expected to contact only a small number of secondary vestibular cells. The architecture of vestibular primaries, taken together with the morphology of secondary vestibular cells suggests that there may be a relatively precise mapping of the vestibular end organ onto second order vestibular neurons.

179.3 SYNAPTIC COVERING OF CELLS IN THE MEDIAL VESTIBULAR NUCLEUS IN THE GERBIL. G.A. Kevetter. Departments of Otolaryngology and Anatomy & Neuroscience, University of Texas Medical Branch, Galveston, Texas 77550

The Medial Vestibular Nucleus (MVN), one of the four primary vestibular nuclei, receives an input from the vestibular nerve. Cells in the MVN, in turn, send projections in three major pathways: the vestibulo-ocular pathways, the vestibulospinal system, and the commissural pathways. We are investigating the morphology and ultrastructure of the medial vestibular nucleus in order to provide a morphological substrate for sensory-motor integration that occurs in this nucleus. In this study we calculated the percent of the cell surface covered by synaptic boutons (Synaptic Covering Ratio or SCR). Control animals were perfused and processed for routine electron microscopy. Experimental animals received large injections of HRP into the vestibular labyrinth. After 48 hour survival period, the animals were perfused, processed with a routine HRP reaction, and processed for EM as the control animals. Thin sections were cut through the MVN and observed. The perimeter of 2 cells cut approximately through the center of the cell was photographed for each block. The cell was considered to be cut through the center if the nucleolus was prominant in the nucleus. The presence of a nucleolar satellite in females was also used as indicative of the approximate largest surface area of the cell. The percent of the cell perimeter that was covered by synaptic boutons was calculated. In 13 cells used as controls, an average of 31.5% of the cell surface was covered by boutons. Most of these boutons contained round clear vesicles. The trend is for the larger cells to have a greater SCR than the smaller neurons. The range of surface area of the neurons investigated was large (Range = 74.3-1389.2 μm^2; $\bar{X}$ ± SEM = 342.31 ±114.68). In material in which the majority of vestibular afferents had been labeled with HRP, a proportional covering ratio was determined. Seven neurons have been studied to date. The neurons sampled were the first two neurons which were sectioned through the center of the cell regardless of whether or not HRP-labeled boutons were present. Thus far, cells in the experimental group have had a lower SCR (17.0%) than somas in the control group and the cells sampled thus far have been smaller (Range = 74.3-262.3 μm^2; $\bar{X}$ ± SEM = 177.43 ± 26.504). Three of the neurons investigated in the experimental material did not have any labeled boutons apposed to the perimeter, indicating that they were not second-order vestibular neurons. The total SCR of second order neurons (16.1%) was the same as that of neurons without labeled boutons (16.4%). The proportional covering of vestibular afferent input to the second order neurons was 16.5%. These morphological findings suggest that a significant proportion of the primary vestibular input synapses directly on the soma of second order neurons. (Supported by NSF grant BNS-84-18559)

179.4 VESTIBULAR COMMISSURES IN THE GERBIL. S.D.Newlands* and A.A. Perachio+. Departments of Otolaryngology and Physiology & Biophysics+, University of Texas Medical Branch, Galveston, TX 77550

The direct connections across the midline between the bilateral vestibular nuclei were examined in the Mongolian gerbil (*Meriones unguiculatus*). Horseradish peroxidase was ionophoretically injected unilaterally into one of the major vestibular nuclei in each experimental animal. The animals were sacrificed two days later and processed with DAB as the chromagen. Each serial transverse section from a series spanning the rostral-caudal extent of the vestibular nuclear (VNC) was evaluated for crossing fibers, contralaterally labelled neurons, and contralateral terminal fields. Contralateral to the injection, the majority of labelled neurons were in the VNC and nucleus prepositus hypoglossi (PrH); additional cells could be found scattered in the reticular formation. Contralateral terminal fields were primarily seen in the VNC, PrH, abducens nucleus, and the parvocellular reticular area just ventral to the lateral vestibular nucleus (LVN). The most extensive commissural system involved reciprocal and non-reciprocal vestibulo-vestibular connections of the medial vestibular nuclei (MVN). The number of retrogradely labelled cells and crossing fibers after MVN injection were an order of magnitude greater than seen for comparable injections in the other nuclei. An average of 94% of contralateral filled neurons were in the MVN following an MVN injection. Furthermore, terminal fields were seen throughout the VNC contralaterally, most densely in the MVN but also prominent in the LVN. In all animals injected in the lateral, superior (SVN), and descending vestibular nuclei (DVN) an average of 69% of the contralaterally labelled neurons were observed in the MVN with the rest distributed among the other nuclei, dependent upon the injection site. Few contralateral terminal fields were observed following injections into the LVN, DVN, and SVN. Most of the crossing fibers between the bilateral VNC coursed through the medial longitudinal fasciculus (MLF) in the dorsal half of the brainstem. The majority of labelled fibers crossed the midline directly at the level of injection. At the rostral pole of the VNC, the crossing fibers were largely seen at the floor of the fourth ventricle while more caudally fibers were more ventrally located but seldom were observed ventral to the MLF. Midline lesions were made in the the commissural system to investigate the possibility that only a discrete bundle of the crossing fibers were actually commissural (vestibulo-vestibular) as opposed to vestibular nuclear efferent projections (vestibulo-ocular, vestibulo-spinal, etc.). We found that partial transection of the midline brainstem decreases the presence of retrogradely filled neurons contralaterally, dependent upon the level of the lesion and the injection site. The vestibular commissural system in the gerbil therefore appears diffuse and limited primarily to reciprocal connections of the bilateral medial vestibular nuclei. These findings differ from findings in the cat where connections between the other vestibular nuclei appear more prominent. (Supported by NASA grant NAG 2-26 and NIH grant NS24391)

179.5 THE EFFERENT AND AFFERENT CONNECTIONS OF THE TANGENTIAL VESTIBULAR NUCLEUS AND THE CENTRAL PROJECTIONS OF THE AMPULLARY NERVES OF THE CHICKEN. R.G. Cox* and K.D. Peusner. (SPON: R. Walsh). George Washington University, Washington, D.C. 20037.

Neurons and fibers were labeled with horseradish peroxidase (HRP:Sigma type VI) using 6-8 week old chickens, unless otherwise stated. Deposition of HRP into the tangential nucleus (TN) and into the second cervical level (C2) of the spinal cord shows that the TN axon output is restricted to a tract which courses anteriorly through the ventrolateral vestibular nucleus without branching before entering the contralateral medial longitudinal fasciculus (MLF). Within the MLF, the TN axons course posteriorly, form collaterals that innervate the abducens nucleus, and then proceed to C2 levels of the spinal cord. This pathway, taken by axons of the 2 main neurons in TN, principal and elongate cells, is found in 1 day, 1 week, and 7 week old animals. No labeled cells were found in either TN after HRP deposition into the uvula, flocculus, pontine reticular formation, nucleus piriformis, nucleus jumeaux, vestibulo-cerebellar nucleus, retrotangential nucleus, or the dorsomedial part of the medial vestibular nucleus (MVNdm).

The TN receives afferents from the colossal vestibular fibers (spoon endings), small collaterals of fine ampullary fibers, flocculus, and C2 level of the spinal cord. The latter input prevails in 1 day, 1 week, and 7 week old chickens.

The ganglion cells of each ampullary nerve occupy discrete portions of Scarpa's ganglion (VG). Ganglion cells of the posterior ampullary nerve (PAN) occupy the posterior VG, while cells of the anterior ampullary nerve (AAN) and the lateral ampullary nerve (LAN) occupy the anterior VG, dorsal and central parts, respectively. The central fibers of these ganglion cells occupy discrete portions of the TN before bifurcating into ascending and descending tracts. The PAN occupies the posterior half of TN, restricted to the dorsal part, while the AAN and LAN share the anterior half of TN, with the AAN dorsal and the LAN ventral. The ascending PAN is associated with the nucleus piriformis, while the ascending AAN and LAN each occupy discrete cell groups of the vestibulo-cerebellar nucleus. In the descending vestibular nucleus (DVN), the descending PAN runs dorsocentral, the AAN ventromedial, and the LAN ventrolateral until they converge at the posterior tip of DVN. The initial part of the ascending tract and the anterior 2/3 of the descending tract of each ampullary nerve form collaterals to the MVN, ventrolateral and dorsomedial parts. These collaterals form a distinctive tract that courses posteriorly within medial regions of the MVNdm. The colossal vestibular fibers, distributed in the 3 ampullary nerves, conform to the ampullary pathways as described. Supported by NIH grant R01 NS 18108.

179.6 INTRACELLULAR INJECTION OF HRP IN VESTIBULAR TYPE I NEURONS IN CAT. T. Ohgaki*, I.S. Curthoys and C.H. Markham. Department of Neurology, UCLA School of Medicine, Los Angeles, CA 90024.

Horizontal canal secondary Type I neurons in ketamine anesthetized cats were identified by their characteristic firing pattern in response to horizontal rotation and monosynaptic activation by stimulation of the vestibular nerve. Cell bodies or axons were penetrated with microelectrodes containing 6% HRP, and HRP was injected intracellularly for 100-200 nA minutes. After 10-24 hours, animals were perfused. The brain was cut in 100 μm horizontal or coronal sections. The sections were treated for HRP using the diaminobenzidine method, placed on slides and counterstained.

Fifty-three neurons were stained and each neuron was reconstructed in the horizontal plane and converted to the coronal plane or vice versa. Type I neurons were located in the rostral portion of the medial vestibular nucleus (MVN). The cell bodies were large and had rather elongated shapes and rich dendritic arborization. Some of these neurons had axon collaterals which projected to ipsilateral MVN near their own cell bodies.

The neurons were divided into two groups, those which projected to the contralateral abducens nucleus (excitatory Type I) and those which projected to the ipsilateral abducens nucleus (inhibitory Type I). Stem axons of excitatory Type I neurons crossed the midline and bifurcated into rostral and caudal branches in the contralateral MLF. Two or three tertiary collaterals arising close to the bifurcations distributed terminals in a relatively wide area in the contralateral abducens nucleus. Some of these collaterals projected to contralateral MVN. Some of the rostral and caudal stem axons had collaterals which projected to the contralateral nucleus prepositus hypoglossi (PH) or nucleus raphe pontis.

There were at least 4 classes of inhibitory Type I neurons, all of which distributed to a relatively limited region in the ipsilateral abducens nucleus. These had either (1) no further collaterals, (2) a branch entering and descending in the MLF, (3) a branch descending and terminating in ipsilateral PH, (4) a branch which ran rostrally, terminating ipsilaterally in the nucleus raphe and nucleus reticularis pontis caudalis areas containing pause neurons and premotor burst neurons.

The results show that the secondary Type I neurons, especially inhibitory Type I's, project not only to abducens nuclei but also to areas associated with the genesis of quick vestibular eye movements and saccades, thus confirming previous physiological studies.

179.7 MEMBRANE PROPERTIES AND POTASSIUM CONDUCTANCES IN ADULT PIGEON VESTIBULAR HAIR CELLS. M.J. Correia[#+], B.N. Christensen[+], and L.E. Moore[+]. Departments of [#]Otolaryngology and [+]Physiology & Biophysics, Univ. Texas Med. Br., Galveston, TX 77550

Membrane properties and K^+ conductances have been studied in 42 enzymatically dissociated vestibular hair cells from the adult pigeon. Twenty-four hair cells were from the anterior crista, 8 were from the horizontal crista, 7 were from the utricle, and 3 were from the lagena. All hair cells were studied using whole-cell patch clamp electrodes filled with either KCL-EGTA or K-Gluconate-EGTA solutions. The electrode impedance varied from 3-5 MΩ. The extracellular bath contained pigeon Ringers in the following concentrations (mM): Na - 152.0; Cl - 162.0; K - 3.5; Ca - 2.5; Mg - 1.0; Glucose - 17.0; and HEPES - 10.0. The mean steady state potential at which zero current was measured was -47 mV (SD = 14, n = 42). Fifty-seven percent of the cells had zero-current membrane potentials between -50 mV and -70 mV. Voltage clamp-I/V curves and voltage clamp admittance functions were calculated. The admittance functions were produced by measuring membrane current, during voltage clamp while applying small level (<5 mV, rms) sum of sines voltages (bandwidth - 1-500 Hz) superimposed on but following the transient phase of step clamp depolarizations and hyperpolarizations of various magnitudes. The admittance functions were fit with an equivalent circuit model for a range of membrane potentials between -56 mV and -86 mV for 16 cells. The mean (±SEM) membrane potential was -69 (±2) mV. The model assumed an isopotential soma described by the equation:

$$Y = j2\pi f C_m + G_m + G_1/(1 + j2\pi f r_1),$$

where C_m is the membrane capacitance; G_m is the frequency independent steady state conductance; G_1 is the frequency dependent conductance; r_1 is the relaxation time constant; f is frequency and $j = \sqrt{-1}$. Mean (±SEM, n = 25) best fit parameter values were: C_m = 1.4 (±0.2) pF/cm^2; G_m = 3.0 (±1.1) mS/cm^2; G_1 = -3.5 (±1.2) mS/cm^2; R_m = 3.0 (±1.5) kΩ-cm^2 and r_1 = 0.6 (±0.3) s. Based on the asymptotic estimate of the corner frequency of the admittance function, the mean (±SEM) membrane time constant was 4.6 ms (±0.7 ms, n = 25). The average (±SEM) input capacitance was 9.7 μF (±1.5 μF, n = 25). Hair cell surface area was calculated to be 438 μ^2 using measurements of dissociated cells' mean (±SEM) lengths (16.2 ±0.8 μ, n = 38) and widths (7.1 ±0.3 μ, n = 38) and the equation for the surface area of a cylinder. Assuming the cilia increase the surface area by 252 μ^2 (Ohmori, H., *J. Physiol.*, 359:189,1985), the mean specific capacitance would be 1.4 μF/cm^2 and the mean specific membrane resistance would be 3.3 kΩ-cm^2. The input impedance was measured from the I/V relation at potentials between -51 and -69 mV and the mean (±SEM) value was 2.9 GΩ (±0.4), n = 5. This work was supported in part by grants from ONR and NASA.

179.8 OTOLITH AFFERENT POLARIZATION VECTORS AND SENSITIVITIES IN THE ANESTHETIZED GERBIL. J.D. Dickman[#] and M.J. Correia[#+]. Departments of [#]Otolaryngology and [+]Physiology & Biophysics, Univ. Texas Med. Br., Galveston, TX 77550

Previously, the preferred axis of maximum sensitivity (polarization vector) for otolith afferents has been determined in primates (Fernandez & Goldberg, *J. Neurophysiol.*, 1976) and cats (Loe, et al., *J. Physiol.*, 1973). The present study addresses the sensitivity and polarization vector orientation for rodent otolith afferents in gerbils (*Meriones unguiculatus*). The animals were initially anesthetized with Nembutal (40 mg/kg), with supplementary injections of Ketamine (25 mg/kg) given as needed. The animal's head was stereotaxically positioned such that at zero degrees pitch and zero degrees roll, the horizontal semicircular canals were coplanar with the earth horizontal plane. Post-ganglionic single fiber afferent responses to small angle pitch and roll rotations (±15 and ±25 deg) about an earth horizontal axis were recorded using solution filled (3M NaCl) micropipettes. To date, responses from 21 isolated utricular and saccular afferents (recordings from both the left and right superior and inferior branches of the VIIIth nerve) have been examined. Sensitivity and polarization vector values were determined using the methods derived by Peterka (*IEEE Biol. Eng.*, 1981). The sensitivity of gerbil otolith afferents ranged widely, with a mean (±SEM) sensitivity of 42.13 (±6.03) spikes/sec/g. This sensitivity value is quite similar to that reported for primates (Fernandez & Goldberg, 1976) and cats (Loe, et al., 1973). The calculated mean (±SEM) resting discharge rate (response rate when the polarization vector is aligned perpendicular to gravity) was 51.73 (±7.36) spikes/sec, which is slightly lower than the discharge rate reported for the monkey. Like Peterka (1981), we adopted the following coordinate reference system: +z is directed out the top of the head; +y is directed out the back of the head; and +x is directed out the left ear. For the 21 units examined, the calculated polarization vectors generally aligned into two groups when projected on to the coronal head plane. Thirty three percent of the units had polarization vectors located between 0-30 deg above the ipsilateral ear. Another thirty eight percent of the units had polarization vectors located between 0 - ±30 deg off the z-axis. When projected on to the horizontal plane, the polarization vectors were also generally aligned into two groups. Thirty percent of the units had polarization vectors located between 0-60 deg away from the animal's -y-axis (nose) toward the ipsilateral ear. Another thirty percent of the units had polarization vectors located between 0-30 deg behind the ipsilateral ear toward the back of the animal's head (+y-axis). Although the current sample of examined units is small, it appears that rodent otolith afferent sensitivities and polarization vectors may be similar to those reported for primates and cats.

Supported in part by NASA grant NAG2-186 and the NASA-Ames Vestibular Research Facility.

179.9 DOES HISTAMINE HAVE A ROLE IN THE SEMICIRCULAR CANAL OF THE FROG? P.S. Guth,[1] C.H. Norris,[2] D.B. Quine*,[3] and G. Housley [1]. Depts. of [1]Pharmacology and [2]Otolaryngology, Tulane Univ. Med. Sch., New Orleans, LA 70112; [3]Wildlife Research, INHS, Champaign, IL 61820.

We have found that histamine has both a suppressive effect and a facilitatory effect on spontaneous and evoked afferent nerve activity in the isolated semicircular canal of the frog.

Beginning with concentrations as low as 20 micromolar, histamine has a facilitatory effect that increases up to concentrations of 100 to 200 micromolar. At higher concentrations the facilitatory effect wanes and a suppressive effect appears. At concentrations of 1 millimolar and greater, histamine is markedly suppressive. Pyrilamine and tripelennamine are H_1 blocking agents. Both suppress normal canal spontaneous and evoked activity at concentrations as low as 60 micromolar. Cimetidine, an H_2 blocking agent, is also suppressive. Its actions can be detected at concentrations as low as 20 micromolar.

The histidine decarboxylase inhibitor, α-fluoromethyl histidine, induces a dose-dependent reduction in spontaneous firing rate.

The cholinomimetic agent, carbachol, which in μM concentrations causes an increase in firing rate of the afferent nerve is felt to act presynaptically on the hair cell to cause it to release the endogenous afferent transmitter (Bernard et al., Brain Res. 338, 225-236, 1985; Guth et al., Acta otolaryngol. 102, 186-194, 1986). This facilitatory effect of carbachol is antagonized by μM concentrations of pyrilamine, implying that histamine is involved "downstream" of the carbachol receptor.

This evidence, taken together, seriously suggests a role for histamine in semicircular canal function and a new site of action for the antihistamines which are effective in vertigo and motion sickness.

179.10 **KYNURENIC ACID AND 2-AMINO 5-PHOSPHONOVALERIC ACID BLOCK SPONTANEOUS ACTIVITY OF THE VESTIBULAR SYSTEM PRIMARY AFFERENTS** **Rosario Vega and Enrique Soto. Departamento de Ciencias Fisiológicas, ICUAP, Universidad Autónoma de Puebla, P.O.Box 406, Puebla, México.**

Excitatory amino acid agonists have been shown to produce a dose dependent increase in the activity of primary afferents of the vestibular system. This effect seems consistent with the idea of a *glutamatergic* transmission at the recepto-neural junction between hair cells and primary afferent fibers. In this report we present the results obtained with excitatory amino acidic antagonists (Kynurenic acid KY and 2-amino-phosphono-valeric acid APV). These drugs seem useful to distinguish between different kinds of amino acidic receptors (Watkins, Trends in Pharmacol. Sci. 5 (1984) 373; Coleman et al, Brain Res. 381 (1986) 172).

We studied the effects of KY and APV on the basal activity of the primary afferents from the sacculi and lagena of the axolotl *(Ambystoma mexicanum)* inner ear. Drugs were applied manually by micro perfusion in the vicinity of the synapses (20 μl in a 5 ml bath). This method of drug application produces a brief increase of drug concentration followed by quick dilution. APV and KY inhibit the basal activity of primary afferents in a dose dependent manner. KY exerts a more intense and long lasting inhibitory effect; it completely inhibits the basal activity when applied at 10 mM; APV inhibition is less intense and at the same concentration reaches a 60% inhibition of basal activity.

These results are consistent with the hypothesis of an amino acidic mediated transmission at the afferent synapse in the vestibular system. They also support the idea of a Kainic-Quisqualic type receptor sustaining the basal activity of the vestibular system primary afferents in the axolotl.

179.11 RESPONSE DYNAMICS OF CANALICULAR AFFERENT NEURONS IN THE BULLFROG.

L. Hoffman* and V. Honrubia, Div. of Head and Neck Surgery UCLA School of Medicine; Los Angeles, California 90024.

Activity from individual neurons innervating the horizontal and anterior cristae was recorded from bullfrogs to describe their response dynamics to a series of sinusoidal stimuli. Following surgical exposure of the vestibular nerve, glass microelectrodes filled with 0.2 M KCl were used to penetrate the anterior branch in an area between Scarpa's ganglion and the anastomosis with the posterior branch. Neural spike trains representing the cell's spontaneous activity and responses to sinusoidal stimuli were analyzed on-line to determine the spontaneous firing rate coefficient of variation (CV), and gain and phase to the stimulus sinusoids. Units were identified as innervating the horizontal or anterior cristae based upon the direction of yaw rotation which produced excitatory and inhibitory modulation of spontaneous activity. Transfer functions quantifying each unit's response gain and phase across the stimulus bandwidth (usually 0.00625 to 3.2 Hz) were determined with methods that have been used to describe the response dynamics of canal afferents of the cat (Tomko et. al., J. Neurophys. 45:376, 1981). The elements used to derive the best-fit transfer functions included zeroes and poles, the adaptation operator, and s^K (fractional exponent of s).

We found that the transfer functions describing the response dynamics of the bullfrog's canalicular afferents assumed one of three basic forms. A second order equation, which included a gain term and two poles, provided the best fit for cells which had values of CV less than 0.5. These have been found to correspond to the smallest and most numerous afferents innervating the semicircular canals in the bullfrog (Honrubia et. al., Laryngoscope 95:1526, 1985). Most of the remaining units exhibited response properties which required additional terms to fit the data. These properties included phase leads (re: acceleration) at the low frequency stimuli. The responses of some cells to high frequency stimuli had phases that asymptotically approached -90° (re: acceleration), and were best fit by transfer functions that included an adaptation operator. However, the high frequency response phase from the majority of cells exhibiting low frequency phase leads approached asymptotes less than -90°. These data required the implementation of s^K which provided the phase shift necessary to fit this response characteristic.

179PO CAT VESTIBULAR UNITS RESPONDING TO VIBRATION. James H. Fuller Dept. Oral Anatomy, Univ. Illinois, Chicago, IL 60612

Single units were recorded in the vestibular nuclei in cats trained to make accurate eye and head movements to light targets. Seven categories of units were designated based on firing rates associated with head movements (Categories 1-4) or eye movements (5-7). Initial tests were passive whole body rotation (vestibular input), head fixed in space rotation (neck proprioceptor input), and ocular saccades between targets. Vestibular stimulation resulted in related modulation in Category (Ctg) 1,2,3, and 7 units. Neck sensory modulation was weak in Ctg 1, strong in 2 and 3, absent in Ctg 7 (units in Ctg 4-6 will not be considered). Only Ctg 7 units showed activity related to eye movements (burst and/or tonic).

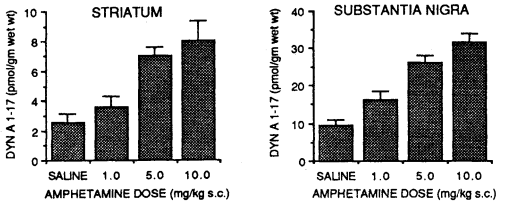
In another procedure the head was braked for 50-200 msec during identical repeated voluntary head movements between targets. The temporal events of head braking were: 1) 0.0 msec, solenoid coil activation; 2) 3.0-4.0 msec, brake plate contact; 3) 6.0-7.0 msec, brake engagement; 4) 10-15 msec, clear head deceleration. Ctg 1 and 2 units had a discernible leading and trailing edge with the onset and offset of the brake. The response was less stereotypical in Ctg 3 units with a series of two or more aggregates of spikes during the engagement of the brake. Characteristic of Ctg 1, 3, and 7 units was a single early spike, latency of ca. 1.5 msec, jitter of ca. 60 microsec. The early spike typically had the shortest latency, least jitter, and most reliable response when the brake occurred in "matched" directions. For Ctg 1 and 3 units, the matched direction was the same as vestibular sensitivity, whereas for Ctg 7, it was the same as the eye movement sensitivity (which was opposite vestibular sensitivity).

A likely stimulus to account for the early spike was the surge of vibration along the head holder shaft prior to actual braking. This stimulus was most effective during active head movements (ca. 80% in matched, and 25% in unmatched); brake activation with a stationary head was less effective. Other forms of vibration were examined in Ctg 3 units; e.g., mechanical tapping of the shaft produced similar responses, although of longer latency (3-4 msec). Other evidence suggests these responses originate from paciniform receptors located in the cervical perivertebral area. The early spike may reflect the direct pathway shown by Hikosaka and Maeda (Exp. Brain Res., 1973) between cervical receptors and the vestibular nuclei, and may be the origin the neck-eye or cervico-ocular response (COR). It is most prevalent in units having no apparent association with eye movement; the COR is likely not essentially related to the eye.

180.1 INCREASES IN STRIATONIGRAL DYNORPHINS FOLLOWING REPEATED AMPHETAMINE INJECTIONS. K.A. Trujillo, R. Day and H. Akil. Mental Health Research Institute, University of Michigan, Ann Arbor, MI, 48109.

Prodynorphin neurons in the striatum project heavily to the substantia nigra pars reticulata. Anatomical, biochemical and behavioral evidence suggests that this descending pathway may modulate, and be modulated by, ascending nigrostriatal dopamine neurons. In the present study we administered repeated amphetamine injections to rats in order to study the influence of nigrostriatal dopamine on striatonigral prodynorphin neurons.

Adult male Sprague-Dawley rats were injected with amphetamine sulfate (1.0, 5.0 or 10.0 mg/kg s.c.) once daily for seven days, and sacrificed 1 hour or 24 hours following the final injection. The striatum and substantia nigra were removed and assayed for four prodynorphin peptide products: dynorphin A 1-8, dynorphin A 1-17, dynorphin B 1-13 and alpha neo-endorphin. In animals sacrificed 24 hours following the final injection there was a dramatic, dose-dependent increase in both the striatum and the substantia nigra for all four prodynorphin products, suggesting that repeated amphetamine administration causes an increase in synthesis and/or decrease in release of these peptides from striatonigral prodynorphin neurons. The increase in peptide s levels was much less pronounced in animals sacrificed 1 hour following the final injection, suggesting that acutely, amphetamine causes release of stored peptides. These results lead us to suggest that amphetamine-dependent release of s dynorphins results in an increased synthesis of prodynorphin peptide products in the striatonigral pathway. These results are consistent with the suggestion that striatonigral prodynorphin neurons are modulated by dopamine.



180.2 EFFECTS OF CHRONIC MORPHINE TREATMENT ON BETA-ENDORPHIN IMMUNOREACTIVE FORMS IN RAT BRAIN. D. M. Bronstein and H. Akil. Mental Health Research Institute, University of Michigan, Ann Arbor, MI 48109.

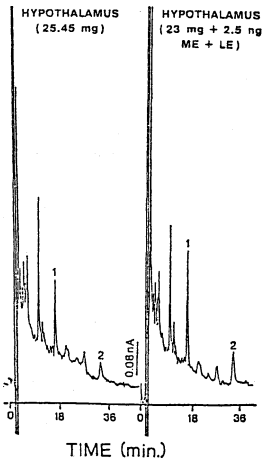
Even prior to the discovery of the enkephalins, it was postulated that morphine tolerance/dependence might be the result of a decrease in endogenous opiate activity due to negative feedback effects of exogenously administered opiates. It has since been shown by a number of investigators that 1-2 weeks of morphine administration causes no change in the concentration of Beta-endorphin immunorectivity (BE-ir) in the pituitary or in various brain regions. However, BE-ir measured in these studies did not distinguish between different immmunoreactive BE forms. In the brain, the majority of BE-ir consists of BE(1-31) and to a lesser extent, the carboxy terminal cleaved BE(1-27), which has been suggested to act as an endogenous antagonist to BE(1-31). Although no changes are observed in total BE-ir in morphine tolerant animals, it is hypothetically possible that there is increased processing of BE(1-31) to BE(1-27), (i.e. brains from morphine treated animals might contain a greater ratio of "antagonist" BE relative to opiate active BE). The purpose of the present study was to determine whether there were differences in the concentrations of BE(1-31) and BE(1-27) in the brains of control, morphine tolerant , or morphine withdrawn animals.

Male Sprague-Dawley rats were implanted with 2 morphine (75 mg/pellet) or placebo pellets on Day 1 and an additional 3 pellets on Day 4. In the morning of Day 7, animals were injected with 2 mg/kg of naloxone (to induce precipitated withdrawal in morphine tolerant animals) or saline and killed 30 min later. The results of radioimmunoassays showed, as expected, that there were no changes in the concentrations of total BE-ir in the hypothalamus, midbrain (containing the periaqueductal grey region), or caudal medulla (including the nucleus tractus solitarius) as a result of any of the experimental manipulations. Samples from the 4 groups were then applied to Sephadex G-50 chromatography columns and developed with a 1% formic acid solvent containing .01% bovine serum albumin. The collected fractions (1.3 ml) were assayed for BE-ir. There were no apparent differences between the 4 treatment groups in the amounts of BE(1-31) and BE(1-27) detected in any of the brain regions examined. The results of this study indicate that chronic morphine treatment does not appear to alter the processed forms or the content of BE stored in the brain. However, these results do not preclude the possibility that the rate of POMC processing or BE(1-31) turnover may be affected by morphine administration.

180.3 Assay of Enkephalins from Rat Brain By Liquid Chromatography - Electrochemical Detection, L. H. Fleming* and N. C. Reynolds, Jr., Dept. of Neurology, University of Wisconsin Medical School (Milwaukee Clinical Campus), Milwaukee, WI 53201

Several groups have used electrochemistry (ED) as the basis of detection for brain extracts of neuropeptides separated by liquid chromatography (LC). (Sauter, A. and W. Frick, J. Chromatogr. 297:215, 1984, Mousa, S. A. and G. R. Van Loon, Life Sci. 37:1795, 1985 and Dawson, R., Jr., J. P. Steves, J. F. Lorden, and S. Oparil, Peptides 6:1173, 1985). In these reports, alternative analytical methods were not used to verify peak identity or to evaluate quantitative data.

Our current work has focused on the development of an LC-ED assay for enkephalins from rat brain extracts. Most of the difficulties in devising a workable protocol were in three areas: 1) Elimination of early and late eluting electroactive contaminants from tissue, 2) discovering the origin of other electroactive interfering substances and eliminating them and 3) maintaining an adequate recovery of endorphins to allow detection with the present ED technology. The chromatogram of hypothalamus shown below was obtained using a "clean-up" protocol designed to maximize recovery (78%) while eliminating interfering substances. To evaluate peak identity and purity, several analytical techniques were used, including peak current ratios and radioimmunoassay. This LC-ED technique allows for the quantification of both methionine- and leucine-enkephalin in a single assay performed on extracts from rat brain regions.



1 = Methionine enkephalin
2 = Leucine enkephalin

180.4 ISOLATION OF HUMAN SYNENKEPHALIN FROM PHAEOCHROMOCYTOMA TISSUE. R. Corder*, R.C. Gaillard* and J. Rossier. (SPON: Philippe Magistretti). Dept. of Medicine, University Hospital, 1211 Geneva 4, Switzerland, and Laboratoire de Physiologie Nerveuse, C.N.R.S., 91190 Gif-sur-Yvette, France.

The amino-terminal region of the enkephalin-peptide precursor, pro-enkephalin, is composed of a non-opioid polypeptide of unknown function referred to as synenkephalin (SYNENK). However, antisera raised in rabbits against SYNENK purified from bovine adrenal medullary chromaffin granules are highly species-specific and unsuitable for studies of the functional significance of either human or rat SYNENK. Using a radioimmunoassay which employs an antiserum raised against the synthetic tyrosinylated carboxy-terminal sequence of SYNENK (YEESHLLA) and the same peptide as standard and tracer, preliminary investigations have shown human adrenal medullary phaeochromocytoma tissue to be a rich source of SYNENK-like material. The identified immunoreactivity possessed gel filtration and ion exchange characteristics consistent with the weakly acidic 8KDa polypeptide predicted from cDNA studies. Thus we elected to purify human SYNENK using these tumours as a tissue source.

Sections (total wt. 70g) from three adrenal medullary tumours, identified histologically as phaeochromocytoma, were extracted in 15 volumes 0.1M HCl. The resultant extract was fractionated using $(NH_4)_2SO_4$ to produce a SYNENK enriched precipitate at 50% saturation. SYNENK was then purified by employing sequentially the following chromatographic procedures: gel filtration (Sephadex G50, 2.6 x 96cm), anion exchange HPLC (Protein Pak DEAE 5PW, 7.5 x 75mm), reverse phase HPLC (Nova-Pak Phenyl, 3.9 x 150mm) and cation exchange HPLC (UltroPac TSK CM-3SW, 7.5 x 150mm). The carboxy-terminal SYNENK RIA was used throughout to identify the SYNENK peptide. A single peak of immunoreactivity was obtained from each chromatographic step, with cation exchange HPLC yielding a homogeneous peak (25nmoles) suitable for chemical characterization. The NH_2-terminal sequence was determined using 0.2nmol of this peptide, using an Applied Biosystems 470-A sequencer. This identified the NH_2-terminal Glu residue and confirmed the sequence predicted by cDNA studies as far as the 27th residue.

Thus, using an antiserum specific for the 67-73 sequence of human SYNENK, we have isolated and chemically characterized the authentic human peptide. The raising of specific antisera against this peptide should allow the development of an immunoassay for pathophysiological studies of SYNENK in man.

180.5 CHARACTERIZATION OF METHODOLOGY FOR CONCURRENT MEASUREMENT OF SMALL PROENKEPHALIN FRAGMENTS IN CSF, TISSUE AND BLOOD. D.L. Lucas* and T.L. Yaksh* (SPON: J.R. Daube). GI Hormone Research Lab. and Lab. of Neurosurgical Research, Mayo Clinic, Rochester, MN 55905.

Processing of the proenkephalin molecule will result in several short forms of the form: ( )-YGGFM-( ). We have characterized a separative-radioimmunoassay (RIA) methodology which permits concurrent measurement of several enkephalin derived peptides in a single sample. Samples (tissue extracts, ventricular or spinal superfusates, EDTA plasma) are passed over a C_{18} disposable column (Sep-pak). Hydrophilic components are eluted with distilled H_2O (5 ml) and discarded. Hydrophobic elements are eluted with 50% acetonitrile. The sample is lyophilized, reconstituted in .5 ml of borate buffer and passed over a YM-2 filter (Amicon, 14 mm, nominal cutoff of 2000 DA) using a centrifugation holder. A second .5 ml of buffer is passed through the filter and combined. The filter is then inverted and washed by centrifugation with .5 ml buffer to measure the levels of encrypted enkephalin in >2000 DA fragments in the retentate. The filtrate is lyophilized, reconstituted in buffer (.5 ml) and an aliquot placed on an LKB HPLC (Rainin short one C_{18} column). The column is eluted at a rate of .5 ml/min with a gradient of 10-60% acetonitrile in .1 M acetate buffer (pH = 4). Each 1-min HPLC sample is incubated with trypsin (Try: Sigma 25 µg for 1 hr at 37°C) followed by carboxypeptidase B (CPB: Sigma .05 mg for 1 hr at 37°C). The reaction is stopped by boiling for 10 min. Met-enkephalin (ME) RIAs are carried out (antibody N-382: carboxy terminus directed; sensitivity 9 fmole/tube: interassay reliability: 8%). Table 1 indicates the recovery of the molecular forms of standard containing encrypted enkephalin. The HPLC elution studies revealed reliable separation of the several forms. Examination of spinal perfusate samples has indicated that during the addition of substance P to the spinal perfusate, the ratio of ME to total encrypted ME activity rises from 1.7±0.4 to 7.6±0.9. (NIH grant NS-16541 to TLY.)

180.6 CHARACTERIZATION OF OPIOID RECEPTOR SUBTYPES IN THE BRAINSTEM WITH RESPECT TO ANALGESIA. N. Al-Rodhan* and T.L. Yaksh* (SPON: B.F. Westmoreland). Department of Neurologic Surgery, Mayo Clinic, Rochester, MN 55905.

There is increasing pharmacological and biochemical evidence to suggest that opiates exert their effects through heterogenous receptor populations (µ, δ, κ, σ, ε). Subtypes of these receptors have been postulated to exert specific effects at different sites in the central nervous system. This study is part of an ongoing series of investigations to characterize the distribution of opioid receptor subtypes in the brainstem of the rat and their role in analgesia. In the present studies, focussing on the periaqueductal gray (PAG) region, we have systematically examined the dose dependency and the relative activity of several µ and δ receptor preferring ligands following their intracerebral administration through chronically implanted guides placed stereotaxically into the PAG. All injections were given in a volume of 0.5 µl saline. Antinociception was measured using: 1) the hot plate test (HP; 52.5°C; baseline latency = 10.8±2.6 sec; 60 sec cutoff), and 2) the tail flick test (TF; baseline latency = 2.9±0.6 sec; 6 sec cutoff). Each rat received no more than 3 injections, at least one of which was with a "probe dose" of drug known to be effective. In this series of experiments, the ability of naloxone (1 mg/kg, i.p.) to reverse the effects of the PAG microinjection was assessed using the lowest dose of opiate producing a just maximal effect. As indicated in the table, the ordering of agonist potency on the HP and TF was: SUF > PL017 = MOC = DAGO = DSTLE >> DPDPE. Slopes for the dose response curve of SUF, PL017, MOC, DAGO and DSTLE did not differ. The degree of reversal produced by the high dose of naloxone was similar for all agonists (e.g. 65 to 85% reversal).

Conclusions: (1) These studies in the rat suggest that the opioid receptor in the PAG which modulates thermal antinociception displays a structure-activity relationship suggesting the primary characteristics of a "µ" receptor. (2) Failure of DPDPE to act over a broad range of concentrations suggests the absence of δ receptors in the PAG modulation of thermal nociception and suggests that DSTLE may mediate antinociception by an effect on a µ-receptor. (Supported by NIH grant NS-16541, TLY.)

180.7 HETEROGENEITY OF KAPPA OPIOID RECEPTORS ACROSS SPECIES. A. Mansour, H. Akil, W. Essman*, and S.J. Watson. Mental Health Research Institute, University of Michigan, Ann Arbor, MI 48109-0720.

There is a wealth of evidence to suggest the existence of species-differences in opioid receptors. Among the more striking differences have been those described for kappa receptors. While pursuing these findings we have been able to show not only a differential localization of kappa receptors across species, but also a heterogeneity of kappa sites. Several lines of evidence support this conclusion.

I. Selective kappa agonist, such as U50,488H, have differential affinities for kappa sites labelled with [^{3}H]bremazocine across species, while non-selective compounds such as bremazocine and EKC do not. Brains of monkey, rat, pigeon and guinea pig were frozen in isopentane (-30°C) and forebrain sections were thaw-mounted on microscope slides. The brain sections were incubated with [^{3}H]bremazocine (0.5-0.6 nM) in a 50 mM Tris HCl (pH = 7.4 at 25°C) buffer (in the presence of a 300 fold excess of DAGO and DPDPE) and varying concentrations of either U50,488H, Cambridge 20, U69,593, PCP, ethylketazocine (EKC), cyclazocine, tifuladom, nalorphine, or bremazocine. Following a 60 min incubation, the sections were washed in four 4 min Tris (pH = 7.5, 4°C) washes, dried and quantified with a beta counter. Representative Ki values for U50 and EKC (nM) are presented below.

	Monkey	Rat	Pigeon	Guinea Pig
U50, 488H	3.5	140.9	165.1	7.1
Ethylkectazocine	1.3	1.1	5.9	1.8

II. U50,488H competition studies with varying concentrations of [^{3}H]bremazocine (0.06-6.0 nM) in the presence of mu and delta blockers, resulted in parallel curves in some species (e.g. guinea pigs) and non-parallel, multiple site curves in others (e.g. rat).

III. Direct binding experiments with the selective kappa agonist U69,593 suggest that it binds to two sites. Brain sections were incubated for 2 hrs with varying concentrations (0.15 - 20.0 nM) [^{3}H]U69,593 in a 50 mM Tris buffer (pH = 7.4, 25°C), followed by four 1 min Tris (pH = 7.5, 4°C) washes. Non-specific binding was defined by 1 uM bremazocine and quantification of binding was as described above. In monkey cortical sections, for example, scatchard analysis suggests that U69 binds to two sites with Kds of 0.4 and 14.5 nM as determined by the LIGAND program. Similarly, in the guinea pig forebrain two sites can be resolved with Kds of 0.6 and 44 nM, respectively. While further work is needed to pharmacologically characterize each of these binding sites, these results and those presented above support the notion of a heterogeneity of kappa opioid receptors with possibly distinct functions.

180.8 EVIDENCE FOR KAPPA OPIATE RECEPTOR HETEROGENEITY BETWEEN RAT AND GUINEA-PIG BRAIN. K. Reinertsen*, W. Bowen, and J.M. Walker. Sect. of Biochem., Div. of Biology and Medicine and Dept. of Psychology, Brown Univ., Providence, RI 02912.

We have investigated binding sites labeled by [^{3}H]-(-)-bremazocine ([^{3}H]-(-)-BREM) and [^{3}H]-(-)-ethylketocyclazocine ([^{3}H]-(-)-EKC) in rat and guinea-pig brain membranes. We present evidence for two subclasses of kappa receptor based on the following criteria: a) affinity for the kappa-selective ligand U50-488H and b) sensitivity to a low temperature/high salt incubation condition.

Assays were carried out with 2 nM ^{3}H-ligand for 60 or 90 min at 25°C in 10 or 50 mM Tris-HCl (pH 7.4) containing 100 nM DAGO and 100 nM DSTLE to mask mu and delta sites, respectively. Nonspecific binding was determined with 10 uM levallorphan. The ability of U50-488H and dynorphin analogs to displace 2 nM [^{3}H]-(-)-BREM binding to membranes from rat brain (RB) and guinea-pig brain (GPB) was assessed. U50-488H was 8-fold more potent in GPB than in RB. By contrast, the dynorphin analogs D-Ala^2-dynorphin-1-13-NH$_2$ and D-Ala^2,F$_5$Phe^1-dynorphin-1-13-NH$_2$ were nearly equally potent in the two tissues. Thus, there appear to be two types of [^{3}H]-(-)-BREM binding sites which differ in their affinity for U50-488H. Guinea-pig brain contains a preponderance of [^{3}H]-(-)-BREM binding sites with high affinity for U50-488H, while rat brain contains a preponderance of sites with lower affinity for U50-488H. Dynorphins bind with nearly equal affinity to both sites, indicating that they are kappa receptors.

Binding of 2 nM [^{3}H]-(-)-BREM and [^{3}H]-(-)-EKC to membranes from rat brain, guinea pig brain, and guinea pig cerebellum (GPC) under the above incubation condition was compared to binding in incubations carried out in presence of 50 mM K-phosphate (pH 7.4) with 400 mM NaCl at 4°C for 4 hrs. For both ligands, the low temp/high salt condition produced only a moderate (30 - 40%) enhancement of binding in the guinea-pig tissues. However, the low temp/high salt condition produced a marked (140 - 155%) enhancement of binding in the rat tissue. Thus, rat brain contains binding sites for [^{3}H]-(-)-BREM and [^{3}H]-(-)-EKC whose ability to bind ligand is markedly enhanced by incubation at low temperature in presence of high salt. This site is largely absent in guinea-pig brain. Ligand selectivity analysis of this site is in progress to determine its relationship to kappa receptors.

These results support the notion of heterogeneity within the kappa opiate receptor class. Rat brain is reported to contain fewer kappa receptors than guinea-pig brain. This difference may in fact reflect species variation in kappa receptor subtypes and differences in optimal assay conditions for these receptors.

180.9 DEVELOPMENT OF COMPOUNDS SELECTIVE FOR KAPPA-OPIATE RECEPTORS. L. Toll, J.A. Lawson* and G.H. Loew*. Division of Life Sciences, SRI International, Menlo Park, CA 94025.

Structure activity studies, receptor characterization and receptor purification have proceeded at a much slower rate for kappa-opioid receptors than for mu and delta receptors, partly for the lack of suitable ligands selective for this site. This problem has been partially alleviated by the discovery of the benzodiazepine opiate tifluadom and, more importantly, the benzamides U-50,488 and U-69,593, developed by VonVoigtlander and colleagues. The lengthy synthesis and the chiral nature of the Upjohn compounds make extensive SAR studies time-consuming and expensive. The chirality of the compounds necessitates difficult resolutions to determine absolute structural requirements for binding to the kappa receptor. We have recently developed a new class of compounds which are structurally related to U-50,488, but which are readily synthesized and which are achiral. In this class of compounds, small structural changes modulate affinities and selectivities so that high affinity compounds with significant selectivities for the kappa or mu receptor are obtainable. In addition to the benefits for structure activity studies, several positions are available for the insertion of a moiety which could bind irreversibly to the receptor and may be suitable for affinity labeling of the kappa or mu receptor. Data will be presented on binding affinity and selectivity of these achiral aminoamide compounds, and on the usefulness of these compounds as potential affinity probes for kappa and mu receptors.

180.10 LOSS OF MU OPIOID RECEPTORS IN THE NUCLEUS ACCUMBENS FOLLOWING MESOLIMBIC DOPAMINERGIC LESIONS. E.M. Unterwald, G.F. Koob*, and R.S. Zukin. Dept. of Neuroscience, Albert Einstein College of Medicine, Bronx, NY 10461 and *Res. Inst. Scripps Clinic, La Jolla, CA 92037.

The modulation of dopaminergic function by opioids in the mesolimbic system is well documented. Opioid receptors and peptides have been found in relatively high concentrations in areas of the limbic system that are extensively innervated with dopaminergic neurons. The present study investigates the nature of the opioidergic-dopaminergic interaction in the nucleus accumbens. The organization of the different opioid receptor types with respect to their pre- and postsynaptic localization and their relationship to dopaminergic neurons is determined.

Dopaminergic terminals in the nucleus accumbens of rats were destroyed by unilateral injection of 6-hydroxydopamine (2 µl; 4 µg/µl). Separate groups of animals received unilateral injections of ibotenic acid (0.5 µl; 10 µg/µl) in order to lesion postsynaptic elements and cell bodies. Fourteen days after the lesions, the fraction of each opioid receptor type lost was determined by binding studies on nucleus accumbens membranes. The highly specific ligands used were [^{3}H]-D-Ala^2, N-Phe^4, Gly-ol^5-enkephalin (DAGO) for mu receptor assays, [^{3}H]-D-Penicillamine^2, D-Penicillamine^5-enkephalin (DPDPE) for delta receptor assays, and [^{3}H]-bremazocine in the presence of DAGO (100 nM) and D-Ala^2,D-Leu^5-enkephalin (DADLE) (100 nM) for kappa receptor assays. Quantitative in vitro autoradiography at the level of the light microscope was used to visualize the neuroanatomical pattern of the receptors on the lesioned and non-lesioned sides of the brain. The same specific ligands used in the receptor binding assays were used in the autoradiographic studies to identify each receptor type.

Results indicate that 6-hydroxydopamine lesions produced a 30% loss of mu opioid receptors in the nucleus accumbens. No change in mu receptor affinity was observed. Delta and kappa receptors remained unchanged. The time course of the loss of mu receptors paralleled the time course of the depletion of dopamine. These results suggest the absence of delta and kappa opioid receptors on presynaptic dopaminergic terminals in the nucleus accumbens. Approximately one-third of mu opioid receptors in the accumbens appear to be located on either the presynaptic dopaminergic terminals or on the neurons upon which they impinge. Preliminary results with ibotenic acid are consistent with the former hypothesis.

180.11 DIRECT AUTORADIOGRAPHIC LOCALIZATION OF MU$_1$ BINDING SITES IN RAT BRAIN WITH A NOVEL OPIATE LIGAND. R.R. Goodman, M. Price* and G.W. Pasternak, The Cotzias Laboratory of Neuro-Oncology, Memorial Sloan-Kettering Cancer Center and Cornell U. Medical College, New York, NY 10021.

A new naloxone derivative, NalBzoH (6-desoxy-6-benzoyl-hydrazido-N-allyl-14-hydroxydihydronormorphinone), has been characterized in our laboratory. Extensive binding studies demonstrate that the ligand labels mu$_1$ sites pseudoirreversibly. Binding to other classes of opioid sites is freely reversible. Using conditions to selectively label mu$_1$ sites, we directly examined the autoradiographic labeling of mu$_1$ receptors for the first time. Non-fixed thin rat brain sections (8 µm) were incubated with ^{3}H-NalBzoH (57.4 Ci/mmole) at 25°C for 60 min after which levallorphan (1µM) was added to some sections and the incubation continued for an additional 120 min to dissociate reversibly bound ligand, leaving mu$_1$ binding. Total binding was determined in sections incubated at 25°C for 60 min without the addition of levallorphan and nonspecific binding with sections preincubated with levallorphan (1µM) prior to the addition of the radioligand. The regional distribution of binding of the pseudoirreversible binding was very similar to mu$_1$ binding determined in rat brain using digital subtraction autoradiographic techniques or in the mouse using subtraction of grain counts. Initial studies demonstrate high concentrations of mu$_1$ binding in layers I and IV of the cerebral cortex, clusters in the striatum, the nucleus accumbens, medial and intralaminar thalamic nuclei, pyramidal cell layer of the hippocampus, superficial layer of the superior colliculus, medial geniculate body, mamillary body, and medial habenula. Moderate concentrations were noted in the periaqueductal gray, consistent with the suggestion of mu$_1$ mechanisms of morphine analgesia in this region. Interestingly, the highest concentration of mu$_1$ binding sites seen to date appear to correspond to the accessory nucleus of the optic tract. More detailed studies are currently in progress to determine the pre- or postsynaptic localization of mu$_1$ sites.

180.12 A NOVEL OPIATE ANALOG WITH VERY HIGH AFFINITY FOR MU$_1$ BINDING SITES. M. Price*, M. Luke*, E.F. Hahn* and G.W. Pasternak, [SPON: K.M. Foley]. The Cotzias Laboratory of Neuro-Oncology, Memorial Sloan-Kettering Cancer Center and Cornell U. Medical College and Rockefeller University, New York, NY 10021.

Over the past few years, our laboratory has synthesized and characterized a series of azines, hydrazones and acylhydrazones, such as naloxonazine. One goal of these studies was to develop a compound which could be used to selectively label mu$_1$ receptors. Attempts to use radiolabeled naloxonazine were only partially successful. Although binding could be demonstrated, the very high nonspecific binding prevented detailed studies. Similar difficulties were encountered with a series of other compounds. Recently, we synthesized a novel naloxone derivative, ^{3}H-NalBzoH (6-desoxy-6-benzoylhydrazido-N-allyl-14-hydroxydihydronor-morphinone), with high specific activity. In binding assays using bovine striatum, the ratio of total to nonspecific binding is approximately 10:1. The ligand labels two types of binding sites. Approximately 60% of binding is freely reversible and dissociates in the presence of a high concentration of levallorphan (1µM) at 25°C in under 2 hours. The remainder of the binding is resistant to dissociation and persists for up to 6 hours with no noticeable loss of specific binding. By 24 hours approximately 30% of this dissociation-resistant binding still remains. Competition studies indicate that the freely reversible binding is selective for morphine as opposed to enkephalins and therefore probably corresponds to mu$_2$ sites while the dissociation-resistant binding is sensitive to both morphine and the enkephalins and probably represents mu$_1$ binding. Although the mu$_1$ binding of this ligand is highly resistant to dissociation, it is not covalent. Thus, ^{3}H-NalBzoH is a novel opiate derivative which binds mu$_1$ sites pseudoirreversibly. In certain respects, it is similar to α-bungarotoxin which also labels its receptor tightly, but not covalently. Although covalent bonding would permit studies of the binding site under denaturating conditions, ^{3}H-NalBzoH still offers a number of advantages in the study and biochemical characterization of mu$_1$ opiate receptors.

180.13 A CHEMICAL MECHANISM FOR WASH-RESISTANT BINDING OF OPIATE AZINES TO OPIOID RECEPTORS. A. Garzon-Aburbeh*, A.W. Lipkowski*, and P.S. Portoghese. Dept. of Medicinal Chemistry, College of Pharmacy, University of Minnesota, Minneapolis, MN 55455.

Opiate azines such as naltrexonazine (NTX=N-N=NTX) have been reported to possess a wash-resistant binding component at opioid receptors. However, the chemical nature of such binding has not been reported. In view of the presence of thiols at opioid receptors, and our observation that such groups catalyze the hydrolysis of the C=N bond, we have investigated the possibility that NTX=N-N=NTX is converted to NTX=N-NH_2 which would then react with a membrane component. We have synthesized an unsymmetrical analogue of NTX=N-N=NTX where one of the hydrazone double bonds is reduced (NTX-NH-N=NTX). In this regard, two tritiated analogs (*NTX-NH-N= NTX and NTX-NH-N=NTX*) were prepared with the label at either part of the unsymmetrical molecule for binding experiments to mouse membranes. Only with *NTX-NH-N=NTX (5 nM) was the radioactivity retained (42% specific binding) in the membrane after three washes. This suggested that only the portion of the molecule carrying the hydrazine moiety accounts for the wash-resistant binding. After five washes of the membranes incubated with *NTX-NH-NT=NTX a new tritiated compound with high R_f (0.8) was detected in the washes whose R_f corresponds to a synthetic linolenoyl hydrazide of naltrexone. Moreover, after 5 washes, no wash resistance could be demonstrated with NTX=N-N=NTX. Reconstitution of the previously washed membranes with the wash components restored the wash-resistant binding, suggesting that some essential component was washed out during the washing procedure. This component is thought to be a phosphatide based on the fact that treatment of the washes with phospholipase A_2, followed by denaturation of the enzyme and reconstitution with the washed membranes, failed to show any wash resistance with NTX=N-N=NTX. Furthermore, adding phosphatidic acid, phosphatidyl serine, or phosphatidyl choline to the previously washed membranes restored the wash-resistant binding characteristic. On the basis of these experiments, the mechanism proposed involves the reaction of NTX-NH-NH_2 liberated in situ with the C-2 ester carbonyl group of a phosphatide to afford a fatty acid hydrazide of naltrexone. This mechanism is consistent with the fact that cerebroside sulfate, which does not contain an ester group, is unable to restore the wash-resistant binding of the washed membranes. The wash resistance of opiate azine and related ligands therefore can be viewed as the receptor-mediated formation of fatty acid hydrazide derivative of the opiate. Its lipophilic chain may give rise to increased affinity (wash resistance) due to hydrophobic interaction with a portion of the opioid receptor that normally accommodates the receptor-associated phosphatide.

180.14 **IN VIVO ACYLATION OF THE LOWER AFFINITY [^{3}H]DADL BINDING SITE BY THE ENANTIOMER OF SUPERFIT AND ITS PROTECTION BY THE DELTA ANTAGONIST ICI174864: EVIDENCE THAT ICI174864 INTERACTS IN VIVO WITH THE LOWER AFFINITY [^{3}H]DADL BINDING SITE.** K. C. RICE[1], A. E. JACOBSON[1]*, J. B. LONG[2], V. BYKOV[3]* AND R. B. ROTHMAN[3].
[1]Laboratory of Chemistry, NIDDK, Bethesda, MD, 20892
[2] Neuropharmacology Branch, Dept. Med. Neurosci., Div. N.P., Walter Reed Army Institute of Research, Washington, DC 20307-5100
[3]LPP, NIMH, St. Elizabeths Hospital, Washington, DC 20032.

[^{3}H]DADL labels two sites in vitro which are distinguished by interactions with mu ligands. The lower affinity mu-noncompetitive binding site, commonly identified as mu, is the delta binding site of an opiate receptor complex, and is termed the delta$_{cx}$ binding site. The higher affinity mu-competitive delta binding site, commonly identified as delta, is the delta binding site not associated with the receptor complex, and is termed the delta$_{ncx}$ binding site. Previous studies demonstrated that the i.c.v injection of ESF (enantiomer of superFIT,((3S,4R)-(-)-cis-N-[1-[2-(4-aminophenyl)ethyl]-3-methyl-4-piperidyl]-N-phenylpropaneamide hydrochloride) to rats 18-24 hr prior to sacrifice decreased the binding of [^{3}H]DADL to the delta$_{cx}$ and delta$_{ncx}$ binding sites, when the assay was conducted in the presence of 1 mM 2-mercaptoethanol (Rothman et al., Neuropeptides, in press). The goal of this study was to examine the interaction of the delta antagonist ICI174864 with the delta$_{cx}$ binding site in vitro, and in vivo utilizing ESF.

The in vitro affinities of ICI174864 for the delta$_{cx}$ and delta$_{ncx}$ binding sites were determined by displacement of 2 nM [^{3}H]DADL using membranes pretreated with the site-directed acylating agents BIT (2-(p-ethoxybensyl)-1-diethylaminoethyl-5-isothiocyanatobensimidisole)-HCl or FIT (N-phenyl-N-[1-(2-(p-isothiocyansto)phenylethyl)-4-piperidinyl]propanamide)-HCl, allowing the selective assay of the delta$_{ncx}$ and delta$_{cx}$ binding sites, respectively. [^{3}H]DADL binding assays were conducted without 2-mercaptoethanol using two different "salt solutions:" 1) 100 mM NaCl, 3 mM $MnCl_2$ and 2 uM GTP and 2) 100 mM choline chloride, 3 mM $MnCl_2$. The IC50 of ICI174864 for the delta$_{cx}$ and delta$_{ncx}$ binding sites were 2472 nM and 169 nM using condition 1, and 5538 nM and 733 nM using condition 2. These data demonstrate a Na-dependent high affinity interaction of ICI174864 with the delta$_{ncx}$ binding site, and a very low affinity interaction with the delta$_{cx}$ binding site, suggesting that ICI174864 should not interact in vivo with this binding site.

To test this hypothesis, 24 hr prior to sacrifice and preparation of membranes, rats received i.c.v. injections of vehicle (group 1), 25 ug ESF (group 2), 3 ug ICI174864 (group 3) or 3 ug ICI174864 15 min prior to 25 ug ESF (group 4). Binding parameters of the delta$_{cx}$ binding site were determined using the method of binding surface analysis. I.c.v. injection of ESF almost completely eliminated the delta$_{cx}$ binding site. Pretreatment of rats with ICI174864 prior to the injection of ESF (group 4), prevented the in vivo acylation of this binding site. In contrast, the density of mu binding sites, labeled with [^{3}H]FOXY (3,14-dihydroxy-4,5alpha-epoxy-6beta-fluro-17-methylmorphinan), were identical in all 4 groups.

These data demonstrate that the delta antagonist interacts with the delta$_{cx}$ binding site in vivo but not in vitro, clearly illustrating the failure of in vitro data to predict in vivo occurences. Furthermore the almost total loss of delta$_{cx}$ binding sites, commonly identified as mu, following i.c.v. injection with ESF without a concomitant loss of mu binding sites supports the hypothesis that the delta$_{cx}$ and mu binding sites are not the same entity.

180.15 ALTERATIONS IN KAPPA AND MU OPIOID RECEPTOR BINDING BY VOLATILE ANESTHETICS IN VITRO. C. Ori* and E.D. London (SPON: J.E. Johnson). Neuropharm. Lab., NIDA Addiction Res. Ctr., Baltimore, MD 21224.

The mechanism by which general anesthestics act is largely undefined. Although specific targets for the actions of some anesthetics, like ketamine or xylamine, have been hypothesized (Lawrence, D. and Livingstone, A., Br. J. Pharmacol., 73:435, 1981), a nonspecific mechanism, implying a general physical perturbation of macromolecules, might better explain the effects of a wide variety of structurally different substances which all produce general anesthesia. Many inhalational anesthestics can generally affect all macromolecules, including proteins and lipids (Mashimo, T. et al., Mol. Pharmacol., 29:149, 1986). Inhalational anesthestics also have effects on muscarinic (Aronstam, R. S. et al., Biochem. Pharmacol., 35:667, 1986) and nicotinic (Firestone, L. L. et al., Anesthesiology, 64:694, 1986) acetylcholine receptors, and opioid receptors (Daras, C. et al., Eur. J. Pharmacol., 89:177, 1983; Inoki, R. et al., Life Sci., 33 (Suppl. 1):223, 1983) which vary with the receptors and the anesthetics.

We investigated the in vitro effects of the inhalational anesthetics, nitrous oxide (N_2O) and halothane, on mu and kappa opioid receptor subtypes in membranes from the guinea pig brain. Membrane suspensions were bubbled with 100% N_2O and 2% halothane for 1 h to achieve saturation before they were used in binding assays. Untreated and oxygen-saturated membranes were used as controls. Mu receptor binding was assayed using [^{3}H]dihydromorphine as the ligand, and kappa binding was assayed with [^{3}H](-)ethylketocyclazocine in presence of 100 nM DADL and 30 nM morphine to block binding to delta and mu sites, respectively.

Both O_2 and N_2O produced slight increases in Kd's for mu binding (control, 0.87 nM; O_2, 1.40 nM; N_2O, 1.45 nM) with no changes in Bmax. Halothane greatly decreased the affinity (Kd = 2.70 nM) without affecting Bmax. The values of Kd for kappa binding sites were slightly but significantly increased both by O_2 and N_2O (control, 0.25 nM; O_2, 0.29 nM; N_2O, 0.31 nM), but only N_2O altered Bmax (control, 115 fmol/mg protein; O_2, 113 fmol/mg; N_2O, 84 fmol/mg). Halothane greatly decreased both affinity and density of kappa binding sites (Kd and Bmax, 0.20 nM and 38 fmol/mg protein, respectively).

The results demonstrate different effects of inhalational anesthetics on opioid receptor subtypes. Oxygen also showed some effects on these receptors, consistent with a general physical perturbation of the membranes. The observed differences might result from conformational changes in receptors due to effects on the lipoprotein structure of membranes, as influenced by the different physical properties of the gases (Lee, N. M. et al., Life Sci., 26:1659, 1980).

180.16 THC AND THC ANALOGS ALTER OPIATE RECEPTOR BINDING IN RAT BRAIN SECTIONS. J. Margulies* and R. P. Hammer, Jr. (SPON: J. Hardman). Dept. of Anatomy and Reproductive Biology, University of Hawaii School of Medicine, Honolulu, HI 96822.

Delta-9-tetrahydrocannabinol (THC) is known to influence brain function, however, the mechanism and specific sites of drug action in brain are unknown. We have examined the effect of THC and water soluble THC analogs on binding of radioligands in various neurotransmitter receptor systems in vitro. These radioreceptor assays were performed on sections through the caudate nucleus of male Sprague-Dawley rats. Animals were decapitated, brains were removed and immediately frozen at -30°C. Sections through the caudate-putamen were taken; tissue was dried and stored at -50°C overnight. Radioligand receptor binding in the presence of graded concentrations of THC or THC analogs was measured by liquid scintillation counting. To study opiate receptor binding, sections were preincubated for 30 min at 4°C in 50 mM Tris-HCl, pH 7.4, 100 mM NaCl and 1 mg/ml BSA. Sections were then incubated for 1 hour at room temperature in 50 mM Tris-HCl, pH 7.4, 100 mM NaCl and 2.5 nM [^{3}H]naloxone, and rinsed for 15 min in ice cold 50 mM Tris-HCl, pH 7.4. Caudate sections were wiped off the slides with Whatman GF/B filters, and filters and tissue were dissolved in Cytoscint for scintillation counting. Nonspecific binding was determined in the presence of 2 uM etorphine. Opiate receptor binding was found to be affected by both THC and THC analogs in a dose dependent manner as follows.

THC Concentration	1 uM	100 nM	10 nM	1 nM	0.1 nM
% [^{3}H]naloxone Bound	9.3	43	73	89	99

THC Analog #1(SP-111A)	10 uM	1 uM	100 uM	10 nM	1 nM
% [^{3}H]naloxone Bound	51	65	72	76	97

While naloxone in a sodium-containing buffer is known to favor binding to the mu-subtype opiate receptor, we cannot rule out an interaction with the kappa-subtype opiate receptor based on these data alone. To further elucidate the interaction of THC with opiate binding sites, we examined the effects of THC and THC analogs on the binding of the kappa receptor radioligands, [^{3}H]bremazocine and [^{3}H]EKC. These preliminary studies suggest that the drug-induced alteration in opiate receptor binding is mediated by the mu-subtype opiate receptor. These data together with autoradiographic results illustrating the effects of THC on regional brain opiate receptor binding will be presented. 180.17 EFFECTS OF FEEDING SCHEDULE: INVESTIGATION OF MORPHINE-INDUCED FEEDING. H.L. June,* J.R. Andrade, and M.J. Lewis. (SPON: L.H. Hicks). Dept. of Psychology, Howard University, Washington, D.C. 20059.

A growing body of evidence suggests that opioid agonists can significantly influence the feeding patterns of laboratory rodents. While there have been published reports of enhancement of feeding (Sanger and McCarthy, 1980; Tepperman, Hirst, and Gowdey, 1981), some researchers (Kumar and Stolerman, 1971) have reported an attenuation in feeding behavior. In an attempt to further specify the contingencies under which an opioid agonist influences feeding behavior, morphine was administered intraperitoneally to both 18hr food deprived and non-deprived rats. Then, in a subsequent study, using a separate group of animals, morphine was centrally administered to the lateral hypothalamus.

Male Sprague-Dawley rats were allocated to a deprived (D) (n=10) and a non-deprived (ND) (n=10) group. Food was withdrawn from the animals in the D group 18h prior to the experiment. Food intake measures were taken at 2, 4, and 6h intervals. Animals were injected with saline or morphine (.5, 1, or 1.5 mg/kg, i.p.). Fifteen non-deprived animals were implanted with cannulas in the lateral hypothalamus. Morphine (4.5 µg) was then injected with a 25 guage internal cannula.

The results indicate that non-deprived animals failed to show any significant changes in their consumption with any of the drug doses or time intervals. However, morphine significantly enhanced feeding during the first 2h in non-deprived animals, with the 1mg/kg dose producing the largest effect. At the 4 and 6 hr intervals, a nonsignificant increase was observed with the 1.0 and 1.5 mg/kg doses in these animals. Central administration of morphine resulted in a highly significant increase in feeding during the first 2h, then a moderate increase during the second 2h period. No effect was observed during the last 2h period.

These results suggest that while morphine may cause an increase in feeding, its effect appears to be due to feeding schedule and dosage. These results also confirmed that the effect of morphine on feeding appears to be centrally mediated, as have been reported by others (Tepperman, Hirst, and Gowdey, 1981).

180.18 ALTERATIONS IN OPIOID SYSTEMS AND BEHAVIOR IN ADJUVANT-INDUCED INFLAMMATION OF THE RAT HIND LIMB. C. Stein**, M.J. Millan*, R.M. Arendt*, K. Peter** and A. Herz* (SPON: H.L. Altshuler). *Dept. of Neuropharmacology, Max-Planck-Institut für Psychiatrie, D-8033 Martinsried, F.R.G., +Dept. of Anesthesiology, Klinikum Grosshadern, D-8000 München 70, F.R.G.

We have previously characterized neurochemical and functional changes in adjuvant-induced polyarthritis in rats (Millan, M.J. et al., J. Neurosci., 7:77, 1987; Millan, M.J. et al., J. Neurosci., 6:899, 1986). This study evaluates behavioral characteristics and alterations in opioid systems in rats with adjuvant-induced inflammation of a single hind paw. Male Wistar rats received an intraplantar injection of Freund's adjuvant and developed inflammation within 24 hrs. Paw volume of the affected limb increased gradually up to day 4 and remained stable at about 3 times normal size up to day 35. Rats showed a persistent flexion of the inflamed limb and a reluctance to place weight on the paw. They showed a significant reduction in the rate of body weight gain and in food intake beginning on day 4. Acute nociceptive thresholds to pressure applied to the affected limb and motility (open-field test) were significantly reduced compared to controls. One week after inoculation immunoreactive dynorphin levels were significantly elevated only in the ipsilateral dorsal horn of lumbar spinal cord of affected animals. A supersensitivity to the analgesic action of morphine was seen primarily on the inflamed (as compared to uninflamed) paw. The behavioral and physiological changes suggest that adjuvant-induced inflammation of the hind limb in rats is associated with pain. The biochemical changes suggest that an increased noxious afferent input can modify the activity of DYN-containing neurones in anatomically correlated parts of the spinal cord.

180.19 OPIATE RECEPTORS ARE INCREASED IN REGIONS OF DECREASED GLUCOSE UTILIZATION IN PATIENTS WITH TEMPORAL LOBE EPILEPSY MEASURED BY POSITRON EMISSION TOMOGRAPHY. J.J. Frost, H.S. Mayberg, J.S. Fisher, K.H. Douglass*, R.F. Dannals*, J.M. Links*, S.H. Snyder, H.N. Wagner, Jr.*, Division of Nuclear Medicine, The Johns Hopkins Medical Institutions, Baltimore, MD 21205.

Animal models of epilepsy have indicated a role for opiate peptides and opiate receptors in seizure mechanisms. ^{11}C-carfentanil (CAR) was used to quantitate regional mu opiate receptor binding in patients with partial complex seizures and a unilateral temporal lobe seizure focus determined by electroencephalography. Regional glucose utilization was also measured using ^{18}F-fluorodeoxyglucose (FDG). All patients were studied in the interictal state. Quantification of CAR binding was achieved by compartmental modelling studies which indicated the close relation between the region/occipital cortex activity ratio and the value of K_D/B_{max}; the occipital cortex is used to determine nonspecific binding due to the low number of opiate receptors it contains. The region/occipital cortex ratio did not vary as a function of blood flow since near-equilibrium of CAR binding is attained during the measurement.

There was a significant ($p<.01$) elevation in CAR binding on the side of the electrical seizure focus in the termporal cortex but not in the amygdala or hippocampus in 13 patients. By contrast glucose utilization was decreased in the temporal cortex and amygdala. There was a significant relationship ($r=0.74$, $p=0.012$) between the increase in CAR binding in the temporal cortex on the side of the electrical focus and the decrease in glucose utilization.

The increase in opiate receptors may represent a component of an endogenous anticonvulsant system to limit the spread and severity of seizures as suggested by animal models. Measurement of neuroreceptors by PET in epilepsy patients circumvents many limitations of current animal models of epilepsy and can significantly improve our understanding of neurochemical mechanisms which initiate and modulate seizures.

181.1 LEARNING OF A CLASSICALLY CONDITIONED NICTITATING MEMBRANE/EYELID RESPONSE WITHOUT CEREBELLAR CORTEX. D.G. Lavond, J.E. Steinmetz, and R.F.Thompson. Department of Psychology, Building 420, Jordan Hall, Stanford University, Stanford, CA 94305.

Adult male New Zealand White rabbits had their left cerebellar cortex aspirated of crus I and II, paramedian lobe, the lateral margin of the vermis, and Larsell's HVI. After 1 week of recovery they were trained for classical conditioning of the nictitating membrane/eyelid response. The conditioned stimulus (CS) was a 350 msec, 85 dB SPL white noise. The unconditioned stimulus (UCS) was a 100 msec, 2.1 N/cm^2 corneal airpuff. The CS and UCS overlapped and coterminated on paired trials. Daily training consisted of 12 blocks of 9 trials per block, with the first trial of each block a CS alone test trial and the remaining 8 trials were paired. Group 1 was trained first on the lesioned side for 10 days, then contralaterally for 2 days, and again on the ipsilateral side for 2 more days. Group 2 was trained first on the unlesioned side, then on the ipsilateral side, and again on the contralateral side.

All rabbits learned the response without lateral cerebellar cortex as long as the underlying interpositus nucleus (IN) was undamaged. Learning took substantially longer when trained on the lesioned side (Group 1) than when trained on the unlesioned side first (Group 2). Group 2 took about as many trials for learning as reported previously for unoperated animals. In contrast, no learning occured on a side with damage to IN.

Learning occured very rapidly when Group 1 was switched to training on the unlesioned side regardless of whether IN damage prevented learning on the previous side. We have previously reported that although training is one-sided, learning occurs to some degree on both sides.

Two rabbits with extensive bilateral cortical aspirations, including the anterior cortex and most of the posterior vermis but sparing the flocculus and paraflocculus, did not learn on the side with damage to the IN but did learn to the side with an intact IN.

The present study demonstrates that the lateral cerebellar cortex removed is not essential for learning of the classically conditioned eyelid response. However, this cerebellar cortex normally plays a role in conditioning since it takes substantially longer to learn without it.

181.2 DISRUPTED RETENTION OF THE CLASSICALLY CONDITIONED EYEBLINK RESPONSE IN THE ALUMINUM INTOXICATED RABBIT USING BRAIN STIMULATION AS A CONDITIONED STIMULUS. P. R. Solomon, D. Koota*, J. B. Kessler*, and W. W. Pendlebury. Dept. of Psychology, Williams College, and Dept. of Pathology, Univ. of Vermont College of Medicine.

We have previously reported that intraventricular injection of aluminum chloride in the rabbit disrupts both acquisition and retention of the classically conditioned eyeblink response and that this disrupted conditioning is correlated with the number of neurons that contain neurofibrillary tangles. We also reported that the disrupted conditioning was not related to illness, sensitivity to the air puff unconditioned stimulus (UCS) or motor deficits (Soc. Neuro. Abstr., 12: 380, 1986). We were not, however, able to rule out the possibility that altered sensitivity to the conditioned stimulus (CS) contributed to the conditioning deficits. To test this possibility, we used direct stimulation of the medial geniculate nucleus as a conditioned stimulus. We reasoned that if aluminum still disrupted conditioning, this would rule out the possibility that pathology of the primary sensory systems was responsible.

Rabbits were classically conditioned to emit an eyeblink conditioned response (CR) in response to electrical stimulation of the medial geniculate nucleus (CS) paired with a corneal air puff (UCS: 100 msec, 3 PSI) until they attained a criterion of two consecutive sessions of (100 CS-UCS pairings) of greater than 90% CRs. They then received intraventricular injections of 1% AlC_3 (100 µl), HCl (100 µl, to control for pH) or normal saline (100 µl). Ten days post-injection, each animal underwent a retention test consisting of 50 tone alone presentations. Whereas all saline and HCℓ controls gave at least 90% CRs during retention, no aluminum intoxicated rabbit emitted more than 30% CRs. Subsequent tests indicated that this disruption of conditioning could not be attributed to deficits in motor processes or illness.

Neuropathological examination of the tissue revealed widespread neurofibrillary tangle formation involving dorsal cortex, hippocampus, multiple brainstem nuclei, and cervical spinal cord anterior horn cells.

Considered with the results of previous work, these data suggest that aluminum-induced neurofibrillary degeneration disrupts retention of the conditioned response by affecting central associative processes.

181.3 EFFECTS OF VARYING THE INTERSTIMULUS INTERVAL ON CLASSICAL EYELID CONDITIONING WITH PONTINE NUCLEUS STIMULATION AS A CONDITIONED STIMULUS. J.E. Steinmetz, D.G. Lavond and R.F. Thompson. Department of Psychology, Stanford University, Stanford, CA, 94305.

Stimulating electrodes were chronically implanted in the dorsolateral and lateral pontine nuclei of five groups of adult male New Zealand White rabbits. After a 1 wk recovery period, the rabbits received four daily sessions of classical conditioning training by forward pairing a pontine stimulation CS (a 120 uA, 200 Hz train of 0.1 msec pulses) with a 100 msec air puff US. Each daily training session consisted of 12 blocks of 9 trials per block with the first trial of each block a CS alone presentation and the remaining trials paired presentations of the CS and US. The five groups were given either a 150, 350, 600, 1100 or 2100 msec train of CS brain stimulation that coterminated with the 100 msec air puff US thus producing a 50, 250, 500, 1000 or 2000 msec interstimulus interval (ISI). After the initial four days of training all animals were given two days of training with the brain stimulation CS and air puff US and a 250 msec ISI.

Varying the ISI in the present study produced different levels of conditioning in the five groups of rabbits. Specifically, similar to previous ISI studies which have used peripheral CSs such as tones during training, manipulation of the ISI with the pontine stimulation CS produced a concave or "inverted-U" shaped function between conditioned response frequency and ISI. Relatively robust and rapid conditioning was observed with ISIs of 250 and 500 msec, moderate conditioning was obtained with ISIs of 1000 and 2000 msec and no conditioning was observed when a 50 msec ISI was used. All animals demonstrated robust conditioned responding after they were switched to the 250 msec ISI (i.e., 90% CRs by the second half of Day 2 of training). These data indicate that the characteristic ISI function observed for classically conditioned responses established with peripheral CSs can also be observed when classically conditioned responses are established with direct activation of cerebellar mossy fibers as a CS.

181.4 LESIONS OF THE INTERPOSITUS NUCLEUS ABOLISH EYEBLINK CONDITIONING WHEN STIMULATION OF THE AUDITORY CORTEX IS USED AS A CS. B.J. Knowlton and R.F. Thompson. Dept. of Psychology, Stanford Univ., Stanford, CA. 94305.

Learning and retention of the classically conditioned eyeblink/nictitating mebrane (NM) response is dependent on the cerebellum and associated brainstem circuitry. Lesions of the cerebral auditory cortex do not affect formation of the simple learned response, but they have been shown to abolish heart rate discrimination conditioning when tones of different frequencies are used as CS+ and CS-. In the present study, 8 rabbits received stimulation of the auditory cortex as a CS in the standard NM conditioning procedure. The rabbits were implanted with stimulating electrodes in the auditory cortex, which was localized by evoking auditory field potentials. In 3 additional rabbits, stimulating electrodes were implanted in cerebral cortex in areas where no clear evoked potentials were recorded. These 3 rabbits failed to learn the conditioned response (CR). Of the 8 rabbits with stimulating electrodes in the auditory cortex, 5 were implanted with lesion electrodes in the dentate/interpositus region of the cerebellum ipsilateral to the eye trained. The other 3 were implanted with lesion electrodes in the contralateral dorso-lateral pontine nucleus (DLPN). After recovery from surgery, each rabbit was given paired training with CS stimulation currents beginning at 80 µA. An airpuff served as the US. Each rabbit was given daily sessions of 108 trials each. The CS current was increased by 20 µA each day, until learning occurred or until a maximum of 10 training sessions had been given. After overtraining, each rabbit received a lesion to the dentate/interpositus (DI) or the DLPN. After recovery, these rabbits were tested for CR retention. The 4 rabbits in which the anterior interpositus nucleus was destroyed did not relearn the CR in at least 5 days of training. These rabbits all learned the CR when trained on the contralateral eye. In one DI rabbit, much of the interpositus was spared and relearning took place. All of the rabbits with unilateral DLPN lesions retained the CR. These results suggest that stimulation of the auditory cortex can act as a CS in NM conditioning, and that it is similar to a peripheral CS in that conditioning is abolished by anterior interpositus lesions in both cases. By using direct brain stimulation, the connections between auditory cortex and the essential circuit for NM conditioning can be investigated.

Supported by grants to RFT from the NSF (BNS8106648) and the McKnight Foundation, and an NSF predoctoral fellowship to BJK.

181.5 PROPOSED NEURAL PATHWAYS FOR CONDITIONED AND UNCONDITIONED STIMULI IN THE FEAR-POTENTIATED STARTLE PARADIGM. J.M. Hitchcock & M. Davis Depts. of Psychology & Psychiatry, Yale Univ., Ribicoff Res. Fac., Conn. Mental Health Ctr., 34 Park St., New Haven, CT 06508.

Classical conditioning is thought to involve the convergence of neural, pathways transmitting conditioned stimulus (CS) and unconditioned stimulus (US) information. We have previously found that the central nucleus of the amygdala and its efferent projection to the brainstem startle reflex pathway are necessary for fear-potentiated startle (Hitchcock & Davis, Beh. Neurosci., 100, 1986; Mondlock & Davis, Neurosci. Abs., 1985), a model of conditioned fear in which the acoustic startle reflex is enhanced in the presence of a light previously paired with shock. The present studies sought to delineate the neural pathways that transmit CS (light) and US (footshock) information to the amygdala.

To investigate the CS pathway, rats were trained with 20 light-shock pairings. One day later, separate groups of rats received sham operations or bilateral electrolytic lesions of various visual structures. Consistent with previous results (Tischler & Davis, Brain Res., 276, 1983), preliminary data indicate that lesions of the lateral geniculate nucleus (LGN) and aspiration of the visual cortex block performance of fear-potentiated startle tested after a longer recovery time (6 days) than previously used. Lesions of the insular and surrounding cortex, which receives afferents from the visual cortex and projects to the amygdala, also block performance. Further studies will delineate more exactly the critical cortical areas.

To investigate the US pathway, three tests were used: a) enhancement of startle that occurs during the 5-20 minutes after presentation of 10 brief footshocks in rapid succession (shock sensitization), b) acquisition of fear-potentiated startle (lesions made before training), and c) performance of fear-potentiated startle (lesions made after training, before testing). We have found that lesions of the central nucleus of the amygdala block shock sensitization, acquisition, and performance of fear-potentiated startle. However, lesions in a US pathway to the amygdala should block shock sensitization and acquisition, but not performance of fear-potentiated startle, because the US is not necessary for performance. Thus far, these criteria have been satisfied by combined lesions of the medial part of the medial geniculate nucleus (mMGN) and the posterior intralaminar nucleus (PIN) of the thalamus, which receive spinal afferents and project directly to the central nucleus of the amygdala.

Our current working hypothesis is that a CS pathway from the LGN to the visual cortex to the insular cortex and a US pathway from the spinal cord to the mMGN/PIN converge at the amygdala, which then projects to the startle reflex pathway and enhances the startle reflex during fear-potentiated startle.

181.6 ENHANCEMENT OF ACOUSTICALLY- AND ELECTRICALLY- ELICITED STARTLE BY ELECTRICAL STIMULATION OF THE AMYGDALA: LOCUS OF MODULATION AND TEMPORAL RELATIONSHIP. J.B. Rosen and M. Davis. Dept. of Psychiatry, Yale Univ., Conn. Mental Health Ctr., Ribicoff Res. Fac., 34 Park St., New Haven, CT 06508.

The acoustic startle response can be enhanced in the presence of a cue previously paired with a shock (fear-enhanced startle). Startle elicited by electrically stimulating various points along the startle pathway can also be enhanced by a fear-conditioned stimulus (Berg & Davis, Behav. Neurosci., 99:191-199, 1985). Previous work from our laboratory has shown that lesions of the amygdala block fear-enhanced startle (Hitchcock & Davis, Behav. Neurosci., 100:11-22, 1986) and that electrical stimulation of the amygdala enhances acoustic startle (Rosen & Davis, Neurosci. Abstr., 12:517, 1986). The present study demonstrates that activation of the amygdala can enhance both acoustically- and electrically-elicited startle in a very precise and predictable spatial and temporal manner.

Unipolar electrodes were chronically implanted in the amygdala and the acoustic startle circuit [ventral cochlear nucleus (VCN), paralemniscal region of the nucleus of the ventral lateral lemniscus (VLL), nucleus of the reticularis pontis caudalis (RPC) or the medial longitudinal fasciculus (MLF)] of Sprague-Dawley rats. Following recovery, rats were placed in a startle cage and presented with electrical stimulation of the amygdala (0.1 ms cathodal pulse) and either a 20 ms white noise burst or bilateral stimulation of the various nuclei along the startle pathway (1.0 ms cathodal pulse). Whole body startle amplitude was measured by an accelerometer attached to the cage, and in some cases, startle was measured by recording EMG responses through electrodes implanted into neck muscles.

Maximal enhancement of acoustic startle by amygdala stimulation occured when amygdala stimulation was given simultaneously with the onset of the acoustic startle stimulus. The time between amygdala stimulation and maximal enhancement of startle elicited electrically from the VCN or the VLL increased reliably to 1 and 3 ms, respectively. Amygdala stimulation did not enhance startle elicited electrically at the RPC or the MLF.

In agreement with previous results of fear-enhanced startle, modulation of startle by activation of the amygdala seems to enter the startle pathway at the RPC. The transit time from the amygdala to the startle circuit is approximately 3-4 ms. This suggests that only one or two synapses lie between the amygdala and startle circuit. Neuroanatomical tracing studies are in progess to delineate this pathway.

181.7 SENSITIZATION OF ACOUSTICALLY AND ELECTRICALLY ELICITED STARTLE RESPONSES BY FOOTSHOCK. N. Boulis*, M. Davis (SPON: M.Bowers), Departments of Biology and Psychiatry, Yale University, New Haven, CT 06508.

The acoustic startle reflex can be facilitated by the presentation of either a single footshock or a series of footshocks presented in rapid succession (footshock sensitization). This sensitizing effect develops gradually after cessation of footshocks, reaches a peak in approximately 10-20 min, and gradually dissipates over the next 20-40 min. The acoustic startle response is a short latency reflex mediated by brainstem and spinal cord structures. The present study evaluated the anatomical locus along this pathway where footshocks might ultimately alter neural transmission and, hence, the behavioral response.

A total of 32 rats were implanted with bilateral electrodes in either the ventral cochlear nucleus (VCN), an area just medial to the ventral nucleus of the lateral lemniscus (VLL), or the nucleus reticularis pontis caudalis (RPC). These sites contain the three brainstem synapses of the acoustic startle circuit (Davis et al., J. Neurosci., 1982, 2, 791-805). Following recovery, rats were given two matching sessions intended to establish levels of acoustic and electric stimulation that would elicit similar startle amplitudes. Two days later all animals were given a test session which consisted of an hour of alternating acoustic and electric stimulation presented at 30 sec intervals. After 20 min, half of the animals also received a train of ten footshocks (0.5 sec, 0.6 mA) presented at a rate of 1 shock per sec. Two days later the same test conditions were repeated, except that rats which previously did not receive footshocks were now given footshocks and vice-versa.

In all groups, acoustic startle elicited following shocks was significantly elevated over the response level present in the no-shock condition, indicating that prior footshock sensitizes the acoustic startle response. Startle elicited electrically from the VCN and the VLL were similarly facilitated by the presentation of prior footshock. In contrast, startle elicited from the RPC showed no sensitization, despite the fact that acoustic startle measured in these same animals during the same test session was facilitated. Based on these data, we conclude that footshock sensitization ultimately alters transmission at the RPC. A similar pattern of results was found previously when startle was facilitated in the presence of a light previously paired with footshocks (i.e., a conditioned fear stimulus, Berg & Davis, Behav. Neurosci., 1985, 99, 191-199). These and other data suggest that specific brainstem loci may mediate the behavioral changes that occur during footshock sensitization and conditioned fear.

181.8 **THE LATERAL AMYGDALOID NUCLEUS: SENSORY INTERFACE OF THE AMYGDALA IN FEAR CONDITIONING?** *Piera Cicchetti*, Joseph E. LeDoux, and Donald J. Reis* (SPON: M.S. Gazzaniga). Division of Neurobiology, Cornell Univ. Med. Coll., New York, NY 10021.

A specific subcortical pathway, the geniculo-amygdala projection, mediates the classical conditioning of emotional responses to acoustic stimuli in the rat (LeDoux et al., J. Neurosci., 4, 1984, 683-698; Neurosci., 17, 1986, 615-627). Within the amygdala, the central nucleus provides a link between the geniculo-amygdala pathway and efferent motor systems controlling both autonomic and behavioral emotional responses (Iwata et al., Neurosci. Abstr., 1986). The sensory receptive area of the amygdala during conditioning is unknown. However, anatomical tracing studies indicate that the lateral amygdaloid nucleus receives a major input from the acoustic thalamus (LeDoux et al., J. Comp. Neurol., 242, 1985, 192-213) and projects to the central nucleus (Krettek and Price, J. Comp. Neurol., 178, 1978, 225-254). The lateral amygdaloid nucleus may therefore serve as the sensory interface of the amygdala during fear conditioning. If so, lesions confined to this structure should disrupt fear conditioning.

Studies were performed on male Sprague-Dawley rats. Bilateral electrolytic lesions were placed in the lateral amygdala (n=6) or in the striatum immediately above the lateral amygdala (n=6). The lateral amygdala was also lesioned unilaterally (n=5). Controls were either unoperated (n=6) or in operated controls the electrode was lowered into the lateral amygdala bilaterally without passing current (n=8). After 14d, the animals were instrumented for computer-assisted recording of arterial pressure (AP) and subjected to classical conditioning trials involving the pairing of a pure tone with footshock. The next day, changes in AP and freezing behavior (cessation of somatomotor activity) elicited by the acoustic conditioned stimulus were measured during extinction trials (LeDoux et al, J. Neurosci., 4, 1984, 683-698). The rats were then sacrificed and the brains removed and processed histologically.

In unoperated controls the CS elicited increases in AP (18 ± 4 mmHg) and induced freezing behavior (114 ± 5 sec.). Comparable responses were seen in the operated control group (AP: 18 ± 3; freezing: 102 ± 14) and in the groups with striatal lesions (AP: 20 ± 3; freezing: 84 ± 17) or unilateral lesions of the lateral amygdala (AP: 15 ± 3; freezing: 103 ± 16). In contrast, bilateral lesions of the lateral amygdala greatly reduced the magnitude of both the AP (3 ± 1) and freezing (38 ± 18) responses ($p<.01$).

Lesions of lateral amygdala thus disrupt the classical conditioning of both autonomic and behavioral emotional responses. We propose that the lateral amygdala is a critical sensory link in the neural pathway through which acoustic stimuli are transformed into emotional signals.

181.9 AUDITORY CORTEX LESIONS DISRUPT THE ACQUISITION OF DIFFERENTIAL BRADYCARDIAC CONDITIONING TO TONAL STIMULI IN RABBITS.
A.H. Teich*, C.G. Gentile*, P.M. McCabe, T.W. Jarrell*, R.W. Winters, D.L. Liskowsky, and N. Schneiderman. Dept. of Psych., Univ. of Miami, Coral Gables, FL 33124.

Previous findings from our laboratory indicate that lesions of the auditory cortex disrupt the retention of differentially conditioned bradycardiac responses to tonal stimuli in rabbits (Jarrell et al., in press). In the present experiment, the effect of lesions of the auditory cortex on the acquisition of differential bradycardiac conditioning was examined. Lesions were made in either the auditory cortex or the visual cortex. After 7 days of recovery, animals received 7 days of differential Pavlovian bradycardiac conditioning in which one tone (CS+) was paired with the unconditioned stimulus, and another tone (CS-) was never paired with the unconditioned stimulus. All animals demonstrated differential conditioning during the first 3 days of conditioning. On days 4 - 7, however, auditory cortex lesioned animals did not exhibit significant differential heart rate conditioning; visual cortex lesioned animals showed no loss of conditioning during this period. The loss of differential conditioning in animals with lesions in the auditory cortex appears to be due to an increased response magnitude to the CS-. These data further support the hypothesis that auditory cortex plays a role in differential conditioning of bradycardia to acoustic stimuli (Jarrell et al., in press). It is suggested that a corticothalamic pathway is involved in the inhibition of the response to the CS-.

Supported by NIH HL07426 and HL 36588.

181.10 THE PERIAQUEDUCTAL GRAY: PROJECTIONS TO CARDIOREGULATORY NUCLEI AND CONTRIBUTIONS TO CONDITIONED BRADYCARDIA IN THE RABBIT.
A. Wilson* and B.S. Kapp. Dept. of Psychology, Univ. of Vermont, Burlington, VT 05405.

Evidence suggests that the amygdaloid central nucleus (ACE) is involved in the acquisition (Kapp et al., 1979) and retention (Gentile et al., 1986) of vagus-mediated conditioned bradycardia in the rabbit, quite possibly via direct projections to the nucleus of the solitary tract (NTS) and dorsal vagal nucleus (DVN). The latter contains preganglionic cardioinhibitory neurons in this species. However, the ACE also projects to other regions which in turn project to the NTS/DVN complex, and which may also contribute to the conditioned response. One such region, the midbrain periaqueductal gray (PAG), has been implicated in cardioregulation and has recently been demonstrated to project to the NTS in the cat (Bandler et al., 1986). The present experiments were conducted to determine the extent to which projections from the PAG to the NTS/DVN complex exist in the rabbit and the degree to which lesions of the PAG affect the retention of conditioned bradycardia.

New Zealand rabbits received injections of Fast Blue (FB; 5%; 50-150 nl) along the rostral-caudal extent of the NTS/DVN complex. Two to three weeks later the animals were perfused and sections were examined using fluorescent microscopy for the presence of retrogradely labeled cells in the PAG. Labeled neurons demonstrated a predominantly ipsilateral distribution primarily within the ventrolateral region of the caudal PAG. A few were also present in the dorsolateral region.

Additional rabbits were assigned to one of three groups. Two groups (lesion and sham-lesion) were prepared surgically with bilateral lesion electrodes aimed at the ventrolateral PAG. The third group served as an unoperated control group. Following surgical recovery all animals received Pavlovian fear conditioning consisting of 20 conditioning trials during which a 5.0 second tone conditioned stimulus (CS) immediately preceded the presentation of a 0.5 sec, 2.0 mA shock unconditioned stimulus. Lesions were made 24 hours after conditioning and retention of the bradycardic response to the CS was tested 24 hours later by presenting 20 CS alone trials. Rabbits with lesions of the PAG demonstrated an attenuation of the magnitude of the conditioned bradycardic response when compared with sham-lesioned and unoperated control rabbits.

The demonstrated projections from the ACE to the ventrolateral PAG in rabbit (Kapp et al., 1986), taken together with the results of the present study, suggest that in addition to a direct pathway from the ACE to the NTS/DVN complex, an oligosynaptic pathway from the ACE to PAG to the NTS/DVN complex may contribute importantly to conditioned bradycardia in the rabbit. Supported by PHS NS16107 and a Grant-in-Aid from the American Heart Association.

181.11 MEDIODORSAL THALAMIC LESIONS IMPAIR DIFFERENTIAL PAVLOVIAN HEART RATE CONDITIONING.
S.L. Buchanan and D.A. Powell. WJB Dorn Veterans' Hospital and University of South Carolina, Columbia, SC.

We have previously demonstrated that midline prefrontal cortex, which receives projections from the mediodorsal nucleus of the thalamus (MD), is involved in the mediation of conditioned autonomic changes, and that electrical or chemical stimulation of MD evokes cardiovascular responses in the conscious rabbit. The present experiment examined the effect of ibotenic acid (IA) lesions of MD on differential Pavlovian heart rate conditioning. Bilateral ibotenic acid (Sigma) lesions were made by infusing .5 µl (10 µg/µl) at each of two injection sites per side. Control animals received injections of the phosphate buffer vehicle. After recovery, all animals received two 50-trial sessions of Pavlovian conditioning. CSs were 304 and 1216 Hz tones (4-sec duration); the US (on CS+ trials) was a .25 sec, 2.5-3.0 mA paraorbital shock. On each trial, heart rate was recorded for each interbeat interval (IBI) for 10 beats prior to tone onset and for the duration of the tone. On the day before Pavlovian conditioning was begun, the HR orienting response (OR) to tone-alone presentations was assessed in response to ten 4-sec presentations of one of the tones to be used as CSs. Histological analysis of brain sections of 8 animals with IA lesions revealed bilateral neuronal degeneration in MD in all animals. Anterior nucleus damage occurred in 1 animal. Anterior and medial portions of MD were destroyed in all animals, but more posterior portions of MD were intact in 4 animals. Both the HR component of the OR and the HR CR were in all cases decelerations from pre-tone baseline. The HR OR appeared to be slightly enhanced in IA-lesioned animals, although this effect was not significant. Ibotenic acid lesions significantly impaired HR discrimination, due to greater CS- responding in these animals, particularly during the first session. Moreover, these animals demonstrated somewhat larger CR magnitude to the CS+ early in training. These data suggest that MD does not participate in the "vagal drive" necessary for conditioned bradycardia, but may play a role in association formation per se.

181.12 THE AMYGDALA, LONG-TERM HABITUATION OF THE ACOUSTIC STARTLE RESONSE, AND FREEZING IN RATS.
R. N. Leaton and W. F. Supple, Jr. Department of Psychology, Dartmouth College, Hanover, N. H. 03755.

The amygdala often is associated with the central modulation of fear. Lesions of the central nucleus of the amygdala (CNA) block conditioned bradycardia in rabbits (Kapp, et al., 1979) and reduce many other signs of conditioned fear (Kapp, Pascoe, & Bixler, 1984). Amygdala lesions reduce both conditioned and unconditioned freezing in rats (Blanchard & Blanchard, 1972) and block potentiated startle (Hitchcock & Davis, 1986). We have shown significant correlations between freezing, potentiated startle, and startle amplitude generally (Leaton & Borszcz, 1985). Also we have found increased freezing over the early trials in acoustic startle habituation paradigms, freezing that is apparently conditioned to the contextual cues of the startle chamber (Borszcz, Cranney & Leaton, 1984). Since freezing, or the fear-state indicated by freezing, elevates startle amplitudes, it may mask the development of habituation. Given these various outcomes we hypothesized that any brain manipulation that reduced fear may produce what appears to be faster than normal habituation. We found that lesions of the ventral periaqueductal gray increased long-term habituation of the acoustic startle response, providing some support for this hypothesis (Borszcz, Cranney, and Leaton, 1984). We now report the effects of CNA lesions on long-term habituation of the acoustic startle response.

Acoustic startle response was measured to 118-dB, 100-msec, white-noise bursts in 120-day old Long-Evans rats. Each rat received 3 daily sessions in the startle chamber with 120 min between sessions. Each session consisted of 8 presentations of the startle stimulus on a 60-sec interstimulus interval. Rats were tested in this way every other day to complete 4 test days. Freezing behavior was monitored during the 10 sec preceding each startle stimulus. Two groups of 24 rats were tested; one following bilateral electrolytic lesions of CNA and one following sham operations.

Rats with amygdala lesions showed significantly greater reductions in startle amplitude within the first few sessions and across days than did the shams, appearing thus to habituate faster. Amygdala lesions did not affect initial response amplitude, and the group differences had disappeared by the last test day. The groups did not differ initially on freezing behavior, but the shams increased freezing significantly over trials during the first several sessions. After this initial increase, the freezing differences decreased over days as the shams reduced freezing behavior. By the last test day group differences in freezing were no longer significant. We conclude that fear, indexed by freezing behavior, was conditioned to contextual cues and produced elevated startle amplitudes which masked the development of habituation in the sham operated animals. Amygdala lesions, by reducing fear, reduced its response amplifying effects and therby enhanced the apparent development of long-term habituation.

181.13 EFFECT OF OLIVOCEREBELLAR TRACTOTOMY ON A CONDITIONED LIMB FLEXION RESPONSE IN THE CAT. T.J. Voneida, D. Christie-Jefford* and R. Bogdanski*, Department of Neurobiology, Northeastern Ohio Univ. College of Medicine, Rootstown, OH 44272.

This study represents part of a long term effort to identify those brain structures and pathways which are critical to the performance of a conditioned limb response. A limb flexion response (LFR) was conditioned to a tone conditional stimulus (CS) using shock to the limb as the unconditional stimulus (US). Thirteen cats underwent surgical section of the olivocerebellar tracts by a midline cut between the nuclei following attainment of criterion performance (2 scores of at least 80% and a third of no less than 75% on 3 consecutive days). Twelve of the 13 subjects retained the CR postoperatively, showing variable degress of loss, and all 12 were able to attain a criterion level of performance with training. The CR was abolished in one animal, though the unconditional response remained intact.

These results (with the exception of one subject) are counter to those reported by Yeo, Hardiman and Glickstein('86) following dorsal accessory olivary lesions in the rabbit following acquisition of a conditioned nictitating membrane response.

Possible discrepancies between the two studies will be discussed, including species differences, differences in training paradigms and operative procedures.

181.14 AGE OF LESION BUT ALSO AGE AT TESTING AND REWARD CONTINGENCIES DETERMINE DISCRIMINATION LEARNING AND TRIAL-UNIQUE OBJECT RECOGNITION IN NORMAL AND HIPPOCAMPECTOMIZED INFANT RHESUS MACAQUES. T. Alexinsky*, L. Rehbein* and H. Mahut, Psychol. Dept., Northeastern Univ., Boston, MA 02115

Five to six years following removal of hippocampus in infancy, monkeys were significantly impaired on a trial-unique delayed nonmatching-to-sample object recognition task (DNMS) but they were not impaired on the concurrent object discrimination task (COD) with repeated trials in which one member of each of the 8 pairs of objects remained the positive stimulus (Mahut and Moss, The Hippocampus, 4:241, 1986). Possibly, the functional dissociation of performance on the two types of tasks was due to practice with object discrimination tasks in the intervening years. Therefore, groups of 5 unoperated and 5 hippocampectomized infants were tested on both tasks close to the time of surgery.

One-stage, bilateral hippocampectomies were performed at 57, 66, 70, 77 or 81 days of age. Pre-training consisted of hue and five two-choice object discriminations. Testing on the COD task began when normal infants were 5-8 mos, and operated infants were 4½-5 mos of age. No significant group differences in performance were found. Unexpectedly, however, all infants performed better than did any of the 23 adult normal monkeys tested previously (Moss, Mahut and Zola-Morgan, J. Neurosci., 1:227, 1981) or 7 unimpaired adult monkeys after hippocampectomy sustained in infancy (Mahut and Moss, op. cit.). Thus, the capacity that mediates discrimination learning not only matures early but appears to function better early rather than later in life.

The trial-unique object recognition task was given when normal infants were 6-9 mos, and operated infants 5-7 mos. of age. Since infant monkeys are afraid of novelty and the capacity to learn object discrimination reversals does not fully mature until about 2 yrs of age (Mahut and Zola, Abst. Soc. Neurosci., 3:428, 1977; Mahut and Moss, op. cit.), the object recognition task was administered with the matching-to-sample method (DMS). Infants in both groups learned readily the basic task with 10 sec. delays between the presentation of the sample and its re-presentation with a novel object: 90% correct responses in 100 consecutive trials were made after means of 524 and 478 trials with 169 and 142 errors, for the two groups, respectively. For comparison, two normal control adult monkeys took 860 and 900 trials, with 241 and 260 errors, respectively. We are currently introducing longer delays (30-130 sec). This may reveal the state of maturation of mnemonic processes in unoperated infants and it remains to be seen whether delays will lead to a separation of performance between unoperated and operated infants.

181.15 DISASSOCIATION OF VISUAL AND OLFACTORY CONDITIONING IN THE NEO-STRIATUM OF RATS. Marc Viaud and Norman M. White, Department of Psychology, McGill University, 1205 Dr. Penfield Ave., Montreal, Quebec, H3A 1B1, Canada.

A role for the caudate nucleus in learning and memory has been established in studies using lesion (Dunnett & Iversen, Beh Br Res, 6: 213, 1982), stimulation (Wyers & Deadwyler, Physiol Beh, 6: 97, 1971) and neurochemical (Prado-Alcala & Cobos-Zapiain, Neurosci Lett, 14: 253, 1979) techniques. The topographical projection of cortex to striatum (Webster, J Anat, 95: 532, 1961) has led to the hypothesis that anatomically linked regions of the two structures may have similar functions. We made use of this hypothesis to study the involvement of two striatal areas in conditioning. We tested the effect of lesions in the posteroventral striatum (innervated by visual cortex) or in the ventrolateral striatum (innervated by olfactory cortex) on acquisition of a conditioned emotional response (CER) in the presence of a visual or an olfactory conditioned stimulus (CS).

Small bilateral electrolytic lesions were made either in the posteroventral (PV) or in the ventrolateral (VL) areas of the striatum. Sham operated rats were used as controls. Ten days after surgery the rats were water deprived and familiarized with a conditioning box containing a drinking tube for 15 minutes on three consecutive days. On day 4 each rat was placed into the conditioning box with no water available. For half the rats in each group a visual CS (a bright light) was present; for the other half an olfactory CS (a novel smell) was present. Each rat received 10 foot-shocks in the presence of the CS. For the next three days all rats were allowed to drink in the conditioning box. The sum of the latencies to begin drinking over the three days was taken as the measure of conditioning. In both the visual and olfactory conditioning situations the latency was significantly longer for sham-operated animals tested in the presence of the appropriate CS than it was for those tested in the absence of the CS, demonstrating that conditioned responses had been established.

Rats with PV lesions showed impaired acquisition of the visual CER compared to both rats with VL lesions and sham operated rats. In contrast, rats with VL lesions showed impaired acquisition of the olfactory CER compared to rats with PV lesions and sham operated rats.

These findings constitute a double disassociation: damage to the PV area of the striatum impaired the ability of rats to acquire sensori-motor associations involving visual but not olfactory information. Damage to the VL area of the striatum produced impairment of sensori-motor associative memory involving olfactory information but had no effect when visual information was involved. These findings support the hypothesis of regional heterogeneity in the striatum with respect to the nature of the information processed in learning and memory. They also suggest that the different areas of the caudate may perform similar learning-and-memory-related functions using information from a different modality in each case.

181.16 2-DEOXYGLUCOSE MAPPING OF BRAIN STRUCTURES ACTIVATED DURING IMPRINTING RELATED BEHAVIOR. S.C. Müller * and H. Scheich (SPON: ENA), Technical University, Institute of Zoology, Schnittspahnstr.3, 6100 Darmstadt, F.R.G.

The separation of a young chick from cage mates is a situation similar to the separation from the hen under natural conditions. A separated chick having visual and auditory contact to the group enters a state of arousal as indicated by EEG-recordings, while the vocalizations change to intense distress calling. The separated chick exhibits a specific pattern of 14C-2-deoxyglucose labeling in the brain compared to control chicks remaining in the group (Müller and Scheich, Behav Brain Res 19: 93, 1986). Enhanced labeling was found in three rostral forebrain areas, i.e. an area in the wulst (HAD), a lateral portion of neostriatum/hyperstriatum ventrale (LNH) and in a portion of median neostriatum/hyperstriatum ventrale (MNH). The same pattern of 2DG incorporation was described in young acoustically imprinted Guinea fowl chicks, when they heared the imprinting stimulus during 2DG (Maier and Scheich, Proc Natl Acad Sci 80: 3860, 1983). Therefore we conclude, that social separation is a useful paradigm for analyzing neuronal circuits also involved in filial imprinting.

In a quantitative densimetric analysis of 2DG autoradiographs 18 different brain areas were compared in separated chicks and control animals remaining in the group. In the forebrain of separated animals enhanced metabolic activity was found in addition to the three areas HAD, MNH and LNH in the lobus parolfactorius (LPO), in a dorsolateral area of the neostriatum caudale (Nd) and in an dorsolateral area of archistriatum ventrale (Av). Subtelencephalic structures with enhanced labeling were the central mesencephalic grey and the lateral habenula. Monocular chicks while separated develop pronounced asymmetric labeling in the visual nuclei and in HAD and LNH. The latter are in close topographical relation to visual projection areas and therefore assumed to be higher visual centers. In MNH auditory evoked potentials were recorded, characterized by latencies of about 25 ms and by habituation to pure tones.

Interestingly, comparable areas in songbirds were described to be involved in song learning, another imprinting like process. In contrast to the organization in chicks, these areas form discrete nuclei in songbirds. They are area X in the LPO, the magnocellular nucleus of the anterior neostriatum (MAN), HVc of the caudolateral neostriatum and the robust nucleus (RA) in the archistriatum intermedium.

We assume the involvement of similar neuronal circuits in early song learning and filial imprinting.

181.17 LONG-TERM BEHAVIORAL AND HISTOLOGICAL EVALUATION OF THE CONSEQUENCES OF "TOTAL" CHOLINERGIC FOREBRAIN NUCLEUS LESIONS IN THE RAT. D.G. Spencer, Jr., E. Horváth*, T. Schuurman*, U. Benz*, and J. Traber*. Neurobiology Department, Troponwerke (Bayer), Neurather Ring 1, D-5000 Köln 80, FRG.

In a previous study, we found that rats that were pre-trained in a 4-hour delay version of the 8-arm radial maze task and then given multi-site ibotenic acid lesions of the nucleus basalis magnocellularis showed a subsequent deficit in this task. The deficit disappeared over the course of the next few weeks of retraining, however, as also reported for example by Bartus and colleagues (Pharmacol. Biochem. Behav., 23:125, 1985), but performance remained sensitive to disruption by scopolamine. A further group of rats was then trained to nearly perfect performance of the same task (4-hour delay interpolated between arm choices 6 and 7) and then given either sham surgery or a bilateral multisite ibotenic acid lesion along the entire length of the forebrain cholinergic nuclei: medial septum, nuclei of the vertical and horizontal limbs of the diagonal band, and substantia innominata/nucleus basalis magnocellularis. A total of 16 ibotenate injection sites were required, in which relatively low concentrations and volumes were used: ibotenate (1 mg/ml) was prepared in a saline/$NaHCO_3$ solution (pH 7.4), and volumes of 0.5- 0.6 µl, depending on site, were slowly injected. Rats so treated showed a large post-delay deficit in the 8-arm radial maze relative to controls, and this deficit did not recover over 4 months of retraining. Control percent accuracy post-delay during this period averaged approximately 70 % while that of the lesioned rats, about 45 %. Thereafter, a number of further behavioral tests were performed with the lesioned and control rats, along with an additional grow up of inexperienced age-matched subjects. In two tests of gross behavior and open-field performance, lesioned rats showed more locomotion and rearing and much less immobility and scratching-type grooming. Lesioned rats also displayed a large step-through passive avoidance deficit in relation to controls. In shuttlebox active avoidance, however, lesioned rats had a faster acquisition than controls, as well as showing increased inter-trial crossover activity. Learning performance in a water labyrinth, on the other hand, was disturbed in lesioned rats. In general, these data are very similar to the results of acute treatment with large doses of scopolamine. Histological examination and choline acetyltransferase activity determination confirmed the large extent of elimination of magnocellular acetylcholinesterase-positive forebrain cells and cholinergic innervation by the lesion. The present results support the use of animals so lesioned as a non-recovering model of human dementia.

181.18 THE EFFECT OF TRAINING SCHEDULE IN THE MORRIS WATER MAZE ON RATS WITH NUCLEUS BASALIS LESIONS. R.J. Mandel, F.H. Gage, and L.J. Thal. Dept. of Neurol., San Diego VA Med. Ctr. and Dept. Neurosci., Univ. of Calif., San Diego, La Jolla, CA 92093

Rats with excitotoxic lesions of the nucleus basalis (NBM) exhibit performance deficits compared to controls in the Morris Water Maze task. However, treatments designed to attenuate these impairments have had difficulty obtaining significant results. The present study was designed to examine whether different training regimens could further separate the learning curves of NBM-lesioned animals and nonlesioned controls, thus affording the task more sensitivity to potentially ameliorative treatments.

Thirty male F-344 rats received bilateral NBM lesions using 4.5 ug of ibotenate in 1 ul infused over 20 minutes. Thirty sham operated rats served as controls. The animals were divided into three experimental groups each consisting of 10 lesioned and 10 control rats. Training in the water maze consisted of: (1) 4 trials per day (standard) with no intertrial interval (ITI), (2) 4 trials per day with a 10 min ITI or, (3) 2 trials per day (2 trial) with no ITI. Each group was tested in the water maze for 5 consecutive days, followed by a 2-day rest, followed again by 5 additional consecutive testing days.

The two-trial paradigm resulted in an average difference in latency to find the platform between the control and lesioned animals of 22.2 sec/day. The standard paradigm resulted in an average difference in latency of only 9.8 sec/day which was not significantly different from escape latencies obtained in the 10 min ITI paradigm. In addition, the strategies of the animals as measured by percent time in the outer annulus supports the latency data. These data suggest that the two-trial regime is more difficult and may therefore be more sensitive to treatments designed to reverse the learning deficits caused by NBM lesions.

181.19 EFFECTS OF IBOTENIC ACID LESIONS OF THE HIPPOCAMPUS ON ACQUISITION OF A RADIAL MAZE MEMORY TASK. J.R. Leu[1], L.S. Johnson*[1] and L.E. Jarrard[2]. Department of Medical Neurosciences, Walter Reed Army Institute of Research, Washington, DC 20307-5100[1] and Department of Psychology, Washington and Lee University, Lexington, VA 24450[2].

Ibotenic acid, a neurotoxin which destroys neuronal cell bodies but spares fibers-of-passage, was used to destroy selectively the hippocampal cells of young adult male rats. This procedure utilizes multiple, bilateral, microliter injections of the neurotoxin to destroy preferentially the hippocampal cell bodies while avoiding collateral damage to adjacent structures. The resulting lesions include the dentate gyrus and the CA1-CA3 pyramidal cells, but avoid the subiculum.

Previous work by Jarrard has determined that ibotenate lesions of the hippocampus, unlike conventional lesions, do not permanently disrupt post-surgical performance in preoperatively trained rats. In this previous work no lasting differences were found between control and lesioned rats on retention of either a spatial or a non-spatial limited-baiting radial maze task. These results raise the question of whether ibotenate hippocampal lesions in rats cause any impairment suggestive of bitemporal amnesic syndrome in humans.

In the present study the primary question was whether naive rats with selective complete hippocampal lesions could learn a radial maze procedure, or whether learning would be prevented in a way suggestive of anterograde amnesia. Using an eight-out-of-eight arm baiting procedure in a radial maze, rats were allowed to explore the maze and consume food rewards. After a rat returned to the center of the maze following an excursion into an arm, the doors were closed for all eight arms to restrict the rat briefly to the center of the maze. This procedure disrupts patterned response strategies and increases the extent to which the animal must rely on memory to avoid re-entering previously visited arms. The lesioned animals (N=8) were markedly impaired relative to the control animals (N=8). Eighteen days after the operated and unoperated control groups had reached asymptotic performance averaging under one error (repeated arm entry) per trial, the hippocampal group still averaged approximately 8-10 errors per trial.

181.20 IMPAIRED MOTOR LEARNING IN HUNTINGTON'S AND PARKINSON'S DISEASES. W. Heindel*, D. Salmon, N. Butters, and C. Shults. Psychology Service and Depts. of Psychiatry and Neurosciences, VA Medical Ctr. and Univ. of Cal. Sch. of Med., San Diego, CA 92161.

A previous study in our lab found patients with Huntington's Disease (HD), but not patients with Alzheimer's Disease (AD), to be severely impaired in their ability to acquire a motor skill. Since HD patients at different stages of functional disability did not differ in their level of performance, their impairment was attributed to an actual learning deficit and not simply to a motor performance deficit associated with their chorea. These results provided support for a critical role of the basal ganglia in skill learning. The present study extends these results by comparing the performance of HD patients to that of patients with idiopathic Parkinson's Disease (PD) on the same motor task.

A pursuit rotor apparatus was used to assess motor skill learning in 14 HD patients, 16 PD patients, and groups of 10 and 15 control subjects age-matched to the HD and PD groups, respectively. Subjects were told to try to maintain contact between a stylus held in their preferred hand and a small metalic disk on a rotating turntable. The total time on target was recorded for each 20 sec. trial. All subjects were given 6 blocks of 4 trials each, spaced over a period of 2 hours. The initial level of performance was equated across all groups at about 5 sec. per trial by individually adjusting the turntable speed for each subject during a block of practice trials. All subjects were administered the Dementia Rating Scale (DRS), and the PD patients were also rated from 0 (absence of symptom) to 4 (greatest severity) on the classic PD symptom triad of tremor, rigidity, and bradykinesia.

As in our previous study, the HD patients demonstrated significantly less learning over the 6 test blocks than did their age-matched controls. The performance of the PD patients fell in between that of their controls and the HD patients, and did not differ significantly from either group. However, when a subset of HD and PD patients were matched for overall level of dementia, these 2 groups demonstrated similar amounts of learning and were both significantly impaired relative to their control groups. The performance of the PD patients on this task was not related to the severity of their tremor, rigidity, or bradykinesia, but was significantly correlated with their score on the DRS.

These results indicate that PD patients, like patients with HD, are impaired in the acquisition of motor skills, and that the severity of their learning deficit is correlated with their dementia but not with their primary motor dysfunctions. It appears, then, that PD and HD patients both differ from patients with AD in terms of their ability to acquire motor skills.

This study was supported by funds from the Medical Research Service of the VA and by NIA grant AG-05131.

182.1 GLUTAMATE RECEPTORS AND IRREVERSIBLE ANOXIC DAMAGE IN HIPPOCAMPAL SLICES: MECHANISMS OF INTERACTION. D. Lobner* & P. Lipton. (SPON: J. Hind) Dept. of Physiol., Univ. of Wisc. Madison, WI 53706.

There is irreversible damage to synaptic transmission in rat hippocampal slices following short periods of anoxia (Kass & Lipton, J. Physiol., 1982, 1986). Ischemia-induced cell necrosis in vivo and in culture is attenuated by NMA receptor antagonists suggesting that glutamate or aspartate release contributes importantly to anoxic/ischemic cell damage.

In the hippocampal slice model:

i) 10 minutes exposure to 7 mM glutamate irreversibly damages transmission in dentate gyrus and CA1; this damage is blocked in OCa/10 mm Mg buffer. 200 um DL-APV partially blocks the damage. There is no change in ATP or 45 Ca uptake in the neuropil of CA1 or dentate gyrus.

ii) Release of both endogenous aspartate and glutamate from the slices is enhanced by between 150 and 300% during 10 minutes anoxia.

iii) Irreversible damage to perforant path transmission following 10 minutes anoxia is attenuated approximately equally in both the dentate gyrus and CA1 by the following NMA antagonists: Ketamine (1 mM, 100% recovery); PCP (10 uM, 40% recovery); D-APV (50 um, 35% recovery), D-L APV (300 um, 40% recovery). Kynurenic acid (10 mM) allows complete recovery in CA1 but no recovery in dentate gyrus. The NMA antagonists do not prevent the population spikes which reappear in CA1 about 3-4 minutes after the onset of anoxia in CA1 ("reappearing spikes").

iv) In the absence of blockers ATP falls by about 75% and 45 Ca uptake increases by about 60% during 10' anoxia. In CA1 10 mM kynurenic acid attenuated the fall in ATP by 40% and did not affect the increase in 45 Ca uptake at all; 300 um D-L APV elevated control and anoxic levels of ATP by about 30% and also had no effect on the anoxic uptake of 45-calcium.

Thus: a) Exogenous glutamate can irreversibly damage transmission. b) Binding of glutamate/aspartate to NMA receptors contributes to irreversible anoxic transmission loss. c) These toxic effects of glutamate/aspartate are not due to an increase in neuropil calcium uptake.

There are two possibile actions of aspartate/glutamate during anoxia consistent with the proposal that increased cytosolic calcium is a major trigger of anoxic damage (Kass & Lipton, 1986). A) Binding to NMA receptors increases dendritic IP3 and leads to a release of stored calcium from the endoplasmic reticulum or B) increased Na influx resulting from NMA binding leads to a release of calcium from mitochondria. A kinetic model will be presented to show calculated effects of such actions on cytosolic calcium during anoxia.

182.2 ISCHEMIA INDUCES PROTEIN SYNTHESIS INHIBITION IN THE HIPPOCAMPAL SLICE- AN AUTORADIOGRAPHIC APPROACH. K.Raley and P.Lipton. Dept. of Physiology. Univ. Wisconsin, Madison, WI 53706.

Utilizing the rat hippocampal slice preparation, we have established that in vitro "ischemia" produces a profound and long-lasting inhibition of protein synthesis (Raley and Lipton, Neurosci.Abs.1986). In those studies, we measure radiolabelled lysine incorporations into PCA precipitates of tissue samples from the CA1 and dentate gyrus (DG) regions of the slice. It is not possible to localize the cell types in which protein synthesis is inhibited using this approach. Consequently, in the current study, we have developed an autoradiographic technique whereby we can actually visualize, at the light microscope level, the cell types affected by ischemia. Thus, it is possible to discern increases as well as decreases in protein synthesis in capillaries, glia, principal neurons and interneurons.

We prepare 500um transverse hippocampal slices from adult male rats using a vibratome (model G), and incubate the slices in 95%O_2-5%CO_2-buffered modified Ringers solution at 36°C. Experimental slices are rendered "ischemic" (95%N_2-5%CO_2-buffered Ringers without glucose) for 10 or 20 minutes and then allowed to recover for between 3 and 5 hours (in oxygenated buffer). All slices are exposed to ^{3}H leucine (6 uCi/ml) for the last 90' of this recovery period. Incorporation of label into protein is stopped by further incubating the slices for 60' in unlabeled buffer containing 100 ug/ml cycloheximide to inhibit further protein synthesis and wash out unincorporated label. Slices are fixed in an ice-cold 2% paraformaldehyde-2.5% glutaraldehyde fixative and later sectioned (40um) with a freezing microtome, mounted on slides, dipped in Kodak NTB2 emulsion, and developed for autoradiographic analysis one week later. Developed autoradiographs are analyzed by microspectrophotometry. 230 um diameter areas are observed under dark field illumination. The light reflected by silver grains is recorded on a chart recorder and the average output in a region is calculated. Differences due to the ischemic treatment are expressed as percent of the control light output for a cell region.

The distribution of label in sliced tissue is not entirely homogeneous but rather is often patchy. The CA1 pyramidal layer exhibits more patchiness than either the granule cell layer or the neuropil. In contrast, interneurons, glia and capillaries appear to be uniformly labelled.

	Light output per unit area		
	CA1 layer	DG layer	Molecular Layer (DG)
Control tissue (Arbitrary units)	27.9	29.8	22.0
3 Hr recovery from 10' ischemia (% control)	46%	22 %	36%

10' ischemia dramatically reduces the incorporated label, measured after 3 hr recovery , in the major neuronal cell layers of the slice. However, label incorporation remains in glial cells, interneurons and capillaries; in fact, incorporation may be increased in post ischemic endothelial cells. These results demonstrate a selective vulnerability of the principle cells in the hippocampal slice to 10' of ischemia. The degree of inhibition in the granule cell layer is more profound than that in the CA1 pyramidal cells, a difference which does not reflect the greater vulnerability of CA1 cells to ischemic damage in vivo. In vivo, this early inhibition is reversed in dentate granule cells but not in CA1 cells. An increased endothelial cell protein synthesis may indicate stress protein synthesis, which is known to become elevated for relatively prolonged periods following such injuries as heat shock, ischemia, and decapitation trauma (Kiessling et al, J.Cereb.Blood Flow Metab. 1986).

182.3 THE EFFECT OF BLOCKING SODIUM INFLUX ON ANOXIC DAMAGE TO THE DENTATE GYRUS AND CA1 REGION OF THE RAT HIPPOCAMPAL SLICE. I.S. Kass, J.A. Boening, J.E. Cottrell. Anesthesiology Department, State University of New York, Health Science Center at Brooklyn, Brooklyn, New York 11203.

An interruption of the brain's oxygen supply leads to the irreversible loss of brain function. We have investigated the mechanism of anoxic damage using the hippocampal slice preparation. Recent studies have implicated high intracellular calcium as an important event leading to anoxic and ischemic brain damage. Sodium is another ion whose intracellular concentration increases dramatically during anoxia and ischemia. We therefore examined the effect of blocking sodium channels on anoxic damage.

Hippocampal slices from adult rats (100-120 days old) were superfused with oxygenated artificial cerebrospinal fluid (ACSF). To generate anoxia the fluid superfusing the slice was switched to one preequilibrated with 95% N_2 - 5% CO_2.

Two regions of the hippocampus were examined. The population spike in either the dentate granule cell layer or the CA1 pyramidal cell layer was examined after stimulating either the perforant path or the Schaeffer collaterals respectively.

When the dentate granule cells were studied they were subjected to 10 minutes of anoxia. Untreated slices showed virtually no recovery from anoxia ($\bar{x}$ ± S.E.M.; 3±3%). If the slice was treated with Tetrodotoxin (TTX) (200 µg/l) during and 5 minutes before and after anoxia the evoked population spike measured in the dentate granule cell layer recovered (43±10%). Thus blocking sodium channels with TTX provides protection against anoxic damage.

The CA1 pyramidal cells are more susceptible to anoxic damage than the dentate granule cells. There was no recovery of the population spike from the CA1 pyramidal cells after 5 minutes of anoxia (0±0%). When the hippocampal slices were treated with TTX (200 µg/l) during and 5 minutes before and after anoxia the response recovered from 5 minutes of anoxia (69±20%). Thus as with the dentate granule cells the CA1 pyramidal cells are protected from anoxic damage when sodium channels are blocked with TTX.

Possible mechanisms by which reduced sodium entry could lead to reduced anoxic damage include: 1) reduced ATP utilization 2) reduced depolarization and depolarization induced calcium entry, and 3) reduced cytosolic calcium secondary to a decrease in sodium induced calcium release from intracellular organelles. We are currently investigating some of these mechanisms.

182.4 PURIFICATION OF BOVINE BRAIN CYTOCHROME OXIDASE FROM SYNAPTOSOMAL AND NON-SYNAPTOSOMAL MITOCHONDRIA. R.F. Hevner* and M.T.T. Wong-Riley. Dept. of Anatomy & Cellular Biology, Med. College of Wis., Milwaukee, WI 53226.

Cytochrome oxidase (C.O.) is a mitochondrial enzyme used as a marker of energy metabolism in brain. C.O. histochemistry shows that neuronal C.O. activity levels change in response to altered functional (synaptic) input. We hypothesize that such C.O. activity changes reflect changes in the amount of enzyme present. This hypothesis can be tested by C.O. immunocytochemistry. While such studies have been successfully pursued using antibodies prepared against C.O. from heart, the existence of tissue-specific C.O. isozymes suggests that antibodies to brain C.O. might be optimal immunocytochemical reagents. We have isolated the brain isozyme of C.O. for use as immunogen by an affinity chromatography procedure optimized to give high yields (>30%) with high purity (~7.75 nmol heme a/mg protein). This procedure uses a cytochrome c-linked thiol-Sepharose 4B matrix to bind C.O. at low ionic strength, with elution by a potassium phosphate gradient (modified from Broger et al., Meth. Enz. 126:64-72, 1986). C.O. was prepared from synaptosomal and non-synaptosomal mitochondria separately in order to examine possible heterogeneity of C.O. within brain tissue. For isozyme comparison, bovine heart C.O. was purified as well. Heart, brain synaptosomal, and brain non-synaptosomal C.O. were compared electrophoretically using a high-resolution urea-SDS-PAGE system (Kadenbach et al., Anal. Biochem. 129:517-521, 1983) which separates C.O. into 13 subunits. No differences in subunit mobilities were evident between synaptosomal and non-synaptosomal populations of brain C.O. This result suggests that the majority of C.O. in brain consists of a single isozyme. A clear difference was observed in the mobility of subunit VIII between brain (M_r = 9.7 kDa) and heart (M_r = 9.9 kDa) isozymes, whereas no other differences in subunit mobilities were apparent between those two tissue isozymes. In particular, subunit VIa, which, like subunit VIII, differs imunologically between heart and brain C.O. isozymes (Kuhn-Nentwig and Kadenbach, Eur. J. biochem. 149:147-158, 1985), displayed identical electrophoretic mobilities in those isozymes. These studies confirm the existence of tissue-specific C.O. isozymes based on subunit VIII electrophoretic mobility differences, but provide no indication for the presence of more than one isozyme in a single tissue (brain). Antigenic specificity of brain C.O. suggests that antibodies to the brain C.O. isozyme will have optimal specificity and, possibly, affinity for use as reagents in immunocytochemical studies of cytochrome oxidase in brain. (Supported by MCW MSTP Fellowship to RFH and NIH NS18122 and EY05439 to MWR.)

182.5 A RAPID EXTRACTION AND ION-PAIRING HPLRC METHOD FOR THE QUANTITATION OF [3H]-INOSITOL PHOSPHATES IN RAT BRAIN. P.J. Egofske* and D.L. Hammond (SPON: R. Kochman). CNS Diseases Research, G.D. Searle & Co., Skokie, IL 60077

A number of pharmacologically important receptor systems are coupled to phosphatidylinositol hydrolysis. This second messenger response is commonly monitored in vitro by quantitation of tritiated inositol phosphates ([^{3}H]-IPs) after tissue preparations have been prelabelled with tritiated inositol. Current methods for the quantitation of [^{3}H]-IP's in rat brain require numerous solvent extractions and an anion-exchange chromatography system which is either laborious, lengthy or inadequately separates [^{3}H]-IP's. In order to circumvent these problems, we have developed a novel extraction and ion-pairing high performance liquid radiochromatography (HPLRC) method for the quantition of [^{3}H]-IP's.

Rat brain cortex cubes were prelabelled in batch using a modification of the procedure described by Berridge et al. (Biochem. J. 206:587, 1982). Fifty-ul aliquots of the prelabelled cubes were incubated in 900 ul buffer for 10 min, then 100 ul of a test compound was added. The incubations were continued for specified times after which the reactions were terminated by replacing the buffer with 1 ml ice-cold 40% methanol:H_2O (0.7N HCl). The samples were then sonicated and centrifuged. The supernatants were dried and pellets reconstituted for protein determinations. Each supernatant residue was reconstituted in mobile phase A and an aliquot injected for HPLRC analysis. HPLRC conditions consisted of a 15 min 0 to 100% B linear gradient at a flow rate of 2 ml/min using a reverse phase column; where mobile phase A = 100% H_2O (Pic A^{TM}) and B = 40% methanol:H_2O (Pic A^{TM}, pH 2.0). The eluent was collected into scintillation vials at a rate of 10 drops/fraction. Five ml PCS^{TM} containing 2N HCl was added to each fraction and vials were counted by LSC.

In situ spiking experiments demonstrated that the recovery of tritiated inositol, Ins1P_1, Ins(1,4)P_2, Ins(1,4,5)P_3, and Ins(1,3,4,5)P_4 through the procedure exceeded 95% for each agent. Only 1-3% of each compound was lost to degradation after extraction and three days storage of dried extracts at -20 °C. The detection limit was 2.1 femtomoles/[^{3}H]-IP/100 ul injection. Stimulation with 100 uM carbachol, a muscarinic agonist, produced significant time-dependent differences in the amounts of [^{3}H]-IP's as compared to control values. Thus, this method for measuring [^{3}H]-IPs can be used to assess the activity of drugs at receptors coupled to this second messenger system.

182.6 **RECEPTOR-MEDIATED PHOSPHOINOSITIDE BREAKDOWN IN HUMAN OCULAR CILIARY EPITHELIUM.** Martin B. Wax, M.D. and Miguel Coca-Prados, Ph.D.*, Depts. of Ophthalmology and Pharmacology, Univ. of Pennsylvania School of Medicine, Phila., PA and Dept. of Ophthalmology and Visual Science, Yale Univ., New Haven, CT.

The hydrolysis of phosphoinositides (PI) in peripheral tissues can be stimulated by a number of putative neurotransmitters and this stimulation can be blocked by specific antagonists. PI breakdown was studied in cultured human ciliary epithelial cells similar to those cells previously described (PNAS 83: 8754). Epithelial cells derived exclusively from the non-pigmented layer of the ocular ciliary epithelium were transformed by simian virus 40 and grown in culture to semi-confluency. The cells were incubated in 3 µCi/ml of (^{3}H)-myoinositol for 2 days. The accumulation of inositol phosphates in response to several agonists (carbachol, 1 mM; ATP, 100 µM; arginine vasopressin, 1 µM; and phenylephrine, 100 µM) was determined at 37°C for times ranging from 5 sec to 15 min. In the presence of 10 mM $LiCl_2$, the maximum net production of the (^{3}H)-inositol phosphates (expressed as % of conversion of (^{3}H)-phospholipids) was approximately 5% for inositol-1 phosphate (IP1), 0.5% for inositol-1,4 bisphosphate (IP2), and 1.0% for inositol-1,4,5 trisphosphate (IP3). Carbachol elicited PI hydrolysis with an EC_{50} value of 39±9 µm. The EC_{50} values obtained for Arg-8 Vasopressin and ATP initiated PI breakdown were 32 ± 10 nM and 11.9 ± 1 µM respectively. Phenylephrine alone failed to stimulate the production of (^{3}H)-inositol phosphates in these cells. The production of all (^{3}H)-inositol phosphates in response to carbachol (1 mM) was inhibited by the selective muscarinic antagonists pirenzepine (K_i=148 nM) and AFDX-116 (K_i=1.49 µM). These observed potencies are consistent with those found in other peripheral secretory tissues such as the lacrimal gland. Phorbol 12,13 dibutyrate (1 µM) rapidly desensitized the production of (^{3}H)-inositol phosphates by carbachol to 25% of control values. Pertussis toxin treatment reduced the PI hydrolysis elicited by carbachol (40% of control), Arg-8 Vasopressin (15% of control) and ATP (50% of control). Thus we have demonstrated a role for G protein regulation in PI coupled, receptor-mediated mobilization of intracellular calcium in response to several drugs in these cells.

182.7 **CNS EFFECTS OF THYROID HORMONE INVOLVE STIMULATION OF CYTOSOLIC PROTEIN KINASE ACTIVITY.** L. Kragie*, M. Schoenl*, W.D. Lawrence*, P.J. Davis* (Spon: L. Hershey), SUNY/Buffalo School of Medicine and V.A. Medical Center, Buffalo, NY 14215.

Changes in thyroid hormone homeostasis cause profound neurobehavioral symptoms through unknown mechanisms. In a previous report we described changes in synaptosomal Ca^{2+}-ATPase activity and neuronal intracellular Ca^{2+} concentration upon direct exposure of synaptosomes or cells, respectively, to iodothyronines in vitro (Soc Neurosci Meeting 1985, abstract 164.10). We presently describe significant stimulation of phosphatidylserine-dependent protein phosphorylation in synaptosomal cytosol when the latter is incubated in vitro with physiological concentrations of L-thyroxine (T_4) and L-triiodothyronine (T_3).

P_2 pellet from NZW rabbit cerebral cortex was obtained by the method of Hajos (Brain Res 93:485, 1975) and subjected to hypotonic lysis. The post-50,000 x g supernatant was diluted in assay buffer and protein kinase activity was measured as phosphorylation over 10 min at 30°C in the presence of 10 µM unlabeled ATP, tracer [γ-^{32}P]ATP, 25 mM Tris (pH 7.4), 0.25 mM Ca^{2+}, 6.25 mM Mg^{2+}, 0.25 mM EGTA, 0.01% leupeptin, 5 mM mercaptoethanol, 0.4 mg/ml calf thymus type III-S histone. Variables were presence and absence of phosphatidylserine, 1,2-diacylglycerol and thyroid hormone analogs. Analog incubations were carried out for 60 min at 37°C prior to protein kinase assay.

INCREASE IN PROTEIN PHOSPHORYLATION
(pmoles/mg/min, mean ± SEM)

Control		10^{-11}M	10^{-10}M	10^{-9}M	N	P (ANOVA)
433±100	T_3	+138±40	+263±51	+155±60	5	0.00078
283±107	T_4	-	+175±57	+159±56	7	0.00087

Maximal effect (+60% in enzyme activity) was seen at 10^{-10}M with both T_4 and T_3. There was no stimulation of phosphorylation with D-T_4 or D-T_3 (10^{-11} M - 10^{-9}M). Significant effects were obtained in both male and female brain preparations and in fresh and previously-frozen tissues. Thus, physiologically relevant levels of thyroid hormone regulate brain cytosolic phospholipid-dependent protein kinase activity in vitro. Hormonal activation of the enzyme(s) is non-nuclear and represents a novel, direct mechanism which is independent of signal transduction at the cell membrane.

182.8 QUANTITATIVE HISTOCHEMISTRY OF ENZYME CHANGES OVER TIME IN RAT SPINAL MOTONEURONS FOLLOWING AXOTOMY. Chr. Marx* and A.C.Nacimiento. Neurosurgical Research Laboratory, Saarland University Medical School, D-6650 Homburg/Saar, F.R.G.

Peripheral nerve injury brings about remarkable metabolic changes in the affected cells, as reflected by posttraumatic activity shifts in various intracellular enzymes. Relevant data available for spinal motoneurons (SMN), however, show considerable discrepancies, particularly regarding quantification of time dependence. To set a base-line for the evaluation of enzyme changes in SMN during regeneration after peripheral nerve graft repair, we obtained a time-activity profile after unrepaired sciatic nerve transection. At 2, 4, 6 and 8 weeks after axotomy SMN were examined in 20um cryostat sections processed for histochemistry of the following enzymes: glucose-6-phosphate-dehydrogenase (G6PDH), 6-phosphogluconate-dehydrogenase (6PGDH), cytochrome-oxidase (CO) and acetylcholinesterase (AChE). Microphotometric extinction measurements of enzyme activity were made at randomized 5-10 cytoplasmic spots in single SMN on both control and axotomized sides. The values obtained were averaged, and the results expressed as the ratio axotomy to control sides. Control measurements in 5 intact rats gave a ratio of 1.0±0.1.The measurements are summarized as follows:

	axotomy/control ratio			
	2 ws(n=4)	4 ws(n=5)	6 ws(n=4)	8 ws(n=4)
G6PDH	1.64±0.10**	0.82±0.10*	0.81±0.09*	0.40±0.13**
6PGDH	1.45±0.06**	1.13±0.17	0.75±0.11*	0.50±0.10**
CO	0.99±0.08	0.70±0.14*	0.54±0.16**	0.50±0.14**
AChE	1.00±0.06	0.92±0.07	0.78±0.08*	0.61±0.13**

* p 1%-5%; ** p 0.1%

These results suggest that the validity of any histochemical correlation between posttraumatic changes in neuronal enzyme activity and regeneration processes depends essentially upon a) adequate selection of the enzyme systems involved; and b) quantitative evaluation under standardized measuring conditions assuring a high degree of resolution and reproducibility.

182.9 LOCALIZATION BY IN SITU HYBRIDIZATION OF THE LIVER ISOZYME OF GLYCOGEN PHOSPHORYLASE WITHIN THE HUMAN CORTEX. F. Gorin, P. Ignacio*, R. Gelinas*, R. Mullinax*. Dept. of Neurology, Univ. Calif. Davis Sch. of Med., Sacramento, CA 95817

Brain glycogenolysis is critical in meeting the acute energy requirements of the CNS during hypoxic-ischemic events, hypoglycemia, and seizures. Glycogen phosphorylase is the rate-determining enzyme for the degradation of glycogen. Protein gel electrophoresis has previously demonstrated that there are at least three isozymes of phosphorylase in non-primates and that the brain expresses the muscle (M) and fetal (B) isozymes.

We have isolated and characterized cDNA encoding a portion of the liver (L) isozyme of glycogen phosphorylase from a human fetal brain cDNA library (Gorin et al., J. Neurogenetics-in press). Because the presence of this isozyme has not been previously described in the non-primate mammalian brain, we decided to investigate transcription of the L- phosphorylase gene in human brain and cytologically localize L- phosphorylase within the human and macaque cortex. RNA blot data indicates that the L- phosphorylase gene is transcribed in human fetal (19 week) and adult brain, whereas the M- phosphorylase gene is transcribed in adult but not fetal brain. Ochterlony data using sheep anti-rat L- phosphorylase polyclonal antibody (Osawa et al., FEBS 202:282, 1986) demonstrates the presence of the L- phosphorylase protein as well as transcription of the L- phosphorylase gene in human adult brain.

In situ hybridization using a 3' portion of the human L-phosphorylase cDNA demonstrates specific transcription of this isozyme in human and macaque cortex in white matter but not in grey matter. Counterstaining the tissue sections with a modified Bodian stain indicates that this white matter transcription occurs within glial elements present in white matter. (This work was supported by NIH grant NS 23644)

182.10 AUTORADIOGRAPHIC DEMONSTRATION OF GLYCOGEN IN THE RAT BRAIN, AND CHANGES INDUCED BY TACTILE STIMULATION. R.A. Swanson, F.R. Sharp and S.M. Sagar. Neurology Service, V. A. Medical Center and Department of Neurology, University of California, San Francisco CA 94143.

Glycogen is the single largest energy reserve in the brain, and under normal conditions brain glycogen turnover is several orders of magnitude faster than in liver. However, histochemical demonstration is not feasible due to rapidity of postmortem glycogenolysis and solubility in water-based fixatives and stains. Even by the use of microwave fixation and an ethanol-based PAS staining method, we found that normal brain glycogen levels were too low to stain. However, by the using [^{14}C] glucose or [^{14}C] 2-deoxyglucose precursors, we were able to demonstrate brain glycogen autoradiographically and detect local changes in glycogen metabolism in response to physiologic stimulation.

Rats were injected with 200 microcuries of [^{14}C] glucose or [^{14}C] 2-deoxyglucose and 20 minutes later sacrificed by microwave irradiation *in situ*, which abruptly stops glycogenolysis. Brains were removed, dehydrated in ethanol, delipidized in xylene, and embedded in paraffin. Twenty micron sections were cut and mounted on coverslips in an ethanol:glycerol bath. The sections were washed in hexane:isopropyl alcohol to remove paraffin and glycerol, and free glucose and 2-deoxyglucose were removed in washes of 80% ethanol. Autoradiographs were produced by exposing the sections to X-ray film for 5 days. The same or adjacent sections were then treated with amyloglucosidase to remove glycogen, and again exposed to film. The difference in optical densities of the images so produced were attributed to radiolabeled glycogen.

Differences in glycogen labeling were observed in response to physiologic stimulation. Rat whiskers were manually stimulated unilaterally during the 20 minute interval between radiolabel injection and microwave irradiation. Increased labeling was seen in the ipsilateral trigeminal sensory nucleus. This increased label may reflect either locally increased glycogen synthesis or increase flux of [^{14}C] labeled precursor during the stimulation. By correcting for changes in local glucose uptake, it may be possible to observe physiologic changes in glycogen metabolism at the cellular level.

182.11 RETINOIDS IN THE PINEAL BODY OF THE BOVINE BRAIN. A. T. C. TSIN AND T. S. WEBER*. The University of Texas at San Antonio, San Antonio, Texas 78285.

In mammals, the pineal gland is a brain structure of photoreceptor origin. The photopigment and retinoid contents of the bovine pineal gland have not previously been investigated. In the present study, bovine pineal glands (n = 10) were analyzed by high performance liquid chromatography for levels of all-trans retinol, retinal, and retinyl palmitate. These retinoids were extracted from all tissue samples by acetone, then purified by the use of an alumina column. The amount of all-trans retinol present was 58.71 pmole/gm pineal tissue, or 8.81 pmole/pineal gland. This is a small amount compared to the 4.84 nmole of all-trans retinol/gm tissue detected in fresh retina samples. However, it is approximately comparable to that in the muscle, ie: 32.66 pmole all-trans retinol/gm tissue. There was no all-trans retinal detected in the pineal glands. Of the different tissues assayed (retina, RPE, liver, muscle, brain cortex and subcortex), only the retina contained all-trans retinal, in the amount of 2.05 nmole/gm, or 1.34 nmole/retina. The level of all-trans retinyl palmitate present in pineal gland was 224.86 pmole/gm or 33.68 pmole/pineal gland, significantly higher than other brain tissue (with no detectable level of retinyl esters). The presence of a significant level of retinoids in bovine pineal glands may be cause to reevaluate our present understanding of pineal gland function in mammals. (Supported by Grant Numbers RR-08194-07 and GM-07717)

182.12 A HISTOCHEMICAL STUDY OF THE EFFECTS OF CHLORAL HYDRATE ANESTHESIA ON CEREBRAL METABOLIC ENZYMES. M.J. Ulissey* and M.E. Trulson (SPON: B.H. Rohde). Dept. Anat., Coll. Med., Texas A&M Univ., College Station, TX 77843.

Chloral hydrate is widely used as an anesthetic in neurophysiological experiments in animals. However, electrophysiological changes have been observed during anesthesia with the drug. Since many data have been collected from electrophysiological experiments in which chloral hydrate was used as an anesthetic agent, we examined the effects of chloral hydrate anesthesia on brain metabolism. Five key enzymes responsible for aerobic and anaerobic metabolism and the hexose-monophosphate shunt in the cerebral microvasculature and neuropil of rats were examined during chloral hydrate anesthesia. Male Sprague-Dawley rats were divided into 2 groups. Three rats served as control and received i.p. injections of physiological saline. The other 3 rats served as experimental animals and were anesthetized at surgical levels for 1 hour with chloral hydrate (400 mg/kg, i.p.). While the experimental animals were still anesthetized, all 6 animals were killed by decapitation. Forebrain tissue sections (including primarily the cortex and caudate nucleus) were immediately taken and frozen in cold isopentane. Sections were cut at 6 μm on a microtome-cryostat. Fresh frozen cryostat sections were then used to quantitate the following enzymes: glucose-6-phosphate-dehydrogenase (G6PDH), cytochrome oxidase (CO), lactate dehydrogenase (LDH), β-hydroxybutyrate dehydrogenase (βHBDH), and isocitrate dehydrogenase (ICDH). Enzymes were quantified using a Leitz-Data Acquisition and Display System. Ten arterioles and 10-15 μm x 15 μm sections of neuropil from each rat for each stain were analyzed. Significant decreases were observed in CO (-46%) and βHBDH (-28%) in arterioles, while G6PDH (+15%) and ICDH (+29%) showed a significant increase and LDH showed no significant change. In the neuropil, CO (+13%), ICDH (+12%) and G6PDH (+25%) showed significant increases following chloral hydrate while βHBDH and LDH showed no significant changes. The fact that rate-limiting enzymes of key metabolic pathways in brain were significantly altered during chloral hydrate anesthesia may have implications for electrophysiological changes that have been observed during chloral hydrate anesthesia, as well as responses to pharmacological agents.

182.13 ETHANOL ALTERS FOREBRAIN METABOLIC ENZYMES IN THE RAT. M.S. Cannon,* M.J. Ulissey,* and M.E. Trulson (SPON: M.S. Amoss). Dept. Anat., Coll. Med., Texas A&M Univ., College Station, TX 77843.

The potential effects of ethanol on cerebral metabolic enzymes have not been investigated. Therefore, in the present study we examined the effects of acute ethanol administration on enzymes involved in aerobic and anaerobic metabolism. Male Sprague-Dawley rats were used in all experiments. Three rats served as controls and were given physiological saline orally. The other 6 rats served as experimental animals and were administered a 50:50% solution (3 ml) of ethanol:physiological saline orally. After 1 hour the control animals and 3 of the experimental animals were killed by decapitation. Forebrain tissue sections were immediately taken and frozen in cold isopentane. The other 3 experimental animals were killed 48 hours after administration of ethanol. The sections were cut at 6 μm on a microtome-cryostat and fresh-frozen cryostat sections were then used to quantitate the following enzymes: glucose-6-phosphate-dehydrogenase (G6PDH), cytochrome oxidase (CO), lactate dehydrogense (LDH), β-hydroxybutyrate dehydrogenase (βHBDH), and isocitrate dehydrogenase (ICDH). The enzymes were quantified using a Leitz-Data Acquisiton and Display System. Ten arterioles from each rat for each stain were analyzed. The tissue sections obtained from the 1-hour treatment with ethanol showed the following statistically significant changes in arteriolar enzyme levels: CO was decreased by 26.3%, βHBDH was decreased by more than 98%, and G6PDH showed an increase of 79.9%. The animals that were allowed to recover for 2 days following ethanol administration demonstrated the following changes in enzyme levels: ICDH was increased by 41.6%, CO showed a further significant decrease to 63.2% below the control animal enzyme levels, βHBDH demonstrated an increase to 92.7% over control animal enzyme levels, G6PDH showed an increase of 115.0% over control animal enzyme levels and LDH showed an increase of 12.2% over control animal enzyme levels. These data suggest that the administration of ethanol impairs forebrain metabolism by attacking key enzymes within aerobic and anaerobic pathways. Arterioles play a critical role in adjusting perfusion to the metabolic requirements of tissues. The altered enzyme levels observed following ethanol may result in impaired vasomotor adjustments. These changes in enzymes involved in brain metabolism may account for some of the characteristic behavioral manifestations of ethanol intoxication.

HUMAN BEHAVIORAL NEUROBIOLOGY I

183.1 REGIONAL CEREBRAL BLOOD FLOW IN NORMAL AND BIPOLAR FEMALE SUBJECTS DURING A COGNITIVE ACTIVATION TASK. L. Flowers*, F. Wood*, and N. Gaby* (Spon: K. Campbell). Section of Neuropsychology, Bowman Gray School of Medicine, Winston-Salem, NC 27103.

Cortical responses to an induced behavioral state can be inferred indirectly by the regional cerebral blood flow method (rCBF). This method reliably reflects local metabolic changes during sustained sensory, motor, or cognitive activation.

Twenty-three normal and sixteen bipolar females engaged in three repetitions of a verbal recognition memory task. Subjects made a bimanual finger-lift response to indicate recognition of target words. rCBF was measured during the first and third trials by eight NaI scintillation detectors over each hemisphere. Presence and degree of manic and depressive symptoms in the bipolar group was determined on the day of testing. Eleven subjects were currently in a manic phase and five were mainly depressed.

Subjects differed in behavioral performance as well as blood flow, means, and variances. Normals performed more accurately and improved more over trials than did bipolars. On Trial 1, bipolar manics but not depressives differed significantly from normals in terms of behavioral performance. Trial 3 performances on this recognition memory task revealed a behavioral deficit common to both phases of bipolar affective disorder.

Normal subjects had the highest blood flow values at nearly all sites; bipolar depressives were next highest and bipolar manics had the lowest flow values. Bipolar flow, in general, was more variable on Trial 1 compared to normal flow. However, on Trial 3, the variability among bipolar depressives was similar to that of the normal subjects while the variability among bipolar manics remained high.

These findings suggest that the depressed phase of bipolar disease does not represent as severe a deficit in brain activation as is represented in the manic phase; rather, there appears to be a rough continuum along which depressives occupy an intermediate position between normals and manics. Among the manic subjects, there is a significant positive correlation between presence of depressive symptoms and mean flow values; that is, bipolar manics with some depressive symptoms had higher flow values, more similar to bipolars in the depressive state.

On the initial trial, bipolar depressives are more accurate than are manics. This suggests that, in the depressive phase, novelty may temporarily counteract the deleterious effects of depression on memory.

183.2 MODULATION OF THE ACOUSTIC STARTLE RESPONSE IN THE HUMAN BY TONE ONSET AND OFFSET. S.J. Lane, E.M. Ornitz*, D. Guthrie.* Department of Psychiatry, Division of Mental Retardation and Child Psychiatry, and Brain Research Institute, UCLA. L.A., CA, 90024

Modulation of the startle response (SR) is a polysynaptic brainstem function subject to mediation by cortical attentional mechanisms and intrinsic brainstem mechanisms (see Davis, 1984 and Bruno, 1985 for review). A predictable relationship exists between onset of auditory warning stimuli (WS) and the SR such that short discrete (SD) WS inhibit, while long continuous (LC) WS tend to facilitate SR magnitude. Latency influences are similar albeit more variable. Modulation in the human of auditory startle by offset of auditory stimuli has been less well defined and quantitative comparison of the effectiveness of onset vs offset is lacking. 3 experiments were designed to contrast onset and offset effects and to examine the influence of experimental context on SR modulation. Exp.1 examined modulation using both SD and LC tone onset trials. Exp.2 utilized a continuously present background tone (CT) and examined SD and LC tone offset in SR modulation. Exp.3 examined the influence of both tone onset and offset within the same experiment. Within each experiment responses to the various WS were compared to responses to unwarned startle stimuli. Results indicated that the unwarned SR, measured as eyeblink, was remarkably predictable on both amplitude and latency measures regardless of its occurrence within a background of CT or silence. Additionally, SD onset in Exp.1 and offset in Exps.2 and 3 consistently inhibited SR amplitude (Exp.1 $p<.0001$; Exp.2 $p<.0004$, Exp.3 $p<.007$). LC influences tended to facilitate SR amplitude somewhat more variably depending upon experimental context. Planned contrasts comparing onset and offset influences across experiments indicated that SD WS produced significantly greater SR amplitude inhibition in Exp.1 than in Exps.2 or 3. The trend toward amplitude facilitation following LC WS was significant only in Exp.3 ($p<.02$). Latency responses parallel those for amplitude. Onset of the SD tone significantly inhibited latency in Exp.1 ($p<.004$) and this response was greater than that seen in either Exps.2 or 3. Latency facilitation by the LC WS in Exp.3 was significantly greater than that observed in Exps.1 or 2 ($p<.05$). These results indicate that the SR is modifiable by antecedent WS of either onset or offset natures. Additionally, the degree of effectiveness in SR modulation is linked to experimental context. Finally, in contrast to Graham's suggestion of 2 separate neuronal systems mediating amplitude and latency modulation of the SR, the parallel relationship between these 2 SR parameters seen in our studies, regardless of the onset/offset characteristic of the WS, suggests that the same or similar neuronal mechanism(s) may mediate SR modulation.

183.3 TEMPORAL PERFORMANCE DEFICIT OF SCHIZOPHRENICS IN THE COLOR-WORD TEST (STROOP) - R. Hess, M. Seidlitz*, B. Reinhard*. Department of Psychiatry, University of Göttingen, FRG.

The peformance of schizophrenic patients and normal controls in a modified Stroop (color-word) test was investigated. The modification consisted in the potential to vary the frequency of presentation of the stimuli, such that a minimum presentation period could be determined for each person to fulfill the criterion of less than 10% errors during successive trials within 2 minutes.

Stimuli were the color words red, blue and yellow, each written in an ink different from its meaning. Two conditions were tested, namely 1. reading the word ignoring the color and2naming the color ignoring the meaning of the word. As further control served a series of 3-letter nonsense words written in the same colors and again tested in the 2 possible conditions (3 and 4). The different tasks were presented in the sequence 1 to 4 with brief breaks between successive tasks. Presentation time for a single stimulus could be varied from 800 msec. upwards with no interstimulus interval between two successive stimuli.

The results indicate that, in case of nonsense words, both tasks were performed about equally well, and there was no difference between schizophrenics and controls.

All persons had most difficulties in naming the color and ignoring the meaning of the color-word. This is consistent with previous reports and has been explained with an "overtraining" to perceive the meaning of a written word.

The only striking difference between schizophrenics and controls was in the most difficult task (name color, ignore word) where controls needed presentation times of 800 to 1000 msec. to perform at the level of criterion, while all schizophrenics needed presentation times longer than 1000 msec. some up to 2000 msec. So far there was no overlap between the 2 groups.

Hypotheses explaining this dysfunction in schizophrenics and its possible meaning to the pathogenesis of the disease will be discussed.

183.4 **CENTRAL MECHANISMS OF STEREOPSIS IN MAN AND CATS.** Maryse Lassonde and Maurice Ptito. Groupe de Recherche en Neuropsychologie expérimentale, Université du Québec à Trois-Rivières, Qué. G9A 5H7, Canada.

Stereopsis or binocular depth perception is usually thought to depend on the integration by cortical cells of the binocular information transmitted by two pathways: 1) the geniculo-striate pathway, via the **optic chiasm**; 2) the more indirect interhemispheric route, via the **corpus callosum**. The present set of studies investigated the selective effects of lesions of either pathway and assessed the consequences of striate cortex damage on binocular depth perception. **Human studies:** Four callosal agenesis subjects, five commissurotomized patients, three subjects with unilateral occipital damage and one chiasmatectomized patient were compared to 20 control subjects on random-dot stereoscopic tasks. Results indicate that patients without corpus callosum are able to succeed at most tasks although they show higher thresholds than IQ-matched controls. Similar results were obtained with occipitally-damaged patients when tested in their intact visual field; no stereopsis was found in their blind field Although midline stereopsis was observed in the chiasmatectomized patient, his stereoscopic abilities were very limited. **Animal studies:** Normal cats and cats with lesions of the optic chiasm, the corpus callosum or the striate cortex were required to discriminate random dot stereograms. Results parallel the findings obtained in the human studies, namely: a) callosal section produces little or no impairment in stereoperception; b) chiasmatectomy drastically reduces the ability of cats to perform the random-dot task whereas c) bilateral occipital removal abolishes binocular depth perception. Taken together, these results confirm that binocularity is dependent upon the integrity of the striate cortex and that the optic chiasm is the most important pathway in conveying binocular information.

183.5 CEREBRAL MORPHOLOGY ON MAGNETIC RESONANCE IMAGING IN DEVELOPMENTAL DYSPHASIA. T.L. Jernigan, P.A. Tallal*, and J. Hesselink* (SPON: D. Trauner). V.A. Med. Ctr., San Diego, CA 92161, Depts. of Psychiatry and Radiology, UCSD Sch. of Med., La Jolla, CA 92093.

A group of well-defined developmentally language disordered children, who have been followed longitudinally since age 4, were studied with magnetic resonance imaging (MRI) at the age of 8. At entry to the longitudinal study, all subjects had severe developmental receptive and expressive language delay that could not be attributed to hearing loss, mental retardation (Performance IQ exceeded 90), autism, or known damage to the CNS.

Subjects have received extensive behavioral evaluations annually to assess neuropsychological and linguistic development. In addition, academic achievement and social and emotional outcomes were assessed. At the time of the present study, all subjects continue to demonstrate severe developmental language delay.

Previous studies of these subjects (Tallal, P., Stark, R., Mellits, E.D. Neuropsychologia, 23:527-536, 1985) have revealed a specific defect in the processing of rapidly changing sensory stimuli, which predicts the degree of receptive language impairment (r=.89). The neurological substrate of this behavioral deficit is unknown.

Clinical neuroradiological evaluation of the images from the first 9 language impaired subjects revealed significant ventricular asymmetry in one (R)L), and parenchymal abnormalities in the deep white matter in two other of the subjects. No abnormalities were detected in the remaining six subjects. Quantitative measurements of cerebral size and hemispheric asymmetry have been completed and will be discussed in relation to the patterns of linguistic defects. Measures of signal values in white and gray matter areas have been made to attempt to assess degree of myelination. These results will also be presented and discussed, and contrasts between these children and globally retarded children will be made.

183.6 **CORTICAL PHYSIOLOGY DURING AUDITORY DISCRIMINATION IN SCHIZOPHRENIA: A REGIONAL CEREBRAL BLOOD FLOW STUDY.** K.F. Berman, S.C.W. Rosenbaum*, C.A. Brasher*, T.E. Goldberg*, D.R. Weinberger.
Clinical Brain Disorders Branch, NIMH, Washington, D.C. 20032.

We have previously investigated cortical physiology in schizophrenia using a variety of visually presented tasks, some linked to prefrontal cortex and some not, and have demonstrated prefrontal deficits primarily during specific prefrontal tasks. The present study was carried out to investigate regional cortical blood flow (rCBF) during auditory discrimination, a possible temporal lobe task.

The xenon133 inhalation technique was used to measure gray-matter rCBF, an indicator of cortical metabolism, in 15 normal subjects (mean age±SD 29.9±4.9 years) and 10 patients with chronic schizophrenia (age 30.5±6.9 years), all medication-free for at least four weeks. After an initial resting state rCBF procedure, which served to acclimate subjects to the testing procedure, two rCBF measurements were made during two different auditory tasks, which were presented in counterbalanced order. One task involved discrimination between pairs of sounds which consisted of rhythm patterns or speech sounds. For the other task, which served as a baseline control task, subjects heard the same sound pairs as in the discrimination task, but they were not asked to differentiate between them.

rCBF data are shown in the Table.

	PREFRONTAL	PRECENTRAL	TEMPORAL	PARIETAL	PARIETO-OCCIPITAL
Discrimination:					
normals	78±8	73±6	69±7	69±7	67±7
patients	70±8	68±9	62±8	64±9	61±7
p value	.05	.10	.05	.12	.04
Control Task:					
normals	79±7	75±6	70±6	70±6	67±6
patients	72±11	69±10	64±10	65±10	62±8
p value	.09	.11	.10	.11	.08

Patients tended to have lower rCBF in all regions during both conditions, and this reached significance at the $p<.05$ level in prefrontal, temporal, and parieto-occipital regions during the discrimination task. In normal subjects, proficiency on the discrimination task was unexpectedly associated with lower temporal rCBF, especially on the left ($r=-.57$, $p<.03$), as measured during performance of the task. Similar correlations, however, were also found with rCBF measured during the resting state.

These data suggest that, patients with schizophrenia may exhibit cortical functional abnormalities during an auditory dicrimination task. In contrast to our earlier finding with rCBF during a prefrontal task, the abnormalities do not appear to be regionaly specific or to be specific to cognitive state.

183.7 DECREASE IN SHIVERING BY MENTAL COMPUTATION. C. Klenow, F. Simmons, and R. S. Pozos. Dept. of Physiology, University of Minn., Duluth, School of Medicine, Duluth, MN 55812.

Shivering reflects the body's attempt to produce heat during cold exposure. This effector response is mediated via motor nerves and is thought to be initiated by central and peripheral thermal stimuli. Shivering as measured by electromyographic recordings demonstrates synchronized bursts of electrical activity over the body. Little research has been done on how to minimize the shivering except for the study by Martin and Cooper. They reported that shivering subjects who did mental arithmetic and isometric contractions were able to significantly decrease shivering (1). This study was undertaken to further analyze this phenomenon and quantitate any decrease in shivering that might be induced by having human subjects do mental computation.

Eight subjects (4 male and 4 female) who were lightly clad laid prone on a table and were individually subjected to a cold environment (30-32°F) for approximately 40-55 minutes. Electromyographic recordings were made using surface electrodes from five different muscle groups (masseter, trapezius, extensors and flexors of the wrists, and rectus femoris). After the onset of shiver, the subjects were asked to do simple arithmetic assignments. These consisted of having the subject hold a card in his hand and add four different sets of double digit numbers and call out the appropriate response. The control consisted of having the subject hold a blank card for the same period of time that he was holding the experimental card.

A decrement in the amplitude of shivering was seen in all eight subjects during the arithmetic task. Shivering returned when the task was completed. During the control studies, there was no decrease in the amplitude of shivering. Paired t-test analysis showed that there was a statistical difference between the RMS value before shivering and during the math tasks. In addition, there was a significant difference in the RMS value between math computation and the return of shiver. There was no difference between the shivering amplitudes before and after the math computation. This data indicates that the cerebral cortex must play some role in controlling the oscillator(s) responsible for the onset and maintenance of overall body shiver.

183.8 DISSOCIATION OF ABSTRACT REASONING ABILITIES BY LOCUS OF HEAD INJURY. A. Cronin-Golomb, W. A. Rho,* and S. Corkin. Dept. of Brain and Cognitive Sciences and Clinical Research Center, MIT, Cambridge, MA 02139.

The ability to reason abstractly comprises multiple skills that may involve different brain regions. Twenty-seven veterans of the Korean Conflict were tested for the ability to reason abstractly, using two nonverbal tests that measure different aspects of this function. The subject group included 13 veterans with right-sided penetrating head injury (RHI), 9 with left-sided penetrating head injury (LHI), and 5 uninjured veterans who served as age-, education-, and experience-matched control subjects. Each subject performed two tests: the Hukok Logical Thinking Matrices Test (Daryn, 1977), which measures the ability to extend logically an existing pattern by incorporating new elements ("generational" ability); and the Abstract subtest of the Concept Comprehension Test, or CCT-A (Cronin-Golomb, 1986), which examines the ability to relate common objects on an abstract basis ("relational" ability).

The uninjured control subjects scored $\bar{X}$=6.6, sd=1.7 on the Hukok and $\bar{X}$=20.0, sd=1.4 on the CCT-A. The HI subjects as a group performed within the normal range, though not as well as the control group, on the Hukok ($\bar{X}$=5.7, sd=1.8) and the CCT-A ($\bar{X}$=19.1, sd=3.3). No significant differences were found between the RHI and LHI groups for either test. The HI groups were then subdivided by locus of lesion, as determined from medical report and CT scan for each subject. Of the original 22 HI subjects, 13 had injuries that were contained within a single lobe: frontal, parietal, temporal, or occipital. Subjects with exclusively frontal- (N=4) or occipital-lobe (N=1) lesions performed the two tests at the normal control level. The parietal-lobe group (N=5) performed the CCT-A at the normal level ($\bar{X}$=20.4, sd=2.7), but was impaired on the Hukok test ($\bar{X}$=5.0, sd=2.0). In contrast, the temporal-lobe group (N=3) outperformed the parietal-lobe group on the Hukok ($\bar{X}$=5.3, sd=1.5), but showed substantial impairment on the CCT-A ($\bar{X}$=15.0, sd=4.6). Small sample sizes precluded analysis of the data by side of injury for each lobe.

The results suggest that different abstract reasoning abilities may be localized to different brain regions. Specifically, optimal performance on a test of generational ability may require intact temporal and especially parietal lobes; achievement of normal scores on a test of relational ability appears to require intact temporal lobes exclusively.

183.9 STIMULUS CANCELLATION PATTERNS IN MONKEYS WITH HEMINEGLECT. R.K. Deuel and S.P. Schaffer*. Departments of Pediatrics and Neurology, Washington University School of Medicine, St. Louis, MO 63110

We have previously found that monkeys with hemineglect always retire the ipsilateral of two simultaneously presented visual stimuli before beginning to address the one contralateral to their lesion (Deuel and Collins, 1984). It has recently been shown that humans with hemineglect after stroke fail to cross out stimuli (an array of lines on a piece of paper) contralateral to their lesions, but improve when the task is to eliminate (by erasing) the stimuli as they address them (Mark, Kooistra and Heilman, 1987). We therefore hypothesized that monkeys with hemineglect when presented with an array of visual stimuli, distributed equally to left and right of visual fixation, would address this array most efficiently if they used the strategy of starting in the ipsilateral field and eliminating stimuli already addressed. To test this hypothesis cynomologus monkeys were tested with a board encompassing an array of bait at six loci (in three columns of two) that was centered directly in front of the monkey at eye level, before and after frontal (FR, N = 11) or parietal (PA, N = 11) lesions. The hand ipsilateral to the lesion (or the future lesion) performed the motor response. Preoperatively animals showed no tendencies to start at any particular locus and the speed of board emptying was the same wherever emptying was initiated. Postoperatively both groups strongly preferred to begin bait retrieval in the ipsilateral column (and the column closest to the active hand). The FR group used this strategy significantly more frequently than the PA group (χ^2 = 4.27, df = 1, $p < .04$). Despite the frequency with which the frontal group used this strategy, it did not demonstrate greater efficiency at bait retrieval than the PA group, and in fact often left the contralateral side of the array unperturbed. As only the unaffected hand, ipsilateral to the lesion, was active and no eye movement deficits were noted, an explanation in terms of deployment of attention in space still seems likely, but data from human subjects suggests that the explanation of the different patterns of retrieval used by the two groups may differ according to separate pathophysiologies related to lesion locus.

183.10 WHERE DO HEMIANOPSIC PATIENTS FIXATE WHEN THEY LOOK STRAIGHT AHEAD? J. Sergent, G. Bertrand*, and J. G. Villemure*, Dept. of Neurol. Neurosurg., McGill Univ., and Montreal Neurological Inst., Montreal, QC, H3A 2B4, Canada.

Blindness in one visual field produced by destruction of the geniculo-striate pathways or striate cortex is a negative symptom due to absence of sensation. As a result, the patient may be unaware of the blind field and, despite the reduced area of vision, the whole visual field can still be scanned through head and eye movements. However, because of the hemianopsia, the area of highest acuity normally used for fixation falls just at the border of the blind field, which is not convenient to focus on a target. In the course of perceptual experiments on hemianopsics, considerable difficulty was encountered when the patients were requested to fixate a central point. The present study was designed to examine the accuracy of eye fixation in hemianopsics when they have to look straight ahead at a fixation point. The experiment consisted first in measuring Snellen acuity of each patient, then in constructing stimuli made of a row of single letters or digits of a size corresponding to each patient's Snellen acuity, and finally in presenting these stimuli tachistoscopically. Given that Snellen acuity corresponds to the resolving power of the fovea, by requesting the patient to look straight ahead and by presenting, on the horizontal meridian, alphanumeric characters that only the fovea can resolve, the location of the identified character with respect to the center of the visual field would indicate where the patient is actually fixating. While control subjects always identified the character the closest to fixation, there was marked deviation of the eyes toward the blind field in all hemianopsic patients, irrespective of the side of the lesion and of the presence of unilateral neglect. The extent of eccentric fixation ranged from 0.9° to 3.6°, with a mean of 2.5°. In order to correct for this deviation when accurate fixation is required, a simple method was devised whereby the right and the left visual fields were colored in pale blue and pale green of equal luminance, respectively, along with a small black square located at the border of the vertical meridian in the intact field, 3° above and below the central fixation point. When instructed to fixate the central point so that only one color and the two squares were seen, all but one patient reported the character the closest to fixation on the identification task. Eccentric fixation in hemianopsics does not reflect a so-called pseudo-fovea, but an uncontrolled adaptive response to the deficit so that the object of attention is perceived within its surrounding context.

183.11 PERCEPTUAL AND MOTOR SET EFFECTS ON VERY SHORT-LATENCY COMPONENTS OF VERs. Marta Oakley & Robert G. Eason, Department of Psychology, UNCG, Greensboro, N. C. 27412.

Evidence that the behavioral state of an individual can influence short-latency components of visual, auditory, and somatosensory EPs continues to mount (Oakley, et al, NS. Abstr., 1985, 1986; Woldorff, et al, NS Abstr., 1986; McCarthy & Wood, NS Abstr., 1986). However, the question of whether behavioral influences on these components involves precortical gating mechanisms remains unresolved.

The present study was undertaken to provide further information on this issue, and also to ascertain whether motor set, along with perceptual (or sensory) set, contributes to the responsivity of subcortical elements prior to the arrival of poststimulus information at the cortex. Anatomical and physiological data are suggestive of this possibility (e.g., Hammond, J. Physiol., 1956; Evarts & Tanji, Br. Res., 1974; Robinson, et al, J. NS, 1985; Schlag & Schlag-Ray, J. Neurophysiol., 1984; Wurtz & Goldberg, J. Neurophysiol., 1972).

Using the paradigm of Eason, et al (Phy. & Beh., 1969), subjects were required to respond to target stimuli (doublet flashes) appearing 30° peripherally in the relevant (i.e., attended) visual field by (1) making an eye movement to that location, (2) making a foot-lift response, or (3) keeping a silent count of the doublets.

VERs were obtained at frontal and parietal sites (F3,4 and P3,4) of each hemisphere to 100 single flashes presented randomly from within each visual field (one attended, the other not) during which time subjects were set to make one of the types of responses to doublets which were randomly interspersed among the single flashes. The flashes subtended a visual angle of 35' and were about 2.7 log units above threshold. VERs were obtained only to the single flashes to which an overt response was not required.

An early segment of the VERs lying within a latency range of 40-70 msec poststimulus was significantly affected both by the relevancy of the visual field and by the type of response the subject was set to make. When set to count doublets, the segment was relatively more positive when a given visual field was being attended to than when it was not. When set to make eye movements, the segment was relatively more negative under the attend than under the unattend condition. Non-significant results were obtained for the foot-lift condition.

The short latency, low amplitude, and homogeneous distribution of the polarity of the segment across recording sites suggests it was generated within subcortical structures of the visual system. The observations suggest that both selective attention (perceptual set) and motor set can influence the responsivity of the visual system prior to the arrival of poststimulus information at the cortex.

183.12 **BIOBEHAVIORAL RELATIONSHIPS IN DYSLEXIA.** D.W. Shucard, K.R. Cummins* and J.L. Shucard*. Department of Neurology, State University of New York at Buffalo, School of Medicine, Buffalo, NY 14222.

Dyslexia is a disorder characterized by difficulty in learning to read despite conventional instruction, adequate intelligence and socio-cultural opportunity. Evidence derived largely from behavioral studies suggests that dyslexia is most likely a heterogeneous disorder that, in at least some reading-disabled (r-d) children, may be related to a disturbance in the normal functional organization of the brain (e.g. a disturbance in right-left cerebral organization, a failure to develop adequate left hemisphere specialization for language, a disturbance in normal inter-hemisphere transfer of visual-phonemic information). The purpose of the present study was to investigate hemispheric patterns of auditory probe event-related potentials (AERPs) in a large sample of r-d and control subjects in order to determine: 1) if differences in functional cerebral organization exist between normal and disabled readers, and 2) if it is possible to identify different subtypes of individuals within the r-d population through the combined analysis of electrophysiological and behavioral data. Previously, we reported significant differences in the patterns of AERP amplitude asymmetries between 12 - 16 year old normal and disabled readers matched for age, sex and handedness. In this report we describe relationships obtained between electrophysiological and behavioral measures. For example, a significant relationship was found between AERP measures of cerebral asymmetry and the discrepancy between spatial and sequential abilities, derived from the WISC-R, in the r-d subjects ($r = -.42$, $p < .01$). These findings indicate that the greater the spatial score compared to the sequential score, the higher the amplitude of the left temporal AERPs compared to the right in r-d subjects. Normal controls matched for sex, age and handedness did not show any significant correlation between these two variables. These findings suggest that the AERP asymmetry may reflect a neurophysiological basis for reading disability in at least one group of children studied. These results may be indicative of a reduced capacity for sequencing skills in r-d children due to a disturbance in left hemisphere functioning.

183.13 ENCOUNTERING VIOLATIONS IN MEANING: THE N400 AND TEXT COMPREHENSION Banghart, J.G., Danks, J.H., and Vardaris, R.M., Dept. Psychology, Kent State University, Kent, OH 44242

The results of several studies (Kutas & Hillyard, 1980a, 1980b, Neville, 1986) have led resarchers to postulate that the N400 ERP component is an index of semantic integration. Psycholinguistic theorists hold that text consists of large units of meaning, called macrostructure or propositions. Manipulations of these larger units result in changes in meaning of the text by, for example, contradicting some previously stated information. Behavioral studies (e.g Danks & Hill, 1981; Danks & Rittman, in prep.) have shown that factual inconsistencies produce behavioral disruptions (e.g. longer oral reading times) at the end of the sentence containing the critical word. This finding has important implications for psycholinguistic theory in terms of whether meaning is integrated immediately or delayed (clausal integration hypothesis). In the present study we investigated N400 amplitude during text comprehension when semantic anomalies and factual inconsistencies were encountered.

Methods:Strongly right-handed males pre-tested for adequate reading comprehension were assigned to one of four groups: factual inconsistency-behavior, factual inconsistency-ERP, semantic anomaly-behavior, semantic anomaly-ERP. The two texts contained a total of 24 violations and 24 controls. ERPs (Wl, Fz, and Pz) or behavioral latency to move the text across the screen were collected on critical words and final words in critical sentences.

Results:Behavioral results showed that semantic and factual violations disrupted performance relative to control words at the critical and final word locations. Semantic anomalies were associated with a larger N400 than controls at both word positions, and this N400 was greater at the critical word than the final word. This trend was reversed for control words in the semantic group. The N400 for the factual words was not different from the control words at either the critical or the final word, and the amplitude was the same for critical and final words for factual inconsistencies. For control words, N400 was larger in the final position.

Conclusion:N400 for factual inconsistencies does not behave like the N400 for semantic anomalies or control words. The factual inconsistencies may disrupt normal processing of sentences from intermediate or final word positions, confirming previous behavioral findings, and further supporting the clausal-integration hypothesis.

183.14 ANTEROGRADE AND RETROGRADE AMNESIA IN PATIENTS WITH CHRONIC PROGRESSIVE MULTIPLE SCLEROSIS. W.W. Beatty, D.E. Goodkin*, N. Monson* and P.A. Beatty*. Dept. of Psychology, North Dakota State Univ., Dept. of Neuroscience, Univ. of North Dakota School of Medicine, and Fargo Clinic-Meritcare, Fargo, ND 58105.

To better characterize the memory disturbance in chronic progressive multiple sclerosis (MS), 38 MS patients and 26 age-and education-matched controls were administered the Minimental State Exam (MMSE, Folstein et al., 1975) and a battery of tests of information processing speed, language, egocentric orientation, short-term and long-term episodic memory and remote memory. Patients were divided into subgroups of cognitively impaired (MMSE < 28) or cognitively "unimpaired" (MMSE: 28-30, the range for controls). Patients in the cognitively impaired group were seriously impaired on all measures of cognitive function including the Boston Naming Test (a measure of anomia). Patients in the cognitively unimpaired group, although less severely affected, performed significantly below controls on all measures of anterograde and remote memory, verbal fluency, egocentric orientation and the Symbol Digit Modalities Test (which measures speed of information processing), but they were not anomic. Deficits on memory tests were observed using both recall and recognition procedures and the proportion of patients who scored below the 5th percentile for controls exceeded 35% on all measures of recall or recognition memory. The cognitive deficits displayed by these patients could not be attributed to affective illness, concurrent use of medications for depression, spasticity or problems with bladder control, poor visual acuity, or to prior treatment with immunosuppressants.

The pattern of memory failure observed in patients with normal MMSE scores closely resembled that seen in subcortical dementias such as Huntington's Disease. These patients exhibited deficits on the remote memory battery which were equally severe for all past decades and they did not show increases in the proportion of perseverative responses on either the Brown Peterson STM test or any of the measures of verbal fluency. In general, the pattern was similar for the patients with low MMSE scores, but these patients were anomic and showed modest increases in perseveration on some of the verbal fluency tests.

Supported by a grant from The Neuropsychiatric Institute, Fargo.

183.15 N100 AND P300 TUNING EFFECTS DURING AN ATTENTION SWITCHING TASK. Erik Sirevaag* and Arthur Kramer* (SPON: L. Malmgren). Dept. Psych., University of Illinois, Urbana-Champaign, Il 61820. The purpose of this experiment was to examine the relationship between components of the Event-Related Brain Potential (ERP) and processes involving selective attention. Tones (1000 and 1400 hz) were presented randomly to the left and right ears. An arrow presented visually before each sequence of twelve auditory stimuli indicated which ear was to be attended to. Prior to the experiment a target frequency was designated for each subject. If a given tone was presented to the correct ear and was of the target frequency a button press response was required. The interval between tone presentations varied from 550 to 850 msec. Subjects performed 50 blocks of these 13 trial sequences followed by a 5 min rest period. In a single session, 7 groups of 50 blocks were performed. Electroencephalographic (EEG) data from three electrode positions were recorded (Fz, Cz, and Pz). The ERP data were analyzed by examining the amplitudes and latencies of a variety of components as a function of the ear, frequency, and target/non-target classification of the ERP eliciting tones. The ERP components were also examined as a function of the temporal position of the stimulus following a switch in attentional locus (early, middle, and late temporal positions). Larger P300s were associated with tones of the target frequency presented to the attended ear. The difference in amplitude between P300s associated with target and non-target stimuli increased as a function of temporal position -- evidence of a tuning effect upon P300 amplitude. Reaction time (RT) did not vary as a function of sequence. A non-parametric estimate of sensitivity (a') indicated that the increases in P300 amplitude were associated with increases in operator sensitivity. The N100 component was significantly larger for tones of the correct frequency, independent of ear of presentation. This finding may indicate that subjects first selected the tones on the basis of frequency with further selections (as indexed by the P300) occurring on the ear dimension. N100 amplitude also displayed a sensitivity to the sequential position of the stimuli within the temporal sequence. Larger N100s were elicited by the first stimuli in the sequence than in the two latter segments. The frequency and sequence effects on N100 amplitude did not interact indicating a general decline in the N100s to all stimuli. These results indicate that following an attentional switch, the first few stimuli elicit large N100s which decline rapidly in amplitude and then remain constant. In contrast, target P300 amplitudes gradually increase as subjects become more familiar with the response requirements of the given trial sequence.

183.16 NEUROPSYCHOLOGICAL AND NEUROBIOLOGICAL ACCOUNT OF A DISORDER. U. Bellugi, S. Marks*, A. Bihrle*, T. Jernigan, F. Culler*. Cognitive Neurosciences, The Salk Institute, P.O. Box 85800, San Diego, CA 92138-9216.

This paper presents a line of investigation which forges links between a specific metabolic disorder, an unusual neuropsychological profile, abnormal brain organization, and a newly discovered neuropeptide as the basis for the disorder. We have undertaken an investigation of the neurobiological and neuropsychological features of Williams Syndrome, a rare clinical disorder of hitherto unknown etiology which appears to affect behavior, language and learning in highly specific ways. A psychophysical result of this metabolic disorder is an unusual sensitivity to classes of sounds, not characteristic of other syndromes. Our neurobehavioral studies of adolescent Williams children indicate that there is a marked discontinuity between linguistic functions and other cognitive functions -- an island of sparing of language capacities in the face of general mental retardation. This extreme dissociation between language and cognitive development is rare and important to an understanding of language and its functional organization in the human brain.

Several lines of evidence will be reviewed suggesting that the cerebral hemispheres may not be organized in the normal fashion in Williams Syndrome children. Results of Magnetic Resonance Imaging techniques will be reported in Williams children, indicating abnormalities in specific brain structures which relate to the unusual neurobehavioral profile. Studies of brain function, including electrophysiological measures, also implicate abnormal brain organization underlying this disorder. We investigate a hypothesis which relates CNS dysfunction and abnormalities of calcium and calcintonin metabolism in children with Williams Syndrome. We hypothesize that these children may have a single underlying genetic disturbance which results in the abnormal production of a specific neurotransmitter. This hypothesis will be linked to the unusual neurobehavorial profile found across domains.

LEARNING AND MEMORY: PHARMACOLOGY I

184.1 POST-SESSION NALOXONE ADIMINISTRATION IMPAIRS AUTOSHAPED LEVER RESPONSE LEARNING. R.B. Messing, S. Allen*, L. Aanonsen* and S.B. Sparber. Dept. of Pharmacology, Univ. of Minnesota Medical School, Minneapolis, MN 55455.

Naloxone (Nx) given after training enhances memory consolidation (performance in a retention test) in aversively motivated tasks (Gallagher & Kapp, Life Sci. 23 [1978]: 1973; Messing et al, Behav. Neur. Biol. 27[1979]: 266), but it impairs performance if given prior to training (Izquierdo, Psychopharm. 69[1980]: 111). Posttrial Nx also enhances memory-related performance in a food motivated spatial memory task (Gallagher et al., Science 221[1983]:975). The present work further assessed the effects of Nx on appetitive learning.

Food deprived rats were autoshaped in Skinner boxes to touch a retractable lever; delivery of a food pellet followed lever retraction. Intertrial intervals (ITI's) between lever presentations varied between 22 and 68 s. The lever was retracted immediately if a touch occurred within 15 s or automatically after 15 s. In an initial experiment, male Sprague-Dawley (SD) rats were given saline or Nx (2 mg/kg) i.p. 5 min before a training session of 12 trials. Two days later they were tested, in the absence of drug, in a session of 36 (3 blocks of 12) trials. Repeated measures ANOVAs were computed for touches of the extended lever (maximum of 12/block), nose-pokes (touches) directed at the retracted lever during ITI's (a measure less constrained by ceiling effects than extended lever touches), and unconditioned expoloratory rearing activity, measured as touches of a metal strip mounted above the grid floor on two walls of the Skinner boxes. Nx depressed basal (training) levels of lever responding, in addition to slowing acquisition rate (i.e. there was an effect of Treatment on both measures of lever responding, and a Block x Treatment interaction for nose-pokes). No effect of Nx was observed on rearing activity, which declined across trial blocks. Additionally, injection of saline 5 min before behavioral testing increases the rate of autoshaping compared to injections 30 min before (Messing & Sparber, Trends Pharmacol. Sci. [1984]5: 149). These results suggest that effects of Nx on measures of learning may be confounded by both behavioral depressent effects and by an injection effect such a short time prior to testing.

Accordingly, a second experiment was carried out wherein Nx (0.5 or 2 mg/kg) was injected after 5 of 7 training sessions (12 trials each) to male and female SD rats. Also, a 6 s delay of reinforcement was inserted between lever retraction and food delivery, lengthening the acquisition process and making it less likely that ceiling effects would prevent observation of drug-induced facilitation. The low dose retarded acquisition of both lever-directed behaviors. There was no effect of Nx on rearing activity. The results support the notion that low doses of Nx have direct agonist action or stimulate release of endogenous opioids (Levine et al, Nature [1979]278: 740). The higher dose may, in addition, block opioid effects or convey mainly the antagonist component of a mixed agonist-antagonist drug.

184.2 DESGLYCINAMIDE-8-ARGININE VASOPRESSIN REVERSES A TRIMETHYLTIN-INDUCED LEARNING DEFICIT. S.B. Sparber, C.A. Cohen*, and R.B. Messing. Dept. of Pharmacology, University of Minnesota, Minneapolis, MN 55455.

Trimethyltin (TMT) is an organometal neurotoxin which produces lesions primarily in the limbic system. Selectivity seems to depend upon the dose, but the hippocampus and related entorhinal cortical structures, of importance for learning and memory, are most often described as target sites (Dyer *et. al. Neurobeh. Tox and Teratol.*, 4, 141-48, 1982). We have previously demonstrated that subjects treated with a moderate dose of TMT prior to acquisition sessions, are unable to learn a forward autoshaping task with a 6 sec delay of reinforcement, but are capable of acquiring the same task when no delay of reinforcement is used (Cohen *et. al., Neurosci Abs,* 10, 1205, 1984). These data suggested that the performance deficit is one of learning (i.e. consolidation) rather than of memory (i.e. storage), retrieval, or sensorimotor impairment.

To more rigorously test this, we determined if performance of a task already learned would be impaired by the neurotoxin. Subjects were exposed to Skinner boxes, equipped with retractable levers that were presented on a random time 45 sec schedule, with intertrial intervals ranging from 22 to 68 sec. Once the lever was extended, it remained out until a lever touch occurred or 15 sec had elapsed, after which the lever was retracted and a food pellet was delivered 6 sec later. Adult male Long Evans rats were given 10 acquisition sessions of 24 trials, following which TMT (6.0 mg/kg, p.o.) was administered. One month later, these rats performed the lever-touching behavior as well as controls, despite the fact that the same dose of TMT interfered with learning if given one month prior to acquisition sessions, thus confirming our hypothesis.

In a second experiment we determined if the peptide analog of vasopressin, desglycinamide-8-arginine vasopressin (DGAVP), could reverse the learning deficit caused by pretreatment with TMT. Rats treated with TMT one month prior to acquisition training in the autoshaping task, and which did not learn to associate the lever with delivery of a reinforcer after 10 sessions of 12 trials each, were treated with saline or DGAVP (7.5 ug/kg, s.c.) 1 hr before sessions 11-13; treatment was discontinued prior to sessions 14 and 15. Peptide treated subjects showed evidence of acquisition and exhibited higher levels of lever-directed behavior than controls. Performance was maintained after DGAVP treatment was discontinued, indicating that the learning-enhancing action of DGAVP was not transient or state-dependent.

Thus, the automated autoshaped task with various delays of reinforcement, and TMT-induced or other CNS lesions of varied severity, may provide a useful animal model of human cognitive impairments, as well as a tool for investigation into treatment of such disorders.

184.3 **NITROUS OXIDE'S EFFECTS ON HUMAN LEARNING AND MEMORY.** R.J. Leonesio*, D.S. Ramsay*, P. Weinstein*, H.H. Samson III* and B. Jones* (SPON: A.C.N. Chen) Department of Psychology, University of Washington, Seattle, Washington 98195.

Nitrous oxide (N_2O) is a commonly used analgesic and anxiolytic drug. Although it is dentistry's most common form of conscious sedation, little is know about its effects on learning and memory. The effects of nitrous oxide on the acquisition and retrieval of number-word pairs were examined in 95 male subjects (ages 18-35). Using the method of adjusted learning, subjects were asked to acquire the pairs to either of two learning criteria while breathing either "air" (30% N_2 and 70% O_2) or "nitrous oxide" (30% N_2O and 70% O_2). Subjects who received air during the acquisition session acquired (to a criterion of 1 correct response) all 18 pairs with an average of 23.32 trials (SEM = 1.80) whereas subjects receiving nitrous oxide required an average of 48.17 trials (SEM = 3.61). 30% nitrous oxide slowed the acquisition of number-word pairs ($t = 6.12$, $df = 93$, $p < 0.05$).

Two week later, half of the subjects in each of the previous two groups were administered either air or nitrous oxide and were asked to recall the word that accompanied each number cue. There was no evidence of any state-dependent effect of nitrous oxide on recall. Although nitrous oxide inhalation impaired retrieval during the retention session, multiple regression analyses suggested that learning while under nitrous oxide may actually have enhanced recall. The observation that subjects can acquire and store information while breathing nitrous oxide suggests the possibility that psychological techniques that rely on the subject's ability to learn may be used during nitrous oxide conscious sedation.

184.4 CALCIUM INFLUX AND CALCIUM-CALMODULIN ACTIVITY ARE NECESSARY FOR FORMATION OF SHORT- AND INTERMEDIATE-TERM MEMORY IN THE CHICK. E.L. Bennett, T.A. Patterson, M.C. Alvarado*, A. Khorram*, & M.R. Rosenzweig. Dept. of Psychology, Univ. of California, Berkeley, CA 94720.

Research in our laboratory indicates that memory formation in the chick involves at least three stages, distinguishable by their underlying neurochemical mechanisms and temporal parameters (Patterson et al., 1986). Formation of long-term memory is dependent upon protein synthesis. Experiments described below examined the role of calcium influx and calcium-calmodulin activity in formation of short-term memory (STM) and intermediate-term memory (ITM).

Two-day-old male Dekalb-Warren chicks were trained in a one-trial taste avoidance task. In Experiment 1, dose response functions were determined for lanthanum chloride ($LaCl_3$), an inhibitor of calcium influx, and trifluoperazine (TFP), a calcium-calmodulin inhibitor. Injections (10 µl/hemisphere) of saline or drug were made into the medial hyperstriatum ventrale 5 min (for TFP) or 10 min (for $LaCl_3$) pretraining and chicks were tested 24 hr posttraining. 10.0-40.0 mM $LaCl_3$ and 1.2-9.8 mM TFP produced significant amnesia.

Experiment 2 showed that $LaCl_3$ (10.0 mM) produced amnesia when given 30, 15, or 10 min pretraining. $LaCl_3$ was not amnestic when given earlier than 30 min before training, when given 5 min pretraining, or at any time posttraining. TFP (4.9 mM) produced amnesia when given 30, 15, or 10 min pretraining or when given 5 min after training. TFP was not amnestic when given earlier than 30 min pretraining or later than 5 min posttraining.

Experiment 3 determined the time courses of amnesia development following 10 min pretraining injection of $LaCl_3$ or TFP. $LaCl_3$ (10.0 mM) produced amnesia that developed by 5 min posttraining. TFP (4.9 mM) produced amnesia that developed 15-20 min posttraining. Amnesia produced by these agents is permanent. Similarities of the effects of $LaCl_3$ and TFP to other inhibitors of formation of STM and ITM (Patterson et al., 1986) indicate that $LaCl_3$ interferes with formation of STM, and TFP interferes with the formation of ITM.

These results suggest that neurochemical systems involving calcium influx mediate formation of STM and systems involving calcium-calmodulin activity mediate formation of ITM. Hypotheses about the possible roles of these systems in memory formation will be presented.

184.5 IMMATURE PROCESSES OF SPATIAL LEARNING IN HOODED RATS. A.-F. Chevalley and F. Schenk (SPON. C. Marchand). Institute of Physiology, University of Lausanne, 1005 Switzerland.

Previous studies have shown that young hooded rats under approximately 32 days of age do not develop systematic, direct approaches to the invisible platform during training in the Morris place navigation task. During probe trials, however, they show significant discrimination of the training position. We have further developed studies of such immature forms of spatial learning in various homing experiments using a hole board on which rats are trained to find one hole out of many which is connected with their home cage.

Even in the absence of proximal cues, 21-day-old rats show a significant discrimination of the training sector during a probe trial with no connected hole, yet in reaching the goal, even when clearly indicated by an object, their performances lack in precision. In addition, their behaviour is characterized by a stereotyped scanning in the starting area. After 22 days of age, rats run straight to a cued hole and show organized scanning behaviour. However, if it is only possible to locate the training hole with the help of distal room cues, the systematic use of direct approaches is not observed until after the age of 30 days. Until around 42 days, rats rely on proximal, contextual cues (if available inside the enclosure) in combination with distal ones to discriminate the training position, while older rats rely predominantly on distal room cues.

In order to further study the immature processes of spatial learning in rats, young subjects of various ages were trained to find the connected hole surrounded by a configuration of objects dispersed within the enclosure. This procedure has allowed us to assess the variability in routes leading to the goal at different ages, and to estimate the importance of intra-table cues versus distal ones in conflicting situations created by a table rotation. These results will be discussed from the aspect of the sensitivity to steroïd hormones in puberty of the responsiveness to catecholaminergic drugs.

On the whole, our results confirm that young animals are quite capable of place recognition at least one week before they develop their abilities to aim and head straight for a goal from any starting position which represents the criterion for true place learning. The two structures which seem indispensable for this aspect of spatial learning could be the subiculum and/or the parietal cortex, as indicated by a recent lesion study (Kolb and Walkey, 1987).

184.6 THE EFFECTS OF ALCOHOL AND TIME ON DIFFERENT FORMS OF MEMORY. B.L. Schwartz*, E.S. Parker, and E .Tulving . Psychiatry, Georgetown Univ. and VAMC Washington, DC 20422, NPI, Univ. of California, Los Angeles, CA 90024, Dept. of Psychology, Univ. of Toronto, Toronto, Canada M5S 1A1.

A current issue in the science of memory and learning is the distinction among multiple forms of memory . Evidence for the distinction comes from dissociations among performances on various memory tasks. The question addressed here is whether two types of impaired memory function (acute alcohol amnesia and forgetting over time) have dissociable effects on 3 forms of memory (episodic memory, repetition priming, and skill). We examined whether there are differences in the patterns of memory failure produced by alcohol intoxication and the natural passage of time.

In the alcohol experiment, subjects participated in 2 sessions a week apart. In the first session, 32 subjects drank alcohol (1 ml/kg) and studied material on the rising and falling blood alcohol curve. In the second session, memory was tested under the same alcohol conditions. The control group of 32 subjects had placebo drinks instead of alcohol in both sessions. In the time experiment, 32 subjects studied the same materials as subjects in the alcohol experiment. They were tested 3 hrs, 1 week, 1 month, and 4 months later.

A modification of the word fragment completion task was used (Tulving, E., Schacter, D.L., & Stark, H.A., Journ. of Expt. Psych.: Learn., Mem. and Cog., 8:336, 1982). At study, subjects completed word fragments with the aid of successively less fragmented cues (e.g., a--a--in, as-a--in, assa--in) until the entire word was presented. At test, the same successive cuing method was followed using a mixture of studied (old) and unstudied (new) words. After completing the fragment cue, subjects made a yes/no recognition judgment about the word. The recognition test assessed episodic memory. Priming was measured by the facilitation in completing old versus new word fragments, and skill was measured by improvement in the completion of new word fragments with practice.

Alcohol and time both impaired recognition performance. In the case of alcohol, recognition changed as a function of blood alcohol at study. In the case of time, recognition declined as retention interval increased, with a reduction of 70% over a 4-month period. Time, but not alcohol, affected priming. Skill of completing word fragments was resistant to both the effects of alcohol and time.

The different patterns of memory failure produced with alcohol intoxication and the passage of time may serve as experimental models of chronic amnesic disorders such as Korsakoff syndrome and Alzheimer's disease.

184.7 CLONIDINE REVERSES LEARNING DEFICITS AFTER PARTIAL FORNIX SECTION. SJ. Sara, C. Maho* and M. Ammassari*. Lab. de Physiologie Nerveuse, CNRS, Gif-sur-Yvette, 91190 FRANCE and Ist. di Psicobiol.,CNR,Rome.

Studies of memory disorders associated with aging have focused on the cholinergic (ACh) system because of: -massive deficits seen in the brains of Alzheimer's patients, -relative ease of producing learning and memory deficits in animals with ACh dysfunction. The recent report that α2 adrenoceptor agonist clonidine (CLO) improves cognitive function in aged monkeys (Arnsten & Goldman-Rakic, Science, 230, 1273-1276), has prompted interest in the role of the noradrenergic (NE) system in memory dysfunction associated with aging. Our present studies are addressing the possible interaction of these two systems implied at a behavioral level.

Partial section of the fornix produces a consistent deficit in radial arm maze learning and an increase in the dominant theta frequency in the hippocampus. The ACh agonist, oxotremorine restores normal theta as well as behavior, suggesting that the deficit is due to decrease in ACh input to the hippocampus, (Maho et al, in press). Thus a convenient model is provided to study NE-ACh interaction.

Rats received knife cuts to the dorsal fornix or sham operation. They were trained in an 8 arm radial maze to collect food pellets at the end of each arm. They were treated with CLO (.01mg/kg) before each daily trial; controls were injected with saline. The number of repeated choices out of 8 and the number of choices before a repetition were used as performance indices. Lesioned rats were significantly impaired in the acquisition of this task, but did approach the performance of controls on the tenth trial. CLO-treated rats, lesioned or not, had an acquisition profile indistinguishable from that of sham operated saline injected rats. Rats were retested after one week with no drug treatment before the daily trials. There was a performance deficit in all groups on the first test trial, with the lesion-saline group making more errors than the other groups. This lesion group approached the performance level of the others only after 5 retraining trials. Lesioned rats treated with CLO during the 10 original training days, maintained a "normal" performance during the 5 day retraining phase without CLO.

We are presently studying the effect of CLO on reinstatement of normal theta frequencies in the hippocampus to determine if this is a necessary condition for alleviating the lesion-induced behavioral deficit. It is unlikely that the effective site of action of CLO is in the hippocampus, since NE inhibits release of ACh, both directly through α2 receptors and through a GABA-linked mechanism. A more likely mediating mechanism might be through CLO-induced inhibition of locus coeruleus cells with consequent decrease in release of NE, thus permitting an increase in ACh release from spared fiber terminals.

184.8 PREEXPOSURE TO THE PASSIVE AVOIDANCE PARADIGM ALTERS SCOPOLAMINE'S AMNESIC EFFECT IN MICE. M.J.Benvenga and T.P.Jerussi. Pharmacology Group, Anaquest/BOC Health Care, Murray Hill, New Jersey, 07974.

The one-trial passive avoidance paradigm in mice is widely accepted for studying the amnesic effects of drugs. Footshock paired with entering a darkened chamber during a training trial, produces a significant increase in the latency to enter the chamber on a subsequent test trial. However, the latency can be reduced by administering an antimuscarinic, such as scopolamine, 10-30 minutes before the training (Buresova, et.al., Psycopharm., 1964; Bohdanecky & Jarvick, Int. J. Neuropharm., 1967). In the present study we assessed the amnesic effect of scopolamine administered to mice that were initially exposed to a sham passive avoidance procedure (i.e. without footshock).

Male Swiss-Webster mice (25-30g.) were injected with 0 (vehicle = distilled water), 0.5, 1.0, 2.0, or 4.0 mg/kg. of scopolamine 30 minutes prior to one-trial passive (dark) avoidance training (N = 12/dose). Other mice (N = 12/dose/time interval) received a sham passive avoidance trial 30, 60, or 120 minutes, or two sham trials 30 and 60 minutes prior to the dosing regimen (above). Thirty minutes later these groups received passive avoidance training. All mice were then tested 24 hours later and the latency to enter the darkened chamber was recorded. Median latencies were compared by Mann-Whitney U-tests.

The results indicated that the latencies of scopolamine treated mice that did not receive a sham trial were significantly ($p < 0.05$) shorter than vehicle control animals. However, there was a shift of the dose-response relationship for animals that received a single sham trial. Moreover, larger doses of scopolamine were needed to produce an amnesic effect the closer the sham trial was to the training trial. On the other hand, the dose-response shift was not as pronounced when two sham trials were given. Therefore, it appeared that experience with the apparatus and/or procedure mitigated against scopolamine's amnesic effect.

184.9 RETURN OF THE AMOUNT OF MUSCARINIC RECEPTOR TO NORMAL VALUES IN DIFFERENT RAT BRAIN AREAS DURING THE EXTINCTION OF A LEARNED OPERANT BEHAVIOR. A. Ortega*, V. Alemán, A. Meneses* and A. Oscós. Departamentos de Neurociencias and Farmacología, Centro de Investigación y de Estudios Avanzados del IPN, México, D.F. 07000.

Thirty female 90-day old rats were divided ramdomly in 6 groups of 5 animals each. Groups were arranged as follows: active control (AC) group, a maximal learning acquisition (MA) group, a group with 2 extinction sessions (E_{48}) one every 24 hours, one group with 3-extinction sessions (E_{72}) and another group with 4 extinction sessions (E_{96}), finally a group with maximal learning acquisition -- (MA_{96}) but 96 hours later received the last training session in - order to determine its level of learning and to be used as the -- control of the E_{96} group. Active extinction was carried out with - one dayly session of a nonpaired conditioned (CS) and unconditioned (UCS) stimuli. The learning paradigm we used was an "autoshaped" - version of an illuminated press lever associated to an UCS of --- Pavlov's type. The specified brain areas, were dissected, homogenized and the P_2 fractions were obtained in the usual manner. Incu - bations were carried out one hour at 30°C, containing 0.1 mg of -- protein and (-) [N-methyl-^{3}H] scopolamine was used as the labelled ligand. We did not find at any of the extinction days, a signifi - cant change on the number of muscarinic (M) receptors neither in - the frontal cortex nor in the septum nucleus as compared to the -- control group. On the other hand, caudate and temporoparietal cortex ($T\text{-}P_c$) receptor population showed a tendency to increase, that is to return to normal values, as the extinction progresses. The same but less marked tendency, was observed in the hippocampus of these groups. An opposite tendency of the M receptors, was observed in amygdala of these groups, as extinction progresses. In the MA-group, we only observed an increase in the M receptor population of the $T\text{-}P_c$ and a decrease in hippocampus. In other analized brain areas no change was found. When the MA_{96} group was compared against the MA group, we did not detect any change in the M receptor population from amygdala, septum, T-P cortex, hippocampus or frontal - cortex. However, the receptor population from caudate nucleus decreased significantly. In a previous abstract we have demonstrated that the M receptor population in caudate, amygdala, $T\text{-}P_c$ and frontal cortex were increased during the acquisition of learning. These findings and those here reported during extinction, suggest both a cause-effect and a time relationship between the M receptor po - pulation of some brain areas of the brain and the evolving and extinction of a learning process.

184.10 BLOCKADE OF RADIATION-INDUCED CONDITIONED TASTE AVERSIONS AFTER THE DEVELOPMENT OF ETHANOL TOLERANCE. Walter A. Hunt* and Bernard M. Rabin (SPON: John McDonough). Behavioral Sciences Department, Armed Forces Radiobiology Research Institute Bethesda, MD 20814-5145 and Department of Psychology, University of Maryland Baltimore County, Catonsville, MD 21228.

A conditioned taste aversion (CTA) can develop to a novel tasting, but normally preferred solution after it is paired with a toxin. Previous research has demonstrated that a variety of toxins, including ionizing radiation, lithium chloride, WR-2721 (a radioprotectant), copper sulfate, and cisplatin, act similarly through the area postrema (AP) to induce CTAs. An exception is an ethanol-induced CTA, which is not blocked in AP-lesioned animals. Additionally, prior administration of one toxin that is AP-mediated can block the acquisition of a CTA to another AP-mediated toxin. However, this procedure is not successful when ethanol is the toxin. The present research demonstrates that although short-term ethanol preexposure does not block a radiation-induced CTA, the development of tolerance to ethanol will do so. Male Sprague-Dawley rats were rendered ethanol-tolerant (as revealed as shorter sleep-times after a 3-g/kg, i.p. dose of ethanol, compared to nontolerant animals) by administering two doses of ethanol/day (4-6 g/kg, p.o.) for 5 days. The animals were then water deprived for 23.5 hrs/day for the next 5 days. After that time, they were presented with a 10% sucrose solution and the amount consumed in 30 min was recorded, followed by irradiation with 1 Gy (100 rads) of gamma radiation. Two days later, the sucrose was presented again and the amount consumed in 30 min was recorded. A radiation-induced CTA was observed in control animals. However, a CTA was not acquired by ethanol-tolerant animals. Experiments where animals were pretreated with ethanol on 3 days prior to irradiation did not block the development of a CTA. These data suggest that it is not the ethanol itself that provides protection against radiation-induced CTAs, but rather it is the animal's response to the chronic presence of ethanol. Also, they provide evidence that cellular desensitization in general might be an effective approach to radioprotection in order to reduce toxicity associated with exposure to radiation on long-term space flights and during cancer therapy.

184.11 ASYMMETRICAL EFFECTS OF UCS PREEXPOSURE ON TASTE AVERSION LEARNING FOLLOWING TREATMENT WITH IONIZING RADIATION AND OTHER TOXINS. B. M. Rabin and W. A. Hunt*, Behavioral Sciences Dept., Armed Forces Radiobiology Research Institute, Bethesda, MD 20814-5145, and Dept. of Psychology, University of Maryland Baltimore County, Catonsville, MD 21228.

A conditioned taste aversion (CTA) is produced when a novel tasting solution is paired with unconditioned stimuli such as ionizing radiation, lithium chloride (LiCl) or ethanol. Preexposing an organism to a toxin blocks CTA learning when that toxin is subsequently used as a UCS. If the same humoral factor mediates both radiation- and LiCl-induced CTA learning (Rabin & Hunt, Neurosci. Biobehav. Rev., 1986, 10: 55), preexposing the organism to one UCS should disrupt the acquisition of a CTA to the other UCS. In contrast, preexposure to ethanol should have no effects on radiation- or LiCl-induced CTA learning since different mechanisms, not involving the area postrema, mediate the acquisition of an ethanol-induced CTA. Rats were placed on a 23.5-hr water deprivation schedule for 10 days. On days 2, 5, and 8 they were preexposed to one UCS, either radiation (100 rad), LiCl (3.0 mEq/kg, i.p.) or ethanol (4.0 g/kg, p.o.). On the conditioning day (day 10) the rats were given a choice between water and a 10% sucrose solution followed by treatment with either the same or a different UCS. On the test day (day 12), all animals were again given a choice between sucrose and water. The results showed that preexposing rats to LiCl prevented the acquisition of both an LiCl- and radiation-induced CTA. Preexposing rats to radiation blocked the acquisition of a radiation-induced CTA, but not the LiCl-induced CTA. Preexposing rats to ethanol did not affect the acquisition of a CTA following treatment with either radiation of LiCl. In contrast, both radiation and LiCl preexposure disrupted the acquisition of an ethanol-induced CTA in intact rats, but not in rats with lesions of the area postrema. The observation of asymmetrical preexposure effects between the various stimuli indicate that the relationships between these stimuli are more complex than originally hypothesized. In addition, the results with the ethanol-induced CTA suggest that these relationships may somehow involve the area postrema even when the area postrema is not involved in the acquisition of the original CTA.

184.12 AF102B: A NEW M1 AGONIST WITH POTENTIAL APPLICATION IN ALZHEIMER'S DISEASE (AD). A. Fisher, R. Brandeis*, Z. Pittel*, I. Karton*, M. Sapir*, S. Dachir*, A. Levy, F. Mizobe# and E. Heldman*. Israel Inst. Biolog. Res., Ness- Ziona 70450, ISRAEL; # Snow Brand Milk Products, Tokyo, JAPAN.

AD, a disorder characterized by a central presynaptic cholinergic deficit, has no rational and effective treatment as yet. As postsynaptic muscarinic receptors (mostly M1 receptors) are relatively intact in AD, M1 agonists should improve cognitive dysfunctions associated with the cholinergic hypofunction in this disease. In this regard, a novel muscarinic agonist of utmost rigidity, cis-2-methyl spiro (1,3-oxathiolane-5,3')quinuclidine, AF102B, was reported by us recently (Israel Patent, May 10, 1985; Soc. Neurosci. 1986). AF102B induced atropine-sensitive contractions in the guinea-pig ileum and trachea preparations at an $EPMR_{ACh}$ of 100 and 1, respectively. Binding to muscarinic receptors in rat brain homogenates showed: a) the order of potency- oxotremorine> AF102B= pilocarpine> cis-AF30= McN-A-343~ arecoline~ trans-AF30= AF102A (the trans isomer)> methacholine~ carbachol (CCh)= bethanechol [(-)-^{3}H-QNB displacement, cerebral cortex)]; b) that AF102B was more selective for M1 receptors than oxotremorine, AF102A, cis- or trans-AF30 (Eur. J. Pharmacol. 37, 329, 1976) and McN-A-343 [forebrain and cerebellum, (-)-^{3}H-QNB assay)] or by differential displacements of (-)-^{3}H-QNB, ^{3}H-cis-Dioxolane and ^{3}H- Pirenzepine in forebrain]. The agonistic feature of AF102B was also shown by a shift to the right of (-)-^{3}H-QNB displacement curve (forebrain homogenates) in presence of GppNHp. In contrast to CCh, AF102B did neither potentiate phosphoinositides (PI) hydrolysis nor did it inhibit adenylate cyclase (AC) activity (cerebral cortex and cerebellum). However, AF102B blocked CCh-induced PI hydrolysis, without effecting CCh- induced inhibition of AC activity. In a workable animal model for AD, [the AF64A-treated rat (3nmol/2ul/side, icv)], AF102B (1 mg/kg, ip or po), AF102A (1mg/kg, ip), cis-AF30 (1mg/kg, ip) and physostigmine (0.06mg/kg, ip) reversed a cognitive impairment in a step-through passive avoidance task; both AF102B and AF102A (1mg/kg, ip), unlike physostigmine (0.1 mg/kg, ip), were positively active in the Morris water maze (MWM), but only AF102B (5mg/kg, ip) was beneficial in the 8-arm radial maze. Single or repetitive administrations of AF102B (1mg/kg, ip) improved also AF64A-induced working memory deficits in the MWM, but did not effect open field behavior. Restoration of AF64A-induced cognitive impairments by low doses of AF102B, lack of adverse side-effects up to high doses, a wide therapeutic index, and the M1 selectivity -- all indicate that this compound can be considered as a promising candidate drug for the treatment of AD. Supported by SNOW BRAND, JAPAN.

184.13 EFFECTS OF PICROTOXIN INJECTIONS INTO DIFFERENT REGIONS OF THE STRIATUM ON RETENTION OF PASSIVE AVOIDANCE. Rigoberto Salado-Castillo* and Roberto A. Prado-Alcalá. Dept. of Physiol., Sch. of Med., Natl. Univ. of México, P.O. Box 70-250, México, D.F., 04510, México.

Interference with neural activity of the striatum, induced by electrolytic lesions, electrical stimulation, local anesthetics, potassium chloride and neurotoxins produces significant deficits in the retention of passive avoidance. The same is true when cholinergic and dopaminergic synaptic activity is altered. Since these transmitters are functionally related to striatral GABAergic activity it was postulated that direct application of a GABA antagonist would also result in a memory deficit. Male Wistar rats were trained, in one trial, to avoid the darker compartment of a two-compartment box. Independent groups were trained and two minutes later unilaterally injected with picrotoxin (1 ug/1uL) into one of the quadrants of the anterior striatum (medial-dorsal, medial-ventral, lateral-dorsal or lateral-ventral) or in one of three regions of the posterior striatum (medial-dorsal, lateral-dorsal or postero-ventral); a group of intact rats was also studied. Retention of the passive avoidance task was tested 24 h after training. The antero-medial-ventral group did not differ from the control group; the rest of the groups had significantly lower retention scores than the latter groups, and the postero-ventral and postero-lateral-dorsal groups had lower retention scores than the rest of the groups. These data suggest that striatal GABAergic activity is differentially involved in memory processes, since picrotoxin produced a greater effect when injected into the posterior regions of the striatum than when injected into other regions of this structure.

184.14 LIMBIC SYSTEM UNIT ACTIVITY AND BEHAVIOR ALTERED DURING LEARNING BY LOCAL DEPLETIONS OF NOREPINEPHRINE IN RABBITS. S. Sparenborg and M. Gabriel. Dept. Psychol., U. of Illinois, Champaign, IL, 61820.

Based on past studies, we have proposed a model (Gabriel, Sparenborg & Stolar, in The Hippocampus Vol. IV, Plenum, 1986) which explains functional relationships between behavior and neural activity, in relation to discriminative avoidance training, in the anteroventral nucleus of the thalamus (AVN), the cingulate cortex (Brodmann's Area 29), and the hippocampus. The dense innervation of these structures by the locus coeruleus suggests that norepinephrine (NE) may play an important role in the learning-related functions of this system.

To examine this role, localized depletions of NE were induced in either the AVN (n=7 rabbits) or Area 29 (n=7 rabbits) by the microinjection of 6-hydroxy-dopamine (2 ug 6-OHDA in 2 ul saline, 1% ascorbic acid). All subjects, including 7 vehicle-injected control rabbits, received systemic injections of the dopamine uptake inhibitor GBR-12909. Multi-unit activity was monitored through electrodes implanted in the AVN and Area 29. Avoidance training and extinction was given in a rotating-wheel conditioning apparatus 10-20 days after the injections. Positive (CS+) and negative (CS-) conditional stimuli (1 and 8 kHz tones) were each presented for 60 trials in daily sessions. The unconditional stimulus was a footshock delivered five seconds following the onset of the CS+ on trials in which no avoidance response occurred. After training, NE levels in the AVN, Area 29, and neighboring structures were measured with HPLC.

Both cortical and thalamic NE depletions increased AVN CS-elicited unit firing. Thalamic depletions also increased CR performance on the first day of training and during extinction. Viewed in the context of our theoretical model, these results suggest that both cortical and thalamic NE is involved in the attention-related limiting of thalamic activity and behavior in intact animals exposed to unexpected training contingencies. Cortical depletions decreased the rate of CR performance and the frequency of unit firing in Area 29. These results suggest that NE enables the flow of thalamically driven excitation in Area 29 to motor structures (e.g., the striatum) involved in CR output. (Supported by NIMH Grant 37915 to MG.)

184.15 ASSESSMENT OF REFERENCE AND WORKING MEMORY DURING ACUTE AND CHRONIC EXPOSURE TO ANTI-CHOLINERGIC AGENTS. K. Raffaele, D. Olton, and Z. Annau, Johns Hopkins University, Baltimore, MD 21205.

Many studies have evaluated the effects of repeated exposure to drugs or toxins by monitoring physiological and sensory-motor systems (e.g. temperature, rotorod performance, weight gain, etc.) at many time points both during and after the exposure. Few studies have monitored the performance of learning and memory tasks in a similar way. We have developed a task that enables the assessment of both reference memory and working memory on a daily basis. The task uses a cued non-spatial serial reversal with repeated stimuli.

The apparatus had a stem and two interchangeable goal boxes which were painted with different patterns of black and white paint (stripes or spots). After criterion was met (8 correct responses in 10 consecutive trials), the correct goal box was reversed. The correct goal box at the start of each day's testing was the same one that was correct at the end of the previous day's testing (reference memory assessment). The reversal (working memory assessment) was given only after criterion had been met in the reference memory assessment.

Following two to three weeks of training, rats achieved a stable performance level, which was dependent on the length of the delay between trials. The sensitivity of performance on the task to acute or chronic disruption of the cholinergic system was then tested. Performance was disrupted by scopolamine given 20 minutes before testing in doses ranging from 0.25 to 1.0 mg/kg. Chronic exposure to DFP (injected following testing, 1.0 mg/kg on the first day and 0.5 mg/kg every third day thereafter) also disrupted performance on this task.

184.16 EXCITATORY AMINO ACIDS AND MEMORY PROCESSING. J.L. Davis and J.F. Flood, Office of Navel Research, Arlington, Life Sciences Directorate, VA 22217 and GRECC, VA Medical Center, Sepulveda, CA 91343.

Certain of the amino acids, L-glutamate and L-aspartate, are rapidly gaining the status of excitatory neurotransmitters in the central nervous system. Excitatory amino acid receptors are classed as N-methyl-D-aspartate (NMDA) and non-NMDA types. Among the non-NMDA type receptors kainate and quisqualate subtypes are recognized. Glutamic, aspartic and kainic acid simulate both NMDA and non-NMDA type receptors. In spite of the potent effects on neural activity, little is known about their effects on memory processing.

In this study, we found that glutamic, aspartic, and kainic acids administered intracerebroventricularly after footshock avoidance training in a t-maze enhanced retention test performance measured one week after training. In an effort to determine whether enhancement of memory selectively involved NMDA or non-NMDA receptor subtypes, we tested the effects on retention of (-)APV, APH, and GAP, all NMDA antagonists. These were compared to (+)APV (inactive) and GAS (specific non-NMDA kainate type receptor antagonist).

At 25 pg administered icv, (-)APV, APH and GPA all caused amnesia (20% recall score) compared to saline-injected controls (86% recall score). The inactive (+)APV had no effect on retention test performance (86% recall score), but GAS, an antagonist of the kainate receptor subtype impaired retention (25% recall score).

It is interesting that microgram amounts of glutamic, aspartic and kainic acid were needed to improve retention but only pg gram amounts were needed to cause amnesia. Microgram quantities of (-) APV, APH and GAS caused amnesia as well but these doses caused severe and prolonged motor convulsions. Based on these preliminary studies, NMDA and non-NMDA receptors may both be involved in memory processing but this does not rule out subtle differences using different types of training.

ABBREVIATION:
(-)APV, D(-)-2-amino-5-phosphovaleric acid
(+)APV, D(+)-2-amino-5-phosphovaleric acid
APH, DL-2-amino-7-phopnonoheptanoic acid
GAP, gamma-D-gluamylaminomethyl phophonic acid
GAS, gamma-D-gluamylaminomethyl sulphonic acid

184.17 SPATIAL WORKING MEMORY IN C57BL/6 MICE. M. B. Upchurch. Institute for Behavioral Genetics, University of Colorado, Boulder, CO 80309.

Work in this laboratory has indicated that C57BL/6Ibg mice exhibit spatial learning in the Morris water task. These data are in contrast to those reported by Reinstein et al. (Brain Res., 1983, 263, 172), who found that mice of a closely related substrain, C57BL/6J, were incapable of spatial learning in a radial arm maze. The radial arm maze and the Morris water task differ in several major respects. The radial maze is appetitively motivated, while the Morris task is aversively motivated; the radial maze evaluates spatial working memory, while the Morris task examines spatial reference memory; and the radial maze requires the animal to develop a win-shift strategy, while the Morris task requires a win-stay strategy. In addition, the correct form of response in the radial arm maze is more complex than that in the Morris water task, and animals of some strains may require an extensive number of trials in order to achieve criterion levels of performance. It is well documented that C57 mice can learn appetitively motivated operant tasks; thus, it seems unlikely that their failure to learn the radial arm maze was caused by lack of appropriate motivation. This study investigates the possibility that C57BL/6 mice are poor at win-shift learning or lack ability to use spatial working memory.

C57BL/6Ibg mice were trained in a water escape task in which they were required to swim to a slightly submerged platform in a goal arm of a T-maze. Each learning trial consisted of two parts. First, the animal was given a run in which only one goal arm was open. The order of goal arm blocking was pseudo-random, with the restrictions that each arm was blocked for half the trials and that neither arm was blocked more than three times in a row. Upon reaching the platform, the animal was allowed to rest for 30 sec and was then placed in a holding cage for 20 sec. The mouse was then returned to the T-maze for the second part of the trial, in which both goal arms were open and the animal was required to make a choice between the two. For half the mice, the correct response was to choose the arm that was blocked during the first part of the trial. The remaining mice were required to return to the previously open arm. The mice were given ten trials per day for ten consecutive days.

The initial response of the mice was to select one goal arm to visit consistently during the free-choice portion of the trial. After sixty to ninety trials, however, the mice began to develop response strategies based on the position of the open goal arm during the first part of the trial. There was no evidence that mice in the win-shift group were less capable of learning the task than mice in the win-stay group. The data suggest that C57BL/6 mice can learn spatial working memory tasks, but that extensive training is required before they overcome an initial tendency to perseverate and instead exhibit responses based on working memory. (Supported by training grant HD07289.)

184.18 INTRAVENTRICULAR ACETYLCHOLINE REVERSAL OF T-MAZE DEFICITS FOLLOWING LESIONS OF THE NUCLEUS BASALIS OF MEYNERT. J. Mastropaolo and J.N. Crawley. Unit on Behavioral Neuropharmacology, NIMH, Bethesda, MD 20892.

Lesioning of the cholinergic nucleus basalis of Meynert (NBM) produces a deficit in memory for recent events concomitant with a decrease in CAT activity in rats, and has been proposed as an animal model of Alzheimer's disease (Hepler, Olton, Wenk and Coyle, Neuroscience, 5: 866-873, 1985; Flicker, Dean, Pontecorvo, Figueiredo and Fisher, Pharmacol Biochem Behav 23: 125-135, 1985).

To test the ability of centrally administered acetylcholine to reverse these memory deficits, male Sprague Dawley rats received lesions of the NBM and the medial septal area (MSA) by the microinfusion of 4 ng ibotenic acid into each of 5 anatomical sites. Control rats were identically infused with saline. In addition, an indwelling 24 gauge stainless steel cannula was stereotaxically implanted in the lateral ventricle of all rats. After 7 days of postoperative recovery, all rats were food deprived to 85% of their free feeding weight. Behavioral testing was conducted in a T-maze, using a food-reinforced alternation task with a 2 minute delay. When performance was stable at this delay, control rats averaged 9/12 correct, while lesioned rats averaged 6/12 correct responses. Groups of rats were microinjected with either 1, 5 or 10 ug of acetylcholine (ACH) into the lateral ventricle. On the next day, baselines were obtained in which animals were run in the T-maze but received no drug treatment. On the following day, groups of rats received either a) 5 mg/kg of the muscarinic antagonist atropine (i.p.) and 10 ug ACH (ivt), b) 3 mg/kg of the nicotinic antagonist mecamylamine (i.p.) and 10 ug ACH (ivt), c) or saline (i.p.) and 10 ug ACH (ivt). Following another baseline day of testing without drug treatment, groups of rats were injected (ivt) with either d) 10 ug atropine and 10 ug ACH, e) 20 ug mecamylamine and 10 ug ACH, or f) saline and 10 ug ACH.

Control animals showed no significant change in performance with any of the drugs tested. Lesioned animals showed a significant increase in choice accuracy, relative to baseline performance on the preceding day, following the administration of 10 ug of ACH. Increase in choice accuracy produced by ACH was significantly inhibited by atropine but not by mecamylamine when the antagonists were administered either peripherally or centrally. These data suggest that intraventricularly administered acetylcholine can reverse the memory deficit produced by lesions of the NBM and MSA. Further, since this effect was blocked by atropine but not mecamylamine, this effect of acetylcholine appears to be mediated by a muscarinic cholinergic mechanism.

184.19 POLYUNSATURATED FAT DIETS IMPROVE SPATIAL MEMORY IN RATS. G. Winocur* and C.E. Greenwood (SPON: P. Garfinkel). Dept. Psychology, Trent Univ., Peterborough, Ontario K9J 7B8 and Dept. Nutritional Sciences, Univ. of Toronto, Tor., Ont., Canada M5S 1A8.

Our previous studies indicate that alterations in the type of dietary fats fed to rats influence a variety of behaviours, including cognition (Life Sci. 38:1789) measured using a Morris Water Tank thought to reflect spatial learning and memory skills. That is rats fed a semi-synthetic diet containing 20% (w/w) polyunsaturated fat in the form of soybean oil (SBO) learned the task faster and showed a transient increase in resistance to extinguish this response in comparison to rats consuming a saturated fat source, lard. To extend these observations, similar studies were performed using the radial arm maze as a further test of spatial memory, and examining the interaction of dietary fat and the cholinergic antagonist atropine on the rat's performance. Young, rapidly growing rats were fed the SBO (n=21) or lard (n=24) diets for three months prior to behavioural testing. Animals were familiarized with the task by allowing pairs of rats to explore the maze for 15 minutes daily for three days. Performance was then recorded on the next 8 consecutive days. Dietary fat source influenced task acquisition such that the SBO fed rats showed superior performance on the first day of testing (total number of errors/trial = 1.8±0.3; mean±SEM) in comparison to the lard fed animals (# errors = 2.9±0.4). The influence of dietary fat on performance was no longer apparent by day 4 (# errors = 0.9±0.2 vs 1.4±0.2 for SBO and lard, respectively) and remained similar through to day 8 (# errors = 0.8±0.3 vs 1.1±0.3). A subset of animals from each diet (n=9 and 8 for SBO and lard) was further tested following drug challenges and their performance compared with standard laboratory chow fed rats (n=10) of similar age. Drugs were administered intraperitoneally 60 minutes prior to testing. Drug-free performance of these animals was 0.3±0.3, 1.1±0.5 and 1.3±0.5 errors for SBO, lard and chow fed rats respectively. Atropine sulphate (2.0 mg/kg) impaired performance such that lard (2.9±0.9) and chow (2.8±0.9) fed rats made significantly more errors than SBO (1.1±0.3) fed animals following drug administration. This effect of atropine on maze performance appears to be attributable to central cholinergic blockade since neither atropine methyl nitrate (2.0 mg/kg), which does not cross the blood brain barrier, nor amphetamine (0.5 mg/kg) impaired performance. The results of these studies further support our observation that polyunsaturated fat diets improve spatial learning in rats and furthermore suggest that the effect of dietary fat on cognitive performance may be mediated via the cholinergic system since behavioural response to central cholinergic antagonists is influenced by dietary fat fed. (Supported by grants from NSERC and MRC).

MONOAMINES AND BEHAVIOR IV

185.1 THE MASSETERIC REFLEX: A MODEL SYSTEM FOR STUDYING MONOAMINERGIC NEUROTRANSMISSION IN BEHAVING ANIMALS. D.A. Morilak, I.L. Stafford, and B.L. Jacobs. Prog. Neurosci., Dept. Psychol., Princeton Univ., Princeton, NJ 08544.

Fuller understanding of the functional roles of brain monoaminergic neurons would be aided by the study of a simple neuronal system whose circuitry received dense monoaminergic input. In addition, it would be desirable if this system could be studied: in vivo; in intact animals; in the absence of anesthesia or restraint; and under physiological conditions. The brainstem monosynaptic masseteric (jaw closure) reflex is such a system. The reflex can be elicited by activation of stretch receptors in the masseter muscle or by phasic electrical stimulation of the mesencephalic tract of the trigeminal nerve (Mes5). Mes5 neurons make monosynaptic connections with neurons in the motor nucleus of the trigeminal (Mo5), which directly innervate masseter muscles. Mo5 neurons also receive dense input from both noradrenergic (NE) and serotonergic neurons. Reflex amplitude can be measured by means of bipolar recording electrodes placed in the masseter muscles. Previous studies by Chase and colleagues demonstrated that the reflex response was dramatically modulated by changes in state across the sleep-wake cycle (Experientia, 24 (1968) 47-48). In addition, in studies carried out in anesthetized rats, we previously reported that NE exerted a facilitatory effect on this reflex, which was mediated directly in Mo5 (J. Neurosci., 5 (1985) 1300-1306). We now report on our studies of this reflex in behaving cats. This abstract describes the basic methodology and changes in the reflex that are produced by a variety of environmental manipulations, while the following abstract describes our studies of the influence of NE upon this system. The reflex is elicited at each of 3 different current levels ($\sim$100 - 300 μA) by delivering square wave pulses (0.4 msec duration) to Mes5 once every 6 sec, for a total of 8 trials. A mean reflex reponse amplitude is then calculated for each current level. Under quiet waking conditions, the resulting current-response curve represents the baseline condition. All of the following manipulations, which are known to activate brain NE neurons (Prog. Neurobiol., 27 (1986) 183-194), significantly increased the amplitude of the masseteric reflex response in behaving cats: exposure to 15 min of 100 dB white noise; restraint lasting for 15 min; and 5 min exposure to an adult dog. In addition, single clicks presented 100 - 250 msec prior to the test stimulus augmented the reflex, whereas clicks presented either earlier or later failed to do so. These studies demonstrate the utility of this reflex in reflecting changes in response to environmental manipulations. Experiments currently in progress are examining whether this reflex facilitation by environmental stimuli is mediated by NE neurons.

185.2 NORADRENERGIC FACILITATION OF THE MASSETERIC REFLEX IN BEHAVING ANIMALS. I.L. Stafford and B.L. Jacobs. Prog. Neurosci., Dept. Psychol., Princeton Univ., Princeton, NJ 08544.

We previously proposed the masseteric reflex as a model system to index functional changes in brain noradrenergic (NE) activity (see previous abstract; J. Neurosci., 5 (1985) 1300-1306). We also reported that the amplitude of the reflex response was modulated by environmental conditions known to affect the activity of NE neurons. This suggested that the observed changes in the reflex might be attributable to changes in NE activity. The present studies directly examine the effects of NE upon the amplitude of the masseteric reflex in behaving cats. As described in the preceding abstract, cats were implanted with masseteric stimulating and recording electrodes. In addition, 22 ga stainless steel guide cannulae were permanently placed in the motor nucleus of the trigeminal (Mo5). This allowed us to infuse NE (or NE agonists) directly into Mo5 by means of 28 ga injection cannulae, and to examine any resulting changes in the amplitude of the elicited reflex response. During experiments, the injector was prefilled with a test drug, inserted into the guide cannula, and connected to a microsyringe driven by a remotely controlled syringe pump set to deliver 500 nl over a 1 minute period. Following baseline current-response determination, test doses were delivered and current-response curves were determined 1, 5, 15, 30, and 60 min later. Microinfusions of NE (0.125 - 5.0 μg) produced dose-dependent changes in the amplitude of the elicited reflex responses. The peak increase ($\sim$200 - 400% above baseline) occurred in response to infusion of 1.0 μg NE and was observed at all current levels tested. Increases were evident 1 min post-infusion, reached maximal levels at 5 min post-infusion, and returned to baseline levels by 30 min. The increase seen in response to 1.0 μg NE was blocked by pre-treatment with the α_1-adrenergic antagonist prazosin (5 mg/kg, i.p.) but not by pre-treatment with the serotonin (5-HT) antagonist methysergide (0.5 mg/kg, i.p.). (This dose of methysergide did, however, completely block the increase in the reflex seen in response to 1.0 μg 5-HT.) Infusions of the α-adrenergic agonist phenylephrine (0.5 - 5.0 μg) also produced dose-dependent increases in the amplitude of the masseteric reflex. By contrast, infusions of the β-adrenergic agonist isoproterenol (0.5 - 5.0 μg) had no effect on the reflex. Neither saline nor pH control infusions had any effect on the amplitude of the reflex. In summary, these data indicate that NE modulates the amplitude of the masseteric reflex, probably at α-adrenergic receptors, by a direct action in Mo5. Experiments currently in progress are investigating whether activation of the NE input to Mo5 under physiological conditions is responsible for augmentation of the reflex response.

185.3 SYSTEMIC NALOXONE ADMINISTRATION ACTIVATES LOCUS COERULEUS NEURONAL ACTIVITY UNDER STRESSFUL BUT NOT NON-STRESSFUL CONDITIONS. B.L. Jacobs and E.D. Abercrombie. Prog. Neurosci., Dept. Psychol., Princeton Univ., Princeton, NJ 08544 and Dept. Behav. Neurosci., Univ. Pittsburgh, Pittsburgh, PA 15260.

We reported previously that the activity of noradrenergic neurons in the locus coeruleus (LC) of freely moving cats is tonically increased by stressful conditions [Soc. Neurosci. Abstr., 12 (1986) 1134]. Since endogenous opioid peptides are known to be released during stress and because there is a dense population of opioid receptors in the LC, we were interested in determining the degree to which opioid receptor blockade would affect the stress-related activation of noradrenergic LC neurons. The present study examined the effects of naloxone (1 mg/kg i.v.) on LC noradrenergic neuronal activity when administered at the 15 min point of a 30 min duration restraint stress. For restraint, animals were placed in a canvas handling bag and then wrapped with an elastic bandage about the torso thus precluding movement of the limbs. Neurons in the area of the LC were identified as noradrenergic by physiological and neurochemical criteria which included: a) slow discharge rate ($\sim$1.0 spike/sec); b) long duration action potential; c) complete suppression of activity during REM sleep; and d) complete suppression of activity following systemic administration of the alpha-2 agonist clonidine (25 µg/kg i.p.). During the first 15 min of the 30 min restraint period, LC noradrenergic unit activity was increased by 95% above baseline. Following naloxone infusion at 15 min, the firing rate of these neurons showed a further increase to 270% of baseline (n=6). This second increase was not observed during 30 min restraint in the absence of naloxone administration. Naloxone administration during stress also increased signs of distress as evidenced by increased frequency of struggling and vocalization. In contrast, when naloxone was administered to non-stressed animals during quiet waking behavior, no change in LC noradrenergic neuronal activity was observed (n=7). Neuronal activity under this condition was no different from that observed following i.v. infusion of saline (n=6). Although these results cannot be ascribed positively to a direct effect of naloxone upon opioid receptors in LC, a moderating role for endogenous opioids in the responsiveness of LC noradrenergic neurons to stressful stimuli is suggested. Experiments in our laboratory are currently examining whether this activation of LC neuronal activity is attributable directly to the blockade of opioid receptors in the LC. These results also support the idea that the endogenous opioid system is not tonically active during non-stress conditions.

185.4 ACTIVITY OF LOCUS COERULEUS NORADRENERGIC NEURONS DURING DEFENSE REACTION IN BEHAVING CATS. E.S. Levine, E.D. Abercrombie, R.B. Bandler, and B.L. Jacobs. Prog. Neurosci., Dept. Psychol., Princeton Univ., Princeton, NJ 08544.

Locus coeruleus noradrenergic neurons (LC-NE) have been hypothesized to play a role in the response to stress, including fear- and anxiety-producing situations. We have previously reported that the activity of these neurons, recorded in behaving cats, is generally correlated with the level of behavioral arousal. In addition, LC-NE neurons showed a sustained increase in firing rate during the presentation of both environmental and physiological challenges (J. Neurosci., in press; Brain Res., in press), as well as during a conditioned emotional response (Brain Res., 371 (1986) 335-344). In the present study, we further examined this issue by studying the response of LC-NE neurons in behaving cats during exposure to a dog, a naturalistic fear-producing situation. LC-NE units were identified by their a) slow firing rate (<2 Hz), b) long duration action potential (>2 msec), c) complete suppression of activity during REM sleep, d) complete suppression following administration of the $\alpha 2$ adrenoceptor agonist clonidine (25 µg/kg, i.p.), and e) histological localization to the LC. During the recording session, cats were exposed to a dog through a steel mesh screen for five minutes. We have previously shown that this exposure produces a marked increase in heart rate and plasma NE, indicative of strong autonomic activation (Soc. Neurosci. Abstr. 12: 1134, 1986). In response to the dog, cats typically moved to the rear of the booth and showed a strong feline defense reaction characterized by piloerection, arched back, hissing, growling, and broadside stance. LC-NE unit activity was significantly elevated ($\sim$180%) above spontaneous active waking baseline during the entire trial. When the dog was removed, unit firing and heart rate rapidly decreased and returned to baseline within five minutes. These data should be contrasted with our previous findings that exposure of cats to either inaccessible rats or another cat did not increase LC-NE firing above active waking baseline levels (Brain Res., 371 (1986) 324-334). In addition, we have also reported that serotonergic neurons in the dorsal raphe nucleus were not specifically affected by the presentation of a dog (Soc. Neurosci. Abstr. 12: 1134, 1986). In a continuation of this research, we have conducted pilot studies which indicate that LC-NE neurons are dramatically activated during the defense reaction elicited by excitatory amino acid stimulation of the periaqueductal grey. Taken together, these data indicate that stressful or fear-producing situations are particularly effective in activating LC-NE neurons, and that these neurons may play a role in the responses to these challenges.

185.5 STRAIN SPECIFIC BEHAVIORAL EFFECTS OF INESCAPABLE SHOCK AND DESMETHYLIMIPRAMINE. N.Shanks and H. Anisman. Psychology Dept., Carleton University, Ottawa, Ont. CANADA. K1S 5B6

In an attempt to relate the impact of stressors in animals to affective disorders in humans, a series of experiments was conducted to assess the effects of acute inescapable shock on the performance of several strains of mice (A/J, Balb/cByJ, C57BL/6J, DBA/2J, C3H/HEJ, CD-1) in a shuttle escape, forced swim, and exploratory task. Wide ranging differences of performance were noted across strains as a function of inescapable shock treatment. Interestingly, however, behavioral disturbances engendered by the stressor in one particular task did not necessarily result in behavioral disruption in the same strain when performance was assessed in a different task. In effect, it appeared that although uncontrollable stressors may elicit behavioral disturbances in numerous paradigms, an impairment in a particular task was not predictive of impairments in other tasks.

Repeated treatment with desmethylimipramine (DMI) (5mg/kg, 2 X daily) was also found to have strain specific effects in alleviating the stressor induced behavioral disturbances. For instance, in the A/J strain DMI applied chronically either before or after inescapable shock treatment prevented the appearance of shuttle escape deficits. In the CD-1 and Balb/cByJ strains, however, the drug treatment was ineffective in altering performance, while in the C57BL/6J mice, DMI had a prophylactic effect, but not a therapeutic effect. It will be noted as well, that these particular strain specific effects were not evident when other antidepressant agents were employed. Thus, repeated administration of amitriptyline and bupropion were found to prevent behavioral disturbances in the CD-1 strain, where it will be recalled DMI was without effect. It is suggested that genetic factors may influence the behavioral symptoms associated with uncontrollable aversive events as well as the effectiveness of antidepressant drugs ameliorating these symptoms.

185.6 THE EFFECTS OF CHRONICALLY ELEVATED LOCOMOTOR ACTIVITY ON BRAIN DOPAMINERGIC MARKERS. S.G. Speciale, T. Ryschon* and G. Ordway*. Depts. of Psychiatry & Physiology, Univ. Tx. Hlth. Sci. Ctr., Dallas, TX 75235-9070 U.S.A.

There is considerable evidence of a role for brain dopamine(DA) pathways in motor function. A number of laboratories have reported enhanced caudate nucleus (CN) DA metabolism after locomotion in animals, while Parkinson's disease is accompanied by motor impairment and prominent post-mortem reductions in CN DA and its innervating substantia nigral neurons. We reported recently that acute running wheel activity (0.5m diameter, motorized 4rpm for one hour) significantly elevated the DA metabolites, homovanillic acid (HVA) and dihydroxyphenylacetic acid (DOPAC) in rat CN (Speciale et al., Br. Res. Bull. 16:33, 1986). DA and serotonin (5HT) metabolism were relatively unchanged.

We wanted to explore this problem further by examining the effects of longer increased locomotion on metabolism in specific monoamine pathways and correlate their receptor properties. Adult Sprague-Dawley rats ran voluntarily in a freely-moving wheel attached to the home cage with ad libitum food and water, for 1, 4 or 7 weeks. Control (kept in home cages) and experimental animals were anesthetized (pentobarbital, 50mg/kg, i.p.), decapitated, the brains dissected out rapidly, and frozen whole on dry ice. Serial coronal sections were cut in a cryostat: 20um for histology, 20um for in vitro autoradiography, and 300um for neurochemical analysis. Autoradiography for DA D2 receptors was carried out using 3H-spiperone (Herkenham & Pert, J. Neurosci. 2:1129, 1982). NE, DA, HVA, DOPAC, 5HT and its metabolite, 5-hydroxyindoleacetic acid (5HIAA) were analyzed in tissue micropunches, using HPLC with electrochemical detection. In contrast to the acute running wheel paradigm, in the CN from animals running for 4 weeks, both DA and DOPAC concentrations, as well as the DOPAC/DA turnover ratio were decreased significantly from controls. NE, HVA and the HVA/DA ratio, as well as 5HT, 5HIAA and the 5HIAA/5HT ratio were reduced in the experimental group, but fell short of statistical significance. D2 receptor density and affinity will be correlated with monoamine metabolism over the increasing duration of locomotor activity.

185.7 AMYGDALA AND NUCLEUS ACCUMBENS LESIONS IMPAIR COCAINE SENSITIZATION. R.M. Post, S.R.B. Weiss*, J. Smith Jr*., T.L. Sullivan* and A. Pert. (SPON: J. Frascella). Biological Psychiatry Branch, NIMH, Bethesda, MD 20892.

In many species, psychomotor stimulants can produce progressively increasing behavioral responses with repeated administration (behavioral sensitization). These effects can be long-lasting and are affected by dose, gender, and intermittency of administration. In addition, behavioral sensitization has a conditioned component and is environmentally context-dependent, e.g., sensitization occurs in rats that are pretreated and tested in the same environment, but not in rats that are given equal doses of cocaine in a different environment. This aspect of cocaine sensitization led us to examine the role of certain brain areas in this phenomenon which have traditionally been associated with conditioning, memory, or stimulant-induced locomotor activity. Electrolytic lesions of the amygdala, dorsal hippocampus, ventral hippocampus, and cerebellum, and 6-OHDA lesions of the nucleus accumbens were examined for their effects on behavioral sensitization to cocaine. The sensitization paradigm employed is one in which rats receive a single high dose of saline or cocaine (40 mg/kg) in the test cage and are tested the following day with lower dose cocaine 10 mg/kg). Locomotor activity and stereotypy were evaluated. This paradigm reliably produces sensitization which is completely context-dependent.

Lesions of the nucleus accumbens and the amygdala blocked the sensitization to cocaine while the other lesions were without effect. The lesions of the nucleus accumbens produced approximately a 60% depletion of dopamine in this area, and while preventing the sensitization , these lesions did not prevent the hyperactive response to the high-dose cocaine on the pretreatment day.

Pathways involved in cocaine-induced sensitization may involve the amygdala and the dopaminergic components of the nucleus accumbens. The amygdala has also been implicated as a substrate in conditioned fear and in other types of learning and memory paradigms (particularly when lesions are combined with that of the hippocampus). Lesions of the nucleus accumbens have also been shown to impair amphetamine conditioning (Gold et al., 1986). Behavioral sensitization and conditioning may be relevant to the development and evolution of psychopathology in human cocaine users, therefore, further analysis of the neurohumors and pathways related to these phenomena seem warranted.

185.8 THE FUNCTIONAL OUTPUT OF THE NUCLEUS ACCUMBENS AS REVEALED WITH 2-DEOXYGLYCOSE AUTORADIOGRAPHY. A. Pert and L. Estall*. (SPON: T. Bevan). Biological Psychiatry Branch, NIMH, Bethesda MD 20892

It is certain that the nucleus accumbens represents a critical focus for the excitatory effects of sympathomimetic compounds. Injections of indirectly- as well as directly-acting dopaminergic agonists into this structure increase locomotor output, while 6-OHDA lesions attenuate the excitatory effects of amphetamine and cocaine. Recently, Swerdlow et al. (Brain Res., 306, 1984, 141-143) have demonstrated that the efferent pathway from the NA to the subpallidal region appears to serve as one important output of mesolimbic activity for the expression of locomotor behavior. Whether the pallidal output is solely involved in translating the sympathomimetic activation of the NA into locomotor excitation remains to be determined. The purpose of this investigation was to assess the functional outputs of the nucleus accumbens following direct activation with sympathomimetics using 2-deoxyglucose autoradiographic procedures. Rats were implanted with unilateral cannulae guides aimed for the n. accumbens. Following recovery, the animals were injected in the NA with either 15 nmoles of d-amphetamine sulfate or 50 nmoles of cocaine HCl. Three minutes following NA injections, the rats were administered 100 µCi/kg of [^{14}C]-2-deoxyglucose (2DG) through indwelling jugular catheters. Forty-five minutes following 2DG injections, the animals were sacrificed and their brains removed. The brains were prepared for autoradiographic analyses using standard procedures. Injections of amphetamine and cocaine were found to decrease metabolic activity in the head of the caudate nucleus, olfactory tubercle, cingulate cortex, as well as the NA ipsilateral to the injection. Significant increases, however, were found in the ipsilateral ventral pallidum and the striatal fundus. The activity in some thalamic nuclei decreased ipsilateral to the injection. In the hindbrain, increases in activity were found in the zona reticulata and ipsilateral medial and lateral olivary complex. Combined with lesioning procedures, the 2DG methodology may allow a more comprehensive analysis of the functional outflow from behaviorally relevant neural systems.

185.9 INTRAVENTRICULAR (ICV) NOREPINEPHRINE (NE) STIMULATES LOCOMOTION IN NUCLEUS ACCUMBENS (NAC) DOPAMINE-DENERVATED RATS. N.R. Swerdlow and G.F. Koob. Dept. of Psychiatry, UCSD Medical Center and Division Neuroscience and Endocrinology, Scripps Clinic and Research Foundation La Jolla, CA 92037

Locomotor activation in rats following ICV infusion of NE is greatly potentiated by depletion of whole brain catecholamines by ICV injection of 6-hydroxydopamine (6OHDA). This "supersensitive" locomotor response to NE has been suggested to result from the action of NE on supersensitive denervated NE receptors. In a series of experiments, we examined the neural substrates for this NE-stimulated locomotion.

In the first experiment, rats were surgically implanted with ICV cannulae after ICV injection with 6OHDA (n=5) or vehicle (n=5). Beginning 10 d later, all rats were tested for their locomotor response to 4 doses of NE (0,0.2,2.0 or 20 µg ICV) in a randomized design on four test days, with each test day separated by one non-test day. Dose-dependent locomotor activation was observed in ICV 6OHDA -injected rats; no significant locomotor activation was noted in ICV vehicle - injected rats. Biochemical analysis revealed that these 6OHDA infusions significantly depleted brain NE and dopamine (DA) from all brain areas assayed, including the cortex, hippocampus, striatum and hypothalamus.

A second group of rats were surgically implanted with ICV cannulae following pretreatment with desmethylimipramine and infusion of 6OHDA (n=5) or vehicle (n=5) into the NAC. Beginning 10 d later, all rats were tested for their locomotor response to ICV NE as above. Dose-dependent locomotor activation was observed in NAC 6OHDA-injected rats; no significant locomotor activation was noted in NAC vehicle-injected rats. NE-stimulated locomotion in NAC 6OHDA-injected rats was indistinguishable in amplitude and time course from NE-stimulated locomotion in ICV 6OHDA-injected rats. NAC 6OHDA-lesioned rats also demonstrated a supersensitive locomotor response to the DA receptor agonist apomorphine. The NAC 6OHDA lesions significantly depleted NAC DA; NE was not significantly depleted from brain regions assayed.

These results suggest that exogenous NE stimulates locomotor activation in ICV and NAC 6OHDA-injected rats through activation of supersensitive NAC DA receptors. These findings do not support the hypothesis that brain NE systems normally are an independent neural substrate for locomotor activation in the rat, but do suggest that NE might stimulate locomotor activation through an action at NAC DA receptors in states of DA receptor supersensitivity.

185.10 6-OHDA LESIONS OF THE VENTRAL TEGMENTAL AREA AFFECT SIGNALLED ESCAPE RESPONDING, BUT NOT CLASSICALLY CONDITIONED RESPONSES IN THE RAT. W. Jeffrey Wilson & Jennifer C. Hall*, Department of Psychological Sciences, Indiana University - Purdue University at Fort Wayne, Fort Wayne, IN 46805, USA.

Electrolytic lesions of the ventral tegmental area in the rat enhance signalled active avoidance performance by facilitating classically conditioned fear responses to the signal (Wilson & Baeske, Acta Neurobiol. Exp., 1987, 47). We have proposed that this effect was due to damage to the mesolimbic dopamine system; the present experiment tested this hypothesis.

Lesions of the mesolimbic dopamine system were produced in 16 rats by the infusion of 2 µg 6-OHDA in a volume of 1 µl isotonic saline + 1 mg/ml ascorbic acid. Vehicle alone was infused into 16 additional rats. Beginning at least 1 week after surgery, 8 Lesion and 8 Control rats received 8 daily Classical Conditioning sessions in which a 5 sec tone was paired with a 1.5 mA scrambled foot shock in a rectangular plastic shuttlebox. The remaining rats received Pseudoconditioning sessions in which the tone and shock were explicitly unpaired. Each session consisted of 50 presentations of both tone and shock, with tones occurring randomly every 10 to 40 sec. The shock remained on until the rat shuttled, or for a maximum of 5 sec in the absence of a shuttle response. Responses during the tone and during the inter-tone interval were recorded, as was the latency to escape the shock.

The 6-OHDA lesion failed to enhance responses during the tone, i.e., classically conditioned responses, and had no effect on overall responsiveness in the inter-tone interval. Classically Conditioned Control rats tended to escape the shock more rapidly than the Pseudoconditioned Control rats, indicating that the tone came to control their escape responses as a result of its pairing with the shock. This effect was absent in the Lesioned rats: the Classical and Pseudoconditioned rats escaped equally slowly, with a latency comparable to that of the Pseudoconditioned Control rats. Thus the 6-OHDA lesion disrupted the rats' ability to respond to the signal for shock by preparing to escape.

These results are of interest for two reasons. First, they indicate that the enhancement of classically conditioned responses following electrolytic lesions of the ventral tegmental area is not due to damage to the mesolimbic dopamine system, as we thought. Second, the results indicate that the ability of a signal to facilitate escape responses is disrupted by this lesion. Thus, although Koob et al. (Brain Research, 1984, 303) have suggested that lesions of both the mesolimbic and nigrostriatal dopamine systems are necessary to disrupt avoidance performance, damage to the mesolimbic system alone is not without its effect in aversively motivated learning situations.

185.11 GENETIC DETERMINANTS OF SUSCEPTIBILITY TO COCAINE-INDUCED SEIZURES AND DEATH. T.W. Seale and J.M. Carney*. Departments of Pediatrics, Pharmacology and Biochemistry, Univ. of Oklahoma Health Sci. Ctr., Oklahoma City, OK 73190.

Significant inter-individual heterogeneity in susceptibility to (-) cocaine-induced seizures, life-threatening cardiovascular effects and psychological dependency occurs in man. It is unclear whether this variability in responsiveness results from intrinsic, inherent differences in susceptiblity of peripheral and central targets to this drug or from environmentally-induced acquired effects. To examine the role of genotype in the determination of *susceptibility to selected actions of cocaine, we have investigated the* occurrence of variation in susceptibility to acute cocaine-induced seizures and death among 9 strains of inbred mice. All mice used in this study were 8 week old males obtained from the Jackson Laboratory. These strains were chosen for study on the basis of their genetic divergence from one another, not upon previously defined neuropharmacological or behavioral criteria. One strain, DBA/2, was chosen as a prototype strain, against which the responses of the other strains were compared. Dose response curves established a seizure threshold dose of 70 mg/kg ip and a CD_{50} dose of 85 mg/kg ip in DBA/2 mice. Clonic but not tonic seizures occured. Lethal effects were observed at higher doses of (-) cocaine (LD_{50} 135 mg/kg ip). These responses were stereospecific; a (+) cocaine dose of 150 mg/kg ip was without effect. Seizures, but not lethality, were blocked by clonazepam pretreatment (0.5 mg/kg ip). Screening for increased susceptibility, carried out at a dose of 70 mg/kg ip (the threshold dose for DBA/2 mice), identified 4 strains -- AKR, C3H/He, C57BL/6 and SWR -- in which a significantly increased frequency ($p < 0.005$) of animals convulsed after this dose of cocaine. The CD_{50} dose for these strains was approximately 60 mg/kg ip. These inherent differences in susceptibility to cocaine-induced seizures were cocaine-specific, rather than generalized differences in convulsant sensitivity. These strains were not uniquely sensitive to other chemical convulsants such as picrotoxinin or N-methyl-D-aspartate. Relative susceptibility to the convulsant action of cocaine did not correlate with inherent relative susceptibility to the lethal effects of cocaine nor other cocaine-induced behavioral changes. Four phenotypic classes of cocaine responsiveness were identified among the strains -- low susceptibility to both seizures and lethality (DBA/2, BALB/cBy, C57BL/6By strains), low susceptibility to seizures but high susceptibility to death (A, CBA strains), high susceptibility to seizures but low susceptibility to death (AKR, C57BL/6 strains) and high susceptibility to both actions of cocaine (C3H/He and SWR strains). From these data we conclude 1) genetically determined differences in inherent sensitivity to the actions of cocaine do occur, 2) susceptibilities to the convulsant and lethal actions of cocaine are under separate genetic control, i.e., inherent alterations in cocaine responsiveness can be behavior- or target organ-specific, 3) the observed differences in cocaine responsiveness between strains do not apear to reflect pharmacokinetic differences, 4) selected strains of inbred mice offer valuable tools to obtain further insight into the pharmacogenetics of cocaine's actions.

185.12 EFFECTS OF ACUTE AND CHRONIC COCAINE ON SPONTANEOUS LOCOMOTOR ACTIVITY IN RATS. A. Markou. Department of Psychology, University of California, San Diego, La Jolla, CA 92093.

The present study was designed to characterize the effects of acute and chronic cocaine on spontaneous locomotor activity. Thirty Sprague-Dawley rats were housed individually in activity chambers. Several behavioral measures (e.g. crossovers, rearings, eating) were continuously monitored. Animals were assigned randomly to three groups. Group 1 was a saline-control group. *Group 2, after a three day habituation period, was injected (IP)* with 20.0 mg/kg cocaine for seven consecutive days. *Group 3* received only one 20 mg/kg cocaine injection after a nine day habituation period. The experiment was also designed to test for the possible role of conditioning factors in the behavioral augmentation observed after chronic cocaine administration. Twenty-four more animals were used. Animals housed four per cage in the animal room were injected with saline or cocaine for 6 days. All rats were transferred to the individual activity chambers 15 hours before challenge with saline or cocaine on the seventh day.

Analyses of the data indicated that acute administration of 20 mg/kg cocaine resulted in a brief stereotypy phase in which little locomotor activity occurred, followed by a sustained increase in locomotor and rearing activity. Activity levels returned to baseline levels within three hours of injection. The response to acute cocaine was not affected by different pre-injection habituation periods (i.e. 15 hours, 3 or 9 days). When cocaine was administered chronically to animals in the individual activity chambers, the initial stereotypy phase became more pronounced and increased in duration. By contrast, there was no evidence of an enhanced responsiveness to repeated cocaine when animals, injected in their home cages were tested in the experimental chambers. The above finding implies a role for conditioning factors in the changes in the response to cocaine after chronic administration.

185.13 SIMULTANEOUS ANALYSIS OF SEROTONIN NEURONAL ACTIVITY AND RELEASE IN BEHAVING ANIMALS. L.O. Wilkinson, K.M. Martin, S.A. Auerbach, C.A. Marsden, and B.L. Jacobs. Prog. Neurosci., Dept. Psychol., Princeton Univ., Princeton, NJ 08544.

A large body of evidence suggests a specific role for serotonin (5-HT) in various behaviors and physiological processes. However, work in our laboratory and elsewhere has indicated that 5-HT neuronal activity remains unchanged in a number of behavioral and physiological conditions. The present experiments were designed to examine how changes in the neuronal activity of 5-HT cells correlate with extracellular 5-HT levels in the terminal fields of these neurons.

Extracellular 5-HT was measured in the striatum of the awake, freely moving cat using the dialysis technique of Hernandez et al. (1986). In brief, a concentric probe with a permeable tip was lowered through an implanted guide cannula at the time of the experiment. A modified Ringers solution containing 10 µM of the specific 5-HT reuptake inhibitor fluoxetine was pumped through the probe, collected, and injected into an HPLC with EC detection for analysis of 5-HT. Extracellular 5-HT was examined during: 1) electrical stimulation of the dorsal raphe nucleus, 2) systemic administration of 8-OH-DPAT, which acts on the cell body autoreceptor to decrease neuronal firing, and 3) fluctuations in unit activity observed during changes in the behavioral state of the animal during the sleep/wake cycle.

The following generalizations can be made. Low frequency stimulation of the DRN produced an increase in extracellular 5-HT that was directly related to stimulation intensity. Administration of 8-OH-DPAT (250 µg/kg, sc.), produced a 60% decrease in extracellular 5-HT and the duration of this effect approximately paralleled the decrease in unit activity seen after administration of this dose. In one instance of simultaneous 5-HT unit recording and measurement of extracellular 5-HT, the correlation between these 2 measures was 0.85. 5-HT efflux also seems to parallel changes in behavioral state across the sleep/wake cycle. These data demonstrate the coupling of neurotransmitter release to action potential generation under these conditions, and substantiate the validity of the dialysis technique.

185.14 5-HT DEPLETION FAILS TO INHIBIT METHYSERGIDE-INDUCED SUCKLING IN WEANLING-AGE RATS. A. H. Lichtman*, C. R. McLaughlin, & C. P. Cramer. (SPON: H. C. Hughes). Dept. of Psychology, Dartmouth Coll., Hanover, NH 03755.

The hypothesis that an emerging serotonergic (5-HT) inhibitory mechanism is involved in the process of weaning is supported by the finding that acute administration of several 5-HT antagonists, including methysergide, facilitate nipple attachment in weanling-age rats (Williams, Hall, & Rosenblatt, 1979). In addition, several 5-HT agonists inhibit nipple attachment, and pretreatment of methysergide reverses these inhibitory effects. If methysergide facilitates nipple attachment exclusively via a 5-HT system, then depletion of 5-HT should attenuate this effect.

In Experiment 1, we administered the long term 5-HT antagonist, parachlorophenylalanine (PCPA, 300 mg/kg, ip.) or saline to pups at either Days 20 or 22. In Experiment 2, we administered on Day 20 an intraventricular injection of either the 5-HT neurtoxin, 5,7-dihydroxytryptamine (5,7-DHT, 150 µg in 3 µl of isotonic saline with 0.5% ascorbic acid), or an equivalent volume of the vehicle. In addition, all subjects were pretreated with pargyline (50 mg/kg, ip.), an MAO inhibitor, to prevent destruction of noradrenergic neurons (Breese, Vogel, & Mueller, 1978). In both experiments, animals in each group were administered either methysergide (20 mg/kg, ip) or saline 20 minutes prior to a 1 hour attachment test at Day 25. Both the latency to attach to a nipple and the total time attached were recorded.

Methysergide facilitated nipple attachment on both dependent measures in Experiment 1. Suckling was also facilitated in rats treated with PCPA at Day 20, but not at Day 22.

In the second experiment, the animals injected with 5,7-DHT actually attached with longer latencies and for shorter periods of time than the sham-lesioned animals. Again, methysergide facilitated attachment independent of neurotoxin exposure. Another unexpected finding was that the sham-lesioned animals spent more time attached than expected, suggesting that the pargyline pretreatment may have facilitated nipple attachment.

These data suggest that 5-HT may not be the only system involved in methysergide-induced suckling during the weaning period.

185.15 TIME COURSE OF NEUROPHARMACOLOGICAL REORGANIZATION OF STRIATAL FUNCTION FOLLOWING UNILATERAL 6-HYDROXYDOPAMINE LESIONS. R.J. Carey and M.R. Lynch. Psychiatry Department, SUNY Health Science Center at Syracuse, and VA Medical Center, Syracuse NY 13210.

Extensive unilateral destruction of nigral dopamine neurons in adult rats by unilateral intranigral injection of 6-hydroxydopamine produces persistent movement asymmetries. A salient motoric manifestation of this disturbance is a tendency of animals to rotate in a direction ipsilateral to the lesion hemisphere. This ipsilateral turning can be greatly exaggerated by amphetamine treatment. In the present study, the postoperative time course of the effects of a low dose of d-amphetamine sulfate (1.0 mg/kg) on rotational behavior in 6-OHDA treated rats was examined. Separate groups of rats (N=6) given unilateral 6-OHDA intranigral injections (4 ul of 3 ug/ul) were tested for locomotor and rotational behavior at 1, 3, 6 and 9 days postoperative. Following 1.0 mg/kg amphetamine injections the 6-OHDA rats exhibited rotational behavior which was related to the time postoperative. At one day postoperative low rates (0.2/min) of ipsilateral and contralateral rotational responses were observed. On days 3 and 6 vigorous contralateral rotation occurred (6.0/min). On day 9 and all subsequent test days ipsilateral rotation was observed (3.0/min). Vehicle injected and control animals did not exhibit rotational behavior to amphetamine. Measurement of striatal dopamine and dopamine metabolites HVA and DOPAC indicated that the direction of rotational behavior was not always directly related to hemispheric dopamine content. At day one postoperative, dopamine in the 6-OHDA hemisphere was increased but at days 3 and 6 postoperative the level of dopamine was reduced to 30% and 3% of the intact hemisphere respectively. On day 9 postoperative the striatal dopamine level was also at 3% of the intact hemisphere. Increases in HVA but not DOPAC activity in the 6-OHDA hemisphere were closely correlated with the contralateral rotation induced by amphetamine. These findings indicate that a dynamic reorganization of striatal dopamine function occurs during the first week following a 6-OHDA lesion and this process may provide a fruitful model for assessing neuropharmacological plasticity associated with brain injury.

185.16 STIMULATION OF SEROTONIN-1A RECEPTORS PREVENTS CISPLATIN-INDUCED EMESIS IN CATS. J.B. Lucot and G.H. Crampton. Dept. Pharmacol., Wright State Univ., Dayton, OH 45435.

Emesis elicited by cancer chemotherapeutic agents is a significant clinical problem. The novel anxiolytic, buspirone, has been reported to block emesis elicited in cat by motion and by xylazine, which presumably use different neural pathways to trigger the emetic reflex. Buspirone also blocks cisplatin-induced emesis in cat. The mechanism by which buspirone exerts this effect is unknown because it stimulates serotonin-1A (5-HT_{1A}) receptors and at higher doses, blocks presynaptic dopamine receptors. Accordingly, the selective 5-HT_{1A} agonist, 8-hydroxy-2 (di-n-propylamino)tetralin (8-OHDPAT) was evaluated for its antiemetic effects and found to be effective against motion sickness and xylazine-induced emesis in cats. This led to the hypothesis that 8-OHDPAT would block cisplatin-induced emesis.

Jugular catheters were implanted unilaterally under ketamine and pentobarbital anesthesia and sterile conditions, threaded under the skin and externalized through the back of the neck. Patency was maintained by drawing blood, flushing with 50 U/ml heparin and filling with 1000 U/ml heparin after surgery and every other day thereafter. Experiments were conducted 72-96 hr after surgery. All cats received 7.5 mg/kg cisplatin (Sigma) in a solution of 2 mg/ml infused over 4-5 min. Experimental cats received 0.16 mg/kg 8-OHDPAT (Research Biochemicals Inc., n=8) or 0.64 mg/kg (n=6) SC immediately before cisplatin. Controls were done to verify the efficacy of each bottle of cisplatin and added to historical controls (n=10). All emetic events were recorded over a 6 hr observation period, after which the cats were euthanized with T-61 (Hoechst) administered IV.

The dose of 0.16 mg/kg increased the latency to emesis and the dose of 0.64 mg/kg decreased the number of emetic episodes ($P<.05$, Wilcoxin's test). The dose of 0.16 mg/kg produced no nonspecific effects, while the dose of 0.64 mg/kg elicited strong defensive behaviors. These data demonstrate that stimulation of 5-HT_{1A} receptors blocks emesis elicited by a variety of emetic stimuli and that this action is adequate to explain the antiemetic effects of buspirone.

185.17 SEROTONERGIC MECHANISMS OF AGGRESSIVE AROUSAL M. Potegal, L. Haimes and L. Skaredoff* New York State Psychiatric Institute, New York, NY, 10032

"Priming" a female hamster by allowing it one biting attack on a drug-treated target hamster reduces the latency of the subsequent attack. "Satiating" a hamster by allowing it to attack a series of targets until it meets a criterion of 3 successive target presentations without attack increases the latency and reduces the number of subsequent attacks. The half life of the priming effect is approximately 12 hr, that of the satiation effect is 24 hr (Potegal, Agg. Behav,10,303,1984; Potegal and Popken,Behav Process,11,199,1985) Within the N. accumbens/preoptic area there are bidirectional priming/satiation-associated changes in both ^{3}H-5HT uptake and ^{3}H-ketanserin binding (Barkai et al, Neurosci. Abst,10,1170,1984; Potegal and Wagner, Neurosci Abst,11,1176,1985). The finding that 5,7-DHT injections into the POA alter attack satiation is complementary evidence for a serotonergic regulation of aggressive arousal (Potegal et al, Neurosci Abst,10,1170,1984).

We now report two further experiments in this series. In the first of these, radiofrequency lesions were placed in the dorsal or median raphe of female hamsters using movements elicited by stimulation of the III, IV and VII cranial nerves and descending pathways to the limbs for localization of lesion sites. Animals were tested once preoperatively and 3 times postoperatively on a combined priming/satiation test. Dorsal raphe lesions increased aggression relative to controls, median raphe lesions reduced it. The difference between the lesion groups was statistically significant.

In the second study we have found that the $5HT_2$ antagonist ketanserin prevents in dose-related fashion the reduction in attack latency which would otherwise follow the (initial) priming attack. A dose of 150 nmol/kg preceding the test is sufficient to maintain the probe attack latency equal to that of the priming attack. In the dose range where this selective effect can be obtained there appear to be no major effects on the initial attack latency itself nor on the number of attacks in the test. This rules out interpretations such as a generalized decrease in motor function or motivation.

The results of the first study strengthen the evidence for a serotonergic regulation of aggressive arousal. If the results of the second study are confirmed by ongoing work with the specific $5HT_2$ antagonists ritanserin and pizotifen, it will suggest a specific role for $5HT_2$ receptors in this regulation.

185.18 EVIDENCE FOR ADRENERGIC INVOLVEMENT IN FEEDING-INDUCED BEHAVIORAL STEROTYPIES (FIBS) IN PIGEONS.
I. J. Goodman (Spon. C. Craig) Department of Psychology, West Virginia University, Morgantown, WV 26506

In weight reduced pigeons, a restricted daily feeding may induce a variety of behavioral sterotypies (FIBS) (e.g. repetitive pecking) for hours thereafter on such diet days. This phenomenon is suggested to be associated with a functional interaction of brain dopaminergic (DA) and noradrenergic (NA) systems, based on forebrain transmitter assays (Goodman et al, 1983). While a current report (see Fisher & Goodman, 1987) finds that administered adrenergic agents significantly influence apomorphine-induced behavior sterotypies, the present study reports the effects of these agents on FIBS activity.

Adult, male pigeons were observed in their home cages .5 hr before and .5, 1.5 and 2.5 hrs following feeding, and scored for the presence of FIBS on these 4 occasions. Pre-feeding FIBS occurred rarely. On selected days birds were systemically injected with an adrenergic agonist or antagonist. Behavioral comparisons were made with previous non-drug day results. A second test was used to measure peck frequencies for 1 min. epochs over a 2 hr period with drugs that did not suppress FIBS scores in the first test.

Clonidine, an alpha agonist acting at pre- and postsynaptic receptors, significantly decreased FIBS at all doses tested (.005-.2 mg/kg, im). Yohimbine, a presynaptic alpha antagonist, did likewise (.1-1.0 mg/kg, im). Propranolol, a beta antagonist, also suppressed FIBS (1-5 mg/kg, im). Prazosin, (.1-.5 mg/kg, im), a postsynaptic alpha antagonist, and isoproterenol (.03-.1 mg/kg, im), a beta agonist, did not reduce FIBS. In this test, a ceiling effect prevented a FIBS score from indicating true facilitation. In peck frequency testing, thus far, isoproterenol has failed to facilitate pecking; whereas, prazosin caused a significant rise in pecking. These findings support the view that FIBS are dependent upon actions in the adrenergic as well as dopaminergic systems. It appears that the latter system facilitates FIBS (Goodman et al, 1983) and that the former one inhibits it. This is not unlike the circumstance described for drug-induced (APO) sterotypies. In both cases the bridging mechanism(s) betweem DA and NA actions remains to be elucidated in the context of relevant sensorimotor neural circuitry.

186.1 NICOTINIC RECEPTOR ACTIVATION IN RAT SUPRAOPTIC NEUROSECRETORY CELLS IN VITRO : EFFECTS OF MECAMYLAMINE, HEXAMETHONIUM AND ALPHA-BUNGAROTOXIN. C.W. Bourque and D.A. Brown. MRC Neuropharmacology Research Group, The School of Pharmacy, 29/39 Brunswick Square, London WC1N 1AX, England.

The neurohypophyseal release of vasopressin is regulated by the electrical activity of magnocellular neurosecretory cells (MNCs) located in the supraoptic and paraventricular nuclei of mammals. Previous studies in the rat have shown that acetylcholine (Ach) excites putative vasopressin-secreting MNCs (Hatton, G.I. et al, J.Physiol. 345; 297, 1983) and that nicotinic Ach receptor antagonists can block the vasopressin response of hypothalamic explants exposed to an increase in osmolarity (Sladek, C.D. and Joynt, R.J., Endocrinol. 105;367, 1979). In apparent agreement with the presence of nicotinic receptors on these cells, a high density of binding sites for radiolabelled alpha-bungarotoxin (α-BuTX) has been reported in the supraoptic and paraventricular nuclei (e.g. Meeker, R.B. et al, J.Neurosci. 6; 1866, 1986).

In the present experiments the characteristics of these nicotinic Ach receptors have been examined in MNCs impaled in the supraoptic nucleus of perfused explants of rat hypothalamus (c.f. Bourque, C.W. and Renaud, L.P., J.Neurosci.Meth. 7; 203,1983). Bath application of Ach (5-100μM; n=9 cells) caused a depolarization and an increase of membrane conductance. This effect could be observed in the presence or absence of 0.5μM tetrodotoxin suggesting that the origin of the response was post-synaptic. Identical responses were also obtained by applying nicotine (5-100μM; n=13 cells) or dimethylphenylpiperazinium (DMPP, 5-100μM; n=4 cells). Bolus infusions of nicotine or DMPP achieving similar concentrations yielded consistently reproducible responses and were therefore used to examine the effects of various antagonists. Bath application of hexamethonium (20-200μM : n=4 cells) or mecamylamine (5-50μM; n=3 cells) both caused a dose-dependent and reversible reduction of agonist-induced responses. In contrast, 8-40 minute applications of 1μM α-BuTX (purified preparation kindly provided by Dr J.O. Dolly) had no measurable effect on responses observed in any of five cells.

These results further suggest that MNCs in the rat supraoptic nucleus are endowed with nicotinic Ach receptors. Nicotinic responses in these cells resemble those in autonomic ganglia in being blocked by mecamylamine or hexamethonium but not by α-BuTX, the significance of the α-BuTX binding sites present in the supraoptic nucleus is therefore unclear. 186.2 MODULATION OF ADRENERGIC CONTROL OF VASOPRESSIN RELEASE BY HYPOTONICITY IN ORGAN-CULTURED HYPOTHALAMO-NEUROHYPOPHYSIAL EXPLANTS. Celia D. Sladek and Richard W. Clough. Dept. Neurology and Neurobiology and Anatomy, Univ. of Rochester Sch. of Med., Rochester, NY 14642

Previous studies in this laboratory and others have demonstrated both stimulation and inhibition of vasopressin (VP) release by norepinephrine (NE). One hypothesis advanced to explain these findings is that both alpha and beta adrenergic receptors participate in the regulation of VP release. This hypothesis was addressed in the present study by evaluating the effects of receptor-specific adrenergic agonists on VP release from organotypic explants of the hypothalamo-neurohypophyseal system (HNS) in tissue culture. Phenylephrine (10^{-5}M), an alpha$_1$-adrenergic agonist, increased VP release by 455 ± 198% over basal release ($p<.025$, n=7) from HNS explants maintained in static organ culture for 48 hrs prior to the experiment. A beta adrenergic agonist, isoproterenol (10^{-5}M), did not alter VP release, and clonidine, an alpha$_2$ agonist, was ineffective at 10^{-5}M, but stimulated VP release at 10^{-4}M (428 ± 174%, $p<.025$, n=7). These results confirm our previous observation that alpha$_1$ agonists excite VP neurons (Br. Res. 365:192, 1986), but do not provide evidence for an inhibitory action of either beta or alpha$_2$ agonists. Thus, the differential effects of NE on VP release cannot be accounted for solely on the basis of excitation of alpha$_1$ receptors and inhibition by either beta or alpha$_2$ receptors.

A second hypothesis which was evaluated, is that the effect of NE on VP release depends on the other regulatory signals which are simultaneously affecting the HNS. This hypothesis is supported by the observation that NE (10^{-5}M) delivered into the culture medium in isotonic saline stimulated VP release from HNS explants maintained in either static ($p<.005$, n=11) or perifusion culture ($p<.05$, n=5), but NE (10^{-5}M) delivered in 10 ul of dH_2O inhibited VP release from explants in static culture ($p<.025$, n=9). This volume of dH_2O alone did not significantly alter VP release, but it did decrease the osmolality of the culture medium by 3-5 mosmol/kg H_2O. In order to determine if this reflected differential activation of alpha and beta receptors, the effect of hypotonicity on the response to phenylephrine and isoproterenol was evaluated. Use of dH_2O as the vehicle for delivery of phenylephrine (10^{-5}M) eliminated the stimulation of VP release observed when isotonic saline was used as the vehicle, but inhibition of VP release was not observed. Isoproterenol (10^{-5}M) remained ineffective in altering VP release when delivered in either saline or dH_2O. These observations support the hypothesis that hypotonicity modulates the effect of NE on VP release and may represent the in vitro equivalent of the in vivo observation that small decreases in osmolality inhibit stimulation of VP release by hypovolemia (Stricker and Verbalis, Am. J. Physiol. 250:R267, 1986).

186.3 PREGNANCY AND LACTATION ALTER SPINAL CORD LEVELS OF OXYTOCIN AND VASOPRESSIN. C. Miaskowski*, G.L. Ong*, and J. Haldar (SPON: A. Sinha). Dept. of Biological Sciences, St. John's University, Jamaica, NY 11439.

Previous work from our laboratory has shown a cyclic variation in spinal cord levels of oxytocin (OT) and vasopressin (VP) during the stages of the rat's estrous cycle (Miaskowski, C., et al., Endocrinology, 120: 1685, 1987). The purpose of this study was to determine if pregnancy and lactation produced alterations in the levels of these neurohypophyseal peptides. Sprague Dawley rats were sacrificed at 10 and 20 days of pregnancy and lactation. The spinal cords were segmented into cervical, thoracic, and lumbosacral (L/S) regions, homogenized in 0.1 N HCl, and extracted using the Sep-pak method. Hormone content was determined by radioimmunoassay and compared to proestrus and diestrus control values. The table summarizes the increases in OT and VP content in the various segments of the spinal cord during pregnancy and lactation:

		% INCREASE COMPARED WITH DIESTRUS		% INCREASE COMPARED WITH PROESTRUS	
		10 DAYS	20 DAYS	10 DAYS	20 DAYS
PREGNANCY					
Cervical	OT	35.5^{++}	-----	295.7^{++}	87.4^{++}
	VP	-----	-----	-----	-----
Thoracic	OT	33.7^{*}	25.6(NS)	122.5^{++}	109.7^{++}
	VP	5.6(NS)	-----	105.6^{++}	88.3(NS)
L/S	OT	157.0^{++}	47.8(NS)	449.2^{++}	215.8^{++}
	VP	102.9^{+}	50.0(NS)	221.4^{+}	139.3(NS)
LACTATION					
Cervical	OT	33.8(NS)	116.6^{++}	188.4^{+}	366.8^{++}
	VP	-----	31.3(NS)	-----	94.5(NS)
Thoracic	OT	186.2^{++}	113.3^{+}	376.5^{++}	255.1^{++}
	VP	49.4(NS)	-----	190.6^{++}	53.9^{*}
L/S	OT	207.0^{++}_{**}	184.1^{*}_{*}	556.1^{++}_{**}	507.1^{**}_{**}
	VP	151.1^{**}	93.8^{*}	297.7^{**}	206.9^{**}

Statistical significance was determined using a Student's t-test ($*p<0.05$, $**p<0.02$, $+p<0.01$, $++p<0.001$ and NS = not significant). The data demonstrate that pregnancy and lactation produce changes in spinal cord levels of OT and VP with the most dramatic increases occurring in the L/S segment. The exact physiological role for OT and VP within the spinal cord during pregnancy and lactation remains to be elucidated.

186.4 CHANGES IN OXYTOCIN AND VASOPRSSIN LEVELS IN THE RAT SPINAL CORD FOLLOWING HYPERTONIC SALINE ADMINISTRATION. D.Lukic*, J. Vrba* and J. Haldar. Department of Biological Sciences, St. John's University, Jamaica, NY 11439

On the basis of immunohistochemical studies and radioimmunoassay (RIA) data it is well established that nerve endings containing vasopressin (VP) and oxytocin (OT) are present in numerous extrahypothalamic areas and the spinal cord in addition to the classical hypothalamo-neurohypophysial system. It has yet to be determined, however, what physiological role these extrahypothalamic hormones serve. Work from our laboratory documented for the first time that spinal cord OT and VP levels change during different stages of the estrous cycle (Endocrinology 120:1685-1687,1987). Recently we demonstrated that immobilization stress is a powerful stimulus for increasing spinal cord OT level while VP levels were not altered (Fed.Proc.:46,Abs.3068,1987). The purpose of this study was to determine whether increased plasma osmolality is an effective stimulus for altering spinal cord OT and VP levels.

All experiments were conducted with male Long Evans rats (240 + 5g). Rats were injected ip either with isotonic (0.85%, 2 ml/Kg) or with hypertonic saline (1M, 2 ml/Kg). Rats were either sacrificed 15 min. or 3 hours after treatment. The pituitary, hypothalamus, pons-medulla, and cervical, thoracic and lumbosacral segments of the spinal cord were isolated. All samples were homogenized in 0.1N HCl, and centrifuged. The supernatant was separated for protein estimation and the remainder was extracted using C-18 Sep-pak cartridges. OT and VP levels were then determined by RIA. Results obtained from these experiments show (1) hypertonic and isotonic saline-induced changes for both OT and VP are more effective in rats sacrificed at 15 min. as compared to 3 hours (2) At 15 min., OT increased significantly in the pons-medulla and in all segments of the spinal cord following hypertonic saline administration. (3) VP levels decreased in 15 min. with hypertonic saline treatment in both the cervical and thoracic segments of the spinal cord.

In conclusion, these data indicate (1) increased osmolality is an effective stimulus for the alteration of extrahypothalamic OT and VP levels (2) changes observed at 15 min. maybe due to a stress rather than an osmotic effect (3) spinal cord OT levels and not VP levels are more susceptible to stressful stimululi and, (4) spinal cord OT and VP levels are under different control mechanisms.

186.5 REGIONAL HYPOTHALAMIC AND NEUROHYPOPHYSEAL BLOOD FLOW DURING HYPERCAPNIA IN THE RAT: N-ISOPROPYL-P-IODOAMPHETAMINE [ISOPROPYL-2-^{14}C], A NEW TRACER FOR MEASURING CEREBRAL BLOOD FLOW. C.L. Myers*, R.B. Page, and R.M. Bryan. Departments of Surgery (Neurosurgery), Physiology, and Anatomy, M.S. Hershey Medical Center of The Pennsylvania State University, Hershey, PA 17033.

Previous studies have shown that blood flow in the neurohypophysis [median eminence (ME) and neural lobe (NL)] does not increase during hypercapnia as it does in other brain regions. The ME and NL consist of nerve terminals whose cell bodies lie in the paraventricular (PVN) and supraoptic nuclei (SON) of the hypothalamus. It is not known if blood flow to the cell bodies in the PVN and SON fails to respond to hypercapnia as it does to their nerve terminals in the ME and NL or if their regional blood flow increases during hypercapnia like other brain regions. We measured regional cerebral blood flow in the ME, NL, PVN, SON, and other brain regions using a new tracer, n-isopropyl-p-iodoamphetamine [isopropyl-2-^{14}C] (IPIA). IPIA is completely extracted during a single pass through cerebral capillary beds. This property provides several advantages over diffusible tracers for measuring flow in regions such as the ME and NL which have high rates of flow. Rats were surgically prepared with catheters in one femoral artery and vein using nitrous oxide and halothane. A plaster cast was fitted around the hip and groin area to restrain the rats and to protect the catheters. Hypercapnia was produced by increasing the partial pressure of CO_2 in the ventilatory gas mixture. Blood flow during normocapnia and hypercapnia was as follows:

	Regional Cerebral Blood Flow (ml/100g/min)	
	Normocapnia ($PaCO_2$ = 42 + 2 mm Hg)	Hypercapnia ($PaCO_2$ = 66 + 4 mm Hg)
ME	624 ± 95	589 ± 61
NL	954 ± 66	862 ± 75
PVN	310 ± 14	497 ± 31 ($p<.05$)
SON	339 ± 43	484 ± 13 ($p<.05$)

Blood flow in the ME and NL was not affected by hypercapnia while flow in the PVN and SON increased significantly. Not only did blood flow in the PVN and SON increase during hypercapnia but flow in these regions was more sensitive to the increases in $PaCO_2$ than any other brain region studied. We conclude that blood flow in the cell bodies of the PVN and SON are regulated differently during hypercapnia than their nerve terminals in the ME and NL. 186.6 DIETHYLSTILBESTEROL TREATMENT INCREASES RAT NEUROINTERMEDIATE LOBE OXYTOCIN AND VASOPRESSIN BUT NOT METHIONINE ENKEPHALIN. J. A. Schriefer* (SPON: A. Hassen). Dept. of Pharmacology, West Virginia School of Osteopathic Medicine, Lewisburg, WV 24901.

Immunohistochemical evidence suggests that a number of peptides may be co-localized with oxytocin (OT), perhaps in the same granules, in the magnocellular neurons of the hypothalamo-neurohypophysial system (HNS). These peptides may have a role in the feedback regulation of OT release. Changes in oxytocin content might be expected to be accompanied by similar changes in content of the co-localized peptides. One peptide thought to be co-localized with OT and to have an inhibitory effect on oxytocin release is methionine enkephalin (MENK). Estrogen treatment is known to increase neurointermediate lobe OT. The estrogen stimulation paradigm was used to determine whether MENK changes in parallel with OT.

Female Sprague-Dawley rats (200-250 g) were treated with diethylstilbesterol (70 µg/day, sc) for two days. On the third day, the rats were decapitated, the neurointermediate lobe removed and homogenized in 0.25 % acetic acid. The neurointermediate lobe content of OT, vasopressin, and MENK were determined by specific radioimmunoassays. The OT and vasopressin content of the lobes was increased 1.5-2.0 fold in diethylstilbesterol-treated rats but the MENK content was unchanged. The basal and K^+ - stimulated release of OT from isolated, perfused HNS explants and neurointermediate lobes from diethylstilbesterol-treated rats was examined and found to be increased compared to that from controls. In the DES-treated rats, increased OT release rates in the presence of a decreased MENK/OT ratio are consistent with an inhibitory role for MENK in OT release. The effect of diethylstilbesterol on the MENK/OT ratio of the neurointermediate lobe implies that a means for independent regulation of OT and MENK synthesis in the same neuron must exist or that the two peptides are not located in the same neurons.

186.7 CRH NEURONS IN THE PARAVENTRICULAR NUCLEUS OF THE HYPOTHALAMUS: VASOPRESSIN CONTAINING AND VASOPRESSIN DEFICIENT SUBPOPULATIONS. M.H. Whitnall, S. Key* and H. Gainer. Lab. of Neurochemistry, NINCDS, NIH, Bethesda, MD 20892

Half of the CRH axons projecting to the portal capillary system in normal rats contain vasopressin (AVP), co-packaged into the same secretory vesicles as CRH, while the remaining CRH axons contain no immunocytochemically detectable pro-AVP-derived peptides (Whitnall et al., Nature 317:248, 1985; Neuroendocrinol. 45:420, 1987). These axonal subpopulations respond differently to adrenalectomy (Whitnall et al., Endocrinol. 120:2180, 1987), suggesting that the levels of CRH and AVP in portal blood may be modulated by independent regulation of separate populations of CRH neurosecretory cells. This hypothesis predicts that two sub-populations of CRH-containing perikarya exist, regulated differentially by hormones and/or axonal inputs. We have tested this hypothesis using post-embedding E.M. immunocytochemistry in the nucleus of origin of these CRH fibers: the paraventricular nucleus (PVN). Male, 200 g rats were injected with 10 µl of 1% colchicine into the lateral ventricle 24-48 h before perfusion with 4% glutaraldehyde. Hypothalami were embedded in LR White, and serial ultrathin sections were immunoperoxidase-stained for CRH, pro-AVP-derived peptides, and pro-oxytocin (OT)-derived peptides. Very few CRH-positive cells were found in untreated rats, but many CRH-positive cells, both AVP-containing and AVP-deficient, were found in the PVNs of rats treated with colchicine. Three rostro-caudal levels in the caudal portion of the PVN have been analyzed in a 48 h colchicine-treated rat. Of the 192 CRH-positive perikarya found, 4 were OT-containing, 120 were AVP-containing, and 68 were unstained for pro-AVP- or pro-OT-derived peptides. The AVP-containing CRH neurons were concentrated in the dorsal part of the medial parvocellular region of the PVN, while the AVP-deficient CRH neurons were preferentially located in the ventral part of the medial parvocellular region and in the lateral parvocellular region (defined according to Swanson and Sawchenko, Ann. Rev. Neurosci. 6:275, 1983). We are presently mapping the distributions of the CRH neuronal subtypes in normal and adrenalectomized rats. The ability to identify AVP-containing and AVP-deficient subpopulations of CRH perikarya in the PVN strengthens the hypothesis of functionally independent sub-populations of CRH neurosecretory cells, and will allow us to determine what specific receptors and axonal inputs might differentially control the activity of the two components of the CRH neurosecretory system.

186.8 A COMPARISON OF SYNAPTIC AND INTRINSIC PROPERTIES OF MAGNOCELLULAR NEUROENDOCRINE CELLS IN KITTEN AND RAT. M. Fagan and R.D. Andrew. Anatomy Dept., Queen's University, Kingston, Ontario K7L 3N6.

Both rat and kitten magnocellular neuroendocrine cells (MNCs) display firing patterns in hypothalamic slices that reflect activity recorded in the respective intact animal. Specifically, 50% of MNCs recorded intracellularly from supraoptic nucleus (SON) in rat can burst repetitively (35 of 70 cells), a pattern diagnostic of vasopressinergic MNCs in the intact rat. Even though the majority of MNCs in cat SON are vasopressinergic, phasic firing is rarely observed in vivo (Koizumi and Yamashita, J. Physiol. 285 341, 1978) or in coronal slices from kitten. Of 201 MNCs in kitten SON recorded extracellularly to date only 7 were phasic, the remainder being continuous, irregular or silent. Moreover unlike rat, kitten MNCs rarely fired an afterdischarge upon brief orthodromic stimulation. Intracellular recordings (n=14) have revealed that action potentials of kitten MNCs lack the depolarizing afterpotential (DAP) generated intrinsically in rat. Since summation of DAPs cannot occur, a regenerating plateau potential which supports orthodromically triggered or phasic bursts in rat MNCs is missing in kitten.

Given this dramatic difference in the capability of generating bursts intrinsically, it was of interest to compare synaptic properties of kitten MNCs with their rat counterpart. Similar to rat, both inhibitory and excitatory postsynaptic potentials (IPSPs and EPSPs) occurred spontaneously and a compound IPSP or EPSP (40-80 ms) could be evoked by stimulation 0.5 mm dorsal to SON. Unique to kitten however in 3 of 9 cells tested was a fast (approx. 5 ms) depolarizing (3 - 6 mV) event that preceded the evoked PSPs. The origin of the fast event is currently under study.

Longer duration synaptic responses, not exclusive of the first two, were also observed in kitten. A prolonged (up to 20 s) excitatory response was most clearly observed following 10-15 Hz orthodromic stimulation for 1 s, as previously described in rat (Gribkoff and Dudek, Soc. Neurosci. Abstr. 11 1236, 1985). In one cell the amplitude of the response was large enough that a single stimulus supported overriding spikes for 13 s. In addition, extracellular recordings from 6 cells showed an inhibition of spontaneous firing for up to 10 s following a single orthodromic stimulus. Thus, although kitten MNCs normally lack an intrinsic bursting mechanism, the long-lasting effects of brief synaptic input may promote or inhibit firing over many seconds.

186.9 EXCITATORY ACTION OF OXYTOCIN ON PUTATIVE OXYTOCIN NEURONS IN THE SUPRAOPTIC NUCLEUS OF RAT SLICE PREPARATIONS. H. Yamashita, K. Inenaga, S. Okuya and H. Kannan. Dept. of Physiology, Univ. of Occupational and Environmental Health, Sch. of Med., Kitakyushu, 807 Japan.

Oxytocin (OXT) plays an important role in lactation and parturition by releasing into the bloodstream from the neurohypophysis. On the other hand, OXT may also be released centrally to modify the neuronal activity in the central nervous system, including that of OXT neurons themselves. An immunohistochemical study has revealed that OXT-immunoreactive terminals synapse on OXT neurons in the supraoptic nucleus (SON). Moreover, it has been shown that exogenous OXT enhances OXT release from isolated magnocellular nuclei in vitro and that OXT injected into the third ventricle modifies the activities of OXT cells in suckled lactating rats. Eventually neurosecretory cells can be excited by iontophoretically applied OXT. The aim of this study is to clarify the effects of OXT on SON neurons and to determine the sensitivity of OXT to these neurons using the rat hypothalamic slice preparations. Application of OXT to the bathing medium (3×10^{-7} M) made excitation in 13 (93%) of 14 cells which fired continuously and 26 (81%) of 32 cells which fired slowly and irregularly. By contrast, only 2 of 26 phasically firing neurons which were putative vasopressin neurons were excited and none of the SON cells tested were inhibited. The excitation was reversibly antagonized by a synthetic OXT analogue (d[Try(Me)^2]VDAVP). To investigate whether the responses were due to direct or indirect effect on the neurons, a low Ca^{2+} (0.5 mM) and high Mg^{2+} (9 mM) medium was used. Four neurons which had shown excitatory responses to OXT in control medium were still excited after blockade of synaptic transmission, suggesting that the SON neurons themselves were sensitive to OXT. When the actions of vasopressin (AVP) were compared with those of OXT, all 17 neurons tested which had shown clear excitatory responses to OXT showed a much weaker excitatory responses to AVP or no response at all at the same concentration. The results suggest that OXT exerts predominantly excitatory effects in the SON and that putative OXT cells are more likely to be affected than putative vasopressin cells.

186.10 **STUDIES OF THE TOXICITY OF DIISOPROPYLFLUOROPHOSPHATE: SPECIFIC CHOLINERGIC SUPPRESSION OF PROLACTIN, LUTEINIZING HORMONE AND THYROTROPIN SECRETION IN INTACT RATS.** H.G. Fein* and R.C. Smallridge* (SPON: F. Manning). Div. of Medicine, Walter Reed Army Institute of Research, Washington, D C 20307

Diisopropylfluorophosphate (DFP) is an anticholinesterase that has been employed as a model agent for studies of organophosphate poisoning. Recently, pituitary cells have been shown to have muscarinic cholinergic receptors. Therefore, we examined some hormonal effects of DFP in normal animals. DFP (or peanut oil vehicle) was administered subcutaneously to male Sprague-Dawley rats (250-350 gm). Animals were sacrificed by decapitation, trunk blood was collected, and sera were analyzed by radioimmunoassay. At 3 h after injection, DFP (0.6-2.4 mg/kg) caused a dose-dependent rise in corticosterone (cort). It also resulted in a dose-dependent reduction of prolactin (PRL) at 1.4 mg/kg and above (suppression of 64-80 % vs controls, $p<.05$) and of thyrotropin (TSH) at 1.8 mg/kg and above (56-87 % suppression, $p<.05$). Luteinizing hormone (LH) was increased 142 % at 0.6 mg/kg ($p<.01$), but was suppressed at 1.4 mg/kg and above (47-50 %, $p<.05$). The suppressive effects of DFP at 2.4 mg/kg were seen on TSH by 1 h after injection and persisted for 18 h; PRL was suppressed from 1 to 6 h and LH was suppressed at 3 and 6 h; cort was elevated from 1 to 9 h. Pituitary PRL content was increased 200 % ($p<.01$) within one half hour after administration of 2.4 mg/kg of DFP; this effect persisted for 18 h (240 % increase, $p<.01$). Pretreatment with intraperitoneal atropine at doses of up to 30 mg/kg one-half hour before DFP (2.4 mg/kg) had a dose-dependent effect of partially ameliorating the cholinergic symptoms caused by DFP, but did not affect the suppression at 3 h of PRL or LH or stimulation of cort. Atropine at 300 µg/kg had no effect on the suppression of TSH by DFP, but a reversal of TSH suppression occurred after 3 and 30 mg/kg of atropine. Thirty mg/kg of atropine did not block the suppression of PRL at 3 h by 1.8 mg/kg of DFP but did block the suppression of TSH and LH. To determine if the suppression of TSH by DFP might be due to the effects of increased cort levels, we administered DFP (2.4 mg/kg sc) to adrenalectomized rats. At 3 h, cort and PRL levels were unchanged from control but TSH was suppressed ($p<.01$). Conclusions: increased cholinergic tone induced by DFP markedly suppressed serum PRL, LH and TSH but raised intrapituitary PRL, suggesting DFP may act by inhibiting hormone release without having a primary effect on synthesis. Although increased cort levels may have partly mediated effects on PRL, the suppression of TSH appeared to be a direct effect of DFP, confirming other studies in our laboratory showing cholinergic suppression of secretion from cultured pituitary cells.

186.11 SEPTAL NEURONS WITH PROJECTIONS TO THE MEDIAN EMINENCE ARE INFLUENCED BY THE SUBFORNICAL ORGAN IN THE RAT. S.D. Donevan and A.V. Ferguson. Dept. of Physiology, Queen's University, Kingston, Ontario, Canada, K7L 3N6.

The subfornical organ (SFO), a small circumventricular structure, is believed to play an essential role in the control of pituitary hormone secretion. In addition, lesion of the SFO has been shown to disrupt the estrous cycle in the rat, suggesting a possible role in the control of gonadotropin secretion. As well as its efferent projections to the supraoptic and paraventricular nuclei, the SFO also sends axons to the medial septum and diagonal band of Broca (MS-DBB) and the preoptic area. These regions have been shown, using immunohistochemical techniques, to contain the majority of luteinizing hormone releasing hormone (LHRH) containing neurons in the rat brain, many of which project to the median eminence. Electrical and chemical stimulation in these regions leads to an increase in the release of LHRH into portal blood. The present study examines the effect of electrical stimulation in the SFO on the activity of putative LHRH containing MS-DBB neurons that project to the median eminence.

Male Sprague-Dawley rats (140-320 g) were anesthetized with urethane (1.4 g/kg), placed in a stereotaxic frame, and a concentric bipolar stimulating electrode was implanted in the region of the SFO. The medial basal hypothalamus was then exposed using a transpharyngeal approach and a bipolar stimulating electrode positioned in the median eminence. Extracellular single unit recordings were then obtained from MS-DBB neurons antidromically identified as projecting to the median eminence. The effects of electrical stimulation in the SFO on the activity of these identified MS-DBB neurons were then assessed using peristimulus histograms. The anatomical locations of the stimulating and recording electrodes were histologically verified following each experiment.

Recordings were obtained from a total of 447 neurons in the MS-DBB, 18 of which were antidromically identified as projecting to the median eminence (mean latency 18.6±1.3, SEM). Of those antidromically identified cells tested with SFO stimulation 44% responded with an increase in firing rate, 11% a decrease in firing rate, while the the remaining 44% were unaffected.

These studies describe a predominantly excitatory connection between the SFO and putative LHRH containing MS-DBB neurons projecting to the median eminence, and provide further evidence of a role for the SFO in regulating gonadotropin secretion.

186.12 ANGIOTENSIN II ACTS AT THE SUBFORNICAL ORGAN TO INFLUENCE PARAVENTRICULAR NUCLEUS TUBEROINFUNDIBULAR NEURONS. A.V.Ferguson. Dept. Physiol. Queen's University, Kingston, Ont., Canada K7L 3N6.

The subfornical organ (SFO) is now well established as playing a major role in the control of posterior pituitary hormone secretion through it's efferent connections with the hypothalamic supraoptic (SON) and paraventricular (PVN) nuclei. The observations; 1) that SFO lesions abolish ACTH release in response to systemic AII (Keil and Thrasher Fed. Proc. 45:166 1986), and 2) that electrical stimulation in SFO causes the release of ACTH (Ferguson and Plotsky, unpublished observation) suggest a role for the SFO in the control of the secretion of this hormone from the anterior pituitary. Within the PVN are several groups of parvocellular neurons with axonal projections to the median eminence. One of these groups of neurons contain CRH. I have recently reported that electrical stimulation in SFO influences the excitability of these PVN neurons (Ferguson, A.V., Can. J. Physiol. Pharmacol., 1987 - in press). These studies were undertaken to further examine the role of SFO efferents in the control of PVN tuberoinfundibular neurons.

Urethane anaesthetised (1.4 g/kg) male Sprague-Dawley rats were used in all experiments. The medial-basal hypothalamus was then exposed through a transpharyngeal approach and extracellular single unit recordings were obtained from PVN neurons antidromically identified as projecting to the median eminence but not to the posterior pituitary. The effects systemic administration of AII (100-500 ng N=48) or adrenaline (100-500 ng N=20) on the activity of these neurons were examined. Of 48 identified cells tested 54% were specifically activated by AII, while 29% were similarly influenced by adrenaline and AII. In a second series of experiments in which greater than 50% of the SFO was destroyed by electrolytic lesion, only 7% of 30 identified tuberoinfundibular neurons tested were found to be specifically activated by AII.

These studies demonstrate that circulating AII influences the activity of PVN neurons projecting to the median eminence. They also suggest that such effects result from an action of this peptide at the SFO further supporting a role for this circumventricular structure in the control of anterior pituitary hormone secretion.

186.13 **CHANGES IN CEREBRAL AND PITUITARY GLUCOSE UTILIZATION AFTER WATER DEPRIVATION AS DETERMINED BY AUTORADIOGRAPHIC MEASUREMENT OF (1-^{14}C)-GLUCOSE UPTAKE.** S. A. Oglesby, G. E. Duncan*, R. S. Greenwood, R. B. Meeker, J. N. Hayward, and W. E. Stumpf, Curriculum in Neurobiology and Departments of Neurology and Anatomy, University of North Carolina, Chapel Hill, NC 27514.

A high resolution autoradiographic technique was used to investigate effects of water deprivation on cerebral glucose utilization in conjunction with measurements of plasma vasopressin, osmolality, and hematocrit levels. Male Sprague Dawley rats were deprived of water (food ad libitum) for 48-52 hours and (1-^{14}C)-glucose was injected via chronic venous catheters implanted at least 5 days prior to water deprivation. Small venous blood samples (0.2 cc) were taken at the beginning and end of the deprivation period (blood replaced with equal volume of saline) and assayed for hematocrit and plasma osmolality. Rats were anesthetized with isosmotic Na pentobarbital 30 min after injection of the labelled glucose. Left ventricular blood was then taken for determination of plasma radioactivity, endogenous glucose and vasopressin (RIA) content followed by decapitation and removal of brain for mounting and freezing. Autoradiograms were prepared by thaw mounting 4 µm cryostat sections on to nuclear emulsion (NTB-3) coated slides. Radioactivity in selected brain regions was quantitated by automated silver grain counting with an Artek counter.

Water deprived rats showed an increase in plasma osmolality (+11 mosmol/kg), hematocrit (+8%), and vasopressin (+81 pg/ml) while body weight decreased by 17% compared to controls. In water deprived rats significantly higher silver grain densities, relative to controls, were found in the paraventricular nucleus, supraoptic nucleus (SON), anterior hypothalamic area, lateral hypothalamic area, periventricular nucleus, somatosensory cortex, and neural lobe of the pituitary. In contrast, no significant changes were seen in the subfornical organ, OVLT, or the region dorsolateral to the SON.

These results suggest that when rats are dehydrated by water deprivation, glucose utilization increases dramatically in somatosensory cortex as well as in several hypothalamic areas traditionally implicated in osmoregulation but with no concomitant changes in regions thought to be possible sources of osmoreception.

186.14 EFFECTS OF NEONATAL GLUTAMATE TREATMENT ON GALANIN IMMUNOREACTIVITY IN THE RAT BRAIN. S.M. Gabriel, J.I. Koenig, U. McGarvey*, K.J. Swartz*, J.B. Martin and M.F. Beal. Department of Neurology, Massachusetts General Hospital, Boston MA 02114.

Galanin is a resently isolated gut peptide which has a wide distribution in the central nervous system and displays considerable heterogeneity across species. We have developed a radioimmunoassay (RIA) to galanin using antibodies generated in rabbits to synthetic porcine galanin conjugated to BSA. Radiolabeled porcine galanin was produced using the chloramine-T method and purified by HPLC. Studies with the synthetic porcine galanin fragments, galanin(1-10), galanin(7-16), and galanin(15-29) indicated that the galanin antibody is primarily directed towards the conformation of the midportion of the galanin molecule. There was no crossreactivity with a number of other peptides tested. The RIA detects 2 fmoles porcine galanin standard when performed under dysequilibrium conditions. However, under dysequilibrium conditions acid extracts of rat and primate brain displace ^{125}I-galanin binding poorly. In contrast, under equilibrium conditions, the assay has a sensitivity of 6 fmoles and acid extracts of rat, rabbit, human and baboon brain as well as rat pancreas displace ^{125}I-galanin binding in a parallel fashion. Sephadex G-50 chromatography and HPLC chromatography of rat brain acid extracts reveal one molecular form of galanin-like immunoreactivity. On HPLC, however, rat galanin-like immunoreactivity elutes earlier than either porcine standard or porcine brain extracts. This may indicate that the rat and porcine galanin molecules are not identical.

Since galanin neurons in the arcuate nucleus may be important in regulating neuroendocrine function, galanin-like immunoreactivity was measured in brain regions of adult male rats treated with monosodium glutamate during the neonatal period. Galanin-like immunoreactivity in control littermates were 124±11 ng/mg protein in the median eminence, 10.4±0.4 ng/mg in the medial basal hypothalamus, 11.2±0.4 ng/mg in the preoptic area, and 3.61±ng/mg in the septal region. Galanin-like immunoreactivity was reduced 57% in the median eminence, 15% in the medial basal, 22% in the preoptic region and 27% in the septal region. The concentrations of galanin-like immunoreactivity were unchanged in parietal cortex (control= 0.3±0.03 ng/mg). These studies suggest that glutamate-sensitive galanin neurons in the arcuate nucleus project throughout the medial basal forebrain of the rat. The presence of a galanin pathway from the arcuate nucleus to the median eminence indicates that this peptide may have a role in the regulation of anterior pituitary hormone release. Supported by DK07561(SMG), AG05134(MFB), and AM26252(JBM).

186.15 POSSIBLE ROLE OF HYPOTHALAMIC GROWTH HORMONE-REGULATING FACTORS IN THE SUPPRESSION OF GROWTH HORMONE DURING MATERNAL DEPRIVATION OF YOUNG RATS. L.M. Juárez* and L.A. Meserve* (SPON: R. Kantner). Dept. of Biol. Sci., Bowling Green State Univ., Bowling Green, OH 43403-0212.

The clinical syndrome of psychosocial dwarfism has been directly linked to a modification of growth hormone-mediated developmental mechanisms. In maternal deprivation, the animal model of this syndrome, short-term separation of young from the mother has been shown to directly suppress the release of growth hormone by mechanisms unrelated to pituitary-adrenal stress response. The purpose of the present study was to examine possible signals which trigger the suppression of GH during maternal deprivation of rats by quantifying hypothalamic content of growth hormone release-inhibiting hormone (GHRIH) and growth hormone-releasing hormone (GHRH). Circulating levels of GH and somatomedin C were used as peripheral correlates of hypothalamic peptide effects. Ten day old rat pups were maternally deprived in an incubator for 1 or 6 hours; controls remained with the mother during the deprivation period. At the end of the time period, pups were decapitated, trunk blood was collected and centrifuged, and the serum was frozen. Hypothalami were rapidly excised and homogenized in 2N acetic acid. Peptides were extracted by boiling the homogenates for 5 minutes. Homogenates were centrifuged, then the supernatents were flash frozen with liquid nitrogen and lyophilized. Serum samples and reconstituted hypothalamic extracts were subsequently subjected to specific radioimmunoassay for GH and somatomedin C, and for GHRIH and GHRH, respectively. Analysis of hypothalamic peptide content revealed maternal deprivation to elevate GHRIH levels significantly when values for the 1 and 6 hour deprivation were combined. Hypothalamic GHRH content was not significantly modified. Peripheral levels of GH and somatomedin C were compatible with the interpretation that elevated hypothalamic GHRIH represented an increase in its synthesis and secretion in maternally deprived pups. These results suggest an influence of GHRIH in maternal deprivation. Further studies are required to fully characterize the modifications at higher centers, and at the hypothalamic level, which result in suppression of GH by this condition.

186.16 **rGRF(1-29)NH$_2$-INDUCED GROWTH HORMONE SECRETION IN GENETICALLY AND DIETARY OBESE RATS.** P. Gaudreau, G. Renier*, M. Houde-Nadeau* and P. Brazeau*. Neuroendocrinology Laboratory, Notre-Dame Hospital Research Center and Dept. of Nutrition, University of Montreal, Montreal, Canada, H2L 4M1.

Growth hormone (GH) plays an important role in metabolic processes, especially in the stimulation of lipolysis. In genetically obese rats (Heiman et al., Am. J. Physiol., 249, E380-E384, 1985) and in dietary obese humans (Davies, R.R. et al., Clin. Endocrinol., 23, 521-525, 1985) a reduced GH secretion has been observed. In a search for a better understanding of this phenomenon, we have studied the rat growth hormone releasing factor (1-29) amide (rGRF)-induced GH response in adult male Zucker rats, dietary obese Sprague-Dawley rats and in their lean littermates. All the rats were evaluated under sodium pentobarbital anesthesia (40 mg/kg b.w., i.p.). Thirty min after anesthetic administration, rGRF was injected i.v. at a dose of 0.4 ug/kg b.w. and 4.0 ug/kg b.w. in Zucker rats or at a dose of 0.8 ug/kg b.w. and 4.0 ug/kg b.w. in dietary obese rats. Blood samples were collected every 4 min from the jugular vein, starting 4 min before, ending 20 min after rGRF injection. The sera were assayed for rGH by radioimmunoassay. In genetically obese rats (453 ± 12 g) administration of 0.4 ug/kg b.w. rGRF resulted in a rGH rise to 159 ± 16 ng/ml at 4 min post-injection while administration of 4.0 ug/kg b.w. resulted in a rGH rise to 718 ± 134 ng/ml at 8 min post-injection. The same doses increased rGH to 767 ± 85 ng/ml ($p < 0.02$) and to 3553 ± 526 ng/ml ($p < 0.05$) respectively, in lean littermates (345 ± 14 g). In dietary obese rats (551 ± 31 g), administration of 0.8 ug/kg b.w. rGRF resulted in a rGH rise to 776 ± 259 ng/ml at 4 min post-injection while administration of 4.0 ug/kg b.w. resulted in a rGH rise to 1249 ± 275 ng/ml at 8 min post-injection. The same doses increased rGH to 1057 ± 468(NS) ng/ml and to 2314 ± 389 ng/ml ($p < 0.1$) respectively, in lean littermates (458 ± 5 g). In vitro preliminary experiments using perifused anterior pituitary cells of these animals indicate a decrease in somatotroph sensitivity to rGRF. Determination of pituitary rGH content and characterization of pituitary rGRF receptors will be needed to further elucidate physiological deficiencies involved at the pituitary level in obese animal models.

187.1 CATECHOLAMINE AND NEUROPEPTIDE RATIOS IN TISSUE AND DURING RELEASE FROM THE DOG ADRENAL. S.L. Chritton*, M.K. Dousa*, C. Grabau*, D.R. Roddy*, T.L. Yaksh* and G.M. Tyce. Depts. of Physiology and Neurosurgery, Mayo Clinic and Foundation, Rochester, MN 55905.

The adrenal medulla contains epinephrine (E), norepinephrine (NE), dopamine (DA), [Met]enkephalin-like immunoreactive material (ME-IRM), and neuropeptide Y-like immunoreactive material (NPY-IRM). This study compares the ratios of these autocoids in unstimulated adrenal tissues and in perfusates of isolated adrenals before, during, and after high and low levels of nicotinic stimulation. One of a pair of dog adrenals (n=5 in each group) was retrogradely perfused at 37°C with oxygenated modified Krebs-Ringer solution. After 65 min of perfusion, medium containing $5x10^{-5}$M or $3x10^{-6}$M 1,1-dimethyl-4-phenylpiperazinium (DMPP) was introduced into the perfusion cannula for 2 min, followed by 48 min of perfusion without DMPP. Measurement of E, NE, and DA in extracts of unperfused and perfused adrenals and in perfusates was by HPLC with electrochemical detection; ME-IRM (antibody #N382) and NPY-IRM (antibody #221) were determined by radioimmunoassay. Comparison of perfused and unperfused adrenals showed no measurable depletion of autocoid stores; indeed, DA tissue content was increased following stimulation in each pair studied. The results are summarized in the table:

	Tissue Content (μg/g±S.E.)	Efflux in Perfusate (ng/min±S.E.) Basal	Low DMPP	High DMPP
EPI	1329±418	641±132	1053±305	2930±396
NE	281±61	69±17	143±60	640±111
DA	7.2±1.2	4.8±1.3	8.5±2.5	37.4±7.8
ME-IRM	2.22±0.36	1.32±0.23	2.01±0.88	8.51±2.48
NPY-IRM	0.049±0.012	0.025±0.003	0.089±0.071	0.190±0.058

The ratio of E to NE was significantly lower in unstimulated tissues and high DMPP perfusates than in basal and low DMPP perfusates. Comparing NE to DA, the ratio in tissue stores was higher than in any perfusates. Similarly, the E to DA ratio was higher in tissue than in high DMPP-evoked release. The tissue ratio of ME-IRM to NE tended to be lower in tissues than in basal perfusates. The ratios of NPY-IRM to the other autocoids did not change significantly from tissue to perfusates. These results demonstrate that E, NE, and DA are not released in the same manner from the dog adrenal. During basal conditions, there is preferential efflux from tissue stores of E, DA, and ME-IRM relative to NE. During high DMPP-evoked stimulation, DA is preferentially released from tissue stores in proportion to E and NE. DA stores in tissues increased following stimulation with DMPP. Supported by grant NS 17858.

187.2 RELEASE OF CATECHOLAMINES, [MET]ENKEPHALIN AND NEUROPEPTIDE Y FROM EX SITU PERFUSED ADRENALS AFTER CHOLINERGIC RECEPTOR STIMULATION. M.K. Dousa*, S.L. Chritton*, D.L. Lucas*, C. Grabau*, T.L.Yaksh* and G.M. Tyce (SPON: C.L. Kornblith). Depts. of Neurosurgery and Physiology, Mayo Clinic and Foundation, Rochester, MN 55905.

Chromaffin cells in adrenal medulla contain catecholamines (CA) as well as different neuropeptides. The present study is focused on the concurrent release of free CA, [Met]enkephalin-like immunoreactive material (ME-IRM), and neuropeptide Y-like immunoreactive material (NPY-IRM) from adrenals after repeated stimulation by carbamylcholine (carbachol). The experiments were carried out on dog adrenals (n=5) which were surgically removed and retrogradely perfused at 37°C by oxygenated modified Krebs-Ringer solution. After 60 min of adjustment period, four stimulations (S_1, S_2, S_3, and S_4) by carbachol ($3x10^{-5}$M) were introduced, each stimulation lasting 2 min with 40-min periods between subsequent stimulations. Samples from perfused adrenals were collected before, during, and after each stimulation by carbachol. In each perfusate sample, norepinephrine (NE), epinephrine (E), and dopamine (DA) were determined by HPLC with electrochemical detection, while ME-IRM and NPY-IRM were measured by specific radioimmunoassays. Total evoked releases from 10-min samples collected during and after S_1 expressed as means ± S.E. in pmol/min/adrenal gland were: NE, 3,095 ± 300; E, 14,028 ± 1,596; DA, 188 ± 22; ME-IRM, 12.75 ± 2.87; and NPY-IRM, 0.036 ± 0.014. Net evoked releases (R_1, R_2, R_3, and R_4) were obtained by subtracting the basal releases at given times from total evoked releases. R_1, R_2, R_3, and R_4, when expressed as average-fold increases of baseline, were surprisingly stable for each measured substance, i.e., after each carbachol stimulation, R_1, R_2, R_3, and R_4 were for NE, 4.6-fold; for E, 1.7-fold; for DA, 3-fold; and for ME-IRM, 4-fold higher than their respective baselines. NPY-IRM basal release was very low, in some samples below detection level; however, during stimulation the release significantly increased. R_2, R_3, and R_4 expressed as percents of R_1 were for both NE and E on average 80%, 68%, and 50%, respectively. However, DA was secreted during repeated stimulations at more stable rates: R_2, 95%; R_3, 82%; and R_4, 67% of R_1. The composition of adrenal perfusate during basal release was stable during perfusion, averaging 10% NE, 89% E, and 1% DA of the total pool of CA. During stimulations the percentages changed: NE and DA percentages increased to averages of 18.3% and 1.2%, respectively, with E averaging 80.5% of total CA. These results indicate that net release of all autocoids is reduced during repeated stimulations by carbachol but that DA release is reduced less than the others. During stimulation, NE and DA are preferentially released over E. The release of ME-IRM by carbachol paralleled release of NE more closely than release of E.

187.3 MONOCLONAL ANTIBODIES AGAINST UBIQUITIN INHIBIT HIGH AFFINITY CHOLINE TRANSPORT IN RAT BRAIN SYNAPTOSOMES. M.-T.T. Nguyen*, H.T. Smith*, V. Fried*, C. West*, and E.M. Meyer (SPON: W. Millard). Dept. of Pharmacology and Dept. of Anatomy and Cell Biology, Univ. of Florida, Gainesville; and Dept. of Biochemistry, St. Jude Children's Hospital, Memphis, TN.

Since it was previously shown that polyclonal antibodies against ubiquitin bind to rat cerebral cortical synaptosomes with an affinity similar to that with which they block high affinity choline transporters in that preparation, we investigated whether monoclonal antibodies against this peptide similarly affect transport activity. Two mouse hybridoma antibody preparations, termed 4-2D8 BA9 (an IgG1) and 1-2H11 AH5 (an IgM) were found to be specific for ubiquitin. The former antibody preparation inhibited acetylcholine synthesis in rat cerebral cortical synaptosomes by up to 85 + 10% (+ S.E.M.) and total choline uptake (1 uM choline) by up to 68 + 8%. The IgM, in contrast, inhibited these cholinergic markers by only 58 + 7% and 38 + 4%, respectively. Another monoclonal antibody specific for Band 3 anion transporters (an IgG 1 also) with no cro-s-reactivity for ubiquitin was also found to inhibit these transport processes, but by 40 + 6% and 31 + 6%, respectively. None of these antibodies significantly affected low affinity choline uptake. Since culture supernatants were used for these studies, it is possible that some of the observed inhibition was due to other factors in the medium. Alternatively, 4-2D8 BA9 is more efficacious a transport-inhibitor than the other 2 antibodies due to its recognition of a specific epitope of ubiquitin exposed along the extracellular surface of the plasma membrane. Western blot analyses of synaptosome plasma membranes with these 3 antibodies revealed only 1 significant band in the one experiment performed to date. This was at an apparent MW of 25,000-30,000, and it was observed only with 1-2H11 AH5. This band was observed consistently in similar studies using the polyclonal antibody against ubiquitin, as reported earlier.

The present data continue to support the hypothesis that ubiquitinylation of a few extracellular plasma membrane proteins, such as lymphocyte homing receptors and neuron-specific transporters may be involved in cellular recognition processes. The precise function of this ubiquitinylation of the neuronal choline transporter remains unclear, however.

187.4 PARTIAL PURIFICATION OF DIHYDROTETRABENAZINE BINDING ACTIVITY FROM BOVINE *CORPUS STRIATUM*. Joseph A. Near and Michael S. Vincent. Medical Sciences Program and Department of Pharmacology, Indiana University School of Medicine, Bloomington, Indiana 47405.

Accumulation of catecholamines by synaptic vesicles is accomplished by a reserpine sensitive transport system energized by an ATPase-generated proton electrochemical gradient. Two classes of inhibitors block catecholamine uptake and effect depletion through interaction with the vesicle tranporter complex. The first class includes reserpine and other competitive inhibitors of transport, while the second class comprises the benzoquinolizines tetrabenazine and dihydrotetrabenazine that are not competitive with substrate. Recent evidence suggests that the transporter in both peripheral and central catecholamine storage granules contains distinct binding sites for each class localized on separate subunits. Solubilization of a subunit from the transport complex of bovine striatum retaining dihydrotetrabenazine binding activity was sought in an attempt to characterize binding and purify the subunit.

Solubilization was accomplished following the general methods previously described for adrenal chromaffin granules (D. Scherman and J.-P. Henry, *Biochem.* 22:2805, 1983). Cholate (10%) solubilized 50 to 60% of the tritiated dihydrotetrabenazine binding activity from crude bovine striatal synaptosomes. Nonlinear least squares curve fitting analysis indicated a single class of binding sites (Kd = 10nm) and inhibition studies showed sensitivities similar to those in purified synaptic vesicles (tetrabenazine > reserpine > serotonin > dopamine > norepinephrine). The solubilized binding activity exhibited a half life at 4 degrees in excess of five days. Further purification was accomplished by adsorption to fluphenazine-linked sepharose (H. Charbonneau and J. Cormier, *Biochem. Biophys. Res. Commun.* 90:1039, 1979) and elution with 10% cholate. This resulted in a 50-75 fold enrichment over starting material with an overall yield of approximately 25% of the original particulate binding activity. Assuming a 1:1 stoichiometry between dihydrotetrabenazine binding sites and 70 kilodalton subunit a further 100-fold purification will be required to achieve homogeneity. These results indicate that the tetrabenazine binding subunit can be purified in an active form which may be useful in reconstitution studies and antibody elicitation.

187.5 NEUROPEPTIDE Y STIMULATES CHOLINERGIC RECEPTOR MEDIATED SECRETION FROM THE PERFUSED BOVINE ADRENAL GLAND. T.D. Hexum, C. Cherdchu* and L.R. Russett*. Dept. of Pharmacol., Univ. Neb. Med. Ctr. Omaha, NE 68105.

Neuropeptide Y (NPY) has recently been shown to be co-stored with norepinephrine and to participate in various autonomic functions. This peptide is present in the bovine adrenal medulla and released in response to nicotinic receptor stimulation along with catecholamines and pro-enkephalin-derived peptides (Hexum et al., 1986 Soc. Neurosci. Abs., 12, 997). Since bovine adrenomedullary membranes contain binding sites for N-[Propionyl-^{3}H]-NPY (Higuchi, et al., 1987, Fed. Proc., 46, 1448) and NPY is present in the splanchnic nerve (Hexum et a., 1986, Soc. Neurosci. Abs., 12, 997) we proposed that NPY might have a role in the secretion of catecholamines and the pro-enkephalin-derived peptides. We studied its effects using the retrogradely perfused bovine adrenal gland in the presence of various nicotinic receptor agonists. NPY alone had no effect on the secretion of either catecholamines or pro-enkephalin-derived peptides. However, the infusion of 1 x 10^{-8} M NPY in the presence of 5 x 10^{-5} M 1,1-dimethyl-4-phenylpiperazinium (DMPP) resulted in an increase of 50% or more ($p < 0.05$) in the release of norepinephrine, epinephrine and enkephalin-like peptides compared to the release in the presence of DMPP alone. The effect was dose dependent up to 1 x 10^{-7} M NPY. NPY (1 x 10^{-8} M) had a similar effect when either 5 x 10^{-5} M acetylcholine or 5 x 10^{-5} M nicotine were present in the infusing medium.

It has been reported that NPY inhibits the nicotine induced release of norepinephrine and epinephrine from cultured bovine chromaffin cells (Higuchi, et al., 1987, Fed. Proc., 46, 1448). The results described above prompted us to confirm this data using cultured bovine chromaffin cells. We observed that after the introduction of 1 x 10^{-8} M NPY into the culture medium along with 5 x 10^{-5} M DMPP, chromaffin cells responded with a decreased release of norepinephrine, epinephrine and pro-enkephalin-derived peptides ($p < 0.05$) when compared to the release with DMPP alone. This is the first reported instance where the adrenal medulla responds to the administration of regulator substances such as peptides in a manner distinct from that seen with isolated chromaffin cells.

These results strongly implicate a role for NPY in the regulation of adrenomedullary secretion in the bovine adrenal gland and suggest that the immediate environment of the chromaffin cells is important in this effect. (Supported by the American Heart Assoc., Inc., with funds contributed from the Nebraska Affiliate).

187.6 EFFECT OF 3-ACETYLPYRIDINE ON SEROTONIN UPTAKE AND RELEASE FROM RAT CEREBELLAR SLICES. C. Beas-Zárate*, A. Morales-Villagrán*, G. Tapia-Arizmendi* and A. Feria-Velasco. Facultad de Ciencias, Universidad de Guadalajara and Unidad de Investigación Biomédica de Occidente, I.M.S.S. Guadalajara, Jalisco. MEXICO.

Several studies have shown that cerebellum receives indoleaminergic nerve fibers[1,2], mostly influencing the Purkinje cell discharges[3]. Furthermore, recent data from our laboratories[4,5] have demonstrated endogenous release of serotonin (5-HT) and Na^+-dependent uptake and Ca^{++}-dependent release of exogenous 5-HT from tissue slices, homogenates and synaptosomal fraction of rat cerebellar molecular layer. Although several studies oriented to know the neurotransmitter produced by climbing fibers have been done, ruling out some of the classical transmitter substances (GABA, glutamate, acetylcholine), at present, the neurotransmitter released from climbing fibers remains unknown. The aim of this work was to measure the 5-HT uptake and release from rat cerebellar slices, 18 days after intraperitoneal injection of 3-acetylpyridine (3-AP)(65 mg/Kg) to adult rats. A histological study of medulla oblongata in these animals showed complete destruction of neurons in the inferior olivary nuclei.

A significant reduction of 5-HT uptake (60%) and its V_{max} (60%) was seen in the cerebellar preparations obtained from rats injected with 3-AP. Also, the Ca^{++}-dependent release of 5-HT from those preparations was found to be similar to basal values, in spite of a depolarizing stimulus with high-K^+ in the medium (53 mM).

Results suggest that the 5-HT could play a role as neurotransmitter produced by some climbing fibers, aside from some evidences reported in the literature documenting the role of aspartate as neurotransmitter in other group of climbing fibers[6].

187.7 THE EFFECTS OF pH ON RESERPINE BINDING TO CHROMAFFIN GRANULE MEMBRANES. J.D. Deupree and W.F. Herblin. Dept. of Pharmacology, University of Nebraska Medical Center, Omaha, NE 68105 and Medical Products Dept., E.I. duPont de Nemours and Company, Wilmington, DE 19898.

The carrier molecule used to transport catecholamines into synaptic vesicles and chromaffin granules can be studied using [^{3}H]reserpine, but this binding is strongly affected by pH. The binding of increasing concentrations of reserpine to chromaffin granule ghosts was measured in PIPES buffer at pH 6.61, 7.04, and 7.35 and in HEPES buffer at pH 6.8, 7.32, and 7.86. The binding data were analyzed using the MLAB mathematical modeling program. Binding of [^{3}H]reserpine increased with pH, indicating that the unionized form of the ligand was binding to the membranes with the highest affinity. When Kd and Bmax values were calculated based on the concentration of unbound, unionized reserpine, much of the variability was eliminated. There was still a non-random trend toward the over-estimation of binding at low pH which could not be eliminated by either varying the pKa of reserpine or assuming that the ionized form of reserpine could also bind to the site. Extending the model to include an ionizable group on the reserpine binding site eliminated the non-random residuals. The fit to this model suggests that the unionized form of reserpine binds to the unionized site with a Kd of 2.89 $\pm$ 0.1 nM, and the binding site can ionize with a pKa around 6.6. The results are consistent with the concept that catecholamines are transported into the granules in the neutral form. The results suggest that the catecholamine binding site may be deprotonated when exposed to the outside of the granules in the more alkaline environment and protonated when exposed to the more acidic interior of the granules. This would favor the binding of catecholamines on the outside of the granules and the release of catecholamines from the carrier on the inside of the granules. These results should be of interest to other scientists working with ligands which can ionize around the pH of the normal assay such as morphine or naloxone. (Funded by NINCDS #NS15187)

187.8 AN IN VIVO STUDY OF DOPAMINE RELEASE IN STRIATUM: THE EFFECT OF AMINO ACIDS. M.J. During*, I.N. Acworth*, R.J. Wurtman. Department of Brain and Cognitive Sciences, M.I.T., Cambridge, MA 02139.

Intracerebral dialysis was used to monitor extracellular levels of dopamine and its major metabolites, dihydroxyphenylacetic acid (DOPAC) and homovanillic acid (HVA) in the striatum of chloralose/urethane anaesthetized rats. Levels of these compounds were determined after intraperitoneal (i.p.) administration of the amino acids tyrosine, phenylalanine, valine and alanine. Tyrosine was given i.p. at doses of 50 and 100mg/kg, all other amino acids were at 200mg/kg.

Probes were also placed in the nucleus accumbens and dopamine release was followed after a dose of tyrosine (200mg/kg). Control rats received normal physiological saline. Rats were maintained at a temperature of 37°C and kept at a light level of stable anaesthesia by administering additional doses of chloralose/urethane as required. After an initial period of injury release (60-90 mins post probe implantation), stable concentrations of dopamine were obtained. Treatments were administered after a minimum of three stable 15 min collections. Dialysates were collected in 0.5M perchloric acid (flow rate 1.5ul/min) and were directly injected on to a reverse-phase, isocratic HPLC system with an ESA Coulochem 5100 detector. The basal dopamine concentrations in dialysates were similar in all groups, the mean concentration being 4.62±0.3nM, as the in vitro probe callibration gave recovery of 16±1%, the basal dialysates therefore reflected an extracellular dopamine level of 29±3nM. Dopamine release following treatment was determined for every animal by recording the percentage change from its stable baseline. Rats receiving normal saline showed no change in dopamine release during the 120 min following its administration. In contrast tyrosine at both 50 and 100mg/kg, transiently increased dopamine release by 28.2±3.8% and 28.5±3.5%, peaking after 90 minutes and 75 minutes (for the 50 and 100mg/kg doses respectively.) In the nucleus accumbens tyrosine (200mg/kg) increased dopamine release by 220±28%. A dose of phenylalanine (200mg/kg) that, in rats, elevates plasma tyrosine also increased striatal dopamine release by 59±11% peaking at 75 mins. Valine or alanine failed to affect striatal dopamine release. None of the treatments affected DOPAC or HVA levels, in all of the treatment groups. These data affirm that tyrosine administration can enhance brain dopamine release, and indicate that, under normal conditions, this effect is soon terminated, probably by trans-or presynaptic feedback mechanisms.

These studies were supported from a grant from the Brain Sciences and Metabolism Charitable Trust.

187.9 UPTAKE OF GLUTAMIC ACID INTO SYNAPTOSOMES AND BULK-PREPARED ASTROCYTES. J.M. TUCHEK*, D.D. Johnson and R.I. Wilcox*, Dept. of Pharmacology, College of Medicine, Univ. of Saskatchewan, Saskatoon, Sask. S7N OWO.

Although it is well established that both nerve endings and astrocytic cells have uptake mechanisms for glutamic acid, the reported transport constants (K_T) for glutamate vary anywhere from approximately 2 μM to 30 μM and more (see Schousboe, A. (1981) Int. Rev. Neurobiol. 22, 1-45). In view of studies reporting that the concentration of glutamic acid in brain extracellular fluid and cerebrospinal fluid is less than 10 μM (Hamberger et. al. (1983) in "Glutamine, Glutamate and GABA in the Central Nervous System" pg. 473-492, Alan R. Liss, Inc.), transport constants for glutamate above 10 μM would seem to have little physiological relevance. Furthermore glutamate receptor binding studies tend to suggest that the K_D of the glutamate post-synaptic receptor is approximately 1 μM or less. Thus, if reuptake is the main mechanism responsible for terminating the response in glutaminergic synapses then the K_T for glutamate would be expected to be a correspondingly low micromolar concentration.

We have examined the transport of glutamic acid into synaptosomes freshly isolated from rat and avian cerebella and into bulk-prepared astrocytes from rat brain. The uptake of [^{3}H] Glu (47,7 Ci/mmol, NEN) into synaptosomes (50-150 μg Lowry protein) or astrocytes (approx. 60 μg Lowry protein) was studied at 30°C in an incubation mixture that also contained 136 mM NaCl, 5 mM KCL, 1.3 mM $CaCl_2$, 1.3 mM $MgCl_2$ 10 mM glucose and 10 mM Tris/HCl pH 7.4 buffer in a total volume of 500 μl. One minute after the addition of protein, a 400 μl aliquot was taken and filtered on Whatman GF/C filters and washed 2x with 5.0 ml 0.9% NaCl, 5 mM Tris/HCl buffer pH 7.4. The radioactivity on the filter paper was analyzed using standard liquid scintillation counting methods. Eadie-Hofstee analysis of the data indicated that both avian and rat cerebellar synaptosomal transport systems had two affinities for glutamate. The average K_m for the high affinity site was approximately 2.5 μM and 7 μM for the low affinity site in both species of animals. The glutamate transport mechanism in the bulk-prepared astrocytes also displayed two affinity sites for glutamate with K_{Ts} of 4.5 and 11 μM. Synaptosomes prepared from avian cerebral hemispheres, a tissue containing relatively low amounts of glutaminergic nerve endings in comparison to the cerebellum, contained a single affinity transport system for glutamate (K_T= 7-8 μM). The results indicate that glutaminergic nerve endings have a two-affinity transport system for glutamate with K_{Ts} at physiologically relevant glutamate concentrations. Synaptosomes from avian cerebral hemispheres also transport glutamate but with a single, low affinity K_T (7-8 μM). Supported by the MRC.

187.10 THE VESAMICOL (AH5183) RECEPTOR IN VP_1 CHOLINERGIC SYNAPTIC VESICLES: PARTIAL PURIFICATION. Ben A. Bahr and Stanley M. Parsons. Department of Chemistry, University of California, Santa Barbara, California 93106.

The compound 1-trans-2-(4-phenylpiperidino)-cyclohexanol (1-vesamicol; 1-AH5183) inhibits the uptake and storage of [^{3}H]acetylcholine (ACh) by purified Torpedo VP_1 synaptic vesicles (SV). 1-[^{3}H]Vesamicol binds enantioselectively to a saturable receptor present on VP_1 vesicles which bind 300-400 pmoles of the ligand per mg vesicle protein, or 6-8 ligand sites/SV. Cholic acid (5%, w/v) successfully solubilizes nearly all of the vesamicol receptor (VM-R) present in a 0.8 mg/ml SV suspension. Dilution of the cholic acid (0.5-1.0%, w/v) and the addition of phosphatidylcholine (1 mg/ml) and glycerol (25%, w/v) were necessary to stabilize the solubilized VM-R. IC_{50} values for vesamicol analogs ranging over three orders of magnitude in potencies, measuring either inhibition of [^{3}H]ACh uptake in SVs or inhibition of 1-[^{3}H]vesamicol binding to solubilized VM-R, are nearly unaltered by the solubilization procedure. Therefore, the membrane-bound and detergent-solubilized forms of the VM-R are pharmacologically indistinguishable.

After silica-based DEAE ion-exchange chromatography, the binding specific activity of solubilized VM-R increased 6-10 fold. Chromatography of this material on an agarose-wheat germ lectin column achieved an additional 3-fold increase in binding specific activity, to 5500-6500 pmol/mg protein. This partially purified receptor chromatographed on an HPLC gel permeation column with an apparent particle molecular mass (including bound detergent and phospholipid) of approximately 300,000 daltons, in a final yield of about 30%. The protein subunit structure is currently being studied and will be discussed.

(VESAMICOL)

187.11 TAURINE RELEASE FROM ASTROGLIAL CELLS IS NOT DEPENDENT ON INTRACELLULAR Ca^{++}. D.L. Martin[1], J.A. Connor[2], and W. Shain[1], [1]Laboratory of Neurotox. & Nerv. Sys. Disorders, Wadsworth Center for Labs and Research, Albany, NY 12201 and [2]AT&T Bell Laboratories, Murray Hill, NJ 07974.

Beta-adrenergic receptor-stimulated taurine release from astroglia is not inhibited when Cd^{++}, Co^{++} or Mn^{++} are substituted for Ca^{++} or by the Ca^{++} channel blockers nifedipine, diltiazem, or verapamil (Martin et al., Neurosci. Abst. 12:107, 1986). The role of intracellular Ca^{++} on release was evaluated using parallel experiments designed to measure taurine release and intracellular Ca^{++} content. Taurine release was measured by loading cells with tracer quantities of ^{3}H-taurine and monitoring release of radiolabelled taurine. $[Ca^{++}]_i$ was determined by loading cells with the Ca^{++}-sensitive dye fura-2 and measuring the fluorescence ratio (340/380 nm) by digital imaging. Analyses of taurine release and intracellular Ca^{++} were made using three different experimental media to manipulate intracellular Ca^{++} -- control (1.2 mM Ca^{++}), low Ca^{++} (0 Ca^{++}, 10 uM EGTA), high Ca^{++} (100 uM Ca^{++}, 100 uM ionomycin). Cells were stimulated with 100 nM isoproterenol (IPR) under control conditions in all experiments. IPR stimulation in control medium resulted in no apparent increase in $[Ca^{++}]_i$. When the medium was changed to produce low $[Ca^{++}]_i$, $[Ca^{++}]_i$ decreased from highly variable levels to 30-60 nM within 3 min. This lower $[Ca^{++}]_i$ was maintained for as long as cells were observed (20 min). No change in $[Ca^{++}]_i$ was observed in response to IPR. When cells were returned to control medium, there was a transient increase in $[Ca^{++}]_i$. This was variable with peak $[Ca^{++}]_i$ = 300-350 nM, and returned to control levels within 3-4 min. In parallel taurine release experiments, IPR responses were obtained in control conditions and after 30 min in low Ca^{++}. Taurine release was the same under both conditions. In addition there was no taurine release when the low Ca^{++} medium was replaced with control medium. This latter observation suggests that elevation of $[Ca^{++}]_i$ alone will not stimulate release. When ionomycin was added to produce high $[Ca^{++}]_i$, the fura-2 signal rapidly became saturated indicating that $[Ca^{++}]_i$ was > 1 uM. In taurine release experiments ionomycin did not stimulate release. Thus, even very high $[Ca^{++}]_i$ did not stimulate release. These results indicate that beta-adrenergic receptor-stimulated taurine release from astroglial cells can take place without measurable changes in $[Ca^{++}]_i$. In addition, they demonstrate that elevation of $[Ca^{++}]_i$ does not elicit release suggesting that Ca^{++} does not function as a second messenger for, or regulator of taurine release. Clearly, taurine release from astroglia is distinctly different from neuronal vesicular release. Supported in part by NS21219, AA07155 and USAF OSR F49620-85-C-0009.

187.12 REGULATION OF NOREPINEPHRINE UPTAKE BY DIVALENT CATIONS AND ATP IN PC12 CELLS. J.E. Chaffee, Y.H. Ehrlich, and E.D. Hendley. Depts. of Physiology & Biophysics, Psychiatry and Biochemistry, Univ. of Vermont, Burlington, VT 05405.

The potential regulation of norepinephrine uptake by extracellular ATP and divalent cations was examined in PC12 cells, a model of noradrenergic neurons, derived from a rat adrenal medullary pheochromocytoma (Greene and Tischler, PNAS 73: 2424, 1976). The uptake of ^{3}H-(-)-norepinephrine (^{3}H-NE, 1 μCi/ml, 0.4 μM NE) in PC12 cells was determined at 37°C for 3 min in a HEPES-buffered Krebs-Ringer solution (KRH in which $[Ca^{2+}]$ and $[Mg^{2+}]$ were 1.2 mM). Following incubation, the cells were collected by vacuum filtration and the amount of ^{3}H-NE incorporated was determined by liquid scintillation counting. Specific, transport-mediated uptake, referred to as uptake 1, was defined by the addition of 1 μM nisoxetine. Omission of calcium and magnesium ions from the incubation medium reduced uptake 1 by approximately 75%. Replacement of either ion alone, in concentrations ranging from 0.1 mM to 1.2 mM, restored uptake to control levels in a concentration-dependent manner. Extracellular ATP (100 nM) was able to stimulate uptake 1 above control levels by approximately 60%, but only if calcium ions were present in the medium. Previous experiments, in which PC12 cells were incubated with extracellular γ-^{32}P-ATP followed by SDS-PAGE and autoradiography, demonstrated a NE-dependent phosphorylation of surface membrane proteins. These results describe for the first time that NE uptake in PC12 cells requires divalent cations, as has also been demonstrated for NE uptake in brain synaptosomal preparations. These results are consistent with our hypothesis that NE uptake is regulated by a membrane protein kinase that utilizes extracellular ATP, NE, and millimolar concentrations of divalent cations. (Supported by NSF: R11-8610679 and USAFORSR: 84-0331).

187.13 PHOSPORYLATION DEPENDENT AND INDEPENDENT TRANSMITTER RELEASE MECHANISMS IN PC-12 CELLS. H.J.G. Matthies*, H.C. Palfrey*, and R.J. Miller. (SPON: W. Woolverton). Dept. of Pharmacological and Physiological Sciences, U. of Chicago, Chicago,IL 60637

It is well established that an increase in intracellular [Ca^{2+}] can trigger release of neurotransmitters. However the intracellular locus of action of Ca^{2+}has not been identified. As secretion from permeabilized cells seems to be dependent on MgATP, it has been suggested that a Ca^{2+}dependent phosphorylation reaction plays a central role in this process. We have studied the role of different kinases in the release of catecholamines from PC-12 pheochromocytoma cells.

In wild type PC-12 cells (PC-12WT), secretion of catecholamines could be evoked by depolarization or by ionomycin, a Ca ionophore. Evoked release was enhanced by phorbol esters (PE) or by agents that increased cAMP such as 2-chloroadenosine (2CA). As demonstated previously PE was no longer effective in PC-12WT in which protein kinase C (PKC) had been eliminated by down-regulation. In a mutant PC-12 cell line that lack functional cAMP dependent protein kinase (PKA) (A126-1B2, supplied by Dr J.A. Wagner, Dana-Farber Cancer Institute), 2CA was no longer effective but PE still enhanced release. Following chronic PE treatment, release from A126-1B2 cells was no longer enhanced by either 2CA or PE. In A126-1B2 cells permeabilized by digitonin, PE but not cAMP enhanced release induced by Ca^{2+}. Following down-regulation of PKC neither cAMP nor PE enhanced release from permeabilized cells.

Calmodulin(CaM) has been proposed to be the Ca^{2+} receptor involved in transmitter release. In permeabilized, down-regulated A126-1B2 cells several inhibitors of CaM including calmidizolium, mastoparan, and 48/80 failed to block Ca^{2+} induced release even at concentrations snown by others to inhibit CaM dependent phosphorylation. Furthermore release could be produced by Ba^{2+} which does not activate CaM but not by Mn^{2+}which does. Neomycin which does inhibit phospholipase C amongst other actions was able to block secretion from down-regulated permeabilized A126-1B2 cells.

We conclude that Ca induced secretion of catecholamines from PC-12 cells does not depend on the activity of PKC, PKA, or a Ca/CaM dependent Kinase. The locus of action of Ca and MgATP in secretion does not appear to involve protein kinase-mediated events, but kinases may regulate the process.

187.14 MOLECULAR WEIGHT AND PURIFICATION OF THE Ca^{2+}/Mg^{2+} ATPASE OF CHOLINERGIC SYNAPTIC VESICLES. Susan K. Yamagata* and Stanley M. Parsons. (SPON: Steven K. Fisher). Dept. of Chemistry., Univ. Calif. Santa Barbara, Santa Barbara, CA 93106.

Synaptic vesicles from cholinergic nerve terminals are known to contain a membrane associated Ca^{2+}/Mn^{2+} dependent ATPase. This ATPase is thought to set up a proton gradient across the vesicle membrane from which the energy stored in the gradient can in turn be used to drive the uptake of acetylcholine into vesicles. Here, we describe the molecular weight determination and isolation of Ca^{2+}/Mg^{2+} ATPase from the electric organ of Torpedo californica.

The ATPase can be successfully solubilized in octaethylene-glycoldodecyl ether ($C_{12}E_8$) and stabilized with phosphatidylserine, glycerol, dithiothreitol and protease inhibitors. Furthermore, phosphatidylserine was found to activate the ATPase. To determine it's molecular weight the solubilized enzyme was subjected to size exclusion chromatography and sedimentation velocity centrifugation on glycerol gradients made up in H_2O and D_2O. This gave a Stoke's radius of 78 $\pm$ 1 Å for the detergent solubilized complex and a sedimentation velocity coefficient of 6.8 $\pm$ 0.2 $S_{20,w}$. This data was used to deduce a partial specific volume of 0.81 + 0.01 cm^3/g, f/f_0 = 1.75 $\pm$ 0.02 and a protein molecular weight of 222,000 $\pm$ 10,000 (n=3).

Purification of the detergent solubilized and stabilized Ca^{2+}/Mg^{2+} ATPase was achieved using band sedimentation velocity centrifugation on glycerol density gradients followed by sequential chromatography on hydroxylapatite, wheat germ lectin affinity and gel filtration columns. The final yield was approximately 6% of the total starting activity. When examined by sodium dodecyl sulfate-polyacrylamide gel electrophoresis a triplet set of polypeptides was observed which varied in their relative intensities from preparation to preparation. The molecular weights of these polypeptides were 93,000, 91,000 and 85,000 M_r. Also observed was a diffuse polypeptide centered about 61,000 M_r. These subunit molecular weights together with the total molecular weight of the enzyme suggest that this ATPase may be of the phosphoryl-enzyme intermediate class of ATPases.

187.15 ULTRASTRUCTURE OF EXOCYTOSIS IN RAT ADRENAL MEDULLA. S.W. Carmichael, J.C. Brooks, R.K. Malhotra, T.D. Wakade, and A.R. Wakade, Dept. of Anatomy, Mayo Clinic, Rochester, MN 55905, Dept. Basic Sci., Marquette Univ., Milwaukee, WI 53233, and Dept. Pharmacol., SUNY Downstate Med. Ctr., Brooklyn, NY 11210.

Using a method employing tannic acid, we previously demonstrated exocytosis in cultured adrenal chromaffin cells (Am.J.Anat. 178:85-89, 1987). The current study utilized a modification of this technique in an attempt to demonstrate exocytosis in an intact adrenal medulla. The adrenal glands of rats were retrogradely perfused as described previously (J.Physiol. 313:463-480, 1981). During the perfusion, the organs were either unstimulated (control), electrically stimulated (10 Hz) in the presence or absence of calcium ions), stimulated with excess potassium ions, stimulated with vasoactive intestinal polypeptide, or the tonicity of the perfusion medium was varied in a manner that has been shown to cause explosive secretion of catecholamines from the adrenal medulla (J. Neurosci. 6:2625-2634, 1986). These treatments were followed by perfusion with a solution containing tannic acid followed in turn by a buffered solution of glutaraldehyde. Blocks of medulla were excised and prepared for electron microscopy by routine methods. Figures interpreted to represent exocytosis were observed. The figures were essentially identical to those seen in cultured cells. Exocytotic figures were only rarely seen in unstimulated specimens and were not observed in specimens perfused with calcium-free solution. In the other specimens, exocytotic figures were frequently observed along the plasma membrane in a subendothelial position. In addition, figures were frequently observed in positions that appeared to be on the lateral aspect of the cell. Evidence was obtained to suggest that adrenal chromaffin cells may not only secrete their vesicular contents directly into the subendothelial space, but also from the sides of the cell where the secretory products then proceed toward a vessel, either along a narrow intercellular cleft or through an intercellular cannaliculus. Furthermore, our evidence suggests that the secretory products of chromaffin cells may be carried across endothelial cells to enter vessels. This was most strongly suggested in specimens stimulated with potassium. Figures were also obtained that suggested membrane retrieval occurs over all aspects of the plasma membrane.

187.16 DIFFERENTIAL SENSITIVITY TO ETHANOL OF CALCIUM-DEPENDENT DOPAMINE RELEASE FROM PC12. S.B. Oldham*, T. Ritchie and E.P. Noble*. Alcohol Research Center, Neuropsychiatric Institute, UCLA, Los Angeles, CA 90024.

PC12 cells were prelabeled with (^3H) dopamine and the effects of K^+ and bradykinin were studied on dopamine release. Increasing concentrations of K^+ (4.8 mM to 70 mM) and bradykinin (10^{-8}M to 10^{-5}M) dose-dependently enhanced dopamine release. The K^+- and bradykinin-induced releases were dependent on the presence of extracellular Ca^{2+} and were significantly inhibited by 1 mM Co^{2+} or Ni^{2+}. BAYK 8644 (10^{-7}M), a stimulator of the voltage-dependent Ca^{2+} channel, and Verapamil (10^{-5}M), an inhibitor of this channel, respectively enhanced or decreased K^+-induced dopamine release, whereas these substances were without effects on bradykinin-stimulated dopamine release. Exposure of PC12 cells for 6 days to 200 mM ethanol resulted in a significant increase in dopamine release when stimulated with K^+ concentrations greater than 50 mM (mean increase of 128 $\pm$ 9% of untreated cells, $p < 0.0005$); however, the EC50 for K^+ remained unchanged (38 $\pm$ 1 mM). When bradykinin-induced dopamine release was measured in cells exposed to ethanol, neither the maximal secretory response nor the EC50 for this secretagogue was altered. This study shows that the effect of bradykinin on dopamine release is not exerted through voltage-dependent Ca^{2+} channels. Moreover while the present data support previous studies showing enhanced voltage-dependent Ca^{2+} channel activity as a consequence of chronic alcohol treatment (Messing, R.O. et al. PNAS 83:6213, 1986), such treatment does not affect other Ca^{2+} channels in PC12 cells involved in exocytotic release. This selective effect on Ca^{2+} channels by ethanol may explain in part the changes in the CNS during ethanol dependence. (This study was supported by The Seaver Institute.)

187.17 CHOLINE UPTAKE AND INCORPORATION INTO PHOSPHOLIPIDS BY NEUROBLASTOMA CELLS: EFFECT OF HEMICHOLINIUM-3 (HC-3) AND 4-METHYLPIPERIDINE DERIVATIVES OF HC-3. K.Y. Sheff, M.A. Yorek, J.P. Long*, and J.G. Cannon*. Depts. of Internal Medicine and Pharmacology, College of Medicine and College of Pharmacy, University of Iowa, Iowa City, IA 52242.

N41A3 Neuroblastoma cells rapidly take up [methyl-^{3}H] choline and incorporate it into phosphatidylcholine. Choline uptake by neuroblastoma cells occurs by high- and low-affinity uptake systems. K'm and V'max for high- and low-affinity uptake are 6.08 and 679.81 uM and 64.11 and 781.57 pmol/min/mg protein, respectively. The high affinity choline uptake system is sodium dependent.

After a 6 h period about 30% of the choline taken up is incorporated into phospholipid. Greater than 90% of the incorporation is into phosphatidylcholine and a small fraction into lysophosphatidylcholine and sphinogomyelin. Hemicholinium-3 (HC-3) and its 4-methylpiperidine derivatives, A-4 and A-5, all decrease high-affinity choline uptake and choline incorporation into phospholipid. The degree of inhibition of choline uptake and incorporation into phospholipid differs among the 3 compounds examined. When added to the incubations, the tertiary amine A-4 was more effective than A-5, quaternary amine derivative, which was more effective than HC-3 in decreasing choline uptake and its incorporation into phospholipid. There was no significant difference in the potencies of the d, l or meso isomeric forms of A-4 or A-5 on choline uptake from their respective racemic mixture. The extent of inhibition of choline metabolism by these compounds was also concentration-dependent. A-4, at a concentration of 50 uM and after a 6 h incubation, decreased 5 uM choline uptake by 42% and incorporation of choline into phospholipid by 25%. Following a 6 h incubation, A-5 and HC-3 at 50 uM decreased choline uptake by 24% and 14%, respectively, and choline incorporation into phospholipid by 16% and 4% respectively, from 5 uM choline. The ID_{50} for choline uptake by A-4, A-5 and HC-3 was determined to be 28.3, 46.8 and 118.0 uM, respectively. Incubation of neuroblastoma cells with 50 uM A-4, A-5 or HC-3 for a minimum of 24 h causes a decrease in intracellular choline levels. Control cells contain 10.73 nmol/mg protein of choline. Culturing cells in the presence of 50 uM A-4, A-5 or HC-3 for a minimum of 24 h decreases intracellular choline levels by 60, 34 or 26%, respectively. These studies show that two HC-3 derivatives, A-4 and A-5, are more active than HC-3 in decreasing choline metabolism and intracellular choline levels in a cultured neural cell line.

187PO CALCIUM CHANNEL ANTAGONISTS INHIBIT DOPAMINE RELEASE IN VIVO MEASURED BY TRANS-STRIATAL DIALYSIS METHOD. E. Carboni*, M. Morelli and G. Di Chiara. Inst.of Exp. Pharmacology and Toxicology, University of Cagliari, Viale A.Diaz, 182, 09100 Cagliari, Italy.

Calcium ions are essential for the release of neurotransmitter. The study of calcium uptake in CNS has been related to the role that this ion can play in release processes. Although the action of calcium channel antagonists on neurons and CNS preparations has been widely investigated, only recently, it has been provided evidence showing that calcium channel antagonists inhibit voltage dependent calcium uptake in synaptosomes and in neurones. However the effect of dihydropyridines on synaptosomes is debated; it might imply that this preparation may not be suitable for this purpose. We have studied the effect of Ca-antagonists on the release of dopamine in two different models either in vivo or in vitro. We have measured the action of the dihydropyridine (+)PN-200-110 on the release of dopamine estimated by the trans-striatal dialysis method. The drug was applied directly to the striatum by including it in the Ringer used for dialysis. (+)PN-200-110 rapidly reduced in a dose related manner the release of dopamine by about 10, 30 and 50% from basal values when added at concentrations of 0.1, 1 and 10 uM which correspond to about 15 fold lower concentrations in the extracellular space. Dopamine returned to basal level when the drug was withdrawn from the Ringer. The effect of various calcium channel antagonists was studied also in striatal synaptoneurosomes depolarized by increasing conc. of KCl (from 15 to 60 mM). Dopamine was separed by rapid filtration through Whatman GF/C filters and measured in the filtrate by reverse phase-HPLC. DA-release was depolarization and calcium dependent. In this preparation dihydropyridines failed to inhibit dopamine release at concentrations up to 10 uM. Our results indicate that in agreement with previous results (Carboni, E., Wojcik, W. J. and Costa, E., Neuropharmacol., 24: 1123, 1985) dihydropyridines may play a role in the control of calcium uptake and neurotransmitter release although in preparations "in vitro" this effect for still unknown reasons is difficult to evidentiate.

CORTEX: MOTOR CORTEX II

188.1 A PATHWAY MEDIATING SOMAESTHETIC PROJECTIONS TO THE MOTOR CORTEX IN THE CAT. Y. Padel and L. Relova*. Equipe "Mécanismes Sensori-Moteurs", Lab. Neurosciences Fonctionnelles, CNRS, 31, chemin J. Aiguier, Marseille, France.

It has been known since 1939 that the pyramidal cells of the motor cortex can be made to discharge at extremely high frequency with sensory stimulation of the body (Adrian, E.D. & Moruzzi, G., J. Physiol. (Lond.) 97:153, 1939). In view of their short latencies these somaesthetic responses seemed unlikely to take paucisynaptic pathways, such as the trancerebellar pathway via the ventrolateral nucleus of the thalamus to area 4, or the system comprising the dorsal columns, the medial lemniscus and the ventrolateral nucleus of the thalamus, with the sensory cortex acting as a relay. It was therefore assumed that there existed a "direct" projection to the motor cortex from some thalamic region receiving short-latency spinal afferents (Albe-Fessard, D. & Rougeul, A., Electroencephal. Clin. Neurophysiol., 10:131, 1958). Many attempts have been made to identify this sensory pathway to area 4, but the results obtained so far have been highly controversial. Various nuclei have been suggested as candidate thalamic relay sites, and the very existence of a direct thalamocortical link arising in a thalamic region receiving spinal afferents has been questioned up till recently (Greenam, T.J. & Strick, P.L., Brain Res., 362:384, 1986).

In a preliminary series of experiments on cats, it was therefore attempted to establish whether it was possible to record short-latency somaesthetic responses from neurones belonging to area 4. It was confirmed that these cells had axons projecting into the spinal cord by checking that they responded antidromically to stimulation of the contralateral dorsolateral cord where the corticospinal bundle was situated. In these experiments, motor cortical area 4 was completely cut off from all its "classical" afferents: the corticocortical connections were abolished by lesion of the transcallosum pathway and an incision was performed between the sensory cortex and the motor cortex. The transcerebellar circuits towards area 4 were eliminated by transsecting the ascending brachium conjunctivum, and the dorsal spinal somaesthetic pathways, i.e. the dorsal columns and spinocervicothalamic bundles, were transsected within the cervical cord.

In these preparations, neurones in cortical area 4 at the origin of the corticospinal pathway responded consistently to peripheral activation. Electric shocks applied to the limbs were found to elicit spike bursts with very short latencies as well as complex excitation/inhibition sequences.

The pathway along which these sensory messages are conveyed to the motor cortex was found to be located in the ventral and ventrolateral spinal cord. The thalamic region acting as a relay was delimited using a combination of spinal lesion, intracortical microstimulation, and field potential mapping techniques.

188.2 FUNCTIONAL ROLE OF THE SENSORY CORTEX IN LEARNING OF FOOD TAKING MOVEMENT IN CATS. T. Sakamoto*, K. Arissian*, H. Asanuma (SPON: L.L. Porter). The Rockefeller University, New York, N.Y., 10021.

It has been shown repeatedly that removal of the sensory cortex produced little, if any, motor deficits. We have recently demonstrated that association input from the sensory cortex (area 2) produced long lasting exitability changes (LTP) in motor cortical neurons (Brain Research, 1987) suggesting that the association input is related to motor learning. To examine whether this input actually participates in the learning process, we trained cats with or without the sensory cortex intact.

A total of 3 cats was used. After unilateral ablation of the sensory cortex (areas 2, 2 pri and 5) by suction, cats were trained to pick up a small piece of food (cat food) from a beaker rotating at a given speed. The beaker was placed at some distance (2 inches) from the cage, so that the cat had to bring the food back to the cage across a space. Therefore, cats had to learn a special motor skill which consisted of spatially and temporally organized flexion and supination of the forepaw to pick up a piece of food. The learning process (pick up movement) was examined by counting the success rate at a fixed rotating speed (0.4 rev/sec). Both forelimbs, ipsilateral (normal) and contralateral (operated) to the lesioned cortex were trained equally and the performance of the normal limb was used as a control.

In all cats (n=3), the learning process for the operated limb was slower than that for the normal limb. The normal limb reached a stable state of performance (80% success rate) within 2 to 4 weeks, whereas the operated limb necessitated 3 to 8 weeks. There was a statistically significant difference in success rate between the two limbs during the initial 2 weeks ($P < 0.05$). In each cat, the success rate for the operated limb was lower than that of the normal limb. However, there was no significant difference in performance between the two limbs after completion the training.

To evaluate the effects of sensory cortex ablation on the learned motor skill, the sensory cortex for the normal limb was removed after completion of the training (n=2). Following recovery from the operation, the success rate returned to the preoperative level within three days for one cat and a week for the other. This recovery period was significantly shorter than the initial learning period for the operated limbs (3 weeks and 5 weeks). The results strongly suggested that the sensory cortex played a role in learning a specific motor pattern but that the sensory cortex was not essential in maintaining a learned motor skill.

(Supported by the NIH Grant NS 10705).

188.3 THE EFFECTS OF SOMATOSENSORY CORTICAL LESIONS ON THE PARAMETERS OF MASTICATORY MOVEMENTS OF THE RABBIT. S.Enomoto*, G.Schwartz, and J.P.Lund. Département de stomatologie et Centre de recherche en sciences neurologiques, Univ. de Montréal, Canada.

It has been known for many years that ablation of the sensorimotor cortex disrupts the ability to take in, manipulate and prepare food for swallowing. Furthermore, the results of studies using electrical stimulation and microelectrodes suggest that cortical neurons participate in the control of the parameters of the masticatory cycle. However, if food is manually placed between the molar teeth, animals seem to chew it in a rather normal way (Bremer, F., Arch. Int. Physiol., 21: 308, 1923). In the belief that cortical lesions should cause identifiable deficits in this type of movement, we have begun a longitudinal study in rabbits.

The animals were anesthetized with sodium pentobarbital (30 mg/kg, supplemented with ketamine hydrochloride) and chronic Emg electrodes were implanted into the major jaw muscles. A holder for a small light bulb was attached to the midline of the mandible and the rabbit was placed in a frame. Two plugs were attached to the skull so that the head could be replaced in the same position day after day. Movement of the light bulb was recorded in three directions with photodiode transducers: before recovery from the anesthetic the system was calibrated. Over the next few days the rabbits were fed rabbit chow, raisins and pieces of carrot of standard dimensions, while jaw movements and Emg activity were recorded on tape. The animals were then re-anesthetized and the masticatory area of the sensorimotor cortex was ablated. Feeding was repeated daily for up to two months. Data was replayed from tape and analysed with computer assistance.

The major effects of cortical lesions are as follows: 1) The number of cycles needed to transport the food to the molar teeth (preparatory cycles) and to grind it up (reduction cycles) increases; 2) The mean cycle time of preparatory cycles is increased, but there is little change in the length of the reduction cycles; 3) The vertical amplitude of both the reduction and preparatory cycles falls, and there are decreases in velocity in both the opening and closing directions; 5) The number of distinct phases per cycle increases; 6) These effects diminish with time with one exception - the velocity of the Slow Closing phase (in which the food is crushed between the teeth) never returns to normal values. The results support the hypothesis that the sensorimotor cortex participates in the generation of the pattern of the masticatory cycle. It may be particularly important in controlling the grinding force during the reduction cycles, since the fall in velocity during Slow Closure never recovers. Supported by the Canadian MRC.

188.4 MODULATION OF SOMATOSENSORY INPUT TO SENSORY CORTEX DURING ISOTONIC AND ISOMETRIC LIMB MOVEMENTS IN THE MONKEY. W. Jiang*, Y, Lamarre, M-T. Parent*, S. Marchand* and C. E. Chapman. Centre de recherche en sciences neurologiques, Université de Montréal, Montréal, Canada.

It has previously been shown that somatosensory transmission in the lemniscal system is diminished prior to and during voluntary movement. Both central and peripheral feedback probably contribute to this decrease, but their relative importance has not yet been determined. The purpose of this study was to evaluate the contribution of peripheral feedback to the modulation by modifying the feedback associated with the movement. The effects of systematically changing either the type of movement (isometric vs. isotonic) or the direction of movement (flexion vs. extension) were studied.

A monkey, macaca mulatta, was conditioned to perform rapid isotonic and isometric flexions and extensions of its elbow in response to the presentation of, respectively, a tone or a light cue. EMG recordings were taken from selected arm and shoulder muscles by means of chronically implanted electrodes. Recordings were made from the contralateral primary somatosensory cortical representation of the arm. Intracortical evoked potentials were elicited by a brief airpuff (20 ms) directed within the receptive field of the recording site. The airpuff was applied at different delays following the cue to move, concentrating on the initial part of the movement. Control (no movement) records were regulately alternated with the movement trials. The overall analysis (25 experiments) showed a significant decrease of the evoked potentials during both isotonic and isometric movements and during both flexion and extension. While the results of individual experiments showed some differences with the type and direction of the movement, no consistent differences were seen. For the isotonic condition, the response was decreased to 47 ±12% of the control during flexion and 38±12% during extension. For the isometric condition, the response showed a similar decrease, to 39 ±11% for flexion and 46 ±12% for extension. The absence of any difference in the decrease during these different types and directions of movement suggests central feedback plays a large role in this modulation. Supported by the Canadian MRC and the FRSQ.

188.5 SENSORY TO MOTOR TRANSFORMATION WITHIN AREA 5 OF THE POSTERIOR PARIETAL CORTEX IN THE MONKEY. J. Seal* and J. Requin. CNRS Lab. de Neurosciences Fonctionnelles, 13402 Marseille Cedex 9, France.

Using the technique of single unit recording in behaving monkeys, numerous authors have described changes in neuronal activity of the posterior parietal cortex which precede the onset of movement. However, the functional interpretation of these changes is not clear, some authors explaining them as being the result of sensory mechanisms and others as representing a form of motor command. In the present study, we have examined whether the early changes in area 5 can be explained in terms of sensory or motor mechanisms. A rhesus monkey was rewarded when it performed correctly in three experimental conditions: (1) execution of a forelimb movement on presentation of an auditory cue, (2) withholding the movement after presentation of the cue and (3) self-paced forelimb movement. Single neuron activity was recorded in condition 1 and only those neurons which modified their activity prior to movement were subsequently studied in the other two conditions. For each neuron studied, a series of trials were recorded in one condition before changing to another condition.

Of the 254 task-related neurons recorded in condition 1, 64 neurons presented changes in activity prior to movement. These neurons could be divided into three groups according to whether or not they responded in the other two conditions. The "sensory" type neurons responded whenever the cue was present (conditions 1 and 2), the "motor" type neurons whenever the movement was present (conditions 1 and 3) and the "sensori-motor" type neurons responded in all three conditions. Examination of the peri-event histograms showed that the neuronal response of the "sensori-motor" type neurons in condition 1 appeared to have two components, the first related to the cue and the second related to the movement. Statistical analysis of the discharge of this group of neurons showed that the onset of the neuronal response was related to the auditory cue rather than the onset of movement. From an analysis of the timing of neuronal responses, we found that the order of change in activity after the stimulus was, first, the "sensory" type then the "sensori-motor" type and finally the "motor" type neurons.

We have interpreted these results as indicating the presence in area 5 of a central nervous mechanism for sensory to motor transformation by which the neuronal response to a sensory cue becomes transformed into a motor output. The initial change in activity of the "sensori-motor" type neurons is induced by the "sensory" type neurons and this change may represent the sensory component of the neuronal response. The second, motor, component may occur when, under the influence of facilitatory effects, the activity of the "sensori-motor" type neurons reaches the threshold level necessary for the activation of the "motor" type neurons which governs the eventual execution of movement. External influences from structures involved in, for example, the recognition of the stimulus as being the signal for movement or motivation may act on the excitability of the "sensori-motor" type neurons so as to regulate whether or not the movement occurs. Recent experiments have shown that somaesthetic input may be a modulating influence.

188.6 TECHNIQUES FOR ANALYZING ADAPTIVE CHANGE IN COMPLEX NEURAL SYSTEMS. D. Birt , S. Aou, and C.D. Woody, Mental Retardation Res. Ctr., Brain Res. Inst., Depts. of Anatomy and Psychiatry, UCLA Med. Ctr., Los Angeles, CA 90024.

Both neurophysiologic experiments (Woody, Ann. Rev. Psychol., 1986) and theoretical analyses of artificial neural networks (Hopfield and Tank, Science, 1986) indicate that adaptive changes which support learned behavior may arise from relatively simple changes in large numbers of widely distributed elements. Mapping/labelling mechanisms permit the individual elements to participate in a variety of different adaptations. Empirical studies show that the correlation between behavioral change and any randomly chosen neural unit is small and that meaningful analysis of the network requires methods for identifying the ensemble of elements which participate in a particular conditioned behavioral response.

We have developed and tested methods which facilitate the analysis of neural networks underlying the short latency conditioned eyeblink produced by pairing click (CS) with a tap to the glabella (US). Intracellular recordings from neurons of the pericruciate cortex of awake cats were obtained during associative pairings of CS and US and during appropriate control conditions. The impulse behavior of each cell was described using sets of categorizations based on such measures as the cell's spontaneous activity, the onset latency and magnitude of its response to the CS and a different, neutral auditory stimulus (DS), the magnitude of response at latency periods similar to those of major components of the conditioned behavioral response, and the relationship of spike activity with spontaneously occurring myographic activity. Other computerized procedures permitted measurement of such basic cellular properties as excitability, input resistance, parameters of action potentials (rise time, duration, amplitude, afterhyperpolarization), and magnitude and time course of evoked post synaptic potentials. A relational data base program was then used to select subsets of units whose spike activity was most closely correlated with the experimental condition and with behavioral change. In addition, the trial to trial variations in behavioral response and in neural response were correlated to further define those units whose activity was most closely related to the behavioral change. These subsets of units were then used to test specific hypotheses about conditioning related changes in basic cellular properties.

Results of these analyses show that adaptive changes occur preferentially in subsets of units that reflect specific functional outputs of the network, such as the ability to discriminate stimuli and the ability to control appropriate motor responses. (Supported by NICHHD and AFOSR).

188.7 **APPLICATION OF MULTI-CHANNEL TOPOGRAPHIC EEG MAPPING IN ASSESSMENT OF BRAIN FUNCTION IN BEHAVING RATS.** **R.G. Bickford, G. Buzsaki, B. Allen* and F.G. Gage. Dept. of Neurosciences, School of Medicine, Univ. of Calif., La Jolla, CA 92093.**

Topographic maps of spectral EEG and EP have gained popularity in the clinical diagnostic field. These rat experiments aim at: 1) clarifying the neurophysiologic mechanisms underlying the toposcopic display by means of lesion studies in the animal, and 2) using maps as evidence of electrical rhythm restitution following fetal cell grafting experiments.

Methods. Using stainless steel screws embedded into the skull and head mounted cathode followers, artifact-free EEG and EPs have been obtained in rats during wheel running, drinking etc. The 16 channel data is input to the Minicears (LSI 11/23) computer which generates topographic maps. Color maps of the same data are generated on the Zenith 100 computer and color printer system in three perspectives (Allen). In this study we show examples 1.) of how wave patterns with similar frequency and amplitude characteristics can be dissociated based on different spatial distributions and 2.) effect of subcortical lesions on neocortical EEG.

1. Two types of hippocampal rhythmic slow wave activity (RSA) exist in the rat: one is sensitive to muscarinergic blockers, and the second is non-cholinergic (Vanderwolf and Robinson, 1981). Topographic maps derived from the skull revealed that the two types of RSA are produced by different dipoles, i.e. by different sets of synapses.

2. Unilateral lesion of the nucleus basalis increased the power of neocortical delta activity unilaterally (Fig.), but decreased high voltage spindles in the same hemisphere.

On-line color video displays of the EEG and animal behaviour will be presented. **Supported by grant from J.D. Douglas Foundation and Alzheimer grant No. PHS-AGO 5131-03.**

188.8 INTERRUPTION OF VOLUNTARY MOVEMENT BY AN ELECTRICAL OR MAGNETIC CORTICAL STIMULUS IN MAN. J.C. Rothwell, B.L. Day, P.D. Thompson and C.D. Marsden. (SPON: E.A. Jackson). Dept. Neurology Institute of Psychiatry, De Crespigny Park, London SE5 8AF, U.K.

There are now two methods available for stimulating the brain through the intact scalp: high voltage electrical stimulation devised by Merton and Morton (Nature, 285: 227, 1980), and magnetic stimulation pioneered by Barker et al (Lancet, i: 1106-1107, 1985). Both methods have been used successfully to activate areas of cortex and produce elemental sensations or movements. Here we show that such stimuli are capable of interrupting, in addition to mimicking, normal brain function.

Six normal subjects were asked to react to an auditory signal given 1s after a visual warning by flexing their wrist through 20-30° as rapidly as possible. 25% of trials were controls in which no tone followed the warning. Surface EMG recordings from wrist flexor and extensor muscles revealed that the movement was accompanied by a normal bi/triphasic pattern of activity. In about a third of trials, at random, an electrical or magnetic stimulus was given over the contralateral central area of cortex at different intervals after the reaction signal. The intensity of stimulation was above the threshold needed to produce a response in relaxed muscles.

The most striking effect was seen if the stimulus was given so that the muscle response to the cortical shock occurred before the expected time of onset of movement. In this case, the entire movement was delayed, without disrupting the form of the EMG bursts, for periods of up to 200ms depending upon the intensity of stimulation. If the stimulus came later, in the middle of the first burst of agonist EMG activity, only the antagonist (and second agonist) burst was delayed. The delay could not be explained entirely by inhibition of spinal cord mechanisms after the shock since an H-reflex or a second electrical stimulus to the cortex could produce activity in this interval. Neither was the delay caused by interference with perception of the tone, or by changing the intention of the subject to respond. If subjects were required to react bilaterally, and the stimulus was given only to one side of the head, then the movement was delayed only in the arm contralateral to the stimulus.

We conclude that such stimuli can delay the execution of voluntary motor commands, probably by an action at the level of the cerebral cortex.

188.9 FOCAL CEREBRAL STIMULATION IN MAN WITH THE MAGNETIC COIL. V.E. Amassian, R.Q. Cracco and P.J. Maccabee*. Depts. of Physiology and Neurology, SUNY Health Sci. Ctr. at Brooklyn, New York 11203.

The magnetic coil when centered at the vertex has been reported to stimulate arm muscles at least 2 ms later than when transcranial electrical stimulation is used, suggesting that only 'I' waves are evoked in corticospinal neurons (Day et al, 1986, J. Physiol., 378, 36P). Theoretically, with tangential orientation, a substantial fraction of the magnetic flux is coupled transcranially. The resulting electrical field is also tangentially oriented, i.e., optimally oriented for stimulating tangential intrinsic cortical fiber systems and corticocortical afferents. When the plane of the coil is angulated towards the vertical, the fraction of the magnetic flux penetrating the cerebrum is reduced but the orientation of the induced electric field should approximate that of corticospinal neurons in motor cortex and their trajectory in white matter, thus resulting in earlier, 'D' discharge. Using the Cadwell magnetic coil on ourselves, we tested this prediction by comparing the latency of activation of contralateral arm muscles to transcranial electrical and magnetic coil stimulation. The previously described focal anodic configuration was used to avoid distress with electrical stimulation (Amassian, V.E. and Cracco, R.Q., 1987, Neurosurgery, 20: 148-155). The minimum latencies of EMG responses in forearm flexors (e.g., 13.3 ms) and extensors (e.g., 14.8 ms) to near-maximal stimulation with the magnetic coil situated several cm lateral to the midline and optimally oriented towards the vertical, matched those obtained with focal anodic stimulation, also during voluntary contraction. Thus, given the appropriate coil orientation, direct activation of corticospinal neurons is attainable with the magnetic coil. With sub-optimal magnetic coil stimuli, latency jumps as brief as 1.2-1.9 ms were detected in the EMG, possibly reflecting the D-I or inter I periodicity in corticospinal discharge.

Movements evoked by threshold stimulation with the magnetic coil were studied by gluing fluorescent spots onto the tips of the digits, illuminating the spots with UV light and storing the XY coordinates at 60 Hz of each spot with a videcon-computer system. By appropriately angulating the magnetic coil over lateral motor cortex, movements were evoked predominantly of a single contralateral digit. Either flexion or extension could occur. Slight changes in angulation or in placement resulted in movement predominantly of another digit. Such localized responses imply focal cerebral activation had occurred. Other stimuli resulted in movements of many digits. To resolve whether these reflected movements at more proximal joints, a fluorescent spot mounted on a light rod was attached to the hand. Movements occurring at the wrist and digits in any given axis could then be differentiated from those occurring only at the digits.

188.10 LOCALIZATION OF ELECTRICAL BRAIN ACTIVITY IN THE SOMATOSENSORY CORTEX VIA BIOMAGNETIC TOPOGRAPHIC BRAIN MAPPING. L. Narici*§, I. Modena*§, G.L. Romani, P. Rossini*°. Istituto di Elettronica dello Stato Solido - CNR - via Cineto Romano 42, 00156 Roma, ITALY.

Neuromagnetic investigation performed during the last few years has repeatedly shown an impressive capability to perform a three-dimensional source localization on the basis of the measured spatial distribution of magnetic field over the scalp. The ability of the data analysis to calculate location and strength of a bioelectric source depends, of course, on the geometry of the source itself. Here we present a further application of this method to Somatosensory Evoked Field study. We, in fact, have been able to follow, with a time resolution up to a millisecond, the evolution of the position, direction and strength of the equivalent source for the electrical activity evoked in the brain areas adjacent to the central sulcus during the stimulation of the contralateral median nerve at wrist. These results show a reasonable constant behaviour over the subjects we studied. Strength and direction of the equivalent sources seem to behave often as these were undergoing rotations. This would suggest consecutive activations of different areas of the cortex were the curvature of the cortex itself is stronger (for example along the post central wall of the central sulcus down to the floor of the rolandic fissure) or for successive activation of different areas (for example motor/somatosensory). Experiments have been carried out in different conditions to gather more information about the interested areas. In certain cases it has been possible to show that the direction of the current flow is perpendicular to the direction of "motion" of the source. This would provide a hint for an activity following a perpendicular path to the rolandic fissure and moving down/up-ward along the fissure itself.

188.11 NEW VIBRATION EVOKED POTENTIAL METHOD: COMPARISON WITH CEREBRAL BLOOD FLOW MEASUREMENTS IN HUMANS. AZ Snyder*, JS Perlmutter*, PT Fox, ME Raichle (SPON: S Eliasson) Washington Univ Sch of Med, St. Louis, MO 63110.

A new vibration evoked potential (EP) technique was developed in order to provide a means of comparing electrophysiological and regional cerebral blood flow (rCBF) responses to stimuli of the same somatosensory modality. Vibrotactile stimulation is much more effective than direct electrical shocks delivered to peripheral nerves in activating rCBF. Accordingly, the new EP method is based on steady state amplitude modulation of electromechanically generated vibration. The time dependent potential, v(t), sent to the electromechanical vibrator may be expressed as $v(t) = A(1 + \cos(2\pi f_{mod} t))\cos(2\pi f_{vib} t)$, where A is mean amplitude, and f_{mod} and f_{vib} are the amplitude modulation and carrier frequencies, respectively. In pilot studies involving neurologically normal human volunteer subjects, in which f_{mod} was systematically varied between 2 and 43 hz with f_{vib} held constant at 128 hz, it was determined that, as regards topographic distribution, the responses evoked by vibration of the palm and finger pads of one hand are similar to short latency (30 - 40 msec range) somatosensory EPs obtained by direct median nerve shocks.

A clinical application of the new technique is illustrated in the following case presentation. The patient was a 67 year old dextral woman with a 45 year history of unilateral action dystonia which was responsive to Sinemet. EPs and rCBF increments were measured in response to vibrotactile stimulation of each hand individually before and about 30 min after treatment with Sinemet. rCBF responses were determined by $H_2{}^{15}O$ and positron emission tomography (PET) as previously described (PNAS 83:1140, 1986). Vibration of the uninvolved (left) hand induced normal rCBF and electrical responses in the contralateral hemisphere before and after Sinemet. In the pre-Sinemet condition, vibration of the involved (right) hand elicited an abnormally low rCBF response in the contralateral hemisphere (patient: 12% vs. 8 normals: 26 + 5%). The pre-treatment right hand vibration EPs exhibited an abnormal topographic shift towards the temporal regions of the scalp and response dynamics which were asymmetric with respect to stimulated hand. EPs and rCBF responses were normal and symmetric after Sinemet.

188.12 SPATIOTEMPORAL VOLTAGE MAPPING OF MEDIAN NERVE SOMATOSENSORY EVOKED POTENTIALS BEFORE AND AFTER DIGITAL FILTERING. C. G. Widmer. Dental Research Center, Emory University, Atlanta, GA 30322.

Median nerve somatosensory evoked potential recordings consist of both fast (high frequency) and slow (low frequency) components which have been attributed to subcortical and cortical structures in the afferent pathway. Median nerve high frequency evoked potentials include the P14, N17, N20, P22 and P27 components while the low frequency potentials include N18, N30 and P45 (Desmedt, et al., EEG clin. Neurophysiol., 68:1-19, 1987). Topographic mapping studies have been helpful in establishing the spatial distribution of these potentials, although some of the high frequency components (N17, N20, P22) are superimposed on a lower frequency negativity (N18) and are more difficult to observe in a topographic map. The purpose of this study was to selectively remove the slow or fast components by digital filtering and to create a topographic map of the remaining high or low frequency potentials.

In ten subjects, median nerve evoked potentials were simultaneously recorded from 12 cephalic sites located over the left hemisphere including FZ, PZ, CZ, FP1, F3, C3, P3, O1, F7, T5, T3 and A1 (10-20 International System) with reference to the neck. Data were collected using a bandpass of 1 to 1000 Hz, sampled at 4000 Hz and averaged for 512 stimuli. The stimulus of the right median nerve consisted of a 0.2 ms pulse at a stimulus frequency of 2.2 stimuli/second. Analysis time was 64 ms post-stimulus. Digital filtering consisted of two bandpasses: (1) 1 to 62 Hz to identify the low frequency components and (2) 62 to 1000 Hz to identify the high frequency components. Digital filtering of the recordings was obtained by calculating the Fast Fourier Transform, windowing the data and then calculating the inverse Fast Fourier Transform to reconstruct the filtered SEP.

Spatiotemporal voltage maps of the low pass filtered recordings demonstrated that the highest amplitude of the N18 negativity was widespread over the parietal region, the N30 potential was greatest over the frontal region and the P45 potential was located overlying the central sulcus. Mapping of high pass filtered recordings showed that the P14 and N17 potentials were widespread over the frontal, central and parietal regions with smaller amplitude over the occipital area, the N20 potential was more localized at the mid-parietal recording site P3, the P22 potential was located over the central sulcus and the P27 potential was maximal in the parietal region. These topographic maps were similar to those previously reported in the literature. Therefore, digital filtering can allow mapping of high frequency potentials without phase distortion and without the high-amplitude influence of slow wave potentials.

188.13 HUMAN MOTOR CORTEX IS FACILITATED PRIOR TO ONSET OF VOLUNTARY MOVEMENT. A Starr, M Caramia*, F Zarola* and P Rossini*. Lab. of Clinical Neurophysiology, II University of Rome, Rome, Italy 00173

Human motor cortex can be activated by the passage of a single brief electrical current through the scalp overlying the motor area causing a movement of contralateral muscles. The time-course of facilitation of motor evoked potentials (MEPs) to transcranial electrical stimulation delivered at varying intervals near the onset of a voluntary ballistic movement were studied in four normal subjects. MEPs were recorded from the left thenar muscles to unifocal anodal stimulation of the right scalp overlying the hand motor area delivered every 8 to 10 seconds. The level of current used was adjusted to be subthreshold for evoking an MEP while at rest but effective for evoking an MEP if the subject simultaneously contracted the thenar muscle. A click, randomly associated with the scalp stimulus was the signal for the subject to make a brief thumb press on a piston at short latency. The time interval between the electrical scalp stimulus and the click was adjusted so that the former occurred approximately between 150 msec before and 150 msec after the onset of the voluntary movement signaled by the EMG in the thenar muscles. The results showed that MEPs were not detected when the scalp was stimulated 80 msec or more prior to onset of voluntary movement. MEPs then appeared with increasing probability as the time interval before movement shortened reaching 100% with an interval of 40 msec or less. The amplitudes of MEPs in the 80-40 msec period preceding movement onset were small (>20% of maximum) and achieved maximum values 20 msec after movement onset.

188.14 NEUROCHEMICAL DIVERSITY IN THE HUMAN TEMPORAL NEOCORTEX K. Thapar*,N.C. de Lanerolle, J.P. Partington*, D.D. Spencer. Section of Neurosurgery, Yale University School of Medicine, New Haven CT 06510

Little is known of the neurochemical organization of the human neocortex . In the present study lateral temporal neocortex (LTN) removed during surgery for intractable partial complex epilepsy from 25 patients was used for the immunohistochemical localization of aminoacid (γ-aminobutyric acid-GABA, glutamate-GLU) and neuropeptide (somatostatin-SS, cholecystokinin-CCK, vasoactive intestinal polypeptide-VIP, neuropeptide Y-NPY, enkephalin-ENK, neurotensin-NT) containing neurons. Depth electrode studies prior to surgery had established the presence of seizure foci in the hippocampus but their absence in the LTN. Surgical access to the hippocampal seizure focus necessitated removal of this LTN tissue. Immersion fixed tissue was sectioned and immunostained by the PAP or Avidin Biotin complex techniques with primary antisera against the respective neurochemicals.

An abundance of neurons were immunoreactive for GLU. Most were pyramidal cells but a small number were interstitial neurons in the white matter. GABA cells were present in all cortical layers. However, their laminar density and cellular appearance were not uniform: a moderately high density was found in layer I, an even higher density in layers II - III, and a relatively lower density in the remaining cortical layers. At least three populations of SS neurons were recognized: a population of small bipolar neurons in layers II - III; large multipolar nonpyramidal cells in layers V - VI; and some interstitial neurons in the white matter . SS beaded fibres were present in all cortical layers, but were dense and coursing horizontally in layer I. NPY neurons were present throughout layers II - VI, but predominant in layers V - VI. Additional NPY neurons were present in the white matter. All NPY cells were large multipolar nonpyramidal cells with a varied and extensive dendritic pattern. A dense netwc k of NPY fibres coursed through the cortical layers, many extending vertically to the cortical surface. Horizontal NPY-fibres predominated layer I. A population of NPY neurons may co-localize with SS (Vincent et al.,1982). VIP neurons were small, fusiform and bipolar and uniformly present in all layers except layer I. Isolated, beaded VIP fibres were seen in the upper cortical layers. CCK neurons were present in all cortical layers: most numerous in layers II - III and most sparse in layer VI. Although most cells were small fusiform bipolar neurons, larger pyramidal shaped neurons were noted in layers II - IV. Some of the layer I CCK neurons were horizontally oriented. A loose network of CCK- fibres was present in layers I - II with addition fibres scattered in other layers. While no ENK or NT somata were localized within the LTN, scattered isolated fibres were infrequently present in all cortical layers. These results, while demonstrating a neurochemical diversity within the organization of the human LTN, show in particular: (1) The clear existance of GLU within pyramidal cells; and the absence in such cells of any other substance tested. (2)Neuropeptides are mainly within populations of intrinsic neurons which may modulate pyramidal cell activity. (3) Whereas some of these nurochemicals may be co-localized within the same neuron (eg. SS, NPY) independent populations of chemically distinct neurons can be inferred from variations in the proportions of their respective populations. (4) The white matter intrinsic neurons whose function is unclear, contain one or more of the substances GLU, SOM, NPY. These studies establish the basis for future examination of possible cortical reorganization in LTN seizure foci.

189.1 INTRACELLULAR INJECTION OF LUCIFER YELLOW INTO CORTICAL NEURONS IN LIGHTLY FIXED SECTIONS AND ITS APPLICATION TO HUMAN AUTOPSY MATERIAL. G. Einstein and D. Fitzpatrick. Department of Anatomy, Duke University, Durham, NC 27710.

Recently Masland and his colleagues have developed a technique for making intracellular injections into fixed retinal wholemounts (Tauchi, M. and R.H. Masland, Proc. Roy. Soc. Lond. B. 223:101-119, 1984; Sandell, J.H. and R.H. Masland, J. Neurosci. 6:3331-3347, 1986). We have adapted this method to study the intrinsic and projection neurons in the cerebral cortex of a variety of specimens, including those from human autopsy.

Tissue samples of cat and tree shrew visual cortex and human hippocampal cortex were fixed (either by perfusion or by immersion) with a mixture of 2.5% paraformaldehyde and 0.2% gluteraldehyde in 0.1M phosphate buffer (pH 7.4). Slices, 300-400 um in thickness were cut on an Oxford vibratome and collected in cold phosphate buffer. In order to visualize neurons under the fluorescent microscope slices were stained with 4',6-diamidino-2-phenylindole (DAPI). Under visual guidance, selected neurons were impaled by pipettes filled with a solution of 10% Lucifer Yellow CH in distilled water (final impedance of 120-175 megohms). Filling of the neurons was achieved by pulsing a negative current of about 4 nA (frequency, 2 Hz) until the cell and its dendrites fluoresced bright yellow. In some cases we used an antibody to Lucifer Yellow to achieve a stable, electron-dense reaction product (Taghert, P.H. et al.,Dev. Biol. 94: 391-399, 1982).

The dendrites of injected neurons in the visual cortex appeared to be well filled to their distal portions revealing differences in spine morphology and varicosities. In rapid autopsy material from patients with Alzheimer's Dementia, neurons in the hippocampus displayed a variety of morphological abnormalities including bulbous swellings, spines coated with filamentous material, and beaded processes. Equally good results were obtained with tissue fixed by either perfusion or immersion and neurons could be well-filled up to 48 hours after fixation. This technique allows one to obtain a high yield of stained neurons with exquisite morphological detail and may be particularly valuable for the study of diseased neurons from the human brain. We thank Dr. Donald Schmechel for providing us with rapid autopsy material and Dr. Corey Goodman for the antiserum to Lucifer Yellow. Supported by NEI grants EY06661, EY05546, and the Sloan Foundation.

189.2 COMBINATION OF FLUORO-GOLD AND RHODAMINE BEAD TRACT-TRACING WITH IN SITU HYBRIDIZATION HISTOCHEMISTRY. B.M. Chronwall, J.R. Dubin*, R.G. Krause II, M.E. Lewis, and J.S. Schwaber. Experimental Therapeutics Branch, NINCDS, National Institutes of Health, Bethesda, MD and Med. Prod. Dept., Experimental Station, E.I. DuPont Co., Wilmington, DE

In situ hybridization histochemistry has become an invaluable tool for examining the effects of physiological and pharmacological manipulations on specific mRNA at the single cell level in brain. Since treatment effects are likely to be related to the connectivity of the affected neurons, it would be desirable to have a rapid and simple method to determine the projection area of individual hybridzed neurons. The continued development of fluorescent retrograde axonal transport tracers has resulted in the introduction of a new generation of dyes, i.e. fluoro-gold and rhodamine beads, which are now the retrograde tracers of choice because of their ease of use, bright fluorescence, resistance to fading or leakage, and apparent lack of effect on cellular metabolism. We therefore sought to determine whether these tracers could be used in conjunction with our standard in situ hybridization procedures, which are carried out using formaldehyde-fixed brain sections with synthetic oligonucleotide probes labeled on the 3' end with multiple [^{35}S] or [^{125}I]-labeled nucleotides. Rats were anesthetized and either tracer was administered into the nucleus tractus solitarius by pressure injections via glass pipettes in volumes of 50-75 nl. After survival of at least one week, the animals were anesthetized and then perfused with 4% formaldehyde in PBS. The brains were cryoprotected by overnight immersion in 30% sucrose in PBS and frozen for cryostat sectioning.

The sections were hybridized with labeled somatostatin oligonucleotide (39mer), washed in descending concentrations of SSC, and emulsion dipped according to standard methodology. Following variable exposure times (5-30 days), the slides were then developed, fixed, and washed in water. Sections containing rhodamine beads were air dried and mounted in Entellan, while sections containing fluoro-gold were dehydrated through ascending concentrations of ethanol and xylenes and then mounted in Krystallon prior to coverslipping. The tract-tracing and in situ hybridization labels were viewed nearly simultaneously (with transient blockade of the subcondenser light path) using epifluorescence for the dyes and darkfield transmission microscopy for the autoradiographic grains. Many dye-filled and hybridization-positive cells were detected in the paraventricular nucleus of hypothalamus and central nucleus of amygdala, but only a small subset of neurons in either nucleus were actually double labeled. This method has proved to be straightforward and now provides investigators with the means to easily study specific mRNA in relation to the projections of given neurons within complexly organized brain nuclei.

189.3 VISUALIZATION OF RETROGRADELY-TRANSPORTED FLUORO-GOLD IN LIGHT AND ELECTRON MICROSCOPIC PREPARATIONS. L. Schmued,* K. Kyriakidis,* J.H. Fallon and C.E. Ribak. Dept. of Anatomy and Neurobiology, Univ. of Calif. Irvine, CA 92717.

The advantages of axonally transported Fluoro-Gold as a retrograde fluorescent marker are numerous and have been described previously (Schmued and Fallon, 1986). The present study was conducted to determine whether Fluoro-Gold is visible in either semi-thin sections for light microscopy or thin sections for electron microscopy. Rats were pressure injected with 0.1 ul of 2.5% Fluoro-Gold into either the striatum or the spinal cord. After survial times, ranging from 3-20 days, they were perfused with 4% paraformaldehyde and 1% glutaraldehyde in 0.1 M phosphate buffer, and blocks of tissue from the substantia nigra or red nucleus, paraventricular nucleus and cerebral cortex were obtained. Sections were cut at 200 um on a vibratome and analyzed on slides with the fluorescent microscope using ultraviolet excitation to determine the extent of retrograde labeling. Sections that contained labeled cells were embedded in plastic for electron microscopy. Semi-thin sections of unosmicated tissue displayed high resolution fluorescent labeling of somata and dendrites. In contrast, osmicated tissue had the fluorescence quenched but numerous dense punctate structures were observed in the perikaryal cytoplasm of labeled neurons in toluidine blue stained sections. The unosmicated tissue did not display these granules and this finding suggested that the granules are composed of membranes since osmium is lipophillic and membranes are primarily composed of lipid. It is interesting to note that neurons that did not send axons to the injection sites were not labeled. Adjacent thin sections examined with the electron microscope displayed numerous electron-dense lipofuscin-like organelles in the perikaryal cytoplasm. The electron density of these organelles was greater than that of ordinary lysosomes. Another distinctive organelle that was observed in these preparations included relatively dense concentric lamellated bodies of various sizes that were found in the somal and dendritic cytoplasm. The presence of swollen multivesicular bodies in somata was also found in these labeled somata. Control sections did not display these organelles. Also, small neurons in the red nucleus that lack a spinal cord projection did not display these organelles whereas the large projection neurons displayed them. Therefore, the electron-dense lipofuscin granules, lamellated bodies and swollen multivesicular bodies suggest that these organelles are sites of Fluoro-Gold localized in the somata and dendrites of retrogradely-labeled neurons. It is not known whether it is the Fluoro-Gold itself, or its physiologic effect on membrances which provides the electron dense staining. This study extends the previously described advantages of Fluoro-Gold tract tracing to the electron microscopic level. One anticipated advantage of this new application at the ultrastructural level is its combination with other electron microscopic labels, such as horseradish peroxidase. (This work was supported by NIH Grants NS 15669 and NS 15321).

189.4 RETROGRADE TRANSPORT OF THE LECTIN PHASEOLUS VULGARIS LEUCOAGGLUTININ BY RAT SPINAL MOTONEURONS. C.L. Lee, D.J. McFarland, and J.R. Wolpaw. Wadsworth Labs, NYS Dept Hlth, Albany, NY 12201.

The lectin Phaseolus vulgaris leucoagglutinin (PHA-L) has proved to be an excellent CNS anterograde tracer, giving Golgi-like labelling. We are exploring its use as a CNS retrograde tracer (McFarland & Lee, this vol.), and, in this study, as a retrograde tracer in the peripheral nervous system.

Rats (200-300 g) were anesthetized and a right C5-T2 dorsal root rhizotomy was performed aseptically. PHA-L (5-10 ul of a 5% solution) was injected into triceps brachii on both sides or just on the right side. After 2,3,4,5,6 or 10-day survival, rats were sacrificed by anesthetic overdose and perfused with phosphate-buffered saline and 4% paraformaldehyde. The C5-T2 spinal cord was cryoprotected and cut by cryostat into 30-um sections. Sections were reacted for PHA-L using goat PHA-L antiserum and the biotin-avidin (ABC) method.

No label was found in rats that survived 2 days. Labelled motoneurons were seen on the injected side(s) in all rats that survived 3 days or more. In rats injected bilaterally, labelling was comparable on the normal and rhizotomized sides. Motoneuron labelling was granular and appeared to be associated with the cell membrane and nuclear envelope. In some cells labelling extended into primary dendrites, but Golgi-like labelling was not seen. Primary afferent labelling was not apparent.

These results indicate that PHA-L undergoes retrograde transport from muscle in spinal motoneurons, since motoneuron labelling was comparable on normal and rhizotomized sides. Furthermore, the lack of primary afferent labelling makes anterograde transsynaptic labelling very unlikely. This demonstration of retrograde transport in the peripheral nervous system increases the possible uses of PHA-L as an anatomical tracer.

(Supported by NIH 22189 and by United Cerebral Palsy)

189.5 BIDIRECTIONAL AXONAL TRANSPORT OF PHASEOLUS VULGARIS LEUCOAGGLUTININ AFTER INJECTION INTO RAT HIPPOCAMPUS. D.J. McFarland and C.L. Lee. Wadsworth Labs, NYS Dept Hlth, Albany, NY 12201.

Phaseolus vulgaris leucoagglutinin (PHA-L) is an excellent anterograde tracer in the central nervous system (CNS). We have shown retrograde transport of this lectin in the lower motoneuron (Lee, McFarland, and Wolpaw this vol.) and are seeking evidence for CNS retrograde transport. The hippocampus was chosen as the site of injection due to its well-known circuitry and orderly cyto-architecture.

Male rats (250-300 g) were anesthetized and placed in a stereotactic frame. PHA-L (0.05-0.10 ul of a 5% solution) was injected into the dentate gyrus on one side over at least 5 min. Two or three days later, rats were deeply anesthetized and perfused with buffered saline and 4% paraformaldehyde. After overnight immersion in the same fixative and cryoprotection, 30 um sections were cut by cryostat. PHA-L was detected by goat antiserum to PHA-L in conjunction with the avidin-biotin method. At both 2 and 3 days after injection, anterograde labelling was seen in the mossy fiber system of the dentate granule cells, in the Schaffer collaterals of CA4 pyramidal cells, and in the commissural/ipsilateral associational system. Golgi-like filling of axons and collaterals was present. In addition, granular labelling of soma membranes and some principal dendrites was seen in dentate interneurons bilaterally and in regio inferior interneurons on the contralateral side. This granular neuronal labelling was probably the result of retrograde transport because it occurred early and was not in close proximity to extensive anterograde labelling.

These results strongly suggest that PHA-L undergoes bidirectional axonal transport in the commissural/associational system of the rat hippocampus.

189.6 CHOLERA TOXIN CONJUGATED WITH HORSERADISH PEROXIDASE: TIME-DEPENDENT VISUALIZATION OF ANTEROGRADE AND RETROGRADE TRANSPORTED REACTION PRODUCT. M. Kalia, M.E. Hudson* and J.J. Viola. Dept. Pharm., Thomas Jefferson Univ., Philadelphia, PA 19107.

Horseradish peroxidase (HRP) conjugated to cholera toxin (CT) has been shown to be a valuable tracer for the study of anterograde (Trojanowski et al, '81) and retrograde (Trojanowski, '82; Wan et al, '82a) transport in central or peripheral neurons. Recent studies have utilized this material almost exclusively for demonstrating details of the dendritic morphology of retrogradely labeled cells (Wan et al, '82b; Shapiro and Miselis, '83; Shapiro and Miselis, '85). Studies of efferent pathways have used wheat germ agglutinin conjugated to HRP as a preferred substance for anterograde tracing. In this study, we examined the time-dependent labeling of cholera toxin-horseradish peroxidase (CTHRP) in a combined system using both anterograde and retrograde transport. The present study examines the usefulness and time-dependency of CTHRP as an anterograde tracer and compares it with new and existing data on retrograde transport. CTHRP conjugates were made with glutaraldehyde activation according to the method of Avrameas and Ternynck ('71) as described by Gonatas et al ('79) and Trojanowski et al ('82). Type VI HRP was obtained from Sigma Chemical Co. and CT from Schwarz/Mann. Ten µg of 0.1% solution of CTHRP was injected into the extensor digitorum longus (EDL) muscle of a rat in which all other nerves had been sectioned to avoid surreptitious uptake by diffusion of the label to the fascial compartments of the muscle. Survival times from 1 to 21 days were allowed prior to perfusion transcardially with 1% paraformaldehyde, 1.25% glutaraldehyde in phosphate buffer solution, followed by 5% sucrose in phosphate buffer at 4°C. The tetramethyl benzidine method for HRP histochemistry was used to demonstrate HRP reaction product in serial, horizontal, frozen sections of the lumbar cord. Sections were examined without counterstain under bright and dark field illumination. The number of retrogradely labeled neurons and anterogradely labeled bouton terminals was counted in every section and quantitative time-related differences were determined using morphometric analysis (Bioquant Systems). The following striking similarities/differences between retrogradely and transganglionically (anterograde) transported CTHRP were observed: a) survival time required for initial appearance of retrograde transport was one day and for transganglionic transport, three days; b) period required to reach peak labeling from the onset of labeling was 48 hours for both retrograde and transganglionic transport; c) duration of peak responsiveness was six days for retrograde transport and one day for transganglionic transport; d) total duration during which labeling could be detected was over 19 days for retrograde transport and 9 days for transganglionic transport. These results demonstrate that CTHRP is detectable in both retrogradely and transganglionically transported forms and that the optimal visualization of each of these transported forms is different, making it possible to select different survival times in order to optimize visualization for the pathway in a system under investigation. This study is the first demonstration of significant amounts of transganglionically transported CTHRP and provides evidence that CTHRP is far superior to WGAHRP and Pha-L (Phaseolus vulgaris-leucoagglutinin) as a transganglionic label. In addition, the discrepancy observed between the optimal duration and latency of labeling in the two instances (retrogradely transported and transganglionically transported) will permit investigations of systems in which one or the other type of transport is being investigated. By selection of the optimal duration of survival, it is possible to study CTHRP transported either in the retrograde or anterograde direction. Quantitative data from this study indicates that since optimal visualization of retrogradely and transganglionically transported CTHRP does not occur simultaneously, experiments involving selected survival periods can be used to analyze motor and sensory systems independently. (Supported by USPHS Grants HL30991, HL31997, and HL33632 to MK.)

189.7 SUICIDE TRANSPORT ACTIVITY OF VISCUMIN (MISTLETOE TOXIN), *NAJA NIGRICOLLIS* CYTOTOXIN AND THE HYBRID CYTOTOXIN, RICIN B-CHAIN DISULFIDE COUPLED TO THE RIBOSOME INACTIVATING PROTEIN FROM BARLEY. M. Ovadia*, F. Stirpe*, T.N. Oeltmann* and R.G. Wiley (SPON: J.T. Wall). Oncology and Neurology Depts., Vanderbilt University and VAMC, Nashville, TN 37232.

Suicide transport, anatomically selective destruction of neurons by axonally transported cytotoxins, is a useful experimental strategy. A number of agents are known to be effective, particularly the toxic lectins such as ricin; however, none are ideal. In our ongoing attempts to identify new and potentially more useful agents, we sought to determine the suicide transport activity of the toxic lectin from mistletoe, viscumin (V), the purified cytotoxin from the venom of *Naja nigricollis* (**NnCyTox**) and the hybrid cytotoxin composed of the ribosome inactivating protein (RIP) from barley disulfide coupled to ricin B-chain (**RTB-SS-BarRIP**). All three agents are potent cytotoxins in vitro. The toxins were dissolved in saline and pressure microinjected unilaterallly into either the vagus or sciatic nerves or caudate nucleus of 32 anesthetized adult, male Sprague-Dawley rats. Toxin doses were 0.2-1.8 ug of V, 2-20 ug of **NnCyTox** and 0.18-6.5 ug of **RTB-SS-BarRIP**. After survival times of 2-17 days, rats were reanesthetized and perfused transcardially with FAGLU fixative followed by sucrose. Cryostat sections of appropriate ganglia, brain and spinal cord were stained with cresyl violet to assess neurotoxicity. Sections containing the substantia nigra were processed for catecholamine histofluorescence. V was reliably neuronotoxic to vagal sensory and motor neurons and sciatic dorsal root ganglion neurons and less consistently to substantia nigra, pars compacta neurons but not sciatic motor neurons. Both **NnCyTox** and **RTB-SS-BarRIP** were neuronotoxic to vagal sensory neurons only; either of these later agents could be used to produce a selective vagal sensory dennervation. V generally produced incomplete lesions at maximally tolerable doses suggesting limited usefulness as an experimental tool. Ricin, modeccin and volkensin remain the most generally useful, nonspecific suicide transport agents known. (This work supported by Veterans Administration Medical Research Service.)

189.8 TOPOGRAPHY OF NUCLEUS BASALIS CHOLINERGIC NEURONS PROJECTING TO DEFINED CORTICAL AREAS IN THE RAT. M. Piotte, R. Egizii*, G.E. Lucier and A.C. Cuello. Depts. of Pharmacology and Therapeutics, McGill Univ., Montreal, Quebec, H3G 1Y6 and of Medical Physiology, Faculty of Medicine, Univ. of Calgary, Calgary, Alberta, P2N 4N1.

It has now been well established that the Nucleus Basalis of Meynert (NBM) sends numerous cholinergic fibers throughout the neocortex. At present, however, there is relatively little information in the rat concerning the exact limits of the NBM and its precise cortical projection sites. This lack of information stems mainly from the difficulty in restraining spreading of the retrograde labeling substances, such as horseradish peroxidase (HRP), to well defined cortical areas. This problem, however, can be overcome by the administration of HRP in a slow release gel. The cortical projections of NBM cholinergic neurons were thus studied combining HRP retrograde labeling and choline acetyltransferase (ChAT) immunocytochemical staining. A small piece (<1 mm in diameter) of a polyacrilamyde slow release gel containing 15% HRP was carefully inserted beneath the surface of each of the following cortical areas (Zilles,K., The Cortex of the Rat, A Stereotaxic Atlas, 1985) in adult male Wistar rats (270-320g): frontal, parietal, temporal and occipital cortices. Forty-eight hours later the animals were perfused and their brains removed. Serial 40-50 um thick sections of the NBM were cut on a sledge, reacted for HRP, washed in phosphate buffer, and processed for ChAT immunocytochemistry by means of the peroxidase-antiperoxidase method of Sternberger (Immunocytochemistry, 2nd ed., 1979). NBM neurons were examined under a light microscope attached to a projector and traced onto paper. Three types of neurons were identified: those which were exclusively ChAT immunoreactive, those which were exclusively HRP positive and double-labeled neurons which contained both reaction products. Although the majority of cells were only ChAT immunoreactive, the proportion of the different types of labeled neurons varied along the rostro-caudal extent of the NBM as well as with the site of HRP implant. Results are discussed in view of the implications that differently located cortical lesions have on cholinergic neurons in various portions of the NBM.

189.9 ALZHEIMER'S PLAQUES AND TANGLES: A CONTROLLED AND ENHANCED SILVER STAINING METHOD. S.K. Campbell*, R.C. Switzer, III, and T.L. Martin* (SPON: E. O'Connor), University of Tennessee, Department of Pathology and Medical Biology, Knoxville, TN 37920.

The hallmark neuropathological features of Alzheimer's disease are the neuritic plaques and neurons with neurofibrillary tangles (nft). Traditionally, these features have best been histologically visualized by one of a number of protocols utilizing silver. Because of a lack of control in certain steps in many of these protocols, the silver methods are notorious for being capricious. In particular, erratic staining and other problems are common in methods that use a silver-diammine solution (silver nitrate and ammonium hydroxide). Furthermore, the step involving reduction (final development of silver impregnated structures) typically is not easily controlled.

We have combined the silver-pyridine-carbonate incubation step of Hicks (J Lab Clin Med 31:1375, 1946) with the physical development procedure of Gallyas (Acta Neuropathol Berl. 16:39, 1970) to achieve control of the staining reaction. This method works equally well on paraffin or freeze-cut sections. In addition to easily and consistently achieving a high quality of staining of plaques and tangles, the contrast was greatly improved due to little or no staining of myelin. By adjusting the time in the developer, the density of staining can be controlled so that features of interest to a given investigator could be accentuated. We also found that the staining of glia and background neuropil could be reduced by increasing the amount of pyridine in the silver-pyridine-carbonate solution, thus allowing fuller development of the staining of plaques, especially minute ones. This yields spectacular sections that have dark plaques against a clear background, which makes these sections readily amenable for computer image analysis. Neurons with nft's become more orange with increasing pyridine concentrations. With such enhancement, we have found that plaques occur in caudate and putamen more frequently than our other stains had led us to believe. This method allows a wide range of control of silver staining and a means of regulating the amount of staining of normal tissue elements. A synopsis of the procedures is as follows. From water, transfer sections through: 1) 0.6%NH_4OH-5'; 2) H_2O x 2-1' ea; 3) AgPC-40'; 4) 1% citric acid-3'; 5) 0.5% acetic acid-3'; 6) Phys. developer 1.5-3' (3-7' for paraffin); 7) 0.5% acetic acid-3'; 8) H_2O-3'; 9) Mount, air dry; 10) dehydrate, clear, coverslip. AgPC: add to 60ml 1% $AgNO_3$, 2.7ml pyridine, then 45ml 1% K_2CO_3 (anhyd.); phys. developer: add to 50ml 5% Na_2CO_3, 45ml (40ml for paraffin) of [Sol'n B=0.2% NH_4NO_3, 1% tungstosilicic acid (MCB #TX1618)<, 5ml (10 ml for paraffin) of Sol'n C [Sol'n C= Sol;n B with 1.8% formaldehyde (0.7ml of 37% stock/100 ml of B)]. 189.10 NEURONAL HETEROGENEITY AND INCREASE OF FUCHSINORRHAGIC MOTONEURONS IN MURINE MUSCULAR DYSTROPHY. M.A. Khan* (SPON:R.Harvey). Health Sciences., NRCAE, NSW 2480, Australia.

The non-enzymatic histochemical technique Haematoxylin-Basic fuchsin-Picric acid (HBFP) is widely used in the histopathological investigation of the extent of infarction in myocardium. The positive crimson red staining that results due to basic fuchsin binding is termed "Fuchsinorrhagia". The HBFP-negative components of the tissue stain blue or yellow. Application of HBFP technique to rat liver sections revealed two populations of hepatocyte nuclei; some were blue and some were red (Khan,M.A., Histochem.J.,10, 641, 1978; Khan,M.A. & Eberhardt,N.H., Acta. Histochem., 65, 146, 1979). The questions studied in this investigation, based on the HBFP stain, were: Does a heterogeneity exist in the motoneuronal and Purkinje cell populations of mammals? What are the tinctorial characteristics of Purkinje neurons during ontogeny? Whether or not motoneurons of the dystrophic mouse show any variation of the histochemical reaction in comparison with the controls?

Neonatal and adult rats (1,2,3,4,6,8,12 and 26 week old) and 4 4-month old homozygous normal and 7 dystrophic mice of Bar Harbor 129/ReJ-dydy strain were used in this study. They were anaesthetised with ether; their cerebellum and thoracic spinal cord were quickly excised and fixed for 24 hours in Carnoys fixative. Paraffin embedded tissue sections were processed according to the HBFP technique (Khan, M.A. & Eberhardt, N.H. Acta Histochem., 65, 146, 1979).

A marked heterogeneity between Purkinje neurons became evident in rats of all ages, except for the one week old; two varieties were easily identifiable on the basis of presence and absence of fuchsinorrhagia. In HBFP-positive neurons, a gradation of fuchsinorrhagic staining, ranging from low to high intensity was present in both nuclei and cytoplasm. A total of 4838 Purkinje neurons were examined and percentage of HBFP-positive fuchsinorrhagic population showed an age dependent linear increase from the second week postnatal onwards. A similar heterogeneity was evident among motoneurons of both normal and dystrophic mice. The majority of motoneurons in normal mice were HBFP-negative and only about 6% were fuchsinorrhagic. The spinal cords of dystrophic mice revealed about 150% increase in the fuchsinorrhagic motoneurons. In dystrophic mice, neither the size of HBFP-positive motoneurons nor the size of their nuclei/nucleoli differed greatly, either amongst themselves, or in comparison with those of the normal mice.

Recent immunochemical studies have substantiated the existence of Purkinje neuronal heterogeneity. Most of the basic histone proteins are soluble and hence removed during fixation. The fuchsinorrhagic neurons, be they Purkinje or motoneurons, may be due to a greater proportion of phosphate groups, fat and carbohydrate components. Nonhistone nuclear proteins which are acidic, heterogeneous, tissue and species specific may participate in fuchsinorrhagia. However, fuchsinorrhagia may not correlate with neuronal maturation since cerebellar maturation is complete by 8 weeks while the highest percentage of fuchsinorrhagic Purkinje cells occurs at 6 months.

189.11 A NEW METHOD FOR ANTEROGRADE AXONAL LABELING IN THE CENTRAL NERVOUS SYSTEM USING A HORSERADISH PEROXIDASE-PHASEOLUS VULGARIS LEUCOAGGLUTININ (PHA-L) CONJUGATE. D.A. Pandya (1), J.B. Rubin (2), R.E. Fine (3) and P.B. Cipolloni (4). Depts. of Anatomy (1,4), Biochem. (3) and Neurol. (4), Boston Univ. Sch. of Med., Boston, MA, 02118 and ENR VA Hosp., Bedford, MA. 01730 (1,2,3,4).

Specific anterograde axonal marking in the CNS of higher animals for quantification at the ultrastructural level has proven to be difficult. All available techniques have at least one major shortcoming. For instance, the use of horseradish peroxidase(HRP)-wheat germ agglutinin conjugate as an anterograde axonal marker is complicated by concurrent retrograde transport of the compound. Further, PHA-L, which can be used successfully for solely anterograde axonal labeling, requires the use of secondary methods for visualization of labeled axons; ie. introduction of HRP to the lectin through an avidin-biotin system (Gerfen and Sawchenko, Brain Res. 290: 219-238, 1984). However, this technique does not routinely allow for optimum tissue fixation necessary for ultrastructural examination. If measures are taken to ensure good tissue fixation, complete visualization of the transported marker is not easily obtained. In order to obviate the need for subsequent attachment of HRP to the previously transported PHA-L, we have conjugated HRP to PHA-L with the bidirectional cross-linker sulfo-disuccinimidyl suberate forming a compound that is transported anterogradely when injected iontophoretically and can be visulized with the usual HRP-DAB reaction.

In developing methods for the use of this conjugate we focused on two fundamental goals: 1) efficient anterograde marking; 2) limited retrograde filling. As PHA-L has already been shown to be transported predominately in the anterograde direction when iontophoretically injected, the second of these goals involved limiting the conjugate's entry into axon terminals via routes commonly taken by the HRP moiety of the compound; namely, fluid-phase endocytosis and, possibly, receptor-mediated uptake. The fluid-phase uptake of the compound was limited by injecting low concentrations of the conjugate and the receptor-mediated uptake was inhibited by co-injecting an excess of denatured-HRP.

The conjugate was evaluated as an anterograde-specific axonal marker with iontophoretic injections into auditory, visual, somatosensory and motor cortices of the rat. In all cases axonal filling occurred in expected projection sites. The extensive anterograde marking we have observed occurs in the virtual absence of retrograde labeling of neurons.

190.1 ACTIVITY-DEPENDENT FLUORESCENT LABELING OF NEURONS BY TRAPPED REDISTRIBUTION. L. M. Okun* (SPON: D. Yoshikami). Dept. of Biology, Univ. of Utah, Salt Lake City, UT 84112.

I am exploring a new approach designed to mark living neurons with a persistent fluorescent label as the consequence of a transient period of depolarization. The approach depends on fluorescent dyes which are membrane permeant, but intracellularly trappable, anions. The underlying assumptions, combining elements from two earlier methodologies, are (1) that the permeant dye ions will be passively "redistributed" to establish a quasi-equilibrium intracellular concentration that depends on the membrane potential (Vm) during the labeling period (cf. Sims, et al. Biochem. 13: 3315, 1974) and (2) that an enzymatic conversion of intracellular dye to impermeant form (Rotman & Papermaster PNAS 55: 134, 1966; Tsien Nature 290: 527, 1981) will, if concentration limited, trap for later inspection an image (time integral) of that Vm-dependent redistribution. [Strictly, this applies only if trapping is slow relative to the redistribution process (permeation). If, at the other extreme, trapping is much more rapid, all entering dye might be captured, preserving an image of unidirectional, inward flux - a "trapped flux" measure, also expected to be Vm-dependent but generally less sensitively so than "trapped redistribution." At either extreme, or in likely intermediate cases, neurons depolarized during labeling should trap more of the (anionic) dye.]

Promising candidates as dye species with the properties required for this application are certain acyloxyalkyl esters of carboxylated polymethine oxonols. I have prepared a selected member of this class, coba-2,1*(3)/PM, the pivaloyloxymethyl ester of a carboxyalkyl-derivatized barbituric acid trimethine oxonol, and have found that it produces a bright, differential, and persistent (hrs. at room temperature) labeling of cultured chick-embryo dorsal root ganglion neurons depolarized in its presence for a few minutes by isotonic KCl or by veratridine, or of cultured sympathetic neurons depolarized by carbachol. The label is uniformly distributed within cells, is highly resistant to photobleaching, and is not obviously toxic (though it does sensitize cells to photodamage). There is little labeling of dead cells, debris, or flattened nonneuronal cells so that labeled neurons stand out brightly against faint backgrounds in culture.

It remains to be seen whether the approach can be extended to labeling of neurons depolarized in intact tissues, e.g. by a train of action potentials. Several strategies might be employed to augment the approach, if necessary, for this purpose, including use of drugs to enhance or prolong depolarizations, inhibit hyperpolarizations, and control extracellular enzymes, increase of the charge (valence) of the permeant dye to steepen the redistribution's dependence on Vm, and normalizations against second, analogous dyes to correct for labeling variations from factors other than Vm. If the extension to tissue labeling does prove workable, the approach would provide a means for identifying neurons in subsequently dissociated cell samples on the basis of their activation by specific inputs in situ, and would thus complement the recently introduced use of retrograde-transport fluorescence labeling to identify dissociated neurons according to their targets of synaptic output in situ (McPheeters & Okun Soc. Neurosci. Abstr. 6: 733, 1980). In addition, the principles underlying design of the dyes should be applicable to construction of labels bearing other signals, e.g. ones involving positron emission or NMR, susceptible to noninvasive detection. Synthesis of variants suited to fixation for histology should also be possible.

Preliminary results suggest that relatively slowly trapped, weakly ionic dyes, such as CF/PM (carboxyfluorescein pivaloyloxymethyl ester), might provide a related class of "trapped redistribution" labels for transiently altered pH gradients across membranes.

190.2 **IN VIVO VOLTAGE MAP OF THE HIPPOCAMPUS IN CONTROL AND SEIZING RATS USING VOLTAGE SENSITIVE DYE.** R. M. Dasheiff. Dept. of Neurology and Psychiatry, Univ. of Pittsburgh Epilepsy Center, and Veterans Administration Hosp.,Pgh. PA 15213

Monitoring the electrical activity of the brain is a necessary requisite to understanding brain function. This is especially true for epilepsy research. A new technique has been developed to map changes in membrane potential throughout the brain of awake animals. Voltage sensitive dye (VSD) DiO-C(2)-5 is injected into the carotid artery while the EEG is recorded from electrodes in the hippocampus. The brain is stained by the dye, and the differential accumulation of dye reports the averaged membrane potential during the 20 sec injection. The brain is immediately removed and frozen to preserve this voltage map. Cryostat cut sections are thaw mounted onto slides and coverslipped with permount. A computer fluorescence microscope scans each brain slice and produces a pseudocolor, digital image on a TV monitor. Each pixel represents a 10 micron diameter spot.

Eight anatomical regions within the hippocampus were analyzed: stratum oriens (SO), CA1 pyramidal cells (CA1), stratum radiation (SR), lacosum moleculare (LM), molecular layer of the upper and lower blade of the dentate gyrus (MLU) (MLL), granule cells in the upper and lower blade (DGU) (DGL). Each region is identified using the dark field image produced by the scanning computer microscope. The area is then re-directed to the fluorescence image that was scanned separately but in register with the dark field image. The absolute concentration of VSD is calculated for each area from specially constructed dye standards. Voltage differences are calculated from changes in dye concentration using the results of in vitro hippocampal slice experiments (J.Neurosci.Methods 13:199-212, 1985).

Four sets of rats, grouped CON, KA, BIC, were used and each group was yoked throughout the experiment from operation to scanning. Seizures were produced by injecting 12mg/kg kainic acid (KA), i.p., or 0.25 mg/kg bicuculline (BIC) intrajugularly. Controls (CON) received saline.

	SO	CA1	SR	LM	MLU	DGU	DGL	MLL
CON	-60± 2	-57± 4	-60± 3	-50± 4	-55± 3	-55± 3	-54± 8	-50± 5
KA	-62± 7	-61± 9	-63± 7	-57± 9	-60± 7	-60± 7	-62± 7	-58±22
BIC	-50±15	-44±22	-50±18	-36±29	-50±16	-51±15	-43± 7	-39±21

Values in the table are millivolts $\pm\sigma$. The variation in voltage among the 8 regions in CON are statistically significant, $P<.05$ using ANOVA $F(7,24) = 3.4$. Comparing all groups in CON vs. KA, $P<.005$, paired t test, $df=31$; CON vs. BIC $P<.005$.

The application of VSD as a histological method has produced a voltage map. KA seizures produced a uniform depolarization throughout the hippocampus whereas BIC seizures produced a hyperpolarization. The large σ in the seizing rats is apparently due to biological variability since the technique produced tight data in controls. Future studies will provide a 3 dimensional map of the entire brain to visualize the voltage changes in seizure pathways.

190.3 QUANTITATIVE HISTOFLUORESCENCE OF HIPPOCAMPAL MOSSY FIBER ZINC. C.Y. Montano*, E.J. Kasarskis and D.D. Savage. (SPON: G. Ballam). Dept. Pharmacology, Univ. New Mexico School of Medicine, Albuquerque, New Mexico, 87131 and Dept. Neurology, Univ. Kentucky Medical Center., Lexington, Kentucky, 40536.

6-Methoxy-8-p-toluenesulfonamide (TSQ) has been shown to be a useful fluorescent probe for histochemically detectable zinc in brain. However, utilization of zinc:TSQ fluorescence as a quantitative tool required further characterization of the histofluorescence and development of zinc standards.

Spectrofluorometric experiments were conducted to optimize reaction conditions and determine metal cation specificity. One micromolar zinc was added to 0.003% TSQ (in barbital-acetate buffer, pH 10.2). The excitation and emission peaks for zinc:TSQ fluorescence were found to be 362 and 488 nm respectively. Maximum fluorescence occurred between pH 10 and 11. Zinc:TSQ fluorescence was linear over a range of 100 nM to 10 micromolar zinc. Zinc yielded the highest fluorescence among 16 metal cations tested. Strontium was the only other cation to show appreciable fluorescence. The presence of magnesium or calcium in concentrations up to 10 mM did not affect the fluorescence of 1 micromolar zinc.

Zinc:TSQ histofluorescence was examined using an image analysis system at 32.5X magnification. Zinc standards were made by mixing known amounts of zinc with Immuno-Bed embedding medium. Eight micron sections of the polymerized blocks were cut and mounted onto microscope slides. Eighty microliters of TSQ solution was applied to sections, coverslipped and examined one minute later. Fluorescence, expressed as grey levels, was plotted against the log zinc/100 microns^2. Zinc:TSQ fluorescence was linear over a range 1.5 to 105 femtograms zinc/100 microns^2.

Zinc:TSQ fluorescence in brain tissue was characterized using eight micron horizontal sections of rat ventral hippocampal formation (HPF). Fluorescence was measured in the s. lucidum and adjacent s. radiatum of HPF CA3. Specific mossy fiber zinc fluorescence was defined as the difference in fluorescence between the two regions. Mossy fiber fluorescence increased linearly up to 10 micron thick sections. The fluorescence decay constant in tissue was 107 seconds. Mossy fiber fluorescence varied linearly with TSQ concentrations from 0.5 to 30 mM TSQ. Using four sections each from ten male Sprague-Dawley rats, ventral HPF mossy fiber zinc averaged 25.3 +/- 1.6 femtograms zinc/100 microns^2.

This quantitative histofluorescence technique can be used for the study of hippocampal mossy fiber zinc in a variety of nutritional deficiency, teratological and other pathological states. (Supported by the M.B.R.S. program and NIH-AA06548.)

190.4 **A Novel Method for the Relative Quantitation of Lipofuscin Using a Computer Image Analyses System.** C. Jengeleski M.F. Casanova *, V.E. Koliatsos. Clinical Brain Disorders Branch, NIMH, St. Elizabeths Hospital, Washington, D.C. 20032

Lipofuscin granules normally accumulate in certain populations of large neurons within the central nervous system. Although these granules may balloon cells during aging without loss of function, an overabundant accumulation of lipofuscin may be a sign of neuronal degeneration. Thus, the presence of lipofuscin in small neurons, astrocytes, endothelial cells and free in the neuropil is called pigmentary atrophy and has been causally incriminated in Alzheimer's disease, amyotrophic lateral sclerosis, schizophrenia, Huntington's disease, lipofuscinosis and many other diseases. Present day microspectrophotometric techniques for the quantitation of lipofuscin measure absorbance of aggregate fields and rely on the autofluorescence of lipofuscin. We hereby describe a method for the relative quantitation of lipofuscin which preserves the topographical relation of the cells measured, is not limited by artifacts accrued to fluorescence, has excellent inter-rater reliability and is capable of automated processing. Tissue was formalin-fixed paraffin embedded, cut at 20 um thickness and stained for lipofuscin using a modification of the Gabe's method (Bull Mic appl Paris 3:153, 1953). Shrinkage considerations were avoided by quantification of lipofuscin on sections delimited by natural anatomical boundaries and calculating for area, not volume. A LOATS computer image analysis system interfaced to a Nikon microscope digitized microscopic slide sections and displayed them on a monitor. Software routines allowed calibration of illumination, objectives and areas. Transmission values of lipofuscin staining were isolated using a boundary function and contrast adjusted to all gray levels (color steps) of the displayed image. Re-digitization of the orginal slide with the new coloration scheme gave all pixels having an optical density range similar to lipofuscin. The overall pattern of the image was identical to its corresponding lipofuscin autofluorescence. Multiplication of the resolution by the number of pixels gave the area of the slide covered with lipofuscin. The mean optical density and its variation determined the amount of lipofuscin stained per cell, while both the full range of gray levels and their three dimensional representation gave an idea as to its texture. Area measurements were within the 95% confidence limit as determined by repeated regional computations of a microscale standard visualized at the same magnification as the digitized lipofuscin slides. The method described is not limited to lipofuscin but with the use of special stains it can be applied to the quantitation of most cell components including neuromelanin, iron, calcium and chromatin.

190.5 PHOTOCATALYZED REPLACEMENT OF FLUORESCENT MARKERS WITH A DIAMINOBENZIDINE REACTION PRODUCT. J. H. Sandell and R. H. Masland. Massachusetts General Hospital, Boston, MA 02114.

In 1982 Maranto reported that the fluorescence of lucifer yellow in injected neurons could be converted to an electron-dense product by irradiating the labeled cell with intense blue light in the presence of diaminobenzidine (DAB) (Science, 217: 953-955). Sandell and Masland subsequently showed that the fluorescence of a physiologically accumulated molecule, 5,7 dihydroxytryptamine, could be photoconverted in the same way, yielding a Golgi-like stain of the whole population of retinal indoleamine-accumulating cells. Here we describe an extension of these methods to a wider series of fluorescent molecules.

Our photooxidation procedure has been described (J. Neurosci., 6: 3331-3347, 1986). In most cases a piece of fixed rabbit retina containing fluorescent cells was placed on a slide under a drop of DAB solution (1.5 mg/ml in 0.1 M tris buffer, pH 8.2). The retina was irradiated under a fluorescence microscope, at wavelengths that excite the fluorescence of the molecule which with the particular tissue had been labeled.

The fluorescent molecules that caused photooxidation of DAB included 4,6, diamidino-2-phenylindole (DAPI), lucifer yellow CH, fluorescein, acridine orange, propidium iodide, ethidium bromide, and rhodamine. Their wavelengths range across most of the visible spectrum. Histochemically-induced fluorescence could also cause the photooxidation; examples were the aldehyde-induced fluorescence of 5,7 or 5,6 dihydroxytryptamine or norepinephrine. Immunofluorescent labeling (FITC or rhodamine) also caused photooxidation of DAB. Although most of our experiments were on retinal tissue, the reaction occurred in brain sections and cultured astrocytes as well.

The mechanism of the reaction is incompletely understood. As suggested by Maranto, it is probably an oxidation initiated by the generation of free radicals following excitation of the fluorescent molecule. It is blocked by antioxidants and when oxygen is prevented from reaching the tissue. A successful reaction requires bright fluorescence and strong irradiation.

There is variability in how well different fluorescent molecules react. Our results, however, indicate that a wide range of molecules can be photoconverted in this way. The reacted material is permanent and can be further processed to improve its optical quality. Because the reaction is monitored visually, it can be stopped when the density of reaction product is optimal. The method is compatible with electron microscopy. A limitation is the small size ($\sim$ 1 mm^2) of the field that can be irradiated with adequate intensity through the microscope.

190.6 STAINING OF NEURONS AND THEIR PROCESSES WITH CARBOCYANINE DYES IN FIXED TISSUE. P.Godement*, J.Vanselow*, S.Thanos and F.Bonhoeffer*. Max-Planck-Institut für Entwicklungsbiologie, D-7400 Tübingen.

The fluorescent carbocyanine dyes, diI (1,1'-dioctadecyl-3,3,3'3'-tetramethylindocarbocyanine perchlorate) and diO (3,3'dioctadecyloxacarbocyanine perchlorate) have been shown to be able to provide staining of neurons in vivo and in vitro (Honig and Hume,'85). Here we report that these dyes can also label neuronal and glial cell processes in post mortem brain tissue that has been fixed in aldehyde fixatives, and compare this labeling with that obtained in living tissue. Staining in fixed tissue was done on mouse and chick embryos fixed in 4% buffered paraformaldehyde solution. The dyes were applied to the retina, optic nerve, or retinal fiber layer. The brains were then stored for various periods of time (a few days to several weeks) in buffer at room temperature or at 4°C. Observations showed that i) fine orthograde labeling of axons, including their growth cones and terminal arbors, occurs upon storage of the tissue for periods ranging between a few days to several weeks, depending on the distance the dyes have to travel from the site of application. Staining in mouse embryos aged E13-E18 shows optic axons in the chiasm region (E13), approaching their targets (E14-E16), and, at later stages, ramifying within their targets, representing a diffusion length of 10-12 millimeters; ii) retrograde labeling of ganglion cells, including their dendrites and growing tips, can also be achieved with application of the dyes to the optic nerve or retina in mouse and chick embryos; iii) a comparison of retrograde labeling of ganglion cells in fixed chick retinas with that obtained either in chick embryo retinas kept in vitro, or in rat retinas following application of the dyes in vivo, shows that while in fixed tissue the dye seems to be contained in the outer membrane of cells, outlining their finest processes, in living tissue the dyes are mostly present in the form of intracellular granules which can also provide accurate silhouettes of dendritic processes. Thus, two mechanisms, lateral diffusion of the dyes along the membranes of fixed and living neurons, and their intracellular incorporation and axonal transport in vivo, provide two different ways of obtaining detailed staining of neuronal processes with these dyes in fixed and in living tissue.

The property of diI and diO to stain processes in fixed tissue, and the observation that processes can be stained over long distances with this method, should prove useful for embryological studies, especially of mammalian embryos in which in vivo staining is difficult, and also for neurobiological studies in which in vivo experiments are not possible.

190.7 CHARACTERIZATION OF LOBSTER ABDOMINAL POSTURAL INTERNEURONS AND EXTENSOR AND FLEXOR MOTOR NEURONS USING THE INTRACELLULAR DYE 5,6-CARBOXYFLUORESCEIN. G.M. Bablanian and C.H. Page. Rutgers University, Bureau of Biological Research, Piscataway, N.J. 08855.

We have explored the possible use of the dye 5,6-carboxyfluorescein (Eastman Kodak) as an alternative to the Lucifer Yellow staining method in the lobster, Homarus americanus. This fluorescent dye has been used in the mammalian central nervous system to examine dendritic branching in the superior cervical ganglion (Purves, D. and Hadley, R.D., Nature, 315: 404-406, 1985) and for quantifying dye-coupling in the hippocampus (Rao, G. et al., J. Neurosci. Methods, 16: 251-263, 1986).

Lobster abdominal extensor and flexor motor neurons and postural interneurons were filled with a 5% carboxyfluorescein-0.1 M potassium acetate solution using standard micropipettes (75-100 M ohms) backfilled with 4 M potassium acetate. Carboxyfluorescein was ejected from the electrode with 3-5 sec pulses of pressure (10-30 psi) until the cell was bright yellow (approximately 30 sec to 1 min). Following incubation for 1 to 48 hours at 10°C, to allow for diffusion of the dye, preparations were cleared in a solution of 5% n-propyl gallate in glycerol for two hours, and then viewed using standard epifluorescence.

Ninety percent of all fills attempted were successful. Motor neuron fills showed characteristic dendritic fields, similar to those observed in the best Lucifer Yellow fills, with axonal projections into the extensor and flexor roots (roots 2 and 3) extending for a distance of 6 mm and more. Fills of interneurons have shown similar results with axonal projection running through the hemiconnective for a distance of more than 6 mm. Compared to Lucifer Yellow, carboxyfluorescein-filled pipettes are less likely to clog in high potassium solutions, an advantage when working with marine organisms. Thus, the carboxyfluorescein method is an improvement in dye-filling technique for examining neuronal morphology in the lobster.

190.8 DETECTION OF BIOCYTIN FOLLOWING ITS INTRACELLULAR INJECTION ALLOWS VERSATILITY IN THE LABELING OF RECORDED NEURONS. K. Horikawa and W.E. Armstrong, Dept. Anatomy and Neurobiology, Univ. Tenn., Memphis, The Health Science Center, Memphis, TN 38163.

Interest in the microscopic identification of neurons recorded intracellularly has instigated the use of several injectable markers. We explored the use of biocytin (MW=357), a biotin-lysine complex, attractive because of its low molecular weight, high solubility in water and affinity to avidin, the latter of which has been conjugated to several markers.

Solutions of 4-6% biocytin (Sigma) and 0.5M KCl were made in 0.05M Tris buffers of differing pH, influencing biocytin's net charge. Unbroken electrodes containing a glass microfilament were backfilled and had initial DC resistances of 30-100MΩ. Neurons impaled *in vitro* in hypothalamic explants and hippocampal slices were injected through an active bridge amplifier for 1-20min. Positive current injections consisted of depolarizing 1-2nA pulses (1Hz, 220msec). Negative currents were applied with 0.5nA hyperpolarizing pulses (1Hz, 220msec) on a continuous hyperpolarization of 0.5nA.

Fixed tissue (in 10% formalin) was sectioned at 40-60µm on a cryostat (after soaking in 10-30% sucrose) or Vibratome®. Rinsed sections were incubated 1hr in phospate buffered saline (PBS) containing 1% Triton X-100, then incubated with Avidin D conjugated to fluoroscein or rhodamine (1:200) or ABC solution for 1-2hr (reagents from Vector Labs). For fluorescence microscopy, rinsed sections were mounted in glycerol-PBS and examined with standard filter combinations. With the ABC technique, peroxidase activity was revealed using diaminobenzidine as the chromogen.

Labeling was best with positive currents in neutral or acidic pH (3.5), or negative currents with a pH of 9.0. However, with acidic buffer, electrodes quickly became very resistive. Neurons were recovered after 80% of the injections, with both fluorescence and ABC techniques. Labeling was detected after short injections (1-2min) with good impalements, but with poor impalements was weak even after longer injections. With good impalements, longer injections produced detailed labeling resembling that obtained with Lucifer Yellow or horseradish peroxidase.

Intracellular injection of biocytin is useful in that: 1) it is easily injected from electrodes with small tips but of relatively low resistance; and 2) injection of a single compound gives the experimenter the option of producing fluorescent or opaque images.

190.9 GANGLION CELL STAINING IN THE RAT RETINA BY ANTIBODIES TO MICROTUBULE-ASSOCIATED PROTEIN (MAP) 1. L.J. McKerracher*, R.B. Vallee* and A.J. Aguayo. (SPON: D. Lawrence) Neurosci. Unit Montreal Gen. Hosp., McGill Univ., Mtl., Que., Canada H3G 1A4 and Worcester Foundation Expt. Biol., Shrewsbury, MA 01545.

We have used antibodies raised against high molecular weight bovine brain MAPS (Bloom, G.S., Schoenfeld, T.A., and Vallee, R.B., 1984, J. Cell Biol. 98:320-330) to stain adult Sprague-Dawley rat retinas. Three different monoclonal anti-MAP 1A antibodies exhibited identical staining. In radial cryostat or polyethylene glycol (PEG) embedded sections MAP 1A immunoreactivity is mainly confined to the fiber layer, ganglion cell layer, and the dendritic arborizations in the inner plexiform layer. There is some immunoreactivity in the innermost region of the outer plexiform layer. In the ganglion cell layer the largest cells are most intensely stained, suggesting that the smaller displaced amacrine cells may not be recognized by this antibody.

To determine if MAP 1A immunoreactivity in the ganglion cell layer is restricted to ganglion cells we have used several different approaches: a) in vivo retrograde labelling from axon terminals in the superior colliculus to identify retinal ganglion cell bodies labels nerve cells stained with anti-MAP 1A antibodies. b) extensive retrograde degeneration of retinal ganglion cells after axotomy in the optic nerve appears to be associated with a marked loss of immunoreactivity in the retina. c) double labelling of PEG sections with the nuclear stain DAPI and with anti-MAP 1A antibodies demonstrates that not all of the cells in the ganglion cell layer are antibody-labelled, suggesting that displaced amacrine cells may not immunoreact with anti-MAP 1A antibodies.

In contrast to anti-MAP 1A labelling, two different monoclonal antibodies to a related protein, MAP 1B (Bloom, G.S., Luca, F.C., and Vallee, R.B., 1985, Proc. Natl. Acad. Sci. 82:5404-5408), stain all of the different layers of the retina. Thus, high molecular weight MAPS are present throughout the retina yet MAP 1A appears to predominate in the ganglion cell somata and their axonal and dendritic processes. Although MAP 1A has a widespread distribution in many regions of the nervous system (Bloom et al. 1984, op. cit.) anti-MAP 1A antibodies should be valuable as a ganglion cell marker in the rat retina.

190.10 PHOTODEGENERATION OF NEURONS, N. Franceschini[X], S. Picaud[X] and H.J. Wunderer[X] (SPON: N. Ropert). C.N.R.S., Lab. de Neurobiologie, 31, Ch. J. Aiguier, 13402 Marseilles, France.

The fly retina is a crystalline matrix in which small neurons can be studied in vivo in their natural environment. Using epi-fluorescence microscopy, single photoreceptor neurons can be visualized in the intact animal if one simply neutralizes refraction at the corneal surface with a drop of water (Franceschini, N. et al., Science, 213, 1264, 1981). We report here that neurons can be induced to degenerate if they are irradiated in the presence of a dye added to the extracellular fluid.

Sulforhodamine 101, a green absorbing dye, was applied to the extracellular space of the retina of the fly musca domestica and a selected patch of receptor neurons was irradiated for 30 minutes with green light (546nm Hg-line) under a conventional epifluorescence microscope. Two kinds of phenomena were observed depending on the survival time after the irradiation:

1) at zero survival time, irradiated neurons displayed a dark, electron dense cytoplasm that allowed them to be easily recovered, traced and scrutinized both with the light- and electron microscope. The dark axonal staining was fine-grained and did not obscure presynaptic specializations;

2) after several days survival time, the photo-exposed neurons started to be phagocytosed by the surrounding pigment cells in much the same way as degenerated neurons are phagocytosed by glial cells in vertebrates. Several pieces of evidence suggest that the "photodegeneration" we have observed is actually based on "photosensitization" --a deleterious effect that is readily known to alter excitable membranes, whether the dye is applied intra- or extracellularly (Oxford, G.S. et al., J. Membr.Biol., 36, 159, 1977).

In conclusion preselected neurons can be induced to degenerate on command in the nervous system of a living and adult animal. "Photodegeneration" can be achieved with single cell resolution and does not require any mechanical contact with the neurons. The simplicity, precision and adaptability of the procedure offer interesting prospects for both anatomical and physiological studies of neural networks.

190.11 IN SITU FIXATION OF RAT SPINAL CORD USING MICROWAVE RADIATION. D.J. Gower, C. Hollman and M. Tytell. Section on Neurosurgery, Department of Surgery, and Department of Anatomy, Wake Forest University Medical Center, Winston-Salem NC 27103.

The spinal cord is resistant to fixation by simple immersion due to its muscular, bony, and dural investitures. Removal of the cord before fixation may structurally alter the tissue. Furthermore, during the time required for removal, early postmortem degenerative changes may occur, interfering with the evaluation of spinal cord injury. We have examined the use of in situ microwave-facilitated fixation of the spinal cord to improve the quality of tissue preservation and to reduce the occurrence of early postmortem anoxia.

Adult male rats were anesthetized and decapitated, and several centimeters of spinal column with surrounding muscles were removed. In one group (n = 15) the spinal cord was carefully dissected out and fixed by immersion in Bouin's fluid for a period of at least 36 hours. The time necessary for dissection ranged from 10 to 20 minutes. In the second group (n = 22) each tissue block was placed in 100 ml of Bouin's solution and exposed to microwave energy in a 600 watt microwave oven (Amana Corp.) to raise it to temperatures ranging from 60° to 82° C for one to five minutes. The microwave-fixed spinal cords were then allowed to cool to room temperature, dissected out, and embedded in paraffin. Spinal cords from both groups were stained with hematoxylin and eosin and compared to tissue prepared by perfusion fixation. Tissue sections were also examined immunohistologically with antibody against heat shock protein-70 (HSP-70; gift of Dr. William Welch, Cold Spring Harbor Laboratory), a stress protein whose synthesis may be elevated in slowly dying, anoxic tissue.

In the immersion-fixed spinal cords, tissue preservation, particularly of white matter, was clearly inferior, and HSP-70 was present in small quantities, primarily in the white matter. In the spinal cords fixed with microwave energy, there was no detectable synthesis of HSP-70, and the morphology of neurons and glia in the gray matter and axons in the white matter was comparable to that obtained with perfusion fixation.

These results indicate that microwave-facilitated fixation at 60° C for 5 minutes is comparable to perfusion fixation in quality of tissue preservation and is far superior to dissection of the unfixed cord for immersion fixation. Microwave-facilitated fixation thus allows simple and very rapid processing of tissues.

190.12 DESIGN OF AN INVERTED "SLAM " FREEZER FOR ULTRASTRUCTURAL-MICROANALYTICAL STUDIES OF IN VITRO BRAIN SLICES. C.S. Wallace, R.E. Crang*, and W.T. Greenough. Neur. & Behav. Biol. Prog. and Depts. Plant Biol., Psychol., and Anat. Sci., and Center For Elec. Micr., Univ. of Illinois, Urbana-Champaign, IL 61801.

For certain electron microscopic procedures, such as ultrastructural x-ray microanalysis, in which the in situ location of cellular constituents is of interest, quick freezing is the method of choice for tissue preservation. In addition, quick freezing may provide a more accurate representation of in vivo morphology as compared to that obtained by conventional chemical fixation methodologies. Of the freezing methods available, the cold-metal block method, such as that refined by Heuser & Reese, has the advantage over other freezing methods of allowing uniform freezing over a large surface, which has proven particularly useful for examining both peripheral nerve-muscle preparations and CNS regions such as the hippocampus. However, because most currently available "slam" freezing techniques require tissue to be suspended in an inverted position prior to freezing, tissue for which electrical stimulation may be desired, such as hippocampal slices, cannot be frozen directly in the tissue chamber in which electrical stimulation occurs. We describe here an inverted slam type freezer that plunges a liquid nitrogen cooled polished copper freezing surface onto slices of tissue maintained in vitro. This design is intended to facilitate studies of the events that occur at short intervals following electrical stimulation by minimizing the handling of tissue during the period between incubation and freezing and by providing better access for stimulating and recording electrodes immediately prior to freezing. Studies are currently in progress to determine the best methods for achieving the shortest possible time interval between electrical stimulation and freezing of tissue.

191.1 RESPIRATORY SINUS ARRHYTHMIA IN NORMAL INFANTS AND INFANTS WHO SUBSEQUENTLY DIED OF SIDS. K.A. Kluge*, R.M. Harper, V.L. Schechtman, A.J. Wilson* and D.P. Southall* (SPON: E.G. Zimmermann). Dept. of Anatomy and Brain Research Inst., UCLA, Los Angeles, CA 90024; Dept. of Medical Physics, Univ. of Sheffield, U.K.; and Cardiothoracic Inst., Brompton Hospital, London.

Reduced heart rate variability has been found in infants who subsequently died of the sudden infant death syndrome (SIDS) (Schechtman et al., in preparation), as well as in siblings of SIDS victims (Harper et al., Sleep 5:28, 1982) and "near-miss" for SIDS infants (Leistner et al., J. Pediatr. 97:51, 1980). This study examines a component of heart rate variability, respiratory sinus arrhythmia, the respiratory-related modulation of heart rate, in control infants and in infants who subsequently became victims of SIDS, in an attempt to isolate group differences that might elucidate the mechanism of death.

Twenty-four hour recordings of ECG and respiratory movements were obtained from 6,914 full-term infants. Of these, 18 recordings of infants aged 2-65 days who subsequently died of SIDS and 52 recordings of age-matched controls were submitted to analysis. Median respiratory rate and interquartile range were used to classify each nighttime (7pm-7am) minute of data as waking (AW), quiet sleep (QS), rapid eye movement sleep (REM), or indeterminate state using an automated sleep state classification procedure (Harper et al., EEG Clin. Neurophysiol., in press). Heart rate and respiratory waveforms were sampled at 16 samples/s and input to a spectral analysis package that calculated autospectra for heart rate and respiratory waveform and their cross-spectra for each 1-min epoch. Two measures of respiratory sinus arrhythmia were computed: "extent of sinus arrhythmia" (XSA), the logarithm of the power of the heart rate autospectrum in the band containing the peak in the respiratory autospectrum, and "coherence of sinus arrhythmia" (CSA), the cross-spectral coherence between heart rate and respiratory rate in this same band. Median XSA and CSA values in each sleep state for infants who subsequently died of SIDS and control infants were then compared using t tests.

For both the younger infants (those recorded in the first month of life) and older infants (those recorded after the first month), XSA values for the SIDS victims were significantly lower than those of the control infants during REM sleep ($p < .05$ and $p < .025$, respectively) and AW ($p < .025$ and $p < .05$). CSA values of the SIDS victims and controls were not significantly different in any sleep state or age group. The state-related reduction in respiratory modulation of heart rate variation suggests that an interaction between forebrain and brainstem cardiorespiratory areas is inappropriately functioning in victims of SIDS.

Supported by HD-3-2830 and HD-22695.

191.2 DIFFERENCES IN THREE TYPES OF HEART RATE VARIATION IN NORMAL INFANTS AND VICTIMS OF THE SUDDEN INFANT DEATH SYNDROME. V.L. Schechtman, R.M. Harper, K.A. Kluge*, A.J. Wilson* and D.P. Southall*. Brain Research Institute and Dept. of Anatomy, UCLA, Los Angeles, CA 90024; Dept. of Medical Physics, University of Sheffield, U.K., and the Cardiothoracic Institute, Brompton Hospital, London.

Infants at risk for the sudden infant death syndrome (SIDS) exhibit lower overall heart rate variability than do controls. The purpose of this study was to determine which types of heart rate variation are diminished in infants who subsequently succumbed to SIDS.

Twelve-hour portions (7pm to 7am) of 24-hour recordings of ECG and respiratory movements were obtained from 18 SIDS victims and 54 control infants 2 to 65 days of age. Respiratory rate and variability were used to classify each minute of data as quiet sleep (QS), rapid eye movement sleep (REM), waking (AW), or indeterminate state (Harper et al., EEG Clin. Neurophysiol., in press). A peak/trough algorithm (Schechtman et al., in preparation) was used to determine for each minute the median extent of heart rate variation in three period bands (.9-3 s, respiratory-related heart rate variation; 4-7.5 s, mid-frequency heart rate variation; and 12-30 s, low-frequency heart rate variation). The median extent of each type of variation was determined by sleep state for each recording.

Subjects were divided into two age groups (2-30 days and 40-65 days), and one-way ANOVAs were performed for each measure in each sleep state for each of the two groups. Because cardiovascular variables change rapidly over the first month of life, age was used as a covariate in analyses of the younger age group. Since overall heart rate variation has been shown to vary with base heart rate (Mazza et al., Pediatr. Res., 14:232, 1980), each analysis was repeated with heart rate as a covariate to determine the contribution of basal rate to reduction of each type of variation.

In both age groups, the magnitude of respiratory-related heart rate variation was lower in SIDS victims than in controls during REM and AW. In the younger infants, mid- and low-frequency variation were also reduced during REM and AW. When heart rate effects were covaried, the SIDS victims in both age groups continued to show reduced respiratory-related variation during both REM and AW, and SIDS victims under 1 mo continued to show reduced mid- and low-frequency heart rate variation during AW. These results indicate a reduction in heart rate variation over a wide range of frequencies in infants who later died of SIDS, and that these reductions in variability are not mediated by the same factors that control basal heart rate.

Supported by HD-3-2830 and HD-22695.

191.3 **DISSOCIATED CELL CULTURES OF GUINEA PIG PREVERTEBRAL GANGLIA: PHYSIOLOGICAL AND CYTOCHEMICAL CHARACTERISTICS.** S.G. Matsumoto*, D. L. Kreulen and R. Gruener. Depts. Physiol. and Pharmacol., Univ. Ariz., Coll. Med., Tucson, AZ 85724.

The neurons of the prevertebral sympathetic ganglia (celiac, inferior and superior mesenteric) were grown in dissociated cell culture for periods of up to 16 weeks. The neurons were grown in both mass cultures (approximately 1,000 neurons/cm^2) and in microcultures (one to several neurons confined to a collagen drop ca. 0.5 mm diameter). The neurons were cultured in MEM with 2.5% guinea pig serum, NGF, and antibiotics added. In some instances conditioned medium (CM) obtained from cultures of non-neuronal cells derived from the gastrointestinal tract was added.

Immunoreactivity (IR) for the peptides NPY, Somatostatin (SOM) and VIP was observed in the cultures derived from 30-45 day gestation guinea pigs. The percentage of the neurons displaying IR for the peptides was: NPY (60%), SOM (30%) and VIP (<1%). Peptide-IR was observed in the somata after as little as 4 days in-vitro. The relative number of neurons displaying a given peptide-IR did not change over time from 4 days to over 5 weeks although there was an increase in the number of intensely-staining neurons. Cells grown in CM for 14-21 days showed fewer NPY-IR neurons (30%) without a significant change in total cell number.

Using standard intracellular recording techniques we have observed no spontaneous synaptic activity under control culture conditions. The range of resting potentials (-60 to -80 mV) and the action potential amplitudes (60-90 mV) obtained were comparable to those observed in the intact ganglia in-vitro. Patch clamp recordings, in the cell- attached mode, have been used to examine single channel activity in the neurons. The recordings were obtained 1-5 days after plating. In control cells (i.e. pipets containing only extracellular recording medium) channel activity was rarely observed when the patch was maintained at a holding potential of -80 mV. A concentration-dependent increase in channel openings (inward current) was observed when arginine vasopressin (AVP) was present in the pipet (10-100 nM). In three cases, sequential recordings (3 patches with pipets containing 0, 10nM and 100 nM AVP) from the same neuron showed this dose-dependent effect of AVP. The currents reverse at approximately -20 mV. AVP is a suspected mediator of a slow excitatory synaptic potential in the ganglia. VIP at a concentration of up to 10 uM had no effect.

191.4 NEUROPEPTIDE Y SYNTHESIS IN SUPERIOR CERVICAL GANGLION DISSOCIATED CELL CULTURE. K. Marek* and R. Mains. Dept. Neuroscience, Johns Hopkins University, Baltimore, MD. 21205.

Neuropeptide Y (NPY) content and synthetic rate have been measured in rat superior cervical ganglion (SCG) dissociated cell culture. Cultures were maintained in either medium containing 5% rat serum or in complete serum free medium (CSFM) for up to 28 days. NPY content was measured by gel filtration and radioimmunoassay. Synthetic rate was determined after incubation in medium containing [^{3}H]tyrosine followed by immunoprecipitation and SDS-PAGE. The synthetic rate of NPY in day 14 cultures was 0.002 fmole/neuron/h. Similar experiments using [^{35}S]methionine to label SCG neurons, followed by SDS-PAGE or gel filtration, showed that proNPY was processed into NPY and a roughly 30 amino acid C-terminal peptide. Tryptic peptide analyses were used to compare the labeled rat NPY to authentic human NPY, which have identical amino acid sequences. Intact C-terminal peptide was compared in several HPLC systems to authentic human C-terminal peptide. About 30% of all cultured SCG neurons were immunostained for both NPY and the C-terminal peptide of proNPY.

Norepinephrine (NE) content, plus NE, acetylcholine (ACh) and NPY synthetic rates have been measured simultaneously in the cultures. NE levels were measured by RP-HPLC with electrochemical detection and synthetic rates were determined following incubation with [^{3}H]tyrosine or [^{3}H]choline followed by RP-HPLC. The ratio of NE:NPY synthesis was 250:1 in day 14 cultures maintained in either rat serum or CSFM. A developmental profile of NPY in SCG cultures showed an increase in synthetic rate from 0.0002 fmole/neuron/h at day 3 to 0.004 fmole/neuron/h at day 18, similar to that previously shown for NE (Mains,R. and Patterson,P., J Cell Biol., 59:361, 1973). SCG cultures showed transmitter phenotype plasticity as demonstrated by the increase in ACh synthesis in cultures grown with cholinergic inducing factor. Experiments are underway to determine the relative effects of further alterations in culture medium on NPY, NE and ACh synthesis and secretion.

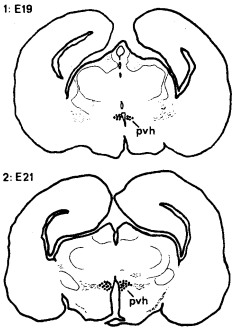
191.5 DEVELOPMENT OF THE SPINAL PROJECTION OF THE HYPOTHALAMIC PARAVENTRICULAR NUCLEUS IN THE RAT. E.A.J.F. Lakke* and J.B. Hinderink* (SPON: P.G.M. Luiten). Lab. Anatomy & Embryology, University of Leiden, The Netherlands.

The paraventricular nucleus of the hypothalamus (PVH) provides a direct link between the hypothalamus and the preganglionic autonomic cell groups in brainstem and spinal cord. It influences the glucose homeostatic mechanism (Luiten et al., Progr. Neurobiol., 28:1-54, 1987), probably by modulating the activity of the adrenals by both neuroendocrine and autonomic pathways. Since glucose homeostasis is of utmost importance to the newborn animal, the neural circuitry necessary for its regulation has to develop before birth.

Timed pregnancy WAG rats were used, starting from the 16th day post-coitem (E16). The spontaneously breathing pregnant dams were operated under continuous flow O_2/NO_2 anesthesia. Injections with 5% WGA-HRP were made into the spinal cord of the fetuses through a small incision in the uterine wall. The fetuses were sacrificed after a 24 hrs. survival time and perfused transcardially with normal saline followed by a phosphate buffered (0.1 M, pH 7.2) solution containing 1.25% glutaraldehyde and 1% paraformaldehyde. The 40 µM serial freeze sections were processed for WGA-HRP histochemistry using TMB as the chromogen.

Though WGA-HRP was transported retrogradely from thoracic injection sites to the medullary raphe nuclei at E17 (injected at E16), no labeled cells were found in the PVH until E19 (injected at E18). These labeled cells are situated close to the ventricular wall (fig 1). At E21, i.e. just prenatally, the quantity of cells has increased, but they are still localized periventricular. The lateral descending fiber bundle of the PVH is labeled (fig 2). Postnatally the position of labeled cells shifts laterally, at P4 they have clearly separated from the ventricular wall.



The spinal projection of the PVH develops before birth, the first fibers arriving in the thoracic spinal cord between E18 and E19. This is early, since the PVH only becomes recognizable as a morphological entity at E17 (Hyyppä M., Z. Anat. Entwickl.-Gesch., 129:41-52, 1969). Neurons in the PVH start projecting their axons toward the spinal cord shortly after their birth from the ventricular matrix.

191.6 **GENDER DIFFERENCE IN A SUBPOPULATION OF SUPERIOR CERVICAL GANGLION NEURONS.** L.L. Wright and P.J. Calecas*. Boston University School of Medicine, Boston, MA 02118.

The number of superior cervical ganglion (SCG) neurons is equivalent in males and females at birth. However, by 15 days of age, males have significantly more neurons than females. This difference arises from differential neuron death and persists in the adult. The present study was undertaken to determine whether this difference exists uniformly throughout the ganglion, or only in a subpopulation of SCG neurons.

To study subpopulations of SCG neurons, one or both of the major postganglionic nerves was severed, thereby axotomizing and killing the neurons projecting through the severed trunk(s), and leaving for study those that project through the remaining nerve(s). Bilateral transection of the internal carotid nerve (ICN), external carotid nerve (ECN), or both nerves (ECN-ICN) was performed on male and female Sprague-Dawley rats within 36 hours after birth. All groups were compared with littermate sham-operated controls. At the age of surgery, there was no gender difference in number of SCG neurons (males have 30067, n=7, se=1768; females have 29264, n=5, se=2307). Animals were sacrificed on postnatal day 15 and their SCGs were removed, fixed and embedded. Neuronal nuclei were counted from thionin stained paraffin sections, and the total number of neurons per ganglion was calculated, correcting for sampling interval and split nuclei.

At 15 days of age, all three groups of sham-operated females had significantly fewer SCG neurons than their respective sham-operated male group, confirming our previous work. The number of neurons remaining in the SCG following neonatal transection of the ICN were not different in males and females, while the number remaining following transection of the ECNalone or in conjunction with the ICN was greater in males than in females. We conclude that the gender difference in numbers of SCG neurons lies in large part in those neurons projecting through the ICN. The number of neurons projecting out the ECN is equivalent in males and females.

NUMBERS OF SUPERIOR CERVICAL GANGLION NEURONS AT 15 DAYS OF AGE
(N per group, standard error of the mean)

	Males	Females
ECNX	12969 (11,1454)	9684 (12,1144)
littermate sham op.	29003 (12,983)	25634 (19,900)
ICNX	12226 (7,2040)	12516 (11,1411)
littermate sham op.	30034 (6,1412)	24395 (6,2694)
ECN-ICNX	3463 (16,517)	3882 (30,386)
littermate sham op.	32162 (4,1545)	27528 (6,1769)

191.7 ONTOGENY OF ADRENERGIC FIBERS IN THORACIC SPINAL CORD IN RELATIONSHIP TO RETROGRADELY LABELED SYMPATHETIC PREGANGLIONIC NEURONS. H.Bernstein-Goral & M.C.Bohn. Department of Neurobiology and Behavior, State University of New York, Stony Brook, New York 11794

Epinephrine and its biosynthetic enzyme, phenylethanolamine N-methyltransferase (PNMT), are phenotypic markers for adrenergic neurons. PNMT is initially expressed in neuroblasts in the presumptive C1 region in the ventral lateral medulla oblongata on embryonic day 14 (E14; Bohn, et.al., Devel.Biol.,114:180,1986). In the adult rat, adrenergic bulbospinal axons from C1 neurons project to the intermediolateral cell column of thoracic spinal cord (Ross,et.al.,J.Comp.Neurol.,228:168,1984). To describe the development of this system, we have studied 1) the appearance and ontogeny of PNMT-immunoreactive (IR) fibers using an antiserum raised against rat PNMT, 2) epinephrine levels in thoracic spinal cord by HPLC, and 3) the relationship of adrenergic fibers to retrogradely labeled sympathetic preganglionic neurons (SPGN) at various postnatal ages.

PNMT-immunoreactive fibers are first observed in the embryonic lateral funiculus of spinal cord on E15. By E16, PNMT-IR fibers are located in thoracic spinal cord gray matter, exclusively associated with preganglionic nuclei including n.intermediolateralis principalis (IML) and funicularis (ILF), n.intercalatus (IC), and central autonomic nucleus (CAN). For two weeks after birth, there is a marked increase in the density of PNMT-IR fibers that declines at older ages. The changing fiber density is paralleled by epinephrine levels in thoracic spinal cord, which are 20 fold greater on postnatal day 10 compared to the adult. Neonatal adrenalectomy does not reduce spinal cord levels of epinephrine.

To study the developmental relationship of adrenergic fibers to identified SPGN, the adrenal medulla and superior cervical ganglion (SCG) were injected with the fluorescent retrograde tracer, true blue. Spinal cord sections containing true blue labeled preganglionic neurons were also processed for PNMT-IR. At postnatal ages 4,7,15,20,30,and 60 days, dense plexuses of PNMT-IR varicose axons enveloped every true blue labeled PGN soma and proximal dendrite, as well as many unlabeled neurons. In the IML and ILF, true blue labeled soma were silhouetted by PNMT-IR varicosities, while dense transverse bundles of PNMT-IR axons coursed between clusters of neurons in IC and CAN. Longitudinal PNMT-IR axons were observed along the ependymal cells of the central canal.

These results demonstrate that adrenergic axons are present in sympathetic nuclei of thoracic spinal cord during embryonic life. In the postnatal rat, sympathetic preganglionic neurons which project to SCG and adrenal medulla receive a rich plexus of PNMT-IR fibers suggesting that these neurons may be postsynaptic targets for adrenergic bulbospinal fibers. In the neonatal rat, these associations are particularly rich and epinephrine levels are high suggesting that epinephrine may play a role in spinal cord development and early autonomic function.

191.8 NEURONS OF THE AVIAN CILIARY GANGLION CONTAIN SOMATOSTATIN. M .L. Epstein and J. L. Dahl. Depts. of Anatomy and Pharmacology, University of Wisconsin, Madison, WI 53706.

Immunocytochemical staining showed the presence of somatostatin-immunoreactivity (SOM-IR) in cell bodies of ganglia removed from newly-hatched chick and quail. Fibers showing co-localization of SOM-IR and choline-acetyltransferase immunoreactivity (ChAT-IR), a marker for cholinergic neurons, were found in the choroid layer of the eye. Immunostaining of the ciliary ganglion showed the presence of ChAT-IR in large ciliary neurons and a less intense ChAT-IR in the smaller choroidal neurons, which also contained SOM-IR. Somatostatin immunoreactivity in ganglia from hatched chicks eluted from high pressure liquid chromatography in the same positions as authentic SOM 14 and 28. We conclude that SOM is found in cholinergic choroidal neurons in the avian ciliary ganglion.

Supported by NIH DK32978.

191.9 ONTOGENY OF NEUROTRANSMITTERS/HISTOCHEMICAL MARKERS IN NEURONS OF THE PARACERVICAL GANGLION OF THE FEMALE RAT. K. Sullivan*, R.E. Papka and H.H. Traurig. Dept. of Anatomy and Neurobiol., Univ. of KY., Lexington, KY 40536.

The chemical neuroanatomy of the paracervical ganglia (PG), which provides much of the efferent autonomic innervation to the female reproductive tract, has been a focus of our research. Currently, we are interested in possible developmental interactions between steroid hormones and PG neurons and/or their chemical "signature". Prior to investigating such interactions, we undertook a baseline study of the developmental expression of histochemical markers exhibited by untreated neurons. Acetylcholinesterase(ACHE)$^+$ ("cholinergic"), tyrosine hydroxylase (TH)/dopamine beta hydroxylase(DBH)$^+$ ("noradrenergic"), neuropeptide tyrosine(NPY)$^+$, and vasoactive intestinal polypeptide(VIP)$^+$ markers are present in adult PG; thus, these were examined in the present study. Female rats were bred and litters killed at 0, 2, 4-5, 8-10, 15-16, 25-26 and 36 days postnatal. PG were removed and processed by standard procedures for immunofluorescence of neuropeptides and histochemical localization of ACHE. On day 0 the PG consisted of neuroblast-like cells, e.g. tightly packed, small, rounded or angular cells. ACHE staining revealed a compact PG in which neurons were difficult to discern; only a small amount of light-staining reaction product was present. However, DBH/TH$^+$ cells were evident at day 0 and were often clustered resembling SIF cells; thus, it was difficult to identify principal neurons. VIP$^+$ cells were numerous and evenly scattered among a large population of non-VIP$^+$ cells. A large population of cells weakly positive for NPY were present at day 0. Few ACHE$^+$ cells were evident at 4 days of age; however those present contained intensely stained pockets of reaction product. By day 4 and clearly by day 8 TH/DBH$^+$ principal neurons and SIF cells could be distinctly identified. With increasing age the number of intensely immunoreactive NPY$^+$ cells increased. No remarkable changes over time were evident with the VIP$^+$ neurons. By 26 and 36 days postnatal, the PG resembled that of the adult - the neurons were distinctly angular and multipolar, there was an increase in neuropil clearly separating the neurons; numerous ACHE$^+$, VIP$^+$ and NPY$^+$, but few TH/DBH$^+$ neurons were observed. It appears that cells with noradrenergic characteristics and VIP$^+$ cells are identifiable earliest in postnatal life relative to those with "cholinergic" markers or NPY. However by puberty the NPY$^+$ cells were most numerous followed by VIP$^+$, ACHE$^+$, and then noradrenergic. This study will serve as a baseline or library of information for future investigations of interactions of steroid hormones and ontogenetic expression of neurotransmitters/histochemical markers in PG neurons. (Supported by BRSG RR05374 and NIH Grant NS22526).

191.10 HORMONAL REGULATION OF NEUROTRANSMITTER SYNTHESIZING ENZYMES AND NEUROTRANSMITTERS IN AUTONOMIC GANGLIA. B.M. Schroeder* & R.W. Hamill. Depts. of Neurology & Medicine, Univ. of Rochester/Monroe Community Hospital, Rochester, NY 14603.

Gonadal steroids appear to influence a variety of morphological and neurochemical characteristics of peripheral sympathetic neurons. Previous studies by a number of investigators indicate that cell number, synapse number, transmitter enzyme activity and plasticity may all be influenced by hormonal factors. The present studies in the sympathetic hypogastric ganglion (HG) are an extension of previous investigations which indicate that testosterone (T) exerts regulatory effects on tyrosine hydroxylase (TH) activity, a marker of noradrenergic functional activity. The current experiments were designed to determine: 1. if T regulates neurotransmitter levels as well as TH in the HG and its major target the vas deferens (VD), and 2. if T regulates TH in the major pelvic ganglion (PG), an autonomic ganglion which is a mixed parasympathetic and sympathetic structure.

Adult Sprague-Dawley rats received either sham-operation or bilateral castration at approximately 60-70 days of age and were randomized to vehicle treated or T replacement treated groups. Animals were killed at various times after surgery and HG, PG, and VD were removed. TH activity was measured with a radiochemical assay and HPLC with EC detection measured transmitter molecules. Within one month, HG TH activity fell by about 85% (control:1661±209 pm/hr; castrates: 280±58 pm/hr: X ±S. E. M.). Within the same time frame HG NE levels decreased 30% and DA 44%. In the target VD there was a 65% decrease in TH activity but there was no change in NE levels (C=748±68.8; Cx=856±52.6 ng/-organ), however VD DA levels fell by approximately 50%. T treatment reversed these changes. Studies of the PG revealed that T regulates TH activity in a manner similar to the HG: TH activity fell by 80% within 4 weeks of castration and T treatment reversed these changes. Thus, gonadal steroids regulate transmitter molecules and enzymes within ganglia and the change in transmitter levels is delayed; also alterations occur initially within cell bodies before their axon terminals. Additionally DA appears to be altered before NE. Furthermore, since T regulates components of the PG (a mixed sympathetic and parasympathetic ganglia) as well as the HG, gonadal steroids exert a broad range of changes in various components of the peripheral autonomic nervous system.

191.11 **NEUROTRANSMITTER METABOLISM IN PERIKARYA AND TERMINALS OF NEONATALLY DENERVATED OR HYPERINNERVATED SYMPATHETIC NEURONS.** Arnold J. Smolen and Patricia Beaston-Wimmer*. Dept. of Anatomy, The Medical College of Pa., Philadelphia, PA 19129.

The early postnatal period represents a time of rapid developmental changes in neurons in the superior cervical sympathetic ganglion (SCG) of the rat. In the present series of experiments, we examined the development of SCG neurons in two experimental conditions: one that results in permanent denervation of the sympathetic neurons and one that results in hyperinnervation of some of these neurons. Turnover of the neurotransmitter, norepinephrine (NE), was measured following synthesis blockade with alpha methyl paratyrosine, and was used as an index of sympathetic activity in neuronal perikarya and terminals.

In the first experiment, the cervical sympathetic trunk was resected at birth, resulting in a permanent deafferentation of SCG neurons. We observed that populations of neurons that project to different targets respond differently to neonatal deafferentation. NE content and turnover are normal in sympathetic terminals in the submandibular gland (SMG), while in the iris NE content is reduced by one-third, and there is no detectable turnover.

In the second experiment, we eliminated approximately half of the SCG neurons at birth by cutting their axons in the internal carotid nerve (ICN) unilaterally. The neurons that project through the external carotid nerve (ECN) survive this manipulation and become hyperinnervated by preganglionic axons. In this case, NE content and turnover in the SCG is only reduced by 25%, indicating that each surviving neuron, on average, contains more NE than normal and demonstrates increased turnover of transmitter. There is no detectable turnover of NE in the ipsilateral iris, which is completely denervated following ICN section. The pineal gland receives bilateral innervation from the SCG through the ICN, and therefore is partially denervated after neonatal section of one ICN. In this region, both levels and turnover of NE are normal, indicating that the intact innervation from the contralateral unoperated side is capable of compensating for the loss of the ipsilateral input. The SMG receives its sympathetic innervation through the ECN from neurons that survive section of the ICN. Increased activity of the terminals of these hyperinnervated neurons is expressed as an increased turnover of NE in the SMG, although the content of NE is unchanged from controls.

We conclude that, in general, transsynaptic influences are important in regulating neurotransmitter metabolism in developing sympathetic neurons. In some instances, however, development can proceed normally in the absence of transsynaptic influences.

(Supported by the NIH Grant NS15952 to A.J.S.)

191.12 CATECHOLAMINE LEVELS AND TURNOVER IN THE SYMPATHETIC NERVOUS SYSTEM OF SPONTANEOUSLY HYPERTENSIVE RATS H. Trenchard, P. Beaston-Wimmer*, K.F. Greif and A.J. Smolen. Dept. of Biology, Bryn Mawr College, Bryn Mawr, PA 19010 and Dept. of Anatomy, Medical College of Penna., Philadelphia, PA 19129.

The Spontaneously Hypertensive Rat (SHR) develops abnormalities in blood pressure regulation during the first two postnatal months which resemble human essential hypertension. It has been proposed that increased sympathetic nerve activity during the developmental period plays an important role in the etiology of the hypertension. As a measure of sympathetic activity, we assayed the content and turnover of norepinephrine (NE), the transmitter used by the sympathetic postganglionic neurons, in both SHR and in the related normotensive strain, the Wistar-Kyoto (WKY).

Levels of norepinephrine in the superior cervical ganglion (SCG) and its targets, the iris, pineal and submandibular gland(SMG) were compared in male SHR and WKY rats in the prehypertensive stage (6 weeks postnatal) and after hypertension is established (16 weeks). Catecholamines were extracted with perchloric acid and absorbed on alumina and quantified by use of HPLC with electrochemical detection. Turnover of catecholamines was determined by treatment for 3 hr with alpha-methylparatyrosine methyl ester to block new synthesis (Smolen et al, Dev. Brain Res. 23: 211, 1985).

NE levels in the SCG of 6 week prehypertensive SHR rats were twice that in age-matched WKY rats. Levels of NE were also elevated in the iris of 6 week SHR rats. In contrast, levels were significantly reduced in the pineal of SHR rats of the same age and equal in the SMG. At 16 weeks, when hypertension is established, NE levels in the SCG, iris and SMG of SHR rats were only slightly higher than in the normotensive WKY. Levels of NE in the pineal gland remained lower in SHR rats at 16 weeks.The continuous depression of NE levels in the pineal will require further investigation.

Turnover of catecholamines was elevated in the SCG and iris of 6 week SHR rats, and was reduced by more than ten-fold in the pineal. Turnover was not measurable in the SMG in either SHR or WKY rats at six weeks. At 16 weeks, turnover was slightly higher in the SCG and iris of SHR rats. However, turnover was significantly greater in the SMG of SHR rats, and remained reduced in the pineal. These results suggest that selective changes in turnover, dependent on the type of target, may occur. Since SCG innervation to the SMG is primarily to blood vessels, the increased turnover after the establishment of hypertension may reflect permanent changes in vascular innervation.

Supported by grants from the American Heart Association (PA Affiliate) and USPHS to AJS, and a grant from the NSF to KFG.

191.13 SYMPATHETIC NEURONAL CONTROL OF CELL REPLICATION IN DEVELOPING RAT HEART AND KIDNEY: EFFECTS OF NEONATAL CENTRAL CATECHOLAMINERGIC LESIONS. S.F. Stasheff*, W.L. Whitmore*, F.J. Seidler*, K.L. Queen* and T.A. Slotkin (SPON: A.L. Sylvia). Dept. of Pharmacology, Duke Univ. Med. Ctr., Durham, NC 27710.

Recent studies suggest that norepinephrine released by sympathetic nerves serves to control the timing of cellular replication and differentiation in peripheral tissues. In the current study, this hypothesis was evaluated by central lesioning of neonatal rats with 6-hydroxydopamine (6-OHDA, 100 µg intracisternally on postnatal day 1 and 150 µg i.c. on day 6), a treatment known to attenuate sympathetic tone without physically destroying peripheral neurons. The degree and specificity of the lesion were verified by measurements which showed near-total depletion of CNS dopamine and norepinephrine content, with maintenance of peripheral norepinephrine stores. Adverse effects of 6-OHDA on development were noted in the heart but not the kidney. During the first two postnatal weeks, cardiac cell acquisition, as measured by DNA content, was slowed in the 6-OHDA group, and although some catch-up occurred by the end of the second week, the lesioned animals still displayed significant deficits in cell number into young adulthood. There was evidence for compensatory cellular hypertrophy, as protein/DNA (protein content per cell) was elevated during the period in which deficits of cell number were present. These results stand in contrast to the effects of large doses of catecholamines, which when administered acutely, shut down cardiac and renal DNA synthesis. Apparently, a low level of tonic sympathetic input serves to maintain cell acquisition during early development, whereas excessive tone terminates cell replication; indeed, the burst of sympathetic activity which occurs in the cardiac neuronal pathway during the third postnatal week is thought to provide the major signal for cessation of cell division. These data are consistent with a dual role of sympathetic activity in trophic control of peripheral tissue development: a low level of tonic input appears to be necessary for normal cardiac (but not renal) cell division to occur, whereas excessive input terminates mitosis in both tissues. The role of low-level tonic input is thus specific to some, but not all peripheral sympathetic pathways. (Supported by USPHS HD-09713 and EPA CR-813769).

191.14 NEURAL CONTROL OF MACROMOLECULE SYNTHESIS IN DEVELOPING RAT HEART, KIDNEY AND LUNG: RELATIONSHIP TO SYMPATHETIC NERVE DEVELOPMENT AND β-ADRENERGIC RECEPTORS. T.A. Slotkin, W.L. Whitmore*, L. Orband-Miller*, K.L. Queen* and K. Haim*. Dept. of Pharmacology, Duke Univ. Med. Ctr., Durham, NC 27710.

Catecholamines derived from sympathetic neurons and/or the adrenal medulla have been hypothesized to play a role in setting the timing of cellular development. In the current study, we evaluated the relationships among the ontogeny of sympathetic projections to peripheral organs, the patterns of macromolecule synthesis in those organs, and the reactivity of synthetic processes to β-adrenergic stimulation by isoproterenol. In agreement with earlier results found in the cardiac-sympathetic axis, the major developmental rise in norepinephrine concentration and turnover occurred during the second to fourth postnatal weeks in renal and lung sympathetic pathways. Concurrently, the numbers of β-receptors, measured by iodopindolol binding, rose from the low levels characteristic of the neonate, to adult levels. Evaluations of sympathetic physiologic function (heart rate control, renin secretion) also indicate that the major phase of development occurs in this period. The developmental decline in DNA synthesis in heart, kidney and lung, also coincided with the maturation of sympathetic projections. Furthermore, direct stimulation of β-receptors by in vivo administration of isoproterenol was able to cause acute reductions in DNA synthesis in an age-dependent manner. In the heart, isoproterenol was first able to reduce DNA synthesis at 5 days of age and a maximal effect was seen at 9 days; this early phase was characterized by a rapid time constant of coupling of β-receptors to the DNA effect (maximal effect at 6 hr after isoproterenol). Reactivity was lessened by 12 days of age and thereafter displayed a longer time constant (maximal effect at 12 to 24 hr). Reactivity of DNA synthesis to isoproterenol challenge was slightly different in kidney and lung (detectable by 2 days of age), but bore similar developmental characteristics to the pattern in the heart (peak of reactivity at 9 days and a decline in reactivity and lengthening of the time constant after 16 days). No such relationship was evident for the basal ontogenetic pattern or effects of isoproterenol on RNA or protein synthesis. These results thus support the hypothesis that sympathetic input regulates cell replication patterns in developing peripheral organs, with a peak of reactivity corresponding to the point at which peripheral sympathetic function is first established (end of the first postnatal week to end of the third postnatal week). Because the coupling of β-receptors to DNA synthesis disappears with the maturation of full physiological function, sympathetic control of cell replication can thus occur only during a critical period in early development. The fact that β-receptors and their ability to modulate DNA synthesis appear prior to the completion of sympathetic neuronal development, suggests that teratologic changes in development of heart, lung and kidney, may be produced by premature exposure of the neonate to catecholaminergic drugs or by factors which accelerate sympathetic neuronal development.

(Supported by USPHS HD-09713 and EPA CR-813769).

191.15 NEUROPLASTICITY OF SUBSTANCE P-LIKE NERVES IN PARTIALLY OBSTRUCTED RAT INTESTINE. T.H. Williams, G. Gabella, J. Jew, M.Q. Zhang and E. Jew. Dept. of Anatomy, Univ. of Iowa College of Medicine, Iowa City, IA 52242.

Over the past century several reports documented that, under the influence of partial obstruction, the gut wall exhibits remarkable hypertrophy occurring on the oral side of the stenosis site. Recently, the response in the intestinal musculature has been addressed both ultrastructurally and quantitatively in a series of studies (Gabella, G., Physiology of the Gastrointestinal Tract, pp. 335-381, 1987). The affected intestine is unchanged in length, but the thickness and circumference of the muscle coat are markedly increased. Previous studies have shown that hypertrophy of myenteric neurons and their sheath (Schwann) cells is substantial. The myenteric neuropil exhibits less growth than nerve cell bodies. In the present study we attempted to establish a histochemical profile for a representative neuropeptide in the myenteric plexus, and especially of neuroplastic changes occurring after introducing obstruction lesions. Many neuropeptide transmitters have been localized immunohistochemically in the myenteric plexus. Because of its functional importance and wide distribution in the GI system we selected substance P-like peptide as a relevant transmitter subsystem to investigate. Male Wistar rats, 3-4 months old, were anesthetized, and a short strip of acetate film 7 mm by 25 mm, preperforated with holes 21 mm apart, was positioned around the terminal loop of ileum. After 3-5 weeks, the animals were anesthetized and sacrificed; the distended portion of gut immediately proximal to the acetate strip was removed and opened lengthwise and placed in Zamboni's fixative solution. After an overnight wash in phosphate buffered saline, 35 µm thick tissue sections were cut with a freezing microtome and processed for substance P-like peptide immunohistochemistry using an avidin-biotin complex procedure. An analysis of changes in immunoreactive elements was based on i) comparison of sizes and staining characteristics of ganglia, and of connecting meshes of the plexus, in experimental versus control preparations; ii) determining sizes and labeling intensities of cell bodies in both groups; iii) evaluation of substance P-like fiber density, staining intensity and degeneration profiles between experimental and control preparations; and iv) changes in terminal axons, including fiber varicosities, staining intensities and numbers of substance P-positive processes in connecting meshes of the plexus. Interpretations were referenced to the measured elongation of the circular musculature. Changes in cell bodies, terminals, and nerve fibers including degeneration products are reported. (Supported by grants AM23986 and NS19578.)

191.16 CATECHOLAMINERGIC NEURONS IN DORSAL VAGAL MOTOR NUCLEUS PROJECTING TO THE UPPER ALIMENTARY TRACT OF THE RAT. D. Vyas*, D. Bieger and D. Hopkins (SPON: D. McKay), Faculty of Medicine, Basic Medical Sciences, Memorial University, St. John's, Newfoundland and Department of Anatomy, Dalhousie University, Halifax, Nova Scotia.

Recent hodological, histochemical and immunocytochemical studies have neccessitated a redefinition of the dorsal motor nucleus of the vagus (DMV) in terms of its topography, viscerotopical organization and cytology. Moreover, present evidence, albeit disputed, suggests that there exist subpopulations of efferent catecholaminergic neurons in the DMV. As yet, it is unclear where these neurons project, which catecholamine they utilize as primary transmitter and whether their intranuclear distribution displays a viscerotopic pattern. In view of the prominent connections between the DMV and the upper alimentary tract, we sought to determine (1) if gastric and oesophageal projection neurons of the DMV exhibited immunoreactivity for both tyrosine-hydroxylase (TH) and dopamine β hydroxylase (DBH) or TH only.

Adult male Sprague-Dawley rats were injected with 0.5 µl of a 20% solution of horseradish peroxidase (HRP) in the left or right cervical vagal trunk or 3 µl of a 5% solution of wheatgerm agglutinin conjugated HRP in the cervical or distal oesophagus or stomach wall. Sagittal sections (25 µm) of the brainstem were double-stained for HRP and either TH- or DBH- immunoreactivity. HRP was visualized using the tetramethylbenzidine and diaminobenzidine/$CoCl_2$ method while TH or DBH were detected by means of the peroxidase-antiperoxidase method of Sternberger.

With either vagal trunk or stomach wall injections, double-staining was observed in a small number of DMV perikarya displaying TH-immunoreactivity; however, HRP/DBH-positive perikarya could not be detected. HRP/TH double-stained neurons represented less than 1% of the total population of retrogradely labelled DMV perikarya and were confined to the portion of the DMV contained within the closed portion of the medulla from the level of the obex to beyond the caudal limit of the pyramidal decussation. Although oesophageal efferent neurons present in the rostral DMV intermingled extensively with TH-immunoreactive perikarya, no evidence for double-staining was obtained.

It is concluded that the DMV contains a subpopulation of catecholaminergic gastric efferents which likely utilize dopamine as a neurotransmitter. These neurons could play a role in noncholinergic vago-vagal reflexes, particularly receptive relaxation.

191.17 ULTRASTRUCTURAL IMMUNOCYTOCHEMICAL LOCALIZATION OF SITES OF EXCESS LAMININ ACCUMULATION IN THE PRESUMPTIVE AGANGLIONIC BOWEL OF *ls/ls* FETAL MICE: RELATIONSHIP TO THE MIGRATION OF NEURAL AND GLIAL PRECURSORS IN THE BOWEL WALL. V.M. Tennyson, R.E. Payette*, H.D. Pomeranz, T.P. Rothman and M.D. Gershon, Departments of Anatomy and Cell Biology and Pathology (Neuropathology), Columbia University, College of Physicians and Surgeons, New York, NY 10032.

The enteric nervous system is formed by precursors of neurons and glia that migrate to the bowel from the neural crest. In the *ls/ls* mutant mouse the terminal colon is abnormal because an intrinsic defect of the presumptive aganglionic zone prevents the entry and colonization of this region by migrating neural crest cells. Previous studies have shown that neural crest cells fail to enter the terminal colon both *in vivo* and *in vitro*. Since components of extracellular matrix (ECM) have been implicated in neural crest cell migration, we have examined the distribution of these elements in the bowel wall. In the adult *ls/ls* mouse, smooth muscle cells in the muscularis mucosa of the aganglionic zone are hypertrophic and surrounded by reduplicated basal laminae. In the *ls/ls* embryo on day E 11, a time prior to the formation of ganglia anywhere in the bowel, we have found an increase in Alcian blue staining in the mucosal basal lamina and in the enteric mesenchyme of the terminal colon and tail gut. Immunostaining of laminin and type IV collagen was also increased at this time in the mucosal basal lamina and extended from it as fronds into the surrounding mesenchyme. Enteric ganglia are formed in the terminal colon of control mice on days E 15- E 16. At this age, the aganglionic zone of the *ls/ls* mouse has an abnormal accumulation of laminin in the basal laminae of both the mucosal epithelium and the smooth muscle cells of the circular layer, especially in the innermost zone adjacent to the submucosa. The myoblasts of the circular muscle layer are hypertrophic, but there are fewer of them than in controls. The presumptive myoblasts of the longitudinal layer of smooth muscle of the *ls/ls* mouse are immature and separated by spaces containing laminin immunoreactivity. The bowel wall in this region is circumscribed by a thickened layer of adventitial fibroblasts. Ultrastructural observations following either ruthenium red or tannic acid block staining reveal that basal laminae of both the mucosa and the myoblasts of the circular smooth muscle layer are thickened. In addition, an irregular fibrillar material consisting of 4.5-6 nm filaments associated with 14-20 nm granules is present in lakes of extracellular space between presumptive myoblasts in the longitudinal smooth muscle layer. Utilizing a pre-embedding immunocytochemical procedure with colloidal gold, we have found laminin immunoreactivity on the irregular fibrillar material in the lakes of extracellular space, as well as on filamentous material extending from the lamina densa of the thickened mucosal basal lamina. Our histochemical and ultrastructural data demonstrate that abnormalities of ECM are present in the terminal colon of the *ls/ls* mouse at the time of enteric ganglion formation and are located at sites that might interact with migrating neural crest cells in the bowel wall. The observations are consistent with the hypothesis that the accumulation of these materials is causally related to the development of aganglionosis in the mutant. 191.18 MIGRATION OF SACRAL NEURAL CREST CELLS TO THE AVIAN BOWEL AND GANGLION OF REMAK: RELATIONSHIP TO LAMININ. H.D. Pomeranz, R.E. Payette* and M.D. Gershon, Department of Anatomy and Cell Biology, Columbia University, College of P & S, New York, NY 10032.

The enteric nervous system (ENS) is formed by precursors that migrate to the gut from the vagal and sacral levels of the neural crest. The sacral crest also forms the ganglion of Remak. There appear to be defined pathways of crest cell migration, but the route taken by sacral crest cells to reach the hindgut and ganglion of Remak is not yet known. The current experiments were done to identify the pathway between the sacral crest and the bowel and to examine the relationship of laminin to migrating sacral crest cells. A monoclonal antibody (MAb), NC-1, that recognizes an epitope on migrating crest cells was used for their immunocytochemical identification. MAb EC/8, which recognizes a neurofilament-associated protein, NAPA-73, was employed to define the subset of crest cells expressing a neuronal marker. Dual-label immunofluorescence on single cryostat sections was used to demonstrate the localization of laminin simultaneously with the MAbs described above. Serial sections were traced in chick embryos from stages 16 to 27. At stage 16, in the region of the most caudal somites, NC-1$^+$ cells appeared to migrate ventrally along the basal lamina of the neural tube, laterally to precede the emerging ventral roots through the somites, and dorsally in close apposition to the epidermal basal lamina. EC/8$^+$ cells were far fewer than NC-1$^+$ cells, and were only found at some distance from the neural tube. Caudal to this region the neural tube was not yet closed and there were no NC-1$^+$ cells. Laminin was present in formed basal laminae and in patches and fibrils between mesenchymal cells. Somites were incompletely enclosed by a laminin$^+$ sheath, especially where penetrated by crest cells. By stage 21, two large masses of NC-1$^+$ crest cells could be seen in the mesenchyme near the developing hindgut. One, more caudal, extending from an accumulation of crest cells ventral to the sacral neural tube, approached the gut in a V formation. Cells at the apex of the V entered the cloacal mesenchyme rostral to the allantoic bud and were EC/8$^-$. Relatively little laminin was found among the crest cells, but was abundant in the surrounding mesenchyme. A second, more rostral mass of crest cells, many of which were EC/8$^+$, approached the hindgut ventral to the aorta between the mesonephric ducts. These cells remained in the dorsal mesenchyme of the bowel and did not move ventrally around the gut. At stage 23, both groups of crest cells could still be identified. The group of sacrally derived cells at the mesenteric attachment extended rostrally and were always separate from another group of NC-1$^+$ cells (of truncal origin) that formed a crescent ventral to the aorta. It seems likely that this cluster of crest cells in the dorsal mesentery gives rise to the ganglion of Remak. Crest cells did not migrate into regions densely laminin-immunoreactive, such as the nephrogenic mesenchyme. At stage 27, NC-1$^+$ cells migrate circumferentially beneath the serosal basal lamina. The colonization of the hindgut by sacral crest cells proceeds in a caudal to rostral direction and lags behind the rostral growth of the ganglion of Remak within the dorsal mesentery. Only a subset of the cells that enter the gut are EC/8$^+$, the remainder may be glial precursors or neuronal precursors not yet committed to a neuronal lineage. The relationship of crest cells to the distribution of laminin is compatible with the view that laminin helps to delineate pathways along which neural crest cells migrate. Supported by NIH grants NS 15547, HD 17736, and GM07367.

191.19 EFFECT OF BILATERAL OVARIECTOMY ON THE KINDLING LIKE-CONVULSIVE ACTIVITIES OF THE ISOLATED FEMALE GUINEA PIG ILEUM. M. Luján*, R. Rodríguez*, M. Velasco*, F. Velasco and I. Márquez*. Dept. of Pharmacology. Mexico University, School of Medicine and National Medical Centre, IMSS.

In previous reports (1), (2), (3) we have shown that iterative subthreshold electrical stimulation of the isolated ileum of the male guinea pig, produced in the majority of cases (18/20 ilea 62/80 ileum segments) a progressive increase of the basic muscular tonus, followed by self sustained, high amplitude muscle contractures; and blocked by various anticonvulsant compounds. These changes represent a plastic modification of the male ileum neuromuscular activity; and are equivalent in many respects to the "epilepsy kindling" produced by the electrical stimulation of the CNS. In contrast, intestinal kindling in the female guinea pig was only occasionally observed (2/20 ilea and 2/80 ileum segments). In the present work, the effect of bilateral ovariectomy on the intestinal kindling of 10 female guinea pig was studied in order to determine to what extent the presence of gonadal hormones is responsable to avoid the kindling process of the intact female quinea pig ileum. Bilateral ovariectomy flattened completely the vaginal cytology, and significantly increased number of kindled female intestines ($P < 0.001$) and intestine segments ($P < 0.01$). Velocity of the kindling process however, were in ovariectomized female ilea similar to that of the male ilea.

192.1 **AGE AND SEX DIFFERENCES IN 3H-THYMIDINE LABELING IN THE DEVELOPING ZEBRA FINCH SONG SYSTEM.** J.R. Kirn & T. J. DeVoogd, Psychology, Cornell University, Ithaca, NY. 14853

Zebra Finch song is a learned, sexually dichotomous behavior for which there are parallel dimorphisms in the nervous system: only males sing and song control brain regions are larger in males than in females (reviewed by DeVoogd, J. Neurobiol. 17(3): 177-201). The developmental mechanisms which produce these brain dimorphisms are largely unknown. Moreover, despite reports of adult neurogenesis in one song control region-HVc (Hyperstriatum Ventralis pars caudalis), little is known about the time course and amount of neurogenesis in male and female vocal control nuclei during development. This report examines neurogenesis from hatching to 30 days of age in 4 interconnected telencephalic song nuclei; HVc , RA (Robustus Archistriatalis), Area X, and MAN (Magnocellular nucleus of the Anterior Neostriatum) (Nottebohm et al., J. Comp. Neurol., 207:344-357).

Male and female finches received 3 injections of 3H thymidine (2.5 uCi/g body weight, sc., specific activity 20 Ci/mM) covering one of the following 5 day intervals: post hatch days 2-6; 8-12; 14-18; 20-24; or 26-30. At 60 days, birds were anesthetized, perfused, and 10um coronal brain sections were processed for autoradiography. In representative cresylecht violet stained sections from each brain region, cells with a clear nucleus, 1-2 nucleoli, and darkly staining cytoplasm plus a 10 x background grain count were classified as 3H labeled neurons.

Neurogenesis in HVc and Area X was found to occur throughout the first 30 days post hatch. Across all injection age groups, 1-5% of neurons in male Area X and 1-3% of neurons in male HVc were labeled at 60 days. In addition, a substantial sex difference was found in the number of labeled cells in HVc: total labeled neurons/injection age group for male HVc was 822 $\pm$ 366 compared to 74 $\pm$ 72 in females (also see Nordeen & Nordeen, Soc. Neurosci. Abstr. 12:1214, 1986). It is likely that augmented cell death in females during the interval between thymidine treatment and sacrifice (Kirn & DeVoogd, Soc. Neurosci. Abstr. 11:532, 1985) accounts for some of this difference in labeled cell number. In contrast, differential cell death cannot account for a prominant male Area X and the apparent absence of this nucleus in females (Kirn & DeVoogd, Soc. Neurosci. Abstr. 12:1214, 1986). Present data indicate that Area X neurogenesis overlaps with known sex differences in steroid levels (Hutchison et al., J. Endocr. 103:363-9, 1984). Thus, Area X dimorphisms may result from differential neurogenesis or migration.

No labeled neurons were found either in RA or MAN following any tritium injections, suggesting that the majority of cells present in these nuclei at 60 days are generated prior to hatching. Primary afferents for male RA and MAN may not arrive until 25 and 45 days post hatch, respectively (Konishi & Akutagawa, Nature, 315: 145-7, 1985; Bottjer et al., Soc. Neurosci. Abstr. 12:1213, 1986) suggesting a surprisingly long delay between neurogenesis and the arrival of major afferents in these nuclei. Ongoing research employing embryonic thymidine injections will provide a more complete description of neurogenesis in song control brain regions.

192.2 DEVELOPMENT OF SYNAPSES IN SONG CONTROL NUCLEI OF THE ZEBRA FINCH. R.P. Clower and T.J. DeVoogd. Department of Psychology, Cornell University, Ithaca, NY 14853.

One of the least understood aspects of the neurobiology of singing in birds is the development of the song system. While auditory experience and prac-tice, important in the "template" theory of song learning, are certainly of fundamental importance, it is as yet unclear precisely how or where in the central nervous system their effects are produced. Clearly, a thorough, multi-level, multi-age description of the anatomy of the brain areas controlling singing in passerines must be made before template formation or song expression can be fully explained.

Song generation is usually traced from hyperstriatum ventrale pars caudale (HVc) to robustus archistriatalis (RA) (both telencephalic nuclei) and then to the brainstem hypoglossal nucleus (nXIIts), both directly and by way of the dorsomedial part of nucleus intercollicularis (ICo), found in the midbrain. These nuclei are well defined in Nissl stained adult tissue from all song birds which have been studied to date. However, RA is just discernible at 5 days post hatching in zebra finches and HVc is still somewhat ambiguous at day 10. Tritiated proline injections have suggested that RA is not innervated by HVc until about day 30 (Konishi and Akutagawa, 1985). It would be useful to know precisely what is taking place at at an ultrastructural level as these nuclei first emerge and as extrinsic innervation occurs.

Male zebra finches are being studied at 5, 10, 30 days post hatching and in adulthood. Birds are anesthetized and their brains are processed according to a standard EM protocol. Approximately 50 - 100 synapses in Hvc, RA and nXIIts are being classified according to synapse class, frequency, length of postsynaptic thickening (PST), size of pre- and postsynaptic processes, and number of synaptic vesicles.

Preliminary data are available for RA. Large numbers of synapses exist in RA in 5 day old birds. Frequency and PST length do not change appreciably over subsequent development (frequency range: 9.9 synapses/100μ at 10 days to 11.9 synapses/ 100μ in adulthood; PST range: .26 μ at 10 days to .34 μ at 30 days). However, synapses in older animals are much more likely to occur on spines than in younger animals (19% of identified synapses on spines at 5 days, 42% at 10 days, 48% at 30 days, and 72% in adulthood). Degenerating profiles are frequently observed at 10 and 30 days, suggesting that synaptic turnover is occuring. Myelinated axons are first seen at 30 days and are frequent in adults. Extracellular space is obvious at 5 days, less clear at 10 days and virtually absent at 30 days and in adulthood.

Supported by NICHD Grant #21033 and an NSF Graduate Fellowship.

192.3 **SENSITIVE PERIODS FOR MASCULINIZATION OF NEURONAL STRUCTURE IN N. ROBUSTUS ARCHISTRIATALIS OF THE ZEBRA FINCH SONG SYSTEM.** T. J. DeVoogd and C. I. Gould*, Dept. Psychology, Uris Hall, Cornell Univ., Ithaca, N.Y. 14853.

There are dramatic sex differences in zebra finches in the appearance of song related brain regions. We have shown that sex differences in neuronal structure in the nucleus RA occur as a result of dendritic spine loss in females as well as neuronal growth and reduced rates of cell death in males (Kirn & DeVoogd, 1985; DeVoogd *et al.*, 1986). These anatomical dimorphisms are probably caused by differing developmental levels of steroid. An adult female zebra finch given testosterone will not sing (Arnold, 1974) unless she has been previously treated with T or E in the first 3 weeks of life (Gurney & Konishi,1980). This increased song capacity in steroid-treated females in response to exogenous androgens during adulthood corresponds to an increase in RA volume (Gurney, 1982) and an increase in mean soma diameter of neurons within RA (Gurney, 1981). Little is known of the timing of endocrine influences on the microanatomy of song control regions.

In this research, endocrine state during development was systematically manipulated to determine sensitive periods for the development of dimorphic features in the neuroanatomy of RA. Females were given subcutaneous T-implants for 5 day intervals over the following ages: 0-4, 5-9, 10-14, 15-19, 20-24, 25-29 days. 25 implanted females and 3 normal males and 3 normal females were perfused at 6 weeks of age. Their brains were processed for Golgi-Cox staining (Glaser & Van der Loos, 1981), dehydrated and sectioned at 120 microns.

We have found that different time periods of gonadal hormone administration to a female zebra finch have different effects on the development of RA. Females implanted with T for 5 days in the interval10-29 days had significantly larger dendritic trees ($p<.025$), greater numbers of dendritic spines ($p<.01$) and larger cell dendritic volumes and Sholl curves than females exposed within the first 10 days of life. Some aspects of RA morphology were restricted in their sensitivity to steroids for a shorter period of time. RA significantly increased in volume only in response to T during 15-19 days of age ($p<.025$); and the number of primary branches on neurons within RA was significantly masculinized in females receiving T within days 10-19 ($p<.05$). Females exposed to androgens before day 10 showed a minimal response in all measures of RA morphology.

Thus, androgen exposure in early life results in masculinization of the appearance and neuronal morphology of RA. The two classes of effects can be dissociated. This suggests that RA size may be more closely tied to number of cells (and therefore directly related to cell death) than to dendritic differentiation. Supported by NICHD 21033

192.4 DEVELOPMENT AND CONNECTIVITY OF SEXUALLY DIMORPHIC SONG NUCLEI. R. Mooney* and M. Rao (SPON: M. Konishi). Div. of Biology, California Institute of Technology, Pasadena, CA 91125.

Nucleus RA of the zebra finch song system is not sexually dimorphic in either cell size or number until approximately 30d posthatch, at which time neurons in the female nucleus begin to undergo extensive atrophy and cell death. The innervation of RA by HVc neurons was studied by injecting 3H-proline into HVc to label HVc axons. Injections at 15-25d in either sex result in a ring of labeled terminals around RA. In the male, labeled fibers first appear in RA at 25d, and by 35d, RA is completely labeled. In the female, RA remains mostly devoid of labeled fibers during development and in adulthood (Konishi and Akutagawa, 1985).

We have begun a physiological study of the HVc projection to RA using in vitro brain slice techniques. We prepared 400 µm thick parasagittal sections of 50-90d male zebra finch forebrain which contained a large portion of RA, HVc and the interposed bundle of HVc axons. Intracellular recordings showed that many RA neurons exhibited EPSPs upon depolarizing stimulation of the HVc fiber tract. Intracellular injection with Lucifer Yellow revealed that the dendrites of RA neurons exhibiting such EPSPs were spinous and confined to RA.

Furthermore, a fluorescent carbocyanine dye (diI) was injected in vivo to allow visualization of HVc axons in the slice preparation. Injecting HVc produced a staining pattern consistent with results achieved with proline autoradiography. Injected birds younger than 25d displayed a ring of label surrounding RA. Neurons in the unstained central portion of the ring exhibited EPSPs upon stimulation of the HVc fiber tract, even though their Lucifer Yellow-labeled spinous dendrites did not arborize outside of RA. Thus, RA neurons appear to be innervated before labeled HVc terminals can be visualized within the nucleus. Either 3H-proline and diI injections made in HVc do not label processes entering RA before 25d, or axons within the HVc fiber tract innervate RA neurons via a polysynaptic input.

192.5 PARADOXICAL HYPERMASCULINIZATION OF THE ZEBRA FINCH SONG SYSTEM BY AN ANTIESTROGEN. G.A. Mathews*, E.A. Brenowitz, and A.P. Arnold. Dept. of Psychology and Brain Research Institute, University of California, Los Angeles, CA 90024.

Estrogen exerts a potent masculinizing effect on the neural system that regulates song production in oscine birds (Gurney, 1982). Male Zebra Finches (Poephila guttata) show higher circulating levels of estradiol in the first ten days post-hatching than do females (Hutchison, Wingfield & Hutchison, 1984). If estrogen masculinizes the song system, then blocking estrogenic action should prevent this pattern of differentiation. We tested this hypothesis by injecting neonatal finches with tamoxifen, an antiestrogen. Contrary to our expectations, we observed anatomical hyper-masculinization of the male song system and masculinization of the female song system.

Ten Zebra Finches of each sex received daily subcutaneous injections of either 100ug tamoxifen in 3ul propylene glycol or only 3ul propylene glycol for 20 days post-hatching. They were sacrificed at 60 days of age. We measured the cross-sectional areas of neuronal somata in the magnocellular nucleus of the anterior neostriatum (MAN) and robust nucleus of the archistriatum (RA) and total volumes of the caudal nucleus of the ventral hyperstriatum (HVc), RA and Area X.

Somal area in MAN of males was 200 ± 21 um2 (X ± SD, tamoxifen-treated) and 164 ± 9 um2 (control) ($p < 0.001$, t-test). In male RA, somal area was 207 ± 30 um2 (tamoxifen) and 167 ± 25 um2 (control) ($p < 0.001$). For female MAN somal area was 126 ± 13 um2 (tamoxifen) and 102 ± 15 um2 (control) ($p < 0.001$). Somal area in female RA was 139 ± 35 um2 (tamoxifen) and 92 ± 25 um2 (control) ($p < 0.001$).

Total volume of RA in males was 0.47 ± .02 mm3 (tamoxifen) and 0.42 ± .03 mm3 (control) ($p < 0.05$). For Area X of males, volume was 2.32 ± .35 mm3 (tamoxifen) and 1.81 ± .26 mm3 (control) ($p < 0.05$). HVc volume in males was 0.73 ± .10 mm3 (tamoxifen) and 0.63 ± .05 (control) ($p>0.05$). For females, volume of RA was 0.12 ± .04 mm3 (tamoxifen) and 0.09 ± .01 mm3 (control) ($p > 0.05$). HVc in females was 0.20 ± .08 mm3 (tamoxifen) and 0.12 ± .03 mm3 (control) ($p > 0.05$). Tamoxifen-treated females displayed a prominent Area X (volume = 0.39 ± .07 mm3). This region was not discernable in control females.

The hypermasculinization of males and masculinization of females could reflect an estrogenic rather than antiestrogenic action of tamoxifen. However, the hypermasculization of males is paradoxical since administration of exogenous estradiol itself does not have this effect. The consequences of a hypermasculine song system for vocal behavior are under study.

192.6 PROJECTIONS OF ANDROGEN-ACCUMULATING NEURONS WITHIN THE ZEBRA FINCH SONG SYSTEM. F. SOHRABJI*, E.J. NORDEEN, AND K.W. NORDEEN.* (SPON: V. Laties) Dept. of Psychology, U. of Rochester, Rochester, N.Y. 14627.

In zebra finches, androgens trigger song development and stimulate growth of the neural regions controlling song. Early exposure to estrogen establishes this ability to respond to androgens probably by increasing the number of androgen target cells in two song regions, hyperstriatum ventralis pars caudalis (HVc) and the magnocellular nucleus of the anterior neostriatum (MAN). Since the neuroanatomical growth induced by androgens extends beyond HVc and MAN, it is likely that some of androgens' effects are mediated indirectly; that is, through connections of these regions with other song nuclei. Powerful, yet indirect support for this idea is that Area X grows substantially in response to androgens, yet does not itself contain androgen-accumulating cells. This song regions does, however, receive a massive projection from HVc, as does the robustus nucleus of the archistriatum (RA), another androgen-responsive region with relatively few androgen-accumulating cells. This study determined whether HVc cells which project to Area X or RA also accumulate androgens. If so, this would be consistent with the hypothesis that the regulation of androgen accumulation in HVc in turn defines the androgenic sensitivity of other song nuclei.

Adult male zebra finches were castrated and injected with fluorescent latex microspheres directed towards Area X (n=3) or RA (n=2). Three to six days later, each bird was injected with 3H-DHT and killed 90 minutes later. Coronal brain sections were processed for autoradiography and HVc cells that accumulated 3H-DHT were identified using the Poisson criterion. Retrogradely-labeled HVc neurons were identified and the density of silver grains over these cells was determined by combining fluorescent and bright field illumination.

In birds in which injections of the retrograde tracer filled most of the intended target, a large number of HVc cells were backlabeled (Area X - 14.3 ± 3.1%; RA - 34.6 ± 6.7%). Many of these projection neurons were also androgen-accumulating. Among HVc neurons projecting to Area X, 38.1 ± 5.2% accumulated 3H-DHT or its metabolites. Similarly, 57.4 ± 3.1% of the HVc neurons projecting to RA accumulated androgens. The overall incidence of androgen-accumulating cells in HVc was 42.6 ± 4.0%. These data imply that androgenic effects on HVc neurons are communicated to Area X and RA, and argues that the masculinization of androgen accumulation in HVc may in turn dictate how other song regions respond to androgenic stimulation. (Supported by USPHS grants HD22160 and the Sloan Foundation).

192.7 NEURONS OF HYPERSTRIATUM VENTRALIS PARS CAUDALIS BORN DURING SONG LEARNING DO NOT PROJECT TO AREA X. E.J. NORDEEN AND K.W. NORDEEN*. Dept. of Psychology, U. of Rochester, Rochester, N.Y. 14627

As juvenile male zebra finches learn song, newly-born neurons insert into the song control nuclei hyperstriatum ventralis pars caudalis (HVc) and Area X. Young females (who do not develop song) produce or incorporate fewer of these neurons, contributing to the development of a marked sex difference in neuron number within HVc and Area X. We are interested in characterizing these sexually dimorphic populations of late-generated neurons to understand better their role in song learning and sexual differentiation. This study examined whether, in males, HVc neurons born during adolescence project to Area X, a principal target of HVc. If so, then sex differences in the production or insertion of these neurons could in turn produce sex differences in the HVc-Area X projection and in the anatomy of Area X.

Beginning at 20 days of age, male zebra finches were injected with ^{3}H-thymidine (2.5 uCi/gm) every 24 hours for 20 days. At 57 days of age, birds were anesthetized and injected bilaterally with .7 ul fluorogold (Flg) directed towards Area X. They were perfused with saline-formalin 7-8 days later, and their brains were removed and embedded in paraffin. Coronal sections (10um) were processed for autoradiography. In 3 birds the Flg injections filled most of Area X bilaterally. Sections through HVc of these birds were first examined under UV illumination to determine the density of Flg-labeled neurons. Then, the silver grain density was determined over each Flg-labeled neuron by combining UV and bright field illumination. Finally, these sections were stained with thionin and the overall neuronal density and incidence of thymidine-labeled neurons were determined. A neuron was considered labeled by thymidine if the density of silver grains over its' soma exceeded 5X background grain density.

A substantial and reliable proportion of HVc neurons were retrogradely labeled by Flg injections into Area X (15.7 ± 2.2%). Of these neurons projecting to Area X only 6.5 ± 1.8% were also labeled by ^{3}H-thymidine. In contrast, thymidine injections between 20 and 40 days of age labeled 18.7 ± 2.1% of HVc neurons overall. Thus, only about 5% of the neurons born and incorporated into male HVc during adolescence project to Area X. The majority of neurons added to HVc during song learning are likely, therefore, to either be interneurons or contribute to the projection of HVc to the robust nucleus of the archistriatum. This latter possibility is presently under investigation.

192.8 DEVELOPMENT OF SEXUALLY DIMORPHIC PHYSIOLOGY IN *XENOPUS LAEVIS* LARYNX; EFFECTS OF ANDROGEN DEPRIVATION. M.L. Tobias, D.A. Sassoon and D.B. Kelley, Dept. Biol. Sci., Columbia Univ., New York, N.Y. 10027; Pasteur Institute, Paris, France

Adult frogs (*Xenopus laevis*) perform sex-typical vocalizations to express reproductive state. The male-specific mate call is more complex in temporal pattern, more rapid (66 vs 6 Hz), and more robust in amplitude and duration than the female-typical call ticking. Male vocal behavior is androgen sensitive; castrated males do not mate call, but calling is reinstated following exogenously administered androgen. Females do not mate call. Two physiological properties of the vocal effector organ, the larynx, have been shown to contribute to the male's unique vocal ability (Tobias & Kelley, J. Neurosci, in press). Male laryngeal muscle, in response to nerve stimulation, generates twitch contractions at rates even greater than those required to produce the mate call; female laryngeal muscle produces only maintained tension at these stimulus rates. Male laryngeal muscle exhibits marked compound action potential (cAP) potentiation in response to laryngeal nerve stimulation at mate call rates; female laryngeal muscle shows little or no potentiation at these rates. At metamorphosis, androgen levels are low and monomorphic. Adult levels are reached by six months p-m in males, but remain low in females (Lambdin & Kelley, Neurosci., 12:332.2, 1986). In this study we examined the electrophysiological properties of male and female larynges during post-metamorphic development. Our aim was to determine when sexually dimorphic properties of laryngeal physiology first appear and whether these properties are controlled by androgen secretion.

Larynges from male and female frogs of different ages were isolated and muscle activity in response to laryngeal nerve stimulation examined. At six months post-metamorphosis (p-m), both contraction rate and cAP potentiation are monomorphic and feminine. At ten months p-m, males begin to demonstrate rapid muscle contractions, but still do not exhibit cAP potentiation. These results suggest that masculinization of these properties occurs relatively late in development, at some time after six months p-m. We next determined whether androgen exposure after six months p-m is necessary for development of male physiological characteristics. Males were either gonadectomized or sham operated at six months p-m and tested at 12 months p-m. Masculinization was completely arrested by gonadectomy. Tension and electromyogram records from gonadectomized animals appeared identical to those of unoperated siblings tested at six months p-m. Sham operated animals were significantly more masculinized than operates ($p<.01$, Wilcoxon Rank Sign Test); the records were indistinguishable from control adult males. Laryngeal weights of sham operated and gonadectomized animals were also significantly different (sham = 0.41 gms, gonadectomized = 0.16 gms). Laryngeal weights of sham operates are equivalent to those of adult males while laryngeal weights of gonadectomized animals are equivalent to those of adult females. Unlike masculinization of fiber number, which increases throughout development in response to gradually increasing androgen titers, (Sassoon & Kelley, Am. J. Anat., 177:457, 1986) masculinization of tension and cAP characteristics occurs relatively late in development and diverges more rapidly. Supported by NS 23684

192.9 CELL BODIES OF ORIGIN OF A SEXUALLY DIMORPHIC ENKEPHALINERGIC FIBER POPULATION IN THE PREOPTIC AREA OF THE RAT. R.E. Watson, Jr., S.J. Wiegand, M.D. Fitzsimmons, and G.E. Hoffman. Department of Neurobiology and Anatomy, University of Rochester Medical Center, Rochester, NY 14642

We have recently identified a sexually dimorphic met-enkephalin (m-ENK) immunoreactive fiber pathway in the periventricular preoptic area (pePOA) of the rat. Expression of the system, normally present only in the female, can be altered powerfully by both an activational and organizational action of the gonadal steroids. In an effort to further characterize this system, we have undertaken experiments aimed at identifying the enkephalinergic cell bodies of origin of this dimorphic system, and of others projecting to adjacent regions in the sexually dimorphic preoptic area.

Pressure injections of the retrograde tracer fluorogold (2% w/v in 0.9% saline) ranging in volume from 3-50 nl were made into the proximity of the pePOA of the female. Two days later, the animals were administered colchicine intracerebroventricularly (100 µg/10 µl) and allowed to survive an additional two days prior to perfusion with saline followed by either Zamboni's fixative or 4% buffered paraformaldehyde. Sections were cut on a freezing microtome at 30 µm thickness, and alternate sections were mounted with no further treatment or were reacted for the immunofluorescent detection of m-ENK. For the latter, following incubation in rabbit anti-m-ENK (ImmunoNuclear) and biotinylated secondary antibody (Vector Labs), immunofluorescence was achieved with reaction with rhodamine- or Texas Red-labelled streptavidin (Amersham).

While many retrogradely filled fluorogold-positive cells and enkephalin immunopositive cells can be identified within many of the same brain regions in the hypothalamus and brainstem, there have been surprisingly few double-labelled cells observed. In many areas, numerous retrogradely labelled cells appear to be in immediate proximity to enkephalin immunoreactive cells. Also surprising are the diverse sites at which double-labelled cells have been detected. These sites include the hypothalamic arcuate nucleus, posterior pole of the ventromedial hypothalamic nucleus, perifornical area, dorsomedial hypothalamic nucleus, lateral hypothalamus, nucleus tractus solitarius, and the lateral parabrachial nucleus.

Presently, these results suggest at least two possibilities regarding the origin of the sexually dimorphic enkephalin system. First, as reflected by the tract-tracing data, widely dispersed cells within the hypothalamus and brainstem may contribute to this dimorphic pathway by converging in the female pePOA. Alternatively, the pathway may be comprised of local circuit fibers originating from enkephalin immunoreactive cells in close proximity to the pePOA, and located within the active zone of uptake of the retrograde tracer. Further experimentation utilizing other techniques, including anterograde tracing methods, will be necessary to conclusively ascertain the location of the enkephalin synthesizing cells which provide the major afferent input to this system. Elucidation of the neural circuitry of this system may help in identifying its potential role in the mediation of a sexually differentiated function.

192.10 ESTROUS CYCLE VARIATIONS IN LEVELS OF CCK IMMUNOREACTIVITY WITHIN CELLS OF THREE INTERCONNECTED SEXUALLY DIMORPHIC FOREBRRAIN NUCLEI. A.E. Oro*, R.B. Simerly and L.W. Swanson. (SPON: D. Simmons). Howard Hughes Medical Inst. and Salk Inst., La Jolla, CA 92037.

The central part of the medial preoptic nucleus (MPNc), the encapsulated part of the bed nucleus of the stria terminalis (BSTe), and the posterodorsal part of the medial nucleus of the amygdala (MeAp) are all thought to be involved in the neural control of female reproductive behavior, as well as other neuroendocrine mechanisms. Although the dependence of the development of these sexual dimorphisms on levels of gonadal steroids early in develpment is well known, the importance of possible activational effects of circulating gonadal steroids in the adult is less clear. Recently, we demonstrated the dependence of CCK levels within these cell groups on circulating gonadal steroids in adult male rats (Simerly and Swanson, PNAS 1987). In the present study we evaluated the number of CCK-immunoreactive cells present within the MPNc, BSTe, and MeAp of regularly cycling female rats over the estrous cycle. Female Sprague-Dawley rats that showed at least two normal 4 day cycles received colchicine injections into the lateral ventricle and were sacrificed 3 days later. The animals were grouped according to the appearance of their vaginal smears on the day of sacrifice and the brains were processed for immunohistochemistry according to procedures detailed elsewhere (Simerly et al., JCN, '86). In addition, the effects of ovariectomy and estrogen replacement on CCK staining in regularly cycling female rats were also examined. The number of CCK-immunoreactive cells that could be detected within each cell group was found to vary over the estrous cycle from a minimum during diestrus, increase 2-4 fold during proestrus, and decline to intermediate numbers during estrus. These changes appear to be due at least in part to changes in levels of circulating estrogen because subcutaneous implants of estradiol prevented the decline in the number of CCK-stained cells within the MPNc,BSTe, and MeAp that was seen in untreated, ovariectomized female rats. Thus, the present findings support the hypothesis that levels of CCK within cells of these three sexually dimorphic cell groups are regulated by circulating gonadal steroids within a physiologically relevant time frame, and may possibly contribute to the activation of female reproductive behavior as well as other neuroendocrine functions.

192.11 CORPUS CALLOSUM: MASCULINIZED VIA PERINATAL TESTOSTERONE. R. H. Fitch*, A. S. Berrebi, and V. H. Denenberg. Biobehavioral Sciences Graduate Degree Program. Univ. of Conn., Storrs, CT 06268.

Previous research on sexual differentiation of the rat brain has focused on measures of adult sexual behavior, hypothalamic cyclicity, the volume of the SDA-POA, and the alteration of these factors through early hormonal manipulation. The differentiation of all factors has been shown to be testosterone mediated (although cellular factors may depend on the estrogen metabolite of testosterone). Recently there has been evidence of a sexual dimorphism at the cortical level. Berrebi et al. (Soc. Neurosci, Abst., 1986, 12:1536)reported that the corpus callosum of the male rat is larger than that of the female. This study was designed to investigate the potential role of testosterone in mediating this dimorphism.

The day after birth, 2 randomly selected males from each of 7 litters were castrated, while 2 others received sham surgery. On Day 4, 2 randomly selected females from these same letters received 1 mg testosterone propionate, while the remaining 2 females received an injection of vehicle only. All litters were handled daily until Day 20.

At 110 days the animals were perfused, brains fixed, and cut sagitally. Morphometric analysis of midline sections yielded 7 width measurements taken at specified percentages of total callosal length: the 8th, 16th, 33rd, 50th, 67th, 84th, and 96th percentiles. In addition, these measures were adjusted for brain weight differences.

Male controls had significantly wider callosa than female controls at the 8th and 16th percentiles (anterior), and near significance ($p<.055$) for the 96th percentile (posterior). When the 84th and 96th percentile widths were combined, the sex difference in the posterior region was significant. These findings confirm our earlier report (Berrebi et al., 1986). Females receiving testosterone in infancy had significantly wider callosal values than control females at the 8th, 84th, and 96th percentile widths. These values were close to, or slightly larger, than sham males. Castration did not affect the widths of the males. These results were not changed after adjusting for brain size.

These data suggest that sexual differentiation of the callosum is testosterone mediated. The failure to obtain an effect from castration is taken to mean that endogenous testosterone had masculinized the callosum during the prenatal period. The sensitivity of the callosum to testosterone is still present at least 4 days postnatally, since the callosa of females receiving TP resembled those of males. Since callosal width measures presumably represent fibers of passage from homotopic cortical regions, these data imply that testosterone affects cortical areas.

192.12 SEXUAL BEHAVIOR OF TESTICULAR FEMINIZED (*Tfm*) MICE: EFFECT OF NEONATAL HORMONE TREATMENTS. K. L. Olsen & K. M. Hock*. Dept. of Psychiatry & Behavioral Science, SUNY-Stony Brook, NY. 11794.

Testicular feminized (*tfm*) rats and mice provide a means to examine the contribution of androgens in the differentiation of neural systems underlying behavior. This X-linked mutation is characterized by defects in the androgen but not estrogen receptor system. As a result, X/Y males are insensitive to androgens secreted by their testes and develop a female phenotype. *Tfm* rats and mice differ in their degree of insensitivity since mutant rats show partial response to androgens. Adult castrated *tfm* rats mount when given testosterone propionate (TP), estradiol benzoate (EB) or EB + dihydrotestosterone (DHT) while *Tfm* mice display little or no male sexual behavior following these hormonal treatments. It is not clear whether this demasculinization results from the inherited androgen insensitivity or from insufficient exposure to testicular hormones during development. Therefore, *Tfm* mice and siblings were given exogenous hormones neonatally and tested for their ability to display adult masculine mating responses.

Mice were bred by mating *Ta+/Y* males and *Tfm/+Ta* females resulting in four genotypes. The neonatal treatments were: (a) TP (500 µg) at birth (D1); (b) TP (500 µg), D1+D2; (c) DHT (250 µg), D1+D2; (d) EB (25 or 250 µg), D1. In adulthood, mice were given eight weekly 1 hr tests for male sexual behavior.

Masculine behavior of *Tfm* mice was not enhanced by neonatal exposure to TP. Like untreated *Tfm* mice, 20% of the androgen-ized mutants displayed sexual behavior but only on three of 80 tests. In contrast, wildtype males exhibited mating behavior and 80% of the tests were positive. Carrier females exhibited variable responsiveness ranging from no effect to showing the ejaculatory pattern. While a single injection of TP had an enhancing effect, TP given on D1 + D2 and EB tended to disrupt the development of male sexual behavior in some genotypes.

These results indicate that *Tfm* mice show deficient levels of male sexual behavior even following excess androgen exposure during development. Similar treatments enhanced masculine behavior of their female siblings suggesting that androgens are involved in behavioral masculinization in mice. We are continuing to examine the differentiating action of other doses of TP, EB and DHT since identifying the hormones that mediate behavioral masculinization and defeminization is necessary for understanding the underlying neural mechanisms. The *Tfm* mutation can serve as a model to identify these hormone(s).

192.13 EVIDENCE FOR LONG LASTING ALTERATIONS IN THE NEUROENDOCRINE REGULATION OF PROLACTIN SECRETION RESULTING FROM NEONATAL PROLACTIN DEFICIENCY IN RATS. G.V. Shah*, S.W. Shyr*, B.L. Carroll* C.E. Grosvenor, and W.R. Crowley. Depts. of Physiology and Biophysics and Pharmacology, Univ. of Tennessee, Memphis, Memphis, TN 38163.

Previous findings of this laboratory (Endocrinology 119, 1217-1221, 1986) suggest a role for milk-borne prolactin (PRL) in development of neuroendocrine controls over PRL secretion. Thus, offspring of mothers treated from days 2-5 postpartum with the dopamine (DA) agonist bromocriptine, a treatment that lowers the concentrations of PRL in milk, show reduced concentrations and turnover of DA in the median eminence and elevated serum levels of PRL at 30-35 days of age. The present experiments were undertaken to investigate whether neonatal PRL deficiency results in 1) a hyperprolactinemia and reduced median eminence DA turnover that persists beyond the onset of puberty and 2) alterations in pituitary responsiveness to hypophyseotropic factors. Lactating female rats received sc injections of either saline vehicle or bromocriptine (125µg/rat/d) on each of days 2-5 postpartum. Blood samples were obtained from female offspring at various postnatal ages and PRL concentrations were determined by RIA. Serum PRL concentrations in both groups of offspring were low until after weaning, but the offspring of bromocriptine-treated mothers showed significant elevations in serum PRL between days 30 and 90 postpartum. The turnover of DA in the median eminence, estimated from the rate of decline after synthesis inhibition, was significantly reduced in the offspring of bromocriptine-treated mothers at 35 days of age, but was not different from controls at 60 days of age. Ovariectomy on day 30 prevented the elevation of serum PRL on days 45 and 60 in bromocriptine-offspring, and the concentrations of estradiol in serum were elevated in these animals compared to controls. Anterior pituitary cells from 100 day old offspring of control- or bromocriptine-treated rats were dispersed, cultured for 3 days, and PRL release during a 4 h incubation was assessed. Pituitary cells from offspring of bromocriptine-treated mothers were less responsive to the PRL release-inhibiting action of bromocriptine in vitro. The content of PRL mRNA in cytoplasm of cultured anterior pituitary cells from the two groups of offspring was measured by dot-blot hybridization. Basal levels of PRL mRNA did not differ in the two groups. Stimulation of DA receptors with bromocriptine significantly reduced PRL mRNA in the control cells but failed to do so in the cells of bromocriptine-offspring. These results suggest that a deficiency in exposure to milk-borne PRL during a neonatal critical period leads to a long lasting hyperprolactinemia that is the result of reduced release of DA from the hypothalamus, decreased pituitary response to DA and increased secretion of estradiol.

192.14 ACTIVATION OF LUTEINIZING HORMONE-RELEASING HORMONE (LHRH) RELEASE ADVANCES THE ONSET OF FEMALE PUBERTY. H.F.Urbanski and S.R.Ojeda. Neuroscience Division, Oregon Regional Primate Research Center, Beaverton, Oregon 97006.

The juvenile-peripubertal transition period in the female rat is associated with an ovarian-independent afternoon increase in the amplitude of plasma LH pulses. Firstly, to determine if the immature pituitary gland could be activated to cause precocious puberty juvenile female rats were stimulated with a microprocessor driven iv pulsatile pattern of exogenous LHRH. The animals received a 1-min pulse of 50 ng LHRH/kg BW every 30 min during the afternoons (1300 - 1701 h) from days 26 through 29, an LHRH regimen that produced a peripupertal pattern of LH release. Secondly, to determine if the LHRH neurons themselves could be prematurely activated to induce such a peripubertal pattern of plasma LH, and hence lead to precocious puberty, the neuroexcitatory amino acid analog N-methyl-DL-aspartic acid (NMA) was similarly administered (20 mg NMA/kg BW per 1-min pulse); NMA does not act at the pituitary gland to alter LH release. In vehicle treated controls (n=5) vaginal opening occurred at 38.4 ±0.4 days of age and was advanced by 5 and 7 days respectively in the LHRH (n=7) and NMA (n=7) treated groups. On average all animals ovulated within 2 days of vaginal opening; this was confirmed by the detection of corpora lutea within the ovaries at first diestrus. Although ovarian weight at diestrus was similar in all of the animals regardless of treatment, a juvenile body weight was retained by the animals that underwent precocious puberty.

These results indicate: a) that the juvenile adenohypophysis can be driven by the episodic administration of exogenous LHRH to initiate puberty, and more importantly, b) that the juvenile LHRH neuronal system can be precociously activated by the episodic administration of an excitatory amino acid analog known to interact with specific brain receptors. It is quite likely, therefore, that the initiation of puberty in the female rat depends on the development of neuronal inputs to the LHRH secreting neurons, rather than maturation of the LHRH releasing system itself.

(Supported by NIH Grant HD-09988, project IV)

192.15 **SEX DIFFERENCES IN SPATIAL MEMORY OF RATS: EARLY ORGANIZATIONAL EFFECTS OF GONADAL STEROIDS ON BRAIN LATERALIZATION.** C. L. Williams and W. H. Meck. Depts. of Psychology, Barnard and Columbia Colleges, Columbia University, New York, New York 10027.

We have recently demonstrated that in rats, superior performance on a spatial memory task may be due to exposure to high levels of gonadal hormones during the first postnatal week of life. All subjects were gonadectomized at 45 days of age and began behavioral testing at 75 days of age. Females treated with 10 ug estradiol benzoate on postnatal days 1, 3, 5, 7, & 9 (n = 9) and control males (n = 11) showed faster acquisition of a 12-arm radial maze task (with 8 baited and 4 unbaited arms) compared to males castrated within 24 hr of birth (n = 8) and control females (n = 12).

Magnitudes of left and right turning biases were used as an index of brain lateralization. During the acquisition phase, lateralization was highly correlated with choice accuracy across all treatment groups ($r = .39$, $p < .01$), while direction of turning was not reliably correlated with performance ($r = .15$, ns). Further analysis revealed that brain lateralization differed reliably as a function of early steroid exposure (brain sex) but not genetic sex, with early steroid exposure leading to increased lateralization and a greater degree of reliance on geometry cues as opposed to landmark cues. After the rats had reached asymptotic performance a test of cue usage was conducted by systematically altering either geometry or landmarks. Lateralization was highly correlated with the use of geometry cues as opposed to landmark cues as a function of brain sex ($r = .42$, $p < .01$), while choice accuracy and use of geometry during acquisition were also highly correlated ($r = .64$, $p < 001$).

These data suggest: 1) The more lateralized the brain of a rat, the better its performance on a spatial memory task due to selective use of geometry cues, and 2) Exposure to gonadal steroids during the first week of life leads to increased lateralization. Moreover, the observed correlations between brain lateralization and choice accuracy across all treatment groups strongly suggests that lateralization is the optimal brain organization for spatial memory in both male and female rats.

192.16 PRE- AND POST-NATALLY ADMINISTERED ACTH, ORGANON 2766 AND CRF FACILITATE OR INHIBIT ACTIVE AVOIDANCE TASK PERFORMANCE IN YOUNG ADULT MICE. L.C. Honour*§ and M.H. White*¶ (SPON: J. Matochik). §Department of Psychology and the Neurobiochemistry Group, Mental Retardation Research Center, Neuropsychiatric Institute, Univ. of California, Los Angeles, CA. 90024 and ¶Department of Psychology, California State University, Fullerton, CA. 92634.

The purpose of this study was to investigate the effect of learning/memory-related neuropeptides and their ontogenetic effect on neural processes associated with behavioral task performance in later life. A 1 mg./kg. dosage of adrenocorticotropic hormone (ACTH) 4-9, Organon 2766; ACTH 4-10; ACTH 1-24; corticotropic hormone releasing factor (CRF); or diluent (0.9% physiological saline) was subcutaneously injected into either pregnant females or into newborn pups during specific neural developmental windows. Each of the progeny was later trained in an active-avoidance task and tested for acquisition on postpartum days 35-37. The mice were then tested for memory task performance and reacquisition on days 42-44 postpartum using the identical experimental paradigm as that used in the training sessions.

Pre-natal treatment with these learning/memory-related neuropeptides resulted in significant facilitation of learning/memory-related task performance in male and female mice treated with Organon 2766 ($p< 0.001$), and a significant inhibition of learning/memory-related task performance in males and females treated with ACTH 1-24 ($p< 0.01$). Additional sex-specific performance facilitations and inhibitions resulted from the pre- or post-natal administration of the various neuropeptides used in this study.

These results suggest that neuropeptides, when available in increased amounts during specific neural developmental windows, can significantly improve or suppress related behavioral performance capability in later life.

193.1 PATERNAL ETHANOL ALTERS BEHAVIOR OF MOUSE PROGENY. G. Friedler*, D.R. Brown*, V. Wooten* and M-E. Meadows* (SPON. M. Oscar-Berman). Boston University School of Medicine, Boston, MA 02118.

This study evaluated the effect of limited paternal exposure to ethanol (ET) on the motor activity of his offspring. Two groups of sexually mature male mice (CD-1, Chas. River) received either ET (3.5 g/kg, 17.5% w/v) or isocaloric sucrose (CON) by gastric gavage twice daily (8½ dys). CON were pairfed to ET males who received ground mouse chow and water ad libitum. Following the final intubation day, food and water were freely available for 7 additional days prior to pairing of males (10/grp) with untreated females for a single estrous cycle. Births were recorded within 12 hrs and litters reduced to 8 (4M, 4F). A blind procedure was used for all behavioral testing and data analysis.

Pivoting locomotion was assessed at 10 days in individual offspring from 6-8 litters/paternal treatment grp. Using a 30 sec period of observation, a significant decrease in both time spent pivoting (13.6±1.6 sec,ET; 19.3 ± 1.4,CON) and number of pivots(90°) (8.8 ± 1.2,ET; 13.5 ± 1.2,CON) occurred in ET grps ($P<.05$). At 12 weeks, individual males (6/grp) representing 6 separate litters/paternal treatment grp were tested for patterns of motor behavior in a plexiglass chamber (15"x15"x9")with midline divider. Pairs of ET and CON progeny were tested simultaneously between 6-8 P.M. in an isolated room under red light. Behavior was recorded (10 min) by videotape for subsequent analysis of quantitative changes in activity patterns and interactions between individual behaviors as detailed elsewhere (Norton, S. Handbook of Psychopharm.7:83, 1977; Brown, D.R. et al, Toxicol. Industr. Health 1:81, 1985). No changes in overall activity or repertoire of behaviors were observed between ET and CON progeny. The distribution of behaviors between grooming, exploratory and attention modes also did not differ for the two grps. Interactions between individual behaviors, reflective of the activity profile during exploration of the test chamber, differed markedly for the two grps. ET mice showed a significant ($P<.05$) increase in number of interactions (70%) when compared with CON (44%). However, the pattern of interactions was more restrictive in individual ET offspring than in CON. An increase ($P<.05$) in 180° turns was also evident in ET mice.

The results indicate that paternal exposure to ethanol, in the absence of maternal exposure, can alter the behavior of both young and adult offspring.

(Supported by USPHS Grant R01 AA 06970, NIAAA).

193.2 EFFECTS OF PRENATAL EXPOSURE TO ETHANOL ON THE GLUCOSE UTILIZATION OF MOTOR AND SOMATOSENSORY CORTICES IN THE RAT. M.W. Miller and D.L. Dow-Edwards. Dept. of Anatomy, Sch. of Osteopathic Med. and R.W. Johnson Med. Sch., UMDNJ, Piscataway, NJ 08854 and Dept. of Neurosurgery, Health Sci. Ctr., SUNY, Brooklyn, NY 11203.

Gestational exposure to ethanol causes multiple behavioral abnormalities such as hyperactivity, learning deficits, and difficulty in response inhibition. Such abnormalities indicate that the function of cerebral cortex is altered. In the present study, 2-deoxyglucose autoradiography was used to determine whether ethanol exposure alters cortical metabolic requirements. Pregnant hooded rats were fed ad libidum a diet consisting of 35% (v/v) ethanol in vitamin fortified Sustacal. Others were pairfed an isocaloric diet. Rats were fed these special diets from gestational day 7-21. Postnatally, mothers and weanling pups were fed chow and water. Plasma samples and frozen coronal sections from 105 day old pups were processed and analyzed by the quantitative autoradiographic technique of Sokoloff et al. (J. Neurochem. 28:897). Rates of glucose utilization were determined in five cortical areas, primary somatosensory area 3, secondary somatosensory area 2, primary motor area 4, and rostral and caudal secondary motor area 6/8. The identity of the cytoarchitectonic areas and the thicknesses of the cortical layers were determined on alternate thionin-stained sections. Despite finding no differences in the thicknesses of the corresponding laminae in each segment of somato-motor cortex of control and ethanol-treated rats, there were striking group differences in the rates of cerebral glucose utilization. The overall glucose utilization of controls was similar in all five regions ranging from 82-88 mol/100 g/min. Specific laminae had different rates of glucose utilization, layer IV had the greatest and layers I and VI the lowest. In ethanol-treated rats, overall glucose utilization in areas 3, 2, 4, and rostral 6/8 was statistically significantly less (-23-24%; t test, $p<0.01$) than in corresponding sites in controls. In each of these four regions, layers IV and V were affected most severely (-21 to -29%; $p<0.01$) and layer I the least (-14 to -19%). Caudal area 6/8 differed from the other somatosensory and motor cortices in that overall, glucose utilization was not significantly different ($p>0.02$) in both groups and that layer I was the most affected stratum. These data corroborate anatomical data which show structural abnormalities in deep cortex and suggest that ethanol exposure preferentially affects a major afferents system (thalamic input to layer V) and two major efferent systems (callosal and subcortical projections from layer V).

193.3 PRENATAL ALCOHOL EXPOSURE ALTERS SEIZURE AND THERMOREGULATORY RESPONSE TO HEAT STRESS IN NEONATAL RATS. B. Zimmerberg, C.D. Khazam*, and E.P. Riley*. Center for Behavioral Teratology, Dept. of Psychology, SUNY-Albany, Albany, N.Y. 12222.

Prenatal alcohol exposure delays the ontogeny of thermoregulation in neonatal rats exposed to cold stress. In this experiment, the effects of prenatal alcohol exposure in neonatal rats exposed to heat stress was investigated using a hyperthermia-induced seizure paradigm. Two-day-old male and female rat pups were chosen from independent litters with one of three prenatal treatment histories: 35% ethanol-derived calories (35% EDC), pair-fed control (0% EDC) or lab chow control (LC). Subjects (n=6 per sex per group) were continuously monitored for rectal temperature while in a chamber which was heated to 47°C. Subjects were observed for loss of righting reflex with onset of tonic-clonic convulsions (hyperthermia-induced seizure). There was a significant effect of prenatal treatment on body weight, the latency to the first seizure, the number of total seizures, and the duration of seizure activity (p's <0.01). The 35% EDC pups seized sooner than control groups (p's<0.05), which did not differ from each other. Alcohol-exposed pups also had more seizures and a greater total duration of seizure activity than pups from both control groups (p's<0.01), which did not differ from each other. However, rectal temperatures at the first seizure and at the peak of heating did not differ by prenatal treatment. This suggests that while the body temperature seizure threshold is not altered by prenatal alcohol exposure, the rate of temperature rise to reach this threshold is markedly increased for alcohol-exposed pups at this age. In addition, 35% EDC pups' body temperatures remained above this threshold for a longer period of time after the first seizure compared to control pups (p's<0.05), which did not differ. This suggests that body weight differences are not solely responsible for these effects, since the smaller 35% EDC pups, with their larger surface/weight ratio, should lose heat faster. It appears, therefore, that prenatal alcohol exposure may cause some deficit in thermoregulation. This altered response to heat stress may have implications for deficits in neuronal function, brain growth and/or behavior in fetal alcohol exposure. (Supported by grants from NIAAA #AA07009 to BZ and #AA03249 to EPR)

193.4 BRAIN/BODY WEIGHT REDUCTION AFTER ACUTE PRENATAL ALCOHOL EXPOSURE IN C57 MICE: EFFECTS OF ASPIRIN PRETREATMENT. C.L. Randall, R.F. Anton, H.C. Becker, and C.K. Williams*. VA Medical Center and Medical University of SC, Charleston, SC 29403.

Acute alcohol administration on a single day of pregnancy has been shown to result in anomalous morphologic development in mice (Sulik et al., 1981; Webster et al., 1983) and suppressed cell division in rat embryos (Pennington et al., 1984). In chicks, alcohol-induced growth retardation was antagonized by the prostaglandin synthetase inhibitors aspirin (ASA) and indomethacin (Pennington et al., 1985). Since previous work from our laboratory (Randall and Anton, 1984) showed a significant reduction in alcohol-induced birth defects in C57BL/6J mice pretreated with ASA, the purpose of this study was to determine the effect of ASA pretreatment on alcohol-induced body and brain weight deficits in mice. C57BL/6J mice were time bred (plug day= gestation day 1). On day 15 of gestation, mice were injected s.c. with 150 mg/kg ASA or phosphate buffer. One hour later, 5.8 g/kg alcohol (or isocaloric sucrose) was administered by gavage. On day 19 of gestation, fetuses were removed from the uterus. Body and brain weights were recorded. The results confirmed a marked reduction in brain ($F= 15.09$, $df= 1/36$, $p< .01$) and body ($F= 16.20$, $df= 1/36$, $p< .01$) weight in fetuses prenatally exposed to alcohol. The brain/body ratio was significantly greater in alcohol-exposed animals, as well, confirming a brain "sparing" effect ($F= 14.84$, $df= 1/36$, $p< .01$). The main effect of aspirin and the alcohol-aspirin interaction terms were not statistically significant. These data suggest that aspirin pretreatment does not antagonize alcohol-induced growth deficits incurred late in gestation in C57BL/6J mice.

193.5 A FURTHER EXAMINATION OF THE EFFECTS OF PRENATAL ALCOHOL EXPOSURE ON THE SEXUALLY DIMORPHIC NUCLEUS OF THE PREOPTIC AREA OF THE HYPOTHALAMUS IN MALE AND FEMALE RATS. S. Barron[1], S.B. Tieman[2], and E.P. Riley[1] (SPON: R. Oesterreich). [1]Center for Behavioral Teratology, [2]Neurobiology Research Center, S.U.N.Y., Albany, NY 12222.

In rodents, prenatal alcohol exposure alters a number of sexually dimorphic reproductive and non-reproductive behaviors that are influenced by perinatal sex steroids. It has been hypothesized that alcohol-induced hormonal alterations might be one mechanism by which prenatal alcohol exposure affects these behaviors. Recently, we examined the effects of in utero alcohol exposure on the sexually dimorphic nucleus of the preoptic area of the hypothalamus (SDN-POA) which is also sensitive to perinatal sex steroid levels. This nucleus is typically larger in males than females. Following prenatal alcohol exposure, the volume of the SDN-POA in male rats, but not female rats, was significantly reduced. To examine the relative specificity of this effect, we have now examined a second nucleus, the nucleus of the anterior commissure (NAC) which is found within the same sections as the SDN-POA but which does not appear to be sexually dimorphic in size. To further examine alcohol-related alterations in the SDN-POA, cell sizes were examined. Subjects were adult male and female rodents who were exposed prenatally to either a 35% ethanol-derived calorie liquid diet or a 0% isocaloric pair-fed control diet on gestation days 6-20. An ad libitum lab chow group was also included. There were no group differences in NAC volume suggesting that the effects previously reported are relatively specific to a sexually dimorphic nucleus. Average SDN-POA cell size was markedly smaller in alcohol-exposed offspring relative to controls in males (p's <0.05) but not in females. This decreased cell size in alcohol-exposed males may be one mechanism by which alcohol alters SDN-POA volume. These findings provide neuroanatomical support for the hypothesis that prenatal alcohol exposure alters sexual differentiation in males and that females may be less sensitive to alcohol's effects on the SDN-POA. (This work was supported, in part, by grants from NIAAA to E.P.R.)

193.6 PRENATAL EXPOSURE TO ETHANOL. EFFECTS ON SYNAPTOSOMAL UPTAKE OF SEROTONIN IN THE CORTEX: Mary J. Druse-Manteuffel and Leo H. Paul* (SPON: J. McNulty) Department of Biochemistry, Loyola University Stritch School of Medicine, Maywood, IL 60153.

Previous studies from this laboratory have shown that the developing offspring of ethanol-fed rats have a deficiency of cortical serotonin (5-HT) and 5-hydroxyindoleacetic acid. In addition, recent studies from this laboratory have found that there is a decreased B_{max} for the binding of [3H]-5-HT to the 5-HT_{1B} receptor (the presumed presynaptic autoreceptor). In an attempt to determine whether other presynaptic components of the serotonergic system are similarly affected by prenatal exposure to ethanol, we studied the uptake of [3H]-5-HT by cortical synaptosomes.

Female, Sprague-Dawley rats were pair-fed using control or 6.6% (v/v) ethanol liquid diets on a chronic basis prior to parturition. Synaptosomes were isolated from whole cortex, motor cortex, and somatosensory cortex from the 19- and 37-day-old offspring of control and ethanol-fed rats. The uptake of 0-1000 nM 5-HT by synaptosomes was determined in the presence and absence of 10 µM fluoxetine.

The results of these experiments demonstrated that the developing offspring of ethanol-fed rats had decreased uptake of serotonin by synaptosomes from the cerebral cortex and cortical regions. These results support our hypothesis that prenatal ethanol exposure has an adverse effect on the development of presynaptic components of the serotonergic system in the cortex.

This research was supported by a grant from the USPHS (AA 03490).

193.7 EFFECTS OF LIMITED POSTNATAL ETHANOL EXPOSURE ON THE RAT CEREBRAL CORTEX. D.E. Phillips and E.A. Harper*. Dept. of Biology, Montana State University, Bozeman, MT 59717.

Although it is known that ethanol exposure during gestation produces behavioral changes and learning and motor deficits in humans, studies of the specific cellular effects of ethanol in the developing sensory-motor cerebral cortex are limited. Most experimental studies have used exposures to rodents during stages of brain development that correspond to the first two trimesters in the human while few studies have examined the effects of exposures during developmental stages equivalent to the third trimester. In this study a limited postnatal ethanol exposure in rats was used to parallel a partial third trimester exposure in human brain development.

Animals were provided controlled exposures by using artificial rearing techniques similar to those of Samson and Diaz (Fetal Alcohol Syndrome, ed., E.L. Abel, 1982, pp 131-150) and West et al.(Alcohol, 1:213-222, 1984). Anesthetized four day old rat pups from normal dams were fitted with a gastrostomy tube and were then provided an artificial diet fed from syringe pumps. Experimental animals received a diet identical to control animals with the exception of 4% ethanol (v/v) added on postnatal days 5 through 9. On day 16 the animals were anesthetized, perfused with aldehydes, and one millimeter slices of the frontoparietal motor cortex at the level of the anterior commissure were prepared for plastic sectioning for light and electron microscopy. Sections (1-2 microns thick) were cut with glass knives, stained with toluidine blue and studied by light microscopy. Measurements of distances and areas were made on a computerized bit pad, either from photomicrographs or directly from the microscope with a drawing tube.

The overall thickness of the cerebral cortex was decreased in ethanol exposed animals to approximately 80% of control values. There were approximately 40% fewer dendrites (greater that 1.3 microns in width) per unit area in experimental animals at a depth corresponding to layer III. The area occupied by dendrites in the same unit area was also decreased a corresponding amount. The number of neurons per unit area at a standardized depth corresponding to layer V were increased in the experimental animals to 145% of control values, probably indicating a slower migration through this layer of later developing neurons. Thus limited postnatal ethanol exposure in the rat causes a delay in maturation of the 16 day frontoparietal motor cortex as evidenced by a probable delay in neuronal migration, a delay in the development of larger dendrites, and an overall decrease in the cortical thickness. 193.8 ULTRASTRUCTURAL STUDY OF LAYER V IN SOMATOSENSORY CORTEX OF MATURE RATS PRENATALLY EXPOSED TO ETHANOL. S. Al-Rabiai and M.W. Miller (SPON: H.J. Gould, III). Dept. of Anatomy, Sch. Osteopathic Med. and R.W. Johnson Med. Sch., U.M.D.N.J., Piscataway, NJ 08854.

Prenatal exposure to ethanol produces abnormalities in the structure of cortical neurons. For example, pyramidal neurons in layer V of ethanol-treated rats have shorter dendrites and dysmorphic spines. Moreover, cortical projection patterns are changed in ethanol-treated rats, e.g., the numbers of cortical neurons projecting to the spinal cord are increased. In this study, we examined the effect of prenatal exposure to ethanol on the ultrastructural organization of layer V. Two groups of rats were fed liquid protein-enriched diets (BioServ) from gestational day 5 to the day of birth. One group was fed a diet containing 37.5% (v/v) ethanol and another group was pair-fed an isocaloric control diet. Postnatally, all mothers and weanlings were fed chow and water. Thirty day old pups were perfused with an aldehyde fixative and somatosensory area 3 was processed by standard electron microscopic techniques. Point counts of the ultrastructural contents of pyramidal and local circuit neurons (e.g., rough endoplasmic reticulum, Golgi apparatus, free ribosomes, mitochondria, and nucleus) were made. For all of these features, no significant differences between the dietary groups were found. The composition of the neuropil also was examined. No significant differences in the percentage of space occupied by dendritic shafts, dendritic spines, axonal varicosities, axonal shafts, myelinated axons, and glia were observed. Comparable numbers of symmetrical and asymmetrical synapses were counted in samples from control and ethanol-treated rats. Analyses of 1.0 µm thick sections revealed that in ethanol-treated rats the numbers of neurons and the space occupied by them was greater, the space occupied by blood vessels was less, and the space taken by the neuropil was less than those in controls. The smaller volume of neuropil coupled with no change in the density of synapses means that the total number of synapses in layer V was less in ethanol-treated rats. This difference may contribute to documented physiological changes such as the lower rate of glucose utilization in layer V of somatosensory cortex of ethanol-treated rats. These changes may underlie clinical characteristics of fetal alcohol syndrome such as mental retardation.

193.9 ASPIRIN AUGMENTS ALCOHOL IN RESTRICTING BRAIN GROWTH IN THE NEONATAL RAT. D.J. Bonthius and J.R. West. Department of Anatomy, University of Iowa, Iowa City, Iowa 52242.

Aspirin has been reported to protect the mouse fetus against the deleterious morphological effects of prenatal alcohol exposure (Randall and Anton, Alcoholism: Clin. Exp. Res., 8:513, 1984), but others have found that aspirin worsens the teratogenic effects of alcohol (Guy and Sucheston, Teratology, 34:249, 1986). The purpose of this study was to determine whether the microencephaly in rats resulting from early postnatal alcohol exposure is altered by a concurrent administration of aspirin. Neonatal rats were gastrostomized on gestational day (GD) 26 (postnatal day 4) and artificially reared from GD 26-32. This includes the period of the brain growth spurt in the rat and is similar to the third trimester of human brain development. The ethanol-treated groups received 6.6 g/kg/day of ethanol and either 0, 12.5, 25 or 50 mg/kg/day of aspirin in a milk solution. The alcohol was administered in 4 of the 12 daily feedings, and the aspirin was administered in all 12 feedings. Control groups received either 0 (gastrostomy control), 12.5, 25 or 50 mg/kg/day of aspirin in a milk solution to which maltose-dextrin had been added, making it isocaloric with the alcohol solutions. Each group consisted of 6 male and 6 female pups. On GD 32, the pups were perfused with a glutaraldehyde/paraformaldehyde fixative, and the brains were removed. Brainstem, cerebellum and total brain weights were measured. Alcohol alone significantly reduced the mean total brain weight, cerebellum and brainstem weight by 20.8%, 22.1% and 12.3%, respectively, relative to gastrostomy controls. A significant interaction [$F(3,80)=4.27$, $p<.01$] between ethanol and aspirin was observed for total brain weight. The mean total brain weight of the group receiving both alcohol and 50 mg/kg/day aspirin was significantly lower than all other experimental groups ($p<.01$), and was reduced 28.9%, relative to gastrostomy controls. The lower doses of aspirin did not significantly alter the effects of alcohol on total brain weight. No interaction occurred between alcohol and aspirin in the measures of cerebellum or brainstem. However, the highest dose of aspirin alone significantly reduced cerebellar weight relative to gastrostomy controls ($p<.05$), but had no significant effect on brainstem or total brain weight. No sex differences were seen in any measurements, nor were body weights significantly different among the groups. No differences in mean peak blood alcohol concentrations were observed among the alcohol-treated groups. In conclusion, 50 mg/kg/day aspirin restricts cerebellar growth and augments the effects of alcohol in restricting brain growth during the brain growth spurt in the neonatal rat. (Supported by NIAAA grant AA05523 to J.R.W. and NIH training grant GM07377 to D.J.B.).

193.10 THE EFFECTS OF RESTRAINT STRESS COMBINED WITH PRENATAL ETHANOL EXPOSURE ON BEHAVIOURAL DEVELOPMENT IN MICE. G.R. Ward*[1] and P.E. Wainwright[2]. [1]Dept. of Psychology, and [2]Dept. of Health Studies, University of Waterloo, Waterloo, Ontario, Canada, N2L 3G1.

Both prenatal ethanol consumption and prenatal stress have been shown to produce behavioural alterations in rodent offspring (Abel, E. Psych. Bull., 90:564, 1981; Ward, I.L., Psychoneuroendocr., 9:3, 1984). Since ethanol consumption increases both the basal levels of corticosterone and the adrenocortical response to stress in pregnant dams (Weinberg, J., & Clendenning, S., Alcohol. Clin. Exp. Res., 8:126, 1984) it is possible that a combination of the two treatments will increase the adverse effects on the offspring. Therefore the present study used a 2 x 2 factorial design to investigate the effects of restraint stress combined with ethanol consumption during the last week of pregnancy on the behavioural development of mouse pups. On day 12 of pregnancy (conception = day 0), female B6D2F mice were fed either of two liquid diets: one in which 25% of the calories were in the form of ethanol, and one in which maltose/dextrin was substituted isocalorically for ethanol. In addition, half the mice in each dietary condition were assigned to a group receiving two daily restraint sessions while the other half remained in their cages. Both treatments were carried out from days 12 to 17 inclusive, and all groups were pair-fed on these days to the group receiving both ethanol and restraint stress in order to control for differences in nutritional intake.

None of the groups differed in terms of pup weight at day 22 or day 32, post-conception, but there were main effects for both ethanol and restraint stress on day 32 behavioural development. While prenatal ethanol exposure retarded development at this stage, restraint stress accelerated behavioural development in the offspring, regardless of the dam's diet or treatment.

In a second study, the animals were sacrificed at day 15 post-conception, the fetuses extracted, and maternal blood assayed for plasma corticosterone and blood alcohol levels. Preliminary analyses of these data support an effect of ethanol on fetal body weight but not of stress. A third study in progress controls for postnatal maternal factors by using a surrogate fostering technique and extends the results to include myelination of forebrain fibre tracts.

193.11 ONTOGENY OF THE BETA-ENDORPHIN RESPONSE TO STRESS: EFFECT OF PRENATAL EXPOSURE TO ETHANOL. P. Angelogianni* and C. Gianoulakis, Department of Psychiatry, McGill University, Douglas Hospital Research Centre, 6875 LaSalle Blvd, Verdun, Quebec, Canada H4H 1R3

Studies on the ontogeny of the hypothalamic-pituitary-adrenal axis in the neonatal rat have shown a reduced response of ACTH and corticosterone to stress in the first 2 weeks of life. Furthermore, prenatal exposure to ethanol was shown to alter the pituitary-adrenal response to stress in adult life. Since in the adult rat ACTH and B-Endorphin (B-EP) are co-released in response to stress, the objective of the present studies was to investigate the ontogeny of the B-EP response to stress and the effect of the prenatal exposure to ethanol. Pregnant rats were fed with an ethanol diet from day 1 of pregnancy till parturition. Control rats were either pair-fed with an isocaloric sucrose diet, or were fed ad lib with lab chow. The response of B-EP to cold and ether stress was investigated in the offspring on days 1, 3, 8, 10, 14 and 22 of life, by estimating the content of B-Endorphin-Like Immunoreactivity (B-EPLIR) in the plasma, the pituitary gland and the hypothalamus at 5 minutes after the onsent of the stress period. All the offspring exhibited either no response or a small response to stress on days 1, 3, 8 and 10 postnatally. A significantly enhanced response of B-EP to stress was noticed on days 14 and 22. On day 14 the release of B-EP in response to cold stress was more pronounced than in response to ether stress. However, on day 22 the responses of B-EP to both cold and ether stress were similar. Ethanol treatment delayed the maturation of the neural pathways mediating the B-EP response to stress as was indicated by the smaller increase of plasma B-EPLIR content on day 14 postnatally, in the offspring exposed to ethanol in utero. However, on day 22 higher responses of B-EP to both cold (40%) and ether (70%) stress were observed in the ethanol treated offspring. In all the offspring the increased plasma levels of B-EPLIR were associated with a decreased content of pituitary B-EPLIR. A small decrease in the hypothalamic content of B-EPLIR following stress was noticed only on day 22 of life. In conclusion the present results indicated the existence of a stress hyporesponsive period for B-EP, and a delay in the maturation of the neural pathways mediating the response of B-EP to stress, by the prenatal exposure to ethanol.

193.12 EFFECTS OF PERINATAL EXPOSURE TO ASPARTAME ON RAT PUPS. M.D. Holder* (SPON C. Harley). Psychology, Memorial University of Newfoundland, St. John's, NFLD Canada A1B 3X9.

Possible side effects of perinatal exposure to L-aspartyl-L-phenylalanine methyl ester (aspartame) on rat pups were investigated. Aspartame (.007%, .036%, .18% or .9% w/v), or phenylalanine (.45%), or nothing was added to the only water source of adult females and later their pups for 12 days prior to conception until the pups were 36 days of age. Compared to the pups that were exposed only to plain water, no effects of aspartame or phenylalanine were detected on two measures of morphological development. Latencies to pinnae detachment and eye opening were similar for all groups. There was also no effect on two tests of reflex development. Latencies for surface righting and negative geotaxis at 7 and 8 days of age respectively did not differ between groups. All groups were similar in spatial memory as assessed with two different mazes with pups 30-36 days of age. The number of arms chosen before reentry in an 8-arm radial-arm maze and the acquisition curves from a Morris milk maze did not differ between groups. Furthermore, the latencies of mothers to retrieve their litters was also unaffected by the aspartame and phenylalanine. These results suggest that perinatal exposure to aspartame does not have side effects on rat pups as assessed with a wide range of measures.

Group	water	aspartame .007%	aspartame .036%	aspartame .18%	aspartame .9%	phenyl
Measure						
Pinnae detachment	4.00	3.79	4.20	4.20	3.50	3.83
litters	11	7	10	5	6	6
Eye opening	15.35	15.57	15.40	15.75	15.25	15.08
litters	10	7	10	4	6	6
Righting Reflex	5.70	4.86	4.70	3.50	2.67	3.67
litters	10	7	10	4	6	6
Negative Geotaxis	27.7	31.4	31.1	28.0	22.5	25.8
litters	10	7	10	3	6	6
Maternal Retrieval	326	478	407	299	513	391
litters	10	7	10	4	6	6
Radial Arm Maze						
arms to reenter	3.22	3.04	3.05	3.08	3.32	3.92
litters	10	7	10	4	6	6

Latencies for pinnae detachment and eye opening are reported in days and for righting reflex, negative geotaxis and maternal retrieval in seconds. Values in table including the number of arms entered before reentering an arm in the 8-arm radial maze were determined by first calculating a mean for each litter and then a mean for each group was calculated using these litter means.

193.13 PRENATAL NICOTINE EXPOSURE AFFECTS DEVELOPMENT OF NORADRENERGIC SYSTEMS. H.A. Navarro*, F.J. Seidler*, W.L. Whitmore* and T.A. Slotkin (SPON: L. Schweitzer). Dept. of Pharmacology, Duke Univ. Med. Ctr., Durham, NC 27710.

Smoking during pregnancy is associated with low birth weight and neurobehavioral alterations in the offspring. Pregnant rats injected with nicotine have been used as a model for smoking, specifically because acute nicotine administration results in hypoxia and ischemia, which are features common to smoking. To distinguish between effects due to hypoxia/ischemia vs. those due solely to nicotine, we implanted pregnant rats with osmotic minipumps on the 4th day of gestation, to deliver a dosage rate of 6-8 mg/kg/day through gestational day 20. Development of catecholamine systems was then evaluated in three brain regions with different cellular maturational profiles (midbrain + brainstem, cerebral cortex, cerebellum) as well as in the peripheral sympathetic nervous system. In the CNS, prenatal nicotine exposure produced alterations which were both regionally-targeted and transmitter-specific. In the midbrain + brainstem and cerebral cortex, neonates exhibited a generalized deficit in norepinephrine levels which resolved by the second to third postnatal week. A similar pattern was seen for dopamine levels in the cerebral cortex, but not in the midbrain + brainstem. No deficits of catecholamine levels were seen in the cerebellum. Because levels of transmitters do not necessarily indicate neural activity, we also assessed turnover rates for the catecholamines after acute administration of α-methyl-p-tyrosine. An initial deficit in transmitter turnover was seen only for the cerebral cortex, where again the effect disappeared by the second to third postnatal week. A different effect was evident in the midbrain + brainstem, where norepinephrine turnover tended to be elevated initially and depressed in young adulthood, with no apparent changes in dopamine turnover. In the cerebellum, only a late increase in turnover was apparent in the nicotine-exposed animals. To rule out the possibility that changes in turnover reflected primary actions on the number of nerve terminals, we also measured synaptosomal uptake of norepinephrine, which was generally unaffected by nicotine exposure; in contrast, tyrosine hydroxylase activity, which is reactive to nerve impulse activity, showed a deficit in the region (cerebral cortex) in which turnover was most affected. These data are consistent with a slowing of development of neural activity in the cerebral cortex of animals exposed to nicotine via maternal infusions. The results can be contrasted with earlier work with injected nicotine (nicotine plus hypoxia/ischemia), where evidence for cortical hyperinnervation and increased turnover was obtained. However, at least some features of the nicotine infusion effect resemble those of injected nicotine, including late elevations in cerebellar noradrenergic activity and suppression of development of peripheral sympathetic innervation of the lung. These data support the view that both nicotine and hypoxia/ischemia contribute to neurobehavioral alterations caused by tobacco consumption. (Supported by a grant from the Smokeless Tobacco Research Council and by USPHS NS-06233).

193.14 THE INFLUENCE OF PRENATAL PHENOBARBITAL EXPOSURE ON THE GROWTH OF DENDRITES IN THE HIPPOCAMPUS. C. D. Jacobson, L. L. Antolick*, R. Scholey* and E. Uemura (SPON: P. S. Lacy). Dept. of Veterinary Anatomy, Iowa State University, Ames, Iowa 50011.

Barbiturates, such as phenobarbital, are often used during pregnancy and early neonatal life to prevent epileptic seizures, hyperbilirubinemia and the stressful effects of labor. However, the long term consequences of barbiturate exposure during the prenatal and neonatal period have not been fully investigated. Several studies have indicated that phenobarbital does effect the resulting morphology and neurochemistry of various components of the central nervous system. In the present study we have investigated the effects of three days of prenatal phenobarbital administration on the growth and development of dendrities within the CA1 region of the hippocampus. Timed pregnant females obtained from our animal colony were used. The presence of sperm in the vaginal smear on estrus was defined as day 1 postfertilization (pf). On days 18, 19 and 20 pf pregnant females were given a subcutaneous injection of sodium phenobarbital (40 mg/kg body weight; PHB) or vehicle. All females delivered on day 23 pf which is defined as day 1 of postnatal life. Pups were sacrificed on days 5, 10, 23 and 35 of postnatal age and the brains were processed for golgi impregnation of neurons. The apical and basilar dendrites of neurons within the CA1 region of hippocampus were analysed with the aid of a scanning stage on a Zeiss universal photomicroscope and a PDP 11/23 microcomputer. In general, results indicated that three days of prenatal PHB severely suppresses the development of the dendritic tree which normally takes place during the first 35 days of postnatal life. There are significantly less branch points and the overall dendritic length of both apical and basilar dendrites is reduced. These results indicate that prenatal PHB, even for short periods of time, affects the normal morphological development of the hippocampus. Thus, the utilization of PHB during the gestational period should be questioned. Supported by NIH grant HD 16148 and the March of Dimes Birth Defects Foundation grants # 1-974 and 15-56.

193.15 EFFECT OF CLONIDINE TREATMENT DURING PREGNANCY ON MATERNAL BLOOD PRESSURE AND THE SENSITIVITY TO SALT-INDUCED HYPERTENSION IN THE OFFSPRING. J.A. McCaughran, Jr. and C.J. Juno*. Department of Psychiatry and Behavioral Science, SUNY @ Stony Brook, Stony Brook, NY 11794.

Hypertension (HT) during pregnancy is a problem that affects a significant number of women each year. The disease presents a threat to maternal health and can compromise fetal development. Although anti-hypertensive drug therapy can reduce maternal mortality and morbidity, there is a risk that the drug may cross the placental barrier and enter fetal circulation. In this study, the effect of chronic administration of the antihypertensive α_2 agonist clonidine on blood pressure (BP) in pregnant inbred Dahl HT-sensitive (S/JR) and -resistant (R/JR) rats maintained on a low salt diet (0.15% NaCl, w/w) was investigated. An Alza miniosmotic pump (#2ML4), containing 0.66 mg/ml clonidine·HCl or the distilled water vehicle, was implanted under the skin of the back in timed-pregnant or age-matched non-pregnant S/JR and R/JR dams on the first day of gestation. BP, heart rate (HR), and body weight (BW) were monitored at 4 day intervals until the removal of the pump on day 20 of gestation. BP, HR, and BW were then monitored once daily until parturition. Overall, BP was greater in the S/JR strain than the R/JR strain. Chronic administration of clonidine to non-pregnant S/JR rats caused a significant reduction in BP and HR relative to vehicle-treated controls. In the same R/JR groups, the drug caused significant bradycardia but did not reduce BP. These contrasting effects suggest that BP in S/JR strain is more sensitive to the anti-hypertensive effects of the drug than the R/JR strain. In pregnant rats from each strain, HR was lower in drug-treated rats than vehicle-treated rats. Interestingly, BP was similar which suggests that antihypertensive effects of the drug did not exceed the reduction in BP that normally accompanies pregnancy in either strain. Treatment with clonidine during pregnancy did not affect fetal mortality or morbidity in the S/JR strain. However, the fetotoxicity of the drug was greater in the R/JR strain, as indicated by a significant reduction in the number of pups/litter relative to vehicle-treated dams. Growth rates within each strain were similar between drug- and vehicle-exposed offspring until weaning at 25 days of age, although BW in S/JR off-spring was consistently greater regardless of the prenatal treatment. At 25 days of age, offspring were weaned to low (0.15%) or high (2.0%) salt diets and BP, HR and BW were monitored. Thus far, the data suggest that prenatal exposure of either strain to clonidine does not effect BP in the R/JR rat or the development of HT in the S/JR rat weaned to the high salt diet.

193.16 EFFECTS OF PRENATAL COCAINE EXPOSURE: I. INITIAL OBSERVATIONS AND REFLEX DEVELOPMENT. C.L. Kirstein, R. Greenbaum*, H. Hoffmann*, N.E. Spear & L.P. Spear. Dept. of Psych. and Centers for Neurobehav. Sci. and Developm. Psychobiol., SUNY-Binghamton, Binghamton, NY 13901.

Offspring of Sprague-Dawley dams that were either: (a) injected s.c. daily on gestational Days 8-20 (E8-20) with 40 mg/kg cocaine HCl, (b) injected daily with the saline vehicle solution and pair-fed to cocaine-treated dams; or (c) not injected and allowed ad lib access to lab chow and water were used in this experiment. All dams were weighed daily from E6-20. On postnatal Day 1 (P1), litters were counted, sexed and examined for gross morphological alterations prior to culling each litter to 10. One female and one male from each litter were examined daily from P3-20 on a test battery including physical maturation measures (body weight at P1,7,14,21; age of eye opening and upper and lower incisor eruption) and sensorimotor reflex development (righting reflex, cliff aversion, horizontal screen, vertical screen and inclined plane tests). No significant differences in maternal weight gain during gestation were observed among the treatment groups. Similarly, the three treatment groups did not differ in number of pups born per litter nor in male/female ratios of offspring. No body weight differences were observed among the treatment groups at P1, although a sex difference in body weight was detected. While no body weight differences were observed in offspring at P7 and 14, at P21 cocaine-exposed offspring exhibited slightly reduced body weights when compared with pups in the control conditions. Other than these body weight differences at weaning, cocaine-treated offspring exhibited very similar patterns of physical maturation and reflex development as offspring in the control groups. Thus, it appears that this dose of cocaine does not have notable adverse effects on pup integrity and maturation, and thus appears to be a suitable dose for further neurobehavioral assessment. Indeed, as is discussed in the following abstract, offspring so exposed prenatally to cocaine did exhibit alterations in both aversive and appetitive conditioning during infancy.

193.17 EFFECTS OF PRENATAL COCAINE EXPOSURE: II. BEHAVIOR, LEARNING AND RETENTION OF APPETITIVE AND AVERSIVE ODOR CONDITIONING IN INFANCY. L.P. Spear, J. Bell*, J. O'Shea*, V. Yootanasumpun*, H. Hoffmann*, N.E. Spear & C.L. Kirstein. Dept. of Psych. and Centers for Neurobehav. Sci. and Developm. Psychobiol., SUNY-Binghamton, Binghamton, NY 13901.

Offspring of Sprague-Dawley dams injected s.c. with 40 mg/kg cocaine HCl daily from gestational Days 8-20, pair-fed dams injected daily with the vehicle alone and ad lib control dams were used as subjects in these experiments. Three offspring per litter were examined in an appetitive odor conditioning experiment on postnatal day 7 (P7). Animals were given either 3 paired or 3 explicitly unpaired presentations of the CS+ odor and milk infusion, together with 3 exposure trials to the CS- (no milk) odor. Pups in a third group were exposed to only the milk infusion. Immediately following training, pups from the pair-fed and lab chow groups displayed evidence of conditioning, whereas prenatal cocaine-treated pups did not. 24 hr. later, retention was evident in the lab chow and pair-fed groups, whereas no significant retention was observed in the cocaine-exposed group. Three additional offspring per litter were examined in an aversive conditioning experiment, using analogous conditioning groups and training procedures as outlined above. Two trials were given per day on P8 and 10. A reversal of the CS+/CS- odors was introduced prior to training on P12, 14 and 16. Conditioning was assessed immediately after each conditioning session and also 24 hr later. On P8, conditioning exhibited on an immediate test was impaired in the pups prenatally exposed to cocaine. Cocaine exposed animals, however, tended to exhibit facilitated 24 hour retention both for the original odor discrimination and its reversal. When compared with the control offspring, cocaine-exposed offspring also appeared to display an earlier ontogenetic peak in wall climbing and matrix crossings in this testing situation. These observations support the suggestion that there are behavioral consequences of prenatal cocaine exposure which are evident ear in the postnatal period.

193.18 **PRENATAL COCAINE EXPOSURE AND DEVELOPMENT OF STRIATAL DOPAMINE RECEPTORS.** **W. Zeng* and L.C. Murrin.** Dept. of Pharmacology, Univ. of Nebraska Medical Center, Omaha, NE 68105

The recent epidemic in cocaine abuse in this country has led to increasing concerns about the effects of prenatal exposure to cocaine on the fetus. A major concern is how this exposure affects development of organ systems, and particularly the central nervous system. Because cocaine has well-defined effects on dopamine neurons, they are a likely site for developmental effects that may be produced by cocaine. We began studies to examine this possibility. Pregnant Sprague-Dawley rats were administered cocaine hydrochloride by one of two routes, i.p. injection or osmotic mini-pump. At 14 and 21 days of age postnatally, striata were dissected and analyzed for D1 and D2 receptors using standard membrane binding techniques. Ligands used were ^{3}H-SCH 23390 + 30 nM ketanserin for D1 receptors [1 uM piflutixol added for blanks] and ^{3}H-spiperone + 30 nM ketanserin for D2 receptors [1 uM (+)butaclamol for blanks]. In initial studies we found that a dose of 40 mg/kg administered i.p. on days E15 and E18 led to small litter sizes and significantly reduced weights in the pups from day 0 to day 7 postnatally. A dose of 30 mg/kg on the same schedule did not significantly reduce litter size but it did produce lower weights in the first week postnatally. A dose of 20 mg/kg i.p. on E15 and E18 produced no significant effect on pup weight from birth through 21 days of age. At 14 days of age this dose of cocaine produced no significant changes in D1 or D2 receptors but at 21 days of age there was a significant increase in the number of both receptors.

21 Day		
Control	4407 ± 334	3586 ± 146
20 mg/kg i.p.	5794 ± 403*	4864 ± 260*

*** - Significantly different from control, p<.02, ANOVA followed by Scheffe's test. n=13 to 15. Data are mean ± SEM.**
Administration of cocaine via osmotic mini-pump at a dose of 30 mg/kg per day had no significant effects on pup weight or development of D1 and D2 receptors, probably due to low plasma levels of cocaine. These data indicate that exposure to cocaine prenatally at doses that do not significantly affect the weight of pups can produce alterations in the normal development of dopamine receptors. Presumably this reflects alterations in the level of dopamine activity in the synapse. E15 and E18 represent times early in the development of the nigrostriatal dopamine neurons. While preliminary, these data indicate prenatal cocaine exposure may alter normal development of the brain. **Supported by NS23975.**

NEUROTOXICITY: METALS

194.1 TRIETHYLTIN NEUROTOXICITY IN AREA CA1 OF THE HIPPOCAMPAL SLICE. S.B. Fountain, Y.L.T. Ting, S.K. Hennes*, J.A. Zuga*, and T.J. Teyler. Department of Neurobiology, Northeastern Ohio Universities College of Medicine, Rootstown, Ohio 44272.

Triethyltin (TET), an industrial plasticizer and biocide, induces reversible edema and splitting of myelin. We examined the effect of TET on the electrophysiology of area CA1 of hippocampus. Hippocampal slices 400-450 um thick were obtained from adult hooded rats and maintained in vitro at the interface of a medium pool containing artificial cerebrospinal fluid and an atmosphere providing a suitable oxygen content. Stimulation of Schaffer collaterals was used to evoke field potentials which were recorded from CA1 pyramidal cells. For each slice, an input/output (I/O) profile was obtained before TET exposure; the I/O profile characterized the CA1 population EPSP and spike responses produced by a wide range of stimulus intensities. In addition, a "paired-pulse" (or "double-shock") procedure was used to assess the status of the recurrent inhibitory system which normally modulates the CA1 pyramidal cell response. Slices that failed to show a stable baseline response to a constant stimulus or that failed to demonstrate significant inhibition prior to TET exposure were excluded from the experiment.

After these baseline measures were obtained, slices were exposed to either 1, 3, or 10 uM TET in the incubating medium. Acute TET exposure was accomplished by medium exchange using a push-pull pump. Following the onset of TET exposure, the timecourse of changes in slice excitability was observed by recording the CA1 population response to a "standard" stimulus every 5 min; the "standard" stimulus was one that produced a 1 mV population spike preexposure. The monitoring of changes in slice excitability was interrupted at the end of each hr postexposure to obtain an I/O profile and to administer a paired-pulse test. Slice excitability was monitored in this way for 3 hr post-exposure.

TET exposure suppressed population EPSP slope and spike amplitude at each concentration tested. In addition, the timecourse of effects was dose-dependent; the population spike elicited by the "standard" stimulus was nearly completely suppressed by 2-3 hr postexposure for 1 and 3 uM exposures, and by 1-2 hr postexposure for the 10 uM exposure. The effects of TET on inhibitory systems assessed by the paired-pulse test were much less pronounced. Additional results will be reported that assess the specificity of TET effects on axonal conduction of Schaffer collaterals.

194.2 SERIAL AUDITORY BRAINSTEM RESPONSES AND NEUROPATHOLOGY IN GUINEA PIGS DRINKING TRIETHYLTIN SULFATE. A.A. Lidsky and E.R. Popovitch*. NY State Institute for Basic Research in Developmental Disabilities, Staten Island, N.Y. 10314

While triethyltin-induced neuropathology has been described in detail for the visual system of several species this paper uniquely presents progressive neurophysiological effects on, and pathology of, the auditory system in guinea pigs. Hartley animals were exposed ad libitum to triethyltin sulfate (TET), a dysmyelinating agent, in drinking water (30 mg per liter). Auditory Brainstem Responses (ABR) to clicks were recorded twice weekly with permanently implanted skull screw electrodes (Cz-Fz) in restrained awake animals, beginning before exposure to TET, to monitor sequential changes in respective ABR components. Significant delays in all ABR peaks were identified in animals receiving TET, in relation both to their pre-TET scores and to repeated tests in Control animals. However, delays of individual peaks - which were most consistent for PIII and PIV - were found to vary as functions of several factors, including number of days on TET (DoT), auditory stimulus rates (5 vs 10 Hz), and the animals' ages at the start of TET ingestion (30 - 90 days).

Morphological analyses of the auditory pathway white matter supported the observations suggested by ABRs. Induced pathological changes consisted most prominently of vacuolation, the severity of which was rated from mild to extensive. While delayed peaks in ABR waves I through IV were evident within three DoT, the most prolonged latencies of components I through V were seen at 18-21 DoT. Until 14 DoT vacuolation was only mild or moderate, with ratings of severe or extensive limited to animals evaluated after 20-54 DoT. Youngest TET animals were affected earliest with delays in ABR components PII, PIII and PV, while more mature animals were initially most delayed at PIV and PIII. The hematoxylin-eosin and myelin stains revealed widespread vacuolation, with the most severe histopathological changes at the levels of the superior olivary complex and trapezoid bodies. The data are also contrasted with sequential results from guinea pigs with experimental allergic encephalomyelitis, in which local inflammatory activity, demyelination, and more selective involvement of ABR peaks are described.

194.3 *EFFECTS OF TRIMETHYLTIN ON CA1 PYRAMIDAL CELLS IN RAT HIPPOCAMPAL SLICES.*

D.L. Armstrong, A.B. Garber*, F. Montemayor* and M.J. Wayner.

Brain Research Laboratory, Division of Life Sciences, University of Texas at San Antonio, San Antonio, TX 78250.

Pyramidal cells of the hippocampus are among the neurons that display pathological responses following exposure to low levels of the neurotoxin trimethyltin (TMT). The mechanisms underlying this selective toxicity is unknown. We have previously studied the effects of TMT on evoked potentials and spontaneous activity of hippocampal pyramidal cells using extracellular techniques. In the present study intracellular recordings of pyramidal cell responses were made before, during and after TMT application to determine the toxin's affect on membrane parameters.

Transverse rat hippocampal slices were placed in a constant perfusion recording chamber mounted on a microscope stage. A miniature concentric bipolar electrode, positioned in the Schaffer collaterals, was used to provide orthodromic stimulation of pyramidal cells in the CA1 region. Intracellular recordings were made from CA1 pyramidal cells to assess the effects of TMT on: (1) resting membrane potential, (2) input resistance, (3) orthodromic synaptic input, (4) action potential amplitude and (5) spike size. Data was used only from cells with resting membrane potentials greater than -50 mV, input resistances >35 Meg ohms, and spike amplitudes greater than 55 mV. Thirty three cells successfully fulfilled all three criteria.

In 18% of the cells tested (n=6), a 10 min exposure to a low concentration of TMT (1 to 2 um) produced a 10 to 15 mV membrane depolarization. The level of depolarization was sufficient to initiate spike activity in previously quiescent cells. These excitatory effects were reversible after superfusing the slice with normal saline for a 20 min period. Despite the change in membrane polarization and firing activity, we did not observe significant effects of TMT on either input membrane resistance, action potential duration or spike amplitude in these neurons. In the remaining CA1 pyramidal cells tested (n= 27), we did not observe any significant change in their electrophysiological parameters with TMT exposure up to periods of 30 min.

The TMT-evoked activity in 18% of the cells was unexpected since previous extracellular experiments in our laboratory have demonstrated a small, but significant decrease in population spike amplititude under similar exposure conditions. It is possible that the excitatory responses produced in one subpopulation of cells is masked by other events occurring during the simultaneous firing that generates a population spike. Higher concentrations of TMT are currently being tested to determine threshold differences between cells. Suported by NIH Grant RR08194.

194.4 DISTINCT RESPONSES OF CHOLINERGIC FOREBRAIN AFFERENTS TO A SINGLE ADMINISTRATION OF TRIMETHYLTIN CHLORIDE IN RATS. J.A.D.M. Tonnaer, D.C.E. De Goey*, J.J. Hagan* and P. Room*. CNS Pharmacology Department, Organon International B.V., 5340 BH Oss, The Netherlands.

Trimethyltin chloride (TMT) is an organotin compound which, following acute administration, induces severe neuropathological changes in the brain's limbic system. In rats, hippocampal CA_3 and CA_4 pyramidal cells and the dentate gyrus afferents from the entorhinal cortex appear particularly vulnerable to TMT. Little information is available, however, on the effects of TMT on an other major hippocampal input system: the cholinergic afferents entering via the fimbria-fornix. In the present study, therefore, the long-term consequences of TMT on post- and presynaptic cholinergic markers were evaluated in the hippocampus and compared to those in other brain regions. For this purpose, adjacent cryostat brain sections from control or TMT-treated Wistar rats were used for histological staining and quantitative autoradiography employing [^{3}H]quinuclinidyl benzilate ([^{3}H]QNB) and [^{3}H]hemicholinium-3 ([^{3}H]HC) as the radioligands. These ligands are considered as post- and presynaptic cholinergic markers, as they specifically bind to postsynaptic muscarinic binding sites and presynaptically located high-affinity choline carriers, respectively.

Rats were treated once by gavage with vehicle or TMT at a dose of 7.5 mg/kg or 10 mg/kg, and sacrificed after time intervals varying from 1 to 12 weeks. Three weeks after 7.5 mg/kg TMT, rats were impaired in a spatial learning task. This points to hippocampal dysfunctioning. Indeed, pyramidal cell atrophy in the CA_3 and CA_4 region was observed, whilst atrophy was extended to other hippocampal areas at the higher dose. Granular cells in the dentate gyrus were preserved but their density exhibited a more condensed package, possibly due to changes in the neuropil. TMT caused a gradual impairment of muscarinic receptor binding, especially in CA_3 and CA_4. At the dose of 7.5 mg/kg, TMT induced a 5 weeks persisting enhancement of [^{3}H]HC binding to cholinergic terminals of both the supra- and infrapyramidal afferents. After 12 weeks, [^{3}H]HC binding in CA_2, CA_3 and CA_4 was decreased below control values whilst binding to CA_1 and the dentate gyrus still was above control values. At the higher dose a much stronger immediate enhancement of [^{3}H]HC binding was observed, whereas this binding started to decline from week 1. Different effects on [^{3}H]HC binding, with respect to magnitude and time course, were evident in the amygdala and neocortex. The present data illustrate distinct responses to TMT of cholinergic projections innervating particular brain structures. The responses observed may be secondary to the typical neurotoxic effects of TMT on hippocampal or cortical neurons. Alternatively, TMT may have a direct action on particular cholinergic neurons in the forebrain.

194.5 SUSCEPTIBILITY OF RAT MESOLIMBIC AND NIGROSTRIATAL DOPAMINERGIC NEURONS TO CHRONIC LEAD EXPOSURE. S.M. Lasley and J.D. Lane. Dept. of Basic Sciences, U. of Illinois Coll. of Med., Peoria, IL 61656 and Dept. of Pharmacology, Texas Coll. of Osteopathic Med., Ft. Worth, TX 76107.

In previous work a decreased radiolabelled dopamine (DA) turnover in nucleus accumbens (NAc) has been observed after chronic Pb exposure as well as associated Pb-induced alterations in the DA response to d-amphetamine in striatum and NAc. Further evidence suggests that Pb results in decreased GABA activity in striatal and NAc efferents. These studies indicate that the neurotoxic action of Pb on DA neurons is largely presynaptic in origin and at least partially related to changes in DA synthesis. A primary form of DA synthesis regulation is the inhibition exerted on synaptic tyrosine hydroxylase activity via dopaminergic autoreceptors. This study assessed the functional status of this mechanism employing a pharmacological model.

At parturition dams received 0.2% Pb acetate in the drinking water while control dams received distilled water. Offspring were weaned to and maintained on the same solution given their dam until sacrifice at 125 days. Forty min before sacrifice rats were given saline or a DA agonist (2.5-20 mg/kg i.p.), 6,7-dihydroxy-2-dimethylaminotetralin (TL-99), followed 10 min later by 750 mg/kg i.p. of gamma-butyrolactone (GBL) or saline. NAc, caudate-putamen (C-P), substantia nigra (SN), and ventral tegmental area (VTA) were analyzed for content of DA and its metabolites.

The ability of TL-99 to prevent the GBL-induced increase in DA content was significantly diminished in NAc of exposed rats compared to controls. A similar result in C-P was not statistically significant. This finding suggests that chronic Pb exposure impairs receptor-mediated regulation of synthesis in mesolimbic DA nerve terminals. Concentrations of DA and dihydroxyphenylacetic acid were significantly decreased by Pb exposure by 23 and 25%, respectively, in VTA - but not SN - from animals receiving only saline injections. In this latter group homovanillic acid content was significantly diminished by exposure in NAc(21%), SN(21%), and VTA (29%).

The basis of the differential effect of Pb exposure on the mesolimbic and nigrostriatal dopaminergic systems is not known. However, other studies have shown the mesolimbic DA system to be more sensitive to treatment with ethanol, opiates, and psychomotor stimulants than the nigrostriatal system. The question as to whether the Pb-induced changes in NAc and VTA are related or discrete is currently under investigation. (Supported by ES04359).

194.6 EFFECTS OF CHRONIC EXPOSURE TO LEAD ON A TERRESTRIAL MOLLUSK FAST BURSTER NEURON. A. Camara*, G. Daston*, and J. Copeland. Department of Biological Sciences, University of Wisconsin-Milwaukee, Milwaukee, WI 53201 and Department of Biology, Swarthmore College, Swarthmore, PA 19081.

Lead is a common environmental pollutant. We have studied the effects of chronic exposure to lead on the spiking of an autoactive burster neuron and the survivorship of a terrestrial slug.

Limax maximus is a terrestrial pulmonate gastropod mollusk, a herbivore commonly found in moist woods, hedgerows, and gardens. It possesses a circumesophageal nerve ring and paired buccal ganglia. Each ganglion contains numerous large re-identifiable neurons, some of which are autoactive.

The salivary burster neuron (SB) is a fast burster neuron found in each buccal ganglion. A process of SB innervates the musculature of the ipsilateral salivary duct and initiates duct peristalsis. SB has been shown to be autoactive, and its autoactivity can be altered by excitatory and inhibitory synaptic drive from other buccal and cerebral ganglion neurons.

Using atomic absorbance spectrophotometry, we found that environmental lead entered the hemolymph of the slugs. Slugs were exposed for 12 weeks to lead ($0.01 - 2 \times 10^4$ ug/l) placed in their food and water. Hemolymph showed a positive dose-response relationship for the presence of lead. However, lead was present at considerably less than environmental levels.

Survivorship of slugs after 12 weeks exposure to all concentrations of lead was significantly reduced. Additionally, survivorship was significantly reduced after 8 weeks of exposure to lead (2×10^4 ug/l). However, there was no reduction in survivorship after 4 weeks of exposure to the same concentration of lead.

We looked for evidence of toxicity at the neuronal level by monitoring the axon spike of SB during five minute recording sessions in all animals chronically exposed to lead. The number of bursts which occured were counted, and the interburst intervals (IBI) were measured.

Lead exposure at the highest concentration had an excitatory effect on burst activity with 12, 8, and 4 week exposure. Both IBI and number of bursts were significantly changed versus controls. Thus, at 4 weeks exposure, when suvivorship was high, a significant toxicological effect could be seen with chronic exposure to lead.

194.7 A NEW MODEL OF GESTATIONAL LEAD TOXICITY: FETAL BRAIN LEAD ACCUMULATION. E. J. Kasarskis and T. M. Forrester*. Depts. Neurology and Toxicology, VA and Univ. Kentucky Med. Ctrs., Lexington KY, 40536-0084.

Skeletal lead (Pb) has been considered to represent a relatively inert depot for this element, with minimal neurotoxicologic consequences. A chance observation indicated significant mobilization of maternal Pb during gestation several months following Pb exposure, accompanied by CNS hemorrhages and Pb accumulation. We report the results of a systematic investigation of this phenomenon.

Groups of Sprague-Dawley dams were exposed to inorganic Pb for 21 days during lactation (0.2% - 2.5% Pb acetate in drinking water) according to the classic postnatal Pb toxicity paradigm of Pentschew and Garro (Acta Neuropath 6:266-78, 1966). Rats were subsequently offered Pb-free commercial chow and distilled water for 5 months, followed by mating to non-Pb exposed males. At 21 days gestation, fetuses were delivered by Caesarian section, weighed, and observed for congenital malformations. After dissection (into femur, kindney, liver, spleen, heart, cortex, brainstem, hippocampus, pons, and cerebellum), pooled fetal tissue samples from a given litter and maternal specimens were analyzed for Pb content by graphite furnace atomic absorption spectrophotometry using the method of standard additions. NBS certified liver was simultaneously analyzed as a secondary comparator standard.

Although estrous cycles and mating behaviors were unaffected, prior Pb exposure was associated with an increased number of fetal resorptions and stillbirths in a dose-related fashion. In viable fetuses, widespread hemorrhages were observed throughout the CNS. Lead, presumably mobilized from the maternal skeleton, was deposited in the developing fetus. Of the tissues sampled, Pb accumulation was greatest in fetal hippocampus and cerebellum (11.0 and 56.9 ug Pb/g dry matter, respectively).

The results of this study indicate that Pb, once deposited in the skeleton, remains a latent toxin which can be mobilized during subsequent pregnancies, even in the absence of overt maternal toxicity in the interim. The mobilized Pb appears to preferentially accumulate in the hippocampus and cerebellum of the developing fetus. By employing cross-fostering techniques, the present model offers the potential to investigate the differential effects of pre- and postnatal Pb exposure upon subsequent behavior. (Suported by the VA Research Service, the MDA, and NIH grants NS00768 and AA05931).

194.8 NEUROTOXICITY OF LEAD IN IMMATURE GUINEA PIGS. T. Rowles*, A.J. Castiglioni, G. Miller*, C. Womac*, G. Wall*, J.-N. Wu*, G.R. Bratton and E. Tiffany-Castiglioni. Dept. Veterinary Anatomy, Texas A&M University, College Station, TX 77843.

Studies have shown behavioral deficits and lower I.Q. in children with moderately elevated blood or dentine Pb levels who are asymptomatic otherwise. These findings are supported by numerous animal studies. However, these studies usually use the suckling rat model and employ much larger Pb doses than children receive, because rats are very resistant to Pb toxicity. A more Pb-sensitive animal model is needed in order to better define the cellular effects of Pb. We evaluated the immature guinea pig as a model because the adult guinea pig is very sensitive to Pb neurotoxicity. In Trial I, Pb acetate (0, 5, or 20 mg/kg body weight) was given orally for 5 consecutive days to 10-day-old guinea pigs. With this regimen, Pb had no effect on body and organ weights. Tissues were collected 24 days after Pb treatment was discontinued. Blood lead levels (ppm) were significantly ($p<0.01$) elevated in the 5 mg (0.02) and 20 mg (0.06) treatment groups over the control value (0.01). Liver and kidney Pb values in the 20 mg group (0.19 and 0.18) were double the Pb values of the control group (both 0.07). In contrast, Pb levels (mg/kg) were only slightly ($p<0.05$) elevated in the cerebrum (0.08 control vs. 0.10 treated). Zinc values in blood were unaffected by 20 mg Pb treatment, but were almost doubled in both cerebrum and kidney, e.g. 2.75 mg/kg in control vs 5.76 mg/kg in treated cerebra. On the other hand, zinc levels in liver were significantly reduced by 20 mg Pb treatment. Copper levels were elevated in blood, but unchanged in kidney, liver and cerebrum. Blood zinc protoporphyrin (ZPP) levels and blood ALAD activity were normal in all groups. The finding that zinc was elevated in brain and kidney indicates that potentially toxic cellular changes may occur that are undetectable by measurements of ALAD and ZPP. Trial II guinea pigs were treated with Pb (0, 10, 20 mg/kg) for two periods of 5 days (10-15 and 18-23). Tissues were collected on day 103. Blood Pb ($p<0.05$) increased in the 20 mg group, but no differences in blood copper, zinc, ZPP, or ALAD values were found. However, image analysis of Golgi-stained brain tissues revealed abnormalities in astroglia and neurons. In particular, maximum diameters (measured from the tips of the processes) of astroglia in the parietal lobe were reduced in the 20 mg group (60.8 um) relative to the control group (60.8 um). The functional significance of these alterations is unknown. Funded by the Center for Energy and Mineral Resources, TAMU and EPA R811500.

194.9 EFFECTS OF *IN VITRO* AND *IN VIVO* LEAD EXPOSURE ON VOLTAGE-DEPENDENT CALCIUM CHANNELS IN CENTRAL NEURONS OF *LYMNAEA STAGNALIS*. Gerald Audesirk. Biology Department, University of Colorado at Denver, 1100 14th Street, Denver, CO 80202.

Currents through calcium channels of members of the B cell cluster of neurons in the brain of the pond snail *Lymnaea stagnalis* were studied under voltage clamp. To maximize the visibility of voltage-dependent calcium currents and minimize contamination by other currents, the normal physiological saline was modified by substituting tetraethyl ammonium for sodium (to eliminate sodium currents and to suppress voltage-dependent potassium currents) and barium for calcium (to suppress calcium-activated potassium currents). Brains were removed from animals never exposed to lead *in vivo*, a B cell was voltage clamped and the brain was perfused with modified saline. Cells were stepped from -100 to 0 mV to obtain a control I-V curve. Depolarizing voltage steps induce an inward current, the magnitude of which varies with the barium concentration. This current is presumably carried by barium and flows through voltage-dependent calcium channels. The same cell was then perfused with modified saline with lead acetate added in concentrations of 0.25 to 14 uM and the I-V curve rerun. Each cell thus served as its own control. Lead acetate exposure *in vitro* inhibits the barium current by 59 $\pm$ 14 % (mean $\pm$ s.d.). The magnitude of barium current inhibition is independent of the lead concentration over this concentration range, although the residual current still varies with the barium concentration. The voltage dependence of the current appears to be unaffected by lead. In contrast to many other calcium-channel blockers, such as cobalt, the inhibition of barium currents by *in vitro* lead exposure is irreversible, at least in short-term experiments of 30 to 60 minutes.

In a separate set of experiments, snails were exposed to either 0 or 5 uM lead for 6 to 12 weeks *in vivo*. Brains were removed and B cells voltage clamped in modified saline without lead. Any differences in barium currents between lead-exposed and control cells must therefore have been due to the residual effects of the *in vivo* lead exposure. B cells from *in vivo* lead-exposed animals showed barium currents approximately twice as large as those of the controls. It is possible that chronic *in vivo* lead exposure may cause an increase in the number of calcium channels in these neurons.

This research was supported by a grant from the National Institute of Environmental Health Sciences.

194.10 DETERMINATION OF POTENTIAL TOXICITY USING A NEURON CELL CULTURE MODEL Charles A. Ferguson* and Gerald Audesirk. (SPON: T. Audesirk) University of Colorado at Denver;Denver, Colorado 80202

Isolated neurons from the mollusc *L.stagnalis* and embryonic chicks were cultured to determine the effect on neurite outgrowth of two insecticides, permethrin and DDT.

We isolated neurons of the pond snail *L. stagnalis* and embryonic chickens. These were then exposed to concentrations of 25uM to 500uM permethrin dissolved in alcohol. *L. stagnalis* and embryonic chick cells were exposed to DDT in concentrations of 500nM to 25uM as well. The effect of these concentrations of toxins on the ability of the neuron to extend new neurites was studied.

The number of *L. stagnalis* cells with neurites as compared to two controls decreased as concentrations of permethrin increased from 25uM to 250uM. An LC_{50} of 50uM for permethrin was found. Cells exposed to 25uM showed an 82% growth rate as compared to controls, and cells exposed to levels of 500uM or greater did not survive.

L. stagnalis cells exposed to DDT showed a decrease in neurite growth as concentrations increased from 500nM to 10uM. An LC_{50} of 750nM was found. Cells exposed to 500nM showed a 93% growth rate as compared to controls. Cells did not survive concentrations greater than 10uM.

Embryonic chick cells showed a sensitivity to these two toxins as well. Cells exposed to permethrin showed a decreased growth rate as concentration increased from 25uM to 250uM with permethrin and 10uM to 500nM with DDT.

Both of these toxins have been shown to exert their effect electrophysiologically in axons by increasing the sodium currents (Narahashi, T. 1985). Activity of neurons of *L. stagnalis* was recorded after exposure to toxins. These exposures ranged from 20 minutes to 16 hours. It was found that as concentration increased, a significantly shorter exposure time was necessary to elicit repetitive spontaneous action potentials with an eventual total depolarization of the cell for several seconds before returning to the original resting potential. Repeated action potentials were also generated following a single stimulus. Exposures to concentrations as low as 1uM permethrin and 750nM DDT elicited this response.

These studies indicate the potential usefulness of these models as assays for the determination of neurotoxicity of different substances in the environment. Further, our data suggest that in vitro models may be useful in determining response between species to specific environmental contaminants. Electrophysiological data support previous work that Na+ channels are being affected by these two toxins.

194.11 TELLURIUM INDUCED HYPOMYELINATION IN THE NEONATAL RAT CENTRAL AND PERIPHERAL NERVOUS SYSTEMS. J.P. Hammang*, S.F. Worth* and I.D. Duncan. (Spon: H.S. Schutta) University of Wisconsin-Madison, School of Veterinary Medicine, Madison, WI 53706.

The effect of elemental tellurium (Te) on the PNS of rats has been well described, but little information is available on the effects of Te on the CNS. Previous work has shown that while extensive Schwann cell and myelin changes occur in the PNS, CNS myelin and oligodendrocytes appear to remain unaffected. It has been reported that there are no neurotoxic effects on either PNS or CNS in rats fed Te from the day of birth to 15 days of age (Duckett, S., et. al., Neuropathol. and Appl. Neurobiol., 5:265, 1979.) This study was designed to determine the effect of Te on both the CNS and PNS of neonatal rats. At the time of whelping, rat dams were fed a 1.25% Te diet, and pups received Te via the mother's milk (Agnew, W.F., et. al., Exp. Neurol. 21:120, 1978). Normally fed rats served as controls. Forty rats were used in this study. Five each of normal and Te fed rat pups were sacrificed at 1,2,3 and 4 weeks of age. Animals were pulse-labelled with ^{3}H-thymidine, anesthetized and perfused with a modified Karnovsky's fixative. The entire CNS and a section of sciatic nerve was removed and embedded in epon for light and electron microscopy.

CNS - The results of these experiments indicate that by 14 days of age, the optic nerves and to a lesser extent, the spinal cords of Te fed rats were notably hypomyelinated and exhibited abnormalities of myelination when compared to age-matched controls. At 21 and 28 days of age this trend continued as the optic nerves of Te fed rats showed marked hypomyelination.

PNS - In sciatic nerves of Te fed rats, Schwann cell changes and myelin sheath abnormalities were evident by 7 days of age. After 14 days on the Te diet, numerous unensheathed axons remained and Schwann cell and myelin sheath changes were evident. At 21 and 28 days of age, there was a marked hypomyelination, with numerous naked axons and abundant Schwann cell abnormalities in the Te fed rats. The effect that Te has on the development of the nervous system in the rat has been clearly illustrated in this experiment. Whether the abnormality of myelination described in the CNS is a result of oligodendrocyte impairment or death, or whether axons fail to mature requires further study. The effect of Te compounds on human CNS development remains an important, unanswered question and it may be that this element should be considered a more important neurotoxic substance.

194.12 EFFECTS OF CHROMIUM (Cr^{3+}) ON NEUROMUSCULAR TRANSMISSION IN THE FROG. G. P. Cooper, Dept. of Environ. Health, University of Cincinnati, Col. of Med., Cincinnati, OH 45267-0056.

In the experiments described here we examined both the pre- and post-synaptic actions of Cr^{3+} on neuromuscular transmission. Conventional microelectrode and electrophysiological techniques were used in experiments on the isolated sciatic nerve-sartorius muscle preparation of the frog Rana pipiens. Preparations were mounted in a suitable chamber which permitted the temperature to be maintained at 16^{o}C and which allowed easy introduction and removal of physiological solutions. Ringer solutions contained 111 mM NaCl, 2.5 mM KCl, 4 mM tris-maleate, adjusted to a pH of 7.0-7.2, and 1 μg/ml neostigmine bromide. Chromium was added as $CrCl_3$. Average endplate potential (EPP) amplitude was obtained by electronically averaging individual responses. Miniature endplate potential (MEPP) frequency was determined as a measure of spontaneous quantal ACh release. The postsynaptic effects of Cr^{3+} were determined by iontophoretically applying acetylcholine (ACh) to the endplate from an extracellular microelectrode filled with 1 M ACh. In some experiments microelectrodes filled with 1 M NaCl were used to record extracellular action potential (AP) and endplate currents. Exposure to 10-50 μM Cr^{3+} irreversibly reduced ACh release resulting from nerve terminal depolarization produced by APs or by exposure to high potassium (20 mM) Ringer's solution. Cr^{3+} did not directly block exocytosis since exposure of preparations to Ringer's solutions containing $PbCl_2$ still produced large increases in MEPP frequency even after all AP-evoked release of ACh had been blocked by Cr^{3+}. Cr^{3+} concentrations of 50-200 μM reduced MEPP amplitude and the endplate response to iontophoretically applied ACh without altering the resting muscle membrane potential or the input resistance. Simultaneously recorded extracellular AP and endplate currents revealed that Cr^{3+} reduced the endplate current without affecting AP current. These results indicate that acute exposure to Cr^{3+} has little or no intracellular effect and that it probably acts mainly to interfere with membrane receptors or channels to block the normal actions of Ca^{2+} and ACh. (Supported by NIH grants ES-00159 and ES-03992.)

194.13 BEHAVIORAL AND NEUROCHEMICAL EFFECTS OF ORAL ALUMINUM ADMINISTRATION TO RATS. D.J. Connor, R.S. Jope and L.E. Harrell. Departments of Psychology, Pharmacology and Neurology. University of Alabama at Birmingham, Birmingham, AL 35294.

Aluminum toxicity has been associated with disorders manifesting memory dysfunction and dementia such as Alzheimer's disease and dialysis encephalopathy. Cholinergic hypofunction has also been associated with Alzheimer's disease and memory impairment. To examine the effects of orally administered aluminum on behavior and cholinergic function, aluminum sulfate was added to the drinking water of rats for one month (0.3% aluminum). The behavioral tasks included open field activity, radial arm maze performance, active avoidance acquisition and retention, and passive avoidance acquisition and extinction. Biochemical measures of choline acetyltransferase activity (ChAT), inositol phospholipid hydrolysis and muscarinic receptor binding of tritiated quinuclidinyl benzilate (^{3}H-QNB) and pirenzepine (^{3}H-PZ) were made in the cortex and hippocampus.

No differences between the aluminum treated animals and controls were observed in open field activity, radial eight-arm maze performance, active avoidance acquisition/retention, or on a standard seven-day extinction passive avoidance task. However, in two paradigms utilizing an extended passive avoidance extinction task (with and without pre-habituation to the apparatus), the aluminum treated animals demonstrated a faster rate of extinction than controls ($p<.0001$ and $p<.01$ respectively).

The biochemical measures indicated no significant effect of aluminum treatment on choline acetyltransferase activity in the cortex or hippocampus. Inositol phospholipid hydrolysis was measured by incubation of brain slices with tritiated myo-inositol and exposure to agonists (Berridge et al., Biochem. J. 206:587-595; 1982). Incorporation of myo-inositol into lipids was not different between groups. Levels of basal, carbachol (100 μM), norepinephrine (200 μm), and K^+ (25 mM) stimulation of hydrolysis showed no significant difference between controls and the aluminum treated animals in the cortex or hippocampus. The B_{max} of muscarinic receptors (^{3}H-QNB) was slightly increased in the hippocampus, but not in the cortex of the treated animals. Pirenzepine binding did not differ between the two groups in either brain region.

Our results demonstrate that oral aluminum administration disrupts some types of learning behavior. The neural substrate of this disruption is unknown, however we found no indication of cholinergic hypofunction from presynaptic (ChAT) or postsynaptic (^{3}H-QNB, ^{3}H-PZ, inositol phospholipid hydrolysis) cholinergic markers.

194.14 ALUMINUM NEUROTOXICITY: ALTERATIONS IN GENE EXPRESSION OF CYTOSKELETAL PROTEINS. N.A. Muma, J.C. Troncoso, P.N. Hoffman and D.L. Price. Neuropathology Lab., The Johns Hopkins Univ. Sch. of Med., Baltimore, MD 21205.

The neuronal cytoskeleton exhibits abnormalities in several human disorders, including Alzheimer's disease, Parkinson's disease, and amyotrophic lateral sclerosis. In order to better understand perturbations of the neuronal cytoskeleton, we are investigating an animal model of pathology of the neuronal cytoskeleton. When rabbits are given intrathecal injections of aluminum salts, several populations of neurons develop striking neurofibrillary pathology. It is possible that the appearance of accumulations of neurofilaments is related to the amplified expression of neurofilament genes. To test this hypothesis, we examined the expression of genes encoding for several cytoskeletal proteins in two neuronal populations in aluminum-intoxicated animals. One cell population, motor neurons, showed neurofibrillary pathology; the other, neurons of the dorsal root ganglia, do not. Animals were sacrificed immediately upon the appearance of neurological signs, i.e., between 7 and 14 days after the first of three injections of aluminum lactate. Using Northern blots to examine spinal cord tissue, we found reductions in the expression of genes encoding for high and low molecular weight neurofilament proteins, tubulin, and actin. The magnitude of the reduction of neurofilament protein and tubulin mRNAs was greater than that of actin mRNA. In contrast, neurons of the dorsal root ganglia, which do not display aluminum-induced neurofibrillary pathology, do not show reduced levels of mRNA encoding the low molecular weight neurofilament protein and tubulin. Thus, reductions in the gene expression of cytoskeletal proteins appear to occur in nerve cells that display neurofibrillary pathology. These studies suggest that neurofilamentous abnormalities in this model are associated with reductions of, and not amplifications of, genes encoding for neurofilaments.

195.1 IMMUNOCYTOCHEMICAL LOCALIZATION OF GLUCOCORTICOID RECEPTORS IN ADRENERGIC DERIVATIVES OF NEURAL CREST DURING POSTNATAL DEVELOPMENT OF THE RAT. G.Yang*, M.F.Matocha* and S.I.Rapoport. Lab. Neurosciences, NIA, NIH, Bethesda, MD 20892.

Differentiation of neural crest results in several adrenergic derivatives, which include adrenal and extra-adrenal chromaffin cells and sympathetic neurons. Of these, the chromaffin cells share morphological and functional characteristics, and it is established that glucocorticoids are essential for maintaining their phenotypes. In vivo, however, adrenal chromaffin cells are exposed to a much higher concentration of glucocorticoids than extra-adrenal chromaffin cells, suggesting that the local hormonal environment is not a determinant of chromaffin cell phenotype. Alternatively, regulation of the cell type may be intrinsic. We investigated this possibility by examining glucocorticoid receptor (GR) localization in the adrenergic derivatives of neural crest during postnatal development.

The adrenal medulla, extra-adrenal chromaffin tissues, and celiac-superior mesenteric ganglia were removed from male Fischer-344 rats, aged 2, 8, 15, and 90 days and were processed for immunocytochemistry. Immunoreactivity was monitored by an avidin-biotin peroxidase complex using a monoclonal antibody against DNA-binding sites of the rat liver GR. In the adrenal chromaffin cells, weak immunoreactivity was detected at day 2. At day 8, immunoreactivity was concentrated in the nucleus. The nuclear immunoreaction intensified markedly at the 15th day and remained high at day 90. Also, immunoreactivity in the nucleus was unchanged following i.p. injection of dexamethasone (DEX, 0.1 mg/kg b.w.) at 30 minutes before killing the 15- and 90-day-old animals. Extra-adrenal chromaffin cells showed a similar time course of GR immunoreactivity and responsiveness to DEX, with the exception that, at day 2, only a subpopulation of these cells was immunoreactive. In contrast, immunoreactivity in the sympathetic neurons was localized in the nucleus at day 2 and was intensified at day 8. Thereafter, heterogeneity in nuclear staining became apparent. Also, nuclear immunoreactivity was enhanced after administration of DEX to animals aged 15 and 90 days.

These results indicate that adrenal and extra-adrenal chromaffin cells have similar temporal patterns of GR localization and responsiveness to DEX, and that these characteristics are not found in sympathetic neurons. The correlation of cytological traits with developmental expression of the GR suggests that this receptor helps to establish phenotypes of adrenergic derivatives of the neural crest.

195.2 DEVELOPMENT OF NEUROPEPTIDES AND CATECHOLAMINE SYNTHETIC ENZYMES IN RAT ADRENAL CHROMAFFIN CELLS. P.D. Henion* and S.C. Landis. (SPON: T.E. DICK). Depts. of Developmental Genetics and Anatomy and Pharmacology, Case Western Res. Univ., Cleveland, OH 44106.

The developmental mechanisms responsible for the determination of phenotype of neural crest derivatives are not fully understood. Adrenal chromaffin cells have proven to be a useful system to study the factors involved in expression and regulation of catecholamine synthetic enzymes. Considerably less is known about the development of neuropeptides in these cells. As a first step in studying the regulation of peptide expression during development we have used an immunocytochemical approach to examine the expression of neuropeptide Y (NPY-IR) and leucine enkephalin (LE-IR) and compared that with the expression of tyrosine hydroxylase (TH-IR) and phenylethanolamine N-methyltransferase (PNMT-IR). Double label indirect immunofluorescence was used to determine the proportion of chromaffin cells containing PNMT, NPY, or LE. Consistent with previous reports, approximately 90% of TH-IR chromaffin cells in the adult rat exhibited PNMT-IR. Approximately 40% had 10% of TH-IR cells were NPY-IR and LE-IR respectively.

Cells from the sympathoadrenal region of the neural crest invade the forming adrenal at 13.5 days of gestation (Bohn et al, Dev. Biol. 82, 1-10, 1981). On embryonic day 15 (E15), TH-IR, NPY-IR, and LE-IR cells were present in small aggregates dispersed throughout the gland and in extra-adrenal chromaffin tissue. In contrast, small numbers of PNMT-IR cells were first detectable on E16 and were present only in the adrenal proper. These observations raise the possibility that the mechanisms responsible for initial expression of NPY and LE are different from those required for PNMT but not necessarily different than those responsible for TH. The relative proportions of chromaffin cells which expressed PNMT-IR, NPY-IR, and LE-IR increased until birth. Postnatally, the proportion of PNMT-IR cells remained constant while the proportions of NPY-IR and LE-IR cells decreased to adult values. This suggests that the postnatal development of the adrenal medulla may involve continued chromaffin cell division without concomitant peptide expression or the loss of peptide expression in post-mitotic cells, possibly due to the absence or alteration of the signals involved in the initial expression of these peptides during prenatal development. (Supported by NS 02378).

195.3 MIGRATION AND DIFFERENTIATION OF NEURAL CREST AND NON-NEURAL CREST CELLS FROM QUAIL NEURAL TUBES IN VITRO. J.F. Loring, D.L. Barker, and C.A. Erickson*. Dept. of Zoology, Univ. of California, Davis, CA 95616 and Protein Databases, Inc., Huntington Station, N.Y. 11746.

During vertebrate development, neural crest cells migrate from the dorsal neural tube and give rise to pigment cells and most peripheral ganglia. To study these complex processes it is helpful to make use of in vitro techniques, but the transient and morphologically ill-defined nature of neural crest cells makes it difficult to isolate a pure population of undifferentiated cells. We produced cultures from quail neural tubes (embryonic spinal cord) containing neural crest cells and non-neural crest cells and compared their subsequent differentiation by HPLC and immunohistochemistry. The cultures examined were: 1) cells that emigrate from explanted thoracic neural tubes (neural tube outgrowths); 2) neural crest clusters, believed to contain exclusively neural crest cells [Loring et al (1981), Dev. Biol. 82:86-94]; 3) dorsal and 4) ventral portions of neural tubes. Both neural tube outgrowths and neural crest clusters contained catecholamines after 5 days in culture. However, 5-HT was only detected in outgrowths, not in cultures of neural crest clusters. Immunohistochemistry confirmed that 5-HT-containing cells were not present in cultures of neural crest clusters, and furthermore that 5-HT cells arise from precursors in the ventral, not dorsal neural tube (see Table). Ventral neural tube cultures did not contain neural crest cells since no pigment cells appeared in these cultures. Therefore, the 5-HT containing cells are not, by definition, neural crest cells. The demonstration that cells from the ventral (non-neural crest) part of the neural tube migrate in vitro suggests that the same phenomenon may occur in vivo. We propose that the embryonic "neural trough", as well as the neural crest, may contribute to the peripheral nervous system of vertebrates. (Supported by NIH Grant DE06530 to CAE and Air Force Grant AFOSR-86-0076 to Dr. G. Mpitsos).

Culture	Pigment Cells	5-HT
1. Neural Tube Outgrowths	+	+
2. Neural Crest Clusters	+	-
3. Dorsal Neural Tube	+	-
4. Ventral Neural Tube	-	+

195.4 CELLULAR HETEROGENEITY IN THE NEURAL CREST AND ITS POSSIBLE DEVELOPMENTAL SIGNIFICANCE. M.E. Forbes*, D.S. Christie, and G.D. Maxwell (SPON. Y. Grimm-Jorgensen). Department of Anatomy, Univ. of Connecticut Health Center, Farmington, CT 06032.

One important issue in neural crest cell differentiation concerns the extent to which developmental potential is limited in individual neural crest cells. We have begun to approach this problem by analyzing operationally the developmental capabilities of cellular subsets present in the early neural crest. Primary quail trunk neural crest outgrowths after 2 days in vitro were stained with the monoclonal antibodies HNK-1 and R24 by double label indirect immunofluorescence using subclass-specific secondary antisera. The percent of cells with a given phenotype was:

HNK-1+ R24+	HNK-1+ R24-	HNK-1- R24+	HNK-1- R24-
12 ± 4	30 ± 3	7 ± 3	54 ± 6

When primary neural crest cultures were treated with HNK-1 and complement at 2 days in vitro and then allowed to grow until 9 days in vitro the number of catecholamine-positive (CA+) cells observed was reduced to 10% of the control number which developed after treatment with antibody alone, complement alone, or no addition. Numerous melanoctyes and unpigmented cells were present in the cultures treated with HNK-1 and complement. This is consistent with the precursors of CA+ cells being HNK-1+ and/or any necessary accessory cells required for CA+ development being HNK-1+.

Fluorescence activated cell sorting was used to isolate HNK-1+ and HNK-1- cells from primary neural crest outgrowths after 2 days in vitro. These isolated cell populations were then grown in culture for one week. Analysis of these cultures showed that the cell population isolated as HNK-1+ gave rise to melanocytes, unpigmented cells, and CA+ cells. The cell population isolated as HNK-1- gave rise to melanocytes and unpigmented cells, but not CA+ cells. These results indicate that the precursors of the CA+ cells as well as any necessary accessory cells existed in the HNK-1+ isolated population. Since other growth conditions may elicit different phenotypic responses one cannot conclude on the basis of these data that HNK-1- cells cannot become CA+ cells, but only that they did not do so under the conditions of these experiments. The development of melanocytes from the HNK-1- population shows that the HNK-1- cells are of neural crest origin and are not a non-neural crest cell type which emigrated from the neural tube.

These experiments demonstrate the feasibility of using positive and negative selection methods for the isolation of defined subsets of neural crest cells and the analysis of the developmental capabilities of these cell populations. Supported by NIH grants NS 16115 and RCDA NS 00696 to GDM and NRSA NS 17841 to DSC.

195.5 CELL AUTONOMOUS EXPRESSION OF LINEAGE-SPECIFIC NEURAL FUNCTIONS IN DROSOPHILA MELANOGASTER. R. Huff* and A.P. Mahowald* (SPON: R. Ruff). Department of Developmental Genetics and Anatomy, Case Western Reserve University School of Medicine, Cleveland, Ohio 44106.

The embryonic central nervous system of Drosophila first becomes apparent at gastrulation when a population of neuroblasts segregates from the ventral ectoderm. These neuroblasts can be isolated and cultured in vitro to produce clonal neural cell lineages. The neural cultures differentiate such that a subpopulation of cell lineages contains cells that produce dopamine and serotonin, as observed by immunohistochemistry. The ratio of serotonergic and dopaminergic neurons in culture correlates well with that described in vivo. In addition, the pattern of expression of these transmitters within their cell lineages is similar to the pattern which is seen in vivo. The production of these neurotransmitters correlates with a subpopulation of cell lineages that transcribe dopa decarboxylase (DDC), based on in situ hybridization analysis. We have also shown that the actual cells responsible for DDC transcription and transmitter synthesis arise at different times within the cell lineage depending on whether the lineage is serotonergic or dopaminergic.

These results indicate that the determination of serotonergic and dopaminergic functions in Drosophila is an early event which occurs at or near the time of neuroblast formation. The program of differentiation then proceeds autonomously within a given neural cell lineage in vitro. Furthermore, the data suggest that the neural regulation of DDC transcription has two distinct patterns depending on whether a cell lineage is determined to produce serotonin or dopamine.

195.6 THE DROSOPHILA S8 GENE PRODUCT IS A NUCLEAR PROTEIN WITH HOMOLOGY TO THE PER PROTEIN. John B. Thomas, Stephen T. Crews* and Corey S. Goodman. Dept. of Biological Sciences, Stanford Univ., Stanford, CA 94305.

Mutations of the S8 locus alter the precise spatial pattern of neuronal precursor cells which give rise to the CNS. In S8 mutant embryos, a subset of precursor cells which lie at the midline fail to emerge. These cells normally delaminate from the ectodermal epithelium along with the rest of the neuroblasts (NBs) and give rise to MP1, the MNB and its progeny, and a set of specialized ectodermal cells at the midline of the CNS.

We have sequenced what is likely to be all of the S8 coding region, and have raised antibodies to portions of the S8 protein fused to B-galactosidase. The S8 gene encodes a predominantly hydrophilic protein of at least 604 amino acids. The protein contains a 51 a.a. repeat separated by 115 a.a. This repeat, as well as the overall spacing between the two repeats is also found in the per protein. Homologies between the four repeats of the two proteins are approximately 25% (without introducing gaps). The significance of this homology is at present unknown.

Staining of embryos with antibodies to the S8 gene product demonstrates that the S8 protein is localized to the nuclei of those midline cells which fail to emerge in the mutant. This suggests that the S8 protein plays a controlling role in the expression of downstream genes involved in the emergence and differentiation of these midline cells.

195.7 USE OF RETROVIRAL VECTOR-MEDIATED GENE TRANSFER TO STUDY CELL LINEAGE AND DIFFERENTIATION IN RAT RETINA IN VIVO. D.L. Turner* and C. Cepko (SPON: R. Masland). Dept. of Genetics, Harvard Medical School, Boston, MA 02115

The mechanisms underlying the generation of different cell types in the CNS, including the role of cell lineage, remain unknown. To begin to investigate these mechanisms, we have developed a cell lineage marking system based on retroviral vector-mediated gene transfer. We have employed a replication-incompetent retroviral vector to stably introduce the E. coli β-galactosidase gene into rat retinal progenitor cells in vivo. Histological detection of β-galactosidase activity allows us to identify individual infected cells and their descendents. The integrated vector is inherited only by cells descended from infected progenitor cells. Clones of cells derived from single progenitors are used to determine cell lineage relationships among different cell types (Price, Turner & Cepko, PNAS 84:156-160, 1987).

We have chosen the postnatal rat retina for our initial experiments since it is easily accessible and it remains mitotic for about a week after birth. Injection of concentrated virus between the retina and pigment epithelium of newborn animals labels numerous clones of retinal cells. These clones contain one to three cell types, with the most complex clones including rods, bipolar cells, and amacrine cells, or rods, bipolar cells and Muller glia. Infections on postnatal days 4 and 7 show that two cell clones, probably generated from terminal mitoses, can give rise to two different cell types, including a rod and a Muller glial cell. This indicates that several types of retinal neurons and Muller glia can arise from common precursor very late in development, probably at or after its final division. We think that the most plausible model for these results is the presence of a multipotential precursor cell which differentiates in response to environmental cues.

In addition to lineage analysis, we are using this system to study retinal differentiation by observing the composition of clones after perturbing retinal development. One approach is to introduce vectors which express the β-gal marker gene and also expresses an additional gene, which may affect differentiation. We are also using various cell type-specific toxic substances in combination with the β-gal marker virus, to see if the depletion of one cell type during development influences the subsequent differentiation of other cells.

195.8 ESTABLISHMENT OF NEURAL CELL LINES USING RETROVIRUS-VECTOR MEDIATED ONCOGENE TRANSFER. E. Ryder*, E. Snyder*, and C. Cepko, Department of Genetics, Harvard Medical School, Boston, Ma. 02115.

We are attempting to establish neural cell lines through the introduction of immortalizing oncogenes into primary cultures via retrovirus vector-mediated gene transfer. These experiments have resulted in the characterization of the viral gene transfer system for transduction of exogeneous genes into primary neural tissue in vitro, as well as provided a series of neural lines. (For information on viral gene transfer into the nervous system in vivo, see the abstract by Turner, D. and Cepko, C.). The lines originated as mouse or rat primary cultures from the olfactory bulb, cerebral cortex, or cerebellum. We used several oncogenes, including Adenovirus E1A, polyoma large T, SV40 large T, N-myc, avian myc, and mouse p53, along with the dominant selectable marker for resistance to the drug, G418 (neo gene), to establish a large number of primary colonies. Infection with a retrovirus vector containing only the neo gene, without an oncogene, was also performed. All of the above tissue sources proved to be readily infectable, in that many G418-resistant colonies were observed after infection with any of these constructs. However, the ability to pass the colonies beyond 1 passage required the presence of an oncogene. All of the oncogenes listed above had activity in prolonging the life of the colonies in vitro. Due to the magnitude of effort required to test the number of passages that any given colony could produce, we do not know if all of the oncogenes can truly "immortalize" in every case. However, most of the colonies which have been carried for several months, and up to 1.5 years, have given very rapid and reproducible growth, without undergoing crisis.

To date, most of the characterization of the nature of these colonies has been with antisera that are defined as markers of the main neural cell types. By far the vast majority (several hundred) of the colonies were quite boring, exhibiting a flat morphology and no staining with many different neural antisera. However, a minority of colonies have proven to be reproducibly positive with classic antisera for the main neural cell types. We have lines that contain the markers for all of the neural cell types; neurons, astrocytes, and oligodendrocytes. Some lines are positive with antibodies which recognize a set of antigens consistent for a given cell type. For example, lines which bind tetanus toxin are also positive with neurofilament antibodies and a variety of glycolipid antisera (e.g. A2B5, R24), and are negative for staining by antisera against GFAP and galactocerebroside. In order to confirm the histochemical identification of neurofilament expression, Northern blot analysis of selected lines was performed, and found to be positive. Interestingly, within many clonal lines, there is heterogeneity of expression for any given marker (e.g. A2B5, R24, GFAP), although certain lines exhibit almost 100% staining for their most characteristic marker (neurofilament or GFAP). In addition, some lines have not maintained their original differentiated status. For example, an galactocerebroside$^+$ line, during routine culturing, developed subclones which are positive for neuronal or astrocytic markers, while losing the expression of galactocerebroside. We are currently attempting to further define the activity and behavior of selected lines, both in vivo and in vitro.

195.9 GENERATION OF PERMANENT CELL LINES DERIVED FROM POSTNATAL SEPTAL AND HIPPOCAMPAL REGIONS. H.J. Lee, D.N. Hammond, and B.H. Wainer. Com. on Neurobiology, The University of Chicago, Chicago, IL 60637.

In order to better understand cholinergic neurotrophic mechanisms, we have generated hybrid cell lines from the postnatal septal area and from a principal target of its cholinergic efferents, the hippocampus. Septal and hippocampal cells from postnatal day 21 C57BL/6 mice were fused with murine neuroblastoma N18TG2 cells using a phytohemagglutinin and polyethylene glycol-mediated somatic cell fusion technique. The fusion products were plated in monolayer with medium containing hypoxanthine, aminopterin, and thymidine (HAT) to select against hypoxanthine phosphoribosyltransferase-deficient N18TG2 cells. Similarly treated septal cells, hippocampal cells, or N18TG2 cells alone produced no viable colonies. Viable fusion colonies were subsequently expanded in medium without HAT and subcloned or frozen.

Characteristics typical of septal cholinergic neurons but not of N18TG2 neuroblastoma cells were examined in several colonies. Twenty-two parent septal colonies were radiochemically screened for choline acetyltransferase (ChAT) activity and yielded specific activities up to 260 pmol acetylcholine formed/min/mg protein. Several first generation subclones have ChAT specific activities over 500 pmol/min/mg. Long neuritic processes more than 1 mm in length were observed in monolayer culture. However, no correlation between the level of ChAT specific activity and morphology was noted. Two first generation subclones have been further characterized immunocytochemically. Both stained positively for ChAT, nerve growth factor receptor, and neurofilament proteins but not for glial fibrillary acidic protein using the antibodies Ab8, alpha 192, TA.51, and 2.2 B10.6 respectively. Fourteen hippocampal derived lines were frozen for later analysis.

These hybrid cell lines are the first permanent cell lines to be derived from normal postnatal central nervous system tissue. Since they are derived from the basal forebrain and from one of its major projection targets, they may provide a controlled system to examine the factors modulating central cholinergic neuronal development and the formation and maintenance of basal forebrain connections.

Supported by NIH grants 5-T32HD070009-12, NS 08018, and NS/AG 25787; and grants from the Alzheimer Disease and Related Disorders Association, the American Philosophical Society, and the French Foundation.

195.10 PATTERN OF EXPRESSION OF A NEURON-SPECIFIC BETA-TUBULIN IN EARLY DEVELOPMENTAL STAGES OF CHICK EMBRYO. M. LEE*, J.B. TUTTLE, A. FRANKFURTER*, Depts. of Neuroscience, Physiology, and Biology., Univ. of Virginia, Charlottesville, VA 22901.

A beta-tubulin specific monoclonal antibody (TuJ1) has been isolated (Frankfurter et al., Soc. Neurosci. Abstr., 12:1123, 1986). Partial characterization of TuJ1 indicates this tubulin antigenic site is expressed in rat, human, and chicken brain and in rat testis. The binding site in brain is expressed exclusively in neurons. Neither the functional significance nor the time of expression of this tubulin is known. The chick embryo was examined immunocytochemically to determine initial expression and distribution of this beta-tubulin isotype.

Stage 17-26 chick embryos (Hamburger and Hamilton) were fixed, frozen sectioned (12-16 um), and immunocytochemically stained via indirect immunofluorescense. At all stages, intense unequivocal immunoreactivity is associated with neurons and their processes in germinal epithelia (brain,retina, and spinal cord) and ganglia. The number of immunoreactive neurons and the intensity of staining increases with development and is related to rostral-caudal position in the neural tube. Somal staining is prominent in the marginal zone, while germinal regions appear free of immunoreactivity. Stained cells most often have processes extending out of the epithelium with early fiber tracts clearly demonstrated. Staining of variable intensity is seen dorso-lateral to the spinal cord before the formation of the dorsal horn. The bipolar aspect of these cells suggests that they are neurons derived from neural crest in various stages of differentiation. No staining is apparent in neural crest prior to migration. A similar pattern is observed during development of the ciliary ganglion: early variable immunoreactivity during coalescence into a definitive ganglion is followed by intense staining at a slightly later stage.

For all stages examined, there is a notable absence of staining in non-neural elements. However, low levels of equivocal reactivity were present in the early mesonephric duct, lens, aorta, and perhaps erythrocytes. Apparently specific staining occurs in the amnionic ectoderm. Whether this reactivity represents transient expression of the antigen or non-specific binding is unclear.

This study indicates that TuJ1 recognizes an antigenic determinant expressed in post-mitotic neurons. Expression of this beta-tubulin isotype correlates with the stage of neuronal development associated with neurite outgrowth.

Supported by grants from NIH and NSF.

195.11 THE CHARACTERIZATION OF A MOUSE NEUROBLASTOMA-DERIVED CDNA CLONE THAT HYBRIDIZES TO AN RNA SPECIES THAT IS INDUCED UPON TRANSFER OF CELLS FROM SUSPENSION TO SURFACE CULTURE. Eugene T. Butler, III and Bruce K. Schrier. Molecular Neurobiology Unit, Lab. of Developmental Neurobiology, NICHD, NIH, Bethesda, MD. 20205

The NS20Y mouse neuroblastoma cell line was adapted for growth in suspension culture in order to enhance phenotypic differences between undifferentiated, suspension cell cultures (S cells) and differentiated cell cultures (P cells) that were grown as surface-attached cultures in the presence of dibutyryl cAMP. Complimentary DNA (cDNA) libraries were constructed from S and P polyA-selected RNA fractions following the application of subtraction hybridization steps to increase the representations of sequences that are differentially expressed under the two sets of growth conditions. A number of cDNA clones have been isolated that correspond to mRNAs that exhibit either increased or decreased levels of expression in cells that have been grown under the two sets of conditions. Via RNA blot-hybridization analyses with probes prepared from two cDNA clones, A216 and F31, we have identified an RNA species, ca. 3 kilobases (Kb) in length, that is expressed in surface-grown NS20Y cells but is virtually undetectable in cells that have been grown in suspension culture. The addition of dibutyryl cAMP to suspension cultures of NS20Y cells does not result in the appearance of the 3 Kb RNA species. While the A216 and F31 cDNAs appear to hybridize to the same RNA species, the two clones do not cross-hybridize. The A216 cDNA insert is 1345 bp in length and its nucleotide sequence has been determined; an open reading frame of significant length is not found in the sequence. Determination of the nucleotide sequence of the F31 cDNA and identification of the protein that may be encoded by the polyadenylated RNA species to which the clone hybridizes are in progress.

195.12 DIFFERENTIAL EXPRESSION OF THE RAS ONCOGENE IN CLONAL RAT GLIAL CELLS. K.A. Zito and J.A. Connolly, Dept. of Anatomy, University of Toronto, Toronto, Canada M5S 1A8.

When C6 glial cells progress from a logarithmic to a stationary phase of growth they begin to differentiate as measured by an initiation of synthesis and accumulation of the brain specific S-100 protein (Labourdette et al, 1977). Both intercellular contact (Labourdette et al, 1975; 1977) and/or the presence of factors present in normal growth media which suppress the ability of these cells to differentiate (Edstrom et al, 1973) have been suggested as possible mechanisms for the control of differentiation in this glial tumor cell line. Treatment with colchicine, which disrupts microtubules, selectively inhibits S-100 synthesis.

The protein ras has been suggested to play an intimate role in the differentiation of certain cell types. Employing the technique of immunofluorescence microscopy we have used a monoclonal antibody to ras to examine its distribution in normal, serum-starved or colchicine treated differentiating C6 cells. Both subconfluent and confluent C6 cells were grown in alpha MEM containing 5% fetal bovine sera. Some cells in both groups were switched to either serum-free media for 48 hrs or treated with 1 uM colchicine prior to being processed for immunohistochemistry.

C6 glioma cells stain positively for ras. In subconfluent cells grown in normal serum conditions the protein is diffusely distributed throughout the cell cytoplasm and additionally can be localized to the plasma membrane. After 48 hrs of serum starvation these cells begin to extend long processes which also stain positively for ras. In serum starved cells ras becomes more intimately associated with the plasma membrane where it appears to be non-uniformly distributed. When cells are treated with colchicine cytoplasmic staining of ras increases to a level above that seen in untreated subconfluent cells. When these cultures are carried to confluency the staining pattern of ras becomes more diffuse and punctate.

These preliminary findings lend support to the notion that ras may be involved in the differentiation of C6 glioma cells and their subsequent expression of S-100. We are currently examining the expression of S-100 in ras transfected glial cells in addition to the localization and expression of other oncogenes in these cells.

195.13 EXPRESSION OF HOMEOBOX-CONTAINING GENE PRODUCTS BY NEURAL CREST-DERIVED CELLS OF EARLY AVIAN EMBRYOS. P. Hill*, O. Civelli* and G. Ciment. Dept. of Cell Biology & Anatomy and Vollum Institute for Advanced Biomedical Research, Oregon Health Sciences Univ., Portland, OR 97201.

The neural crest is a transient structure seen during early vertebrate embryogenesis. Neural crest cells originate within the neural tube, but leave the tube to migrate extensively in the embryo, eventually localizing at various sites and giving rise to a wide variety of cell types.

Crest cells which migrate from rhombencephalic regions of the neural tube colonize a set of structures known as the branchial arches (BAs). Previously, we found that the crest-derived cells within the posterior BAs of avian embryos behaved like their crest cell antecedents. That is, posterior BA cells expressed the neuronal marker NAPA-73 and gave rise to connective tissue elements, endocrine cells, as well as neurons and glial cells in heterospecific grafting studies (Ciment and Weston, Develop. Biol. 111:73,1985). Little is known, however, about the gene products responsible for this generation of cell type diversity, these morphogenetic movements, or other developmental behaviors observed with these crest-derived cells.

In Drosophila, on the other hand, a number of gene products have been identified which clearly govern morphogenesis. Many of these gene products, moreover, contain translated regions which share striking sequence homologies with genes found in vertebrates, including birds. The regions of sequence homology are termed "homeoboxes" and have been proposed to play a role in both vertebrate and invertebrate development.

In order to determine whether homeobox-containing gene products are expressed during neural crest development, a cDNA library was made from mRNA transcripts isolated from dissected posterior BAs of 400 3.5d quail embryos. This library was constructed in lambda gt10 and contained roughly a million clones. This posterior BA cDNA library was then screened using a cDNA insert containing the 180 base pair Drosophila "antennapedia" homeobox sequence (p903g; kindly provided by Wm. McGinnis). We found that 0.018% of the plaques showed strong and reproducible signals when probed under medium-stringency conditions (37°C, 50% formamide), suggesting that homeobox-containing gene products are moderately abundant in posterior BA cells are this developmental stage.

We present here the initial characterization of the tissue-specific and developmental stage-specific expression of these homeobox-containing gene products. Using RNA blotting and in situ hybridization procedures, we show the developmental appearance of homeobox-containing mRNA transcripts in (1) neural crest cells of the posterior branchial arches, (2) various other neural crest-derived cell types, and (3), various non-crest cell types.

195.14 EXPRESSION OF THE MURINE HOX 1.3 HOMEO DOMAIN PROTEIN IN THE DEVELOPING CEREBELLUM VARIES WITH NEURON TYPE AND AGE. M. Tani.* V. L. Friedrich, Jr., W. Odenwald.* and R. A. Lazzarini.* Laboratory of Molecular Genetics, NINCDS, NIH, Bethesda, MD 20892.

First discovered in embryonically active pattern formation genes of Drosophila melanogaster, the homeo box is a highly conserved 180 bp segment of DNA which occurs in genes of diverse species including mammals. Using mouse brain cDNA and genomic libraries, we isolated the Hox 1.3 homeo box gene and found its message in both embryonic and adult tissues (W. Odenwald et al., *Genes and Development*, in press, 1987.) We prepared antisera specific for an oligopeptide predicted from a non-homeo box coding region of the DNA sequence. Immunolocalization studies have shown that the Hox 1.3 protein is present in neurons in many regions of the adult CNS. In the cerebellum, the Purkinje cell layer stains prominently for the protein, but the internal granule cell layer appears largely unstained. Here we examine the distribution of Hox 1.3 immunoreactivity in detail and compare the adult pattern of cerebellar staining with that in early postnatal mice, in which major developmental changes are occurring.

In the newborn cerebellar cortex, the post-mitotic Purkinje cells exhibit intense nuclear staining without distinct cytoplasmic staining. In the adult, they exhibit much reduced nuclear staining but are distinguished by the appearance of cytoplasmic staining extending into the primary dendrites at an intensity matching or often greater than the nuclear staining. Early in postnatal life, the cerebellar granule cells are generated from mitotic precursor cells in the external granular layer (EGL) and migrate after their last mitosis to their final position in the internal granular layer (IGL.) Neither the proliferative cells of the EGL nor the post-mitotic migratory cells show immunoreactivity. The granule cells in the IGL remain unstained in the adult. The molecular layer stellate and basket cells also arise from the EGL, but in contrast to the granule cells they do exhibit moderate nuclear staining in the adult. Golgi type II interneurons scattered throughout the IGL and neurons of the deep cerebellar nuclei exhibit intense nuclear staining at all ages examined.

Our results identify several patterns of Hox 1.3 immunoreactivity characteristic of mature cerebellar neurons and indicate that immunoreactivity can vary systematically during development. Substantial expression of this protein is evidently not necessary for cell division nor for the migration or maturation of all neurons.

195.15 TRANSIENT EXPRESSION OF AN INSULIN GENE CONSTRUCT IN CATECHOLAMINERGIC PRECURSORS OF TRANSGENIC MOUSE EMBRYOS. S. Alpert*, D. Hanahan*, and G. Teitelman. (SPON: A. Suburo). Div. of Neurobiol., Cornell Univ. Med. Ctr., N.Y..N.Y. 10021 and *Cold Spring Harbor Lab., Cold Spring Harbor, N.Y. 11724.

Tyrosine hydroxylase (TH), the first enzyme of the catecholamine (CA) biosynthetic pathway, has been previously shown to be expressed during development of the insulin producing (β) cells of the islets of Langerhans (Teitelman, 1987). This finding raises the question as to whether CA neurons express endocrine traits at any time. It is, therefore, possible that the developmental regulation of insulin is such that it can be expressed in any cell type that can produce the CA biosynthetic enzymes. To examine this issue we used immunocytochemical procedures to examine the nervous system of a line of transgenic mice. These mice, RIP-Tag #2, which contain a hybrid gene consisting of the 5' flanking region of the rat insulin II gene linked to the protein coding sequences for the Simian Virus 40 large T antigen, were examined to detemine the pattern of expression of both Tag and insulin in neural tissues during development. These animals are known to express Tag in the β cells of their islets (Hanahan, 1985). No Tag or insulin containing cells were seen in the locus coeroleus, substantia nigra, sympathetic ganglia, or adrenal glands of adult RIP-Tag #2 mice. This suggests that in those CA cells the insulin gene is inactive.

Next we examined transgenic embryos of embryonic day 10 (e10) and e11. At e10, although no insulin immunoreactivity was detected, Tag was found in migrating neural crest cells from the rhombencephalic to the caudal region. The antigen was expressed only in neural crest cells that were distributed along the ventral pathway of migration, close to the neural tube. At e11 neural crest cells containing Tag were also seen migrating laterally between somites and ectoderm and then aggregating in areas where the sympathetic ganglia will form. In brain, cells containing Tag were seen in the basal plate of the germinal layer of the neural tube. Cells of the mantle layer did not contain Tag. At these stages a large number of Tag cells were seen in the di- and rhombencephalon, but not in mes- or telencephalon. When histological sections of RIP1-Tag #2 embryos were processed for the localization of two antigens in the same section it was found that neural crest cells foresake expression of Tag when TH first appears. Thus neuroblasts that contain TH did not express Tag. Likewise, in brain, cells containing TH present in the mantle layer did not contain Tag. In contrast, pancreatic cells containing TH also express Tag. We conclude that Tag is transiently expressed by cells of the peripheral and central nervous system. These cells, by their location, are identified as CA precursors. Since the expression of Tag is regulated by the insulin promoter the results suggest that the endogenous mouse insulin gene may be active in CA precursor cells and that the activity of the gene is turned off with the initiation of TH synthesis.

196.1 NEUROTENSIN BINDING IN RAT NUCLEUS BASALIS: EFFECTS OF LOCAL IBOTENIC ACID INJECTIONS. E. Szigethy, G.L. Wenk, J. Epelbaum and A. Beaudet. Montreal Neurological Institute, McGill University, Montreal, Quebec, Canada H3A 2B4, The Johns Hopkins University, Baltimore, Maryland 21218, INSERM U-159, 75014 Paris, France.

Previous findings in our laboratory have indicated that the distribution of ^{125}I-NT binding sites in rat basal forebrain corresponds to that of magnocellular cholinergic neurons documented in this region. The aim of the present study was twofold: (1) to quantitatively determine the degree of overlap between cholinesterase-reactive and ^{125}I-NT labeled neurons in nucleus basalis magnocellularis (NBM) using adjacent section cholinesterase pharmacohistochemistry-radioautography in animals pretreated with bis-1-methylethylphosphofluoridate (DFP) and (2) to demonstrate that ^{125}I-NT labeled receptors are directly associated with these putative cholinergic cells, rather than with afferent inputs, by examining the effects of unilateral lesions of the NBM with the selective excitotoxin, ibotenic acid on ^{125}I-NT binding. For quantification, rats were injected with 2 mg/kg DFP and sacrificed by decapitation 10 hours later. For lesion studies, rats were stereotaxically infused with 1.0 µl ibotenic acid (25 nmol in 1 µl PBS) into the NBM and sacrificed 14 days later. In both cases, serial 10 µm thick frozen sections were incubated for 1 h at 4°C with 0.1 nM ^{125}I-NT (2000 Ci/mmole) in Tris buffer in the presence (non-specific binding) or absence (total binding) of excess native NT. After several buffer rinses, sections were fixed with 4% glutaraldehyde and processed for light microscopic radioautography using either film or conventional dipping techniques. Alternate sections were fixed by immersion in Zamboni's fixative and processed for AChE histochemistry according to the procedure of Genneser-Jensen (1971). Densometry measurements were obtained from film radioautographs using a bioquant computerized image analysis system. Between 75-90% of intensely AChE-reactive neurons in the NBM exhibited dense ^{125}I-NT binding in DFP pretreated animals while none of the cells having little or no AChE staining had such discrete cellular labeling. Ibotenic acid selectively abolished cholinesterase staining in the NBM and resulted in a concommitant decrease in ^{125}I-NT binding density in the ipsilateral NBM with respect to the lesion as compared to the contralateral side. In addition, a disappearance of individual ^{125}I-NT-labeled cells was observed in the lesioned area. These results suggest that the vast majority of cholinergic neurons in rat NBM possess NT receptors. It would be of interest to examine if similar changes in NT binding are observed in patients with Alzheimer's disease which involves degeneration of the basal forebrain cholinergic system. Knowledge of such alterations may provide insight into the pathogenesis of AD and offer new avenues for diagnosis and therapy. Supported by the Medical Research Council of Canada.

196.2 MONOAMINERGIC AND CHOLINERGIC SYSTEMS IN THE ROSTAL FOREBRAIN L. Heimer, L.F. Snavely, V.N. Luine, and L. Zaborszky. (Spon: R. Michaelis) Dept. of Otolaryngology and Neurosurgery, Univ. of Virginia, Charlottesville, VA 22908; Rockefeller Univ., New York, NY 10021

In preliminary studies it has been shown that unilateral removal of the ascending brainstem pathways (Zaborszky et al., Soc. Neurosci. Abst. 12:571, 1986), or injection of 6-hydroxydopamine in the substantia nigra (Slevin et al., 1986) or the ascending catecholaminergic pathways (Zaborszky and Luine, J. Cell. Biochem., Suppl. 11D:187, 1987) cause significant reductions of choline acetyltransferase (ChAT) immunoreactivities in forebrain areas containing the cholinergic projection neurons. Moreover, 5,7-DHT lesions of the ascending monoaminergic bundles resulted in similar reductions of ChAT levels in the basal forebrain (Zaborszky and Luine, 1987). The present study was designed to investigate the topographic relationship between cholinergic cells and monoaminergic fibers in the rostral forebrain.

Rats were perfused by a buffered picric acid-paraformaldehyde fixative (Somogyi and Takagi, 1982). Adjacent sections of the rostral forebrain were processed for the simultaneous visualization of ChAT/tyrosine hydroxylase or ChAT/serotonin using the DAB-intensified/DAB technique (Gorcs et al., 1986) or the technique developed by Levey et al., utilizing two different chromagens (DAB/BDHC). A significant number of TH-labeled fibers surround cholinergic cell bodies and dendrites in the sublenticular substantia innominata, and globus pallidus. Furthermore, a few TH-containing fibers are in close proximity to cholinergic neurons in the dorsal part of the horizontal limb and the vertical limb of the diagonal band (DB). In addition, cholinergic cells of the dorsal and ventral striatum are embedded in massive TH-terminal arborizations. Successfully stained sections were embedded in resin. Preliminary EM studies revealed a few TH-terminals synapsing on cholinergic dendrites. Serotonin-labeled terminal varicosities were especially abundant around cholinergic cells in the dorsal part of the horizontal limb of the DB. In addition, a few terminal like processes were seen along the cholinergic cells in the vertical limb of the DB. An electron microscopic analysis is now being performed in order to determine if cholinergic cells indeed receive serotonin-containing terminals.

These findings support the idea that the monoaminergic afferents transynaptically modulate the expression of ChAT in the basal forebrain and this may be particularly relevant to Alzheimer's disease in which a marked loss of noradrenergic (locus coeruleus) and serotoninergic (raphe) neurons are reliably observed. Supported by USPHS Grant NS.23945,17743 and by a Grant from the American Health Association Foundation.

196.3 CHOLINERGIC CONTROL OF AMINO ACID AND MONOAMINE TRANSMITTERS IN SLICES OF NUCLEUS ACCUMBENS. M. Gongwer*, P. Robinson* and W.J. McBride. Depts. Psych. & Biochem., Inst. Psych. Res., Indiana Univ. School of Medicine, Indianapolis, IN 46223.

The effects of two cholinergic agonists, oxotremorine (OXO) and nicotine (NIC), on the K^+-stimulated endogenous release of dopamine (DA), norepinephrine (NE), serotonin (5-HT), glutamate (GLU), GABA and aspartate (ASP) from slices of nucleus accumbens were used to assess cholinergic control of the amino acid and monoamine transmitters in this CNS region. The nucleus accumbens was dissected from adult male Wistar rats and sliced into 300 x 300 um sections with a McIlwain tissue chopper. For each experiment, slices from 3 animals were pooled and distributed among four columns (control, 50, 100 and 200 uM agonist). Slices were superfused for 30 minutes each, first with LKE (in mM : 120 NaCl, 4.75 KCl, 1.2 KH_2PO_4, 1.2 $MgSO_4$, 25 $NaHCO_3$, 10 D-glucose and 1.0 EGTA equilibrated with 95% O_2/5% CO_2), followed with HKE (same as LKE except for 35 mM KCl and 90 mM NaCl) and then with HKC (same as HKE except for 2.5 mM $CaCl_2$ and no EGTA). Initial studies, using 20, 35 and 60 mM K^+, demonstrated that 35 mM K^+ produced a significant, but submaximal, endogenous release of the amino acids and monoamines above resting efflux values.

Using the above protocol, it was determined that DA, NE, 5-HT, GLU, GABA and ASP were released by 35 mM K^+ in a Ca^{2+}-dependent manner. The finding that 16 mM Mg^{2+} inhibited the K^+-stimulated, Ca^{2+}-dependent release provided further support for a transmitter-like release for these monoamines and amino acids. The endogenous release of alanine and glycine was also measured. The release of these two amino acids was not stimulated by elevated K^+ in either the presence or absence of Ca^{2+}. Furthermore, 16 mM Mg^{2+} had no affect on the efflux of alanine and glycine, thereby indicating that these two amino acids are not released in a transmitter-like manner.

OXO and NIC (at a concentration each of 200 uM) potentiated ($p < 0.05$; N=10) the 35 mM K^+-stimulated, Ca^{2+}-dependent release of 5-HT 180 and 90% above control levels, respectively. NIC (200 uM), but not OXO, also potentiated ($p < 0.05$; N=12) the K^+-stimulated, Ca^{2+}-dependent release of GLU 63% above control values. No effects were observed for these cholinergic agents on the K^+-stimulated, Ca^{2+}-dependent release of NE, DA, GABA or ASP. The data suggest both a muscarinic and nicotinic stimulation of the serotonergic system in the nucleus accumbens and only a nicotinic action on the glutamatergic system in this region. (Supported in part by AA-03243 and AA-07462).

196.4 **INVESTIGATION OF A MONOAMINERGIC ROLE IN THE MODULATION OF [3H]HEMICHOLINIUM-3 BINDING SITES IN RAT BRAIN.** M. A. Feldman*, M. D. Saltarelli, and J. T. Coyle (SPON: M.C. Rogers). Depts. of Anesthesiology and Critical Care Medicine and Neuroscience, The Johns Hopkins University School of Medicine, 600 N. Wolfe St., Baltimore, MD 21205.

Monoaminergic systems are attractive candidates as regulators of central cholinergic activity. The role of dopaminergic fibers as inhibitory inputs regulating cholinergic function in the striatum is well established. Evidence from diverse studies suggests modulatory influences of norepinephrine, dopamine, and serotonin on acetylcholine turnover and release.

Changes in cholinergic neuronal activity are associated with parallel increases or decreases in the capacity of the sodium-dependent high affinity choline uptake (SDHACU) system. SDHACU activity *in vitro* has been shown to serve as an index of the antecedent function of cholinergic neurons *in vivo*. Hemicholinium-3 (HCh-3) is a potent, selective, competitive inhibitor of SDHACU. Alterations in the velocity of SDHACU are correlated with changes in the actual number of carrier sites as measured by high-affinity binding of [3H]HCh-3. We have investigated the effects of monoaminergic modulation on cholinergic activity as measured by *in vitro* high-affinity binding of [3H]HCh-3.

To investigate the effect of release of endogenous catecholamines, rats received amphetamine sulfate (10 mg/kg I.P.). [3H]HCh-3 binding was assayed *in vitro* after 60 minutes. No statistically significant changes were observed in cortex (N=3), hippocampus (N = 3), or striatum (N = 8). The monoamine uptake inhibitor cocaine (30 mg/kg I.P.), however, increased cortical [3H]HCh-3 binding from 45 ± 4 to 57 ± 3 fmol/mg protein (X ± S.E.M., N = 7, 30% increase, $P < 0.05$). The discrepancy between cocaine and amphetamine effects may represent differences in the profile of monoaminergic responses or in the response of other neuromodulatory systems *in vivo*.

To investigate the influence of ascending catecholaminergic systems on the choline carrier, the adrenolytic drug 6-hydroxydopamine was injected bilaterally into the medial forebrain bundle. After 7 days, the animals were sacrificed, and specific regional [3H]HCh-3 binding was measured in crude membrane homogenates. When compared to saline-injected controls (237 ± 5fmol/ mg protein, X ± S.E.M., N = 3), a modest (12%) reduction in binding was observed in striatum (209 ± 4 fmol/mg protein, N = 4, $p<0.01$). Examination of neurotransmitter levels, *in vivo* drug stimulations, and *in vitro* regulation experiments will be necessary for interpretation of these preliminary data.

Supported by USPHS grant 13584, a postdoctoral fellowship to MDS (#MH15330), and a grant from the McKnight Foundation.

196.5 PEPTIDERGIC REGULATION OF CATECHOLAMINE SECRETION IN EMBRYONIC SYMPATHETIC NEURONS.

D.C. Valenta, J.E.G. Downing*, and L.W. Role. Columbia Univ.P & S, Dept. of Anat. & Cell Biol. & Ctr. Neurobiol.& Behav., NY, NY 10032.

The neuropeptide substance P (SP) is present in embryonic chick sympathetic ganglia (Hayashi et al, 1983) and is released by ganglionic depolarization (L.Role and J.Krause, unpublished observations). SP enhances the decay of ACh-evoked currents in voltage-clamped chromaffin cells and sympathetic neurons (Clapham & Neher 1984; Role, 1984a). Preliminary studies also indicate that SP increases the decay of synaptic currents in innervated sympathetic neurons *in vitro* (Role1984b). We have investigated the relationship between SP modulation of acetylcholine receptor (AChR) function and neurotransmitter release in sympathetic neurons by measuring both ACh-evoked currents and catecholamine release in the presence and absence of SP.

Dispersed ED10-11 chick sympathetic neurons voltage-clamped to rest potential were exposed to ACh, carbachol, or 1,1-dimethyl-4-phenyl-piperazinium (DMPP) with or without SP. Macroscopic currents decay in the continued presence of these agonists in a manner that is dependent on agonist concentration. The rate of decay of currents evoked by desensitizing concentrations of ACh, carbachol and DMPP are greatly enhanced by co-application of SP. In contrast, SP has no effect on the rate of decay of macroscopic currents evoked by low (non-desensitizing) concentrations of agonist.

Complimentary experiments were conducted to examine the effects of SP on transmitter release from sympathetic neurons. Cultures of ED 10-13 sympathetic neurons were prelabeled with ^{3}H-NE, and then incubated with cholinergic agonists in the presence and absence of SP. ^{3}H-NE remaining in the cells was determined and net stimulated ^{3}H-NE release was quantitated as a percent of total intracellular content.

Stimulation of sympathetic neurons with nicotinic (DMPP, nicotine), muscarinic (methacholine, muscarine), and mixed cholinergic agonists (ACh, carbachol) elicits significant ^{3}H-NE release. The effects of carbachol are dose-dependent, and are blocked by hexamethonium + atropine. Maximal concentrations of carbachol (0.5-1 mM) stimulate net release of up to 30.2 ± 0.86% of total intracellular ^{3}H-NE. While SP alone (10-20 μM) has no effect on catecholamine release, SP significantly inhibits ^{3}H-NE secretion elicited by intermediate to maximally effective concentrations of ACh, carbachol and DMPP (up to 90%, $p < 0.001$). In contrast, SP has little or no effect on NE secretion evoked by non-desensitizing concentrations of DMPP and carbachol.

The transmitter release and electrophysiological data presented here are consistent with the hypothesis that SP enhances agonist-induced desensitization of the neuronal AChR. The observation that SP can inhibit NE release from sympathetic neurons *in vitro* also suggests that SP may modulate lumbar sympathetic outflow *in vivo*.

196.6 SINGLE CHANNEL PROPERTIES OF NEURONAL NICOTINIC ACETYLCHOLINE RECEPTORS: MODULATION BY SUBSTANCE P.

L.K. Simmons, S.M. Schuetze†, and L.W. Role. Columbia University P&S, Dept of Anatomy and Cell Biology and The Center for Neurobiology and Behavior, NY, NY 10032 & †Dept of Biological Sciences, Columbia University, NY,NY 10027.

The modulatory peptide Substance P (SP) specifically enhances the rate of ACh-elicited current decay in voltage clamped chromaffin cells (Clapham and Neher, 1984) and sympathetic neurons (Role, 1984). These and other studies indicate that SP enhances agonist-induced desensitization (see Valenta et al., this volume). Here we report preliminary data that: 1) describe the single channel characteristics of the sympathetic neuronal acetylcholine receptor (AChR), and, 2) suggest that SP enhances AChR desensitization via a second-messenger pathway.

Sympathetic ganglia were dissected from embryonic chickens (ED 9-11), dispersed to single cells and maintained in tissue culture from 4-14 days prior to use. Single channel currents were recorded at room temperature (22-27 °C) using either the cell-attached (with 10-20 μM ACh in the patch pipette) or the outside-out configuration (with ACh applied onto the isolated membrane from a pressure ejection pipette).

The predominant ACh-elicited current observed in cell-attached patches has a unitary current amplitude of 2.1 ± 0.06 pA (n=17 patches) at rest, a single channel conductance of 34 ± 2 pS (n=12), and an extrapolated reversal potential 30 mV depolarized from rest. The mean channel open-time is 4.8± 0.46 msecs (n=5 patches, 24-25 °C) at the resting potential and, unlike muscle AChRs, either remains constant or decreases slightly with hyperpolarization. Single channel currents with comparable conductances and kinetics were observed in outside-out patches in response to pressure-ejected ACh.

We used the cell-attached configuration to determine if the SP-induced increase in AChR desensitization depends upon a second-messenger pathway. Single channel currents were recorded before and after a 10 second application of 20 μM SP to the remainder of the cell. In two preliminary experiments the frequency of channel openings decreased by 4-7 fold within 5-40 secs following SP application. The single channel current amplitude remained unchanged but the mean open-time of the channels decreased by 2-3 fold (eg. from a control $\tau_o = 3.65 \pm 0.27$ to 1.3 ± 0.18 msecs, following SP). Because the patch pipette physically isolates the AChRs being monitored from the applied SP, these results suggest that SP can modulate AChR desensitization via a second-messenger system. Preliminary evidence indicates that a protein kinase C-dependent phosphorylation may be involved in enhancing neuronal AChR desensitization (see Downing et al., this volume).

Supported by awards to LWR from NIH (NS22061), and the Klingenstein and Sloan Foundations.

196.7 MODULATION OF NEURONAL ACETYLCHOLINE RECEPTOR DESENSITIZATION BY GANGLIONIC PEPTIDES AND AGENTS THAT ACTIVATE PROTEIN KINASE C.

J.E.G. Downing*, O.E. Harish* and L.W. Role. Columbia University P&S, Dept of Anatomy and Cell Biology and The Center for Neurobiology and Behavior, NY, NY 10032.

In addition to acetylcholine (ACh), avian lumbar sympathetic ganglia contain a number of peptides including substance P (SP) and somatostatin (SS; Hayashi, M. et. al. Neurosci. 10: 31-39, 1983). We are interested in the interaction of these peptides with ACh in a possible modulation of synaptic function. In voltage clamped sympathetic neurons inward current through the AChR channel decays in the continued presence of agonist, and this decay is dependent on agonist concentration. Both SP and SS enhance the rate of ACh-induced current decay. The increase in the rate of ACh-induced current decay with both peptides is manifest only at concentrations of agonist that evoke noticable desensitization on thier own (see abstract by Valenta et al., this volume), suggesting that the peptides potentiate agonist induced desensitization.

Recent observations from cell attached patch recordings (Simmons et al, this volume) demonstrate that the behavior of single neuronal AChR channels can be modulated by SP. This recording configuration indicates some second messenger involvement. In order to pursue the second messenger mechanism underlying this neurotransmitter modulation of excitability, complimentary biochemical and biophysical studies were performed. Our preliminary studies demonstrate that both SP and nicotine cause a rapid and transient rise in phosphatidylinositol (PI) turnover. An approximately two fold increase in the production of inositol phosphates (IP_1, IP_2, & IP_3) is seen in response to maximal concentrations of either nicotine or SP. Since this enhancement of PI metabolism may result in activation of protein kinase C (PKC) we examined whether PKC might regulate nicotinic AChR function in neurons. We have compared the effects of SP, and several activators of PKC (diglyceride 1-oleyol-2-acetyl glycerol, phorbol 12,13-diacetate and phorbol 12,13-dibutyrate). Neurons were voltage clamped at the resting potential and the response to ACh tested before and after treatment with SP or various activators of PKC. We find that all of these agents enhance the rate of decay of ACh-induced current without affecting peak current amplitude or cellular input resistance. The PKC activators were ineffective if applied concurrently with ACh: Significant effects could be detected only after 60 seconds of pretreatment. A phorbol that does not increase PKC activity (4β phorbol) was ineffective in enhancing the decay of ACh-induced current. Thus, the effects of these agents on AChR function are likely to be mediated via their interaction with PKC, rather than by direct interaction with the AChR channel. More detailed analysis reveals that both SP and the PKC activators enhance the decay of the ACh-induced current by decreasing the time constant of the slow component and decreasing the contribution of this component to the overall current decay. In addition to the mimicry of SP effects by activators of PKC, preliminary results indicate partial occlusion of SP's effect when applied to neurons pretreated with PKC ativators. Our data, therefore, suggest that activation of PKC may mediate a slow phase of neuronal AChR channel desensitization. Experiments to determine if this kinase mediates SP's action are underway. *Supported by awards to LR from the NIH (NS22061), the Sloan Fnd. and the Klingenstein Fdn.*

196.8 ACETYLCHOLINE AND FMRFamide, ACTING THROUGH DIFFERENT RECEPTORS, BOTH ACTIVATE 'S'-LIKE K CURRENT AND SUPPRESS Ca CURRENT IN APLYSIA NEURONS.

V. Brezina* (SPON: D. Junge). Department of Biology, UCLA, Los Angeles, CA 90024.

In certain neurons in the abdominal ganglion of Aplysia californica, the endogenous neuropeptide FMRFamide induces a slow K current resembling the serotonin-sensitive 'S' current (Brezina et al. 1987, J. Physiol. 382, 267), and simultaneously suppresses the Ca current, and consequently the Ca-dependent K current (Brezina et al. 1987, J. Physiol. 388). These effects of FMRFamide may be mediated by a GTP-binding protein, since they are mimicked by injection into the cell of the non-hydrolyzable GTP analog GTP-γ-S (Brezina & Eckert, 1986, Neurosci. Abstr. 12, 1341). Further experiments (using two-electrode voltage clamp of cells L2-L6, and puffed or bath application of neurotransmitter) reveal that acetylcholine (ACh) also has very similar effects in these cells. Thus, ACh activates a slow K current, most likely the current responsible for the slow phase of the two-component cholinergic inhibition studied by Kehoe (1972, J. Physiol. 225, 85), that resembles the FMRFamide-induced 'S'-like current; in particular, the ACh-induced current is also suppressed by injection of cAMP into the cell, and activated by injection of GTP-γ-S. Furthermore, the K-current responses to FMRFamide and ACh are not additive, supporting further the conclusion that ACh, like FMRFamide, activates the 'S'-like current. FMRFamide and ACh act, however, through independent receptors, since the response to either agent can be desensitized without affecting the response to the other, and the response to FMRFamide is unaffected even when the response to ACh is completely blocked by superfusion of 0.2-1 mM arecoline or phenyltrimethylammonium. These findings provide some support for the theory of Swann & Carpenter (1975, Nature 258, 751) that the various neurotransmitter receptors are linked to only a few types of ion channels in Aplysia. In addition to activating the K current, ACh also suppresses both the early inward and the late outward currents elicited by depolarizing voltage steps in Ca-containing solution, an effect indistinguishable from the action of FMRFamide analyzed previously as suppression of the Ca and Ca-dependent K currents. All of these effects of ACh make it, like FMRFamide (Brezina et al. 1987, J. Physiol. 388), a candidate for an agent of presynaptic inhibition in Aplysia. Interestingly, while ACh mimics the effects of FMRFamide on the 'S'-like, Ca and Ca-dependent K currents, it does not mimic yet another effect of FMRFamide in these cells, activation of a relatively fast Na current (Ruben et al. 1986, J. Neurosci. 6, 252). Instead, ACh activates a fast Cl current (Kehoe, 1972, J. Physiol. 225, 85); significantly, neither fast response is affected by GTP-γ-S.

196.9 SELECTIVE DEPRESSION BY ADENOSINE OF CHOLINOCEPTOR RESPONSES IN RAT HIPPOCAMPAL NEURONES. T.W. Stone and P.A. Brooks*, Dept of Physiology, St. George's Hospital Medical School, London University, London, SW17, UK.

We have recently reported an inhibitory effect of adenosine and related purines on the carbachol induced suppression of evoked potentials in the rat hippocampal slice. (J. Physiol. in press). In the present work we have attempted to confirm the selectivity of that effect by comparing neuronal sensitivity to carbachol and excitatory amino acids on single cells in these slices.

Slices were prepared from the hippocampi of adult male rats and stored at room temperature in a humidified atmosphere of 5% CO^2 in oxygen until required. Single slices (400μm thick) were then transferred to the recording chamber and superfused with Krebs-bicarbonate medium at 30°C. Carbachol and amino acids were applied by microiontophoresis from five-barrelled pippettes and cell recordings made via single electrodes glued alongside. Adenosine and theophylline were added to the perfusing medium.

To date 8 cells have been tested in the CA1 region. Carbachol, N-methyl-aspartate (NMA), kainate and quisqualate all excited each of these cells via accepted receptor populations as indicated by selective antagonists. Adenosine 1-10uM selectively depressed sensitivity to carbachol on 6 of these cells with significantly less effect on NMA responses and little change of kainate or quisqualate responses. The reduction of NMA sensitivity may reflect some inhibition of background cholinergic tone which thus lowers excitability and increases the block of NMA activated channels by magnesium. Atropine (1μM) produced a similar effect. At adenosine levels of 30μM or higher sensitivity to kainate was also diminished though quisqualate remained relatively unaffected even at 100μM adenosine. The inhibitory effect of adenosine could be prevented by theophylline, 10-50μM.

The results support the view that adenosine may exert a selective regulation of acetylcholine receptor sensitivity in the CNS.

Work supported by the Wellcome Trust.

196.10 AUTOCRINE EFFECTS OF ADENOSINE IN GH_3 CELLS ARE MEDIATED VIA THE A1 RECEPTOR. T.M. Delahunty*, J. Linden*, E.L. Hewlett* and M.J.Cronin. (SPON: M. Merickel). Univ. Virginia, Charlottesville, VA 22908.

The purine nucleosides adenosine and 2'-deoxyadenosine can regulate the activity of a number of cell types, including those of the nervous and endocrine systems. High concentrations (2 mM) of adenosine inhibited by 30% pituitary secretion and synthesis of growth hormone and prolactin (Endocrinology 99:1612, 1976). Adenosine at more physiological concentrations (μM) inhibited by 40% growth hormone and prolactin release from GH_4C_1 and GH_3 pituitary tumor cells (Endocrinology 117:2330, 1985). Two functionally and pharmacologically distinct adenosine receptors have been identified, the A1 and A2 receptors, which inhibit and stimulate adenylate cyclase activity, respectively. No one, to our knowledge, has characterized the receptor subtype or measured cyclic AMP (cAMP) metabolism associated with adenosine in pituitary cells. Accordingly, studies were carried out on plated GH_3 cells for 10-20 min at 37°C, and cellular c-AMP was measured by radioimmunoassay. All studies were independently repeated at least twice, and significant differences were determined by ANOVA. The adenosine agonists R-phenylisopropyladenosine (PIA), 5'-N-ethylcarboxamide adenosine (NECA) and adenosine all significantly inhibited cAMP accumulation from 0.1 nM to 0.1 mM; all agonists produced the same maximal inhibition of 50% in basal levels and a maximal 75% inhibition of vasoactive intestinal peptide (VIP, 100 nM) stimulated levels. The order of potency was PIA > NECA > adenosine, typical of A1 receptors. The potent and selective A1 antagonist BWA 1433u blocked the inhibitory action of PIA. Pertussis toxin (50 ng/ml) blocked the adenosine-mediated inhibition of cAMP, while somatostatin (100 nM) and carbachol (1 μM), agents which also inhibit cAMP in GH_3 cells, added to the reduction in cAMP imposed by adenosine. In the presence of RO72956, a phosphodiesterase inhibitor devoid of adenosine receptor antagonist activity, addition of adenosine deaminase (Adase, 1 U/ml) to destroy endogenous adenosine significantly increased cAMP content by 50%. This suggests that physiologically active concentrations of adenosine are secreted by GH_3 cells. In contrast, the Adase inhibitor EHNA (erythro-9-2-hydroxy-3-nonyl adenine HCl) decreased basal cAMP levels by 20%. Adase (0.6 U/ml) and BWA 1433u (1 μM) increased the efficacy of VIP by 26% and 180%, respectively. These results indicate that adenosine is produced in and acts on GH_3 cells via an A1 receptor to inhibit cAMP accumulation. A2 receptor activity was not observed. We recommend the use of an adenosine receptor antagonist or Adase to aid in characterizing the role of other agents that modify cAMP levels in GH_3 cells by attenuating the inhibitory action of endogenous adenosine. 196.11 GLYCINE POTENTIATES GLUTAMATE ENHANCEMENT OF [3H] TCP BINDING IN RAT HIPPOCAMPAL MEMBRANES. D. W. Bonhaus and J. O. McNamara. V. A. Medical Center and Departments of Medicine (Neurology) and Pharmacology, Duke University, Durham, NC 27705.

The NMDA-subtype of excitatory amino acid receptors has been implicated in several forms of neuronal plasticity. Glycine, traditionally thought to be an exclusively inhibitory neurotransmitter, has been recently demonstrated to selectively enhance responses to NMDA in cultured mouse neurons (Johnson and Ascher, Nature, 235:529-531, 1987). The molecular basis of this enhancement is unclear, but an allosteric modulation analogous to the GABA receptor-channel complex is one possibility.

To test this idea, we measured the effects of glycine and glutamate on the binding of the phencyclidine analog, [^{3}H]-N-(1-[2-thienyl]cyclohexyl)piperidine (TCP). Electrophysiologic studies suggest that phencyclidine binds to the open configuration of the channel coupled to the NMDA receptor; we therefore used [^{3}H]TCP as a biochemical index of an NMDA receptor coupled response.

Specific [^{3}H]TCP binding (difference in absence and presence of 10^{-6}M phencyclidine) was measured in a Tris pH 7.7 buffer with well-washed membranes prepared from rat hippocampus. Glycine alone had no effect on [^{3}H]TCP binding at concentrations below 5 uM. Glutamate alone produced a 140% increase of [^{3}H]TCP binding with EC50 of 0.1 uM, thereby confirming the results of Loo et al., E.J.P. 123:467-468, 1986. Inclusion of glycine (1 uM) potentiated the effect of glutamate (basal [^{3}H]TCP binding was 66 fmol/mg; with addition of 5 uM glutamate TCP binding was 92 fmol/mg; with addition of 5 uM glutamate plus 1 uM glycine TCP binding was 130 fmol/mg). The effect of glycine was not inhibited by 10^{-6} M strychnine.

These biochemical findings support the hypothesis of a direct physical coupling among an NMDA receptor, a strychnine insensitive glycine receptor and a cation channel in mammalian hippocampal membranes. This may provide a rapid in vitro assay for agonists and antagonists of the strychnine insensitive glycine receptor.

196.12 BEHAVIORAL EVIDENCE FOR INTERACTIONS BETWEEN PHENCYCLIDINE AND NMDA RECEPTORS. G.E. Handelmann, L.J. Christine*, L.L. Mueller*, P.C. Contreras, and T.L. O'Donohue. Central Nervous System Diseases Research, G.D. Searle & Co., St. Louis, MO 63198.

Phencyclidine (PCP) has been shown to be a non-competitive antagonist of the N-methyl-D-aspartate (NMDA) subtype of glutamate receptor (Martin, D., Lodge, D., Neuropharmacol., 24:999, 1985), and the distribution of PCP binding sites closely parallels those for NMDA (Yound, A., Eur. J. Pharmacol., 123:173, 1986). A relationship between PCP and NMDA receptors has therefore been proposed which would allow PCP an inhibitory influence on the NMDA receptor gated ion channel. If such a relationship exists, PCP should produce the same effects on neural function as an NMDA competitive antagonist. We have therefore compared the behavioral effects of low doses of PCP to those of (D,L)2-amino-7-phosphonoheptanoic acid (APH) on several behavioral measures known to be sensitive to AHP.

APH has been shown to have anxiolytic activity (Stephens, D.N. et al., Psychopharmacol., 90:166, 1986; Bennett, D., Amrick, C., Life Sci., 39:2455, 1986), to produce muscle relaxation (Turski, L., et al., Neurosci. Lett., 53:321, 1985), and to impair spatial memory (Morris, R.G.M., et al., Nature, 319:774, 1986). We found PCP to be more potent than APH in producing anxiolytic effect in two types of anticonflict test paradigms. PCP increased exploration of a "plus maze", and increased punished licking in the Vogel paradigm at lower doses than APH. Similarly, PCP was more potent than APH in producing muscle relaxation. Finally, PCP (1 mg/kg IP) impaired long-term memory of a learned spatial discrimination in a t-maze, analogous to APH.

These data, indicating similar behavioral effects of PCP and APH, support the hypothesis that there are interactions between PCP and NMDA receptors, and that PCP may produce inhibitory modulation of the NMDA receptor and associated sodium channel.

196.13 DIGITAL BRAIN ATLAS FOR ANATOMICAL DATA COMPARISON AND INTEGRATION. A.R. Moser*, W.T. Rogers*, L. Rinaman* S.M. Diamond* and J.S. Schwaber (SPON: K.M. Spyer) Med. Prod. Dept. (LR, SMD & JSS) and Eng. Dept. (ARM & WTR) E.I. du Pont de Nemours & Co., Wilmington, DE 19898

Stereotaxic atlases are commonly used for comparison and integration of data from many animals by plotting data onto standard atlas plates. This function has inherent limitations since the plane of section in every experiment is unique and only approximates that of the atlas. In addition, atlas plates represent only a sampling of tissue sections, thus experimental sections can only be approximately matched to corresponding atlas plates. Even if the experimental tissue section falls in the plane and level of an atlas plate, it is distorted with respect to the atlas plate due to processing.

We have developed a digital brain atlas which overcomes these limitations. This atlas consists of a three dimensional image acquired from unstained serial coronal sections. The sections were floated on surfactant to avoid distortion artifacts, and were imaged using a high resolution solid state video camera. The 3-D image, obtained by reconstruction from the serial sections, fully represents the brain of a 300 gm male Sprague-Dawley rat at a resolution of approximately 30 microns. The existence of the 3-D image in digital form allows resectioning of the image in arbitrary planes by defining an origin and a normal vector to those planes. In addition this data can be scaled and warped, resulting in electronic images that geometrically match the experimental tissue sections. This match defines a coordinate transformation, allowing anatomical data from any number of animals to be integrated into a database relevant for the species rather than for the individual. The strength of this approach is that it permits high resolution comparison to be made across treatments, and the integration of multiple data sets in a common coordinate framework.

We are testing the extent to which neuronal structures are conserved and thus the limits of resolution with which data matches can be made. This is being done by matching two reconstructed high resolution mappings of the entire population of neurons efferent to the vagus nerve.

196.14 MOLECULAR SANDWICHES: BINDING SITES ON PEPTIDES AND PROTEINS FOR AROMATIC NEUROTRANSMITTERS AND DRUGS. R. S. Root-Bernstein. Neurobiochemistry, T-85, Veterans Administration Hospital, Brentwood, CA 90073.

"Molecular sandwich" is a term referring to the interaction of aromatic molecules with the cyclic side chains of peptides and proteins. No specific definition of a molecular sandwich exists, however. I suggest the following: stereospecific intercalation of a cyclic molecule between a pair of neighboring cyclic residues of a protein, polypeptide, or peptide. The intercalation may result in pi-pi stacking bonds if aromatic residues are involved, or in hydrophobic (van der Waals) interactions if the binding molecule or amino acid side chain is not aromatic. Specificity is conferred upon the molecular sandwich by the geometry and charge (if any) of the residues forming the sandwich and by the chemical affinities of the amino acid side chains immediately adjacent to the cyclic side chains. These adjacent residues will generally have one of two functions: 1) to form the stereospecific conformation of the sandwich; or 2) to stabilize the binding of an appropriate molecule into the sandwich by means of hydrogen or ionic bonds, van der Waals forces, or charge-transfer complexing with residues on the binding molecule. Theoretically, over a million distinct molecular sandwiches may exist for hexapeptide sequences. Many more sandwiches may be formed by secondary and tertiary protein conformations.

Molecular sandwiching has been reported: serotonin (5HT) binds to similar sequences on LHRH, ACTH, MSH, and myelin basic protein (Root-Bernstein and Westall, Brain Res Bull 12(4) (1984) 425); norepinephrine (NE) and dopamine (DA) bind to the enkephalins and morphiceptin (Root-Bernstein, Brain Res Bull 18(4) (1987)); the tricyclic antidepressants bind to aromatic residues on calmodulin (Reid, J Theor Biol 105 (1983) 63); and various interferons bind differentially to agarose—bound aromatic amino acids and dipeptides (e.g., L-Trp-L-Trp or L-Trp-L-Tyr) (Sulkowski, et al., J Biol Chem 251 (1976) 5381). The concept of molecular sandwiching may be useful for elucidating binding sites for neurotransmitters and drugs on peptides and proteins; for explaining co-transmission of particular peptides with monoamines; for understanding drug activity; and for designing peptides and drugs with specific binding activity.

CHARACTERIZATION OF CHOLINERGIC RECEPTORS I

197.1 ALTERATION IN THE EXPRESSION OF ACETYLCHOLINE RECEPTORS AS A FUNCTION OF THE CELL CYCLE. S. Bursztajn and Y. J. Jong. Neurology and cell Biology Department, Program in Neuroscience, Houston, Texas 77030.

The formation of myotubes is the result of a number of divisions by myoblasts with the final alignment and fusion into multinucleated cells. Previous studies indicate that once myoblasts fuse they withdraw from the cell cycle. We were interested in determining whether all myotube nuclei are post-mitotic, and how the expression of acetylcholine receptors (AChRs) changes when cells are grown in the presence or absence of mitotic inhibitors or stimulators. Studies were carried out on chick myotube cultured cells exposed to cytosine arabinoside (ARAC) or to phorbol 12-myristate 13-acetate (PMA), which we have previously shown to cause dispersal of AChR clusters and the suppression of new AChR synthesis. The number of surface AChRs assayed five days after plating taken at various time periods within 24 hours stayed constant in ARAC treated cells, whereas cells not exposed to ARAC increased their surface AChR number by 23% ± 3%. Cells exposed to ARAC and phorbol esters showed 66% ± 5% decrease in AChR number as compared to ARAC treated controls and a 74% ± 6% decrease when compared non-ARAC treated controls. Removal of phorbol esters from culture media resulted in the return of AChRs to control values. Measurement of total DNA revealed a significant increase in total µg of DNA per dish in phorbol ester treated cells. Cells treated with phorbol, pulsed for one hour with ^{3}H-thymidine and counted in a liquid scintillation counter incorporated 33% ± 4% more ^{3}H-thymidine than controls. In order to differentiate between the dividing cells which are myoblast and the ones which are fibroblasts, double label experiments were carried out. Cells were labelled with ^{3}H-thymidine and a monoclonal antibody to myosin, and subjected to autoradiography. By interchanging filters, both the silver grains over the nuclei and the myosin staining of myotubes were readily visualized. The number of nuclei per myotube segment that incorporated ^{3}H-thymidine was quantitated in the presence and absence of phorbol esters. Cells treated with phorbol esters showed a four fold increase in the number of nuclei per myotube labelled as compared to non-treated controls. Those myotube nuclei which incorporated ^{3}H-thymidine may have arisen either by immediate fusion with a myotube during the division cycle, or by division that occurred within the myotube. Our studies indicate that in a mature myotube culture, the dividing myoblasts contribute toward the increased expression of AChRs, but a continuous proliferative state results in dedifferentiation and suppression of AChR synthesis. Supported by NIH (NS24377) and NSF-(8515025) grants.

197.2 PHOSPHORYLATION OF ASSEMBLED AND UNASSEMBLED ACETYLCHOLINE RECEPTOR SUBUNITS IN CULTURED CHICK MUSCLE CELLS. A. Ross, J. Schmidt, and J.M. Prives (Spon. B. Walcott) Departments of Anatomical Sciences and Biochemistry, State University of New York, Stony Brook, NY 11794.

The four subunits of the nicotinic acetylcholine receptor (AChR) assemble posttranslationally to form the functional ligand gated ion channel that is expressed on the muscle cell surface. The molecular basis for dynamic events in subunit assembly, such as subunit-subunit recognition and conformational rearrangements associated with channel formation is not understood, but may well involve posttranslational modification of AChR subunits (J.P. Merlie, Cell 36;573-575, 1984).

To investigate the potential contribution of phosphorylation-dephosphorylation to the regulation of AChR subunit assembly, we have developed procedures that utilize immunoprecipitation of nonassembled and assembled AChR subunits from extracts of muscle cells labeled with (35S) methionine or with 32Pi. Noncrossreactive antibodies directed against specific subunits, as well as both polyclonal and monoclonal antibodies to AChR are used for immuno-precipitations, sucrose density gradients are utilized to separate unassembled subunits from assembled oligomeric AChR, and these subunits are resolved by SDS-PAGE.

We have found that two AChR subunits, the gamma subunit (Mr 50kDa) and the delta subunit (Mr 55kDa) are phosphorylated in intact chick muscle cells. When cell extracts were fractionated on sucrose gradients and the fractions immunoprecipitated with an antisera which recognized both assembled and unassembled delta subunit, it was found that this subunit is phosphorylated in both the assembled and the unassembled state. A quantitative immunoblotting technique was utilized to show that the pool size of assembled delta subunit greatly exceeded that of the unassembled delta subunit, and by comparing the phosphate content of the delta subunit in the assembled and unassembled pools it was deduced that the unassembled delta subunit is more highly phosphorylated than the assembled delta subunit. These results indicate that phosphorylation of the delta subunit precedes assembly into the oligomer, and that a dephosphorylation of this subunit occurs concomitantly with subunit assembly. These findings suggest that phosphorylation/dephosphorylation may play a role in the regulation of AChR assembly. Our current experiments are aimed at further testing this possibility.

Supported by grants from NSF and AHA.

197.3 INTERNALIZATION OF THE ACETYLCHOLINE RECEPTOR: CHARACTERIZATION OF ACIDIFIED COMPARTMENTS. J.S. Park* and S. Bursztajn (SPON: Y. Tomozawa). Department of Neurology, Program in the Neurosciences. Baylor College of Medicine, Houston, Texas 77030.

We have found that when the nicotinic acetylcholine receptor (AChR) is internalized, it passes through endosome-like organelles before reaching the lysosomes. Because low pH has been shown to play an important role in endosome and lysosome function, we are interested in determining what organelles in the AChR internalization pathway have low pH. AChR endocytosis in cultured chick myotubes was initially studied by incubating the cells with a colloidal gold probe (Mab 35-gold, 12nm) made with a monoclonal Ab against the AChR (Tzartos, et al., J.Biol. Chem., 256:8635, 1981) and tracing the intracellular distribution of Mab 35-gold vs. time by electron microscopy. At time 0, 80% of the Mab 35-gold was found at the outer cell surface and 20% was found in the invaginations of the cell surface. From 5 to 60 min, the Mab 35-gold could be found in endosome-like vesicles, and by 2h, >90% of the gold could be found in structures identifiable as lysosomes by acid phosphatase. In order to label low pH compartments, we incubated chick myotubes for 1 h at 37 C with the acidotropic compound DAMP, 3-(2,4-dinitroanilino)-3´ amino-N-methyldipropylamine, which accumulates in low pH compartments (e.g. lysosomes, endosomes, and trans-Golgi cisternae) and is retained after fixation. (Anderson, et.al., PNAS, 81:4838, 1984). The myotubes were then incubated with Mab 35-gold, and gold internalization over time was followed by electron microscopy as before. After fixation, the myotubes were embedded in Lowicryl, and the DAMP-containing organelles were identified in thin sections by indirect protein A-gold (5nm) labeling where anti-DNP was the first Ab. Although the Mab 35-gold colocalized with small amounts of DAMP-specific gold during early time points of internalization (e.g. 5 min.), the Mab 35-gold was not found in organelles with high DAMP gold density (multivesicular bodies and dense lysosomes) until 30 min. Further work is in progress to characterize the DAMP-rich organelles in the AChR internalization pathway and to determine what role acidification might play in the early stages of AChR internalization.

197.4 CHARACTERIZATION OF MONOCLONAL ANTIBODIES DIRECTED AGAINST A SYNTHETIC PEPTIDE CORRESPONDING TO A BUNGAROTOXIN BINDING REGION ON THE α-SUBUNIT OF THE ACETYLCHOLINE RECEPTOR. P.E. Preston* and E. Hawrot. Dept. of Pharmacology, Yale Univ. Sch. Med. New Haven, CT 06510.

Monoclonal antibodies (mAbs) have been generated against a 32 amino acid synthetic peptide corresponding to amino acids 173-204, from the α-subunit of the acetylcholine receptor (AChR) of Torpedo californica. This peptide has been shown to specifically bind the ligand α-bungarotoxin (PNAS 82:8790, 1985) and has been found to induce experimental myasthenia gravis in mice (Soc. Neurosci. Abstract 338.2, 1986).

All of the mAbs are IgMs and recognize the 32-mer in solid phase ELISA assay. Many of the mAbs also bind to Torpedo electric organ membranes as measured by ELISA. Some of the mAbs also bind to the membranes of intact BC3H1 cells, a mouse muscle cell line that expresses a high level of nicotinic AChR on its surface. The binding of the mAbs to cells was determined using two different assays. In the first assay, mAbs are incubated with intact BC3H1 cells followed by an incubation with ^{125}I-labelled Goat anti-Mouse Ig. The second assay involves metabolically labelling the mAbs themselves and monitoring the binding of the ^{35}S-labelled antibodies to the intact cells. None of the mAbs that bound BC3H1 cells bound to rat PC12 cells, a cell line which expresses a neuronal, rather than a muscle, type of nicotinic AChR.

Despite the fact that a majority of the mAbs recognize AChR in either Torpedo membranes or on BC3H1 cells or both, none of the mAbs recognize detergent solubilized Torpedo AChR. The mAbs failed to bind to purified Torpedo AChR in ELISA and failed to precipitate ^{125}I-Btx labelled Torpedo or BC3H1 AChR in an immunoprecipitation assay. In addition, we have failed to demonstrate binding to SDS denatured AChR subunits on Western blots. Thus these mAbs, although raised against small synthetic peptides, may recognize conformational determinants that are sensitive to detergent treatments. Furthermore, in two different assay systems, an ELISA assay and a ^{35}S-mAb binding assay, we have found that pre-incubation with ligands such as carbachol or curare, is required for mAb binding to purified Torpedo AChR (in ELISA) and increases binding of labelled mAb to Torpedo membranes. These findings suggest that a conformational change in the AChR following ligand binding may be required for optimal binding of these mAbs.

Supported by NIH GM32629, the Muscular Dystrophy Association and the American Heart Association.

197.5 α-BUNGAROTOXIN BINDING TO SYNTHETIC PEPTIDES CORRESPONDING TO SEQUENCES OF THE α SUBUNIT OF THE ACETYLCHOLINE RECEPTOR. P.T. Wilson*, E. Hawrot and T.L. Lentz. Depts. of Cell Biol. and Pharm., Yale Univ. Sch. Medicine, New Haven, CT 06510.

We previously reported that a synthetic peptide of 32 amino acid residues corresponding to residues 173-204 of the α subunit of Torpedo acetylcholine receptor (T32mer) bound α-bungarotoxin (BTX) (PNAS 82:8790 1985). We report here the results of further studies involving synthetic peptides corresponding to sequences in the region of 173-204. [125]I-BTX binding to the T32mer was competed with a variety of cholinergic antagonists and agonists in a solid phase assay. Affinity for binding to the T32mer was measured by the concentration of the ligand resulting in a 50% reduction in BTX binding (IC50). Cholinergic antagonists competed [125]I-BTX binding with IC50's of 42 nM for unlabeled BTX, 440 nM for α-cobratoxin, and 86 μM for d-tubocurarine (dTC). In contrast, cholinergic agonists competed BTX binding with IC50's in the 1-10 mM range and NaCl with an IC50 of 16 mM. These IC50 values are nearly equal to the IC50 values reported for binding to the intact isolated α subunit. We conclude that the T32mer expresses most or all of the determinants of BTX binding expressed on the intact isolated α subunit. Shorter peptides with sequences coresponding to portions of the 32mer sequence were also tested for their ability to bind BTX in solid phase assays. An 18mer, 181-198, bound BTX with an IC50 of 21 μM. Similarly, two 12mers, 185-196 and 193-204, bound BTX with IC50's of 24 μM. The lower affinities of these peptides as measured by IC50 indicates that they do not contain all of the determinants of BTX binding expressed on the 32mer. The affinity of BTX binding to 32mers corresponding to 173-204 of the human (H32mer) and calf (C32mer) α subunits was also determined from competition studies. For the C32mer, the IC50 for unlabeled BTX was 640 nM and for dTC 250 μM. For the H32mer, the IC50 for unlabeled BTX was 6400 nM and for dTC 48 μM. Similar affinities for BTX binding were obtained from equilibrium dissociation constants. For T32mer, Kd = 63 nM; for C32mer, Kd = 223 nM; for H32mer, Kd = 1035 nM. The presence of 0.01% SDS in the binding buffer increased the affinity of BTX binding to all three 32mers, but the effect was greatest for the T32mer. For T32mer, Kd = 7.2 nM; for C32mer, Kd = 49 nM; for H32mer, Kd = 361 nM. Under both conditions the affinity of BTX was greatest for T32mer and least for H32mer. Of the five amino acid differences that occur between the T32mer and H32mer, three are nonconservative and involve the substituion of aromatic residues in the Torpedo sequence for polar residues in the human. We therefore conclude that aromatic residues may be important in the higher affinity of binding of BTX to the T32mer. Supported by NIH NS 21896 and GM 32629.

197.6 GENERATION AND CHARACTERIZATION OF MONOCLONAL ANTIBODIES TO PRESELECTED DOMAINS OF THE DELTA SUBUNIT OF THE MOUSE NICOTINIC ACETYLCHOLINE RECEPTOR. Susan B. Edelstein* and Edward Hawrot (SPON: P. Forscher). Dept. of Pharmacology, Yale Univ. Med. Sch., New Haven, CT 06510.

We have used a synthetic peptide approach to produce a new panel of mouse-specific monoclonal antibodies (mABs) directed against the ectodomain of the delta subunit of the nicotinic acetylcholine receptor (AChR). We chose the mouse sequence SRLQWDANDFGNIT (residues 65-78, #411) and the sequence LSLKQEEENNRS (residues 160-171, #20) for the production of mABs since these regions have diverged considerably from the corresponding *Torpedo* sequence, are rich in charged residues, precede several proline residues and contain a potential site for N-linked glycosylation suggesting that these domains lie on the extracellular surface of the AChR.

Hybridoma supernatants were screened against unconjugated peptide using a solid phase enzyme-linked immunosorbent assay (ELISA). Eight hybridoma clones against peptide 20 and six clones against peptide 411 were chosen for further characterization. All the mABs were found to be IgMs when supernatants were screened for Ig subtype.

To determine if the mABs bound to the ectodomain of the AChR, a modified ELISA was used. BC3H-1 mouse cells, which express high levels of surface AChRs in response to low serum, were grown for 7-10 days in low serum in 96 well plates then lightly fixed prior to ELISA assay under conditions which did not permeabilize the cells. All of the mABs showed significant binding to wells containing fixed BC3H-1 cells compared to similarly processed wells containing no cells or mouse fibroblast LMTK cells.

The mABs also bound to partially purified *Torpedo* AChR in an ELISA assay. Interestingly, the mABs against peptide 20 showed greater cross-reactivity to the *Torpedo* AChR than the mABs against peptide 411 even though peptide 20 has much lower homology to the *Torpedo* sequence than does peptide 411. Regardless of the supernatant assayed, the mABs bound to *Torpedo* at a much reduced sensitivity compared to that seen with BC3H-1 cells. Whereas levels of mABs bound to *Torpedo* AChR and BC3H-1 cells appeared similar, the concentration of *Torpedo* AChR in the assay was 100-1000 times higher than the amount of BC3H-1 receptor present.

To determine if the mABs bound to the AChR, a modified immune precipitation-ELISA assay was used. NP40 extracts of *Torpedo* homogenate, BC3H-1 cells and LMTK cells were incubated with bungarotoxin-Sepharose to specifically bind the AChR. The beads containing bound AChR were then incubated with the hybridoma supernatants and assayed for mAB binding by an ELISA assay. Significant binding of the mABs could be detected in the *Torpedo* and BC3H-1 extracts but not in the LMTK and no cell extracts.

To determine whether the mABs bound specifically to the delta subunit, purified *Torpedo* AChR was used in series of protein blotting experiments. A band at 65kD corresponding to the delta subunit was darkly stained. In addition, some of the mABs appeared to cross-react with the gamma and beta subunits. As with the ELISA assays, the supernatants against peptide 20 showed higher cross-reactivity with the *Torpedo* receptor than did the mABs against peptide 411.

In summary, these studies are the first description of mABs that have been found to bind to the ectodomain of the delta sununit of the AChR, and as such, these mABs will be useful for probing the role this region plays in the functioning of the AChR.

197.7 EPITOPE LOCALIZATION ON THE THREE-DIMENSIONAL AND PRIMARY STRUCTURE OF ACETYLCHOLINE RECEPTOR. S.J. Tzartos, A. Kordossi*, S.L. Walgrave*, A. Kokla* and B.M. Conti-Tronconi*. Hellenic Pasteur Inst., Athens 115 21, Greece, and Dep. Biochemistry, Univ. Minnesota, St. Paul, MN 55108.

The binding sites of several monoclonal antibodies (mAbs) on the acetylcholine receptor (AChR) were localized by two different approaches. The first approach involved competition experiments among mAbs for binding to intact Torpedo AChR. The mAbs used bind to known sites on the amino acid sequences 339-378 and 336-469 of the AChR α and β-subunits respectively, as determined by synthetic peptides[1]. mAbs to sequential epitopes separated by about seven residues did not compete whereas mAbs to more closely neighbouring epitopes mutually excluded each other. Our experiments strongly suggested that these mAbs bind to intact AChR at the sequences already determined by synthetic peptides and not at irrelevant discontinuous epitopes. This finding has important implications for current models of the AChR transmembrane structure.

The second approach involved mAb mapping by the use of 26 synthetic peptides corresponding to 83% of the sequence of the human α-subunit. Several mAbs of the above studied group were mapped at the expected[1] or at neighbouring amino acid sequences. This technique also allowed the fine localization of the main immunogenic region (MIR) of the AChR. The MIR to which the majority of the anti-AChR antibodies are directed had been localized earlier within residues 6-85 of the AChR α-subunit[2]. With the present experiments we localized the MIR in an 18-mer of the α6-85 region.

197.8 COMPUTER MODELING OF BRAIN MUSCARINIC ACETYLCHOLINE RECEPTOR TOPOGRAPHY. L. Antonian and A. S. Lippa*, Matrix Research Labs, City College of New York, New York, NY, 10031, USA.

A few theoretical models for the muscarinic acetylcholine receptor (mAchR) have been suggested based on structural requirements of acetylcholine and certain of its analogues. More recent pharmacological classification of Ach agonists into full (class A) and partial (class B) agonists has made it possible to test the validity of these models and to further refine the receptor topography.

By using computer molecular modeling programs, we have compared the structures of full and partial agonists to their known binding properties and physiological activities of phosphoinositide hydrolysis and receptor desensitization at the hippocampal pyramidal cells. The full agonists examined were Ach, carbachol, S-metacholine, muscarine, and oxotremorine-M. The partial agonists studied were arecoline, pilocarpine, oxotremorine, and S-bethanechol. From such comparisons we propose a topographical model for the muscarinic acetylcholine receptor which enables the distinction between class A and B agonists.

The energetic and conformational studies were accomplished by using MacroModel, via quantitative and visual examinations of computerized molecular models. MacroModel is a molecular modeling program, especially designed for the purpose of structurally comparing small molecules. Relaxed geometries were determined using molecular mechanics MM2 force field and the conformational energies were then evaluated by energy minimizations. Quantitative data were obtained on relevant atom distances. Atomic charges were determined for all agonists by using ChemGraph, a different molecular modeling program.

A model for the agonist fit at the receptor, suggesting a two-step binding process, will be presented.

197.9 IRREVERSIBLE INHIBITION OF MUSCARINIC CHOLINERGIC RECEPTOR BINDING BY TYROSINE-DIRECTED ALKYLATING AGENTS IN RAT CEREBRAL CORTEX AND HEART.

J.-X. Wang", H.I.Yamamura, W.Wang" and W.R. Roeske. Department of Pharmacology and Internal Medicine. The University of Arizona, Tucson, AZ 85724.

In order to find the composition of amino acid residues in the ligand binding sites of M_1 and M_2 receptor subtypes, two tyrosine-directed alkylating reagents, p-nitrobenzensulfonyl fluride (pNSF) and flurosulfonylnapthonic acid (FSNA) were used to modify muscarinic receptor proteins from rat forebrain and heart. The ligand binding properties of these modified receptors were then studied.

The chemical reaction was carried out by incubation of rat forebrain and heart homogenates (5% in 10 mM Na/K phospnate buffer supplemented with 25 mM $MgCl_2$) with concentrations of either of tnese two agents at room temperature for 15 min. Tne reaction was stopped by immersing the samples in an ice-water bath followed by immediate centrifugation at 48,000 X g at 4°C for 10 min. The precipitants were washed 3 times with ice-cold buffer by centrifugation at the same conditions to remove unreacted chemicals. The final pellets were resuspended in the same buffer for receptor binding assay. Both reagents caused an irreversible dose-dependent inhibition of specific binding of [^{3}H](-)QNB with an ED_{50} of about 1 mM for FSNA and 2.5 mM for pNSF in both tissues. Saturation experiments performed in the homogenates with or without chemical modification using 0.8 mM or 1.6 mM FSNA indicated that alkylation of tyrosine residue resulted in a decrease of receptor density (B_{max}) without a siginificant alteration of the affinity (K_d) of remaining receptors. The effect of FSNA (1.5 mM) was blocked by incubation of the homogenates with muscarinic agents prior to the addition of FSNA. The relative potency of muscarinic antagonists (at a concentration of 1 uM) in protecting of muscarinic receptors was atropine > pirenzepine > AF-DX 116 in both tissues. The agonist carbachol was about 100,000 times less potent than atropine in protecting muscarinic receptors. Including 100 uM of Gpp(NH)p in the tissue preparation did not reverse the protection of muscarinic receptors by carbachol. Our results suggest that there is a tyrosine residue(s) in the ligand binding area of both M_1 and M_2 receptors in rat forebrain and heart, respectively. This amino acid residue does not seem to be responsible for the heterogeneity of ligand binding affinity for the muscarinic receptors in these two tissues.

197.10 Partial Purification of Muscarinic Receptors with Antibodies to Propylbenzilylcholine Mustard-BSA Conjugates. Priscilla F. Strang and Donna D. Flynn, Department of Pharmacology, University of Miami School of Medicine, Miami, FL 33101.

Propylbenzilylcholine mustard (PBCM) is an affinity alkylating agent for the cholinergic muscarinic receptor (MR). Polyclonal antibodies (PAb) were produced in mice and rabbits immunized with PBCM-coupled to bovine serum albumin (BSA) (Biochem Pharmacol. 35: 1209, 1986). PAb's to PBCM, BSA, and the PBCM-BSA conjugates were present in the serum as shown by immunodots. IgG fractions were purified by DEAE ion exchange chromatography. PAb's to PBCM also crossreacted and bound with high affinity to ^{3}H-Quinuclidinyl benzilate (QNB) as evidenced by ammonium sulfate precipitation of PAb-^{3}H-QNB complexes. These data suggest that these PAbs share some structural features with the binding site for PBCM and QNB on the muscarinic receptor. Antibodies to these PAb's may recognize directly the ligand binding site on the MR. To test this possibility MR were solubilized from rat brain in 10 mM CHAPS/50mM $NaPO_4$ buffer (pH 7.4) containing Na_3EDTA. Antibodies were reacted with solubilized receptor and the antibody complexes were precipitated with Pansorbin. These pelleted complexes were dissociated with 2.5m $MgCl_2$. Soluble supernatants containing the dissociated antigen were run on SDS-PAGE. An enrichment in a peptide band at ~70,000-80,000 daltons was observed. This peptide has the identical mobility as the PBCM-affinity alkylated MR.

These results suggest that anti-anti-PBCM PAb's may be useful in the selective purification of muscarinic cholinergic receptors.

Supported in part by a grant from the NIH (#NS19065-04).

197.11 MOLECULAR DYNAMICS OF CHOLINERGIC LIGANDS BOUND TO THE NICOTINIC ACETYLCHOLINE RECEPTOR. K.A. McGroddy *, G.L. Millhauser, Z.Lieberman* and R.E. Oswald, Department of Pharmacology, New York State College of Veterinary Medicine, Cornell University, Ithaca, N.Y., 14853.

The connection between the molecular details of ligand binding to the nicotinic acetylcholine receptor (AChR) and the complex behavior of its ion channel is not yet understood. The hypothesis that specific structural fluctuations of the protein are related to the gating properties of the ion channel has been difficult to prove experimentally. We have used ^{19}F Nuclear Magnetic Resonance (NMR) spectroscopy of fluorinated cholinergic ligands to investigate the static and time-dependent properties of ligand binding to the AChR. Our ultimate goal is to correlate these results with single channel recording measurements in order to understand the relationship between the dynamics of agonist binding and channel activation.

^{19}F Nuclear Magnetic Resonance spectroscopy was used for several reasons. The fluorine nucleus is very sensitive both to local motion and to its chemical environment. In addition, fluorine is rarely present in the biological systems of interest so there is little background signal. A trifluorinated system was desirable in order to increase the strength of the NMR signal. Several ligands were synthesized and tested in order to determine their cholinergic activity. Patch clamp experiments showed that a recently reported trifluorinated agonist, 1,1-dimethyl-4-trifluoroacetyl-piperazinium iodide (F-PIP), bound with high affinity and induced considerable single channel activity.

The NMR experiments were performed using AChR from *Torpedo californica* electroplaque and F-PIP as the agonist. The resulting spectrum consisted of two signals: one corresponding to unbound F-PIP and the other to the receptor-bound ligand. The bound signal was characteristic of a molecule undergoing highly anisotropic reorientation. This motion could be either intramolecular ligand motion, movement of the protein-agonist complex in the membrane, or rotation of the entire bound molecule about a preferred axis in the binding site.

Intramolecular ligand motion was ruled out after a careful study of the unbound agonist using ^{1}H NMR spectroscopy. Although the free molecule does experience rotation about internal bonds, this rotation is several orders of magnitude slower than the observed bound state rotation. Motion of the receptor-agonist complex was also an unsatisfactory explanation for our results since the time scale of protein motion in the membrane does not correspond to the time scale of the observed motion. We conclude that the bound cholinergic ligand is able to rotate about an axis through its length as it sits in the AChR binding site. This is the first step toward determining the molecular dynamics of an agonist molecule in its binding site.

197.12 NICOTINE: INTERACTIONS OF ITS STEREOISOMERS WITH THE NICOTINIC ACETYLCHOLINE RECEPTOR. R. Rozental*, Y. Aracava*, K.L. Swanson, E.X. Albuquerque. Dept. of Pharmacol. and Exp. Therap., Univ. Maryland Sch. Medicine, Baltimore, MD 21201.

The multiple actions of nicotine stereoisomers were evaluated at the peripheral nicotinic acetylcholine receptor (nAChR). The agonist potencies of (-)-nicotine, (+)-nicotine (both ditartrate salts) and carbamylcholine were compared by assay of rectus abdominis (*Rana pipiens*) contracture. In order to minimize desensitization, low drug concentrations were selected. Compared to carbamylcholine, complete recovery from nicotine-elicited contractures, (-) or (+), was prolonged (30 min) and a relatively reduced tension was observed upon subsequent application of agonist after a wash phase. The order of potency was carbamylcholine ≈ (-)-nicotine > (+)-nicotine with 15, 23, and 130 μM, respectively, being necessary to produce 20% of maximal contractures. The (-) isomer was 8 times more potent than the (+) isomer.

Antagonistic effects of both nicotine isomers (0.5 - 5.0 μM) were illustrated by concentration-dependent depression of peak amplitude of the endplate current (EPC) in voltage-clamp studies of the frog sartorius muscle. For instance, 1 μM of either (-) or (+)-nicotine halved the peak amplitude of the EPC. Neither isomer modified the decay time constant of the EPC significantly. Trains of EPCs were elicited to test if desensitization could account for the depression of the peak EPC amplitude. There was no significant effect of either nicotine isomer from 0.5 to 5.0 μM on the relative amplitude of the last EPC versus the first EPC evoked by tetanic stimulations (25 Hz for 2 sec), although concentration-dependent reduction of the initial peak EPC amplitude was observed.

Single channel currents, recorded from perijunctional regions of single fibers of the frog interosseal muscle, showed the agonist property of nicotine isomers in the concentration range of 1-50 μM. The (-) isomer was more potent than its enantiomer, concurring with the results of the contracture assay. Both nicotine isomers activated single channel currents which were interrupted by a greater number of short closures than were the ACh-activated currents. Single channel conductance was similar to that reported for ACh (≈30 pS, 10°C). In the presence of a stimulating concentration of ACh (0.4 μM), lower concentrations of either nicotine isomer (0.1 to 10 μM) induced bursting-type channel activity. This effect, which was not significantly stereospecific, may be correlated with the decreased peak amplitude of the macroscopic EPC. These actions of nicotine suggest competitive and noncompetitive interactions with the acetylcholine receptor at the agonist recognition site and an allosteric site, possibly associated with the ion channel and/or coupled with desensitization. (Support: U.S. Army Med. Res. & Dev. Comm. Cont. DAMD17-84-C-4219.)

197.13 BISPYRIDINIUM COMPOUNDS SAD-128 AND HI-6 MODULATE ENDPLATE CURRENTS OF FROG SARTORIUS MUSCLE. M. Alkondon* and E.X. Albuquerque. (Spon: D. Burt) Dept. Pharmacol. & Exper. Ther. University of Maryland Sch. Medicine, Baltimore, MD 21201.

Pyridinium compounds with oxime groups such as, 2-PAM and HI-6, have earlier been shown in our laboratory to have a modulatory effect on the ionic currents occurring at the frog endplate region. In the present study another bispyridinium compound named 1,1'-oxybis(methylene)bis4-(1,1,dimethylethyl) pyridinium dichloride (SAD-128) which lacks the oxime group in its structure has been tested on the endplate currents (EPCs) measured at the frog neuromuscular junction and its effects compared with that of the closely related compound HI-6. SAD-128 at concentrations below 10 μM did not significantly alter the EPC parameters. At concentrations between 100-500 μM, SAD-128 produced a depression of EPC peak amplitude which was greater at negative holding potentials. The current-voltage (I-V) relationship was linear in the range between +50 mV to -70 mV. However, between -100 and -150 mV, especially at high concentrations (500 μM) of SAD-128, there was a curvature and negative slope observed in the I-V plots. On the other hand, the decay phase of the EPC appears to be prolonged at concentrations between 50 and 500 μM. At holding potentials between -100 and -150 mV, two phases of EPC decay were noticed especially at concentrations between 50 and 100 μM. At these doses, analysis of the two phases revealed the following points: When the holding potential was increased from -100 to -150 mV, the time constant of the fast phase decreased, slow phase increased whereas an inverse relation of the percentage current in each of these phases was noticed. At higher concentrations (500 μM), the slow phase became predominant and a clear distinction between the two phases could not be discernible. SAD-128 also produced similar biphasic decays in the miniature EPCs at concentrations between 10 to 100 μM at holding potentials between -100 to -140 mV. HI-6, on the other hand, produced single exponential decays of EPCs even though it produced similar nonlinear depression in I-V plots. Moreover, HI-6 in most of the doses, appear to fasten the EPC decays especially at negative potentials. Acetylcholine (ACh)-induced channel openings (open times) were shortened by HI-6 in a voltage-dependent manner as revealed by patch clamp studies. The ACh-receptor channel-blocking effect of these pyridinium compounds (as revealed by the above results) may remain as one of the mechanisms by which they produce antidotal effects against organophosphate agents. (Support: U.S. Army Med. Res. & Devel. Com. Contr. DAMD17-84-C-4219).

197.14 INTERACTION OF AMANTADINE WITH THE NICOTINIC ACETYLCHOLINE RECEPTOR MACROMOLECULE OF FROG SKELETAL MUSCLE. L.M. Dumbill* and E.X. Albuquerque. Dept. of Pharmacol. and Exp. Ther., Univ. of Maryland Sch. Med., Baltimore, MD 21201.

Amantadine hydrochloride (1-adamantanamine hydrochloride) is a prophylactic drug used in the treatment of A_2 influenza (Asian flu) and is also effective in the treatment of human Parkinsonism. Earlier binding and voltage-clamp studies showed a depression of the peak endplate current amplitude and a shortening of the half-decay time, suggesting a non-competitive ion channel blockade (*Mol. Pharmacol.* 14:787, 1978). However, at positive potentials amantadine induced a lengthening of the half-decay time. To discern the mechanisms underlying these alterations, it was decided to study the micromolecular effect of the drug. The effect of amantadine upon the nicotinic acetylcholine receptor (nAChR) macromolecule was studied using patch clamp technique. Single channel recordings were made on interosseal muscle fibers of the frog, *Rana pipiens*.

Amantadine exhibited an agonistic effect on the nAChR complex at high concentrations (1 - 50 μM). At 50 μM, the frequency of amantadine-induced channels was comparable to that observed in ACh controls (300 nM). In contrast to ACh, at holding potentials between -60 and -160 mV, amantadine activated channel currents with a significantly increased level of open channel noise. The opening events caused by amantadine appeared as bursts interrupted by many rapid channel closures. Single channel conductance, however, remained similar to that reported for ACh-activated channels, i.e. ≈30 pS at 10°C. At depolarized membrane potentials (+80 to +120 mV), channel lifetimes appeared to be very brief (≤ 0.8 msec) with a decreased frequency of openings. This decrease in detected frequency may result from the exclusion of brief events by the instrument filtering bandwidth (3 kHz).

In an admixture of ACh (300 nM) and various concentrations of amantadine, channel openings with increased flickering during bursts were recorded. Single channel conductance was unaffected. Although further analysis of the kinetics of amantadine action on the nAChR of the neuromuscular junction and other cholinergic synapses is required, our results indicate that the agent has agonistic and open channel blocking properties. (Support: U.S. Army Med. Res. & Develop. Comm. Contract DAMD17-84-C-4219).

198.1 AUTORADIOGRAPHIC LOCALIZATION OF FLOW OF TRACER SUBSTANCE IN EXTRACELLULAR FLUID COMPARTMENTS OF RAT CNS B. Hutto*, L. Brady, and M. Herkenham Unit on Functional Neuroanatomy, NIMH, Bethesda, MD 20892

The cerebrospinal fluid (CSF) is rich in many of the brain's informational substances as well as their metabolites. CSF flows through two continuous compartments: the large cavities (ventricles and subarachnoid spaces) and the extracellular spaces surrounding all brain cells. The CSF may thus serve as a conduit for the parasynaptic transport of informational substances to receptors dispersed throughout the central nervous system. The possibility of endocrine forms of intercellular communication in the central nervous system is predicated on the existence of ample intercellular space for the movement of the messenger molecules.

To visualize these intercellular channels and to demonstrate access to them from the CSF, [^{14}C]inulin was intracisternally (20 µl) or intraventricularly (5 µl) injected into 200-280 g male Sprague Dawley rats. Inulin is an inert carbohydrate, similar in MW (~5000) to several of the larger neuropeptides (e g : CRH, GRF, ß-endorphin), but it remains in the extracellular space. Intracisternal injections were made via cannulae implanted 3 days earlier. The rats were sacrificed 5, 10, 30, 60, or 120 min after injection, and the brains were frozen. Thin sections were cut, rapidly dried, and apposed to LKB Ultrofilm.

The films showed that after cisternal injections most of the inward spread and the movement rostrally was from the subarachnoid space along the ventral and lateral surfaces of the brainstem, although the choroid plexus and ependyma of the lateral, 3rd, and 4th ventricles were eventually labeled lightly. At 5 and at 10 min inulin penetrated into the brainstem, cerebellum, entorhinal cortex, cerebral peduncle, ventral hypothalamus, mammillary nuclei, alveus, and the olfactory and optic tracts. By 1 h the label entered the hippocampus and retrosplenial cortex. Elsewhere penetration was greatest in the brainstem, ventral diencephalon, and ventral and medial forebrain, attaining a depth of 2-3 mm. By 2 h the label reached the thalamus and septum, and the brainstem and spinal cord were rather homogeneously labeled. The dorsolateral cerebral cortex remained free of label. At no time did the median eminence or the pituitary have appreciable label.

Inulin injected into the lateral ventricle followed a caudal course at the early time points and by 30 min had spread from the lateral, 3rd, and 4th ventricles into adjacent structures such as the septum, caudate, hypothalamus, periaqueductal gray matter, dorsal medulla, and ventral cerebellum. At 1 h the ipsilateral hippocampus and deep layers of somatomotor cortex were labeled, and penetration in the aforementioned areas was deeper. Penetration from the contralateral lateral ventricle did not occur.

Comparing ventricular with cisternal injections, it appears that site of injection determines structures initially labeled, though at longer time points similar structures along the ventral and medial surfaces are labeled, suggesting a similar route of clearance. Taken together the data show a rapid movement of inulin along CSF flow routes throughout the major cavities and a slower penetration into interstitial spaces adjacent to these cavities.

198.2 **QUANTITATIVE AUTORADIOGRAPHY: COMPARISON OF LABELING IN CEREBRAL CORTEX OF RHESUS MONKEY WITH [^{3}H]- [^{125}I]- AND [^{14}C]-COMPOUNDS.** M.S. Lidow, D.W. Gallager, P.S. Goldman-Rakic and P. Rakic, Yale University, School of Medicine, Section of Neuroanatomy, New Haven, CT 06510

Film autoradiography is widely utilized for localization of radiolabeled probes in nervous tissue. However the technique suffers from certain limitations. The most commonly used isotope, [^{3}H], emits low energy ß-particles which are absorbed more by myelinated axons than by myelin-free cell bodies. The resultant quenching interferes with estimates of the concentration of labeled compounds in myelin-rich areas. To avoid this problem, the use of [^{125}I] or [^{14}C] is often recommended. In the present study, a possible advantage of using [^{125}I] and [^{14}C] versus [^{3}H], was evaluated by labeling adjacent cryostat sectioned cortex of rhesus monkey with pairs of similar compounds, one of which labeled with [^{3}H] and another - with [^{125}I] or [^{14}C]. These included: [^{3}H]spiperone and [^{125}I]iodospiperone; [^{3}H]formaldehyde and [^{14}C]formaldehyde; and others. Sections were pressed against [^{3}H]-sensitive Ultrofilm. Computer-aided image analysis was used to measure the optical densities (OD) of film images corresponding to different layers of the cortex. In most cases, [^{3}H]-labeled compounds produced finer patterns of dark and light bands within the cortex than their [^{125}I]- or [^{14}C]-labeled counterparts. The dark bands were usually wider on images of [^{125}I]- and [^{14}C]-labeled sections than on images of [^{3}H]-labeled sections and images of sections labeled with [^{125}I] or [^{14}C] tended to have fewer light bands. The light bands that were present usually corresponded to light bands on images of [^{3}H]-labeled sections, though the former were often narrower and less pronounced. The light bands on [^{3}H] generated images that had no corresponding [^{125}I]- or [^{14}C]-generated images were usually ≤ 0.1mm wide and/or were not very prominent. As the position of such bands sometimes corresponded to cortical layers poor in myelin, their presence could not easily be explained by greater absorbtion of ß-particles emitted by [^{3}H]. Rather the differences in labeling with [^{3}H] and [^{125}I] or [^{14}C] could be explained by scattering of emissions from [^{125}I] and [^{14}C], which easily penetrate tissue and travel for relatively long distances in all directions, thereby exposing the film not only directly above the labeled compound (as in the case of [^{3}H]) but also at some distance from it. The result is that small areas with a low density of label are obscured and the size of areas with a high density of label is artificially increased. In support of this conclusion we found a significant increase in OD as far as 0.7mm from the images produced by [^{125}I] and [^{14}C] standards. Our findings indicate that substitution of [^{3}H] by [^{125}I] and [^{14}C] may address the quenching problem but results in a loss of resolution for fine detail such as laminar patterns in cerebral cortex.

Supported by U.S. Public Health Service Grants NS22807 and NS07224.

198.3 THE USE OF HIGH ACTIVITY ^{3}[H] STANDARDS TO QUANTITATE ^{125}[I] FILM AUTORADIOGRAPHY. R.P. Artymyshyn and B. B. Wolfe Dept. of Pharmacol., U. of PA, Phila., PA 19104

Film autoradiography using ^{125}[I] as the radionuclide is attractive because of the relatively short exposure times required. Quantitating the autoradiographs requires the generation of tissue mash standards with known amounts of radioactivity/mg protein. To determine the amount of radioactivity present in a given tissue, the density (darkness) of autoradiographs produced by labelled tissue sections is compared to the density of the autoradiographs produced by sectioned tissue mash standards. The production of tissue mash standards is time consuming and must be done relatively often because of the short half life of ^{125}[I]. To avoid the repeated production of standards and to decrease interexperiment variability we calibrated a set of high activity ^{3}[H] standards for use with ^{125}[I] autoradiography.

Standards with a range of 7390 to 0.0 µCi of ^{3}[H]/g of plastic were obtained from American Radiolabeled Chemicals, Inc. (#123A) St. Louis, MO. It was found that these standards would produce autoradiographs of suitable density at times of 4 to more than 72 hours.

Tissue mash standards were prepared in a conventional manner (Unnerstall et al, '82, J. Neurosci. Meth) in a concentration range of 470 to 4 pCi/ug protein. These standards were frozen and sectioned at varying thicknesses, and the sections thaw mounted onto slides. To check for possible variations in the amount of label within each standard, the radionuclide concentrations/ug protein were measured at regular intervals throughout the block.

Because the relationships between film response, tissue quenching and section thickness are not linear, the calibration of the ^{3}[H] standards was done separately for each time point and thickness. Brain mash standards at 12 concentrations of ^{125}[I] were produced and sectioned at thicknesses of 6, 10, 14, 16, 20, 24, 32, 40, and 60 microns. Each set of tissue standards was placed in x-ray cassettes along with slides bearing the plastic ^{3}[H] standards, apposed to LKB Ultrofilm for times of 2 hours to 1 week. autoradiographs were analyzed using a DUMAS image analysis system. A standard curve was generated for each set of tissue standards and this was correlated with a ^{3}[H] standard. This accurate calibration of the ^{3}[H] standards gives us long lived standards for ^{125}[I] autoradiography useful over a wide range of radionuclide concentrations, tissue thicknesses and exposure times. Supported by MH09499 and NS22040.

198.4 **A NEW DENSITOMETRIC PROCEDURE TO MEASURE PROTEIN LEVELS IN TISSUE SLICES USED IN QUANTITATIVE AUTORADIOGRAPHY.** J.A. Miller*, P. Curella* and N.R. Zahniser (SPON: M.K. Ahlijanian) Dept. Pharmacology, Univ. Colorado Hlth. Sci. Ctr., Denver, CO 80262.

Receptor densities obtained from quantitative autoradiography (QAR) analysis do not always agree with those obtained from scintillation counting of tissue sections which have been scraped from the slide. Disparate protein measurements may contribute to these differences. Using QAR it has been possible to normalize receptor binding data only by expressing the molar quantities of receptor bound as a function of wet weight of tissue or amount of protein in tissue paste standards. We have developed a new quantitative staining technique using the dye Coomassie Brilliant Blue G 250 (2.5% in isotonic buffer, pH 7.5) using a 180 min incubation and a 10 min wash in buffer at room temperature. This is a densitometric procedure which uses commercially-available hardware and software employed in the quantitation of receptor autoradiographs. A nonlinear curve-fitting procedure to a logistic function was employed for the quantitative densitometric analysis of both protein and receptors. Using the densitometric assay for protein to correct for regional variations in protein levels, as opposed to using the average protein concentration in the radiolabeled tissue paste standards, results in approximately a two-fold decrease in the density of ß-adrenergic receptors measured in several brain areas (Table 1). Also, better agreement is seen with Bmax values determined with membrane binding assays and normalized for protein with a spectrophotometric assay (Bradford, M.M., Anal. Biochem. 72: 248, 1976; Table 1). Additionally, the process of staining tissue with Coomassie Blue for protein is reversible; allowing further histological analysis after protein measurement. This technique is a more reliable method for normalizing receptor densities of tissue protein levels and allows for more accurately comparing results obtained with QAR and membrane binding techniques.

Table 1. Estimation of density of ß-adrenergic receptors from Scatchard analysis of IPIN binding (n = 4 to 6).

Bmax values (fmol/mg protein)

198.5 **NEUROCHEMICAL BASIS OF IN VIVO IMAGING OF BRAIN DOPAMINE NEURONS BY RADIOACTIVE LABELED L-DIHYDROXYPHENYLALANINE (DOPA).**
P.M. Douillet*, R.M. COHEN* and C.C. CHIUEH, (SPON: N. Ostrowski), NIMH, Bethesda, MD 20892

The goal of the present study was to provide a neurochemical basis for developing labeled L-DOPA derivatives to be used in positron emission tomography (PET) imaging studies of dopamine (DA) neurons. The metabolic pattern of ^{3}H-L-DOPA (1 nCi/kg i.v., 90 min) in striatum (ST) and cerebellum (CB) of Swiss mice pretreated with carbidopa (25 mg/kg, i.p., -30 min) was determined by HPLC after various pharmacological pretreatments.

The background activity was due mainly to 3-O-methyl-DOPA and to a sulfate conjugate. These background peaks were found equally in both ST and CB and their sum consists of more than 90 % of the background activity in the ST. However, the total background activity in CB was 20 % higher than in ST because of the slower decarboxylation of L-DOPA and the higher norepinephrine content. The ratio of total activities in ST and CB was 2.1 ± 0.1 (N=7). Inhibition of the DOPA-decarboxylase by NSD-1015 decreased completely the decarboxylated labeled DOPA metabolites, i.e. those related to DA activity (DA, DOPAC, HVA) in ST and thus decreased the ratio ST/CB to 1.1 ± 0.1 (N=7). The background activities in ST and CB were correlated with the total plasma activity but were not affected by GBR-12909 (DA uptake inhibitor) or haloperidol pretreatments. GBR-12909 did not alter the DA activities. Haloperidol increased the DA turnover of both endogenous and labeled DA and decreased the total DA activity in ST by 20 % (ST/CB = 1.7 ± 0.1, N=7).

The current neurochemical results indicate that the imaging of DA neurons by radioactive labeled L-DOPA is due mainly to the intraneuronal formation and storage of newly synthesized DA. The ratio of activities in ST and CB at 90 min could be a biased but sensitive index of labeled DA activity in ST which would allow to adjust for labelled L-DOPA input. The ratio ST/CB could be improved when 6-^{18}F-L-DOPA is used for imaging of brain DA since it is less methoxylated than L-DOPA. Our and other studies show that 2-^{18}F and 5-^{18}F-L-DOPA are not good imaging tracer since they are O-methylated extensively in vivo. Therefore, it is necessary to purify the radioactive labeled L-DOPA for brain imaging procedures, i.e. PET and autoradiography. Deficit in intraneuronal DOPA-decarboxylase activity or DA storage capacity as observed in parkinsonian subjects could be quantified. Change in the turnover rate of DA neurons following acute neuroleptic challenge could be measured in vivo in neuropsychiatric patients by using radioactive labeled L-DOPA.

198.6 LOCALIZATION OF DOPAMINE UPTAKE SITES AND DOPAMINE D1 AND D2 RECEPTORS USING AXOPLASMIC TRANSPORT AUTORADIOGRAPHY.
S.J. O'Dell* and J.F. Marshall. (SPON: D. Aswad).
Dept. of Psychobiology; Univ. of California, Irvine, CA. 92717

The cellular localization of striatal dopamine (DA) receptors and high-affinity DA uptake sites as presynaptic on the afferent DA neurons or postsynaptic on striatal cells has proven to be challenging. Localization by direct methods is technically difficult and most indirect methods are based on the analysis of changes in ligand binding in the striatum seen after lesions to striatal afferents. An alternative approach is based on the transport of neural components from the soma to the nerve terminals, which can be interrupted either by knife cuts, electrocoagulations, or injections of 6-hydroxydopamine (6-OHDA) or colchicine. Such lesions have been shown to produce buildups of neurotransmitter, enzymes and receptors proximal to the injury. In this study we disrupted axonal transport to investigate the localization of D1 and D2 receptors and DA uptake sites in the nigrostriatal and striatonigral fibers.

Unilateral lesions of the ascending nigrostriatal DA neurons were produced by injection of 6-OHDA (8 ug/4 ul) in the lateral hypothalamic area at the level of the entopeduncular nucleus. Unilateral lesions of the descending striatonigral pathway were produced by electrocoagulation (25 mV, 2 mA, 100 kHz for 30 sec) in the internal capsule. DA binding sites were localized by autoradiography following in vitro binding of either [^{3}H]SCH 23390 (D1 receptors), [^{3}H]spiroperidol or [^{3}H]sulpiride (D2 receptors), or [^{3}H]mazindol (high-affinity DA uptake sites). Adjacent tissue sections were processed for acetylcholinesterase (AChE) histochemistry by a modified Karnovsky-Roots procedure. Disruption of the nigrostriatal pathway produced a buildup of [^{3}H]mazindol binding sites caudal to the lesion, in the vicinity of the ipsilateral substantia nigra. There was also a buildup of D2 binding sites and AChE near the SN which corresponded with the mazindol buildup. We found no evidence of a buildup of D1 receptors. These data suggest that at least some striatal D2 receptors, DA uptake sites, and AChE are located presynaptically on nigrostriatal dopaminergic fibers. There appear to be no striatal D1 receptors transported in these neurons.

In contrast, electrocoagulations along the striatonigral tract produced a buildup of D1 receptors near the entopeduncular nucleus, rostral to the site of the lesion. No corresponding buildup of D2 receptors, DA uptake sites, or AChE was seen. This suggests that at least some of the nigral D1 receptors are located presynaptically on striatonigral terminals.

198.7 D_1 DOPAMINE RECEPTORS IN HUMAN CHOROID PLEXUS. S.J. Boyson and L. O'Keefe*. Depts. of Neurology & Pharmacology, University of Colorado Health Sciences Center, Denver, CO 80262.

A high density (2800 ± 180 fmol/mg protein) of D_1 receptors in the choroid plexus of rat brain was noted in quantitative autoradiographic studies of rat brain (Boyson et al., J. Neurosci.6:3177-3188, 1986). Dopamine has been shown to increase, and haloperidol to decrease, choroid plexus blood flow in sheep (Townsend et al., Brain Res. 290:165-169, 1984).

Human choroid plexus was collected within 24 hours of death and stored at -70°C until use. Membranes were prepared by homogenizing tissue in buffer (50 mM Tris, 10 mM $MgSO_4$, 2 mM EDTA, 154 mM NaCl, pH 7.4) and centrifuging at 20,000g for 20 min. 3H-SCH-23390 was used to label receptors, and alpha-flupenthixol was used to define nonspecific binding in Scatchard analysis of saturation binding. The density of D_1 receptors was 470 ± 230 fmol/mg protein (n=3). The K_d was 3.0 ± 0.5 nM.

The presence of dopamine receptors in the choroid plexus and the modulation of blood flow in this region by dopamine and haloperidol suggests, by analogy with the kidney, where production of urine is proportional to blood flow, that dopaminergic agents might be useful therapeutically to modulate cerebrospinal fluid production. Disorders in which this could be useful include pseudotumor cerebri and acute elevations of intracranial pressure.

198.8 COMPARATIVE DISTRIBUTION OF DOPAMINE D-1 AND D-2 RECEPTORS IN THE CEREBRAL CORTEX OF RATS, CATS AND MONKEYS
E.K. Richfield, J.B. Penney and A.B. Young
Dept. of Neurology, University of Michigan, Ann Arbor, MI 48104

The laminar and regional distribution of dopamine D-1 and D-2 receptors were studied in adult rats, cats and monkeys. Adjacent cryostat sections were processed for D-1 and D-2 dopamine receptors and cresyl violet staining. D-1 receptors were labelled using [^{3}H]-SCH 23390 and D-2 receptors were labelled using [^{3}H]-spiroperidol in the presence of unlabelled mianserin to block 5HT-2 binding. Both ligands were used at a concentration equal to their respective receptor K_D values to allow direct comparison of receptor densities. Receptor density histograms were determined in a variety of cerebral cortical regions for all three species. Nissl stained sections were used to determine the depth of each lamina in the different regions.

The cerebral cortex of all three species contained both D-1 and D-2 receptors. The density of D-1 receptors exceeded the number of D-2 receptors in most laminae and regions. The D-1 receptor had a more heterogeneous laminar pattern than did the D-2 receptor. Both D-1 and D-2 receptors were seen in homotypic, heterotypic and mesotypic cortex.

The rat cortex displayed regional differences in the laminar pattern of the D-1 receptor, with lamina V and VI generally denser than other laminae. The D-2 receptor was more homogeneous in it's laminar pattern, with lamina I being denser than other laminae.

The cat and monkey displayed a strikingly different pattern of D-1 receptors in the cortex compared to the rat. The density was much higher in the cat and monkey than in the rat. The cat and monkey also displayed more heterogeneous laminar and regional patterns of D-1 receptors than did the rat. Generally, layers I, II, V and VI were highest. The D-2 receptor was more homogeneous. The D-1 receptor had different regional patterns of distribution that varied in a longitudinal pattern. These results have some similarities to the pattern of tyrosine hydroxylase-immunoreactive fibers seen in primate neocortex (Lewis et al., J. Neurosci. 1:279-290, 1987).

These results support the notion that the dopamine system has a more complex role in cerebral cortical function than was previously suspected based on flouresence and other histochemical techniques. The role of dopamine in cortical function may also differ among mammalian species.

198.9 AUTORADIOGRAPHIC EVIDENCE FOR THE MECHANISM OF MPTP-INDUCED TOXICITY IN THE DOPAMINE SYSTEM OF MONKEYS.
M. Herkenham, M. D. Little*, J. N.Johannessen, S. -c. Yang*, S. P.Markey*, and K. Bankiewicz*. Unit on Functional Neuroanatomy (MH, ML), Lab. Clinical Science (JJ, SM), NIMH, and Surgical Neurology Branch, NINCDS, Bethesda, MD 20892.

MPTP administered intravenously to primates produces a parkinson-like effect characterized by extreme rigidity which can be reversed by L-DOPA. Histological examination of treated brains shows selective destruction of midbrain dopamine neurons in the substantia nigra pars compacta. The mechanism of toxicity which leads to selective destruction of subpopulations of dopamine neurons is largely unknown. We addressed this question by examining the anatomical distribution of $^{14}C_6$-phenyl-MPTP or ^{14}C-methyl-MPTP (200 - 500 µCi) given intravenously to monkeys (rhesus and cynomolgus) which were either normal or had prior unilateral destruction of the dopamine system induced by a single carotid artery injection of unlabeled MPTP 1 year prior to the injection. Survival times after the injections were 1, 3, or 10 days. The animals were then anesthetized, and their brains were removed fresh, hemisected, and frozen for cryostat sectioning. Sections 25 µm thick were melted onto slides, quickly dried on a hot plate, exposed to LKB film with C-14 standards for several weeks, and subsequently fixed, defatted and Nissl-stained. The films were developed and examined for localization of radioactivity with respect to underlying cytoarchitecture. Sections not used for autoradiography were homogenized and analyzed by HPLC, which confirmed that 98% of the radioactivity was MPP+. After 1 day survival in normal monkeys, radiolabeled MPP+ was heterogeneously distributed throughout the brain, as previously described (Markey et al., *Nature*, 1984, **311:** 464). After 3 and 10 days, MPP+ was selectively and highly retained in the striatum relative to cerebral cortex, although the locus coeruleus, parabrachial area, hypothalmus and intralaminar nuclei also retained label. ***At no survival time was there significant MPP+ labeling in the substantia nigra pars compacta.*** In monkeys which had received prior unilateral destruction of the nigrostiatal pathway (as evidenced by absence of dopamine markers in the striatum on the side of the prior carotid artery MPTP injection and by examination of the Nissl-stained sections), there was no significant radioactivity in the denervated caudate and putamen, though the caudal nucleus accumbens retained label bilaterally. Since the caudate-putamen on the lesion side appeared normal in other respects, we interpret the absence of label to indicate that MPP+ in the normal striatum resides in dopamine terminals. In another set of animals, in which [^{14}C]MPTP was given at the same time as a toxic dose, there was tremendous accumulation of radioactivity in the location of the degenerating nigrostriatal pathway after 3 and 10 days survival, but again, there was no accumulation in the nigra itself. Taken together, these data suggest that MPP+ kills dopamine neurons by a process of retrograde degeneration after it has been incorporated into and poisoned dopaminergic terminals and fibers.

198.10 **AUTORADIOGRAPHIC LOCALIZATION OF ^{3}H-CYANOIMIPRAMINE BINDING SITES IN RAT BRAIN.**
G.B. Kovachich, C.E. Aronson*, J. Ryu*, G.A. Ordway*, A. Frazer and D.J. Brunswick. Veterans Administration Medical Center and Department of Psychiatry, University of Pennsylvania School of Medicine, Philadelphia, PA 19104.

Cyanoimipramine (CN-IMI) is a potent antidepressant which has been shown to bind with high affinity to sites associated with serotonin uptake. We have demonstrated that this ligand binds to slide-mounted tissue sections of rat brain with pharmacologic specificity consistent with binding to sites associated with serotonin uptake (Kovachich and Brunswick, Neurosci. Abstr. 12:1079, 1986).

We have investigated the localization of binding sites for (^{3}H)-CN-IMI in rat brain using quantitative autoradiography. Slide mounted tissue sections (20 u thick) were incubated with varying concentrations of (^{3}H)-CN-IMI (0.01 to 2.0 nM) for 24 hrs at 4° in buffer (pH 7.4) containing sodium chloride (150 mM) and Tris (50 mM). Saturation curves were performed for 3 brain regions: olfactory tubercle, frontal cortex (agranular insular cortex) and caudate putamen. Analysis of the saturation curves using the Prophet computer system indicated that binding was to a single class of high affinity sites. The Kd (nM) values were similar for the three regions (mean ± s.d.), 0.09±0.05, 0.08±0.03 and 0.12±0.01, respectively. The Bmax (fmoles/ mg protein) values were 1624±297, 835±75.4 and 483±70.0, respectively. Based on these data, a concentration of 0.5 nM (^{3}H)-CN-IMI was chosen for analysis of the distribution of its binding sites in various brain areas. Highest densities (1000 to 4000 fmole/mg protein) were found in the dorsal raphe nucleus, interpeduncular nucleus, locus coeruleus, central gray areas, paraventricular thalamic nucleus and olfactory tubercle. Moderate levels of binding (500 to 1000 fmole/mg protein) were detected in the superficial layer of the superior colliculus, suprachiasmatic nucleus, reuniens thalamic nucleus, parietal cortex area 1, and lateral hypothalamic area. Low levels (less than 500 fmole/mg protein) were found in globus pallidus, caudate putamen, ventral thalamic areas, and throughout the cerebellum. Nineteen days after bilateral intraventricular injection of a total of 200 ug 5,7-dihydroxytryptamine the binding of (^{3}H)-CN-IMI was reduced to less than 100 fmole/mg in all areas tested, except in the dorsal raphe and interpeduncular nuclei (where an approximate 65% reduction in binding occurred). This distribution of binding sites is similar to that seen previously with (^{3}H)indalpine (Savaki et al., J. Neurochem., 45:521, 1985). The results indicate that (^{3}H)-CN-IMI is a useful ligand for autoradiographic analysis of the serotonin transporter. **(Supported by research funds from the Veterans Administration and from NIMH (MH 36761).**

198.11 AUTORADIOGRAPHIC LOCALIZATON OF ^{3}H-PAROXETINE-LABELED SEROTONIN UPTAKE SITES IN RAT BRAIN.
E.B. De Souza and B.L. Kuyatt*. Neuroscience Branch, NIDA Addiction Research Center, Baltimore, MD 21224

Inactivation of brain serotonin is achieved primarily by high affinity uptake into synaptic nerve terminals. Since serotonin uptake sites are highly concentrated on serotonin-containing nerve terminals, we can directly localize and quantify the distribution of serotonergic nerve terminals in brain using autoradiographic procedures following the labeling of binding sites associated with the uptake of serotonin. Paroxetine is a potent and selective inhibitor of serotonin uptake into neurons. In the present study, serotonin uptake sites have been identified, localized and quantified in rat brain by autoradiography with ^{3}H-paroxetine. ^{3}H-Paroxetine binding in slide-mounted sections of rat forebrain was of high affinity (K_D = 10 pM) and the inhibition affinity constant (K_i) values of various drugs in competing for ^{3}H-paroxetine binding significantly correlated with their reported potencies in inhibiting synaptosomal serotonin uptake. ^{3}H-Paroxetine-labeled serotonin uptake sites were highly concentrated in the dorsal and median raphe nuclei, central gray, superficial layer of the superior colliculus, lateral septal nucleus, paraventricular nucleus of the thalamus, and the islands of Calleja. High concentrations of ^{3}H-paroxetine binding sites were found in brain stem areas containing dopamine (substantia nigra and ventral tegmental area) and norepinephrine (locus coeruleus) cell bodies. Moderate concentrations of ^{3}H-paroxetine binding sites were present in laminae I and IV of the frontal parietal cortex, primary olfactory cortex, olfactory tubercle, regions of the basal ganglia, septum, amygdala, thalamus, hypothalamus, hippocampus and some brain stem areas including the interpeduncular, trigeminal and parabrachial nuclei. Low densities of ^{3}H-paroxetine binding sites were found in other regions of the neocortex and very low to nonsignificant levels of binding were present in white matter tracts and in the cerebellum. Lesioning of serotonin neurons with 3,4-methylenedioxyamphetamine and 3,4-methylenedioxymethamphetamine caused large decreases in ^{3}H-paroxetine binding. The results of the present study demonstrating an excellent correlation between drug specificity for ^{3}H-paroxetine binding and for synaptosomal serotonin uptake, and an autoradiographic pattern of ^{3}H-paroxetine binding which is virtually identical to the reported distribution of serotonin-containing nerve terminals and cell bodies, indicate the feasibility of using this approach for mapping serotonin uptake sites and serotonin terminals in rat brain.

198.12 A COMPARISON OF THE IN VIVO DISTRIBUTION OF ^{3}H-GBR 12935 IN NAIVE RATS AND RATS WITH UNILATERAL NIGRAL LESIONS.
N. Touchet* J.M. Trugman, G.F. Wooten. Department of Neurology, University of Virginia, Charlottesville, VA 22908.

The in vivo distribution of ^{3}H-GBR 12935, a potent neuronal dopamine uptake inhibitor, was studied in naive rats (male Sprague-Dawley) and in rats with unilateral 6-hydroxydopamine lesions of substantia nigra (SN). ^{3}H-GBR 12935 (10 µCi/0.5 ml saline) was administered by tail vein injection. The animals were killed by decapitation at 5, 10, 20, 30, 60, 90, or 120 min after administration of the drug. Brains were removed and dissected over ice into 5 regions: left and right samples of sensory-motor cortex, striatum, olfactory tubercle-nucleus accumbens (OA), midbrain, and cerebellum. Tissue samples were weighed, sonicated in 0.5 ml of H_2O, and tritium content determined by liquid scintillation spectroscopy. Data were expressed as a ratio of regional tritium content (DPM/mg) to tritium content in the cerebellum of each animal (region/cerebellum ratio).

In naive animals, region to cerebellum ratios increased with time in striatum and the OA and remained the same in sensory-motor cortex and midbrain (N=3 rats for each time point). For striatum the ratio increased from 1.09±.03 at 10 min to 1.76±.48 at 90 min, and 1.75±.16 at 120 min. The OA ratios were 1.02±.11 at 10 min, 1.33±.16 at 90 min, and 1.40±.17 at 120 min; sensory-motor cortex was 1.08±.04 at 10 min, 1.09±.17 at 90 min, and 1.15±.4 at 120 min; and midbrain ratios were .74±.36 at 10 min, .98±.09 at 90 min, and 1.01±.07 at 120 min. The animals with a unilateral SN lesion showed a lower ratio in the striatum ipsilateral to the lesion. Lesioned rats (N=6) killed 120 min after administration of the drug had striatal/cerebellar ratios of 1.21±.21 ipsilateral to the lesion and 1.77±.17 contralateral to the lesion. The striatal/cerebellar ratio in the striatum ipsilateral to the lesion was different from the 120 min naive group ($p<0.01$). In the SN lesioned group, the ratio of region/cerebellum tritium content for OA, sensory-motor cortex, and midbrain did not differ from controls.

In summary, ^{3}H-GBR 12935 selectively localizes in the striatum in normal rats after in vivo administration. In rats with unilateral SN lesions there is a decrease in the striatum:cerebellum ratio of drug ipsilateral to the lesion. The tissue ratios for the OA, sensory-motor cortex, and midbrain regions in lesioned rats did not differ from controls. These results are consistent with prior studies that show ^{3}H-GBR 12935 to be a potent and selective ligand at neuronal dopamine uptake sites and suggest that ^{3}H-GBR 12935 may also be used as an in vivo marker to label the neuronal dopamine uptake system.

199.1 FRONT-END CONTROL LAWS FOR HUMAN ARM MOVEMENT. B.J. McFadyen. Dept. of Kinesiology, Univ. of Waterloo, Waterloo, Ontario, Canada, N2L 3G1.

Due to the purposeful nature of the human being, movement control must have a predominant anticipatory component which will accommodate goals and account for internal and environmental constraints. Although discussed within the motor behavioural and neurophysiological literature, most simulations of motor control do not provide details of the use of anticipation. Simulations rely, for the most part, on servo and reflexive mechanisms. Good results may be obtained from elaborate non-linear feedback models; however, more attention and detail should be given to representing control at the front end of the model where operations are performed on both system inputs and feedback information together to provide anticipation.

Simulating a second order, single actuator system, data from perturbed forearm movements were used. Feedforward configurations (transfer functions operating on system inputs) provided a base on which to introduce front-end control and further expand and speculate on general anticipatory control strategies. Different feedforward configurations produced good results (no more than 0.3 degrees deviation from desired trajectory for unperturbed movement) compensating for both system loads and environmental disturbances. It is recognized that single joint motion is not the best representation of natural human movement; however, these configurations would also account for the interaction torques in multi-limb movement.

A first approximation to an internal, predictive model allowed the combination of information from the environment, internal inputs, as well as feedback to form an anticipatory control system. The use of an internal model accommodates the interactions between the various system elements, and introduces a simulated tie between neurophysiological mechanisms and cognitive processing. Although feedback is always necessary for accurate limb movement, control at the "front end" allows for the inclusion of anticipatory strategies. Physiological significance and multi-segmental control are discussed.

199.2 EMG ACTIVITY DURING HUMAN ARM MOVEMENTS MADE AT CONSTANT VELOCITY. J.D. Cooke, Dept. of Physiology, University of Western Ontario, London, Ontario, Canada.

"Fast"movements are normally associated with phasic muscle activation whereas "slow" movements are associated with gradual or tonic EMG changes. We have had subjects perform movements which display both phasic and tonic EMG components during the movements. Subjects performed visually guided tracking movements about the elbow. The target template was a ramp position change (constant velocity) presented as a phase plane (velocity vs position).

Movements were initiated by phasic agonist/antagonist activity (AG1/ANT1). This was followed by tonic EMG activity during the constant velocity phase. Movements were terminated by phasic antagonist/agonist activity (ANT2/AG2). As movement duration was decreased, the two sets of phasic activation formed an EMG pattern typical of that seen in "fast" step tracking movements.

During the constant velocity phase EMG activity of the individual muscles was non-linearly related to mean velocity during the constant velocity phase. However, relative EMG activity (biceps - triceps) during this phase of the movement varied linearly with the mean velocity. This relation was the same for flexions and extensions and was not dependent on whether velocity was varied by changing movement duration or movement amplitude. Mean relative EMG activity during the constant velocity phase also varied linearly with the magnitude of externally applied viscous loads.

The data show that, in the same way that length-dependent muscle non-linearities are linearized in the whole limb, so too are velocity-dependent non-linearities. Although the EMG - viscous force relation may be non-linear for the individual muscles, the relations is linear when the forces produced by the opposing muscles are considered. The data also shows that acceleration and deceleration of the limb are produced by paired or linked phasic activation of agonist and antagonist muscles. The data suggests that these paired activations underly the "triphasic" pattern seen in many "fast" movements.

Supported by the Natural Sciences and Engineering Research Council of Canada.

199.3 ACQUISITION OF ARM MOVEMENT SKILL AND MOVEMENT ADAPTATION IN HUMANS WITH CEREBELLAR DYSMETRIA. J.N. Sanes, B. Dimitrov* and M. Hallett. Human Motor Control Section, Medical Neurology Branch, NINCDS-NIH, Bethesda, MD 20892.

The cerebellum has been implicated in the acquisition and retention of motor skills. It has been reported that eye movement processes of cerebellar patients adapt slower when distorting prisms are worn. There have also been numerous reports indicating that classical conditioning is disrupted by cerebellar lesions and by lesions of cerebellar input-output pathways. To further the understanding of the cerebellar role in motor learning, we examined repetitive arm movements performed under different visual conditions.

Patients (n = 8) with spino-cerebellar degeneration or diffuse cerebellar atrophy were evaluated. The patients were selected for the presence of arm dysmetria and for the absence of intention tremor. Two-dimensional arm movements were evaluated. These movements consisted primarily of elbow and shoulder joint rotations, performed by sliding a hand-held electric stylus, across the surface of a digitizing tablet. The patients made movements so as to trace a closed lined pattern with 4 or 5 vertices that was placed on the digitizing tablet. The patients were required to perform the movements as fast and as accurate as possible, to come as close as possible to each of the vertices in the pattern, and to make the movement continuous without intermediate stops. First, patients made 50 movements about a pattern with 5 vertices with normal vision. Second, patients made 50 movements about a pattern with 4 vertices under mirror-reversed vision without being able to view their hand. Elapsed movement time and movement accuracy were the primary measures for data analysis.

For the task in which movements were performed repetitively with normal vision, movement time decreased and movement accuracy improved across the series of movements. When patients performed movements with mirror-reversed vision, several abnormalities of performance were observed. Several patients had long delays in movement initiation and completion for the first several movements. For these patients, the duration of the first mirror-reversed movement could be well in excess of 30 sec, even with encouragement by the examiner. The first movement performed by normal subjects were never that long. This movement initiation and elapsed time deficit rarely persisted beyond 5-10 movements. The accumulated time to complete the movement decreased with successive movement repetition for all cerebellar patients, but continued improvements were typically not observed beyond repetitions 10-20. Indeed, it was often the case that additional repetitions beyond the first 20 movements resulted in a deterioration of performance.

These data indicate that cerebellar patients can improve performance of arm movements made under different visual conditions, but that there are limitations to visuomotor adaptation due to cerebellar dysfunction. Cerebellar patients improve upon both the elapsed time and accuracy of movements performed with normal vision. Although the total time taken by patients to complete movements made with mirror-reversed vision decreased, this improvement was not nearly as great as normal subjects. It is possible that improvement of movements requiring complex visuomotor coordination is limited by cerebellar dysfunction.

199.4 ARM MOVEMENT TRAJECTORIES AND MOVEMENT CONTROL STRATEGIES OF EXPERT AND NON-EXPERT DART THROWERS. J.L. Leavitt*, R.G. Marteniuk, and H. Carnahan*. Dept. of Kinesiology, Univ. of Waterloo, Waterloo, Ontario, Canada, N2L 3G1.

We addressed three questions concerning the three-dimensional trajectories of dart throwing. First, our previous work on Fitts' Law suggested that for aiming movements terminating on impact with the target, unique movement trajectories (resultant velocity profiles) were produced for targets of different sizes; however, for different movement amplitudes the trajectories scaled to a common profile. We wanted to see if similar results could be obtained for a throwing task where throwing distance and accuracy were manipulated. Second, we wanted to verify the claim by expert dartmen that regardless of the target size, the release of the dart always occurs at the peak vertical height of the displacement trajectory. Third, we wanted to determine the extent to which expert dart throwers are bound to the context of actual competition. We did this by contrasting dart throwing in a regulation environment with a reduced context situation (non-regulation throwing distance and a non-dart board target).

While manipulations of throwing distance and target size influenced movement outcome (landing accuracy of the darts), neither the time from the start of the forward movement to dart release nor the time from dart release to peak vertical displacment were affected. Overall, the results indicated that expert dart throwers vary the force with which the dart is released by varying the distance over which the arm travels while keeping time of contact with the dart constant. This type of strategy is consistent with a pulse-height movement generation model where a constant movement trajectory duration is maintained while trajectory slopes are varied to accomplish different impulses required by the task demands.

Other results suggested that expert dart throwers do not release the dart when they think they do. The dart is released an average of 58 ms prior to the peak vertical displacement of the hand. Finally, while there were qualitative differences between the movement trajectories of expert and non-expert performers, neither group was affected by the reduction of task context.

199.5 JOINT VELOCITY PROFILES DURING VERTICAL ARM MOTION. J. Hollerbach and D. Bennett* (SPON. C. Atkeson). Dept. Brain and Cognitive Sciences, MIT, Cambridge, MA 02139.

Previously, we have inferred from experimental arm movements that a trajectory between targets is planned at the joint level with a staggered joint interpolation stategy (*Motor Control,* ed. G.N. Gantchev et al., Plenum, 1987, pp. 197-208). Stagger is seen in many motions and appears to be invariant with the direction of movement, arguing against it being an artifact caused by gravity or dynamical interactions. The stagger is hypothesized to be set in order to achieve relatively straight-line motions without calculating inverse kinematics.

We present further evidence for this notion based on simulations and experiments, focusing particularly on the time profiles. Unlike strict joint interpolation, the specific velocity profile in staggered joint interpolation definitely affects the path. A question then arises whether one velocity profile is generally best at yielding straight-line paths. Simulation shows that a gaussian velocity profile achieves a straighter line than do other profiles such as minimum jerk in almost all of the work space.

A second question concerns the tangential velocity profile, which was previously found to be invariant across a variety of experimental conditions (*J. Neuroscience, 5*(1986): 2318-2330). Strictly speaking, this invariance is not possible under staggered joint interpolation, yet simulations show that tangential velocity profiles are generally unimodal and vary little in shape. This indicates that tangential velocity profile shape is not a good indicator of coordination strategy, lacking sensitivity.

A third question is how well the experimental joint velocity profiles agree with the prediction of shape invariance, save for a delay and scaling. The data bear out this prediction reasonably well, although the exact velocity profile shape cannot be inferred directly because of the variance in the data. Gaussian velocity profiles do qualitatively capture the tails in the data better than do minimum jerk profiles. Simulations with experimentally determined stagger and scaling produce good agreement with the data.

Although subjects make relatively direct movements between targets, they have great difficulty in producing a perfectly straight vertical line, where substantial elbow joint reversal is required. This led us to perform some visual studies which seem to indicate that our perception of straightness in the saggital plane is biased in a characteristic manner that corresponds to the curvature in the motor movements. This research is supported by NIH Grant AM26710.

199.6 VARIATION IN HUMAN POSTURAL ACTIVITY PREPARATORY TO WELL-PRACTICED RAPID ARM MOVEMENT. C.S. Layne and L.D. Abraham. Dept. of Physical Education and Institute for Neurological Sciences Research, The University of Texas, Austin, TX 78712.

Patterns of postural activity preceding rapid voluntary arm movements have been described by several investigators (e.g. Belen'kii et al., Biofizika, 12:135, 1967; Lee, J. Mtr. Beh., 12:185, 1980) consisting of a relatively stable proximal-to-distal pattern of leg muscle activation, often preceded by silent periods in postural muscles. Such data have been collected primarily using a reaction time (RT) paradigm. We examined these early postural patterns (EPP) in a similar task which required coincidence anticipation (CA) of (rather than reaction to) a visual stimulus. The results suggested that in CA tasks inter-individual variation in EPPs exceeds that reported in RT tasks.

Five normal right-handed adult males were given extensive practice in very rapid bilateral reaching to acquire a ball located at shoulder height in front. The movement was cued by a visual stimulus and was to begin coincident with a criterion (visual) stimulus, which followed the first by 1000 ms. Prior to data collection, each subject practiced reaching for 100 trials on each of three days, ultimately displaying consistent coincident movement onset. Surface EMG was used to monitor the activity of the following muscles of the right side: soleus and gastrocnemius (TS), biceps femoris (BF), and biceps brachii (BB). The subjects stood on a platform capable of producing small backward shifts. These postural perturbations, and the addition of 3 lb wrist weights, were used to probe the consistency of EPPs over a range of mechanical postural constraints.

Data were analyzed from blocks of ten trials for each experimental condition. Six different patterns of muscle onsets were identified, with each subject showing little or no variation in pattern. Only one pattern involved an initial silent period; two of the patterns contained no consistent leg muscle activity prior to BB onset. In four of the patterns the TS were the first leg muscles to become active. All but one of the subjects used the same EPP with the addition of wrist weights as without, and each subject's EPP was largely unaffected by unexpected backward perturbations during the EPP. Perturbations just prior to the EPP abolished most of the EPPs. These data suggest that the EPP patterns described previously may have been significantly affected by the temporal constraints of an RT task. Since our well-practiced CA task allowed more time to prepare for rapid movement onset, each subject was able to prepare to move in his preferred way, which was fairly resistant to mechanical task modification. (Supported in part by a BRSG grant through the University Research Institute.)

199.7 TRUNK CONTROL DURING ARM MOVEMENTS - STUDIED WITH THE VICON SYSTEM. A.M. Iannone, M. Hallett, V. Reese and S. Stanhope. Department of Neurology, Medical College of Ohio, Toledo, Ohio 43699, and NINCDS, Bethesda, Maryland 20892.

The Vicon system was used to study arm movements in the human. Our objective was to develop a standard set of movements from which we could compare the effects of neurologic disease. 7 normal subjects were studied. Movements studied were Finger-to-Nose (F-N), Reach for paper cup and lift (R), and Catch a ball (C). Subjects were seated on a backless stool, arm was placed in an identical position, from which (F-N), (R), or (C) could be done. Movements were carried out over three distances:

a. The length of the subject's arm (shoulder joint to finger tip).
b. 80% of normal arm length.
c. 120% of normal arm length.

There were two sets of commands used: the first was to make the move as accurately as possible, without regard to speed; the second to make the move as rapidly as possible without regard to accuracy.

Each different movement utilized different strategies for arm placement; for normal (F-N) the hand was put into the pointing position at the beginning of the movement and the bulk of the moving was done at shoulder and elbow joints; for short (F-N) the elbow was left in greater flexion and there was backward movement of the trunk at the same time; for long (F-N) full extension of the elbow and simultaneous forward movement of the trunk occurred during the reaching.

(R) movements required different strategies in which hand and finger placement at the necessary angles to grasp the cup placed different constraints on the subjects.

Strategies to counteract arm momentum while reaching, and to correct for the gravitational effects of the extended arm, are used in controlling the muscles of the shoulder and spine. The motor program from its beginning must contain these elements.

199.8 REVERSAL OF RECRUITMENT ORDER DURING VOLUNTARY LENGTHENING CONTRACTION OF TRICEPS SURAE MUSCLES IN MAN. M. Schieppati*, C. Romanò* and A. Nardone*. (SPON: F. Clementi). Istituto di Fisiologia Umana II, Via Mangiagalli 32, I-20133 Milano, Italy.

Recruitment and derecruitment characteristics of soleus (Sol), gastrocnemius lateralis (GL), medialis (GM), peroneus (Per) were studied by means of surface EMG recording, during voluntary movements implying muscle shortening or lengthening contractions, or during isometric contractions (ICs). The subjects had their foot fixed to a mould allowing rotation along an axis centered on the tibio-tarsal joint and performed the following tasks under visual control of position or force signal: plantar flexions (PFs) against a constant load, dorsal flexions (DFs) starting from a maintained foot flexion and yielding to the load by muscle relaxation, augmenting or decreasing plantar torques (ICs). The tasks were performed at various angular velocities or rates of force change. In all the tasks, the tibialis anterior was silent.

In all the subjects the muscles gradually increased or decreased their activity roughly in parallel, during ICs and PFs. During DFs, gradual derecruitment was present in Per; the behavior of the triceps muscles, instead, varied between two extremes. 1) Sol activity decreased prior to onset of movement, GL (or GM, depending on subject or knee angle) activity increased to well above the level of the tonic contraction and remained high through out DF. Amplitude and rate of rise of GL EMG were larger, and Sol derecruitment more rapid, the higher the velocity of DF. GL EMGs of similar extent were reached only during ballistic PF. 2) Sol EMG decreased prior to DF onset, but displayed during DF bursts of large amplitude, superimposed on low-level background activity. GL EMG showed only minor increases during DF. In the various subjects the extent of GL recruitment during DF was positively correlated with the duration of the Sol twitch relaxation. Irrespective of the activation patterns of Sol and GL, the excitability of their motoneurones tested by the H reflex was depressed to a similar extent during DFs. This gives further evidence that the increases in GL or Sol EMG are sustained by fast motor units, since H reflex amplitude depends mainly on activation of slow motor units.

We suggest that substitution of GL for Sol, or of fast for slow motor units within Sol, allows better force gradation during DF lengthening contraction, owing to shorter duration of relaxation times in fast muscles or motor units.

199.9 CHARACTERISTICS OF SYNERGIC RELATIONSHIPS IN HUMAN ELBOW JOINT MUSCLES DURING STATIC THREE DEGREE-OF-FREEDOM JOINT TORQUES. T.S. Buchanan* and W.Z. Rymer (SPON: W.T. Rainey). Sensory Motor Performance Program, Rehabilitation Institute of Chicago, and Physiology Department, Northwestern University Medical School, Chicago, IL 60611.

Previous studies on the synergic relationships of human elbow joint muscles during flexion/extension (f/e) and varus/valgus (vr/vl) isometric tasks have demonstrated that (1) patterns of muscle activity are independent of joint torque magnitude and (2) intermuscular relationships can vary as a function of load direction, even among "synergists" (Buchanan et al., *J. Neurophys.* 5:1225-1241, 1986). The current study uses myoelectrical information to study the central command involved in muscle coordination and joint stabilization during supination/pronation (s/p) torques and to study the effects that such torques have on f/e and vr/vl tasks.

The myoelectrical activities in the biceps brachii, brachioradialis, brachialis, and triceps brachii have been simultaneously recorded with both surface and bipolar, fine-wire intramuscular electrodes. These recordings were made while the subject was in a fixed position with the elbow at 90° flexion, the shoulder at 0° flexion, and the wrist at a mid-supinated position. The subject was instructed to match a visually-displayed, three degree-of-freedom force target by isometrically contracting against a 3-d.o.f. load cell apparatus fixed to the wrist via a short forearm cast. The displayed targets scanned a ranged from 10% to 30% of maximum vr/vl torque. The amplified, bandpass-filtered EMGs were digitally recorded together with the three torques: f/e, vr/vl, and s/p. The data was later reduced off-line to determine the average rectified EMG for all trials under each load condition.

The EMGs were analyzed separately for each of 5 s/p torques. From these data sets, patterns of activity were obatined that could be described in terms of f/e and vr/vl torques. These patterns showed distinct relationships that were simply scaled up and down with f/e and vr/vl torque magnitude. Most significantly, the shapes of these patterns were found to be independent of s/p loads. That is, supination and pronation forces did not influence the relative EMG activity observed between f/e and vr/vl torques. The magnitude of the EMGs were relatively constant for different s/p torques for some muscles (e.g. brachialis), but were observed to scale with supination and pronation in others (e.g. biceps brachii).

These patterns of activity imply that flexion/extension and varus/valgus elbow torques are controlled independent of supination/pronation torques. This type of control scheme — treating these loads as two independent variables — could be advantageous from a neural control perspective. For example, separate interneuronal pools could be responsible for supination/pronation torques while flexion/extension and varus/valgus torques would be much more closely coupled.

199.10 ASYNCHRONOUS INITIATION OF COORDINATED ROTATIONS ABOUT THE SHOULDER AND ELBOW. Z. Hasan and G. M. Karst. Department of Physiology, University of Arizona, Tucson, AZ 85724.

In the study of target-directed limb movements involving rotations about several joints it is often assumed that the nervous system prescribes the trajectory of the distal point along an approximately straight-line path, and subsequently computes the joint torques necessary to obtain that trajectory. From a computer simulation of this strategy we were struck by the precision needed, even for the initial torques, in order to aim the initial acceleration toward the target. We explored experimentally the possibility that a less stringent strategy may be employed for the initiation of movement.

During arm movements to different targets in the horizontal plane the shoulder and elbow angles were monitored by means of potentiometers. We recorded the EMG activity of the clavicular portion of pectoralis major and of the posterior deltoid (horizontal shoulder adductor and abductor muscles, respectively) in addition to that of the biceps and triceps brachii.

Our main experimental finding was that the rotations about the shoulder and elbow joints were not, in general, initiated simultaneously. The order of shoulder and elbow rotations depended in a consistent manner upon the placement of the target. Simultaneity was seen when the two rotations were comparable in magnitude, and especially when the two were in opposite directions (e.g., shoulder adduction and elbow extension), confirming earlier reports. But when, for instance, the target was so placed that the shoulder adducted by 26 deg and the elbow flexed by 7 deg, the initiation of elbow rotation occurred approximately 80 ms after the initiation of shoulder rotation. A similar delay was seen when a comparably small elbow rotation occurred in the extension direction. In either case, elbow flexor activity was seen during the delay interval, presumably to prevent elbow extension that would have arisen from inertial effects of the moving upper arm.

Conversely, when the target position required a large elbow rotation but small shoulder rotation, the former was initiated earlier than the latter. During the delay interval, which could exceed 100 ms, activity of the appropriate shoulder muscle prevented rotation about the shoulder despite the inertial coupling with the forearm. (The order of muscular activation was always proximal to distal, even when elbow rotation preceded shoulder rotation.) Staggering of the rotations according to magnitude may be a simplifying aspect of the strategy for movement initiation.

199.11 INVARIANT CHARACTERISTICS AND INVOLUNTARY RESPONSES. G.L.Gottlieb, A.S.Tanavde* and G.C. Agarwal,Department of Physiology, Rush Medical College, Chicago, IL 60612.

We have previously reported plastic behavior of human elbow compliance when subjected to sudden torque perturbations[1,2]. Recent questions have been raised [3] concerning the possible contamination of our results by involuntary responses of the subjects, particularly when subjected to loading, as compared to unloading perturbations. This report summarizes our findings using three methods to characterize the compliant response of the elbow and two sets of instructions to the subjects.

Step torque perturbations were applied to the elbows of normal human subjects who were instructed either a) do not react to the perturbation or b) resist the perturbation as rapidly as you can. Compliance was measured either as *i.* the ratio of elbow displacement to perturbing torque when the elbow reached a stable equilibrium, *ii.* the same ratio measured at the peak velocity of the displacement and *iii.* the elastic component of a linear, second order differential equation, fit to the first 100 ms of the perturbation trajectory.

When the subject does not react, qualitatively similar results are found with all three methods. Those are that for both loading and unloading perturbations, the effective stiffness of the joint is greatest for the smallest perturbations. When the subject resist the perturbation however, the first method gives radically different results while the other two methods are unaffected.

We conclude that the S-shaped compliance curve we have previously reported is significant for both loading and unloading. Furthermore, if measurements can be made within about 100 ms of the perturbation's onset, the results are unaffected by reactions by the subject.

SUPPORTED IN PART BY NIH GRANT AR-33189. [1] Gottlieb,G.L. and Agarwal,G.C, Soc. Neurosci. Abst. 9:632, 1983, [2] Gottlieb, G.L. and Agarwal,G.C., J.Neurophysiol (in press), [3] Berkinblit, M.B, Feldman, A.G. and Fukson, O.I. Beh.&Brain Sci.9, 1986

199.12 PERCENT OF MAXIMAL VOLUNTARY ISOMETRIC CONTRACTION (MVIC) ON QUADRICEPS FEMORIS MUSCLE (QF) INDUCED BY NEUROMUSCULAR ELECTRICA STIMULATION (NMES) OR TRANSCUTANEOUS ELECTRICAL STIMULATION (TENS). L.E. Tremblay*, D. Dufour*, Y. Lessard* and V. Poulin (SPON: A.Y. Bélanger). Physical Therapy Dept., Fac. of Medicine, Laval University, Québec, Canada, G1K 7P4

Neuromuscular electrical stimulation and transcutaneous electrical nerve stimulation are known to strengthen and reduce nociceptive perception, respectively. Both of these in adjunct to a management rehabilitation program have been proved very useful. Since these modalities (NMES) and (TENS) aim different goals, two kinds of apparatus were proposed for each treatment strategies. This projet was designed to compare the capacity of each apparatus to induce a torque in the (QF). Seventeen healthy male volunteers ($\bar{X}$ = 23.1 ± 4 years old) were involved in this study. All subjects were tested in standardized protocol for dynamic knee extension with cybex II+ at 30° sec in order to determine the angle at which the QF's peak torque is observed on the isokinetic curve. Thereafter each MVIC and the torque of the evoked contraction was measured at this angle. Two commercial stimulators (medtronic$_r$), respond II (NMES) and selectra (TENS) were used with quite similar electrical parameters (waveform, skin impedance, pulse duration, rate (50 HZ), electrode width). Two experimental strategies were used for each stimulator; bipolar method (surface electrode over the QF muscle) and monopolar (cathode just over the femoral nerve). The following parameters were measured; % of MVIC, maximal intensity tolerated (I, in mA), confortability (visual analog scale) (V.A.S.).

	Bipolar Method			Monopolar Method		
	% MVIC	I	V.A.S.	% MVIC	I	V.A.S.
NMES:	41.2±12.4	99.7±1.2	7.1±2.3	67.1±16.3	83.1±12.3	9.1± .9
TENS:	6.5± 9.8	100	4.7±2.3	81.3±15.4	94.2± 9.1	7.4±1.2

The selectra was found more comfortable ($P < 0.01$) and more effecient ($P < 0.01$) in the monopolar fashion to produce a QF torque. The TENS was probably more successful because of its antinociceptive properties. Strangely the NMES stimulator (designed to increase muscular strength) was less effective in evoking a large torque in the QF.

199.13 DIFFERENCES BETWEEN MONKEY TIBIALIS ANTERIOR AND GASTROCNEMIUS EMG BEHAVIOR DURING PERFORMANCE OF COMPARABLE TASKS-S. A. Sahrmann, M. H. Clare, E. B. Montgomery, and Wm. M. Landau, Department of Neurology, Washington University School of Medicine, St. Louis, Missouri 63110

Limb postures associated with central nervous system lesions suggest qualitative differences in motor control of flexor versus extensor motoneurons. This report provides quantitative information regarding the differences between tibialis anterior (TA), and gastrocnemius (G) during performance of a conditioned controlled task.

A macaque nemestrina was trained to perform two mirror image isometric ankle tasks triggered and guided by light signals. One from rest (0 force) to large plantarflexion (LP, 650 gms), hold for a random period (0.5 - 1.5 sec), rapidly reverse into large dorsiflexion (LDr, 450 gms) and return to rest and the other the mirror image task (LD with LPr). Surface electrodes were used to record TA and G emg. Force and rectified and integrated emg were converted to digital signals and recorded on-line by a VAX 11 computer. Trial by trial and averaged records were reconstructed by the computer and used for data analysis.

Averages of 12 repetitions from 20 recordings over a 5 month period were used for data analysis. The onset and offset of the TA was slower than the G. The time to peak for the TA for LD was 323 msec while that for the G during LP was 42 msec. The emg duration of the TA for LDr was 326 msec while that of the G for LPr was 132 msec. The reciprocal relationships of these antagonist muscles also differed. G emg had ceased for 40 msec before onset of TA emg for LDr. TA emg was still subsiding during the onset of G activity for LPr and after a brief period of inhibition had an afterdischarge which occurred during the return to dorsiflexion. No afterdischarge was present in the G during the mirror image task LPr. Force behavior followed the EMG for all but the sustained hold. TA emg was maintained at 87% of peak during the last 500 msec of the hold, while the G dropped to only 65% of peak even though the force was maintained at a constant level.

Analysis of fiber types in a non-exercised monkey indicated that the distribution of type I was 16% in the TA and 27% in the G, while type II was 84% in the TA and 73% in the G. The differences of movement behavior cannot be attributed to muscle fiber types.

These results indicate that even though the animal performed comparable tasks in dorsal and plantar flexion with similar time and force requirements, there were different central control patterns of reciprocal contraction and timing.

199.14 THE EFFECTS OF INSTRUCTIONS ON THE SPEED AND ACCURACY OF VISUALLY GUIDED LIMB MOVEMENTS. J.D. Fisk and M.A. Goodale, Camp Hill Hospital, Halifax and University of Western Ontario, London, Canada.

Visually directed movements of the eyes and limbs are coordinated to provide the maximal amount of information for the accurate completion of the movement. Many studies have examined the environmental determinants of movement speed and accuracy but in the present study the environmental conditions remained constant, while the demands for speed and accuracy varied according to the subject's instructions. Thus it was the volitional set of the subject that determined the changes in their response characteristics.

Sixteen subjects participated in the study. Each subject was seated, with his head supported in a head rest, facing a black screen at 50 cm viewing distance. The targets were 4 LEDs at 10° and 20° to the left and right of a central point. The subject's eye position was monitored by infrared reflection while the position of the limb in 3-dimensional space was determined by a computer-assisted analysis of the images provided by 2 rotary-shutter video cameras. All subjects performed 3 blocks of trials in which each target was illuminated 8 times in a random sequence. The speed and accuracy demands of the blocks of trials were varied by asking the subject to point to the target "as quickly as you can" (Speed condition); "as accurately as you can" (Accuracy condition); or both "quickly and accurately" (Speed/Accuracy condition). The order of the blocks was randomized across subjects. The eye and hand latency were analysed as were numerous kinematic measure of the limb movement and the accuracy of the finger position.

The Speed/Accuracy condition was considered as the baseline condition since speed and accuracy were equally emphasized in the instructions. Eye movement latency was reduced by increasing either the speed or accuracy demands of the task while hand movement latency was reduced only in the Speed condition. The increased discrepancy between eye and hand movement latency in the Accuracy condition would have allowed the eyes to attain the target position before the arm movements were initiated. Kinematic measures indicated no difference in the acceleration phase of the movement for the Accuracy or Speed/Accuracy conditions. In the Speed condition however, the subjects reached a higher maximal velocity. The deceleration phase of the movement differed systematically according to the instructions. Deceleration was most rapid in the Speed condition and was slowest in the Accuracy condition, providing more opportunity for visually based modifications of the movement trajectory. Constant and variable error were largest in the Speed condition. The results indicate the subtle, changes in the programming and execution of visually guided movements can occur if instructions alter the volitional set of the subject.

199.15 PATTERNS OF AGONIST MUSCLE ACTIVITY IN MONKEYS TRAINED TO PERFORM WRIST MOVEMENTS IN DIFFERENT DIRECTIONS. D.S. Hoffman and P.L. Strick. V.A. Med. Ctr. and Depts. of Neurosurg. and Physiol., SUNY-HSC at Syracuse, Syracuse, NY 13210.

We have examined the patterns of muscle activity in monkeys trained to perform step-tracking movements of the wrist joint. The movements required eight different combinations of radial-ulnar deviation and flexion-extension and differed from one another by 45 deg. Pairs of fine wire electrodes were inserted percutaneously into 10 different finger and wrist muscles. Each wire was stimulated to determine the direction of wrist movement evoked by muscle contraction. Stimulation also confirmed that both electrode wires were placed in the same head of each muscle.

Each forearm muscle examined produced a prominent **agonist** burst of muscle activity for more than one direction of movement. The agonist burst began in all forearm muscles at approximately the same time and preceded movement onset by approximately 50 msec. No clear differences were observed between wrist and finger muscles either in the timing or pattern of agonist bursts during movement. Four muscles had substantial agonist bursts for 4 or more directions of movement. The activity in these muscles was considered to be "broadly tuned" for movement direction. Three muscles had substantial agonist bursts for only 2 directions of movement. The activity in these muscles was considered to be "narrowly tuned." The tuning in the remaining 3 muscles was intermediate; these muscles had substantial agonist bursts for 3 directions of movement.

A **best agonist direction**, i.e., the direction of movement for which the agonist burst was greatest, was determined for each muscle. The amplitude of agonist bursts was reduced for directions of movement which differed from the best agonist direction. The reduction in amplitude, however, could be as little as 18% for movements which differed from the best agonist direction by as much as 75 deg. There was a close correspondence between the best agonist direction and the direction of movement evoked by electrical stimulation for 4 wrist muscles. However, in 3 wrist muscles, the best agonist direction differed from the direction of movement evoked by electrical stimulation of the muscle by as much as 60 deg.

Our observations indicate that each direction of wrist movement was produced by adjusting the amplitude of agonist bursts in more than one muscle. In fact, most directions of movement (n=6) were produced by agonist bursts in 4-5 muscles. These results do not support the concept that the direction of wrist movement is determined by a limited number of muscle synergies.

199.16 GOAL-DIRECTED POINTING MOVEMENTS FOLLOWING CHEMICAL MICROLESIONS WITHIN THE POSTERIOR PARIETAL CORTEX OF TRAINED MONKEYS. O. Bock*, R. Eckmiller, and R. Andersen (SPON: W.J. Daunicht) Division of Biocybernetics, University of Düsseldorf, FRG.

Two monkeys (Macaca fascicularis) had been trained to point at visual targets, presented on a cylindrical screen 15 cm in front of their eyes. The pointing arm grasped a manipulandum which restricted hand movement to a horizontal arc just underneath the target display. Manipulandum position was visible to the animal via an LED.

Following baseline data acquisition, chemical microlesions (injections of 3x1 µl 15% Ibotenic acid) were administered to the left parietal cortex. Subsequent histology verified lesion sites at the border between Areas 7a and 7b.

Results

1. Several hours after the lesion deficits gradually developed and persisted throughout the examination period of more than one week.
2. Some deficits were side-specific relative to the lesion, whereas others depended on the movement direction (ipsilateral, i.e. right arm to the right and left arm to the left, versus contralateral) of either arm in the entire pointing space.
3. Dynamic overshoot in the movement trajectories increased markedly in incidence and size for ipsilaterally directed pointing movements within the entire pointing space. In contrast, the overshoots for contralaterally directed movements were considerably smaller.
4. Latency increased markedly for contralaterally but not for ipsilaterally directed pointing movements within the entire pointing space.
5. Dynamic overshoot and latency were not correlated on a trial-to-trial or a day-to-day basis.
6. When visual feedback on manipulandum position was turned off, static pointing accuracy was significantly reduced only in the right hemispace (i.e. contralateral to the lesion), independent of the pointing arm.

Conclusions

A. Dynamic overshoot and latency deficits strongly suggest an involvement of the posterior parietal cortex in two independent and direction-selective mechanisms of pointing movement control.
B. An additional hemispace-specific mechanism is indicated by the accuracy deficit in the absence of visual feedback.

199.17 BLOCKING THE ANTAGONIST NERVE REDUCES THE AMPLITUDE OF THE SHORT-LATENCY STRETCH REFLEX RESPONSE IN TRICEPS SURAE MUSCLES OF CATS. T. Sinkjaer* and J.A. Hoffer. Dept. of Clinical Neurosciences, Univ. of Calgary, Alberta T2N 4N1, Canada.

The objective of this study was to quantify the contribution from afferents in antagonist muscles to the short-latency reflex response measured in ankle extensors of freely standing cats.

Cats were trained to stand unaided on four pedestals and produce a desired force with the left hindlimb (J Neurosci Meth, in press). Once trained, they were chronically implanted with EMG, force, length and temperature transducers and nerve recording, stimulating and blocking cuffs in the left hindlimb (Soc Neurosci Abstr 9:470, 1983 and 10:330, 1984). Conduction in the common peroneal (CP) nerve was reversibly blocked by infusing 2% lidocaine into a CP nerve cuff. The completeness of the block was demonstrated by the disappearance of the compound action potential recorded by a sciatic nerve cuff when the CP nerve was stimulated distal to the block. Reflex responses in freely standing cats were elicited by displacing the left rear pedestal randomly up- or downward with a servo-controlled motor as the cat was maintaining a given force.

The peak amplitude and area of the short-latency EMG burst (8-12 ms after stretch onset) were measured in the soleus (S) and lateral gastrocnemius (LG) muscles. Results obtained before and after CP nerve block were compared for matched values of background muscle force, length and temperature. The experiment was repeated after decerebration. Results are shown in the table with arbitrary units:

	Normal				Decerebrated			
	S EMG		LG EMG		S EMG		LG EMG	
	Peak	Area	Peak	Area	Peak	Area	Peak	Area
before CP block	1.56	1.00	2.50	1.37	4.24	2.01	12.60	7.08
after CP block	1.14	0.74	1.48	0.90	2.54	1.44	5.24	3.00
percent change	-27	-26	-41	-34	-40	-28	-58	-58

In the normal cat, the background triceps force and soleus muscle length were 25 N and 7.8 cm before block and 27 N and 7.8 cm after block. After decerebration the values were 49 N and 8.3 cm before block and 47 N and 7.9 cm after block.

The reduced short-latency reflex in stretched ankle extensors after blocking the CP nerve demonstrates that ankle flexor afferent input can have powerful influence on short-latency autogenic and heterogenic reflexes to ankle extensor muscles in freely standing normal as well as decerebrated cats. This observation is consistent with the "antagonogenic" reflex action described by Nichols (Soc Neurosci Abstr 11:213, 1985) for decerebrated cats.

199.18 EFFECT OF ANTAGONIST MUSCLE VIBRATION ON POSITION SENSE DURING VOLUNTARY MOVEMENTS. J.T. Inglis* and J.S. Frank (SPON: E. Cafarelli). Dept. of Anatomy, Queen's University, Kingston, Ontario and Dept. of Kinesiology, University of Waterloo, Waterloo, Ontario, Canada, N2L 3G1.

During voluntary movement, muscle spindles of both the agonist and antagonist muscles potentially can supply information about position of the limb. The following 3 experiments attempted to examine these contributions by separately vibrating over the triceps and biceps muscles during forearm positioning. Muscle vibration is known to increase muscle spindle discharge (Burke et al., J. Physiol., 261:673, 1976) and cause systematic distortions of limb position sense in humans (Goodwin et al., Brain, 95:705, 1972). In the first experiment, subjects (n=8) performed a horizontal flexion of the right arm to a mechanical stop randomly positioned at 20, 40 or 60°. Vision was occluded and vibration was applied to the right arm. The perceived position of the right limb was assessed by instructing subjects to simultaneously match the right arm position with the left limb. Vibration of the biceps muscle had no effect on limb matching accuracy. However, triceps vibration resulted in a significant overestimation of the vibrated limb position by 6-13° ($p < .01$). The procedures for the second experiment were similar to the first, except that movements of the right limb were self-terminated. A screen was mounted over the arms and subjects were instructed to move the right arm until it was positioned beneath a marker on the screen. Vibration of the biceps muscle had no effect on either the positioning accuracy of the right limb or matching accuracy of the left limb. However, triceps vibration resulted in significantly shorter movements (6-10°, $p < .05$) by the right limb and an overestimation of right limb position by the left, matching limb. In a final experiment vibration was applied to the stationary left arm, while subjects attempted to position the right arm beneath a marker on the screen covering the arms. Positioning accuracy of the right arm was not effected by this vibration, suggesting that the mismatch between left and right limb performance reported in experiments 1 and 2 is due to a perceptual and not a motor bias. These findings further support the hypothesis that muscle spindle afferent information from the lengthening antagonist muscle contribute to limb position sense during voluntary movement (Capaday and Cook, Exp. Brain Res., 42:228, 1981).

199.19 KINEMATICS OF BODY MOVEMENTS ASSOCIATED WITH POSTURAL ADJUSTMENTS. M.W. Woollacott, C. von Hofsten* and B. Roseblad*. (SPON: Peter M. O'Day). Psychology Dept., University of Umea, Umea, Sweden.

Studies examining the participation of both leg and upper body muscles in postural control have shown that, in response to support surface translations in the anterior or posterior direction, responses are activated first in the ankle muscles at about 90 ms and radiate upward to the upper leg and trunk muscles. In addition to these responses, there are very early responses in the neck muscles on the opposite aspect to the body, activated at latencies close to those seen in the stretched ankle muscles. These responses could be activated by stimulation of the vestibular system, or neck proprioceptive system, if head movements were induced very early with respect to platform movement onset. Alternatively, if head movements occurred later in time, the ankle proprioceptive inputs themselves could be hypothesized to trigger the neck muscle responses as part of a preprogrammed synergy encompassing agonist and antagonist muscles of the entire body.

This study examined the movements of the individual body segments of a group of 10 standing adults during anterior and posterior platform displacements and compared body movements to neck and ankle muscle response onset times. A Selspot optoelectronic system was used to measure the displacement of the ankle, knee, hip, hand, shoulder and head. Though anterior/posterior neck and head displacements were late (145 and 197 ms respectively for 3 cm posterior platform movements), in comparison to neck flexor muscle response onset (121 ms average), vertical movements of the shoulder and head occurred early (40 and 67 ms after platform movement onset). This head movement could activate neck proprioceptors and/or the vestibular system to cause neck muscle responses.

In order to determine if neck proprioceptors were primarily responsible for response activation, we repeated the experiment using a neck stabilization device, on one of our subjects. In this condition, with minimal neck muscle stretch but normal vestibular and ankle joint somatosensory inputs, we found normal neck muscle response latencies. This supports the hypothesis that the ankle joint somatosensory and/or vestibular systems are the primary contributors to the early neck muscle responses seen during horizontal support surface displacements.

199.20 THE EFFECT OF VISUAL FIELD, EXTRACORPOREAL SPACE AND LIMB ON LOCALIZATION OF VISUAL TARGETS. B. Sivak, C.L. MacKenzie, Dept. of Kinesiology, University of Waterloo, Waterloo, Ontario, N2L 3G1 and D. Elliott*, School of Physical Education, McMaster University, Hamilton, Ontario, L8S 4L8.

The precision with which subjects can localize a target in space can be influenced by a number of factors. Assessment of the spatial relationship between limb, body and extracorporeal space in relation to the target are important in the generation and execution of appropriate movement commands. This study represents an effort to examine the relationship among visual space, responding limb and body space on the spatial control of pointing accuracy.

A specially designed contact lens system was used to isolate specific visual fields (Sivak, Sivak and MacKenzie, 1985). The left visual field of the left eye and the right visual field of the right eye were used in this study. Because testing was monocular, visual information was thus lateralized to either the left or the right hemisphere. Monocular no lens control conditions were included. Eight right-handed subjects made slow positioning movements with either the left or the right arm (without vision of the arm) to target lights located on a planar surface to the left,right or in front of the body midline. The target lights remained on for the duration of the trial. Using an X-Y digitizer, the subject's produced position was compared to the X-Y coordinates of the target light on each trial. Directional, amplitude and radial error measures were computed.

Results revealed a tendency to overshoot the targets in all conditions as determined by amplitude error. Subjects had smaller directional error when vision was restricted to the left visual field of the left eye than when vision was restricted to the right visual field of the right eye. Localization of the target was more accurate with the right than the left hand; localization with the left hand showed a rightward bias in directional error. Surprisingly, the lens conditions were no less accurate than the monocular control conditions on any error measure even though the lens conditions eliminated a whole visual field as well as much of foveal vision. It appears that for this type of slow positioning movement in which vision of the limb is not available, peripheral vision provides adequate information for localization of visual targets.

200.1 CALCIUM SPIKE DURATION: PROLONGATION IN HIPPOCAMPAL NEURONS OF AGED RATS. P.W. Landfield and T.A. Pitler, Dept. of Physiol. Pharmacol. Bowman Gray Sch. Med., Winston-Salem, NC 27103.

There is increasing evidence that altered Ca homeostasis is a concomitant of neuronal aging. However, it is uncertain whether initial changes in Ca function depend on altered Ca buffering, extrusion, effectiveness, or influx, and whether these changes result in a net increase or decrease in internal Ca (cf. reviews in Khachaturian, 1984, Handbook of Studies on Psychiatry and Old Age, Elsevier; and Gibson and Peterson, 1987, Neurobiol. Aging).

Several studies from this laboratory have indicated that high Mg can counteract some of the effects of aging on hippocampal neurophysiology and behavior and, therefore, that some of the aging changes may be due to an increased action of Ca (e.g., Landfield, 1981, Soc. Neurosci. Abstr., Landfield and Morgan, 1984; Brain Res.; Landfield et al, 1986; J. Neurophysiol.). In addition, we have found that Ca-dependent, K-mediated afterhyperpolarizations (AHPs) are prolonged in brain cells of aged rats (Landfield and Pitler, 1984, Science).

To determine whether this apparent age-related increase in Ca-dependent actions results from reduced buffering/extrusion, increased effectiveness of Ca, or increased Ca influx, we studied Ca-mediated potentials in CA1 neurons from hippocampal slice preparations. Neurons were impaled with CsCl-filled micropipettes, to block Ca-dependent K conductance, and were then treated with tetrodotoxin, to block active Na conductance. Only cells in which the AHP's were fully blocked, and in which input resistance was greater than 30 MΩ were used in these analyses.

Under these conditions, Ca spikes could be elicited readily by intracellular depolarizing constant current pulses (70 ms). Spikes were generated with pulses at 150% of spike threshold, and the duration of the spike (from peak of the fast component to the return to baseline) was measured.

Cells from aged rat slices exhibited significantly prolonged Ca spikes (mean $\pm$ SE (ms) = 276.2 $\pm$ 19.2) in comparison to cells from young rat slices (mean $\pm$ SE (ms) = 216.7 $\pm$ 11.6).

These results suggest that an increased Ca current occurs in hippocampal neurons during aging and raise the possibility that increased membrane Ca conductance plays an important role in age-related alterations of Ca homeostasis. Although a number of factors could be responsible for the prolongation, apparent Ca-mediated inactivation of Ca conductance is found in hippocampal cells (Pitler and Landfield, 1987, Brain Res.). Therefore, age changes in the Ca inactivation process could be a factor in prolonged Ca conductance. (Supported by AG-04542 and AG-04207).

200.2 SYNAPTIC CHANGES IN THE DENTATE MOLECULAR LAYER OF AGED RATS. E. Fifkova and K. Cullen-Dockstader*. Dept. of Psychology, Univ. of Colorado, Boulder, CO 80309.

Previously we have shown that there is a significant age-related increase of cytoplasmic Ca^{2+} in dendritic spines with age (Fifkova and Cullen-Dockstader, Brain Res., 376:351, 1986) and a significant decrease in the density of synaptic vesicles at the active zone of axon terminals (Fifkova and Cullen-Dockstader, Neurosci. Abstr., 11:894, 1986). Both changes were observed in the dentate molecular layer (DML), and they suggest that synaptic transmission may be impaired. In order to find out whether other synaptic parameters also suffer with age, we have undertaken the recent studies in the DML and in the stratum oriens (SO) of CA_1, in male rats (Fischer 344) ages 3, 9, 24 and 30 months (5 animals per age group). Since in both layers the majority of synaptic contacts are on dendritic spines, the parameters examined were: cross-sectional area and perimeter of spines and axon terminals, length and width of the spine stalk, length of synaptic apposition and synaptic density. In the SO no morphometric changes were detected as a function of age. In the DML the results were computed separately in three zones which are determined by individual inputs to this layer. The perimeter and cross sectional area of spines and the length of synaptic apposition were increased across ages and thirds, with the differences significant in the proximal third of the DML. The dimensions of axon terminals were stable in the proximal and middle thirds, however, in the distal third they were significantly larger. Measurements of the width and length of the spine stalks were taken when the entire stalk profile was in the plane of section. In random sections, only 5% of the spine population meets this criterion, therefore, the measures were pooled for the entire DML A significant increase of the stalk width was observed by month 24. Since it is the spine stalk which determines the strength of synaptic transmission in an axospinous synapse, this change may have important implications regarding neuronal plasticity in senescent animals. The previously observed age-related increase of cytoplasmic Ca^{2+} in spines suggests a decrease of Ca^{2+} signaling function. This function requires a large Ca^{2+} concentration gradient which, given the high extracellular Ca^{2+}, can be achieved only if the intracellular Ca^{2+} is very low. Therefore, a persistently high intraspinous Ca^{2+} in aged rats may impair synaptic transmission. The decreased density of synaptic vesicles at the active zone in aged rats will contribute to this impairment. The observed age-related enlargement of synaptic parameters, which in young animals would be associated with increased synaptic transmission, may in old animals compensate for the observed defects at the pre- and postsynaptic site. The enlargement of the spine stalk is of particular interest, since this change is induced in young animals by increased synaptic activity and is thought to be involved in the mechanism of synaptic plasticity in the DML. Permanently enlarged spine stalks may have no more capacity for further changes, which may explain an age-related decline in the plasticity of the system. Supported by NIA grant AG04806.

200.3 THE EFFECTS OF AGING ON BASAL LAMINA AND NEUROVASCULAR APPOSITIONS IN THE RAT DENTATE FASCIA. A. Topple, E. Fifkova and K. Cullen-Dockstader*. Dept. of Psychology, Univ. of Colorado, Boulder, CO 80309.

Aging cerebral blood vessels in humans, primates and rats show a number of morphological alterations, including increased thickness of the basal lamina (Hicks et al., Neurosci. Abstr., 7, 183, 1981), reduced capillary wall thickness and numbers of endothelial mitochondria per capillary (Burns et al., J. Gerontol., 34, 642, 1979), and an increased capillary lumen (Hunziker et al., J. Gerontol., 34, 345, 1979). The present study reports similar basal lamina findings in the rat dentate fascia and extends the analysis to include an examination of the effects of aging on neurovascular appositions.

Fifteen male Fischer 344 rats 3-, 9-, 24- and 30-months old were perfused via the descending aorta with 3% glutaraldehyde and prepared for electron microscopy. The tissue was stained with 5% uranyl acetate followed by four component or Reynold's lead stain. All measurements were made from micrographs enlarged to 70,200 X. Increasing age is associated with progressively increasing total thickness of the basal lamina compared to the 3 month animals: a 22% increase at 9 months, a 44% increase at 24 months ($p < 0.05$), and a 69.8% increase at 30 months ($p < 0.01$). The number of individual layers of basal lamina did not change with age.

Aging is not associated with a significant change in the number of neuronal appositions per vessel. The number of axon terminals, of small axons, of myelinated axons and dendrites were analyzed. There was a noticeable trend towards reduced numbers with age for the terminals, dendrites and small axons which however did not reach significance levels. These neural processes rarely contact the vessel basal lamina directly. Rather, they are usually separated from it by a narrow space containing a thin glial process and what appears to be extracellular space. The width of this space, which does not change with age, is 26 nm. No presynaptic densities, characteristic of synaptic contacts, were observed. Further, no postsynaptic densities similar to those observed at the neuromuscular junction were seen. These results replicate earlier findings on age-related changes in vascular basal lamina in the hippocampus and extend them to include vessels in the dentate fascia. Additionally, this study reports no age-related alterations in neurovascular appositions in the dentate fascia. Supported by AG04804.

200.4 INCREASED SENSITIVITY TO KAINIC ACID INDUCED SEIZURES IN AGED RATS. R. Dawson, Jr. and D.R. Wallace, Dept. of Pharmacodynamics, Univ. of Florida, Gainesville, FL 32610

Kainic acid is a potent excitatory and neurotoxic analogue of glutamic acid. Systemic administration of kainic acid produces convulsions and subsequent widespread neuronal loss. While it is known that neonatal rodents are much more susceptible than adults to the convulsive and neurotoxic action of excitatory amino acids, few studies have examined the sensitivity of the aged brain to excitotoxic amino acids. The aim of the present study was to compare the seizure susceptibility of aged rats to that of young adults using kainic acid to provoke seizures via an excitotoxic mechanism.

Aged, female (Long-Evans) rats (30 months) and young adult (6 months) females were injected i.p. with 15 mg/kg kainic acid and observed for 2 hours. Preconvulsive and convulsive behaviors were noted and the latency to the first clonic-tonic seizure recorded, as well as, the number of clonic-tonic seizures. A second group of 6 month old female rats were injected i.p. with 30 mg/kg kainic acid and their behaviors were recorded.

The data ($\bar{X} \pm$ SE) are presented below:

Group	Seizure Incidence	Latency(min)	No. of Seizures
30 month (15mg/kg)	7/7*	45 $\pm$ 8*	9.7 $\pm$ 2.6*
6 month (15mg/kg)	0/9	---	---
6 month (30mg/kg)	4/6	83 $\pm$ 13	1.8 $\pm$ 0.5

*$p < 0.05$ old vs. 6 month (15mg/kg) or 6 month (30mg/kg).

These data suggest an increased sensitivity of the aged brain to the convulsive actions of systemically administered kainic acid. An increase in the sensitivity of the aged brain to excitotoxic amino acids may be of importance in age-related neuronal loss and neurodegenerative diseases. Supported by a grant from The American Federation for Aging Research.

200.5 SYNAPTOGENESIS IN AGED RATS ASSOCIATED WITH LONG TERM POTENTIATION. F.-L.F. Chang, K.R. Isaacs, D. Treacy*, & W.T. Greenough. Neural & Behav. Biology Program and Department of Psychology & Anatomical Sciences, University of Illinois, Champaign, IL 61820.

We and other laboratories have demonstrated that in adult rat hippocampal CA1, there is an increase in the number of shaft synapses associated with the expression of long term potentiation. Furthermore, we noted an increase in the number of sessile spine synapses which is consistent with a process of synaptogenesis through a sequence of shaft to sessile spine to well formed spine synapse. In the current study, we examined whether the same phenomena occur in normal healthy aged rats.

We used 7 Sprague-Dawley rats aged from 24 to 27 months. 400 micron transverse hippocampal slices were preincubated for one and half an hours before the start of stimulation and recording. Long term potentiation was produced by 6 trains of 100 Hz, 1 sec duration stimulations (stimulation intensity was adjusted to produce half maximal postsynaptic response), while activity control slices received 600 1 Hz stimulations of comparable intensity over a period of 10 min. Slices were then immersion fixed in 1% paraformaldehyde, 2.5% glutaraldehyde in phosphate buffer and processed for conventional electron microscopic examination.

LTP slices showed an average 73% increase in spike amplitude, while the control slices showed a decrease of 6%. This electrophysiological expression of LTP is comparable to those we obtained from young adult rats aged from 3 to 4 months (LTP: 80% increase, control: no change). For morphological study, an area adjacent to the recording electrode in the stratum radiatum 100 to 150 microns from the s. pyramidale / s. radiatum border was examined. We found an increase in the number of both sessile and shaft synapses (for sessile: 1.09 ± 0.17 per 100 square microns for LTP and 0.51 ± 0.19 for activity control, $t = 3.47$, $p < .01$; while for shaft synapses: 1.59 ± 0.20 per 100 square microns for LTP and 1.13 ± 0.19 for activity control, $t = 2.52$, $p < .025$) The 41% increase in the number of shaft synapses and 114% increase in the number of sessile spine synapses are lower than the effects we have observed in young adult rats (95%, 174% respectively). However, the equally robust electrophysiological expression of LTP suggests that there are potentially other mechanisms in addition to the synaptogenesis that may contribute to longer lasting components of LTP.

The decreased magnitude of synapse effects may be attributed to aging, but the still sizeable increase in synapse number in addition to the normal physiological expression of LTP suggests that the process of LTP is not impaired in normal aging.

200.6 LESION-INDUCED SYNAPTOGENESIS IN THE LATERAL SEPTAL AREA OF AGED AND YOUNG ADULT F344 RATS. S. Scott, D. Price*, S.T. DeKosky and S.W. Scheff. Depts. of Anatomy and Neurology, Lexington VA and Sanders-Brown Research Center on Aging, University of Kentucky, Lexington, KY 40536.

Aged rodent hippocampus has been reported to manifest a defect in lesion-induced axon sprouting and synapse replacement, requiring a significantly longer time course to attain pre-injury levels of synaptic density. The universality of this finding is currently being tested. Since the septal area was the first CNS structure to show lesion-induced synaptic plasticity and a limbic structure, we tested the capacity of this aged brain structure to cope with extensive denervation.

Young adult (2-3 mos) and aged (24-28 mos) Fischer 344 rats were subjected to a unilateral aspiration of the fimbria. This lesion results in massive denervation of both septum and hippocampus. Subjects were allowed to survive 4,10,15,30 and 60 days after the injury and were perfused with 1% glutaraldehyde and 4% paraformaldehyde in phosphate buffer. Both septum and hippocampus were prepared for ultrastructural analysis; only the ipsilateral lateral septal area was evaluated for changes in the synaptic density as a function of time post fimbrial lesion.

Both young and aged animals show a precipitous drop in synaptic density at 4 days following the injury. By 10 days both age groups have begun to show substantial increases in synaptic density and by 15 days post lesion both age groups show an over production of synaptic contacts. This over production is greater than the normal synaptic density for this area. By 30 days after the lesion the young adult animals begin to "shed" some of the synapses and return to prelesion density by 60 days. Aged animals manifest the same increased density in synaptic contacts but fail to shed synapses by the 30 days. By 60 days the aged rats return to prelesion levels. This failure of the aged group to "shed" extra synaptic contacts in a timely manner may represent a different type of defect in plasticty. The over-production of synaptic contacts in the lateral septal area following massive denervation has not been reported for other limbic structures indicating that the lateral septal area responds very differently than the hippocampus following damage. Finally, the overproduction of synaptic contacts and the eventual "shedding" of the contacts supports the contention that lesion-induced synaptogenesis closely mimics developmental synaptogenesis in significant ways. (Supported by NIH grant NS21541 and the VA Medical Research Service)

200.7 **NGF RECEPTOR IMMUNOREACTIVITY IN AGED RAT BRAIN.** F. Gómez-Pinilla, C.W. Cotman and M. Nieto-Sampedro. Department of Psychobiology, University of California, Irvine, CA 92717.

Brain NGF receptors (NGFR) appear to be associated to cholinergic structures. There is increasing evidence that in several cholinergic areas the system NGF/NGFR may play a role in neuronal plasticity. Since the potentiality for plasticity is different in young vs. old animals we decided to study the distribution of NGFR in some selected brain areas of aged rats (24-27 month-old) and compare it to the distribution of NGFR in young adults (2-5 month-old). In order to study the distribution of NGFR we used affinity-purified monoclonal anti NGFR (IgG 192, kindly provided by Dr. E.M. Johnson,Jr.) and peroxidase-anti peroxidase immunohistochemistry.

In young-adult rats, NGFR immunoreactivity was found in the olfactory bulb (OB) (glomerular layer), medial septum (MS), diagonal band of Broca (DB), nucleus basalis of Meynert (BM) and hippocampus (H). Parallel immunohistochemical staining of aged rat brain showed the following. In the olfactory bulb, the immunostaining was at least as strong as young-adult rats. In the MS, DB and BM, NGFR immunoreactivity was mainly located in cell bodies. Immunostaining in dendrites was weak and occurred only in the proximity of the soma. In contrast, NGFR immunoreactivity in young-adult rats was distributed in numerous neuronal processes and subprocesses which extended long distances from the soma. The number of NGFR-positive neuronal processes per unit of cross-section area in aged rats was about one third of the number seen in young animals. In the hippocampus NGFR immunoreactivity was practically non-existent These findings show that there are local differences in contents of NGFR (i.e. OB: high, MS-DB-BM-H: low). In addition, the low levels of NGFR in the septal-hippocampal system of normal aged rats may account for the slower sprouting response observed in this system after entorhinal ablation. These results suggest that a local loss of NGFR may be a potential cause for the decline in plastic capabilities observed in aged brain cholinergic systems.

200.8 NERVE TERMINAL CURRENTS IN YOUNG AND OLD CBF-1 MOUSE NEUROMUSCULAR JUNCTION. N. Anis* and N. Robbins (SPON: R. W. Hardy). Department of Developmental Genetics and Anatomy, Case Western Reserve University, Cleveland, Ohio 44106.

Neuromuscular transmitter output and turnover is altered in muscles of old CBF-1 mouse, but the mechanism of these alterations is poorly understood. Morphological studies from our laboratory showed that this change in transmitter output in aged animals is not due to a change in the number of release sites or nerve terminal contact area. Other explanations include altered Ca buffering capacity in aged terminals, or changes in nerve terminal ionic channel properties. We examined the latter hypothesis by inserting microelectrodes close to the nerve terminals inside the perineurial space and recording external current along the superficial nerve bundles (Mallart, J. Physiol. 368:565, 1985) in sternocleidomastoid muscle of mature (8-12 mo.) and old (24-30 mo.) CBF-1 mice. Signals recorded in curarized preparations consisted of double negative peaks. The first peak is generated by local inward Na current (blocked by tetrodotoxin) during propagation of nerve action potentials. The second negative deflection is generated by nerve terminal K current (blocked by tetraethylammonium; TEA or 3,4-diaminopyridine; 3,4-DAP). Blocking of K currents with TEA and 3,4-DAP gave rise to a positive-going Ca current (blocked by Cd++, Co++ and Mn++) with slow and fast components. In aged muscles, the rise and half-decay times of Na, K and fast Ca currents and the timing of the K and fast Ca currents were similar to those in young muscles. The relative current amplitudes of both K and Ca (relative to Na current) were also unchanged in aged animals.

These results indicate that the presynaptic channel kinetics of young and old SCM muscles are similar. However, the half-decay time of the slow Ca current in old muscle was at least twice as long as in young muscle. The physiological role of this slow Ca current remains to be elucidated, but to the extent that may be present in unblocked preparations, it could transiently elevate intracellular Ca, perhaps producing long-term effects. (Supported by NIH AG00795)

200.9 LITHIUM EFFECTS ON NEURONAL MEMBRANES IN SENESCENT RATS. I.J. Wajda, M. Banay-Schwartz*, T. De Guzman*, I. Manigault*, and A. Lajtha. Center for Neurochemistry, N.S. Kline Institute, Ward's Island, New York, NY 10035.

Chronic treatment with lithium affects the density of a number of receptors, influences the levels of several amino acids, and sometimes produces changes in the ionic content of the brain. These changes indicate that lithium has an effect on neuronal membranes. In the previous studies we used adult and 6-week-old Wistar rats. Since senescence is characterized by many morphological and biochemical alterations in the brain tissue, and since lithium is used in the treatment of affective disorders in geriatric patients, it was of interest to study the effects of lithium on senescent brain. We used two groups of female Fisher-344 rats, one 6 months old and one 20 months old. They were placed on lithium diet for 3 weeks.

Serotonergic binding sites were assayed in cerebral cortex with [^{3}H]ketanserin. We found an increase in K_d in the older group kept on lithium, indicating a decrease in the affinity of the serotonergic receptors. The density of those sites was not affected by lithium. The 6-month-old rats showed a decrease in serotonergic binding sites and no change in the affinity of the receptors. Dopaminergic binding sites were examined in the caudate nuclei with [^{3}H]domperidone, and there was no change in either the density or the affinity of dopaminergic binding sites in either the old or the young rats. In comparing the two control groups of the older and young animals, we noticed a decrease of the serotonergic binding sites in the old rats but little change in the dopaminergic system.

The lithium levels in the brain and plasma of lithium-treated rats were close to 1.0 mEq/kg or L. Free amino acid levels were estimated in five parts of the brain: cerebral cortex, midbrain, pons, medulla, and cerebellum. Amino acids were extracted from the tissue, and derivatized products were resolved by HPLC and detected fluorometrically. Twenty amino acids were estimated. GABA, glycine, alanine, aspartic acid, and glutamic acid increased in several parts of the brain. These increased in old rats were brought down by the lithium treatment. Glutamine, on the other hand, showed a decrease in older animals and was not affected by lithium treatment.

It is of interest to remember that GABA, glycine, and glutamic acid belong to the group of putative neurotransmitters, and that both glutamine and alanine are involved in the metabolism of ammonia in the brain. It is possible that the alteration produced by lithium treatment are connected to the therapeutic action of lithium.

Supported by a grant from the Institute of Aging - NIH AG05011-01A1.

200.10 REGULATION OF FREE INTRACELLULAR CA^{2+} LEVELS IN SYNAPTOSOMES FROM AGED RATS. M.L. Michaelis, C. Foster* and E.W. Nunley.* Dept. of Pharmacology and Toxicology and Center for Biomedical Research, University of Kansas, Lawrence, KS 66045.

The possibility that alterations in neuronal Ca^{2+} regulation occur with aging has led to a number of studies on Ca^{2+} homeostasis as a function of brain aging. Our work has focused on characterization of synaptic plasma membrane systems responsible for transporting Ca^{2+} out of the neurons, i.e., ATP-dependent Ca^{2+} transport and the Na^+ - Ca^{2+} antiporter. We reported earlier that the kinetic characteristics of the antiporter and the (Ca^{2+} + Mg) ATPase are altered in synaptic membranes from aged Fisher 344 rats, and the changes suggest that Ca^{2+} extrusion may be less efficient in nerve terminals from aged animals. More recently we examined the antiporter activity in 27-28 month old Fisher 344 rats and found the V_{max} for Ca^{2+} transport in these animals to be substantially lower than that for adult (6-8 month) rats. Detailed examination of the ATP-dependent transport of Ca^{2+} in synaptic membranes from 7, 22, and 27 month old animals has also revealed decreases in the V_{max} for transport activity.

Since a decrease in Ca^{2+} extrusion may lead to elevated free $[Ca^{2+}]_i$ levels, studies were undertaken to determine the free $[Ca]_i$ in synaptosomes from aged and adult animals under a variety of conditions. We used the fluorescent Ca^{2+} indicator dye Fura-2 to monitor $[Ca^{2+}]_i$ in synaptosomes under basal conditions, following depolarization by KCl or veratridine, and following activation of receptors or membrane events that might lead to elevations in $[Ca^{2+}]_i$. The resting free $[Ca^{2+}]_i$ levels in nerve terminals from the 23-24 month old rats were higher than those in 7-8 month-old animals (158 ± 10 nm for the adult versus 203 ± 12 nm for the aged animals). In addition, depolarization of the synaptosomes with elevated KCl or veratridine led to substantial increases in free $[Ca^{2+}]_i$ and the aged animals consistently showed greater increases in the free Ca^{2+} signals. The release of Ca^{2+} from internal sites by activation of receptors linked to inositol phosphate turnover was also detected by the Fura-2, but the aged animals differed only slightly from the controls in their response to this type of activation. Nevertheless, the data obtained with the Fura-2 support the notion that the Ca^{2+} buffering capacity of aged nerve terminals is less effective than that of terminals from younger animals. It is possible that the decreases in Ca^{2+} extrusion activities may contribute to the elevated free $[Ca^{2+}]_i$ levels in the nerve terminals of aged animals (Supported by PHS grant AG 04762, AA 04732, and Ctr. Biomed. Res., U. of Kansas).

200.11 AGE RELATED ALTERATION IN CENTRAL RECEPTORS FOR CALCIUM CHANALES BLOCKERS. A. Golik* and D. Modai* (SPON: N. Allon). Dept of Medicine, Assaf Harofeh Med. Ctr. - Tel Aviv Univ. Israel.

Calcium antagonists such as nifedipine, verapamil and diltiazen, modulate the activity of calcium channels via specific receptors. These calcium channel blockers are increasingly used in elderly patients. Since age related decrease in the density of various receptors has been reported, it is of interest to examine age related changes in the distribution of calcium channel receptors. We used ^{3}H-labelled PN-200-210 and studied its binding to brain of CW1 mice at different age groups (3,6,9,12,15,18 and 32 months). In vitro analysis were based on both whole brain autoradiography and on binding studies. The autoradiograms enabled the evaluation of binding to specific brain regions using a computerized image analyzer. Kd and Bmax values were obtained by Scatchard analysis of the binding data. No significant age related changes could be found with either of the two methods. The highest density of binding sites was seen in the hippocampal formation independent of age group. Binding affinity and receptor density were similar in all age groups studied (Kd=60pM, Bmax=190 fmole/mg protein). Since peripheral binding sites were not included in this study, further research is required in order to fully evaluate the clinical implication of the above data for geriatric pharmacology.

200.12 **REMOVAL OF LIPOFUSCIN GRANULES FROM CELL BODIES OF AGED MICE BY COLCHICINE.** M. C. Bundman, V. J. Roberts and C. Gorenstein. Dept. Pharmacology, University of California, Irvine. Irvine, CA 92717.

One of the most significant and reliable changes which can be correlated with aging is the progressive accumulation, in postmitotic cells, of pigmented organelles known as lipofuscin granules. Although the accumulation of lipofuscin is linear with age in many areas of the brain, the actual role of lipofuscin in the aging process is unclear. A number of studies have demonstrated a correlation between the accumulation of lipofuscin and interference with normal metabolic activity, loss of dendrites, decrease in total cellular RNA and cell death. Prolonged treatment with centrophenoxine has been shown to reduce the amount of neuronal lipofuscin and to improve performance in certain learning tasks.

Previously, we showed that a single i.c.v. injection of colchicine results in a redistribution of lysosomes from the soma of neurons to the dendrites. In light of the close relationship between lysosomes and lipofuscin granules we asked whether colchicine treatment could also induce a redistribution of neuronal lipofuscin granules.

Male, CFW mice, 28 months of age, were injected i.c.v. with 40 µg colchicine and sacrificed 24 hours later. At the light microscope level we observed a redistribution of dipeptidyl aminopeptidase II (Dpp II), a lysosomal and lipofuscin granule marker enzyme, from the soma of neurons to the dendrites. All neuronal populations containing Dpp II displayed this response to colchicine except neurons in the mesencephalic nucleus of the trigeminal nerve. Quantitation of this phenomenon at the electron microscope level demonstrated that, in the facial nucleus, colchicine induced a rapid and significant redistribution of both lysosomes and lipofuscin granules. In cell bodies there was a 44 % reduction in the density of lysosomes and a 63% reduction in the density of lipofuscin granules. In the dendrites, we observed a five-fold increase in lysosome density and a ten-fold increase in the density of lipofuscin granules. Under these conditions we did not observe a redistribution of mitochondria from the cell bodies to the dendrites.

These results indicate that colchicine may prove useful as a tool to study the role of lipofuscin in the aging process.

200.13 TIME COURSE OF ASTROCYTE RESPONSE TO NEURAL TRAUMA IN YOUNG AND AGED RATS. B.T. Faddis* and K.S. Topp* (SPON: A. Gabor). Dept. of Human Anatomy. School of Medicine. University of California. Davis, CA 95616.

Neuroglia appear to play an important role in repair of damaged neural tissue. It is not presently known whether this glial function is modified during aging. We evaluated numerical changes and hypertrophy in astrocytes in young and aged rats following neural trauma. Male Fischer 344 rats of 3 and 16-19 months of age received unilateral needle wounds through the cortex (CO) and underlying hippocampus (HC). Animals were allowed to survive for 2-5 days following injury and were sacrificed by vascular perfusion with 1.5% paraformaldehyde, 1.25% glutaraldehyde. Vibratome slices through the lesion were stained immunohistochemically for glial fibrillary acidic protein (GFAP), flat-embedded in methacrylate, sectioned at 1.0 um and counterstained with toluidine blue. Differential cell counts from oil-immersion subfields adjacent to the lesion in the CO and HC were averaged for each animal. The mean nuclear size of astrocytes in the CO and HC was determined for each animal and astrocyte counts were adjusted to reflect the size changes observed following injury.

In young animals, HC astrocyte counts increased on postlesion day 2, while CO astrocyte counts did not significantly increase until day 3. There was no further increase in astrocyte numbers and the counts remained steady through days 3, 4 and 5. HC astrocyte hypertrophy was significant on postlesion day 2 and maintained on days 3 and 4, but diminished on day 5. Astrocytes in the CO were hypertrophied on day 2 and remained enlarged through days 3, 4 and 5.

In aged animals, HC astrocyte counts showed a significant increase on postlesion day 3, while CO astrocyte counts did not increase until day 4. There was no further increase in astrocyte numbers and the counts remained steady through days 4 and 5. HC astrocyte hypertrophy was significant on postlesion day 2, but gradually decreased thereafter revealing no significant size differences between days 3, 4 and 5 and controls. Astrocytes in the CO were hypertrophied on day 2 and the enlargement was maintained through days 3, 4 and 5.

Our observations show that, in both young and aged rats, trauma-induced hypertrophy of astrocytes in the HC and CO increased on postlesion day 2. Similarly, in both animal populations the numerical density of astrocytes increased in the CO one day later than the response in the HC. Despite these parallels, in the aged rats there appears to be a delay in the numerical increase in astrocytes in the HC and CO following neural trauma.

200.14 DEVELOPMENTAL CHARACTERISTICS OF ELECTRICAL PROPERTIES IN CULTURED RAT BRAIN NEURONS. G.W.Lu and H.W.Wang. Department of Neurobiology, Capital Institute of Medicine, Beijing, China

The rat brain neurons taken from 15-17 day embryo were grown in dissociated cell culture and maintained in vitro for 3 weeks. The developmental process of the neurons was observed from early stage of development in terms of passive and active electrical properties and their changes under perfusion of channel blockers.

The neurons development could be morphologically divided into stages I(from plating time to 6 days), II(7-11 days), III(12-21 days), and IV(21-22 days). The relative value of resting membrane potentials (RMP) for stages I, II, III and IV was 1, 3.46, 4.07 and 6.54, respectively; the correponding value of input resistance (Rin) was 1, 1.48, 2.53 and 4.56, respectively. The current-voltage curve in stages II and III was exponential in the direction of depolarization and the Rins change with time was nearly linear; occurrence rate of spontaneous activity increased with prolongation of culture and the amplitude of evoked action potentials reached maximum during stages III and IV. The RMP and Rin were markedly decreased by perfusion of TEA-containing solution, while no effect was seen during TTX perfusion.

The results indicate that potassium ion channels develop slower in stages I and II, faster in stages III and IV, and nature by the end of stage IV.

200.15 EFFECTS OF THE OSMOLAL CONCENTRATION CHANGE OF EXTERNAL SOLUTION ON TISSUE CULTURED NERVE CELLS FROM A FETAL STAGE TO AN AGED STAGE. H.Horie,S.Ikuta*,T.Takenaka & S.Ito*.Dept of Physiol. Sch. of Med. Yokohama City Univ., Yokohama,236,Japan.

Membrane fluidity, sensitivity to fibronectin and fibronectin receptor density of neurons change with aging. These results indicate that one of the basic functions of nerve cell membranes, respose to the osmolal concentration change of external solutions , might change with aging . In this paper we measured the membrane function by using tissue cultured dorsal root ganglion neurons dissected from 3 age groups of mice (fetal, 3-month-old and 27-month-old). Neurons were cultured on glass coverslips, 40x50mm, and the coverslips were fixed with a thin tape on the bottom of a 0.6mm thick stainless steel plate(50x80mm) with an elliptical hole : 30x50mm. The plate was placed on the inverted Zeiss Axiomat microscope and neurons were observed by the AVEC-differential interference contrast video microscopy. (Hamamatsu Photonic, Japan)

When an external control solution (67mM NaCl and 134mM sucrose containing Tyrode solution) was replaced with a sucrose free control solution whose osmolality was about a half of the control , diameters(Do) of neurons rapidly icreased to a maximum value(Dm) (1st stage) and then decreased slowly to the original sizes(2nd stage). After this stage cell sizes were constant and decreased rapidly by perfusing the control solution(3rd stage). The relative value Dm/Do was 1.10 in a half osmolal concentration solution of the control and 1.05 in a three quarters osmolal concentration solution. The time (Tm) for diameters to reach maximum values was changing with aging, 74 sec in 18-day-old fetus, 183 sec in 3-month-old and 312 sec in 27-month-old. Dm/Dt was 1.10 and this value was common in 3 age groups. When two times higher osmolal solution was applied to neurons, the diameters rapidly decreased and the relative value of diameters to the initial ones reaced 0.87. This value was constant under the treatment. This change was reversible. It is plausible from these results that the cell membrane expansion in the first stage was caused by entrance of water. After cell sizes reach to the maximum value, channeles in the membranes might open by this membrane expansion and intercellular solutes might pass through the open channels to an external solution. This decrease of intracellular osmolal concentration can explain the decrease of cell size in the second stage. This explanation was supported by the fact that at the third stage cell sizes rapidly decreased by the application of the control solution. The increase of Tm with aging indicates that rate of elastic response of neurons to osmolal change might decreases and the cell membrane might become rigid with aging.

200.16 EFFECTS OF AGE ON THE RESPONSE TO PARTIAL DENERVATION IN MOUSE MUSCLE: MORPHOLOGICAL CORRELATES. J.M. Jacob* and N. Robbins. (SPON: R.A. Ratcheson). Department of Developmental Genetics and Anatomy, Case Western Reserve University, Cleveland, Ohio 44106.

After transection of the L5 spinal root in CBF-1 mouse, soleus motor neurons expand their field of innervation 2-3 fold. This expansion of the motor unit size can be used as a test of the relative capacity of young and old motor neurons to increase or redistribute cellular metabolites to a larger nerve terminal field. Both young (5-8 mo.) and old (25-30 mo.) mouse soleus muscles have the same number of motor units and muscle fibers. Twitch tension in both young and old muscle largely recovered by 60 d after operation, but in old muscles, transitter release was reduced in both original and sprouted terminals, and latency from nerve stimulus to epp was prolonged (see Jacob and Robbins, Neurosci. Abst., 1986). Therefore, we sought morphologic correlates of these findings.

Two methods were used: zinc iodide osmium staining of individual or whole mount muscle fibers or whole mounts of muscle using fluorophores coupled to tetanus toxin c-fragment to stain nerve terminals and FITC-coupled alphabungarotoxin to stain post-synaptic receptors (see Robbins and Polak, this volume). Terminals in muscle partially denervated for 60 d showed junctions of near normal size, close overlap of nerve terminals and receptors and innervation by myelinated nodal sprouts. At 60 d in the old operated muscle, there were four classes of nerve muscle junctions: I) denervated, i.e. receptors but no nerve terminals (22%); II) fine nerve terminals over receptors (28%); III) nerve terminals covering 50-85% of the post-junctional receptors (20%) and IV) normal nerve muscle junctions (30%). The innervation of class II and III nerve terminals was primarily by unmyelinated or lightly myelinated nodal sprouts. Studies are currently in progress to determine the approximate axon calibers of the sprouted axons but preliminary data indicate that the relative lack of myelination resulted from failure to increase axonal size.

In summary, after partial denervation, functional maturation of nerve terminals appears complete by 60 d in young but not in old mice. In the latter, some denervated fibers do not obtain long-term innervation, and in others, terminal reinnervation by sprouts tends to be sparse or incomplete. These last findings may account for the reduced transmitter release. In addition, failure of adequate myelination of the sprouted nerve fibers readily explains the longer latency. 200.17 DYNAMIC MORPHOLOGICAL REMODELLING OF SOLEUS AND EDL NEUROMUSCULAR JUNCTIONS OF C57BL/6J MICE WITH AGE. M.H. Andonian, D. Weese and M.A. Fahim. USC Andrus Gerontology Center, Los Angeles, CA 90089-0191.

The mammalian neuromuscular junction (NMJ) appears to undergo a dynamic remodelling process with advancing age. Previous studies suggest that the aging NMJ becomes progressively larger and more complex, and that this phenomena occurs to a greater degree in the EDL than the Soleus (Robbins & Fahim, J. Neurocytol, 14, 1019-1036, 1985). In order to better understand this process, quantitative morphometry was conducted on SOL and EDL nerve terminals of C57BL/6J mice aged 4, 8, 10, 12, 18, 22, 24, and 32 months. Each age group consisted of five animals.

The muscle were dissected from the mice under Metofane anestnesia, and stained with the zinc-iodide-osmium (ZIO) technique. Camera lucida drawings were made of between 5 and 15 acceptable NMJs (showing >90% of area) in each muscle in each animal. The drawings were digitized into the computer using the planar morphometry system of Southern Micro Instruments (Atlanta, Georgia), and the area, perimeter, longitudinal extent length and fiber diameter determined.

Repeated-measures ANOVA of the data revealed significant ($P < .05$) differences between many of the ages in both the SOL and EDL nerve terminal morphometry. The levels of significance were greater when the fiber diameters were covaried. When the seperate age groups were treated as a continuous variable, regression analysis of the data showed significant ($P < .05$) positive age trends for area, perimeter, and length for the EDL, with similar trends in the SOL perimeter.

The morphology of the NMJ underwent a dynamic remodelling in both muscles with advancing age. Older NMJs were progressively more complex, highly branched and regionalized. The magnitude of the changes was greater in the EDL than the SOL. These results suggest that remodelling is an ongoing process which may be subject to age-related changes in the animal, or its environment.

200.18 AGE-RELATED CHANGES IN THE REGIONAL DISTRIBUTION OF HORMONES IN THE ANTERIOR PITUITARY OF THE MALE RAT. J.M. Goldman*, R.L. Cooper*, G. Rehnberg*, J.F. Hein* and W.K. McElroy*. (SPON: C. Lau). Reprod. Toxicol. Br., Hlth. Effects Res. Lab., U.S. Environ. Protect. Agency, Res. Tri. Pk., NC 27711.

In mammals, there is a differential distribution of hormones in the anterior pituitary (AP) (e.g., Schafer, S.J. and McShan, W.H. Proc. Soc. Exp. Biol. Med. 146:546, 1974), which corresponds to the localization of particular types of hormone-containing cells. Since age-related changes in AP hormonal concentration (conc) have been reported (e.g., Bethea, C.L. and Walker, R.F. J. Gerontol. 34:21, 1979; Emanuele, N.V. et al., Dev. Brain Res. 20:179, 1985), the present study was intended to explore the effects of age on these patterns of distribution. Four and twenty-four month-old male Long-Evans rats were quickly decapitated. Trunk blood was collected and AP free of micro- or macroadenomas were each cut on ice into 8 fragments of approximately equal weight [2 rostral (left/right), 3 central (left/medial/right), and 3 caudal (left/medial/right)]. Weighed fragments were sonicated in medium 199/0.3% bovine serum albumin (Hepes-buffered, pH 7.4) and aliquots taken for analyses of luteinizing hormone (LH), follicle-stimulating hormone (FSH), prolactin (Prl) and thyroid-stimulating hormone (TSH). The patterns of distribution of LH and FSH were similar, with a decrease in conc seen in the more caudal fragments. Age-related declines in gonadotropin conc were seen in both rostral regions and in the medial fragments of the central and caudal regions. TSH conc increased along the rostral-caudal axis in the 4-mo. rats, but no statistically significant age differences were present for any region. While Prl was evenly distributed among all regions, there was a general decline in regional conc. Since the gonadotropin- and TSH-containing cells are apparently clustered regionally, comparisons were also made between ages using measures of total hormonal content per fragment, thus circumventing any influence of age-related alterations in AP (and fragment) size upon the obtained values. The principal effect with this comparison was a decrease in LH and FSH within the medial area of the caudal strip. The regional hormone relationships were as before. The results indicate that, while in general there is no decline with age in the content of LH, FSH, Prl or TSH in the rat AP, there could be a selective loss of gonadotropes from the medio-caudal area, either through cell loss or a decline in cell number due to a shift of the gonadotropes out of the region. Given the regional and hormonal specificity, it is unlikely that the observed effects represent changes in the amounts of LH and FSH within a stable cellular population.

200.19 ALTERATIONS IN BRAIN ANGIOTENSIN II BINDING IN THE AGED RAT. B.W. Massey*, L.M. Plunkett, R.H. Kennedy* and E. Seifen. Dept. of Pharmacology, Univ. of Arkansas for Medical Sciences, Little Rock, AR 72205.

Recent studies have localized angiotensin II (ANG) binding sites and immunoreactivity to brain areas associated with sympathetic nervous system activity and cardiovascular function. The peptide has been proposed to act as a neuromodulator in these brain areas. In the present study, ANG binding was studied in senescent and adult Fischer 344 rats using quantitative autoradiographic techniques. Aging in the Fischer rat is accompanied by changes in sympathetic nervous system and cardiovascular function. This study was designed to examine ANG binding in specific brain areas associated with sympathetic activity and peripheral cardiovascular control.

ANG binding was determined in discrete brain nuclei of 5 and 25 month old male Fischer rats. Quantitation was performed by incubation of 16 um thick tissue sections with 2 nm ^{125}I-(Sar^{1})ANG followed by autoradiography, computerized densitometry, and comparison to ^{125}I-standards. The areas examined included the nucleus tractus solitarius (NTS) and the organon subfornicalis (SFO). In both of these areas ANG injection produces changes in cardiovascular parameters. ANG binding was significantly increased in the SFO from 589 $\pm$ 79 to 1048 $\pm$ 47 fmol/mg protein in 5 versus 25 month old rats respectively. In the NTS, binding was significantly decreased from 1378 $\pm$ 91 to 806 $\pm$ 116 fmol/mg protein (5 versus 25). These results suggest that ANG receptor density is altered during aging and that these changes are associated with brain areas known to regulate the peripheral cardiovascular system.

200.20 BINDING OF PHORBOL ESTERS IN THE BRAIN OF YOUNG AND AGED RATS AFTER ACUTE AND CHRONIC ETHANOL TREATMENT. F.Battaini, R.Del Vesco*^, S.Govoni^, M.S.Magnoni*^ and M. Trabucchi. Chair of Toxicology II University of Roma and ^Inst. of Pharmacological Sciences,University of Milano, ITALY.

Increasing evidence indicates that protein kinase C (PKC) regulates neuronal excitability interfering with neurotransmitter release,K+ and Ca++ channels,receptor function.

Phorbol esters specifically bind and stimulate PKC and their tritiated derivatives provide a tool to investigate the involvement of this enzyme in brain functioning. In fact changes in phorbol ester binding have been correlated with modifications in PKC activity in various systems.

The physiologic activator of PKC is diacylglycerol produced after activation of the phosphoinositide (PI) cycle by a number of transmitters and conditions known to alter neuronal excitability.

Recently it has been demonstrated the ability of ethanol to interfere with PI metabolism in discrete brain areas and after specific stimuli.

We have used labeled phorbol 12,13,dibutyrate (3H-PDBu) to investigate PKC function in rats of different ages acutely and chronically treated with ethanol (3 g/kg per os, 3 hrs and 6% v/v in the drinking water for 21 days respectively).

In adult rats (3 month old) the chronic ethanol treatment was able to specifically modify 3H-PDBu binding in cortical membranes decreasing Bmax values by 25%. The acute treatment decreased Bmax values and increased the affinity. No significant modifications were observed in hippocampus in both conditions. In aged animals (24 month old) 3H-PDBu binding in cortical membranes was not significantly different from adult values; the chronic and acute ethanol treatment down regulated Bmax values (-27% and -24% respectively).

The data indicate that ethanol specifically down regulates 3H-PDBu receptors in rat cortical membranes; this may be related to the reported ethanol induced increase in the sensitivity of brain PI turnover to selected agonists. The down regulation of 3H-PDBu receptors could be a compensatory process controlling brain cellular excitability modified by chronic ethanol.

The modification in cortical 3H-PDBu binding, observed in aged rats, indicate the capability of old animals to still react in a compensatory manner at selected stimuli.

200.21 **MORPHOLOGICAL CHANGES IN NEURONS IN AREA 17 OF AGING RHESUS MONKEYS.** S. Vincent* and A. Peters (SPON: D. L. Rosene). Dept. of Anatomy, Boston Univ. Sch. of Med., Boston, MA 02118 and Yerkes Regional Primate Research Center, Atlanta, GA 30322.

Neuronal populations in the primary visual cortex of 27 and 35 year old monkeys have been compared with those in 5 year old monkeys. On the basis of counts of neuronal profiles containing nuclei in 250 μm wide strips of 1 μm thick sections passing through the entire depth of the cortex, no obvious neuronal loss with age could be detected. The counts were made in a portion of area 17 on the lateral surface of the hemisphere just behind the lunate sulcus. This lack of obvious neuronal loss is compatible with our electron microscopic observations on this area of cortex, for in the older monkeys the neurons show little cytological alteration beyond the presence of a few lipofuscin granules. In contrast to the neuronal cell bodies, however, profiles of dendrites with large vacuoles in their cytoplasm are not uncommon in the old animals. Sometimes these vacuoles are enlarged so that only a thin rim of cytoplasm remains in the dendrite, and it is possible that this vacuolation leads to the formation of a not infrequent profile in old animals, one of a membrane bound hole. Such holes often contain remnants of mitochondria and other membranous debris. The dendritic origin of these holes is suggested because the membrane bounding them sometimes form synaptic junctions. In addition to these smaller diameter holes, there are other, much larger holes, or spaces in the neuropil of the old animals. These larger holes can be 10 μm or more in diameter, and some of them appear to be a late stage in the degeneration of myelinated axons, for they are bounded by a thin laminated sheath. Such holes are often empty, but the remnants of compressed axoplasm may be present along one side of the hole. By contrast, other large spaces often contain membranous debris and have a very attenuated rim of cytoplasm, with a disrupted membrane bounding them. Many of these spaces are the size of neurons, and we are examining additional material to try to determine if these spaces are the result of neuronal degeneration. Similar spaces have been previously encountered in the cerebral cortex of 48 month old, diet restricted rats, in which neuronal loss was significant (Peters, Harriman and West. Neurobiol. Aging 8:7-20, 1987). Supported by NIH grants AG 00001, T32 NS 07152, and RR-00165.

200.22 AGE RELATED ALTERATIONS IN PREDOMINANTLY FAST MUSCLE IN FISCHER 344 AND LONG EVANS RATS. T.J. Walters, H.L. Sweeney, and R.P. Farrar. Dept. of Kinesiology, Institute for Neurological Sciences Research. Univ. of Texas at Austin.

Aging has been reported to produce either declines in or no change in aerobic capacity of skeletal muscle. Some of the disparity in results has been attributed to strain related neuropathies in Sprague Dawley and Wistar rats. Two strains that have been reported to be free of disturbances in neuronal function are the Fischer 344 (F344) and Long Evans (LE). In this study we examined the plantaris muscle for changes in mass, muscle/body weight ratios, aerobic capacity, and shifts in the myosin light chain (MLC) pattern. Pathogen free rats were purchased from the Harlan Sprague Dawley facility and maintained in quarantine until sacrifice. Muscles were weighed fresh,and a portion saved at -80°C for both MLC ratios and citrate synthase (CS) activity. F344 rats were analyzed at 10-14 , 24 and 30 mos. of age while LE were analyzed at 10-14 and 30 mos. of age.

30 mo. old rats of both strains demonstrated a reduction in CS activity compared to strain matched 10-14 mo. old rats, however the decline was greater in the LE (21% decline in F344 versus a 32% decline in LE.) In the F344 strain the decline in CS activity was complete at 24 mos. without a further decrease between 24 and 30 mos.. An age related decline in muscle mass of 37% and 17% occured in the 30 mo. LE and F344 respectively. The decline in muscle mass in the F344 occured completely between 24 and 30 mos. When the muscle wt. to body wt ratio was examined in the 30 mo. rats the decline in muscle mass was significantly greater in the LE when compared to the F344 (46% decrease vs 19% decrease). Examination of the myosin LC ratios revealed a relative reduction in MLC_{3f} to MLC_{1f} in both strains of 30 mo. rats.

The results of this study demonstrates that although declines in aerobic capacity and mass of predominantly fast muscle occur in both LE and F344 rat strains, reductions are greater in the LE. Additionally both strains display a shift in MLC pattern with age.

RECEPTOR REGULATION II

201.1 CHRONIC (BUT NOT ACUTE) STRESS INCREASES HYPOTHALAMIC A_1 ADENOSINE RECEPTORS IN RATS. S.M. Anderson, J.R. Leu, G.J. Kant. Department of Medical Neurosciences, Walter Reed Army Institute of Research, Washington, D.C. 20307-5100.

Previously, we presented data demonstrating a 15% increase in the binding of the A_1 adenosine receptor ligand, [^{3}H]cyclohexyladenosine ([^{3}H]CHA) (5-7 nM) to membranes prepared from the hypothalamus but not from the frontal cortex, striatum, or hippocampus of rats exposed to chronic stress for three days (Soc Neurosci Abstr 11:773, 1985; Pharmacol Biochem Behav 26:829, 1987). That behavioral model incorporates continual performance, avoidance/escape from footshock and disruption of sleep.

The multidimensional nature of our 'sustained performance procedure' prompted us to examine the effects of stress on hypothalamic A_1 adenosine receptors in rats exposed to several different types of stress. 1) [^{3}H]CHA (5-7 nM) binding to hypothalamic membrane preparations from individual rats chronically stressed for 14 days in our 'sustained performance procedure' was 13.5% greater than binding to membranes from controls. These data are consistent with our previously published results (using a three day stress trial) and demonstrate maintenance of this receptor up-regulation during a longer (14 day) stress period. 2) In other experiments, rats were stressed by restraining them in lucite cylinders (5.7 cm diameter) three hours per day for one day (acute) or ten days (chronic, recurrent). [^{3}H]CHA binding to hypothalamic membrane preparations was 13% higher in the chronically stressed rats vs. controls. The acutely restrained rats were not significantly different from control in amount of [^{3}H]CHA binding to hypothalamic membranes. 3) In an abbreviated variation (four day trial) on the classical 'activity-stress' paradigm stressed rats were fed ad lib for one hour each day and provided 24 hr access to running wheels. [^{3}H]CHA binding to hypothalamic membranes of rats stressed in this activity wheel experiment was 10% higher than binding to membranes from control animals. 4) There was no difference in the binding of [^{3}H]CHA (5-7 nM) to hypothalamic membranes between controls and animals given acute footshock (15 min trial, 1.6 mA electric shock, variable schedule with an average intershock interval of 30 sec and shock duration of 5 sec).

Data from saturation binding experiments (0.09-26 nM [^{3}H]CHA) using pooled membrane preparations from stressed or control rats (from the 14 day 'sustained performance procedure') indicate that the up-regulation of the A_1 adenosine receptors in the hypothalamus of chronically stressed rats is due to an increase in the apparent number of binding sites without change in the affinity of the receptor for [^{3}H]CHA. Similarly, data from saturation binding experiments using pooled hypothalamic membranes from chronically restrained rats demonstrate that the up-regulation of hypothalamic A_1 adenosine receptors in these animals vs. controls is due to a change in the number of receptors rather than receptor affinity.

Our present data demonstrate small but consistent increases in the number of hypothalamic A_1 adenosine receptors in rats stressed in several chronic stress models and no change in these receptors by acute stress.

201.2 TEMPORAL RELATIONSHIP OF THEOPHYLLINE-INDUCED UPREGULATION OF CENTRAL A_1 ADENOSINE RECEPTORS AND ALTERATIONS IN SEIZURE SUSCEPTIBILITY. R.C. Sanders, P. Szot and T.F. Murray. College of Pharmacy, Oregon State University, Corvallis, OR 97331.

Chronic caffeine or theophylline (THEO) exposure elicits increases in rat cerebral cortical A_1 adenosine receptor (ADO-R) densities (upregulation) (B.B. Fredholm, Acta Physiol. Scand. Suppl., 508, 31, 1982, T.F. Murray, Eur. J. Pharmacol., 82, 113, 1982). However, the temporal requirements for A_1 ADO-R upregulation have not been established. The purpose of this study was to determine the magnitude of A_1 ADO-R upregulation associated with selected THEO exposure-periods and to compare this time-course with that for alterations in seizure threshold in similarly treated rats. Male Sprague-Dawley rats received twice daily injections of THEO (75 mg/kg) or 0.9% saline (SAL) for 1, 3, 7, 14, or 21 days. Forty-eight hours after the final dose rats were sacrificed and brain regions rapidly dissected and frozen for radioligand binding assays. A_1 ADO-R were selectively labeled in brain membrane preparations using N^6-cyclohexyl-[^{3}H]adenosine ([^{3}H]CHA) (New England Nuclear, spec. act. 9 Ci/mmol) as the radioligand. In cerebral cortical membranes significant increases of 13%, 27% and 19% in specific [^{3}H]CHA binding occurred at 7, 14 and 21 days, respectively. Cerebellar membranes demonstrated significant increases of 15% and 19% at 14 and 21 days, respectively. Previous reports have demonstrated these increases in [^{3}H]CHA binding following THEO exposure occur as a result of changes in receptor densities with no significant alterations in affinities. A_1 ADO-R upregulation has been suggested to play a role in reduced susceptibility to various chemoconvulsants (P. Szot, R.C. Sanders and T.F. Murray, Neuropharmacol., in press). To further define the role of A_1 ADO-R involvement in seizure susceptibility, bicuculline (BIC) seizure threshold determinations were performed in rats following the above chronic regimens. These experiments revealed a temporal pattern similar to A_1 ADO-R upregulation. THEO-exposed rats displayed significant increases in BIC seizure threshold of 17% and 25% following 1 and 2 weeks of exposure, respectively. These results lend further support to the contention that A_1 ADO-R upregulation is a consequence of chronic THEO exposure and that increased seizure thresholds following THEO exposure represents a functional correlate of the observed upregulation. (Supported by N.I.H. grant NS 23227)

201.3 DECREASED DENSITY OF PERIPHERAL BENZODIAZEPINE BINDING SITES IN CHRONIC, BUT NOT ABSTINENT ALCOHOLICS. F. Lafaille*, M. Dongier*, M. Dumas*, R. Quirion and B.E. Suranyi-Cadotte. (SPON: M. Ball). Douglas Hospital Research Centre and Dept. of Psychiatry, McGill University, Verdun, Quebec, H4H 1R3.

PK 11195 is an isoquinoline carboxamide derivative, which has been shown to bind with high affinity to peripheral benzodiazepine binding sites (PBR) in several tissues, including platelets (Benavides et al, Biochem. Pharmacol. 33; 2467, 1984). Although the functional role of PBR remains to be clarified, these sites may participate in the potent electrophysiological, convulsive and anxiogenic effects of peripheral benzodiazepine ligands (Mizoule et al, Life Sci. 36, 1059, 1985; Drugan et al, Pharmacol. Biochem. Behav., 24, 1673, 1986). Additionally, chronic alcohol administration in rats has been found to alter the density of PBR in brain (Schoemaker et al, Eur. J. Pharmacol. 120, 1248, 1983). To extend these findings, we studied platelet PK 11195 binding in 10 alcoholics (6 males, 4 females; mean age ± SEM = 43 ± 6 years), 10 recovered alcoholics (7 males, 3 females; mean age = 51 ± 8) and 11 healthy, non-alcoholic subjects (6 males, 5 females; mean age = 38 ± 4). All subjects were drug free for at least 4 weeks prior to platelet ^{3}H PK 11195 binding assays (Benavides et al, Biochem. Pharmacol. 33, 2467, 1984). The density (Bmax, fmol/mg protein) of ^{3}H PK 11195 binding on platelets of alcoholic subjects who continued to drink was significantly lower (mean Bmax ± SEM = 2115 ± 37; $p < 0.01$) than in healthy controls (3560 ± 54), with no significant difference in the affinity (Kd, nM) of ^{3}H PK 11195 for its binding site between the two groups (alcoholics, mean Kd ± SEM = 4.8 ± 1.7; controls = 5.1 ± 1.9). In contrast, mean Bmax values of platelet ^{3}H PK 1115 binding in alcoholics abstinent for at least 4 months was not significantly different from controls (mean Bmax = 3472 ± 46). Ethanol, in vitro (5 mM-43 mM) did not compete for ^{3}H PK 11195 binding sites on platelet membranes. These data suggest that a reduction in the density of platelet ^{3}H PK 11195 binding sites in chronic alcoholics is not due to a direct ethanol effect, and that a normalization of this variable may occur in abstinent alcoholics. Furthermore, these findings support the role of PBR in the physiological changes associated with alcoholism. Supported by the Douglas Hospital Alcoholism Research Program.

201.4 THE EFFECTS OF SWIM STRESS ON THE OCCUPANCY OF BRAIN BENZODIAZEPINE RECEPTORS MEASURED WITH $[^{3}H]$Ro-15-1788 IN MICE. S.I. Deutsch*, R. Weizman*, A. Weizman*, F.J. Vocci, Jr.*, K. Kook*, and S.M. Paul*. (SPON: P. Skolnick). Clinical Neuroscience Branch, NIMH, Bethesda, MD 20892.

The GABA-benzodiazepine-receptor complex has been recently shown to be modified by environmental "stressors". There have, however, been conflicting results concerning the direction of these changes using classical in vitro techniques. Recently, an in vivo method for measuring benzodiazepine receptor binding using $[^{3}H]$Ro15-1788 was described that avoids many of the artifacts associated with the traditional in vitro approaches (Goeders and Kuhar, 1985; Deutsch et al., 1987). Using this method, we examined the effects of acute and chronic ambient temperature swim stress on the occupancy of benzodiazepine receptors measured with $[^{3}H]$Ro15-1788 in seven regions of mouse brain. In addition, we studied the effects of adrenalectomy on specific and nonspecific $[^{3}H]$Ro15-1788 binding in vivo in both stressed and unstressed animals.

Acute ambient-temperature swim stress (2 and 10 minutes) resulted in a significant increase in the in vivo binding of $[^{3}H]$Ro15-1788 in all brain regions when compared to nonhandled (naive) and sham stressed mice. Specific binding was unaltered 24 hours after a single swim-stress. Repeated swim stress (2 and 10 minutes) for seven consecutive days resulted in a significant decrease in specific $[^{3}H]$Ro15-1788 binding in some but not all brain regions. Adrenalectomy did not significantly alter basal levels of specific $[^{3}H]$Ro15-1788 binding in unstressed animals. However, adrenalectomized mice showed an even greater increase in specific $[^{3}H]$Ro15-1788 binding when measured 20 minutes after a single 10 minute ambient-temperature swim stress. Experiments are in progress to determine whether these changes are due to alterations in the distribution of $[^{3}H]$Ro15-4513 in the adrenalectomized/stress group. These data support a role for the involvement of central benzodiazepine/GABA receptors in the response to stress. Furthermore, glucocorticoids may play a role in the regulation of the sensitivity of the GABA receptor complex.

201.5 AVERSIVELY-MOTIVATED COPING BEHAVIOR AND LEARNING ALTER THE BENZODIAZEPINE/GABA CHLORIDE IONOPHORE RECEPTOR COMPLEX IN THE RAT: Robert C. Drugan[1,2], Steven M. Paul[1], Phil Skolnick[2] and Jacqueline N. Crawley[1], [1]Clinical Neuroscience Branch, NIMH, and [2]Laboratory of Neuroscience, NIDDK, NIH, Bethesda, MD, 20892

We have recently reported that rats exposed to escapable or inescapable shock who subsequently did not develop "learned helplessness" revealed significant changes in the binding of radioligands to the benzodiazepine/GABA receptor complex. Rats that did not develop learned helplessness (coping animals) had a significant increase in the binding of $[^{3}H]$muscimol to the $GABA_A$ receptor, and a significant decrease in the binding of $[^{35}S]$TBPS to the chloride channel in cerebral cortex, when compared to rats who developed learned helplessness 24 hours following inescapable tail shock. Moreover, 2 hours following exposure to a session of escapable shock a significant decrease in the binding of $[^{35}S]$TBPS in cerebral cortex when compared to inescapably shocked rats and naive controls was observed. In addition, exposure to an aversively-motivated learning task, (a two-way shuttlebox-escape from footshock task without prior stress exposure) resulted in a rapid (5 min. post-test) reduction in the binding of $[^{35}S]$TBPS to cerebral cortical membranes when compared to yoked shock and naive controls. These data suggest a rapid alteration in the benzodiazepine/GABA receptor complex in response to aversively-motivated coping behavior or to a simple learning task.

We are presently characterizing the binding kinetics, timecourse, and specificity of observed changes in $[^{3}H]$muscimol and $[^{35}S]$TBPS binding in several brain regions following exposure to escapable and inescapable "stress".

Preliminary results suggest that the changes in $[^{35}S]$TBPS (~20% decrease) measured in vitro from membranes prepared from escapably shocked rats are rapid and short-lived. In contrast, 26 hours following escapable shock we observed an increase in $[^{35}S]$TBPS binding to cerebral cortical membranes. Adrenalectomy does not appear to modify the escapable shock-induced decrease in $[^{35}S]$TBPS binding, suggesting that glucocorticoid feedback is not the primary mechanism mediating the effects of coping behavior on the benzodiazepine/GABA receptor complex.

201.6 COCAINE-INDUCED CHANGES IN BENZODIAZEPINE RECEPTORS IN DISCRETE AREAS OF THE RAT BRAIN. N.E. Goeders, M.A. McNulty*, S.M. Dworkin*, S.I. Dworkin and K.H. McAllister*. Departments of Pharmacology and Psychiatry, Louisiana State University Medical Center, Shreveport, LA 71130.

A variety of clinical and animal data suggest that the repeated administration of cocaine may be associated with numerous neurobiological alterations including changes in D_2 dopaminergic receptors in the striatum and nucleus accumbens (Goeders and Kuhar, Alcohol and Drug Res 7:207, 1987). Other investigations have demonstrated that a complex interrelationship exists between dopaminergic and GABAergic neuronal systems (Scheel-Kruger, Acta Neurol Scand 107:9, 1986). Since GABA is an integral component of the GABA/benzodiazepine receptor complex (Richards et al. Experientia 42:121, 1986) and since chlordiazepoxide affects intravenous cocaine self-administration in rats (McAllister et al., Soc Neurosci Abstr, 1987), this investigation was designed to investigate the effects of chronic cocaine administration on benzodiazepine receptors.

Adult male Fisher 344 rats were injected daily with cocaine HCl (20 mg/kg, ip) or an equivalent volume of saline (1 ml/kg) for 15 days. Twenty minutes following the final injection, the animals were sacrificed by decapitation and the brains were rapidly removed and dissected over ice. The dissected brain regions were stored at -70°C until assay. Saturation experiments were carried out with $[^{3}H]$ Ro 15-1788 to characterize changes in benzodiazepine receptors (i.e., K_d and B_{max} values) resulting from the treatment conditions. The concentration of benzodiazepine receptors (B_{max}; mean fmol/mg protein ± SEM) was significantly increased in the caudate nucleus (397 ± 19 vs 492 ± 39, $p<0.05$; saline vs cocaine treated) and the cerebellum (471 ± 21 vs 544 ± 17, $p<0.05$). In contrast, the concentration of benzodiazepine receptors was slightly reduced in the frontal cortex (876 ± 27 vs 800 ± 15, $p<0.05$) following cocaine treatment. However, cocaine did not affect benzodiazepine receptor binding in the diencephalon, hippocampus or brain stem. No significant changes in K_d values (affinity) were seen in any brain region examined.

The results of this investigation suggest that chronic cocaine administration can differentially affect benzodiazepine receptors in discrete brain regions, although the mechanism of action for this effect is unclear. A potential role for dopamine is currently being investigated.
(Supported by USPHS grant DA04293.)

201.7 VISUALIZATION OF BENZODIAZEPINE AND T-BUTYLBICYCLOPHOSPHOROTHIONATE [(^{35}S)TBPS] BINDING SITES FOLLOWING ANXIOLYTIC AND ANTIDEPRESSANT TREATMENT. B.E. Suranyi-Cadotte, M.J. Meaney, S. R. Bodnoff, F. Lafaille*, M. Dalpé and R. Quirion. Douglas Hospital Research Centre and Dept. of Psychiatry, McGill University, Verdun, Québec H4H 1R3.

Considerable evidence suggests that anxiolytic drug effects are mediated through an interaction with the benzodiazepine (BZ)/GABA receptor/chloride ionophore complex. In addition to the anxiolytic BZ's, several classes of antidepressants are also known to exert anxiolytic effects. Results from our laboratory indicate that chronic administration of tricyclic antidepressants, results in a decrease in BZ receptors. This suggests a possible role for the BZ/GABA receptor-ionophore complex in the actions of both antidepressants and anxiolytics. To extend these results, we investigated the effects of acute and chronic treatment with the benzodiazepine, diazepam, and the tricyclic antidepressant, desipramine (DMI) on BZ receptors and (^{35}S)t-Butylbicyclophosphorothionate (TBPS) binding to the GABA receptor/chloride ionophore in areas of rat brain using quantitative receptor autoradiography. Male Long Evans rats received once daily i.p. injections of either vehicle, or 2 mg/kg diazepam or 10 mg/kg DMI for 1 or 21 days. Four hours after the last injection, animals were decapitated, brains rapidly removed and frozen. Serial sections of brain from control and drug-treated animals were processed for in vitro ^{3}H-flunitrazepam or (^{35}S)TBPS autoradiography as described previously by Young and Kuhar (Nature 280:393-395, 1979) and by Wamsley et al (Life Sci. 33:2321-2329, 1983) respectively. Various brain regions from control and drug-treated animals were compared after acute and chronic treatment using computer-assisted quantitative densitometric analysis. Chronic, but not acute DMI treatment elicited a significant reduction in BZ receptor densities in lateral septum (28%), olfactory tubercle (16%), and CA_3 region of hippocampus (20%). In addition to the above regions chronic diazepam caused decreased BZ binding in several other brain areas, including cortex (20%), n. accumbens (20%) and hypothalamus (24%). DMI, like diazepam produced a significant decrease in (^{35}S) TBPS binding sites (24% and 28% respectively) after chronic treatment. This decrease was observed in the hippocampus, but not in other regions where the drug-induced decreases in BZ receptors occurred. Thus, hippocampal TBPS binding sites, may be an important site of interaction between antidepressants and anxiolytics. These data also indicate that anxiolytic and antidepressant agents are capable of differentially regulating BZ receptors and GABA-gated chloride ionophore binding sites.

201.8 MODULATION OF GLUCOCORTICOID BINDING CAPACITY IN SELECTED BRAIN REGIONS AND PITUITARY OF ADRENALECTOMIZED RATS BY VARIOUS STEROIDS. A. Sarrieau*, W. Rostene, T. Antakly, D.H. Aitken and M.J. Meaney. (SPON: J. Bradwejn). INSERM Unité 55, Paris, France and Departments of Anatomy and Psychiatry and Douglas Hospital Research Ctr., McGill Univ., Montreal, Canada.

Glucocorticoid receptors (GR's) are widely distributed in the rat brain. These receptors bind with high affinity to glucocorticoids, mineralocorticoids, and, to a lesser extent, to progesterone. GR concentrations in brain and pituitary are regulated by endogenous corticoids, such that long-term (>4 days) adrenalectomy (ADX) results in a large (>100%) increase in GR concentrations. In the experiments presented here, we have examined the ability of a wide range of naturally occurring and synthetic steroids to regulate GR concentrations in principle glucocorticoid target regions, including the pituitary hypothalamus, hippocampus, and cortex.

Adult, male Long-Evans rats were ADXed and treated with one of the following steroids for 4 days: RU 28362 (a GR agonist), corticosterone (the principle glucocorticoid in the rat), dexamethasone, progesterone, estradiol, or spironolactone (a mineralocorticoid receptor antagonist). All steroids were dissolved in absolute ethanol and added to the animals' drinking water (0.9% NaCl) to a final concentration of 100 µg/ml. The animals were then sacrificed by decapitation and the frontal cortex, hippocampus, hypothalamus, and pituitary were dissected and frozen on dry-ice. GR binding capacity was measured in soluable fractions using an exchange assay. Cytosol was incubated with 10 nM [^{3}H]dexamethasone for 20 h at 2°C alone or in the presence of a 500-fold excess of cold corticosterone in TEGMD buffer (30 mM Tris, 1 mM Na EDTA, 10 mM Na molybdate, 10% (v/v) glycerol, and 1 mM dithiothreitol; pH adjusted to 7.4). Bound from unbound steroid was separated on Sephadex LH-20 columns.

In all regions examined RU 28362 and dexamethasone decreased [^{3}H]dexamethasone binding (in comparison to ADX + NaCl controls) by approximately 85 and 70%, respectively. In the hippocampus and frontal cortex corticosterone and progesterone produced a 50% down-regulation of [^{3}H]dexamethasone binding, but were less effective (~30%) in the hypothalamus and pituitary. Neither spironolactone nor estradiol influenced [^{3}H]dexamethasone binding in any region examined. These data indicate a region-specific, differential pattern of GR regulation that is consistent with descriptions of two types of GR sites in the rat brain and pituitary. These findings are also discussed in terms of the affinity of the various steroids for the GR sites as well as the ligand-receptor interactions necessary for GR regulation.

201.9 THE OCCURRENCE OF [^{3}H]-IMIPRAMINE BINDING INHIBITOR(S) IN HUMAN BLOOD PLASMA. A. Strijewski*, J. Chudzik* and S.W. Tang. Psychopharmacol. Unit, Clarke Inst. of Psychiat., Toronto, Canada M5T 1R8

In our attempt to isolate the postulated endacoid for [^{3}H]-imipramine (IMI) binding site, platelet-free human plasma was first fractionated according to Cohn. Fractions II/III and VI were found to contain high inhibitory activities of IMI-binding which could be partially attributed to the presence of non-specific plasma protein inhibitions. We observed that various blood plasma proteins (e.g. α_1-acid glycoprotein, α_1-antitrypsin, IgG and lipoproteins) affect imipramine binding to platelet membranes via non-specific ionic or hydrophobic interactions. After separation of non-specific proteins by several chromatographic steps, an additional inhibitory activity, associated with an as yet unidentified protease, was revealed. This enzyme is heat stable, digests casein at pH 7.4 and is inhibited by α_1-antitrypsin. Several synthetic chromogenic peptides were tested as potential specific protease substrates but these experiments failed to provide any positive identification of the protease. However, the presence of thrombin, plasmin, urokinase, or trypsin-, chromotrypsin- and elastase-like protease activity can be excluded. When protease fractions of DEAE-Sepharose chromatography were subjected to further purification by ultrafiltration (PM-10 ultrafilter), followed by Sephadex G-25 and Bio-Gel P-2 gel filtration, a partial separation of IMI-binding inhibitor from protease was achieved. However, the protease fraction still retained a substantial inhibitor activity. TLC analysis of both fractions on cellulose plates showed a complex composition of the analyzed material. At least 8 ninhydrin positive compounds were detected.

Persistent occurrence of the protease and inhibitor in the same fractions at various purification steps raises the possibility of the existence of some kind of protease-inhibitor interaction. It cannot be excluded that the protease itself may modulate the receptor binding site thus altering its binding properties. Further investigation should lead to the purification and identification of the protease and [^{3}H]-IMI binding inhibitor.

201.10 CHRONIC PHENYTOIN TREATMENT DOWN-REGULATES SPECIFIC 3H-PHENYTOIN BINDING SITES IN RAT BRAIN. J. FRANCIS AND L. SPERO. Dept. of Pharmacology, University of Toronto, Toronto Ontario, Canada M5S 1A8.

3H-Phenytoin has been previously shown to have specific, satureable binding to rat, calf and human brain (1,2). The present study was conducted to look at the effects of chronic modulation of these binding sites by phenytoin (PHT). Male Long-Evans rats were treated initially with 25 mg/kg PHT, or its vehicle alone, by intraperitoneal (i.p.) injection once daily for 14 consecutive days. Rats were sacrificed on the 15th day by decapitation and their brains were removed and frozen in dry ice-ethanol until use. Synaptosomal (P2) fraction of whole brain homogenates were assayed for specific 3H-PHT binding, as previously described (1). A second series of rats were treated for 14 days by daily i.p. injections with one of vehicle only or 10 mg/kg, 35 mg/kg, or 50 mg/kg PHT in vehicle. Upon sacrifice, these latter rat brains were dissected into whole cortex and cerebellum (regions previously shown to be high in specific 3H-PHT binding sites) and assayed for specific 3H-PHT binding.

Whole brain, one-site analysis of 3H-PHT binding, using the program LIGAND (3) on an IBM-PC computer, revealed a decreased density of binding sites (Bmax) in the treatment versus vehicle control groups from the first series of rats. There was no change in the binding dissociation constants (Kd) from either group. In the second series of rats, 3H-PHT Bmax was lower in the cortices from the treatment groups versus the vehicle controls while there was minimal change in the cerebellar Bmax's amongst these groups. Kd's in both cortex and cerebellum were not changed in the treatment versus vehicle control groups. There did not appear to be a dose-dependent change in the Bmax's of the three PHT dosage groups.

These results would suggest a down-regulation of specific 3H-PHT binding sites following chronic PHT treatment. In light of the chronic nature of clinical phenytoin therapy, this down-regulation may occur in man and be important to the clinical anticonvulsant actions of PHT.

201.11 CHRONIC LITHIUM TREATMENT REDUCES AGONIST-STIMULATED INOSITOL PHOSPHOLIPID HYDROLYSIS IN RAT BRAIN. T.L. Casebolt* and R.S. Jope, Department of Pharmacology and Neuropsychiatry Program, University of Alabama at Birmingham, Birmingham, AL 35294.

Lithium is widely used as a therapeutic agent for bipolar affective disorders, but its mechanism of action is unknown. Altered catecholaminergic and cholinergic function has been implicated in the etiology of affective disorders and some experimental evidence indicates that lithium may alter the activity of these neurotransmitter systems. Because it has been suggested that inositol phospholipid metabolism may mediate the therapeutic action of lithium, we investigated the effects of chronic dietary lithium on norepinephrine (NE), serotonin (5HT), and carbachol-stimulated inositol phospholipid hydrolysis in rat cortical, hippocampal and striatal slices.

Sprague-Dawley rats were fed either commercial diet or diet containing LiCl (1.696g/kg diet) with ad libitum water and saline for 30 days. After decapitation, brain regions were rapidly removed and cross-chopped cortical, hippocampal, and striatal slices (0.3mm) were rinsed and preincubated in HEPES-bicarbonate buffer containing 10 mM LiCl at pH 7.4 and 37°C for 45 minutes. After incubation with 0.53μM [^{3}H]inositol for one hour, inositol phospholipid hydrolysis was measured by the method of Berridge et al. (Biochem. J., 206: 587, 1982).

Chronic lithium treatment reduced NE-stimulated [^{3}H] MIP production an average of 36% in cortex. Smaller reductions were observed in carbachol and 5HT-stimulated [^{3}H] MIP production, with carbachol being least affected by the treatment. Similar changes were observed in striatum and hippocampus. Incorporation of [^{3}H]inositol into phospholipids was not altered significantly after chronic lithium treatment.

These results demonstrate that chronic lithium treatment alters the activity of receptors coupled to inositol phospholipid hydrolysis, and that adrenergic-mediated inositol phospholipid hydrolysis is affected to a greater extent than either cholinergic or serotonergic mediated responses.

RECEPTOR REGULATION: CHOLINERGIC

202.1 SOLUBLE NON-NEURONAL CELL FACTORS REGULATE RECEPTOR EXPRESSION BY SYMPATHETIC NEURONS AND PC12 CELLS. K.E. Smith*, N.E. Kremer, K. Spiegel and J.A. Kessler (SPON: E. Masurovsky). Depts. of Neurology and Neuroscience, Albert Einstein College of Medicine, Bronx, New York 10461.

Neurotransmitter receptor as well as neurotransmitter phenotypic expression is influenced by the neuronal microenvironment. The present study examines factors which regulate muscarinic and nicotinic receptor development and alpha-bungarotoxin binding in sympathetic neurons and in pheochromocytoma (PC12) cells. Previously we reported that treatment of sympathetic neurons with rat fibroblast conditioned medium (RFCM) simultaneously reduced muscarinic receptor number and stimulated cholinergic transmitter traits such as choline acetyltransferase (CAT). To further characterize actions of RFCM on receptor expression, alpha-bungarotoxin binding and nicotinic receptor (alpha subunit) mRNA levels were examined after treatment. Treatment of sympathetic neurons with RFCM resulted in no change or a slight increase in ^{125}I-alpha-bungarotoxin binding while decreasing muscarinic receptor number (determined by ^{3}H-QNB binding) by at least 50%. RFCM treatment of PC12 cells exposed to NGF elevated alpha-bungarotoxin binding by more than 75% while simultaneously decreasing muscarinic receptor numbers by 65%. The factor mediating these effects on muscarinic binding was heat-labile and had a MW greater than 30kD as determined by Amicon ultrafiltration. Thus RFCM contained a soluble factor(s) which simultaneously decreased muscarinic receptor binding while stimulating alpha-bungarotoxin binding. Using Northern blot analysis and a cDNA clone encoding a neural nicotinic receptor alpha subunit (Boulter et al., 1986) nicotinic receptor mRNA levels were measured after RFCM treatment of sympathetic neurons and PC12 cells. Treatment did not significantly alter levels of the two RNA species in sympathetic neurons which are recognized by this probe. Treatment of PC12 cells with NGF elevated levels of both transcripts by 2-3 fold compared to untreated PC12 cells, but additional treatment with RFCM produced no significant changes. These observations indicate that soluble factors produced by non-neuronal cells may alter the proportions of different receptors expressed by the neuron in a manner analogous to previously described effects of such factors on transmitter expression.

202.2 Differential Regulation of Muscarinic Receptor Subtypes in the Cerebral Cortex by Chronic Tetrahydroaminoacridine Administration. D.D. Flynn, A. Suarez,* A. Cordoves,* and D.C. Mash, Departments of Pharmacology and Neurology, University of Miami School of Medicine, Miami, FL 33101.

Tetrahydroaminoacridine (THA), a potent central acetylcholinesterase inhibitor, is being used in cholinergic replacement therapy for the treatment of senile dementia of the Alzheimer type. Chronic esterase inhibition in rodents leads to a down regulation of total muscarinic receptor numbers. Comparable changes in patients given esterase inhibitors may diminish the efficacy of these agents in degenerative dementias. We have examined the effect of chronic THA administration on muscarinic receptor subtypes in the rat cerebral cortex.

Male Long Evans rats (150-200 g) were injected intraperitoneally with THA dissolved in saline for a minimum of ten days (2.5 mg/kg starting dose, increased in increments to a peak dose of 10 mg/kg). Eighteen hours after the last injection, animals were sacrificed by decapitation and the brains were rapidly removed. Cortical tissue was dissected and homogenized in 50 mM $NaPO_4$ buffer (pH 7.4) containing Na_3EDTA. Membranes were collected by centrifugation and resuspended in the appropriate buffers for assays of total muscarinic receptors and M1 and M2 receptor subtypes. The prevalences of 'uncoupled' M1 and M2 receptors were determined by carbachol-[3H]-quinuclidinyl benzilate (QNB) competition. Carbachol binding to high-and low-affinity pirenzepine sites in the cerebral cortex was also measured in these experiments.

Chronic THA administration resulted in a 20-74% decrease in M1 receptors assayed by [^{3}H]-pirenzepine. This decrease in the number of [^{3}H]-pirenzepine sites was positively correlated with the duration of drug treatment. Carbachol-[^{3}H]-pirenzepine competition revealed no change in the ratio of high-and low-affinity agonist states of the M1 receptor. Total muscarinic receptors showed a 13-20% decrease, whereas M2 receptors, measured directly with [^{3}H]-OXO-M or estimated by carbachol-[^{3}H]-QNB competition, were unchanged.

These results demonstrate a selective regulation of the M1 receptor subtype by chronic THA administration. Down regulation of M1 receptors by chronic agonist occupancy, if accompanied by a reduction in the M1-mediated hydrolysis of phosphoinositides, may lead to diminished efficacy of long-term THA treatment in Alzheimer's disease.

Supported in part by grants from the NIH (#NS 19065-04 and #NS 25785-01).

202.3 PHOSPHOINOSITIDE METABOLISM LINKED TO MUSCARINIC RECEPTORS IN PURIFIED MYELIN. F. GOLLY*, J.N. LAROCCA* and R.W. LEDEEN (SPON W.T. NORTON). Dept of Neurology, Albert Einstein College of Medicine, Bronx, NY 10461.

The original view of myelin as a metabolically inert membrane has undergone radical revision in light of the numerous intrinsic enzymes that have been revealed over the past two decades. These enzymes are involved in lipid metabolism, ion transport, protein acylation, phosphorylation / dephosphorylation etc. Phosphoinositide metabolism in myelin has been reported (Deshmukh and al., J. Neurochem., 36:594, 1981) and recent studies have shown that incorporation of ^{32}P into phosphatidic acid, phosphatidylinositol-4-phosphate and 4,5-bisphosphate (PIP and PIP_2) could be increased in myelin by cholinergic stimulation of brain slices (Kahn and Morell, Trans. Am. Soc. Neurochem. 17:446, 1986). Previous studies of our laboratory (Larocca and al., J. Neurosci., in press) have shown the presence of high affinity muscarinic receptor(s) in purified myelin from rat brainstem. These receptors appear to be linked to both adenylate cyclase and phosphoinositide metabolism. 5'-guanylylimidodiphosphate (Gpp(NH)p), a non metabolisable analog of GTP, decreased the agonist affinity for N-methylscopolamine binding sites in myelin, indicating a linkage to a second messenger system via a G regulatory protein. Treatment of freshly isolated myelin (from rat brainstem prelabeled by intracerebral injection of [^{3}H]-inositol) with carbachol plus Gpp(NH)p resulted in an increase of inositol di- and trisphosphate (IP_2 and IP_3). This increase was more pronounced for IP_3. We found no change in inositol monophosphate, suggesting that only polyphosphoinositides are involved in this phenomenon. This was done in the presence of lithium, known to block phosphatase activity. We have found shorter times of incubation (5 to 15 min) to give better results than longer time (30 min). In the absence of calcium (with EGTA), carbachol plus Gpp(NH)p induced formation of IP_2 and IP_3, but the effect was more prononced with calcium; the response was dose-dependant (10 to 100 nM). We have found that GTP was also effective, but less so than Gpp(NH)p, in increasing formation of IP_2 and IP_3.

These results suggest that some myelin phosphoinositides are functionnaly linked to muscarinic receptor(s) in the myelin membrane and involved in transmission of extracellular signals.

202.4 DOWN-REGULATION OF MUSCARINIC CHOLINERGIC RECEPTORS FOLLOWING SHORT-TERM TREATMENT IN MOUSE NEUROBLASTOMA CELLS IN SUSPENSION. C.L. Cioffi and E.E. El-Fakahany. Department of Pharmacology, University of Maryland, School of Pharmacy, Baltimore, MD, 21201.

We have reported that short-term desensitization of muscarinic receptors in mouse neuroblastoma cells (clone N1E-115) maintained in monolayer results in approximately 50% decrease in the specific binding of the muscarinic antagonist [^{3}H]N-methylscopolamine ([^{3}H]-NMS) and that this receptor population which is highly susceptible to rapid regulation by agonists includes both the pirenzepine high-affinity and the agonist low-affinity receptor conformations (Cioffi and El-Fakahany, J. Pharm. Exp. Ther.,238: 916, 1986). It has previously been suggested that this agonist-sensitive subset of muscarinic receptors might be the receptor subpopulation linked to receptor-mediated increases in cyclic GMP in this same neuronal clone (McKinney et al., Mol. Pharmacol., 27: 223, 1985) The present study was undertaken to determine if down-regulation of [^{3}H]-NMS binding could be observed under the same conditions in which desensitization of the cyclic GMP response occurs.

For the desensitization experiments, mouse neuroblastoma cells were prelabeled with [^{3}H]guanosine, diluted with iso-osmotic HEPES buffer and distributed into conical tubes where the cells were desensitized for 2 to 16 minutes with 1 mM carbamylcholine (CBC) at 37° C. The cells were then centrifuged, washed with HEPES buffer, resuspended and distributed into wells. Cells were then incubated at 37° C for 5 min before stimulation with 1 mM CBC for 30 sec. The time course of desensitization of the cyclic GMP response was very rapid. For binding experiments, cells were also desensitized with 1 mM CBC at 37° C for up to 30 min, harvested and washed. This treatment resulted in a time-dependent decrease in the specific binding of 1 nM [^{3}H]NMS to muscarinic receptors in intact cells measured at 15° C. Scatchard plots of saturation curves using 0.02-1.0 nM concentrations of [^{3}H]NMS in control and desensitized cells resulted in a significant decrease in Bmax in the desensitized cells with no change in the k_d. These results indicate that challenging mouse neuroblastoma cells in suspension with muscarinic receptor agonists elicits both down-regulation of [^{3}H]NMS binding sites and desensitization of receptor-mediated cyclic GMP responses. (Supported by contract #DAAG-29-85-K-0123 from the U.S. Army Research Office).

202.5 MUSCARINIC RECEPTOR REGULATION IN SLICES OF RAT CEREBRAL CORTEX F. Van Huizen*[1], C. Shaw*[1], M. Wilkinson[2], and M.S. Cynader[1] (SPON: R.A. Leslie) [1]Dept. of Psychology and [2]Physiology and Biophysics, Dalhousie Univ., Halifax, N.S., B3H 4J1

Neurotransmitter receptor up- or down-regulation in response to alterations in bioelectric activity or receptor-ligand interactions have been well documented. Down-regulation may involve both receptor internalization and degradation. We have examined regulatory mechanisms of muscarinic acetylcholine receptors (mAChR) in slices of rat cerebral cortex.

Rats were killed by decapitation and the brains rapidly removed and placed in cold Dulbecco's phosphate buffered saline, pH 7.3, to which glucose (1 mg/ml), 0.004% H_2O_2 and Hepes (10 mM) was added (Dulb$^+$). Blocks of neocortex were dissected and sliced at 400 μm. Trypan blue exclusion tests showed that about 30% of the neurons in the 100 μm from each cut edge were dead (approx. 15% of total). Electron microscopy revealed healthy tissue in the middle of the slice, but after several hours in Dulb$^+$, swollen dendrites were seen without cytoplasmic organelles. Axon terminals, however, were still attached to these processes. Electrophysiological single unit recordings showed spontaneous action potentials in these slices.

For receptor binding experiments, slices were incubated in Dulb$^+$ (0.5 ml) containing either [^{3}H]N-methyl scopolamine ([^{3}H]-NMS), a hydrophilic mAChR ligand which does not penetrate the cell membrane, or the lipophilic [^{3}H]quinuclidinyl benzylate ([^{3}H]-QNB). Binding of both ligands was saturable, specific and could be displaced by cold atropine sulphate, NMS and QNB. In these experiments, bioelectric activity of the slices was raised for 2-4 hours at 30°C by either veratridine (10^{-5} M), which increases sodium-channel dependent depolarizations, L-glutamate (10^{-5} M), picrotoxin (10^{-5} M) or high K^+ (50 mM). Increases in neural activity decreased [3H]-NMS labelled mAChR number, with the largest effects seen for veratridine (-28.3±9.6; N=4). This decrease was not accompanied by any change in K_d. [^{3}H]-QNB labelled mAChR number was also lower (-9.8%) following veratridine. This implies an internalization and partial degradation of mACh receptors after this treatment. Stimulation of mAChR by ACh (10^{-5} M) or carbachol (10^{-3} M) also lowered mAChR number. Tetrodotoxin, a blocker of sodium-dependent neural activity, gave an insignificant increase in mAChR number.

The present results suggest that mAChR number is down-regulated following increases in neural activity or agonist activation of the receptor. These data may support the idea that 'rapid' alterations of synaptic responsiveness following altered activity are induced by alterations in receptor number, e.g. inside/outside ratio. (Supported by Killam postdoctoral fellowship to FvH and MRC grants to MW and MSC.)

202.6 ACETYLCHOLINE RECEPTOR mRNA LEVELS ARE INCREASED BY THE CALCIUM IONOPHORE A23187. J.P. Alsobrook II* and J.L. Pinkham** (SPON: C. Scheffey). *Dept. of Human Genetics and **Section of Molecular Neurobiology, Yale Univ. Sch. of Med., New Haven, CT 06510.

The mouse muscle cell line BC3H1 can be induced to exit the mitotic cycle and express acetylcholine receptors (AChR) on the cell surface. Induction is accomplished by allowing cells to grow to confluence or by incubation in low (0.5%) serum media. Levels of receptor subunit mRNAs have been shown to increase after such treatments.

We report that the calcium ionophore A23187 causes an increase in the levels of AChR mRNA. A23187 is known to increase the intracellular availability of calcium. After a 30 minute exposure to 1uM ionophore, BC3H1 cells have a steady-state level of AChR alpha subunit mRNA approximately equal to that seen in 3-day low serum induced cells. After 120 minutes the mRNA level is reduced to that seen in mitotic cells. These results point to calcium as a second messenger in the differentiation of muscle cells. Since the increased AChR mRNA level is not sustained by continuous exposure to ionophore, other signals may be required for maintenance of the differentiated phenotype.

202.7 PARAMETERS AFFECTING THE UP-REGULATION OF BRAIN NICOTINIC RECEPTORS BY DIETARY CHOLINE. B.J. Morley, L.L. Garner*, C. Larsson*, D.L. Fleck*, and C.L. Murrin. Research Division, Boys Town National Institute, Omaha, NE 68131, and the Department of Pharmacology, Univ. of Nebraska Medical School, Omaha, NE 68105.

The administration of dietary choline increases brain acetylcholine levels[1,2] and alters certain post-synaptic events[3,4]. The chronic administration of dietary choline also increases the concentration of nicotinic receptors, as measured by ^{125}I-α-bungarotoxin binding[5]. Several studies were carried out to further describe parameters affecting the increase in nicotinic receptors by dietary choline and to determine the mechanism by which choline produces the up-regulation. The studies indicate that the effect of choline on the concentration of nicotinic receptors (1) is attributable to choline-supplementation rather than choline-deficiency; (2) occurs rapidly (within 24 hrs); (3) is reversible (over a period of days) upon the elimination of choline; (4) is dose-dependent and (5) is age-dependent. Dietary choline affects the concentration of receptors without altering binding kinetics. Dietary choline and lecithin have been ineffective in improving functional improvement or objective cognitive test scores in Alzheimer's disease patients or elderly individuals[6]. One possible reason is that high-affinity uptake sites are decreased in number in these individuals. To test the hypothesis that the effect of dietary choline on the concentration of nicotinic receptors is related to the integrity of the high-affinity choline uptake (HACU) system, we administered intraventricular injections of AF64, a choline analogue that irreversibly blocks HACU, and measured the concentration of HACU sites and the concentration of nicotinic receptors in the hippocampus and cortex. The results of these studies will be presented.

202.8 THE REGULATION OF BRAIN α-BUNGAROTOXIN BINDING SITES BY NICOTINIC CHOLINERGIC AGENTS. C. Larsson*, D.L. Fleck*, and B.J. Morley. Research Division (SPON: G.R. Farley), Boys Town National Institute, Omaha, NE 68131.

Nicotine up-regulates and diisofluorophosphate (DFP) down-regulates high-affinity acetylcholine binding sites in rat brain (Schwartz, R.D. and Kellar, K.J., *J. Neurochem., 45:*427, 1985). Up-regulation of mouse brain α-bungarotoxin (BuTX) receptors was observed following the constant infusion of high doses of nicotine but the administration of nicotine by injection produced no change in the concentration of BuTX binding in rat brain (Marks, M.J., Stitzel, J.A., Romm, E., Wehner, J.M., and Collins, A.C., *Mol. Pharmacol., 30:*427,1986).

We now report the effects of the chronic administration of several cholinergic agents, including nicotine, DFP and mecamylamine, on the concentration of rat brain BuTX receptors. Drugs were administered by injection or osmotic mini-pumps in several doses and for several time periods.

The lowest effective dose of nicotine (tartrate) was 3.0 mg/kg/day administered in 2 injections. The effect was observable within 3 days of administration. Upon withdrawal of nicotine, the concentration of receptors returned to baseline in approximately 24 hrs in most brain areas. There was some evidence for a re-bound effect (decreased receptor concentration) in certain areas upon the withdrawal of nicotine.

DFP reliably decreased the concentration of BuTX binding sites in the cortex but not in the hypothalamus nor hippocampus. The effect was reversible upon the withdrawal of DFP treatment.

Mecamylamine affected the concentration of BuTX receptors in a complex manner, apparently depending upon dose, length of of treatment, and type of administration (injection or mini-pump).

REGULATION OF AUTONOMIC FUNCTION III

203.1 ORGANIZATION OF VISCERAL SENSORY THALAMUS IN THE RAT. D.F. Cechetto and C.B. Saper, Department of Pharm. & Physiol. Sci. and Neurology, University of Chicago, Chicago, IL 60637.

The insular cortex of the rat contains a topographically organized visceral representation. We have studied the organization of its thalamic relay nuclei by injecting antero- and retrograde tracers at physiologically characterized sites in cortex and thalamus.

Injections of WGA-HRP at the sites of neurons in the dysgranular insular cortex that were selectively responsive to gustatory stimulation resulted in anterograde and retrograde labeling in the ventroposterior medial parvicellular (VPMpc) thalamic nucleus. Injections into cardiopulmonary responsive sites in the posterior granular insular cortex resulted in labeling in a parvicellular region, lateral to VPMpc, along the surface of the medial lemniscus, that we term the ventroposterior lateral parvicellular (VPLpc) nucleus.

Injections of WGA-HRP or fluorescent dyes into VPMpc and VPLpc have confirmed their complementary relationship to the different subfields of insular cortex. In addition, these experiments confirmed our earlier reports that the ventrobasal thalamus receives ascending afferents from the medial and ventrolateral parabrachial subnuclei. Injections of anterograde tracers (PHA-L and tritiated amino acids) into the parabrachial nucleus showed that the projection to the visceral thalamic relay nuclei originated primarily from the contralateral external medial subnucleus. Within this cell group, the rostrodorsal portion projected primarily to VPMpc and the caudoventral part to VPLpc. The remainder of the parabrachial-thalamic projection was mainly directed at the intralaminar nuclei that are adjacent to the visceral relay nuclei.

Recordings of single units in the VPLpc confirm that they are selectively responsive to cardiopulmonary (but not somatic sensory) stimulation. Our results indicate that there is a continuum of parvicellular neurons along the medial lemniscus that is viscerotopically organized for the relay of special and general visceral afferent information to the insular cortex. Earlier studies of this system may have overestimated the extent of the parabrachial input to the thalamic relay nuclei, and overemphasized the gustatory representation compared to the other visceral modalities.

203.2 PEPTIDERGIC PROJECTIONS FROM THE NUCLEUS OF THE SOLITARY TRACT TO THE PARABRACHIAL NUCLEUS. H. Herbert, M.M. Moga, C.B. Saper, Dept. Pharm. & Physiol. Sci., University of Chicago, 947 E. 58th Street, Chicago, IL 60637

The parabrachial nucleus (PB) is the main relay for ascending visceral information from the nucleus of the solitary tract (NTS) to the forebrain. The NTS consists of a number of anatomically and functionally discrete subnuclei. Neurons in the rostral (r) NTS respond to gustatory stimulation, those in ventrolateral (vl) NTS are driven by pulmonary stimuli, and those in medial (m) and commissural (c) NTS respond to cardiovascular and gastrointestinal afferents.

Using anterograde and retrograde axonal tracers, we found previously that the functional specificity of the NTS is maintained in its projections to PB by the selective termination of the fibers in particular PB subnuclei. Briefly, rNTS was found to project to parts of the medial PB, particularly to the caudal portions of PB around the dorsomedial end of the superior cerebellar peduncle (waist area); vlNTS is reciprocally connected with the Kolliker-Fuse nucleus of PB, and also innervates part of the adjacent external lateral PB subnucleus; finally mNTS and cNTS project to a distinct terminal field involving parts of the external and central lateral PB and a second small field in dorsal lateral PB.

We now report the results of experiments combining retrograde (Fast Blue) and anterograde (PHA-L) tracing with immunohistochemistry to examine the neuropeptide specificity of some of these connections. In addition to SOM-, CCK-, APP-, ENK-, NT-, SUB P-, TH- and DBH- like immunoreactivity (li) that have previously been identified in the projection from mNTS and cNTS to PB (Manthy & Hunt '84, Milner et al. '84, Milner & Pickel '86a, b), we have found GAL-, AII- and NPY-li in this system. These neuropeptides may allow chemical coding in relaying specific types of visceral information to PB.

(H. Herbert is a recipient of a DAAD/NATO Research Training Fellowship)

203.3 PROJECTIONS OF THE CANINE PARABRACHIAL COMPLEX. C.H. Block, C.L. Chernicky and C.M. Ferrario. Department of Brain and Vascular Research, The Research Institute of The Cleveland Clinic Foundation, Cleveland, OH 44106.

The parabrachial nuclear complex (PB) is a pontine structure that is involved in the regulation of autonomic and chemosensory function. In the rat, afferent input to the PB has been demonstrated from the dorsomedial medulla, a site that functions in autonomic regulation and includes the nucleus of the tractus solitarii (nTS), the area postrema, and the dorsal motor nucleus of the vagus. In addition, cells in the PB project to the periventricular preoptic/hypothalamic area (PV), a forebrain region involved in hydromineral balance. The present study was designed to determine the anatomical relationship of the PB with the dorsomedial medulla and PV in the dog.

Microinjections of wheat germ agglutinin (WGA) were placed in the PV of 3 mongrel dogs. In these same animals, cholera toxin-horseradish peroxidase (HRP) was microinjected into the area postrema. The animals survived 48-72 hours, at which time they were perfused with a solution of picric acid, paraformaldehyde, and glutaraldehyde. Frozen sections were cut in the coronal plane at 30 μm and processed for histochemical localization of HRP and immunocytochemical localization of WGA. Projection fields were analyzed microscopically and mapped with an X-Y plotter interfaced to the microscope stage.

Injections of HRP into the area postrema resulted in local labeling of fibers and scattered cells within both the area postrema and the adjacent medial nTS. No retrograde or anterograde label was observed elsewhere in the brain. Injections of WGA into the PV resulted in a label of a distinct population of neurons in the dorsolateral aspect of the PB bilaterally. Scattered neurons were observed within the medial PB, the dorsal cap of the brachium conjunctivum, and in the adjacent locus coeruleus.

These results suggest that efferent projections from the area postrema do not extend beyond the medial aspect of the dorsomedial medulla and also do not include the PB. Although the present findings are consistent with the results from fiber degeneration studies in the dog by Chernicky et al., (1979) and Morest (1967) in cat, they are not consistent with the observation of abundant area postrema input to the PB in the rat (Shapiro and Miselis, 1985). In contrast, the distribution of PB cells that project to PV is similar to that reported in the rat by Block, et al.,(1984). From these anatomical observations it appears that the canine PB can influence sites in the forebrain that are critical to hydromineral balance.

(Supported by NIH grants HL-37927 and HL-6835).

203.4 PROJECTIONS OF THE PERIVENTRICULAR HYPOTHALAMIC/ PREOPTIC REGION IN THE CANINE BRAIN. C.L. Chernicky, C.H. Block and C.M. Ferrario. Department of Brain & Vascular Research, Research Institute of The Cleveland Clinic Foundation, Cleveland, OH 44106

The periventricular region of the anterior portion of the third ventricle (PV) is critically involved in hydromineral balance. Lesions of specific periventricular nuclei result in hypernatremia, adipsia, and a reduction of the pressor response to intravenous infusion of angiotensin II (Lopes et al., 1986). Since little is known of the interrelated connections of this region in the dog, the present anatomical study sought to examine the afferent projection field of the PV region.

Wheat germ agglutinin alone (WGA) or coupled to horseradish peroxidase (HRP) was injected into the PV of 3 mongrel dogs. After 48 hours, the animals were perfused and the tissue was cut at 30 μm and processed for HRP or WGA and for immunocytochemical localization of the catecholamine-synthesizing enzymes, tyrosine hydroxylase (TH) and phenylethanolamine-N-methyl transferase (PNMT). The location of these cells was mapped using an X-Y plotter interfaced to the microscope stage.

Injections of WGA or HRP placed in the PV region resulted in a retrograde filling of neurons in the forebrain, mesencephalon, pons, and medulla. Specifically, retrogradely-labeled neurons were found ipsilaterally within the bed nucleus of the stria terminalis, lateral septum, medial amygdaloid nuclei, nucleus medianus, and medial preoptic area. In the mesencephalon, bilateral retrograde labeling was found in the peripeduncular region, however the ipsilateral label was more intense. In the pons, retrogradely-labeled cells were observed bilaterally in the dorsolateral aspect of the parabrachial nucleus. Scattered retrogradely-filled neurons were found within the locus coeruleus, medial parabrachial nucleus, and the dorsal cap of the brachium conjunctivum. Of these, only a few cells within the medial parabrachial nucleus also contained TH immunoreactivity. In the medulla, retrogradely-labeled neurons were found within the dorsal motor nucleus of the vagus and the medial nucleus tractus solitarii. Several of these neurons also contained TH. Scattered cells within the ventral aspect of the medulla were found to project to the PV and contain either TH or PNMT. In addition, a population of retrogradely-labeled cells was located in the medullary reticular formation, extending dorsoventrally between the hypoglossal nucleus and the nucleus ambiguus.

These results demonstrate a diverse afferent input to the PV of the dog from both forebrain and brainstem regions that are involved in autonomic and chemosensory regulation. Additionally, it appears that the brainstem afferents to the PV may contain catecholamines. These pathways may provide the anatomical substrates through which brainstem structures influence forebrain mechanisms of fluid balance.

(Supported by NIH grants HL - 6835 and HL - 37927).

203.5 PROJECTIONS OF THE RAT CENTRAL NUCLEUS OF THE AMYGDALA TO THE VENTROLATERAL MEDULLA. R.L. Thompson* and M.D. Cassell* (Sponsored by J.R. West). Dept. of Anatomy, Univ. of Iowa, College of Medicine, Iowa City, IA 52242.

The central nucleus of the amygdala (CNA) is known to project to autonomic areas of the brainstem including the parabrachial nucleus, the dorsal motor nucleus of the vagus (DVN) and the nucleus tractus solitarius (NTS). Though the anatomical data suggest a predominantly parasympathetic relationship for the CNA, physiological studies indicate a strong sympathetic component in its role in autonomic regulation. The CNA does not appear to project to preganglionic sympathetic neurons in the spinal cord, and sympathetic components of CNA function may be mediated via intermediate cell groups in the brainstem. The present study is part of a series of experiments designed to determine anatomical relationships between the CNA and sympathetic structures in the brainstem. One area of the brainstem whose connections with the CNA have not been studied in detail is the A1 catecholaminergic cell group in the medulla. Small injections of 0.05μl of either bisbenzimide or Fast Blue were made in the region of the A1 catecholaminergic cell group in male Sprague-Dawley rats. The animals were sacrificed after appropriate survival times and the brains and brainstems were removed and sectioned. The injection sites were found to be confined to the ventrolateral medulla and did not infiltrate the NTS/DVN or the nucleus ambiguus. In the CNA, retrogradely labeled cells were located throughout the rostrocaudal extent of the nucleus and were restricted to its medial part. Comparing the distributions of labeled neurons with counterstained material indicates that almost all of the neurons are confined to the medial subdivision of the CNA. The distribution pattern of CNA-ventral medulla neurons was compared to the distribution pattern of neurons labeled following bisbenzimide or fast blue injections into the NTS/DVN. CNA neurons projecting to the dorsal medulla were found not only in the medial subdivision but in considerable numbers in the lateral and ventral subdivisions. The results indicate that the distributions of CNA neurons projecting to the dorsal or ventral medulla are different but overlap in the medial subdivision. This may indicate a common innervation of both populations by afferents ending in the medial subdivision but suggests that a sizeable proportion of CNA neurons projecting to the dorsal medulla may be innervated by different afferents. This may represent an important anatomical substrate by which parasympathetic and sympathetic components of CNA function are affected differentially. (Supported in part by BRSG RR05372 from NIH.)

203.6 CORTICOSTERONE-INDUCED NUCLEAR LOCALIZATION OF GLUCOCORTICOID RECEPTORS IN CA1 NEURONS OF ADRENALECTOMIZED RATS: AN ULTRASTRUCTURAL ANALYSIS. C. Gonzales*, J.-Å. Gustafsson*, B. Nathan*, K. Fuxe and M. Kalia (SPON: W.H. Vogel). Dept. of Pharmacology, Thomas Jefferson Univ., Philadelphia, PA 19107(CG, BN, MK); Dept. of Medical Nutrition, Huddinge Univ. Hosp., Huddinge, Sweden (J-ÅG); Dept. of Histology, Karolinska Institute, Stockholm, Sweden (KF).

Light microscopic examination of a number of regions of the telencephalon and diencephalon of the adrenalectomized rat by means of a monoclonal antibody raised against glucocorticoid receptors (GR) has demonstrated that GR translocate from the cytoplasm to the nucleus in the presence of exogenously administered corticosterone (Fuxe et al, '85). A recent study by McEwen et al ('86) has demonstrated that receptors for adrenal steroids in the hippocampus are negatively regulated by corticosterone. The glucocorticoid receptors appear to be unique in their ability to translocate from the cytoplasm to the nucleus in the presence of their target hormone (corticosterone) since recent studies on the estrogen receptor have yielded negative data regarding the translocation hypothesis (King and Greene, '84; Welshons et al, '84). A crucial step in understanding the mechanism of action of steroid receptors in general is the "activation process," ie, the process whereby steroid receptors acquire the ability to bind to cell nuclei or DNA leading to their involvement in the regulation of gene expression. Although some differentiation of nuclear vs. cytoplasmic labeling is possible with high magnification light microscopy, definitive details of the localization of glucocorticoid receptors in the nucleus or the cytoplasm under different conditions can be revealed only with electron microscopy. We examined the ultrastructure of the CA1 region of the hippocampus of bilaterally adrenalectomized (ADX) rats (3 days post-ADX) with and without corticosterone treatment (10 mg/kg injected IP) administered 2 to 4 hours prior to perfusion. Non-corticosterone treatment was achieved by injecting an equal volume of the vehicle IP. The acrolein fixation protocol of Pickel ('85) (acrolein 3.75% in 2% paraformaldehyde in phosphate buffer) was used. Control studies in sham operated animals were included in each experimental series. Serial 50 μm thick vibratome sections of hippocampus were incubated in different (serial) dilutions of a mouse monoclonal antibody raised against molybdate-stabilized glucocorticoid receptors (Okret et al, '85). We analyzed tissue immunoreacted with 1:8000 dilution of the GR antibody and used the biotin/avidin system for demonstration of positive immunoreactivity. No colchicine pretreatment nor the addition of Triton X-100 to increase the immunoreactivity and penetration of the antibody, respectively, was used. Serial 70-80 μm ultrathin sections on formvar-coated slot grids were examined under a JEOL 100CX electron microscope with an accelerating voltage of 60 volts.

Intense GR positive immunoreactivity was detected in the nuclei of cells in the CA1 region of the hippocampus of adrenalectomized rats treated with corticosterone. Adrenalectomized rats without corticosterone treatment (vehicle treated) showed nuclei without any GR positive immunoreactivity. Sham operated animals appeared similar to corticosterone treated animals. These results demonstrate that corticosterone induces the localization of glucocorticoid receptors within the nucleus of CA1 neurons. In the pyramidal layer of the CA1 region GR positive immunoreactivity was limited to the pyramidal cells which had the following ultrastructural characteristics: large central nuclei with a completely smooth contour, prominent nucleoli and nuclear inclusions; the average nuclear-cytoplasmic ratio was 1.7:1; the cytoplasm contains a number of arrays of rough endoplasmic reticulum, lysosomes, a well-developed Golgi apparatus, free ribosomes, multivesicular bodies, scattered mitochondria and agranular vesicles. A number of small axon terminals containing clear, round vesicles (6 per ultrathin section) made synaptic contact with the somal surface. (Supported by USPHS Grants HL30991, HL31997, HL33632 to MK.)

203.7 ASCENDING AXONAL PROJECTIONS OF THE NUCLEUS TRACTUS SOLITARIUS IN THE PIGEON. M. L. Berk. Dept. of Anatomy, Marshall Univ. Sch. of Med., Huntington, WV 25704.

The nucleus tractus solitarius (NTS) has an important role in integrating peripheral autonomic inputs. In the pigeon, the visceral afferent fibers to the NTS are partially segregated to specific NTS subnuclei (Katz and Karten, '83). In this study, the NTS projections by which visceral sensory information can be relayed to the forebrain and pons was investigated by the anterograde transport of WGA-HRP. Injections (5-10nl) of 2 percent WGA-HRP were placed at several rostral-caudal levels of NTS. Anterogradely labeled fibers leave NTS by coursing ventrolaterally into the plexus of Horsley in the medullary lateral reticular formation. At pontine levels, a great number of fibers sweep dorsally into the parabrachial region (PB). Many of these fibers appear to terminate within the medial part of the PB. Labeled NTS fibers ascend into the midbrain tegmentum and enter the medial forebrain bundle in the posterolateral hypothalamic area (PLH). These fibers are interspersed amongst PLH neurons, which have descending projections to NTS. A dense, oval shaped field of axonal termination is located in the posteromedial hypothalamus just ventrolateral to the paraventricular organ. The NTS fibers in the medial forebrain bundle ascend into the ventral basal telencephalon and terminate amongst the cells of the bed nucleus of the stria terminalis - ventral striatum, which also have descending projections to NTS. Labeled NTS fibers also course into the periventricular zone of the anterior hypothalamus - preoptic area, where fibers were found amongst the cells of the avian homologue of the paraventricular nucleus. The majority of NTS fibers pursue an ipsilateral course, although contralateral projections were observed including projections to the contralateral NTS.

The NTS perikarya of origin of the projections to the PB and basal forebrain were determined by the retrograde axonal transport of WGA-HRP. All basal forebrain nuclei and PB are mostly innervated by NTS perikarya within subnuclei medialis superficialis (pars posterior) and the part of NTS caudal to the obex. Visceral sensory input to subnucleus medialis superficialis has not been described, while the caudal NTS could act as a relay of esophageal and gastric information. A few cells in the NTS subnucleus lateralis dorsalis (pars posterior) were labeled. This subnucleus could act as a relay for baroreceptive information to the basal forebrain and PB. In addition, the lateral PB receives fibers from a few cells of the lateral parasolitary subnucleus. This pathway could provide a relay for pulmonary information to the PB. 203.8 THE EFFECT OF REDUCING THE SODIUM CONCENTRATION INTO THE III CEREBRAL VENTRICLE ON THE RENAL EXCRETION OF SODIUM AND WATER IN THE RAT. A. Guevara-Rojas*, P. Vergara-Aragón*, M.P. Rosas-Arellano*, and B. Barrera-Mera. (SPON: Dr. J. Roig-Varela). Dept. of Physiology. Fac. of Medicine. U.N.A.M. Apdo. Postal 70250, 04510 México, D.F.

Evidence provided by several experimental groups indicates the existence of hypothalamic receptors which respond to variations in the extracellular concentration of sodium. For some authors these are osmoceptors involved in the regulation of the water intake, — while for us, these sodium sensors are part of an antinatriuretic mechanism specifically in charge of the bodily sodium contents.

To solve the doubt we planned to study the effect on the sodium and water renal excretion of a transient reduction of the sodium - concentration into the III cerebral ventricle (III CV), preferably without any osmolar change.

Female Wistar rats of 250-300 g. of body weight (b.w.), with a chronically implanted canula into the III CV and another into the bladder were used. They had free access to water and food until the begining of the test. During the test, they remained quietly resting, conscious and unrestrained. Their urine was collected in 15 min. periods and after the 2 initial ones, a water load (3% - b.w.) was generally given to maintain a convenient urine flow. At the end of one or two more periods, 5µl of isotonic glucose solution or distilled water were injected in 12 min. into the III CV. The urine volume, very small in the control periods, usually began to increase before the end of the first experimental period, after the water load was given. This increase frequently coincided with a marked increase of the sodium and chloride excretion which, like the urine volume, was proportional to the rat's ingestion of food and water before the test. In 15-30 min. this rise reached its -- maximum and then decreased. The III CV injection, especially that of distilled water, always was immediately followed by a fall of the sodium and chloride excretion rates to values lower than those of the control periods, but without change in the water diuresis. We interpret this intense antinatriuresis as the response of the hypothalamic sodium sensing mechanism to a sudden decrease of the extracellular sodium concentration, in order to preserve the bodil sodium contents, as we had postulated.

203.9 EFFECTS OF INTRACEREBROVENTRICULAR COLCHICINE ON ARTERIAL PRESSURE AND BRAIN CYTOCHROME OXIDASE ACTIVITIY IN NORMO- AND HYPERTENSIVE RATS. T.L. Krukoff and D. Vincent*. Dept. of Anatomy and Cell Biology, Faculty of Medicine, Univ. of Alberta, Edmonton, Canada. T6G 2H7.

Intracerebroventricular (i.c.v.) colchicine injection facilitates immunohistochemical localization of neuropeptides in neurons. Little is known, however, about the physiological effects of this procedure. We have studied the effect of i.c.v. colchicine on arterial pressure (AP) in normotensive Sprague-Dawley (SD) and Wistar Kyoto (WKY) rats and in spontaneously hypertensive rats (SHR); its effects on cellular metabolism in brain were also assessed by cytochrome oxidase (COX) histochemistry. APs of SD, WKY, and SHR were measured for three consecutive days using standard tail cuff techniques. Rats were anesthetized (sodium pentobarbital, 40 mg/kg i.p.) and 70 ug colchicine in 20 µl saline were injected into the right ventricle of the brain. APs were measured 1 and 2 days after injection. Rats were then reanesthetized and perfused through the heart with 50 ml saline and 200 ml Zamboni's fixative. Brains were removed, frozen, sectioned in a cryostat (50 µm), and prepared for COX histochemistry (Krukoff et al., Brain Res. 280: 160, 1983). Pre-injection AP values (mm Hg, mean ± S.E.) were: SD, 140 ± 2 (n=9); WKY, 156 ± 2 (n=14); SHR, 195 ± 3 (n=11). As there were no differences in measurements made 1 or 2 days after injection, these values were combined. Post-injection values were: SD, 124 ± 5; WKY, 133 ± 4; SHR, 145 ± 8. These values were all significantly lower than pre-injection values and reductions were greatest in the SHR. As colchicine blocks axonal transport and may affect neural transmission, these results support the hypothesis that the CNS is at least partly responsible for maintaining elevated AP in the SHR. Colchicine-induced cellular changes assessed by COX histochemistry were similar for all strains: neurons in the paraventricular and supraoptic nuclei of the hypothalamus, nucleus circularis, and the dorsal motor nucleus of the vagus were shrunken and more intensely stained for COX than in controls. Colchicine induces mitochondria to migrate to the perinuclear cytoplasm in placental cells 'in vitro' (Addai & Ockleford, J. Anat. 147: 219, 1986); similar factors may explain the changes in neuronal COX activity as COX is a mitochondrial respiratory enzyme. Why only select groups of neurons undergo these changes is not known. These results suggest that i.c.v. injection of colchicine has widespread physiological effects in the CNS and that caution should be exercised in interpreting results obtained after its use.

203.10 **VASOPRESSIN INHIBITS SYMPATHETIC GANGLIONIC TRANSMISSION BUT POTENTIATES SYMPATHETIC NEUROEFFECTOR RESPONSES IN HINDLIMB VASCULATURE OF RABBITS.** K.P. Patel and P.G. Schmid. V.A. Med. Ctr., C.V. Ctr., & Dept. Int. Med., Univ. of Iowa, Iowa City. IA 52240.

Vasopressin (AVP) has been shown to modify sympathetic nervous system responses. However, the site (sympathetic ganglia, sympathetic terminals, or sympathetic adrenergic receptors) of action of AVP is not clear. In addition the AVP receptor or receptors (V_1 or V_2) involved in this response is/are not identified. To determine whether AVP affects vasoconstrictor responses to electrical stimulation of sympathetic nerves or intra-arterial norepinephrine (NE), changes in perfusion pressure were measured during lumbar sympathetic nerve stimulation (LSNS, 1-8 Hz), or administration of NE (50 - 200 ng), in an isolated constant-flow perfused hind limb of chloralose anesthetized rabbit (n=7) before and after intra-arterial infusion of AVP (0.65 mU/Kg/min). At this dose AVP produced an increase in perfusion pressure of 5.3 ± 0.9 mm Hg and no detectable changes in systemic arterial pressure or heart rate. AVP significantly potentiated responses to LSNS (relative potency (RP) = 1.59) and to NE (RP = 5.17). The potentiation of LSNS and NE to AVP infusion was abolished by AVP antagonist ($d(CH_2)_5[Tyr(Me)^2]$AVP, 400 ng) (n = 6).

Since there was a significant difference between the RP of LSNS (stimulation of both preganglionic and postganglionic nerves) and NE (direct effect on the vascular smooth muscle), we reasoned that this difference might represent disparate actions of AVP on the ganglia and sympathetic neuro-effector sites. To evaluate responses to stimulating only the postganglionic sympathetic nerves, we repeated the above study in animals with ganglionic blockade (hexamethonium - 25 mg/kg, supramaximal dose for ganglionic blockade). After ganglionic blockade the responses to LSNS were reduced to 22% of control. In the presence of ganglionic blockade, AVP potentated responses to LSNS (RP = 4.09) (n = 6). Potentiation was not different for postganglionic LSNS and NE.

We draw the following conclusions from these data: 1) AVP potentiates vasoconstrictor responses to LSNS and NE, 2) AVP mediated potentiation of vasoconstrictor response to these stimuli is mediated via V_1 receptors, 3) AVP seems to have disparate actions ie., inhibition at the sympathetic ganglia and potentiation at the neuro-effector site.

203.11 PARTICIPATION OF ALPHA$_2$ ADRENOCEPTORS AND VASOPRESSIN IN CARDIOVASCULAR RESPONSES INDUCED BY CENTRAL ANGIOTENSIN II IN RATS. L.C. Lopes*, W.A. Saad, L.A.A. Camargo*, A. Renzi*, L.A. De Luca Jr.*, J.V. Menani*, H. Milani* and William A. Saad*. Dep. of Physiology and Pathology. Faculty of Dentistry, UNESP, Araraquara, SP, 14.800 and Dep. of Surgery, Faculty of Medicine, USP, São Paulo, SP.

Intracerebroventricular (ICV) injection of angiotensin II (AII) produces an increase in mean arterial pressure (MAP) and heart rate (HR). In a recent communication we demonstrated that adrenodemedullation reduces the pressor effect, whereas previous treatment with guanethidine prevents the tachycardia due to ICV AII injection. In this study we investigated the influence of previous treatment with prazosin* or arginin vasopressin antagonist (AVPa) on the MAP and HR increase caused by AII injected ICV. Holtzman rats with delay cannulae implanted into the lateral ventricle had the jugular vein and femoral artery cannulated. Twenty minutes after intravenous injection of the antagonist, AII was injected ICV and MAP and HR were recorded. Intravenous injection of prazosin (0.5 mg/kg) reduced the MAP of rats (n=10) from 110 ± 2 mmHg (control) to 92 ± 2 mmHg, whereas HR was increased from 395 ± 17 bpm to 488 ± 12 bpm. The increase in MAP by ICV injection of AII (12 ng) after intravenous injection of prazosin (8 ± 2 mmHg) was smaller than that observed in control before prazosin (14 ± 2 mmHg). The tachycardic response to ICV injection of AII was not modified by prazosin (HR increased by 20 ± 10 bpm in control versus 17 ± 10 bpm after prazosin). Intravenous injection of AVPa (10 µg/kg) also reduced the pressor response produced by ICV injection of AII (12 ng) from 14 ± 1 mmHg in control to 5 ± 1 mmHg after AVPa treatment (n=7). The tachycardia observed with ICV injection of AII before AVPa (11 ± 7 bpm) was not altered after AVPa treatment (10 ± 3 bpm).The basal values of MAP (107 ± 4 mmHg) and HR (346 ± 15 bpm) was not altered by AVPa treatment. The results demonstrated that vasopressin and α_2-adrenergic receptors participate in the pressor response induced by centrally injected AII, but neither participate in the tachycardic response.

203.12 HISTAMINE AND EPINEPHRINE MICROINFUSIONS INTO THE PARAVENTRICULAR NUCLEUS CAUSE HYPERGLYCEMIA IN RATS. M.W. Gunion, S. Miller*, B. Butler*, and B. Shryne*. GRECC, Sepulveda V.A. Med. Ctr., Sepulveda, CA 91343.

Histamine has recently been localized in neurons of the paraventricular nucleus of the hypothalamus, which is thought to be involved in glucoregulation. Epinephrine terminals have also been located in this region. To determine if paraventricular histaminergic neurons and adrenergic terminals may be involved in central glucoregulation, histamine and epinephrine were microinfused into the paraventricular nucleus, and their effects on circulating glucose determined.

After 24 hr food deprivation, male Sprague-Dawley rats (225-350 g; Hilltop) were anesthestized with enflurane-methoxyflurane and given bilateral microinfusions of histamine (0, 10, 100 nmol/rat) or epinephrine (0, 10, 30, 100 nmol/rat) into the paraventricular nucleus or caudate-putamen (0.5 ul/1.0 min/side). Blood samples (120 ul) were taken from the tail tip immediately prior to anesthetization and 15, 30, 60, 90, and 120 min postmicroinfusion.

Microinfusion of histamine into the paraventricular nucleus caused mild hyperglycemia which was not statistically significant until 60 min postmicroinfusion (10 nmol=+23, 100 nmol=+25 mg/dl, both p .05). Hyperglycemia was still present at 120 min postmicroinfusion after the 100 nmol dose (+17 mg/dl, p .05). Epinephrine caused significant hyperglycemia at 15 min postmicroinfusion when given into the paraventricular nucleus (10 nmol=+43, 30 nmol=+43, 100 nmol=+58 mg/dl, all p .01). Statistically significant hyperglycemia was still present at 90 min only at the highest dose (+20 mg/dl, p .01), and was not present at any dose at 120 min (all p .05). Neither histamine nor epinephrine microinfusion into the caudate-putamen had any significant effect on blood glucose levels (both p .05).

The results suggest that histaminergic neurons and adrenergic terminals in the region of the hypothalamic paraventricular nucleus may be involved in glucoregulation.

203.13 HYPERGLYCEMIA EVOKED BY CENTRAL INJECTION OF EPINEPHRINE IS LINKED TO A NICOTINIC MECHANISM IN RAT BRAIN. L. Console and R.F. Orzechowski*. Phila. College of Pharmacy and Science, Phila., PA 19104.

We previously reported that central injections (intracerebroventricular, ICV) of epinephrine (EPI) evoke dose-related hyperglycemia in both conscious and anesthetized rats (Fed. Proc. 46 (3):699, 1987). In the present study, we used ganglionic blocking drugs and adrenergic antagonists to explore possible mechanistic aspects of this phenomenon. EPI was centrally injected into conscious, freely moving rats that had been pretreated either centrally or peripherally (intraperitoneal injection, IP) with one of the ganglionic or adrenergic blockers.

Central drug injections were made via stainless steel (30 gauge) cannulae stereotaxically implanted in the right lateral cerebral ventricle. Drugs were given at the following doses in a volume of 3ul: EPI (50 nmol), hexamethonium (83 nmol), propranolol (34 nmol) and tolazoline (51 nmol). Peripheral (IP) pretreatment with ganglionic blockers (hexamethonium, 8 mg/kg or mecamylamine, 5 mg/kg) involved repetitive dosing, 15 and 5 minutes prior to and 60 and 90 minutes after EPI injection, to maintain continuous ganglionic blockade.

Peripherally administered mecamylamine, but NOT hexamethonium, abolished EPI-induced increases in plasma glucose. Centrally administered hexamethonium also completely prevented the hyperglycemic response to ICV EPI. Hexamethonium, unlike mecamylamine, is a quaternary amine which does not readily cross the blood-brain barrier. Therefore, blockade of the EPI-induced hyperglycemic reaction by IP administration of mecamylamine may be a centrally mediated effect.

Preliminary data from experiments with adrenergic antagonists suggest that ICV injections of either the beta-blocker propranolol or the alpha-blocker tolazoline only partly suppress EPI-induced hyperglycemia. Neither caused abolishment of the response as was observed when rats were pretreated with ganglionic blockers. The results of this study suggest a link between central adrenergic and central nicotinic mechanisms in the mediation of EPI-induced hyperglycemia in conscious rats.

203.14 IMPAIRED GLUCOSE TOLERANCE IN RATS WITH SUBSTANTIA NIGRA LESIONS. B.J. Davis, S.E. Hawes*and T.H. McNeill. Departments of Neurology and Neurobiology and Anatomy, Univ. Rochester School of Medicine and Dentistry, Rochester, New York, 14642.

Previous studies showed that bilateral lesions of the substantia nigra (SN) in rats led to reduced pancreatic islet volume due to impaired growth of the insulin-producing B cells (Davis and Smith, 1984, 1985). In the present study, we asked whether loss of dopamine (DA) cells in the SN was associated with altered insulin responses to glucose or to impaired glucose tolerance. Young adult male Sprague-Dawley rats were food restricted preoperatively and were given limited access to a high fat diet postoperatively to minimize lesion-associated decrements of body weight as described previously. SN lesions were produced by stereotaxic injection of 6-hydroxydopamine (6-OHDA) into the SN bilaterally (12ug/hemisphere).Sham operated rats underwent identical dietary and surgical manipulations except that no drug was injected. Insulin responses to intravenous glucose (40mg in 0.5ml saline) and intragastric glucose tolerance tests (150mg/100gm body weight) were administered to separate groups of rats 3-10 weeks following surgery. Basal levels of glucose, insulin and glucagon were determined at the time of sacrifice. Brains were processed for formaldehyde-induced fluorescence (FIF) or for tyrosine hydroxylase immunocytochemistry (TOH-ICC) to determine the extent of loss of DA cells in the SN.

Compared with sham operated rats, rats that received intranigral 6-OHDA showed bilateral reductions of DA cells as revealed by a loss of TOH immunoreactive or fluorescent perikarya and processes in the zona compacta of the SN. Reductions of DA cells were most pronounced in the caudal and medial aspects of the SN. Consistently the extent of cell loss appeared greater in brains analyzed with FIF when compared with brains analyzed with TOH-ICC.

When compared with sham operated rats, SN lesioned rats showed impaired insulin responses to glucose as reflected by the absence of acute insulin responses and significantly elevated glucose levels at 5 and 10 minutes following IV glucose. SN lesioned rats also showed significantly higher glucose levels than the sham operated rats at 30 and 60 minutes following intragastric glucose loads. While basal levels of glucose were comparable between sham operated and SN lesioned rats, the lesioned rats showed significant reductions of basal serum insulin levels and significantly elevated basal serum glucagon levels.

These results provide a functional correlate for our previously reported morphologic investigation of islet changes following SN lesions. The mechanisms leading to alterations of the pancreatic islets and to impaired glucose tolerance following SN lesions are not known, but altered autonomic input to the islets may be a contributing factor. Supported by AG 05937.

203.15 EFFECTS OF GLYCINE AND MILACEMIDE IN DDT INDUCED HYPERTHERMIA. D.D. Truong*, J.J. Claude, G. Pezzoli and S. Fahn (SPON: R. Burke). Department of Neurology, Columbia University, New York, New York.

The DDT toxic syndrome consists of tremor, myoclonus, running seizures and hyperthermia. Decreased brain glycine levels have been reported in the DDT syndrome (Kar and Matin, Eur. J. of Pharmacol. 25, 36, 1974). We tested the effects of glycine i.c.v. (26 umol in 10 ul) and milacemide, a glycine prodrug, in the DDT induced hyperthermia in adult Sprague-Dawley rats who simultaneously received DDT 600 mg/kg (or corn oil control) by orogastric intubation. Rectal temperature was measured every half-hour for 4 hours in controlled room temperature using a Noralco digital thermometer. Results reported are average of mean body temperature (C°) (MBT) $\pm$ S.E.M. between 0.5 and 3 hours. In the DDT treated rats, MBT increased to 39.0 $\pm$ 0.11 vs. control 37.77 $\pm$ 0.22 ($p<.05$). When DDT treated rats received i.c.v. glycine, MBT decreased to 35.27 $\pm$ 0.16 vs. 38.36 $\pm$ 0.16 ($p<.05$) in DDT controls, which received iso-osmolar and pH corrected saline. DDT rats treated with milacemide 200 mg/kg or 400 mg/kg i.p. showed a decrease of MBT to 37.38 $\pm$ 0.11 and 36.31 $\pm$ 0.08, respectively, vs. DDT rats of 39 $\pm$ 0.16 ($p<.05$). In non-DDT rats i.c.v. glycine decreased MBT to 34.72 $\pm$ 0.27 vs. control 37.72 $\pm$ 0.16 ($p<.05$) Milacemide 200 mg/kg and 400 mg/kg showed a dose dependent decrease in MBT in naive rats. We conclude that glycine and milacemide have hypothermic effects and its action on the DDT-induced hyperthermia may be non-specific.

203.16 FEVER IN GUINEA PIGS WITH KNIFE CUTS IN THE BRAINSTEM. C.M. Blatteis. Dept. of Physiol. Biophys., Univ. of Tenn. Coll. of Med., Memphis, TN 38163.

Although the preoptic-anterior hypothalamus (POA) is thought to be the main site of the febrigenic action of interleukin-1 (IL1), several studies have shown that fever can develop after destruction of this region and, indeed, extra-POA sites responsive to IL1 have been localized in the lateral hypothalamic area (LHA), pons (PON) and medulla oblongata (MO) of guinea pigs. These experiments were undertaken to examine the possible interactions among these secondary sites by disconnecting them by microsurgery, then injecting IL1 either i.v. or directly into these sites. When wide bilateral coronal microcuts were made between the POA and LHA, no fever developed after IL1 was microinjected into the LHA either above or below the transections; however, IL1 injected i.v. induced significant fever. Similarly, microinjections of IL1 into the PON after coronal separation of the midbrain reticular formation from the brainstem, both above and below the cuts, also did not evoke pyrogenic responses; yet fevers were produced by i.v. injections of IL1. By contrast, sharp fevers of similar magnitudes were elicited when IL1 was microinjected into the MO of these operated animals or when administered i.v. It is concluded that, although in intact guinea pigs locally applied IL1 evokes fever not only from the POA, but also from the LHA, PON and MO, only the medullary site appears capable of activating fever independently of connections with the POA. It may be, therefore, a true subsidiary, autonomous controller of fever, activated particularly when the POA is impaired. (Supported by NIH grant NS-14929.)

203.17 THERMOSENSITIVITY OF PREOPTIC NEURONS *IN VITRO* IS INDEPENDENT OF TEMPERATURE. D.S.F. Ling*, N.L. Geller*#, H.M. Geller. (SPON: G.S.F. Ling). Depts. of Pharmacology and Biomedical Engineering, UMDNJ-Robert Wood Johnson Medical School and Rutgers University, Piscataway, N.J. 08854; #Memorial Sloan-Kettering Cancer Center, New York, N.Y. 10021.

The preoptic anterior hypothalamus (POAH) is a region of the brain considered important in thermoregulatory function. Many neurons in this region are thermosensitive, responding to alterations in environmental temperature (T) with a change in action potential generation. In this study, we examined the effects of thermal stimulation on neuronal firing rate (FR). We compared the effects of stimulation over a wide range of temperatures (25 - 45°C) to the effects of stimulation over more physiological temperatures (37-39°C). This was done to test the hypothesis that POAH neurons are thermosensitive over the physiological range of temperatures.

POAH tissue explant cultures were prepared from neonatal Sprague-Dawley rats and incubated for 2 to 4 weeks prior to extracellular recording. Cultures were placed in a 0.5 ml recording chamber and perfused with a heated, balanced salt solution at 1 ml/min. As bath temperature was varied, the temperature and interspike interval (msec) were recorded on-line by a Data General Eclipse S/140 minicomputer.

Using the statistical technique of simple linear regression, the relationship between neuronal firing rate and temperature was examined by both linear and semi-log models. Two measures of thermosensitivity were thus used: the thermal response coefficient (TRC, slope of the regression line of FR on T) and Q_{10} (inverse log of 10 times the slope of the regression line of the log of FR on T). Three groups of neurons were found. Those with TRC > 0.6 Hz/°C or Q_{10} > 2 were considered warm-sensitive (WS). Those with TRC < -0.6 Hz/°C or Q_{10} < 0.5 were classified as cold-sensitive (CS). All others were considered temperature insensitive (TI).

Records from 43 neurons in 14 cultures were analyzed. When the analysis was performed over the wide temperature range, 10 neurons were found to be WS by both TRC and Q_{10} criteria. 2 neurons were classified as CS. The remaining 31 neurons fit the criteria of TI. When the analysis was confined to a narrow (and more physiological) range of temperatures, 7 neurons exhibited WS characteristics as determined by TRC and 6 were found to be WS by Q_{10}. Only 1 neuron was classified as CS by TRC and Q_{10}. 36 neurons were found to be TI by TRC criterion and 35 by Q_{10}.

In conclusion, this comparison of correlated data appears to show that the thermosensitive characteristics of POAH neurons does not change significantly between narrow and wide ranges of temperatures. This suggests that the temperature sensitivity of preoptic area neurons is independent of temperature and that they may act as thermosensors over the physiological range.

203.18 REVERSIBLE INHIBITION OF THE NASOPHARYNGEAL REFLEX IN THE MUSKRAT. W.M. Panneton. Department of Anatomy and Neurobiology, St. Louis University School of Medicine, St. Louis, MO 63104.

Stimulation of nasopharyngeal areas in mammals causes an abrupt apnea and bradycardia, but little is known of the brainstem circuits mediating these responses. The fact that the nasal cavity and upper pharynx is innervated by branches of the trigeminal nerve suggests that neurons located within the trigeminal sensory complex are obligate links for relaying the stimulus to respiratory and cardiac neurons. The purpose of the present study was to locate the trigeminal region which mediates the nasopharyngeal reflex.

The common muskrat, Ondatra zibethicus, displays dramatic cardiorespiratory adjustments to nasal stimulation and was used for these experiments. Muskrats were anesthetized with either urethrane or alpha chloralose, or a mixture of them, and their tracheas transected below the larynx. The distal tracheal stump was intubated while a cannula was passed rostrally through the proximal trachea to the posterior nasal cavity. The animal was secured in a stereotaxic unit and the caudal medulla exposed. Both heart rate and respirations were monitored via subcutaneous electrodes and recorded on a physiograph. Ammonia vapors were used as the stimulus; the vapors were pulled with gentle suction through the nasal cavity from a cotton ball soaked in a solution of ammonium hydroxide and held in front of the nose. A 2% solution of lidocaine hydrochloride was injected bilaterally into the rostral spinal and medullary dorsal horns through a micropipette. Both the apnea and bradycardia normally induced by ammonia stimulation were either partially or totally blocked for 20-30 minutes by lidocaine injections into middle and rostral parts of the medullary dorsal horn but were uneffected by injections into the rostral cervical spinal cord and spinomedullary junction. Injection sites were verified histologically.

In those trials where the responses were blocked successfully, intravenous injections of 10-20µg of phenylephrine were administered to induce the baroreceptor reflex to insure that the inhibition was at the level of the trigeminal neurons rather than nearby cardiac or respiratory neurons or the fibers of the vagus nerve running through the spinal trigeminal nucleus.

These results indicate neurons in the medullary dorsal horns as mediators of autonomic reflex behaviors induced by nasal stimulation.

203.19 SOMAN-INDUCED CHANGES IN MEDULLARY RESPIRATORY-RELATED UNIT DISCHARGES AND DIAPHRAGMATIC EMG IN AWAKE, BEHAVING GUINEA PIGS. F.-C.T. Chang, R.E. Foster, T.J. Kerns, E.T. Beers, D.L. Rickett, and M.G. Filbert. U.S. Army Medical Research Institute of Chemical Defense. Aberdeen Proving Ground, Maryland 21010-5425

Knowledge of the relative contributions of CNS, peripheral and other actions to soman-induced respiratory depression is essential for development of medical countermeasures to its toxicity. Definitive data are not available since findings from earlier research either lacked sufficient information or were confounded by the presence of anesthetics. To elucidate these mechanisms, we developed a model system that permits electrophysiological studies of soman-induced respiratory failure in awake, behaving animals.

Guinea pigs were chronically instrumented under barbiturate anesthesia so as to allow concurrent monitoring of medullary respiratory-related unit (RRU) activity, diaphragmatic electromyogram (DEMG), and heart rate. At least seven days post-surgery, and following control period recording, bolus doses of soman were administered (15 ug/Kg, s.c.) at 10-min. intervals until all signs of respiration had ceased.

A hyperpneic profile consistently appeared as the first sign of soman-induced respiratory perturbation. Electrophysiologically, this profile was characterized by augmenting RRU burst frequency, decreasing interspike interval, and brief but increasingly robust DEMG oscillations. As the dose was increased, the hyperpneic profile began to show: a) progressively degenerative RRU-DEMG phase synchrony (phase shift and phase reversal); b) increasingly variable RRU discharge duration and periodicity; c) high within-burst RRU spike frequency; d) increase in background medullary neuronal activities; and e) diaphragmatic muscle fasciculations. Shortly before respiratory arrest, RRU and DEMG cycle frequencies showed a dramatic decrease. Seconds before respiratory arrest, RRU's and background medullary neurons invariably began to engage in erratic discharges. Ineffective respiratory attempts were always observed after respiratory failure. They occurred, however, between long intervals (tens of seconds), and were considered functionally and physiologically inconsequential. It is noteworthy that with doses of soman sufficiently high to produce respiratory arrest, diaphragm muscles were still responsive to occasional centrally mediated respiratory drive.

Our findings show that many, but not all, electrophysiological events associated with soman-induced respiratory failure in awake animals are qualitatively similar to those seen in anesthetized preparations. The effects of anesthesia on various aspects of toxic responses, relative central versus peripheral actions, and other pathophysiological changes will be discussed.

203.20 VENOMOTION IN MAN DISPLAYED BY A NON-INVASIVE METHOD. J. García Ramos. Lab. of Neurophysiology, Escuela de Medicina. U. A. Q. Querétaro, Qro. MEXICO.

Veins possess smooth muscle with sympathetic innervation. Mechano-receptors in their walls play a role in reflex venomotion. Carotid sinus reflexes are accompanied by venoconstriction. Venoconstriction by cold or injury are well recognized. More subtle reflex activity can be displayed by a non-invasive method employing one or more photoelectric transducers. The method was used for the superficial veins of the dorsum of the hand or on the forearm in twenty volunteers. Venomotion was followed at rest during normal respiration and after several experimental maneuvers. Venous caliber showed spontaneous fast rythmic oscillations and slower and prolonged reductions after an amotional situation even a very light one. Venous distension by occlusion of its central end, or by a sudden change in its position from the horizontal were followed by an active and prolonged venoconstriction. Normal respiration, but particularly a deep inspiration, the pasive raising of the arms above zero venous pressure, a small muscular effort, or the Valsalva maneuver elicited also venoconstrictions that appear locally and may produce distension of more peripheral portions which in turn provokes a second constriction of these parts. Venous pulsations may occur during an active and prolonged constriction. Nicotine administered by tobacco smoking produced a clear vanoconstriction which may not have the same temporal course of the arteriolar vasoconstriction followed by the simultaneous d.c. recording of the capillary pulse at a finger. These observations show that peripheral veins in humans present tonic and phasic contractions in responses of locally elicited reflexes and also from central influences. These responses occur in many physiological conditions. The mechanisms involved appear to be very sensitive. Venoconstriction and arteriolar constriction not necessarily occur simultaneously and with the same degree.

REGULATION OF AUTONOMIC FUNCTION IV

204.1 CORRELATION BETWEEN BLADDER ACTIVITY AND NEURONAL FIRING IN THE PONTINE MICTURITION CENTER OF THE CAT. H. Noto,* J.R. Roppolo, and W. C. de Groat (Spon: J. Krier). Dept. of Pharmacology, Univ. of Pittsburgh, Sch. of Med., Pittsburgh, PA 15261.

A variety of studies suggest that a group of neurons located in the dorsolateral pontine tegmentum are essential for reflex micturition. This area has been called the "pontine micturition center" (PMC). The present study examined the response characteristics of individual neurons in the PMC to a variety of stimuli, including: rhythmic reflex bladder contractions, pelvic nerve afferent (PN) stimulation, and somatic afferent stimulation (cutaneous, joint).

Precollicular decerebrate cats were used in these studies. Bladder pressure was recorded via a urethral catheter. Single neuron activity was recorded with either NaCl micropipettes or with carbon fiber microelectrodes.

A total of 243 single neurons were recorded in 8 animals at stereotaxic coordinates: AP -1.5 to -3.0, ML 2 to 3, H +1 to -4. Of these 168 neurons were isolated for sufficient time to be studied for at least three bladder contractions; these neurons are reported here. Four basic patterns of activity were seen: (1) Direct neurons (DIR) (20% of our sample), which increased their firing frequency (5-30 Hz) just prior to or at the onset of a bladder contraction, maintained their firing throughout most of the contraction, and then decreased their firing rate as the bladder began to relax. (2) Inverse neurons (INV) (50%), which were active (5-30 Hz) during bladder relaxation and were inhibited during bladder contraction. (3) On-off neurons (5%), which increased their firing frequency at the onset of a bladder contraction and at the onset of bladder relaxation. (4) Independent neurons (25%), which had no relationship to bladder activity. Within each group of neurons various subtypes were seen. For example, some DIR neurons had background spontaneous activity while others had none. Likewise the activity of some INV neurons were completely inhibited during a bladder contraction while others had only a reduction in firing frequency. Neurons encountered dorsal to the PMC did not exhibit firing correlated with bladder activity.

Electrical stimulation (2-10 V, 0.05 msec, 20 msec trains at 100 Hz) of pelvic nerve afferents (PN) excited some DIR neurons at a latency of 30 to 60 msec, while PN stimulation inhibited INV neurons at a latency of 20-150 msec. Somatic afferent stimulation activated some of the DIR (15%) and INV (30%) neurons.

These studies indicate that several populations of neurons in the PMC are involved in the regulation of the urinary bladder. Since some PMC neurons receive PN afferent input and fire prior to bladder contractions it is possible that these cells are involved in the initiation of micturition.

204.2 DOPAMINERGIC AND CHOLINERGIC MODULATION OF BLADDER REFLEXES AT THE LEVEL OF THE PONTINE MICTURITION CENTER IN THE CAT. J.R. Roppolo, H. Noto*, B. Mallory and W.C. de Groat. Dept. of Pharmacology, Univ. of Pittsburgh, Pittsburgh, PA 15261.

Pharmacological studies using intravenous administration of drugs suggest that dopaminergic and cholinergic mechanisms may be important in modulating bladder reflexes, at sites within the CNS. Histochemical and receptor binding studies are consistent with the view that an area of the rostral pons known as the "pontine micturition center" (PMC) may be one site for these pharmacological effects. Thus the present study was undertaken to examine the effects of dopaminergic and cholinergic agonists and antagonists injected directly into the PMC.

In precollicular decerebrate cats voiding cystometrograms (CMG) and isovolumetric rhythmic bladder contractions were recorded via a catheter in the dome of the bladder. Electromyograms (EMG) were recorded from the external uretheral sphincter (EUS). The PMC was identified in each animal by: (1) stereotaxic coordinates (AP = -1.5 to -3, ML = 2 to 3, H = +1 to -3), (2) electrical stimulation (2-10 V, 0.5 msec. 300 msec train, at 50 Hz) which produced short latency ($<$2 sec) voiding, and (3) chemical stimulation using excitatory amino acid L-glutamic acid (100 mM, 0.2 to 0.4 ul). The site which gave the best voiding response to L-glutamic acid was then used for further experiments.

Dopamine (DA) 100 mM (0.1-0.8 ul) injected unilaterally into PMC reduced the capacity of the bladder 10-60% as measured by CMG and increased the frequency of rhythmic contractions recorded at constant volume. Apomorphine (APO) 50mM (0.1-0.6 ul), a DA agonist, elicited a similar reduction in capacity. The effects of both DA and APO could be partially reversed by haloperidol (HAL) 13 mM (0.5-1 ul) given into the PMC or given I.V. (0.5-1 mg/kg). Pretreatment with HAL either I.V. or into PMC prevented the effects of DA or APO. HAL also elicited a small (10-20%) increase in bladder capacity. DA, HAL, or APO had little effect on EUS activity.

Carbachol (CARB) 10 and 100 mM (0.05 to .4 ul), a muscarinic cholinergic agonist, increased the capacity of the bladder (10-150%), inhibited isovolumetric bladder contractions and reduced EUS activity. Atropine (ATRP) 100 mM (0.4 to 1 ul) a muscarinic antagonist, partially reversed the effects of CARB. Pretreatment with ATRP into the PMC prevented all the effects of CARB, while ATRP alone caused only a small (15%) decrease in capacity.

These data suggest that dopaminergic and cholinergic mechanisms in the pontine micturition center may be important in modulating reflex bladder activity.

204.3 PONTINE MICTURITION CENTER IN RAT REVEALED BY RETROGRADE TRANSPORT OF RHODAMINE-LABELLED BEADS INJECTED INTO THE SACRAL INTERMEDIOLATERAL COLUMN. Irving Nadelhaft and Cecelia Devenyi*. VA Med Cent. and Univ. of Pittsburgh Med. Sch., Depts. of Neurological Surgery and Pharmacology, Pittsburgh, PA.

About 30 nl of rhodamine-labelled latex microspheres were injected into the intermediolateral column (IML) in the L6-S1 spinal cord. One week later, the animal was sacrificed and perfused with 4% paraformaldehyde. The brain was frozen-sectioned into 30 micron sections which were treated in one of three ways: mounted for viewing with the fluorescent microscope, stained with neutral red, or reacted with an antiserum to dopamine beta hydroxylase (DBH) to reveal noradrenergic neurons.

At the injection site (L6 segment) rhodamine label was concentrated mainly in a small area about 300 microns in diameter covering the IML and extended almost 1 mm in the rostrocaudal direction.

In the brainstem DBH-labelled cells of the locus coeruleus (LC) were observed along the lateral floor of the fourth ventricle for a rostrocaudal distance of about 2 mm. A small nucleus of rhodamine-labelled neurons was located slightly medial and ventral to the neurons of the LC. In transverse sections the center of this nucleus was situated about 1 mm lateral to the midline and at a depth of about 250 microns below the surface of the fourth ventricle. The nucleus was round and had a diameter of about 150 microns. Consistent with previous reports (Satoh et al.(1978) Neurosci. Lett. 8:9-15) we identify this nucleus as the pontine micturition center (PMC). Following a unilateral injection into the sacral IML, PMC neurons were labelled bilaterally in approximately equal numbers. There were about 350 neurons per side. PMC neurons extended over a distance of about 1 mm and were located in the middle of the rostrocaudal extent of the LC. The PMC neurons were small and round in transverse sections. A measurement of a sample of 50 PMC neurons resulted in an average diameter of 13.9 +/- 3.2 microns.

204.4 URETHRAL AND PELVIC FLOOR FUNCTION IN THE CHRONIC SPINAL DOG. James S. Walter, John S. Wheeler, Jr*., Charles J. Robinson, Robert D. Wurster. Rehabilitation R&D Center, Hines V.A. Hospital, Hines IL 60141, and Dept. of Urology and Physiology, Loyola Medical Center, Maywood, IL. 60153.

Eight spinal dogs (complete T8-9 transection) were urologically managed once a day for 8 weeks with sacral stimulation using either surface electrodes over sacral foramina or epidural electrodes implanted adjacent to sacral nerves. This study was in accord with NIH and AAALAC guidelines for the humane care and use of laboratory animals and each dog remained in excellent health throughout the experiment. Post-stimulus voiding was obtained using 10 to 35 pps applied for 1 to 3 sec. Currents ranged from 1 to 5 ma for implanted electrodes and 20 to 40 ma for surface electrodes. At 4 weeks post-injury (i.e., after resolution of transient hyporeflexia) voiding of 10 to 60 ml occurred following each stimulation period.

Since one factor that influenced voiding with sacral stimulation was urethral resistance, we evaluated urethral responses by EMG, cystoflouroscopy and cystometry. Contrast medium (150 ml) was placed in the bladder and bladder pressure was recorded with a small urethral catheter. Bladder pressure rose to 40-60 mmHg during stimulation. Voiding started immediately, or within 2 sec after the end of stimulation, but before voiding commenced there was a large amount of pelvic foor EMG activity, and the contrast medium filled the prostatic urethra but not the sphincteric urethra. Voiding commenced with the opening of the sphincteric urethra distal adjacent to the prostate, and voiding continued for 5 to 15 sec as bladder pressure slowly declined. The stream of urine was pulsatile with 2 to 4 squirts per sec. Correlated with these pulses was a spiking pelvic floor EMG and an opening and closing of the sphincter that set up a peristaltic movement down the urethra, in the area from 1 to 5 cm distal to the prostate just prior to the level of the pelvic floor; (flouroscopic and post-mortum measurements). The pulsatile rate significantly increased ($P<0.05$) during voiding from 2.5 ± 0.4 during the first two sec to 3.8 ± 0.2 during the last two seconds of voiding. A strong urethral closure and high voltage EMG was seen at the end of voiding. Two urethral flexures were noted, one just distal to the prostate and a second at the entrance to the pelvic floor.

These observations indicate important aspects of lower urinary tract physiology: 1) In addition to the continence function of the sphincter urethra, the peristaltic urethral activity suggests a second role promoting urine flow, 2) The sphincter urethra activity above the pelvic floor indicates that intrinsic urethral muscle (rhabdosphincter) and not the pelvic floor is necessary for sphinteric activity, 3) Flexures probably allow for urethral length adjustments, 4) Pulsatile urine flow was seen in the spinal intact dog, and in the early and late spinal dog, indicating a spinal organization of this urethral reflex, 5) The independent activity of the rhabdosphincter and pelvic floor can expain why the spinal dog may not be a good model for the vesical-sphincter dyssynergia that is seen in spinal cord injured (SCI) humans. However, pulsatile urine flow that is seen in SCI humans may involve in part some of the mechanisms described here. Supported by funds from Hines Veterans Administration Hospital, Rehabilitation R&D Center, and V.A. Rehab. R&D Grant 8394-A.

204.5 SEROTONERGIC- AND NORADRENERGIC-LIKE IMMUNOREACTIVE TERMINALS IN THE THORACIC INTERMEDIATE GREY MATTER OF THE RABBIT PROJECT TO RETROGRADELY IDENTIFIED SYMPATHETIC PREGANGLIONIC NEURONS. P.L. Vera, D.R. Liskowsky, P.M. McCabe & N. Schneiderman. University of Miami, Psychology Dept., P.O.B. 248185, Coral Gables, Fl. 33124.

Serotonin (5-HT) and noradrenaline (NA) have been localized in the intermediate grey matter of the spinal cord of several species and have been implicated in the regulation of sympathetic preganglionic neuron (SPNs) activity. Sympathoadrenal preganglionic neurons receive 5-HT terminals in the rat (Holets & Elde, 1982, Neurosci., 7:1155) and tyrosine hydroxylase-like terminals in the rabbit (Blessing et al,1987,JANS, 18:121). In the present study we examined the distribution of these two transmitters in the thoracic spinal cord of the rabbit and their relationship with retrogradely identified SPNs projecting to a different autonomic target.

All rabbits were perfused with 4% paraformaldehyde in phosphate buffer (0.1 M, pH=7.4) at 4^{o} C. Serial horizontal sections were taken of segments T1- T12 of 2 rabbits and alternate segments were exposed to antisera against 5-HT (1:5000; 48 hr) or DBH (1:800; 5 d.) at 4^{o} C. The tissue was processed according to the avidin-biotin procedure using DAB as a chromagen. In an additional 4 rabbits, both cervical sympathetic trunks were exposed to horseradish peroxidase 72 hrs prior to perfusion. The retrogradely labeled SPNs were visualized using DAB with the nickel intensification procedure in serial horizontal sections (20 um). T2-T5 segments were then processed for 5-HT (n=2) or DBH (n=2) immunoreactivity, since these segments contain most SPNs projecting to the superior cervical ganglion .

5-HT- and DBH-like immunoreactivity was observed at all levels of the thoracic cord studied. Longitudinal fibers were present in the lateral funiculus, very close to the surface. In addition, fibers were also seen in the lateral funiculus perpendicular to the horizontal axis and oriented towards the intermediate grey matter. A very heavy accumulation of fibers and terminals was observed in the intermediolateral nucleus (IML) in the upper thoracic levels (T2-T5), in agreement with findings in the cat (Krukoff et al, 1985,JCN,240:103). This innervation appeared continuous at these levels and contrasted with lower thoracic levels where the termination pattern in IML was patchy. 5-HT- and DBH-like immunoreactive terminals were observed in close apposition to both retrogradely and non-retrogradely labeled SPNs in the IML. The intermediolateral fasciculus did not contain immunoreactive fibers. Immunoreactive fibers were also observed in the intercalated nucleus at all levels, and they appeared to contact retrogradely labeled SPNs present in that area .Transverse bundles of fibers extending from IML towards the intercalated nucleus pars paraependymalis (ICpe) were observed starting at the level of T2, and were most prominent at the level of T5-T9. A longitudinal bundle of fibers was observed in the ICpe region, lateral to the central canal at all levels of the cord. In addition, fibers were observed crossing into the contralateral side via the dorsal grey commissure, and were also present in the ventral aspect of lamina X.The present findings confirm a serotonergic and catecholaminergic innervation of SPNs. In addition, the greater innervation of IML by these two transmitters at the upper thoracic levels suggests a rostro-caudal differentiation, in which 5-HT and NA might play a greater functional role in regulating the activity of rostrally located SPNs (projecting to the superior cervical and stellate ganglion) than more caudally located SPNs projecting to the adrenal gland. Supported by NIH HL0742608 & HL36588.

204.6 DORSOLATERAL PATHWAYS IN CERVICAL SPINAL CORD MAY TONICALLY INHIBIT ADRENAL SECRETION OF CATECHOLAMINES D.A.Bereiter, A. Benetti*, and D.S. Gann. Depts Surg. & Neuroscience, Brown Univ., Providence, R.I. 02902.

Tonic sympathetic nervous system (SNS) activity depends on supraspinal descending inputs that in turn, differentially influence various sympathetic efferent nerves. Although electrophysiological methods have been used extensively to estimate the relative contributions of different spinal cord pathways on SNS activity, few studies have directly assessed the acute influence of spinal pathways on adrenal secretion of catecholamines. The purpose of this study was to determine the early effects of dorsolateral (DL) cervical spinal cuts at C1 made ipsilateral or contralateral to the adrenal sample on the secretion of catecholamines in the anesthetized cat.

Adult cats were anesthetized with alpha-chloralose (75mg/kg, iv), paralyzed with gallamine triethiodide (5mg/kg, iv), and respired artificially. Blood pressure, heart rate and expiratory CO_2 were monitored. Catheters were placed in the cephalic vein (drugs), femoral vein (peripheral blood samples), and thoracic aorta (blood pressure). Selective sampling of adrenal venous blood was obtained via a catheter placed in the left lumboadrenal vein (Bereiter et al, 1986) and timed sampling permitted estimates of adrenal blood flow to be made. Adrenal venous plasma catecholamines were determined by HPLC with EC after extraction. Peripheral plasma ACTH was determined by RIA. Cats were placed in a stereotaxic frame and high cervical (C1) DL quadrant cuts were made ipsilateral or contralateral to the adrenal vein sample with a scalpel blade. Blood samples were obtained prior to transection and at 1, 5, and 60 min postcut.

Ipsilateral DL cuts caused a prompt increase in secretion of epinephrine by 1 min that remained elevated at 60 min ($+161\pm55$ ng/min, n=4). In contrast, contralateral DL cuts had no significant effect on secretion of epinephrine by 60 min ($+2.7\pm1.1$ ng/min, n=4). Secretion of norepinephrine increased after ipsilateral cuts by 60 min ($+33.8\pm20$ ng/min, $P<.05$), but not after contralateral cuts ($+5.7\pm3.4$ ng/min). The E/NE secretory ratio was increased after ipsilateral cuts (precut= 2.4 vs postcut= 7.8, $P<.001$), but was not affected by contralateral cuts (precut=1.5 vs postcut=1.2). Adrenal blood flow was not influenced consistently by ipsi- or contralateral cuts. Cuts of either side caused similar transient increases in blood pressure and heart rate that returned to precut levels after 5 min. Plasma ACTH was not affected by DL cuts at 60 min. To assess the effect of spinal cuts on brain stem-evoked adrenal secretion, microinjections of substance P (30 ng) were made into lamina I-II of trigeminal nucleus caudalis and preliminary results indicate increased secretion of epinephrine in response to substance P before and after ipsilateral DL cuts.

These results suggest that descending pathways in the ipsilateral DL cervical cord tonically inhibit the adrenal secretion of catecholamines. Phasic adrenal secretory responses evoked by n. caudalis are not blocked by such cuts. The apparent release from inhibition by ipsilateral cuts preferentially increases the secretion of epinephrine over that of norepinephrine and does not affect adrenal blood flow. These data further indicate the non-uniform influence of supraspinal pathways on autonomic function. Supported by NIH grants AM-26831 and GM-27946.

204.7 INTERACTION OF ALPHA$_1$- AND ALPHA$_2$-ADRENOCEPTOR ANTAGONISTS ON A CNS AUTONOMIC REFLEX. J.A. Hey, T. Ito* and M.C. Koss. Departments of Pharmacology and of Ophthalmology and Dean A. McGee Eye Institute, University of Oklahoma Health Sciences Center, Oklahoma City, OK 73190.

Reflex pupillary dilation (parasympatho-inhibition) was elicited by electrical stimulation of the afferent sciatic nerve (ScN) or by stimulation of the posterior hypothalamus in pentobarbital anesthetized cats. Inhibition of oculomotor tone due to ScN stimulation is mediated by a monoamine (perhaps NE) whereas that following hypothalamic activation utilizes a non-monoaminergic inhibitory neurotransmitter (Koss et al., J. Auton. Nerv. Syst. 10:55-68, 1984). In the present experiments, intravenous administration of the alpha$_2$-adrenoceptor blocker idazoxan (30-300 µg/kg) blocked ScN-induced mydriasis in a dose-related fashion. In contrast, the selective alpha$_1$-adrenoceptor antagonist prazosin (3-300 µg/kg, i.v.) produced a dose-dependent enhancement of the reflex pupillary dilation. Idazoxan produced about 70% inhibition, whereas prazosin caused about 50% potentation of the reflex mydriasis. Neither antagonist significantly altered the mydriasis elicited by stimulation of the posterior hypothalamus. A CNS site of action of these drugs was confirmed by direct recordings made from the short ciliary nerves.

To further delineate possible modes of interaction between these alpha-adrenoceptor antagonists on this system, prazosin and idazoxan were administered concurrently with the effect on ScN mydriasis observed. Idazoxan (30-300 µg/kg, i.v.) given after prazosin (1 mg/kg, i.v.) still reversed the pupillary dilation in a dose-dependent manner. Conversely, prazosin (3-1000 µg/kg, i.v.) given after pretreatment with idazoxan (300 µg/kg) continued to potentiate the reflex parasympatho-inhibition.

These results support earlier studies which indicate that activation of an ascending inhibitory mechanism involves alpha$_2$-adrenergic receptors in that ScN-induced mydriasis is blocked by alpha$_2$-adrenoceptor antagonists. The potentiation of this reflex parasympatho-inhibition by alpha$_1$-adrenoceptor antagonists, even in idazoxan pretreated cats, suggests that alpha$_1$-adrenoceptors either 1) directly stimulate oculomotor tone or 2) provide a brake on the alpha$_2$-adrenoceptor inhibitory input. We hypothesize that the potentiating effect of alpha$_1$-adrenoceptor antagonists is mediated primarily by a facilitation of ascending inhibitory tone. (Supported by Research to Prevent Blindness and Grant # RII-8610676 from the National Science Foundation)

204.8 BOMBESIN CENTRAL NERVOUS SYSTEM SITE OF ACTION TO INCREASE PLASMA CONCENTRATIONS OF EPINEPHRINE. K. Carver* and M.R. Brown (SPON: P. Plotsky). Autonomic Physiology Laboratory, UCSD Medical Center, San Diego, CA 92103.

Bombesin administered into the lateral cerebroventricle (icv) has previously been demonstrated to increase plasma concentrations of epinephrine greater than norepinephrine. The current study has been performed to identify the central nervous system site(s) of action of bombesin that mediate changes of adrenal epinephrine secretion. Experiments have been performed in awake, male Sprague-Dawley rats equipped with chronic icv and right atrial catheters. Microinjections of bombesin (10-100 ng/200 nl) into brain parenchymal sites were made through 28 ga cannulae. Cannulae placements were verified histologically. The effects of injections of bombesin into selected brain regions on plasma epinephrine levels are shown in the following table:

	3V	AHy	Ce	DPB	PnC	Amb	NTS
Treatment	Plasma Concentrations of Epinephrine pg/ml						
Control	60±14	52±16	44±8	50±17	90±14	64±2	52±14
BOM, 1ng	--	--	--	--	--	--	163±63
BOM, 10ng	--	--	--	--	--	--	619±225
BOM, 50ng	675±26	144±22	44±10	156±12	1036±620	1936±448	3710±686

3V=Third Cerebroventricle; AHy=Anterior Hypothalamus; Ce=Central Amygdaloid Nucleus; DPB=Dorsal Parabrachial Nucleus, PnC=Pontine Reticular Nucleus, caudal part; Amb=Nucleus Ambiguus, NTS=Nucleus of the Solitary Tract (AP -2.3).

To further define the site of action of bombesin within the area of the NTS, the medulla at AP -2.3 and -1.3 (interaural) was divided into quadrants. Bombesin (10 ng) was then injected into one of these areas or into the 4th ventricle. The medial quadrant at AP -2.3 was the most responsive site. Parenchymal injections made at AP -1.3 or the 4th ventricle at -2.3 or -1.3 resulted in minimal elevations of plasma epinephrine levels.

Previous studies have demonstrated somatostatin-28 to decrease bombesin-induced elevation of plasma concentrations of epinephrine. Co-injection of SS-28 (300 ng) into the NTS attenuated bombesin-induced elevation of plasma epinephrine levels. These studies are consistent with the conclusion that a potent site of action for bombesin exists within or near the rostral NTS. Using the present methodologies, more caudal sites could not be assessed.

204.9 MULTIPLE NEUROPEPTIDES IN VAGAL AND GLOSSOPHARYNGEAL AFFERENT NEURONS IN THE RAT. K.M. Hill* and C.J. Helke (SPON: E.Frey). Dept. of Pharmacol., Uniformed Services Univ. of the Health Sciences, Bethesda, MD. 20814.

Visceral afferent neurons of the vagus and glossopharyngeal nerves transmit sensory information from major organ systems of the thorax and abdomen to the nucleus of the solitary tract. The cell bodies reside in the nodose (NG) and petrosal (PG) ganglia of the vagus and glossopharyngeal nerves, respectively.

The presence and localization of neuropeptides in NG and PG neurons were examined with immunocytochemistry in tissue from 4% paraformaldehyde perfused rats. Calcitonin-gene related peptide (CGRP), substance P (SP), vasoactive intestinal polypeptide (VIP), cholecystokinin (CCK), somatostatin (SOM), and neurotensin (NT)-immunoreactivities (ir) were studied. With the exception of neurotensin, ir cells in NG and PG were seen with each antiserum. Peptide-ir neurons were scattered throughout the NG; however, the greatest numbers were generally found in the rostral part of the NG. In the NG, the relative number of peptide-ir neurons was SP>CGRP>VIP>>CCK>SOM. CGRP and SP showed very similar distributions with scattered cells in the NG and numerous groups in the PG. VIP-ir neurons were also scattered throughout the NG, but in relatively larger numbers than seen in PG. Whereas numerous SP and CGRP-ir cells were detected in the PG, fewer CCK, VIP and SOM neurons were seen. VIP-ir cells were also found in the glossopharyngeal nerve 1-2mm caudal to the PG. Following intranodose injections of colchicine, accumulations of SP, CGRP, VIP, and CCK-ir were seen in caudal nodose and vagal fibers. SOM-ir fibers were not detected after colchicine and very few SOM-ir cells were seen in NG or PG. To date, double-labeled SP and VIP-ir in the NG have been seen following retrograde transport of Fluoro-Gold from the cut end of the cervical vagus. IR for each peptide was blocked by preabsorption of the antisera with the homologous antigen. In addition, as reported in spinal and trigeminal ganglia (Neurosci. Lett. 68:305, 1986), CCK-ir was preabsorbed with CGRP raising the possibility that NG and PG CCK-ir represents endogenous CGRP.

These data demonstrate the presence of several different peptide-ir neurons in vagal and glossopharyngeal afferents and suggest a multiplicity of visceral sensory neurotransmitters. (Supported by NIH Grant #NS20991.)

204.10 MONOSYNAPTIC CONTACTS WITHIN THE NUCLEUS TRACTUS SOLITARIUS BETWEEN VAGAL AFFERENT AND EFFERENT NEURONS INNERVATING THE STOMACH IN RAT. L. Rinaman* and R.R. Miselis (SPON: P. Hand). Depts. Neurosci. and Animal Biology, Univ. Pennsylvania, Philadelphia, PA 19104.

It has recently been demonstrated that neurons within the dorsal motor nucleus of the vagus (DMV) which innervate the stomach in rat have dendrites which penetrate discrete subregions of the nucleus tractus solitarius (NTS), where they are coextensive with the central terminals of gastric primary sensory neurons (Shapiro and Miselis, 1985, JCN 238: 473). This coextensive distribution provides indirect evidence that monosynaptic contacts between gastric vagal afferent and efferent neurons may occur and thereby provide a substrate for reflex regulation of vagal motor outflow. In the present investigation we have accrued data which provide the first direct ultrastructural evidence that these proposed gastric monosynaptic vagovagal contacts do in fact exist. The DMV and NTS were analyzed by light and transmission electron microscopy three days following injection of 70 ul CT-HRP into the musculature of the stomach of adult male Sprague-Dawley rats. TMB was used as the chromagen to demonstrate CT-HRP labeled neuronal profiles within the DMV/NTS complex at both light and EM levels. Light microscopy confirmed the presence of retrogradely labeled DMV neurons bilaterally whose dendrites extended into dorsomedial subfields of the NTS where they overlapped with labeled gastric afferents; specifically, the subnucleus commissuralis, the subnucleus gelatinosus, and the medial solitary subnucleus. EM examination of these regions revealed discretely labeled dendritic and terminal profiles. Transganglionically labeled gastric afferents routinely formed asymmetric synaptic contacts with the labeled dendrites of backfilled DMV gastric neurons, as well as with unlabeled dendrites. The majority of these synaptic contacts were on distal dendrites and their appendages. Labeled dendrites exhibited characteristic fine structure and also received dense synaptic inputs from unlabeled afferents. Labeled afferents were characterized by a homogeneously dense axoplasm that was filled with large numbers of lucent, spherical vesicles (40 nm) and scattered dense core vesicles (60 nm). Our data demonstrate unequivocally that central monosynaptic connections exist between vagal afferents and efferents whose peripheral axons innervate the stomach in rat. These monosynaptic circuits can provide the bases for a feedback relay of visceral interoceptive information directly to the appropriate visceral effectors. Supported by NIH # GM-27739 to R.R.M., an Office of Naval Research Fellowship to L.R., and E.I. duPont de Nemours and Co., Medical Products Dept.

204.11 ELECTROPHYSIOLOGICAL STUDY OF GASTRIC VAGAL AND SPLANCHNIC INTERACTIONS IN THE BRAINSTEM OF THE CAT. C.S. Yuan*, W.D. Barber and T.F. Burks. (SPON: S. Hsiao). Departments of Anatomy and Pharmacology, College of Medicine, University of Arizona, Tucson, AZ 85724.

Gastric vagal projections to the dorsomedial region of the caudal brainstem were examined electrophysiologically in cats anesthetized with halothane and nitrous oxide supplemented with oxygen. Single shock stimulations (0.3 msec, 500 uA, 0.5 Hz) were applied to the gastric vagal branches which serve the proximal stomach, and to the left greater splanchnic nerve. To date, single unit activity was recorded extracellularly from 80 neurons in both sides of the caudal brainstem during gastric vagal nerve stimulation. Based upon stereotaxic coordinates and electrophysiological correlates, the results showed that the units responding to gastric nerve stimulation were located in the region of nucleus solitarius, in the same area where responses to gastric distention were previously reported in our laboratory (W.D. Barber and T.F. Burks, 1983). Stimulation of gastric vagal branches and the splanchnic nerve simultaneously resulted in an inhibition in 34 neurons of a total of 210 brainstem unitary discharges activated by gastric vagal stimulation. These results indicate that 16% of the brainstem neurons activated by electrical stimulation of the gastric vagal branches also received splanchnic input which was inhibitory. Further analysis showed that when the splanchnic nerve stimulation was increased to a frequency of 20 Hz, it produced a weak inhibitory effect upon some brainstem neurons. These data provide evidence that gastric vagal and splanchnic interactions occur upon the same cell in the brainstem. Brainstem neurons which shared vagal and splanchnic inputs were always inhibited when electrical stimulation of the splanchnic nerve and gastric vagal branches were paired. These data provide evidence in the cat of brainstem neurons in the region of nucleus solitarius which share gastric vagal and splanchnic input. The differences in quality or precise nature of sensory information conveyed via the splanchnic and gastric vagal fibers is not known at this time. This study adds important information concerning the organization of gastric vagal and splanchnic visceral neuronal interactions at the level of the caudal brainstem. (Supported by USPHS Grant AM 31804).

204.12 **BRAINSTEM SENSORY AND MOTOR PROJECTIONS FROM THE ESOPHAGUS IN THE RAT: VISCERAL TOPOGRAPHY.** **S.M. Altschuler*, X. Bao*, and R.R. Miselis, Departments of Pediatrics and Animal Biology and Institute of Neurological Sciences. University of Pennsylvania, Philadelphia, PA 19104.**

In contrast to the stomach, the medullary organization of afferent and efferent connections from the esophagus has not been extensively studied. Although retrograde labeling of efferent cell bodies has been reported, little information concerning the dendritic architectonics of retrogradely labeled neurons and location of afferent terminal fields is available. We employed the neural tracer cholera toxin-horseradish peroxidase (CT-HRP) to simultaneously determine the afferent and efferent connections of the esophagus within the medulla of the rat. CT-HRP (0.25% - Lowry assay) was injected in either the cervical or subdiaphragmatic esophagus of anesthetized rats. Tracer diffusion from the injection site was limited by isolating the esophagus using sterile saline-soaked gauzes and by diluting the injection site surfaces. Fresh gauzes were left in place, isolating the injected structures during the survival period. Control injections were made in the stomach, larynx, and trachea. After a 72-hour survival the animals were sacrificed for histological analysis using the TMB protocol. Afferent terminal labeling was limited to the medial portion of the nucleus of the tractus solitarius (NTS) at a level just anterior to the area postrema, in an area medial-ventromedial to the tractus solitarius, particularly in the subnucleus centralis (Ross et al., JCN 242:511, 1985). Other areas of the NTS previously shown to receive terminals of gastric vagal afferent fibers (Shapiro and Miselis, JCN 238:473, 1985) contained no labeling. Following both cervical and subdiaphragmatic esophageal injections, retrogradely labeled perikarya were observed in the rostral portion of the nucleus ambiguus (NA). Dendrites of labeled NA neurons were limited to the NA. Subdiaphragmatic injections also resulted in labeling of predominantly the left dorsal motor nucleus (DMN) neurons with dendrites confined to the boundaries of the DMN. Labeled DMN neurons were observed simultaneously with afferent terminal field labeling confined to the subnucleus centralis as opposed to the stomach injections, in which case there was occasional specific caudal NA and DMN labeling and labeling of afferent terminal fields in the subnucleus gelatinosus. Our findings suggest that gastrointestinal afferents project to the medial NTS with a degree of viscerotopic organization. The cervical esophagus receives motor innervation entirely from the rostral NA. The subdiaphragmatic esophagus receives motor innervation from both the rostral NA and left DMN. The innervation by the DMN may provide for coordination of activity of the lower esophageal sphincter and stomach during deglutition. Supported by N.I.H. grants GM27739 and DK01747.

204.13 ALTERATION OF GASTRIC MOTILITY BY PICOMOLE QUANTITIES OF GLUTAMIC ACID AND TRH IN THE DORSAL VAGAL COMPLEX (DVC) IN RATS. L.J. Jakobsen*, H.E. Raybould*, Y. Tache and D. Novin. Center for Ulcer Research and Education, VA Wadsworth Medical Center, Dept of Pyschology and Medicine, Brain Research Institute, University of California, Los Angeles, CA 90024.

Electrical and chemical stimulation of the nucleus of the solitary tract (NTS), where vagal afferents terminate, has demonstrated the importance of this region in control of gastric function. We further evaluated excitatory and inhibitory influences on gastric motility from this region by microinjection of glutamic acid (glu) and TRH. Tonic and phasic changes in intragastric pressure (IGP) were measured in chloralose-urethane anesthetized rats using a catheter placed in the body of the stomach and secured at the pylorus. Glu and TRH (0.1-10 mM) were injected in 1-10 nl volumes by micropressure ejection from glass multibarrelled micropipettes. Gastric responses were monitored while pipettes were advanced from surface to a depth of 1 mm of the dorsomedial medulla in 100 μm increments. Track positions were marked by 2.5% pontamine blue and verified histologically. Injections of glu (1-100 pmol) caused rapid onset, dose dependent decreases in tonic IGP (0.5 - 4 cmH_2O) at 32 of 35 sites within NTS and attenuated phasic contractions. Injection of TRH at these sites (0.5 - 100 pmol) increased tonic IGP by up to 8 cmH_2O and increased amplitude of phasic contractions. Bilateral cervical vagotomy abolished responses to glu and TRH. Glu and TRH were most potent when injected into the NTS but were effective throughout the DVC.

Conclusions: Injection of Glu into DVC produces predominantly inhibitory effects on gastric motility. In contrast, injection of TRH at the same loci increases gastric motility. Subpopulations of neurons in the DVC may therefore be activated by specific neurotransmitters having opposite effects on gastric function.

204.14 GASTRIC ACID SECRETORY EFFECTS OF INJECTION OF NEUROPEPTIDE Y INTO THE PARAVENTRICULAR NUCLEUS OF THE HYPOTHALAMUS OF RATS. G.A. Humphreys*, J. Davison* and W.L. Veale. (SPON: K.E. Cooper). Department of Medical Physiology, Faculty of Medicine, University of Calgary, Calgary, Alberta, Canada T2N 4N1.

Injection of neuropeptide Y (NPY) into the paraventricular nucleus of the hypothalamus (PVN) of rats enhances feeding behavior (Stanley, B.G. and Leibowitz, S.F., Proc. Natl. Acad. Sci. 82: 3940, 1985). The PVN has bidirectional neural connections with medullary autonomic areas known to influence gastric acid secretion. Experiments were done to determine if NPY given to the PVN of anaesthetized rats alters the autonomic regulation of a feeding related organ such as the stomach. The response of interdigestive levels of total gastric acid output, systemic arterial blood pressure and gastric mucosal blood flow were measured to injections of NPY (200 pmole) in rats anaesthetized with ketamine. Total acid output was also measured in rats that had received subdiaphragmatic vagotomy. Acid output was measured using a modification of the perfusion method of Ghosh and Schild (Brit. J. Pharmacol. 13: 54, 1958); arterial blood pressure using a femoral artery cannula connected to a pressure transducer and strip chart recorder; and mucosal blood flow by clearance of hydrogen gas. Total acid output dropped by 7.1 ± 1.4 μeq/10 minute interval, 20 minutes following injection of NPY into the PVN ($p < 0.01$ compared to saline injected controls). Arterial blood pressure was elevated by 9.8 ± 4.8 mm Hg only during the period of NPY injection, after which it promptly fell to baseline levels. This elevation was not statistically different from saline injected controls. Preliminary results indicate that gastric mucosal blood flow was not altered by injection of NPY into the PVN ($p=0.78$ paired with saline injected levels). Trunkal vagotomy abolished acid secretory response to PVN injections of NPY. These results indicate that injection of NPY into the PVN of anaesthetized rats decreases the interdigestive levels of total gastric acid output in a vagally dependent manner and that the effect is not dependent on alteration of mucosal blood flow.

204.15 RECIPROCAL CONNECTIONS BETWEEN THE CENTRAL NUCLEUS OF THE AMYGDALA AND THE MEDULLARY VAGAL COMPLEX: AN ELECTROPHYSIOLOGICAL STUDY IN THE RAT.

R.C.Rogers, Department of Physiology and the Neuroscience Program, The Ohio State University College of Medicine, Columbus, OH 43210.

Reciprocal connections between the CNA and the dorsal vagal complex (DVC - i.e. the solitary and dorsal motor nuclei) have been implied from anatomical studies. These direct amygdalo-autonomic connections may play a role in modulating gastric acid secretion and motility as well as other visceral functions. This study sought to determine the functional parameters and general organization of this CNA-DVC projection.

Our electrophysiological studies on the urethane anesthetized rat verify this conclusion in that microstimulation of the DVC region causes both antidromic and orthodromic activation of neurons in the CNA [antidromic latency = 56 +/- 10 msec (SD), orthodromic latency = 62 +/- 7 msec (SD), conduction velocity ~ 0.2 meters/sec] . The distribution of CNA neurons activated by DVC stimulation suggests that the dorsomedial CNA provides input to the dorsal medulla while the ventrolateral portion of the CNA receives input from the solitary nucleus within the DVC.

Supported by NIH grant NS 2435Ø.

204.16 DORSAL MEDULLARY SOMATOSTATIN CAUSES AN INCREASE IN GASTRIC ACID SECRETION. G.E. Hermann and R.C. Rogers , Department of Physiology and the Neuroscience Program, The Ohio State University College of Medicine, Columbus, OH 43210.

Immunohistochemical and neurophysiological evidence supports the existence of a somatostatinergic projection from the central nucleus of the amygdala and the dorsal medulla. Since intracerebro-ventricular injections of somatostatin have been shown to increase gastric acid secretion, it seems likely that this CNA-dorsal medullary path may be involved in the parasympathetic control of gastric function. The observation that CNA stimulation usually produces an increase in gastric acid secretion adds further support to this view.

If somatostatin acts on the dorsal motor nucleus of the vagus (DMN) as an excitatory neurotransmitter to regulate gastic function, then the injection of very small amounts of this putative peptide neurotransmitter into the DMN should increase gastric acid secretion.

Urethane anesthetized rats were prepared for perfusion with 0.9% saline at a rate of 2 ml/min. Perfusate was collected and titrated to neutrality with 0.05M NaOH to determine the rate of acid production by the stomach. After mounting the rats in a stereotaxic frame, the dorsal medulla was exposed and a combination stimulation electrode/micropipette placed in the DMN under physiological guidance. Though artificial cerebrospinal fluid injections (2 nl) had no effects, somatostatin (10 picomole in 2nl) increased acid output considerably. Intraperitoneal atropine (1mg/kg) completely suppressed the effects of intra - DMN somatostatin.

These results support the view that somatostatin acts on vagal efferent neurons to control gastric function.

204.17 *IN VITRO* TRACING OF MICROCIRCUITS BY RETROGRADE AND ANTEROGRADE TRANSPORT OF FLUORO-GOLD: PROJECTIONS OF SUBMUCOSAL NEURONS TO THE MYENTERIC PLEXUS OF THE GUINEA PIG SMALL INTESTINE. M. D. Gershon, G.M. Mawe, and A. L. Kirchgessner*. Department of Anatomy and Cell Biology, Columbia Univ., Coll. of P & S, New York, NY 10032.

The enteric nervous system (ENS) is a unique division of the PNS because it can mediate reflex activity without input from the brain or spinal cord. The ENS thus contains intrinsic primary afferent neurons and complete microcircuits that link mucosal sensory receptors with motor neurons in the myenteric plexus. Neither the sensory receptors, nor the primary afferent neurons of these microcircuits have been identified. Pseudounipolar and bipolar neurons (Schofield, 1968), as well as neurons that appear physiologically to receive no synaptic input (Suprenant, 1984), have been described in the submucosal plexus. These cells may be intrinsic primary afferent neurons; however, although the submucosal plexus is known to innervate the intestinal mucosa, where enteric sensory receptors are known to be located, no projections of submucosal neurons to the myenteric plexus have previously been found. In order to determine whether such projections exist, the submucosal plexus was examined following the microinjection of a retrograde tracer into a single ganglion of the myenteric plexus. The mucosa was removed from the guinea pig ileum, the remainder of the wall of the bowel was stretched flat with the serosal surface facing up, and the tissue was superfused in a chamber on the stage of an inverted microscope with nifedipine-containing (1.0μM) Krebs solution at 37°C. Individual myenteric ganglia were visualized using differential interference contrast optics and were injected with the fluorescent tracer Fluoro-Gold (FG; 4%). Injections were made with pressure pulses (100 msec in duration at 8 psi for 1.5 min at a frequency of 1.0 Hz) from the beveled tip (12 μm) of a glass micropipette; 2.5-3.0 hrs were allotted for retrograde transport *in vitro*. Preparations were then fixed with 4 % formaldehyde (from paraformaldehyde), dissected into layers containing the submucosal or myenteric plexuses, and examined as whole mounts by fluorescence microscopy. In the myenteric plexus, the injection sites could readily be visualized and were restricted to a portion of single ganglion. Some spread of FG beyond the confines of the injected ganglion occurred and led to staining of the surrounding connective tissue and smooth muscle. As previously observed following the microinjection of SITS, a small number of the neurons of the injected ganglion were fluorescent and additional neurons in distant ganglia (predominantly oral, but not immediately adjacent to the injection site) were also retrogradely labeled. In the submucosal plexus, scattered neurons deep to, but not directly underneath, the injected myenteric ganglion showed an intense granular cytoplasmic fluorescence indicative of retrograde labeling by FG. About 5-6 submucosal neurons were labeled/myenteric ganglion injected and only rarely was there more than one labeled neuron in a submucosal ganglion. Varicose terminal axons were also fluorescent in the submucosal plexus (not necessarily in ganglia that also contained labeled cell bodies), suggesting that anterograde, as well as retrograde transport, occurred. Controls were done to ensure that labeling of submucosal neurons was due to retrograde transport of FG from myenteric ganglia and not diffusion of the tracer into the submucosal layer. When FG was injected into the adjoining muscle, instead of a ganglion, occasional myenteric neurons in a ganglion near the injection site became labeled; however, there was no labeling of neurons in the submucosal plexus. Similarly, if connections between the myenteric and submucosal plexuses were severed by dissection before injecting FG, no neurons were labeled in the submucosal plexus. It is concluded that submucosal neurons project to the myenteric plexus. These observations are consistent with the hypothesis that intrinsic enteric primary afferent neurons reside in the submucosal plexus. Supported by NIH grants NS 12969, NS 07062, and the PMAF.

204.18 MARKERS SHARED BETWEEN SUBSETS OF DORSAL ROOT GANGLION (DRG) AND ENTERIC NEURONS A. L. Kirchgessner*, J. Dodd, and M. D. Gershon. (SPON: L. Coté). Dept. of Anatomy and Cell Biology, Columbia Univ., Coll. of P & S, New York, NY 10032

Alone among peripheral organs, the gut is able to mediate reflex activity when cut off from the CNS; therefore, the bowel must contain intrinsic primary afferent neurons. These enteric primary afferent cells have not yet been identified. The current study was undertaken to determine whether antigenic determinants or other markers common to primary sensory neurons could be found in enteric neurons. Functional subpopulations of cutaneous sensory neurons of the rat DRG can be identified by their expression of structurally defined lactoseries and globoseries carbohydrate differentiation antigens. Lactoseries antigens have also been found on other primary sensory neurons and sensory transduction cells; therefore, in dissected laminar preparations and cryostat sections of the rat small intestine, the presence of epitopes recognized by mouse monoclonal antibodies (MAbs) against lactoseries (α-SSEA-1, AC4, 1B2/1B7, LD2, LA4, TC6) and globoseries (B2) antigens was studied immunocytochemically. Dual-label immunofluorescence was used on single sections to demonstrate the labeling pattern of rabbit antibodies against VIP, substance P [SP], calcitonin gene related peptide [CGRP], enkephalin [ENK], and the MAbs described above, in order to study the coincident expression of neuropeptides and carbohydrate differentiation antigens. Preparations were used from animals treated 24 hrs previously with colchicine (5mg/kg). Carbonic anhydrase activity, also present in a subset of DRG neurons, was visualized histochemically in similar preparations of gut. Subsets of enteric neurons were labeled by α-SSEA-1, AC4,1B2/1B7, and carbonic anhydrase. α-SSEA-1/AC4$^+$ neurons were found (~1% of the total) in the myenteric plexus. These cells were morphologically classified as Dogiel type 1 (many short clubby dendrites) neurons. α-SSEA-1/AC4 co-localized with ENK, but the correspondence was not 1:1. 1B2/1B7$^+$ neurons were found in both the submucosal (~50% of neurons) and myenteric plexuses (~5% of neurons). All submucosal VIP$^+$, but no other submucosal neurons were marked by 1B2/1B7. In the myenteric plexus 1B2/1B7 was found in ~50% of VIP$^+$ and NPY$^+$ neurons and in additional neurons, the transmitter of which has not yet been identified. Carbonic anhydrase activity was intense in ~50% of the neurons of the submucosal plexus and moderate in a small number of myenteric neurons. A further evaluation of the correspondence between enteric neurons and DRG neurons labeled with antibodies to lactoseries antigens, was to administer capsaicin (50 mg/kg) to newborn rats. Two months later, 1B2/1B7, VIP, and SP immunoreactivities were depleted in DRG and the dorsal horn of the spinal cord. In the bowel of the same animals 1B2/1B7 immunofluorescence was lost from all submucosal and most myenteric neurons, but VIP immunoreactivity was depleted only from submucosal nerve fibers and not cell bodies. Enteric α-SSEA-1 was not affected by capsaicin. It is concluded that subsets of enteric neurons share properties with subsets of DRG neurons (α-SSEA-1$^+$, 1B2/1B7-VIP$^+$ [sensitive to capsaicin], carbonic anhydrase activity). The hypothesis that some of these enteric neurons function as primary afferents remains to be confirmed. Supported by NIH grants NS12969, NS 07062 and the PMAF.

204.19 GALL BLADDER GANGLIA: PROJECTIONS, INPUTS, PUTATIVE TRANSMITTERS, AND ENTERIC PROPERTIES. G.M. Mawe & M.D. Gershon, Dept. of Anatomy and Cell Biology, Columbia University, P&S, New York, NY 10032

The structure and chemistry of the ENS differ from those of the remainder of the PNS. Like the CNS, the ENS is supported by enteric glia and lacks internal collagen and basal laminae. Although the gall bladder originates as an outgrowth of the fetal gut, its innervation differs from that of the bowel in that the gall bladder has one, rather than two ganglionated plexuses. Nevertheless, it is not yet clear whether the intrinsic ganglia of the gall bladder are like those of the ENS or whether, instead, they resemble extraenteric autonomic ganglia. Moreover, the possibility that communication between the gut and the gall bladder may be mediated by nerves, as well as by the endocrine release of hormones, such as cholecystokinin, has not previously been examined. The current study of the guinea pig gall bladder was therefore undertaken to determine whether the ganglia of the gall bladder are part of the ENS. Studies were done inMarkers that were used included the immunocytochemical demonstration of laminin and 5-hydroxytryptamine (5-HT). Laminin is present in the basal lamina that surrounds enteric ganglia, but not in their interior. In contrast, laminin is abundant inside all other peripheral ganglia. 5-HT is found in the cell bodies of neurons of the myenteric, but not in the submucosal plexus of the gut or in extraenteric parasympathetic ganglia. In order to locate gall bladder ganglia, neurons were simultaneously visualized by the immunodetection of microtubule associated protein II (MAP II). Immunoreactivity (IR) was demonstrated using rabbit polyclonal or mouse monoclonal primary antibodies followed by biotinylated species-specific secondary antisera in combination with avidin-Texas Red or species-specific secondary antisera directly coupled to fluorescein isothiocyanate. To determine whether neurons in the duodenum project to the gall bladder, Fluoro Gold (FG) was injected into the wall of the gall bladder and the duodenum was examined after a 48 hour survival period.for the presence of neurons labeled by retrograde transport. MAP II-IR was found in the somata and dendrites of all gall bladder neurons, but not in their axons. The size of the ganglia and the shape of their neurons resembled submucosal, rather than myenteric ganglia. On the other hand, 5-HT-IR was present in the varicosities and somata of some gall bladder neurons, although these neurons represented a relatively small proportion of the neurons of the gall bladder. All gall bladder ganglia, were devoid of internal laminin-IR, whereas intense laminin immunofluorescence was seen in the basal laminae surrounding ganglia, smooth muscle cells, and blood vessels. Other putative transmitters found in gall bladder ganglia by immunofluorescence included, NPY, VIP, substance P, and CGRP. The detection of fibers with tyrosine hydroxylase-IR showed that gall bladder ganglia receive a noradrenergic sympathetic innervation. When FG was injected into the wall of the gall bladder, FG-fluorescence appeared in the perikarya of a subset of myenteric neurons in duodenal ganglia near the sphincter of Oddi. Some varicose FG-fluorescent terminal axons were also seen in these ganglia; thus, the duodenal myenteric plexus appears to be labeled both by retrograde and anterograde transport of FG from the gall bladder. Neurons in the celiac ganglion were also labeled by retrograde transport of FG, and as in the myenteric plexus, FG-fluorescent varicose fibers were observed in the celiac ganglion.

These observations indicate that the intrinsic ganglia of the gall bladder should be considered part of the ENS because they are enteric in structure, contain transmitters characteristic of the ENS, and they receive an input from and project to the duodenal myenteric plexus. Moreover, like the myenteric plexus, the gall bladder ganglia also appear to be innervated by the celiac ganglion and to send fibers centripetally to it. Further studies are needed to determine the role played by gall bladder ganglia in the physiology of the organ as well as to ascertain the functional significance of gut-gall bladder neural communication . Supported by grants NS 12969, NS 07062 and the PMAF.

204.20 SYNAPTIC BEHAVIOR OF MYENTERIC NEURONS IN THE GUINEA-PIG STOMACH IN VITRO. M. Schemann* and J.D. Wood. Department of Physiology, Ohio State University, Columbus , Ohio 43210

Much is known about synaptic behavior of myenteric neurons in the small intestine and less is known in the large bowel. However, there are no reports on synaptic behavior in the myenteric plexus of the stomach. Neurally controlled behavior of effector systems in the stomach differs from behavior in the intestine suggesting that the neurophysiology of the gastric nervous system may also be different. The aim of the present study was to investigate synaptic correlates of neurally controlled gastric behavior. Conventional methods were used for intracellular recordings in 156 neurons from 51 animals. The results revealed that electrical and synaptic behavior of gastric neurons differed significantly from the small intestine. Gastric neurons could be divided into three classes: Type I cells (n=64) were highly excitable, discharged multiple spikes on depolarizing current pulses and had relative high input resistance. Type II cells (n=63) were less excitable, discharged one spike only at the onset of depolarizing current pulses and had relative low input resistance. Type III cells (n=30) were inexcitable to intrasomal injection of depolarizing current pulses and showed the lowest input resistance. All cells showed fast excitatory postsynaptic potentials (fEPSP's) that were evoked by focal electrical stimulation of interganglionic fiber tracts. The mean amplitude of the fEPSP's was 7.9mV in Type III cells, and 15mV and 16mV in Type I and Type II cells, respectively. The mean duration of the fEPSP's was 18.2msec in Type III cells, and 25msec and 22.1msec in Type I and Type II cells, respectively. In Type I cells fEPSP's often reached threshold for spike discharge. Spontaneous fEPSP's occurred in 36% of Type I cells, 27% of Type II cells and 10% of Type III cells. All fEPSP's were suppressed by Hexamethonium (200μM), Tetrodotoxin (0.1μM) and in the presence of elevated Mg^{++} and reduced Ca^{++}. Estimated reversal potential for the fEPSP's was at a membrane potential of -20mV to +10mV. Microapplication of acetylcholine mimicked the fEPSP. During microapplication of acetylcholine the amplitude of fEPSP's was suppressed. Suppression of the fEPSP's was not produced by application of substance P or 5-HT. The fEPSP's followed high stimulus frequencies (>20Hz), without showing the "run-down" phenomenon, and sometimes summated to spike-threshold. Antidromically evoked potentials were recorded in only 7% of the cells. The results suggest that gastric neurons have characteristic electrical and synaptic behavior different from small intestinal neurons. This may be a reflection of the specialized motor and secretory functions of the stomach.

204.21 **MORPHOLOGY OF THE POSTERIOR VAGAL PLEXUS AND ITS NODULAR PARAGANGLION.** J.C. Prechtl and T.L. Powley. Lab. of Regulatory Psychobiology, Purdue University, West Lafayette, IN 47907

The concept that the posterior celiac and gastric branches of the rat vagus are formed by a simple bifurcation of the posterior vagal trunk is based on dissection studies and is inaccurate. Previously, we reported (Prechtl & Powley, 1985, J. Comp. Neurol., 235: 182) on the number and size of the posterior vagal branch components. In the present whole-mount study, we describe the organization of the branching, the intricate plexus it forms, and its association with an identifiable paraganglion.

Nerve whole-mounts were prepared from 13 adult male Sprague Dawley rats. The whole-mounts were stained with osmium tetroxide vapor, cleared in xylene, and mounted in permount. Four additional specimens were embedded in Epon and serially sectioned at 0.5-9 μm, in order to re-construct the nodular paraganglion and calculate its volume.

The whole-mounts revealed that the celiac branch was comprised of 4.8±0.4 nerve bundles which ramified separately from the posterior trunk within a rostro-caudal interval of 0.3 to 1.1mm. The gastric branch was formed by the division of the residual vagal trunk into 2.8±0.2 bundles at a level usually about 0.3mm distal to the first celiac bundle, but sometimes (23% of cases), at or before the celiac branching. Within 1mm of their branch point, some bundles (celiac or gastric) contributed to a plexus, by forming anastomoses. Included in this plexus of every specimen, were extrinsic (non-vagal) bundles which coursed between, and anastomosed with, distal segments of the two vagal branches. Despite some variations in this posterior vagal plexus, it always contained a large nodular paraganglion (vol.=113±21 X 10^4 μm^3, whole-mount dimensions -- 86 by 171 μm), which was regularly found attached to the side of the posterior vagal trunk opposite the celiac branch point. The paraganglion contained hundreds of glomus cells and 2-7 neuronal somata. Whole-mounts and serial reconstructions showed that it was traversed by 3-6 distinct nerve bundles, some of which could be traced to the posterior vagus. Numerous smaller paraganglia were also present in the branch plexus, but their sizes and locations were less predictable.

Extrinsic fibers have also been found in anterior vagal branches (Prechtl and Powley, 1987, Anat. Embryol., 176), and may represent sympathetic or enteric nerve bundles. The function of abdominal vagal paraganglia remains uncertain. The nodular paraganglion reported in this study is as large as any we have seen in the subdiaphragmatic vagus (see same ref.); because it would be identifiable in vitro, it could be adopted as a model for physiological studies. Supported by NIH Grant DK27627.

205.1 DISTRIBUTION AND POSSIBLE ROLE OF A GALANIN-LIKE PEPTIDE IN MUDPUPPY CARDIAC TISSUE. D.S. Neel* and L.M. Konopka* and R.L. Parsons. Department of Anatomy and Neurobiology, University of Vermont, Burlington, VT 05405.

Galanin, a 29 amino acid peptide, initially isolated from pig intestine, has recently been found in many regions within the CNS and PNS. Further, galanin immunoreactivity coexists with many other peptides and transmitter substances. Although previously found in numerous ANS targets, we found no reports of galanin immunoreactivity in cardiac tissue. However, the results of the present study demonstrate the presence of a galanin-like peptide in cells and fibers in the mudpuppy (Necturus maculosus) cardiac septum, which contains the parasympathetic cardiac ganglion. Whole mount septal-sinus venosus preparations and atrial preparations were stained immunohistochemically to determine the distribution of galanin-like peptide. Galanin immunoreactive fibers were found coursing diffusely across the septum and sinus venosus, and forming complex networks over cardiac muscle strands. Individual muscle strands in atrial preparations also appeared to be densely innervated. Galanin immunoreactive fibers were present in the nerve trunks connecting clusters of ganglion cells and could be seen making close appositions to individual ganglion cells. The majority of the parasymapthetic postganglionic neurons in the cardiac ganglion exhibited galanin immunoreactivity. Many of the small intraganglionic neurons (SIF-like cells) also exhibited galanin immunoreactivity. The density and distribution of galanin immunoreactive fibers was unchanged in preparations taken from animals pretreated with 6-hydroxydopamine, indicating that the fibers were not sympathetic postganglionic axons. The staining pattern also suggested that the galanin-like peptide was not contained in processes of primary afferent fibers. However, the pattern of galanin immunoreactivity, both in ganglion cells and innervating cardiac muscle, was very similar to the staining pattern obtained for AChE. Galanin in the range 1×10^{-7} to 1×10^{-6}M decreased the spontaneous rhythm of isolated sinus venosus preparations. Cardioinhibition was obtained in many preparations exposed to 1×10^{-6}M galanin. Galanin also produced a concentration dependent (1×10^{-7} to 1×10^{-6}M) decrease of the twitch tension development in electrically stimulated atrial preparations. Local application of galanin produced hyperpolarization of cardiac muscle fibers in both isolated septal-sinus venosus preparations and atrial preparations. The response to local application of galanin to individual parasympathetic ganglion cells varied between neurons; some neurons being depolarized whereas others were hyperpolarized. We conclude that a galanin-like peptide is contained in the parasympathetic neurons and further that it may work in conjunction with ACh to regulate cardiac function. Supported by PHS RO1-23978 and NSF BNS-8605611.

205.2 INNERVATION OF SEPTAL CARDIAC MUSCLE IN N. Maculosus. R.M. Kriebel, G.M. Hendricks*, L.M. Konopka, D.S. Neel*, and R.L. Parsons. Department of Anatomy and Neurobiology, The University of Vermont College of Medicine, Burlington, VT 05405.

The major constituents of the septal area stretching between the two limbs of the sinus venosus are neuronal: postganglionic parasympathetic neurons, preganglionic vagal fibers, sympathetic fibers, sensory fibers, and intrinsic neurons. Among these neuronal elements, there are also numerous bundles of cardiac muscle. These cardiac muscle fibers receive branches from aminergic nerve fibers coursing through the septum and may also receive an innervation by peptidergic fibers. This electron microscopic study was done to examine the type of cardiac muscle which is contained in the septum and to study the innervation of the muscle which apparently is not active in pulsations of the heart chambers. Many of the cardiac muscle cells in the septum ultrastructurally were characterized by well organized cytoplasmic arrays of myofibrils and complex intercellular junctions. Interspersed with these fibers were bundles of cardiac muscle which were less spindle shaped and more importantly had poorly arranged and dispersed myofibrillar elements. The cytoplasm of these cardiac muscle cells was also less electron dense when compared to the other muscle type. These features are similar to those described for the specialized conduction type cardiac muscle found in hearts of other animals. Immunofluorescence staining for actin filaments also showed septal cardiac myocytes with well organized myofibrils and some myocytes with cytoplasmic clumping of actin filaments. Several bundles of unmyelinated nerve fibers were seen coursing in parallel with the cardiac muscle strands. These unmyelinated fibers branched and single nerve fibers were found coursing between the individual muscle cells. Varicose profiles containing clear and granular synaptic vesicles were enclosed by profiles of several myocytes. Terminals containing only clear vesicles were seen in close apposition to cardiac myocytes having well developed contractile protein organization. Generally, amphibian myocardium has been thought to contain a single type of myocyte specialized for force production. These studies suggest that a conduction-type myocyte may be present within the septal area of the heart in the mudpuppy. Supported by PHS RO1-23978 and NSF BNS-8605611.

205.3 PHARMACOLOGICAL EFFECTS OF VASOACTIVE INTESTINAL PEPTIDE ON THE ISOLATED PERFUSED GUINEA-PIG HEART. D.B. Hoover. Dept. Pharmacol., Quillen-Dishner College of Medicine, East Tenn. State Univ., Johnson City, TN 37614.

Vasoactive intestinal peptide (VIP)-like immunoreactive nerves are found in right atrium, nodal tissue and coronary vessels of guinea-pigs (Weihe et al, Cell Tissue Res 236:527-540, 1984). This suggests that VIP plays a role in the neuroregulation of the heart and coronary circulation. Other investigators have shown that porcine VIP is a coronary vasodilator in the dog. Positive inotropic and chronotropic effects have also been demonstrated with porcine VIP in several species. In the present investigation, the pharmacological effects of guinea-pig VIP were examined using isolated perfused guinea-pig hearts.

Hearts from male Hartley guinea-pigs were perfused with a modified Krebs-Ringer bicarbonate solution (8 ml/min; 37° C; pH 7.4) containing 0.1% BSA. Experiments were started after a 30 min stabilization period. Perfusion pressure (mmHg), isometric ventricular contractions (g) and ventricular rate were monitored. Guinea-pig VIP (Peninsula) was given by bolus injection in 100 µl of saline containing 0.1% BSA. VIP (0.01-1.0 nmole) produced a dose-dependent increase in ventricular rate (40 ± 6 beats/min at 1.0 nmole dose, n=4). Perfusion pressure was reduced, but changes were small because of the low basal perfusion pressure (32 ± 1.3 mmHg, n=11). The vasodilator response to VIP was substantially larger when basal coronary tone was elevated with 1 µM [Arg^8]-vasopressin. VIP caused a delayed reduction in amplitude of ventricular contractions and, in many cases, increased baseline tension. Norepinephrine (0.1 and 0.5 nmole) had a marked positive inotropic effect in the same preparations. A brief positive ionotropic response has occasionally seen with 10 nmoles of VIP, but these contractions were not as impressive as those elicited by norepinephrine. Atenolol (3 µM) blocked positive inotropic and chronotropic responses to norepinephrine but did not affect responses to 1.0 nmole VIP. Tachyphylaxis occurred to guinea-pig VIP when doses were repeated at 15 min intervals. The positive chronotropic and vasodilator effects of guinea-pig VIP are consistent with actions previously demonstrated for porcine VIP. The failure of guinea-pig VIP to consistently evoke a positive inotropic response in guinea-pig heart was surprising and needs further study. The latter finding could represent a species difference or could be a consequence of the structural difference between porcine and guinea-pig VIP. (This work was supported by a Grant-in-Aid from the American Heart Association, Tennessee Affiliate.)

205.4 DEVELOPMENT OF PHYSIOLOGICAL RESPONSIVENESS TO ADENOSINE ANALOGS IN EMBRYONIC CHICK HEART. T.A. Blair*and T.F. Murray (Spon: R.A. Dodson) College of Pharmacy, Oregon State University, Corvallis, OR 97331

The developing chick heart has been used extensively to study the biochemical events involved in the activation and regulation of various neuroreceptors. In the present study we have used the embryonic chick heart to study the development of caridac adenosine receptors. Adenosine has been reported to have negative inotropic, chronotropic and dromotropic effects and has also been shown to be capable of inhibiting the myocardial effects of catecholamines. These effects of adenosine are competitively antagonized by methylxanthines indicating the involvement of specific receptors on the cellular membrane. We have determined the ontogeny of a physiological response to adenosine analogs by measuring atrial beating in embryos at various stages of development. Intact beating hearts were removed from the embryos and placed in buffered aerated media maintained at 37°C. Atria were separated from the ventricles and pinned to a Sylgaard-coated petri dish. Beating rates were determined visually with the aid of a dissecting scope. Atria isolated from 4-, 5-, and 6-day embryos were minimally responsive to 2-chloroadenosine (ClADO) with a 10 µM concentration inhibiting spontaneous beating rate by only 4-5%. Physiological sensitivity to ClADO-induced negative chronotropic response gradually increased from embryonic day 5 to day 12 at which time the beating rate was completely suppressed by ClADO (3-10 µM). Analysis of ClADO concentration response curves revealed that the development of physiological sensitivity to ClADO reflects a change in the maximal response and not the affinity for ClADO. A virtually identical ontogenetic pattern was demonstrated for R-phenylisopropyladenosine (R-PIA). The relative potencies of the adenosine analogs R-PIA (EC50 0.176 ± 0.065 µM), NECA (EC50 0.516 ± 0.009 µM), ClADO (EC50 0.789 ± 0.079 µM) and S-PIA (EC50 2.94 ± 1.74 µM) indicate the involvement of an A-1 type of adenosine receptor. 8-(p-sulfophenyl)theophylline (8-PST), a methylxanthine that does not cross the cell membrane, was capable of competitively inhibiting the actions of ClADO. Schild analysis of antagonist data demonstrated that 8-PST had a K_i of 0.287 ± 0.145 µM with a slope not significantly different than unity. These results suggest that A-1 adenosine receptors in the chick atrial myocardium are responsible for the physiological response to adenosine analogs and the developmental profile for this response is later than previously reported for the negative chronotropic effects of muscarinic agonists. 205.5 DIFFERENTIAL EFFECTS OF RAPID EYE MOVEMENT AND SLOW WAVE SLEEP ON CORONARY HEMODYNAMIC FUNCTION. Debra A. Kirby* and Richard L. Verrier. Cardiovascular Laboratories, Harvard School of Public Health, Boston, MA 02115.

The sleep/wake cycle results in distinctive patterns of autonomic nervous system activity. Whereas the influence of these changes on systemic hemodynamic function has been characterized, little is known about the influence of sleep on the coronary circulation. Investigation of this issue is particularly germane since it could provide insights into the mechanisms involved in coronary vasospastic disease. In the present study we examined the effects of rapid eye movement (REM) and slow wave sleep (SWS) on coronary hemodynamic function in 5 chronically instrumented dogs. Mean arterial blood pressure (MAP) was measured via a catheter in the aorta, and coronary blood flow (CBF) was determined using Doppler probes placed around the left anterior descending or circumflex coronary artery. Mean coronary vascular resistance was calculated as the quotient of MAP and mean CBF. Instantaneous heart rate (HR) was obtained with a cardiotachometer. Identification of sleep stages was accomplished by implanting electrodes via the frontal sinus to record electro-oculogram, electromyogram, and electroencephalogram. After a surgical recovery period of 4 weeks the animals were studied in the afternoon hours during natural sleep. The cycles were divided into 1 minute epochs of either quiet wakefulness, SWS, or REM sleep. The following results were obtained (means ± SEM, * p<0.02 compared to awake and REM, and † p<0.02 compared to awake, SWS and REM).

	Awake	SWS	REM Baseline	REM Surge
MAP (mmHg)	107±4	106±4	105±7	111±7
HR (beats/min)	85±11	78±10*	83±10	102±9†
CBF (ml/min)	33±5	30±4*	34±4	52±8†
CVR (mmHg/ml/min)	3.6±0.7	3.9±0.7*	3.4±0.7	2.5±0.6†

These results indicate that during SWS there are moderate but significant reductions in HR and CBF and increases in CVR. In REM, the CBF baseline is moderately elevated compared to SWS and there are striking, episodic surges in flow. CVR is reduced correspondingly. HR and MAP are also elevated during the flow surges, indicating an increase in cardiac metabolic activity. Whether or not there is a component of primary coronary vasodilation remains to be determined.

205.6 **DEPRESSED VENTRICULAR INOTROPISM DURING PROLONGED MAXIMAL STELLATE GANGLIONIC STIMULATION IS NOT PRIMARILY DUE TO DECREASED ß-ADRENERGIC FUNCTION**

W.M.Watson-Wright*, M.Wilkinson, D.E.Johnstone* and J.A.Armour
Dept. of Physiology/Biophysics, Dalhousie Univ., Halifax, N.S. B3H 4H7

Electrical stimulation of a thoracic sympathetic ganglion results in increased inotropism which rapidly peaks and then becomes diminished within 1-2 minutes, even though stimulation continues (inhibition of augmentation). This inhibition could be due to a decreased availability and/or responsiveness of myocardial ß-adrenergic receptors. To investigate this phenomenon, the acutely decentralized stellate ganglia of 8 dogs were stimulated (15V, 10 Hz, 4 ms) following administration of atropine sulphate (1 mg/Kg). Intramyocardial pressure (IMP) in the ventral midwall of the left ventrical was monitored. Noradrenaline (NOR) (0.025-2 µg/Kg) or isoproterenol (ISO) (0.025-1.2 µg/Kg) was administered into the left atrium (1) during the basal state (2) at the peak of inotropic response elicited by the stimulation (3) after 20 minutes of stimulation while stimulation continued and (4) after stimulation ceased. Ganglionic stimulation increased IMP from 98±7 to 257± 29 mm Hg initially but after 20 minutes of continuous stimulation it was 107±9 mm Hg. After the cessation of stimulation it fell to 69±7 mm Hg (p<0.005 vs all other pre-drug values). IMP was increased significantly after administration of NOR, except during peak stimulation when this drug had no significant effect on inotropism. Responses to these drug doses were less in the post-stimulation period (p<0.005). On the other hand, the NOR dose-response curve for IMP sensitivity (expressed as % of peak response) was similar for pre- and post-stimulation periods, but was shifted to the left at 20 minutes of stimulation. IMP responses to ISO were qualitatively similar to those for NOR. These results suggest that decreased ß-adrenergic receptor availability is not primarily responsible for the inhibition of augmentation noted with continuous maximal electrical stimulation, but that the sensitivity of these receptors and/or post-receptor events is increased at that time. Decreased ß-adrenergic function may be implicated in the post-stimulation depression in inotropism.

205.7 BILATERAL STELLATECTOMY IN THE RAT PRODUCES A MORE SELECTIVE AND SUSTAINED CARDIAC SYMPATHECTOMY THAN 6-HYDROXYDOPAMINE. D.D. Lund, P.G. Schmid, C.L. Putz*, A.R. Subieta*, & B.J. Pardini. Vet Admin Med Ctr & CV Ctr, Dept Int Med, U of Iowa, Iowa City, IA 52242.

Cardiac sympathectomy in small animals is commonly achieved with systemic administration of 6-hydroxydopamine (6-OHDA). This technique is limited because it produces: 1) sympathectomy of all peripheral tissues, 2) incomplete sympathectomy, 3) temporary norepinephrine depletion, and 4) hyperplasia of the adrenal medulla. Our previous study (Fed. Proc. 45(3): 294, 1986) which demonstrated that over 90% of all cardiac sympathetic fibers originate bilaterally in the stellate ganglia implies that removal of the stellate ganglia should produce long term cardiac sympathectomy. Additionally, the sympathetic innervation to more caudal organs supplied by other ganglia should remain intact. The purpose of the present investigation was to compare the effectiveness of bilateral stellatectomy (BI-STEL) and 6-OHDA on regional cardiac norepinephrine concentration. Male, Sprague-Dawley rats were anesthetized with Equithesin and either injected with 6-OHDA (80 mg/Kg, i.v.) or atropinized and intubated in preparation for BI-STEL or sham surgery (CONTROL). After the experimental procedure, rats were allowed to recover and were sacrificed after 7 or 28 days. Norepinephrine concentration was measured by HPLC with electrochemical detection in 4 cardiac and 4 non-cardiac regions. The following data represent norepinephrine concentration (ug/g tissue, wet wt; mean ± SEM in CONTROL and % of control in experimental groups) in right (RAAP) and left (LAAP) atrial appendage and right (RV) and left (LV) ventricle, 7 or 28 days after surgery (n = 6 or 7):

AREA	CONTROL	BI-STEL 7	BI-STEL 28	6-OHDA 7	6-OHDA 28
RAAP	1.80 ± 0.15	5.5%	4.4%	9.9%	18.3%
LAAP	1.68 ± 0.16	2.3%	6.3%	8.4%	20.2%
RV	0.67 ± 0.05	11.1%	9.6%	25.0%	45.3%
LV	0.70 ± 0.05	4.8%	3.4%	22.0%	39.4%

Bilateral stellatectomy produced a greater reduction in cardiac norepinephrine than 6-OHDA in all cardiac regions and at all times. Furthermore, while cardiac norepinephrine after 6-OHDA demonstrated significant recovery by a two-fold increase in norepinephrine content from 7 to 28 days, hearts of BI-STEL rats remained depleted at 28 days. In 4 non-cardiac peripheral organs tested 7 days after BI-STEL, norepinephrine concentration in sub-diaphragmatic (spleen, left adrenal gland) but not supra-diaphragmatic (left intrascapular fat, left forelimb muscle) organs was preserved at control levels. The present evidence suggests that bilateral stellatectomy may provide a more selective and longer lasting cardiac sympathectomy than chemical sympathectomy with 6-OHDA. (Supported by Veterans Administration and NIH HL 35484, HL 38137, and HL 14388.)

205.8 CONTRIBUTION OF MUSCARINIC TRANSMISSION IN THE STELLATE GANGLION TO THE MAINTENANCE OF CARDIOACCELERATOR TONE. M. M. Caverson, M. Bachoo* and C. Polosa*. Department of Physiology, McGill University, Montreal, Quebec, Canada H3G 1Y6.

Muscarinic receptors are present on the sympathetic ganglion cell membrane, but their physiological role in ganglionic transmission is unclear. In the decentralized stellate ganglion (SG), preganglionic (SPN) stimulation after nicotinic block produces an atropine-sensitive cardioacceleration but in the absence of nicotinic block the evoked cardioacceleration is not modified by atropine (J.Physiol.191:271,1967). Presumably, when nicotinic ganglionic transmission is unimpaired and activation of the SPN input to the SG is highly synchronous, muscarinic transmission is redundant. Muscarinic transmission may have a role, however, under physiological conditions, i.e. when only a fraction (20-30%) of SPN axons are active and their activity is largely asynchronous (Can.J. Physiol. Pharmacol.46:887,1968). The present study was done to estimate the contribution of muscarinic transmission to the tonic activity of the sympathetic cardiac nerves from the effect of muscarinic antagonists on heart rate (HR). Cats were anesthetized with alpha-chloralose, vagotomized, sino-aortic denervated, paralyzed and artificially ventilated. Doses of the muscarinic antagonist scopolamine (SCO) as low as 10 µg/kg were found to block the cardioacceleration evoked by SPN stimulation in cats in which the SG was decentralized and its SPN input electrically stimulated during constant infusion of hexamethonium. These doses also blocked the bradycardia evoked by vagal stimulation in the same animals. When SCO in doses of 5-100 µg/kg was injected i.v. in cats with an intact SG input, a dose-dependent, sustained decrease in HR was observed in 6 cats. The maximum sustained decrease in HR was 25 ± 5 bpm (223 ± 24 to 198 ± 21 bpm). In these cases, i.v. administration of hexamethonium produced a further decrease in HR of 63 ± 13 bpm (198 ± 21 to 135 ± 22 bpm). SCO had no effect if the SG was decentralized, the inferior cardiac nerves (ICN) sectioned or the animals pretreated with propranolol. These doses of SCO had no effect on the cardioacceleration evoked by stimulation of the right ICN and on the tonic activity of the SPN input to the SG recorded from the T_3 white ramus. Close intra-arterial injections of SCO towards the right SG, using doses (<1 µg/kg) below that which produced an effect by i.v. administration, elicited a sustained decrease in HR (30 bpm). Further i.v. doses of SCO in these animals did not augment the bradycardia. These observations suggest that the SCO-evoked bradycardia is due to a decrease in the tonic activity of SG cells. Thus, during natural activity a component of the input to these cells is mediated by muscarinic receptors.

205.9 NORADRENERGIC CARDIAC PROJECTIONS FROM THE STELLATE GANGLIA IN THE RAT. B.J. Pardini, P.G. Schmid, C.A. Whiteis*, and D.D. Lund. Veterans Administration Medical Ctr. and Cardiovascular Ctr., Dept. of Internal Medicine, Univ. of Iowa, Iowa City, IA 52242.

We have previously demonstrated, using retrograde tracers, that the sympathetic postganglionic innervation of the rat cardiac ventricles originates bilaterally in the stellate ganglia (approximately 92% of all labeled cells), with lesser contributions from the superior cervical and fourth and fifth thoracic ganglia (Fed. Proc. 45(3):294, 1986). The innervation is primarily ipsilateral (approximately 60%) in nature, with significant (40%) contralateral contributions. Presumably, removal of left, right, or both stellate ganglia should produce reductions in cardiac norepinephrine concentrations consistent with the retrograde tracer results. The purpose of the present investigation was to determine the effect of unilateral and bilateral stellatectomy on regional cardiac norepinephrine concentration in the rat. Male, Sprague-Dawley rats were anesthetized with Equithesin, atropinized, and intubated in preparation for left (L-STEL), right (R-STEL), or bilateral (BI-STEL) stellatectomy, or sham surgery (CONTROL). The stellate (middle and inferior cervical) ganglia were approached from the dorsal aspect of the first and/or second intercostal space. After surgery rats were allowed to recover and were sacrificed 7 days later. Norepinephrine concentration was measured after separation by HPLC with electrochemical detection in four cardiac regions: right (RAAP) and left (LAAP) atrial appendage and right (RV) and left (LV) ventricle. The following data represent norepinephrine concentration (ug/g tissue, wet wt; mean ± SEM; n = 6 or 7):

AREA	CONTROL	R-STEL	L-STEL	BI-STEL
RAAP	1.68 ± 0.08	0.57 ± 0.07	1.36 ± 0.16	0.09 ± 0.04
LAAP	1.52 ± 0.10	1.01 ± 0.09	0.49 ± 0.11	0.04 ± 0.04
RV	1.19 ± 0.05	0.77 ± 0.04	0.55 ± 0.07	0.13 ± 0.04
LV	0.58 ± 0.02	0.38 ± 0.04	0.20 ± 0.04	0.03 ± 0.01

One week after bilateral stellatectomy regional cardiac norepinephrine was reduced by 89% to 97%, indicating the removal of almost all cardiac noradrenergic cells of origin and possibly similar fibers of passage from other ganglia. Unilateral stellatectomy indicates that the RAAP, LAAP, and LV receive bilateral, predominantly ipsilateral, innervation from the stellate ganglia, which is consistent with prior neuroanatomical results. In contrast with earlier results, the left stellate ganglion appears to contribute a majority of the norepinephrine to the RV. The present neurochemical evidence largely corroborates our previous neuroanatomical study and suggests that bilateral stellatectomy may be an effective method to produce cardiac sympathectomy. 205.10 THE INTERACTION OF INTRADENTAL NERVE ACTIVITY AND PULPAL BLOOD FLOW AS MEASURED BY XENON-133 AND LASER DOPPLER FLOWMETRY. G. BILOTTO, M-T. LIU*, K. MARKOWITZ* and S. KIM*. Lab of Oral Physiology, Columbia University, New York, NY 10032.

Previous reports (Soc. Neurosci. abstr. 12:226, 1986; IDR 65:210, 1986) have shown the effects of 3M NaCl and 0.756M KCl on intradental nerve activity (INA). However since pulpal nerve terminals contain vasoactive peptides the above substances via the activation of these terminals can alter the pulpal blood flow (PBF). The altered blood flow can in turn affect the A-δ nerve fibers since they are kown to be very sensitive to change in oxygen supply. The above substances were applied to canine teeth of 3 dogs or 1 cat anthesthesized with sodium pentobarbital. The canine teeth were prepared with two dentinal cavities (incisal and gingival cavities). The solutions were applied to the incisal cavity while the INA was monitored with Ag/AgCl electrodes from the same cavity. 2 μCi of Xenon-133 suspended in saline was given as a bolus injection in the maxillary artery. A specially designed extracorporal γ-counting probe detected the γ-emissions from the canine tooth. A Tracor Multichannel Analyzer provided the Xenon-133 washout curve. A two compartment non-linear model provided the time contants for the fast and slow components. The laser Doppler flowmetry consisted of a He-Ne laser directed at the incisal cavity with associated electronic circuitry measuring the Doppler shift and hence indicating the PBF changes (Med Pacific LD5000 Laser). The Xe-133 washout in dogs indicated that with 3M NaCl applied for 5 min in the dentinal cavity, the PBF decreased by an average of 5.26% whereas a 22 min application cause a 53% decrease from the control level of an intact tooth. The laser Doppler revealed a decrease in the PBF by an average of 14% 30 sec after a 2 min application of 3M NaCl both in dog and cat preparations. 0.756M KCl caused a decrease in PBF by 8.45% after 26 sec of a 2 min application of the KCl. Xenon-133 indicated a decrease of 28% in PBF when KCl remained in the cavity for 6 or 8 min. Electrical stimulation of the intact canine tooth with different stimulus parameters to preferentially activate A-δ fibers vs C-fibers indicated that at low stimulus current (80 μA, 1 ms, 100 Hz) applied for 6 min reduced PBF by 6%-8% whereas high current levels (350 μA, 10 ms, 10 Hz) applied for 3 min reduced PBF by 6-20%.

Therefore from the above preliminary results INA evoked either by chemical agents or electrical stimulation reduced the PBF. It is interesting to note that KCl which has a biphasic effect-first eliciting INA for a short time and then causing a longer depolarizing phase which reduces INA still caused a lowering of the PBF.

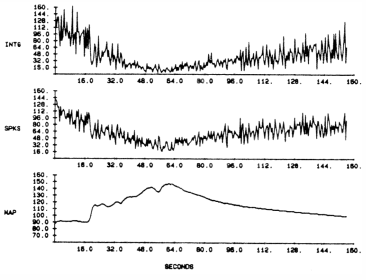
205.11 MICROCOMPUTER BASED DIGITAL ANALYSIS OF NERVE TRAFFIC. DR Brown*, DC Randall, and CF Knapp*. Center Biomed. Engin. & Dept. Physiol. & Biophys., Univ. Kentucky, Lexington, KY 40506.

Nerve traffic is often integrated or counted by analog methods. Digitizing amplified nerve traffic and using digital methods to analyze the resulting data would circumvent several problems with analog techniques. We developed a program which digitizes nerve traffic and performs "on-line" peak detection and integration. The nerve signal was digitized by a Data Translation 2821-F A-to-D converter at 10,000 samples/sec.; a Direct Memory Access controller on an 80286 microprocessor stored the digitized data alternately into two 5,000 sample memory buffers. The program determines the current buffer being filled and then scans the alternate (i.e., previously filled) buffer, digitally integrating and counting the spikes above a preset level. The integrated activity and spike frequency, calculated every 5,000 samples or .5 seconds, were stored on magnetic disks along with digitized mean arterial pressure. The reference level was determined by first digitizing and displaying the nerve signal on a video monitor and then setting the reference level above background noise. The figure below exemplifies the output of this system for percent changes in whole bundle renal sympathetic nerve activity during an increase in arterial pressure (phenylephrine injection) in a rat. The upper panel shows the change in integrated activity (INTG), the middle panel the percent change in spike frequency (SPKS), and the bottom panel the increase in mean arterial pressure (MAP, mm Hg).



This system enables "on-line" digital analysis of nerve traffic using conventional algorithms; it permits the eventual application of more complex analytical techniques to the digitized data. (Supported by NIH grant HL19343)

205.12 ANALYSIS OF THE COMPONENTS OF H_2 CLEARANCE CURVES IN PERIPHERAL NERVE. Timothy J. Day*, Phillip A. Low and Terrence D. Lagerlund* (SPON: E. H. Lambert). Dept. of Neurology, Mayo Foundation, Rochester, MN 55905

Hydrogen polarographic measurement of nerve blood flow (NBF) was performed in healthy Sprague Dawley rats using H_2-sensitive Pt microelectrodes inserted in the sciatic nerve. Biexponential clearances were often observed and further studies were performed to determine the physiological mechanisms responsible for each component.

NBF measurement were made (1) before and after inferior vena caval (IVC) occlusion using a noose of polyethylene tubing; (2) before and after intravenous infusion of 5-hydroxy tryptamine (5HT) at rates of 5 and 10 μg base/kg/min. Both these maneuvers caused abolition or reduction in the weight of the fast clearance rate (80-120 ml/min/100 g) suggesting that arteriovenous (AV) shunts are responsible for this component.

H_2 clearance curves were also recorded after H_2-saturated rats were killed with KCl. Slow clearance rates (median 2.4 ml/min/100g) were observed indicating that diffusion to air (in this exposed, oil-covered preparation) is very slow and, therefore, unlikely to be confused with nutritive flow. Mathematical modelling of the diffusion component yielded very slow clearances of approximately 2 ml/min/100g).

Intermediate clearance rates (10-30 ml/min/100g) were consistently found in all healthy animals and compare well with values for tissue flow obtained from microsphere and iodo-antipyrine techniques. No other postulated clearance mechanisms produced rates in this range and, therefore, these rates are thought to represent nutritive (capillary) flow.

Mathematical modelling indicates that biexponential clearances are expected where near-arteriolar recordings are made and that the two exponents reflect capillary and arteriolar (or AV shunt) flow, respectively. H_2 consumption by polarographic oxidation, a theoretical cause of H_2 clearance, would be expected to produce extremely slow clearances.

Therefore, H_2 polarography can be used to quantitate nutritive NBF, and also the degree and rate of AV shunting in tissue by separate consideration of the exponents of the H_2 clearance functions. (Supported in part by grants from NINCDS (NS-14304; NS-22352) MDA, Mayo and Mogg funds.

205.13 EFFECTS OF 6-HYDROXYDOPAMINE ON CATECHOLAMINE RELEASE AND PRESSOR RESPONSES TO ADRENAL STIMULATION IN PITHED RATS - ROLE OF ANGIOTENSIN. K. Richter*, S.A. Meyers*, S.J. Fluharty*, S.E. Corey*, E.M. Stricker and R.R. Vollmer*. (SPON: E. Krimmer). Dept. of Behavioral Neuroscience, U. of Pgh., Pittsburgh, PA 15260 and Sch. of Vet. Med., U. of PA, Philadelphia, PA 19104.

Partial sympathectomy (6-hydroxydopamine, 6-HDA, 100 mg/kg, s.c., 1 wk. previously) is known to increase adrenal tyrosine hydroxylase activity via a centrally mediated increase in splanchnic nerve activity. The present experiments in the pithed rat were conducted to determine if the increase in adrenal synthetic capacity is associated with alterations in catecholamine release or the responsiveness of the cardiovascular system to released catecholamines.

The thoracolumbar portion of the spinal cord was electrically stimulated (4 and 16 Hz) to activate noradrenergic neurons and the adrenal medulla. Compared to control rats, the damage to noradrenergic neurons in 6-HDA treated animals was reflected by a decrease in the increment in plasma norepinephrine (NE, measured by HPLC with electrochemical detection) and an attenuation of the blood pressure rise produced during stimulation. Plasma epinephrine (EPI) levels and the blood pressure-dose response curves to exogenous NE or EPI were similar in control and 6-HDA treated animals.

In a separate series of experiments the adrenal gland was directly stimulated by placing the gland on bipolar platinum electrodes. Blood pressure-frequency response curves generated (2-32 Hz) were not different in 6-HDA and control animals. Moreover increments in plasma EPI during stimulation at 4 and 16 Hz were similar. Interestingly, the plasma NE responses to direct adrenal stimulation were augmented in 6-HDA-treated animals.

In agreement with our previous studies, blockade of the renin-angiotensin system (captopril, 5 mg/kg, i.v.) significantly reduced the blood pressure-response curves to electrical stimulation of the adrenal gland and to exogenous EPI. In rats treated with 6-HDA the extent of the reduction was greater; however, this enhanced sensitivity to captopril does not appear to be related to a decrease in adrenal catecholamine release since the plasma catecholamine responses to stimulation were similar in control and 6-HDA treated rats.

The results of the present study suggest that despite marked increase in catecholamine synthetic rate following 6-HDA treatment the amount of catecholamine released from the adrenal gland in response to preganglionic stimulation is not altered. In addition, endogenously formed angiotensin II facilitates responses to adrenal catecholamines in 6-HDA treated animals via a mechanism that is independent of catecholamine release. (Supported by grants from NIH HL26212, NS19608 and NSF BNS85-18035.)

205.14 EFFECTS OF ACUTE SINO-AORTIC DENERVATION ON CEREBRAL GLUCOSE UTILIZATION DURING ADMINISTRATION OF ANGIOTENSIN II. M. Kadekaro, M.L. Terrell*, H. Lekan*, H. Gary, Jr.* and H.M. Eisenberg. Div. of Neurosurg., Univ. of Tex. Medical Branch, Galveston, TX 77550

Angiotensin II (AII) infused intravenously elicits a pressor and drinking response and an increase in the rates of glucose utilization in the subfornical organ (SFO) and pituitary neural lobe of water-sated Sprague-Dawley rats (Gross, P.M. et al, Peptides 6 supp 1:145-152, 1985). The firing rates of units in the SFO vary according to the arterial blood pressure suggesting an input of baroreceptors to the SFO (Nicolaidis, S. et al, Brain Res. Bull., 10:357-363, 1983). The objective of the present experiments was to study, with the quantitative deoxyglucose method, the influence of baroreceptors on metabolic response of the SFO to AII. Our previous studies in chronically sino-aortic deafferented animals indicated that the influence of baroreceptors on glucose metabolism of the SFO may be too small to be detected with the deoxyglucose method. A compensatory metabolic adjustment may, however, occur in chronic preparations obscuring such an influence. We, therefore, investigated, in acute preparations, the effect of sino-aortic denervation on glucose metabolism of the SFO and neural lobe in response to AII.

Adult male Sprague-Dawley rats were anesthetized with halothane and the sino-aortic baroreceptors denervated according to Krieger's technique (Krieger, E., Circ. Res. 15:511-521, 1964). The deoxyglucose experiments were performed 2-4 h after the denervation. Four groups of animals were studied, 2 sham-operated and 2 with baroreceptor denervation; each group was infused with saline or AII (2.5 ug/min) for 40 min. The results showed that AII increases glucose utilization in the SFO to the same extent in the sham and denervated rats. The response of the neural lobe in deafferented animals was larger than in sham-operated animals, even though this difference was not statistically significant. This finding confirms our previous investigation in chronic preparations that the influence of baroreceptors on the functional activity of the SFO is negligible.

In the course of this study, we also investigated the effect of sino-aortic denervation on local cerebral glucose utilization. The results showed that glucose utilization was increased in the median eminence but was decreased in 11 out of 20 brain structures examined. These structures included the dorsal motor n. of the vagus, n. ambiguus, ventrolateral medulla, locus coeruleus, parabrachial n., medial forebrain bundle, paraventricular n. and periventricular n., medial and lateral preoptic area and diagonal band of Broca. These structures may be involved in the baroreflex control of blood pressure.

205.15 CENTRAL AND PERIPHERAL ACTIONS OF ALPHA-2 ADRENERGIC AGONISTS ON RENAL FUNCTION IN LONG-EVANS (LE) AND BRATTLEBORO (DI) RATS, D.R. Wallace and R. Dawson, Dept. of Pharmacodynamics, Univ. of Florida, Gainesville, FL 32610.

Systemic administration of clonidine, a prototypical alpha-2 (partial) agonist produces diuresis and natriuresis in the conscious rat. The exact mechanism of the alpha-2 adrenergic mediated diuresis and natriuresis is unknown, although a centrally mediated inhibition of vasopressin (AVP), an alteration in sympathetic neural function and a direct renal action have all been postulated. This study employed LE and rats deficient in (AVP) (homozygous DI rats) to examine the renal actions of alpha-2 adrenergic agonists that have both central and peripheral actions (guanabenz and guanfacine) and an alpha-2 agonist with very poor blood brain barrier penetration (ST-91).

Male LE (n = 10) and DI (n = 10) rats were housed in metabolic cages and acclimated to a daily 4 hour collection period. Saline injections were performed and stable baseline measures were obtained prior to the randomized presentation of various doses (0.1 or 1.0 mg/kg) of alpha-2 adrenergic agonists. Drugs were prepared fresh on the day of injection in saline vehicle and administered subcutaneously. Water intake and urine volume were measured and urinary sodium excretion was determined by an ion sensitive electrode technique.

Alpha-2 adrenergic agonists with both central and peripheral actions (guanabenz, guanfacine) significantly ($p < 0.01$) increased sodium excretion in a dose related manner (1.5-3 fold above baseline) in LE rats but had no significant effect on sodium excretion in DI rats. In contrast, the peripherally acting alpha-2 adrenergic agonist, ST-91, significantly ($p < 0.001$) increased sodium excretion in both LE and DI rats, although at 1.0 mg/kg the increase in the LE rats (5.4 fold) was significantly ($p < 0.05$) greater than in DI rats (2.9 fold). The alpha-2 adrenergic agonists all increased urine output in both LE and DI rats, however the magnitude of the increase was greater in the LE rat. Water intake was stimulated in both LE and DI rats by 0.1 mg/kg of either guanfacine of guanabenz. ST-91 significantly ($p < 0.001$) decreased water intake in both LE and DI at the 1.0 mg/kg dose and guanabenz (1 mg/kg) reduced water intake in DI rats.

The results of this study suggest that in the absence of vasopressin, centrally acting alpha-2 adrenergic agonists have limited natriuretic action, although peripheral activation of alpha-2 adrenergic receptors is sufficient to elicit natriuresis irrespective of the presence of AVP. The diuretic response to alpha-2 adrenergic agonists is independent of AVP or direct CNS involvement, suggesting a direct renal action. This project was supported by a grant from the Division of Sponsored Research of the University of Florida.

205.16 Single Units From Fibers in Rabbit Carotid Sinus Nerve With Both Baro- and Chemoreceptor Characteristics. Long Qu and Sherry L. Stuesse, Neurobiology Department, N.E. Ohio Univ. College of Medicine, Rootstown, OH 44272

Fibers in cardiac depressor nerves have traditionally been classified as either baro- or chemoreceptive based on their firing patterns to pressure increases and/or chemical activation. We recorded single unit activity from the carotid sinus nerve in 16 urethane anesthetized, spontaneously breathing, rabbits with a bilateral cervical sympathectomy. The carotid sinus area was vascularly isolated and perfused with oxygenated Locke's solution. Of 48 single units recorded, 18 fibers gave a typical baroreceptive response with a mean firing threshold of 47.5 $\pm$ 3.1mmHg. 10 of the fibers were chemoreceptive since they increased their discharge frequency in response to 5 hydroxytryptamine (5HT) but failed to respond to intrasinus pressure (ISP) changes from 0 to 100mmHg ($P>0.5$). Twenty single fibers, with a discharge pattern similar to the chemoreceptive fibers, were active (22.0 $\pm$ 2.7 impulses/sec) when ISP was 0mmHg. 5HT increased their activity significantly ($P<0.01$) but unlike traditional chemoreceptive fibers, their unit discharge frequency increased from 22.0 $\pm$ 2.7 to 30.2 $\pm$ 2.8 impulses/sec ($P<0.001$) with the pulse of peristaltic ISP. Thus fibers with both baro- and chemoreceptive characteristics may exist in rabbit carotid sinus nerve. (Supported by grants from the Ohio Board of Regents).

205.17 COMPARATIVE EFFECTS OF ACTIVATION OF THE TRIGEMINAL GANGLION AND THE SUPERIOR SAGITTAL SINUS ON CEREBRAL BLOOD FLOW AND SPINAL EVOKED POTENTIALS IN THE CAT. P.J. Goadsby, G.A. Lambert*, A. Zagami* and J.W. Duckworth* Department of Neurology, The Prince Henry Hospital, and School of Medicine, University of New South Wales, Sydney, Australia.

The pain of migraine and other vascular headache involves regions innervated by the trigeminal and cervical sensory systems, and is usually accompanied by changes in cerebral blood flow (Lance, J.W. et al., Headache, 23:258,1983). The cranial vasculature and some parts of the dura are pain sensitive, innervated by the trigeminal nerve and may be involved in migraine. Stimulation of the trigeminal ganglion leads to increases in regional cerebral blood flow (RCBF) limited to the frontal and parietal cortex (Goadsby & Duckworth, Am. J. Physiol., 1987, in press). In these experiments we stimulated one of the pain sensitive structures innervated by the trigeminal nerve the sagittal sinus to measure changes in RCBF and cervical cord electrical activity. RCBF was measured in the d-chloralose anesthetised cat using the freely diffusible tracer [^{14}C]-iodoantipyrine and brain dissection. Multiple unit and field potentials were recorded from the cervical cord using standard electrophysiological techniques. Data were collected on-line with a microcomputer for processing of results. The sagittal sinus was exposed, isolated from the surrounding brain and stimulated at a rate of 10/s with 500us duration, 100v square wave pulses. RCBF was increased in restricted areas in stimulated animals, the effect was bilateral and involved the frontal and parietal cortices and thalamus. The increases were larger than those seen with trigeminal ganglion stimulation. Stimulation of the sagittal sinus produced either a single component slow wave response seen maximally caudal to the C2 root entry dorsolaterally or a complex fast wave response seen maximally in a ventromedial location 4mm further caudal from the slow wave response. Stimulation of the trigeminal ganglion produced similar responses topographically but ones that were quantitatively smaller. We conclude that craniovascular pain input can have powerful effects on central nervous system processing and that these effects strongly interact with other trigeminal sensory components.

205.18 INCREASES IN CEREBRAL CORTICAL PERFUSATE ADENOSINE AND INOSINE CONCENTRATIONS DURING HYPOXIA AND ISCHEMIA. M.H. O'Regan*, G.A. Walter*, R.E. Stair*, J.W. Phillis (SPON: R.R. Gala). Dept. of Physiol., Wayne State Univ. Sch. of Med., Detroit, MI 48201.

Changes in the partial pressure of oxygen in the brain evoke appropriate responses in the cerebral vasculature. Adenosine, a potent pial vessel dilator, has been proposed as a mediator of this metabolic regulation of cerebral blood flow. This study used the cerebral cortical cup technique to monitor changes in adenosine and its major metabolite, inosine, levels in the rat cerebral cortex during periods of hypoxia, anoxia, or hemorrhagic hypotension. Basal levels of adenosine and inosine in cortical perfusates of artificial CSF stabilized within 10 minutes at concentrations ranging from 30-50 nM and 75-130 nM respectively. These levels are significantly lower than published estimates using implanted dialysis fibers. Normal CSF, collected from the cisterna magna, gave values for adenosine and inosine comparable to our perfusate concentrations. In response to reductions in the oxygen content of inspired air (14%, 12%, 8%, 5% O_2) adenosine and inosine levels in the perfusates increased in a dose dependent manner (180%, 510%, 754%, and 1224% above control levels of adenosine respectively). Cerebral ischemia/anoxia, induced by 100% N_2 inhalation, resulted in a rapid increase in adenosine and inosine concentrations. However, no significant elevations in either adenosine or inosine levels were obtained upon hemorrhagic hypotension of a magnitude (46.1 ± 1.7 mmHg) greater than the hypotension that frequently accompanied hypoxia. Thus, in response to decreases in the pO_2, adenosine is released into the interstitial space of the cerebral cortex in concentrations capable of dilating vessels supplying the area. This supports the adenosine hypothesis of metabolic regulation of cerebral blood flow during hypoxia and ischemia, but the autoregulatory response to moderate hypotension, unaccompanied by hypoxia, does not appear to be mediated by adenosine.

205.19 HEMODYNAMIC RESPONSES TO INTRAVENOUS COCAINE ADMINISTRATION IN RATS. M.M. Knuepfer, D.M. Wehner* and A. Poklis*. Dept. of Pharmacology St. Louis University School of Medicine, St. Louis, MO 63104.

Cocaine is a potent CNS stimulant and local anesthetic that is widely abused for its euphorogenic effects. Cocaine is known to cause an increase in arterial pressure (AP) and in heart rate (HR). The hemodynamic effects of acute and chronic cocaine administration are unknown. These are particularly important since cocaine abuse is becoming more widespread and reports of related cardiovascular dysfunction are increasing. The present studies are designed to describe the hemodynamic effects of cocaine in unanesthetized (U) and Dial-urethane anesthetized (DUA) rats. Pentobarbital-anesthetized rats (N=6) were instrumented with arterial (carotid) and venous (jugular) cannula that were exteriorized at the nape of the neck. Miniaturized pulsed Doppler flow probes were placed around the superior mesenteric artery and on the abdominal aorta. These were connected to a socket mounted on the skull for measurement of hindquarter (HQ) and mesenteric (MES) vascular flow changes. Rats were treated with antibiotics and allowed to recover for two days. After acclimatization, rats were given cocaine (0.25-10 mg/kg, i.v.) and their responses were recorded on a chart recorder and on magnetic diskettes using a data acquisition system (PC Chart Recorder). Results were variable particularly at low doses but, in general, HQ vasodilation and MES vasoconstriction were observed at all dose levels. AP and HR were hardly affected at low doses (0.25-1 mg/kg) whereas increases were observed at higher doses. Behaviorally, increasing doses produced an increase in motor activity and apparent arousal. Administration of cocaine hourly produced progressively smaller changes in hemodynamic responses. A separate group of rats (N=10) were examined for responses under DUA to avoid vascular responses due to increased skeletal muscular activity. DUA rats were prepared as described above and allowed to stabilize for 30-60 minutes. Treatment with cocaine (5-10 mg/kg, i.v.) produced a prolonged fall in AP and HR accompanied by moderate HQ vasodilation. For example, 5 mg/kg cocaine caused the following effects in U (N=4) and DUA (N=6) rats 2 minutes after injection:

	AP	HR	HQ Resistance	MES Resistance
U	22%	45 b/m	-23%	136%
DUA	-5%	-25 b/m	-18%	11%

These results indicate that cocaine causes specific changes in regional vascular blood flows that contribute to its effect on AP. Tolerance to these effects develops rapidly. DUA prevents MES vasoconstrictor and behavioral responses but does not affect HQ vasodilation. The specific mechanisms for these changes and the effects of chronic cocaine administration will be determined.

(Supported by NIH grants HL37224 and HL38299 and by a grant from the American Heart Association, Missouri Affiliate.)

205PO CLONIDINE REDUCES THE AVP RESPONSE AND THE DOSE REQUIREMENT DURING NITROPRUSSIDE-INDUCED HYPOTENSION. L. QUINTIN, O. CALVILLO, M. GHIGNONE*. Anesthesiology, University of Pittsburgh, Pittsburgh, PA, 15261 and Neuropharmacology, School of Medicine Alexis Carrel, Lyon, France.

This study was designed to investigate the effect of moderate and severe hypotension (blood pressure BP=75 and 55 mmHg respectively) induced by sodium nitroprusside (SNP) on arginine vasopressin (AVP) and catecholamines (CA) response and on its modulation by clonidine.6 mongrel dogs were anesthetized with thiopentone and maintained with halothane in O_2 with controlled mandatory ventilation. Hemodynamic variables, plasma CA and AVP were measured as follows : baseline condition (BL1) ; during SNP infusion after 30 min of BP=75 mmHg (SNP1A) and BP=50 mmHg (SNP1B) ; 20 min after SNP1B (BL2) ; 20 min (CLO) and 90 min (BL3) after clonidine infusion 7µg.kg^{-1}iv ; during SNP (SNP2A and SNP2B) and 20 min post SNP2B (BL4). Similar reduction of BP and filling pressure were obtained with SNP, before and after clonidine. However clonidine induced a sustained reduction of 20% of HR and CO ($p<.01$) and of 50% of AVP levels at BL3. Furthermore it induced a significant reduction of AVP levels during SNP2A and 2B ($p<.01$) but not of plasma CA. The reduction of SNP requirement for a given hypotensive level were proportional to the suppression of AVP secretion ($p<.01$). Clonidine in this dose did not suppressed, peripherally, the activation of the sympathoadrenal and neuronal responses to hypotension in contrast to what was observed, centrally, in the caudal ventrolateral medulla (Quintin L., Soc Neuro Sci Abstract, 12 (2):1157, 1986). The significant reduction in AVP secretion after clonidine and the parallel reduction of SNP dose strongly indicates that AVP play a major role in the short term regulation of BP during hypotension. Clonidine increases the sensitivity to SNP by lowering AVP secretion. This may be secondary to an inhibitory effect on hypothalamic cells (Reid I.A., JPET 229:1, 1983). Clonidine may also interferes with the AVP dependent baroreceptor facilitation (Undesser K., Circ Res 58:882,, 1986).

206.1 UPREGULATION OF RENAL α_2 ADRENOCEPTORS IN NaCl LOADED SHR IS NOT RELATED TO RENAL NERVE ACTIVITY. W. Sripairojthikoon, S. Oparil, and J.M. Wyss. Department of Cell Biology and Anatomy, University of Alabama at Birmingham, Birmingham, AL 35294.

The density of renal α_2 adrenoceptors is increased in the spontaneously hypertensive rat of the Okamato strain (SHR) and the NaCl loaded Dahl NaCl-sensitive rat compared to their normotensive controls. It had been postulated that this increase is related to the sodium retention and the resulting hypertension displayed in both models. Further, renal nerve activity is relatively high in both models. In the present study, we tested the hypothesis that the increase in the number of renal α_2 adrenoceptors in the NaCl loaded SHR is the result of an interaction between dietary NaCl and renal nerve activity. Seven week old, NaCl-sensitive male SHR (Taconic Farms, IBU3 colony) were placed on diets containing 8% or 1% NaCl. One week later half the rats in each group received either a bilateral renal denervation or a sham operation; the operations were repeated at 11 weeks. Both NaCl loaded groups displayed significantly higher systolic blood pressure than their 1% NaCl fed controls, but renal denervation effected the same relative decrease in blood pressure in both the 8% and 1% NaCl fed rats.

		High Affinity (fmole/mg protein)	Low Affinity (fmole/mg protein)	Blood Pressure (mm Hg)
1% NaCl	Sham	20 ± 1	80 ± 4	201 ± 6
	Denervated	40 ± 2*	122 ± 7*	162 ± 5*
8% NaCl	Sham	32 ± 2 +	109 ± 6 +	236 ± 8 +
	Denervated	55 ± 6*+	151 ± 12*+	206 ± 10*+

*$p<.05$ compared to sham group; +$p<.05$ compared to 1% NaCl group

Analyses of renal α_2 adrenoceptors, using the agonist [^{3}H] para-aminoclonidine, revealed that both denervation and NaCl loading effected increases in α_2 adrenoceptor binding (both high and low affinity), but there was no interaction between the effects of renal denervation and NaCl loading. There were no significant between group differences in the agonist binding affinity (Kd) for either site. These data strongly suggest that in the NaCl-sensitive SHR, dietary NaCl loading and renal nerve activity have independent effects on renal α_2 adrenoceptor regulation.

206.2 DIFFERENCES IN BRAIN AMINES AND NEUROPEPTIDES IN INBRED HYPERTENSIVE AND HYPERACTIVE RAT STRAINS. V.R. Holets[1], T. Hökfelt[2]* and E.D. Hendley[3]. [1]Dept. of Neurological Surgery, Univ. of Miami, Miami, FL, 33136, [2]Dept. of Histology, Karolinska Institute, S-10401 Stockholm, Sweden and [3]Dept. of Physiology and Biophysics, Univ. of Vermont, Burlington, VT 05405

Two new rat strains have been developed to separate the hyperactivity trait from the hypertensive trait, as these currently co-exist in the SHR strain (Hendley et al., Hypertension 5:211, '83). From an original SHR X WKY cross, selected recombinant inbreeding resulted in the development of 2 new strains, WK-HT with hypertension but not hyperactive behavior, WK-HA with hyperactivity but not hypertension. These 2 strains, along with SHR and WKY rats, were analyzed for the immunohistochemical localization of peptides, monoamines and catecholamine synthetic enzymes.

Normal rats and rats which received an icv. injection of colchicine 36 hours earlier (n=8 for each group) were perfused transcardially. The brains (10 levels) and spinal cords (10 levels) were sectioned (14 µm sections). One brain or spinal cord segment from each of the four strains was sectioned together in one block to allow for direct comparison between the strains. Sections were processed for immunohistochemistry using antisera raised against neuropeptide Y (NPY), peptide YY, galanin (GAL), substance P, proctolin (PROC), neurotensin, methionine-enkephalin, thyrotropin releasing-hormone, phenylethanolamine N-methyltransferase (PNMT), tyrosine hydroxylase, dopamine ß-hydroxylase and 5-hydroxytryptamine The slides were analyzed by four observers, each blind to strain.

PROC-immunoreactive fibers in the medullary reticular formation were denser in the hypertensive strains (SHR and WK-HT) than in the normotensive WKY or WK-HA. The number of NPY- and PNMT-immunoreactive fibers was reduced in the intermediolateral cell column of the thoracic and lumbar spinal cord (T2, T6, T12, L2) in the hypertensive strains. The NPY- and GAL-immunoreactive fibers were less dense in the dorsal horn of the spinal cord at all levels investigated. No strain differences were observed at any level of the spinal cord or brain with the other antisera used.

The specific alterations in NPY, PNMT, PROC and GAL immunoreactivity were all associated with the genetic hypertension among these 4 strains. No differences were observed at the level of the cell bodies where these chemical messengers or enzymes are synthesized, but were observed at the level of the fiber terminals in the medulla and spinal cord. Supported in part by NIH Fellowship NS07287.

206.3 EFFECTS OF ADRENAL DEMEDULLATION ON CARDIOVASCULAR RESPONSES TO ACUTE STRESS IN RATS WITH STRESS-INDUCED HYPERTENSION. S. Knardahl*, B. Sanders, and A. K. Johnson. (SPON: I. Gormezano) Departments of Psychology and Pharmacology, and the Cardiovascular Center, The University of Iowa, Iowa City, IA 52242

Because chronic infusions of adrenaline have been shown to produce hypertension rats, it has been suggested that adrenaline is a mediator in stress-induced hypertension. In order to test the hypothesis that lowering adrenaline will attenuate stress-induced hypertension, the adrenal medulla, which is the main source of adrenaline, was removed (ADM-group). Sham-operated rats served as controls (C). All rats were offspring of a cross between spontaneously hypertensive rats and Wistar-Kyoto rats (borderline hypertensive rats), hence they had a genetic predisposition for hypertension. Prior to the chronic stress, the systolic pressures (measured with a tail-cuff method) were 150.8 mmHg in the ADM and 149.2 mmHg in the C-group. The chronic stress consisted of 60 2-hour sessions of a shock-shock conflict paradigm over an 18-week period. At the end of the chronic stress the rats were implanted with catheters in the femoral arteries and allowed two days to recover. The resting mean arterial pressure (MAP) was 141.2 mmHg in the ADM and 142.3 mmHg in the C (ns). Cardiovascular responses to an acute stressor were then examined. The rats were transferred to a test-box in which they were subjected to 1.0 mAmp pulsed footshocks (0.5 sec duration at 5 sec intervals for 5 min. The increase in MAP after transfer was 22.3 % in the ADM and 4.2% in the C ($p < .001$). Immediately after termination of the shocks, the MAP was increased 22.2% above baseline in the ADM and 8.1% in C ($p < .02$). Five min after footshocks, the increase in MAP was 21.6% in the ADM and 7.2% in C ($p < .02$). The adrenal demedullation increased the pressor response to acute stress. Because adrenal demedullation in all lilelihood reduced adrenaline release in response to stress, the beta-adrenoreceptor mediated vasodilation of skeletal muscle vasculature may have been attenuated, resulting in larger pressor responses to stress. If lowering the level of adrenaline has a beneficial effect it may have been offset by the attenuation of skeletal muscle vessle vasodilation.

Supported by NIH grant F05 TW03623 to S.K.

206.4 CHANGES IN NOREPINEPHRINE (NE) INDUCED ENHANCEMENT OF LATERAL HYPOTHALAMIC NEURONAL RESPONSIVENESS TO PUTATIVE NEUROTRANSMITTERS IN HIGH SALT DIET RATS. F.M. Sessler, J.T. Cheng, S.M. Grady* and B.D. Waterhouse. Dept. of Physiology and Biophysics, Hahnemann University, Philadelphia, PA 19102-1192.

The lateral hypothalamus (LH) has been implicated in the central integration of fluid and electrolyte balance and ingestive behaviors. The results of a number of studies have suggested the participation of NE in these functions and, in fact, changes in hypothalamic content of NE and numbers of alpha- and beta- adrenoceptors have been observed during disturbances of hydromineral balance. In previous studies, we presented evidence in support of a modulatory role for NE within the local circuitry of the LH, i.e. NE was capable of facilitating responses of LH neurons to synaptic inputs and putative transmitters. In the present experiments we examined interactions of NE with LH neuronal responses to amino acid transmitters in animals maintained on a high salt diet (HSD). Male rats were given 1% NaCl in their drinking water for 1-2 weeks. Control subjects received tap water. Extracellular activity of single. LH neurons was then recorded from anesthetized animals LH neuronal responses to iontophoretic pulses (5-50 nA; 10 sec. duration) of GABA or glutamate (Glu), were examined before, during and after NE microiontophoresis (5-50 nA). In control rats, inhibitory responses of LH cells to pulses of GABA were routinely potentiated above control levels during NE administration (31 of 46 neurons, 67%). On the other hand, Glu-evoked excitation was antagonized by NE iontophoresis in 66% (17 of 26) of LH neurons tested. In HSD rats the ability of NE to potentiate GABA-induced depressant responses was reduced such that GABA augmentation was observed in only 5 of 22 cases (23%). The effect of NE on Glu excitation was also modified in HSD rats: in 2 of 15 cases (13%), Glu-evoked responses were antagonized by NE whereas Glu excitation was enhanced relative to background firing in 60% (n=9) of LH neurons during NE application. In summary, these findings indicate that chronic HSD can alter the modulatory influences of NE on LH neuronal responsiveness to putative amino acid transmitters. Although many, as yet undetermined mechanisms including adrenoceptor changes are likely to be reponsible for these alterations in noradrenergic action, the present results provide evidence of a specific parameter of NE function that is altered in response to a perturbation of hydromineral balance. This plasticity of noradrenergic action may represent the physiologic expression of a mechanism whereby the LH circuitry can change its sensitivity to afferent synaptic signals as a means of compensating for changes in salt intake. (Supported by AFOSR-85-0155 and NS 18081 to B.D.W.)

206.5 GROWTH AND BEATING RATE OF EMBRYONIC SHR AND WKY HEART MATURING IN THE ANTERIOR EYE CHAMBER OF SHR AND WKY HOST RATS. D.C. Tucker and C.H. Gautier*, Dept. of Psychology, Univ. Alabama at Birmingham, Birmingham, AL 35294.

Culture of embryonic heart in the anterior eye chamber is a model system in which control of cardiac growth and beating rate by genetic and neurohumoral influences can be separated. Both increased heart size and tachycardia characterize weaning-aged Spontaneously Hypertensive Rat (SHR) pups. To examine genetic and neurohumoral controls of heart growth and beating rate in SHR rats, we cultured heart tissue from SHR and Wistar-Kyoto (WKY) embryos in the anterior eye chambers of adult SHR or WKY host rats. Differential influences of sympathetic innervation on SHR and WKY hearts developing in oculo were also studied.

A sample of hearts dissected from SHR and WKY fetuses at 13 days gestation did not differ significantly in weight (1.85 + 0.38 vs 1.07 + 0.08 mg). However, the body weight of WKY fetuses was greater than SHR (89.05 + 5.16 vs 59.65 + 3.19 mg), resulting in a significantly higher heart weight to body weight ratio in SHR compared to WKY fetuses (3.13 vs 1.25, $p<.01$). Atria and ventricles were separated at the AV junction and either atria (N=70) or ventricles (N=96) were implanted into anterior eye chambers of SHR or WKY host rats. Neither atria nor ventricles from SHR fetuses cultured in oculo showed greater growth than WKY tissue. Beating rate of transplants was measured from chronically implanted recording electrodes while host rats were awake and freely moving. Functional autonomic innervation was assessed by rate changes in response to changes in ambient light; intrinsic beating rate was estimated after pharmacologic blockade of beta-adrenergic and muscarinic receptors. The intrinsic beating rate of SHR and WKY atria cultured in oculo did not differ as a function of the host strain or the genetic source of the tissue ($p>.10$).

An additional study compared SHR or WKY atria implanted into sympathetically denervated and innervated eye chambers of SHR and WKY hosts (N=80). Sympathetically innervated implants were larger than noninnervated implants ($p<.05$). Neither final size nor intrinsic beating rate of SHR and WKY implants was differentially affected by sympathetic innervation. During weekly measurements from ether-anesthetized hosts, the baseline beating rate of SHR and WKY atria were similar in WKY hosts (226 + 25 vs 235 + 21 bpm). In anesthetized SHR hosts, SHR atria beat significantly faster than WKY tissue (205 + 20 vs 280 + 14; $p<.03$). These results argue against the hypothesis that cardiac hypertrophy and increased intrinsic beating rate are genetically programmed in the SHR rat. (Supported by American Heart Assoc, Ala. Affiliate and R23 HL37045.)

206.6 ENHANCED BINDING OF [3H]HEMICHOLINIUM-3 TO MEMBRANES PREPARED FROM SEVERAL BRAIN REGIONS OF SPONTANEOUSLY HYPERTENSIVE RATS. N.F. Makari*, R.S. Aronstam and J.J. Buccafusco (SPON: D.S. Feldman). Dept. Pharmacology and Toxicology, Medical College of Georgia and Veterans Administration Med. Ctr., Augusta, GA 30912.

Stimulation of cholinergic receptors in unanesthetized rats evokes a hypertensive response. This pressor response has been shown to be exaggerated in spontaneously hypertensive (SH) rats compared to age-matched, normotensive Wistar Kyoto (WK) rats. A biochemical basis for this hypercholinergic state is suggested by our recent demonstration of a marked increase in the capacity of the high affinity choline uptake system in brain synaptosomes derived from SH compared to WK rats (Neurochem. Res. 12:247, 1987). Hemicholinium-3 (HC-3) binds with high affinity to choline uptake sites on synaptosomal membranes, and in vitro [^{3}H]HC-3 binding provides an estimate of the number of these sites as well as an indirect measure of cholinergic activity. The purpose of this study was to compare the binding properties of [^{3}H]HC-3 in synaptosomes prepared from several brain areas of adult (16 week old) SH and WK rats. Systolic pressures (tail cuff) in three SH and WK rats averaged 200 and 125 mmHg, respectively. Brain regions were isolated after decapitation, and rapidly homogenized in cold 50mM Tris buffer. A crude synaptosomal fraction was obtained by centrifugation and the binding of [^{3}H]HC-3 (137 Ci/mmole) was examined using 100ug of membrane protein, an incubation time of 30min at room temperature, and various concentrations of unlabeled HC-3. The reaction was terminated by rapid filtration through glass fiber filters. Competition studies indicated multiple components of [^{3}H]HC-3 binding: 1) a high affinity component having a K_d of < 0.1uM and 2) a low affinity component having a K_d of 5-30 uM. Both components were observed in cortex and medulla. The relative concentrations of high and low affinity sites were determined using 2uM and 1mM unlabeled HC-3, respectively. [^{3}H]HC-3 binding was significantly higher in samples derived from medulla, pons, hypothalamus and midbrain of SH rats compared to WK animals. These differences ranged from about 1.5 to 3 fold and were greater for high affinity binding than for low affinity binding. In contrast, binding of [^{3}H]HC-3 to striatal membranes was not different in the two strains. These results are consistent with our earlier studies (cited above) of high affinity choline uptake, which demonstrated a highly significant correlation between increases in the Vmax for the high affinity uptake system and the development of hypertension in SH rats. This enhancement in choline uptake was observed in hypothalamic and medullary samples, but not striatal samples. These results are also consistent with a role for brain cholinergic neurons in the development and/or maintenance of hypertension. Supported by HL30046 & the Veterans Administration.

206.7 HYPERTENSION FOLLOWING SELECTIVE INHIBITION OF SPINAL ACETYLCHOLINESTERASE IN CONSCIOUS, FREELY-MOVING RATS. V. Magri* and J.J. Buccafusco. Dept. of Pharmacology and Toxicology, and Psychiatry, Medical College of Georgia and Veterans Administration Medical Center, Augusta, GA 30912.

Activation of brain cholinergic receptors in several animal models and in man results in a hypertensive response. Recent studies in this laboratory have indicated that similar responses could be obtained following intrathecal (i.t.) injection of cholinergic agonists in conscious rats. It is possible, however, that the hypertensive response might be due to redistribution of drug from the intrathecal CSF to higher brain structures. The purpose of this study was to determine whether local intraspinal cholinergic neurons mediated the cardiovascular response to i.t. cholinergic agonists. Male, normotensive Wistar rats were surgically implanted with a chronic indwelling i.t. catheter (the length of which was varied so as to terminate at cervical, thoracic or lumbar segments) and a chronic intra-arterial (aortic) catheter. After recovery from surgery rats were freely-moving in their home cages while arterial pressure and heart rate were recorded via the arterial line. I.t. injection of 5 ug of the cholinesterase inhibitor, neostigmine, resulted in a marked increase in mean arterial pressure (MAP) of up to 70 mmHg when the i.t. catheter was at the thoracic level. The pressor response began 2-3 min after injection, became maximal by 30 min and remained significantly higher than pre-injection levels between 1.5-2 hr after injection. Heart rate changes accompanied the pressor response; however, both increases and decreases were observed, often in the same animal. In some cases these changes reached up to 100 beats/min in either direction. The cardiovascular responses observed in animals in which the i.t. catheter was at either the cervical or lumbar regions were qualitatively similar to those for the thoracic level, but significantly reduced in magnitude and duration. Accompanying the cardiovascular response to neostigmine were a number of behavioral and motor changes characterized by tremor, chewing and grooming motions and head bobbing. Several rats which received 5ug of neostigmine at the thoracic level were killed 35 min later and the medulla and spinal cord removed for measurement of cholinesterase activity. No significant enzyme activity was recorded for cervical, thoracic or lumbar spinal segments, however, medullary enzyme activity was near normal. The effects of neostigmine, therefore, are mediated at spinal, not higher brain levels. These results indicate that cholinergic neurons at the thoracic spinal level mediate a hypertensive response. The possibility of an ascending system should be considered in view of the marked behavioral changes observed which accompany the cardiovascular response. Supptd. 206.8 ENHANCED PRESSOR RESPONSE TO ACUTE STRESS IN SPONTANEOUSLY HYPERTENSIVE RATS ON A HIGH NaCl DIET. R.M. Thornton*, D.C. Tucker+ and S. Oparil. Hypertension Research Program, Division of Cardiovascular Diseases, Department of Medicine and Department of Psychology+, Univ. of Alabama at Birmingham, AL 35294.

The purpose of this study was to test the hypothesis that spontaneously hypertensive rats (SHR) fed a high NaCl diet manifest enhanced pressor responsiveness to acute environmental stress compared to SHR maintained on a normal NaCl diet. Seven week old male SHR (Taconic Farms) were placed on an 8% NaCl diet (n=20) or a 1% NaCl diet (n=20) for 3 weeks. A catheter was inserted in the femoral artery for measurement of arterial blood pressure and sampling of blood for plasma norepinephrine (NE) and epinephrine (EPI) as indices of sympathoadrenal activity. Two days later, mean arterial pressure (MAP) was recorded for 30 min at room temperature, following which blood was drawn from 6 rats on each diet for measurement of control levels of catecholamines. The remaining animals were placed in 4°C temperature and MAP recorded. Blood was drawn from 7 animals on each diet at 45 and 90 min of cold exposure. In a separate group of animals, multifiber lumbar sympathetic nerve activity (LSNA) was recorded during cold stress in conscious, free moving animals. Prior to cold stress, MAP (163±3mmHg for 1% vs. 159±4mmHg for 8%) was similar in the 1% and 8% groups. MAP increased within 15 min of cold exposure by 27 mmHg in the 8% NaCl group and 14 mmHg in the 1% NaCl group. This elevation in MAP was maintained throughout cold stress in both groups. The maximal increase in MAP and the level at which MAP stabilized in the 8% group were significantly higher than in the 1% group. NE and EPI levels were similar for the two groups at control (NE: 298±43 pg/ml for 1% vs. 255±44 pg/ml for 8%; EPI: 78±31 pg/ml for 1% vs. 61±15 pg/ml for 8%) and increased similarly in both groups at 45 min and at 90 min of cold exposure. LSNA increased within 15 min of cold stress by 296% in the 1% group and 265% in the 8% group and remained elevated at a similar level for both groups throughout cold exposure.

These data support the hypothesis that SHR fed a high NaCl diet manifest increased pressor responsiveness to acute cold stress compared to SHR maintained on a normal NaCl diet. The similar cold induced increment in plasma catecholamines and LSNA in 1% and 8% NaCl groups suggests that the enhanced pressor response in SHR on a high NaCl diet does not result from an exaggerated increase in sympathoadrenal activity. Other mechanisms, such as enhanced responsiveness to a given level of catecholamines at the vascular receptor, or selective enhancement of other pressor systems, e.g. ACTH or AVP, must be invoked to explain the phenomenon.

206.9 NORADRENERGIC INPUT TO ANTERIOR HYPOTHALAMUS OF Dahl-SALT SENSITIVE RATS IS NOT ALTERED FOLLOWING HIGH NaCl INTAKE. Y.F. Chen, Q. Meng*, H. Jin*, J.M. Wyss, S. Oparil. Hypertension Research Program, University of Alabama at Birmingham, Birmingham, AL 35294.

Our previous studies demonstrated that chronic NaCl loading in NaCl-sensitive spontaneously hypertensive rats of the Okamoto strain (SHR-S, Taconic Farms, IBU3 colony) reduced noradrenergic (NA) input to the anterior hypothalamic area (AHA), increased peripheral sympathetic nervous system activity and exacerbated hypertension. The current study tests the hypothesis that reduced NA input to sympathoinhibitory neurons in AHA contributes to NaCl-induced hypertension in a second NaCl sensitive model, the Dahl-S rat. Male Dahl-S rats (4 wks old; Brookhaven National Laboratory) were maintained on a diet containing either 8% (n=20) or 1% (n=20) NaCl for 4 weeks, after which NA stores, synthesis and release was measured in AHA and other brain regions involved in cardiovascular control, including posterior hypothalamic area (PHA), pons and medulla (MED). NA content in each area was measured at time 0 (t_0), and 60 and 120 min after administration of CHMI (50mg/kg, i.p.), a DBH inhibitor. Rats were sacrificed by decapitation without anesthesia, brains were removed rapidly and dissected on ice. Regional NA concentrations were determined by HPLC/EC. NA turnover rate was determined by calculating disappearance rates from tissue following CHMI administration. Results (mean ±SEM) are:

8% NaCl diet			1% NaCl diet		
BP(mmHg)	HR(bpm)	BW(g)	BP(mmHg)	HR(bpm)	BW(g)
171±6Δ	432±11	243±4	138±2	424±9	229±4

	t_0 NA Content (pg/mg)	Turnover Rate (pg/mg/hr)	$t_{1/2}$ (hr)	t_0 NA Content (pg/mg)	Turnover Rate (pg/mg/hr)	$t_{1/2}$ (hr)
AHA	2323±228	715.4	2.25	2356±253	954.3	1.71
PHA	1532±63	407.2	2.61	1605±61	582.4	1.91
PONS	626±17	154.8	2.81	632±14	203.1	2.16
MED	621±22	182.6	2.35	647±56	210.0	2.13

Δp<0.05 compared to 1% NaCl group.

There were no between group differences in NA turnover rates in any brain region studied. These results indicate that NA alterations in NA input to the AHA do not contribute to NaCl induced hypertension in Dahl-S rats, suggesting that the neural mechanisms of dietary NaCl sensitivity are different in Dahl-S and SHR-S models of hypertension.

206.10 PROTEIN CHOICE IN SPONTANEOUSLY HYPERTENSIVE RATS (SHR) DURING THE DEVELOPMENT OF HYPERTENSION. J.M.B. Pinto and T.J. Maher. Department of Pharmacology, Massachusetts College of Pharmacy, Boston, MA., 02115.

Studies in normotensive animals indicate that with age there is a preference for an increased protein/carbohydrate (CHO) ratio. The ingestion of protein increases brain tyrosine levels in the rat, and under certain conditions, i.e., in the SHR, this can lead to enhanced CNS catecholamine synthesis. In the SHR, increments in CNS catecholamines have been shown to lower blood pressure (BP). Our studies were designed to determine whether a preference for dietary protein exists in the SHR during the development of hypertension. Male SHRs and normotensive Wistar-Kyoto rats (WKY) were obtained at 4 weeks of age and maintained on a 20% high quality protein (casein) - 60% CHO diet for 13 weeks, until hypertension, as determined by tail-cuff measurement, was fully established in the SHR. Food choice, at the beginning of the dark cycle, between isocarbohydrate (60%) diets containing 0% or 40% protein was determined at 5-6 day intervals during the 13-week period and each animals choice recorded at various times throughout the day. Results indicated that at 1 hr and 24 hrs a significant difference in preference ($p<0.01$) for SHR compared to WKY during weeks 6-11, when BP increased by 70 mmHg in SHR compared to 40 mmHg in WKY. SHR had a higher protein/CHO ratio choice (range over the 6 weeks of 0.26-0.55, mean ± S.E. 0.37 ± .04 at 1 hr, and 0.30-0.54, 0.42 ± .08 for 24 hr) when compared to WKY (range of 0.16-0.45, mean = 0.27 ± .10 at 1 hr and 0.13-0.40, mean = 0.31 ± .04 at 24 hr). The preference ratio was not significantly different between groups during weeks 1-5, when BP of SHR and WKY did not differ significantly, or after 11 weeks when the rapid increase in BP in SHR was absent. Although there was no significant difference in weight gain between groups during the study. SHR ate more food than WKY (28.2±2.3 g vs 21.7± 1.6 g for SHR and WKY, respectively).

These results suggest the possibility that the increased protein selection by SHR during the phase of rapid development of hypertension may be the result of a requirement for amino acid precursors of neurotransmitters which have been shown to play a significant role in the regulation of BP in this genetically hypertensive model.

206.11 THE BORDERLINE HYPERTENSIVE RAT: RECIPROCAL F1 HYBRIDS COMPARED. C.H. Woodworth, S. Knardahl*, B.J. Sanders, R.F. Kirby, and A.K. Johnson. Departments of Psychology and Pharmacology, and The Cardiovascular Center, University of Iowa, Iowa City, IA 52242.

The borderline hypertensive rat (BHR) is the non-segregating F1 generation produced by crossing the spontaneously hypertensive rat (SHR) with its normotensive progenitor strain, the Wistar-Kyoto (WKY). This mating can result in two genetic variations, depending on which strain is selected to sire the offspring: (SHR♀ X WKY♂)F1 and (WKY♀ X SHR♂)F1. Although no systematic comparison of these reciprocal F1 crosses has been made, there is evidence to suggest that parental effects need to be considered when interpreting results from experiments that use SHR X WKY derivatives. The purpose of our study was to compare reciprocal F1 hybrids with respect to open-field behavior, to resting blood pressure (MAP, mmHg) and heart rate (HR, bpm), and to change in MAP and HR elicited by transfer to a novel chamber. Beginning at 112-120 days of age, 10 (SHR♀ X WKY♂)F1 and 12 (WKY♀ X SHR♂)F1 male offspring from independent litters were tested daily for three days in a dimly-lighted open field. Behaviors recorded in each 15-min session included number of squares entered with all four paws, number of rearings, and number of fecal boli. A week later, animals were anesthetized (ketamine, 0.11 mg/100 g body weight, IP) and catheters implanted in the left femoral artery. Following a 48-hr recovery period, MAP and HR were measured under basal home-cage conditions and immediately after transfer to a novel chamber. Statistical analyses (repeated-measures MANOVA) showed no difference between the reciprocal F1 hybrids in open-field behavior or in cardiovascular measures taken in the home cage or following transfer. Open-field activity showed significant changes over days and over blocks of time within days, although larger blocks were required to detect changes in squares entered than in rearings. These data show that reciprocal F1 hybrids have similar open-field behavior and cardiovascular measurements at 16-17 weeks of age, but do not permit rejection of the hypothesis that parental effects may be manifested at other stages of development or in response to chronic stress. To provide more detailed information on the behavior of BHR in general, intercorrelations were determined between open-field measures for the combined F1 hybrids. Factor analysis of this correlation matrix revealed two factors that load high for activity in the early minutes (Factor 1) or later minutes (Factor 2) of the test sessions, respectively. When these factors were correlated with the cardiovascular measures, a relationship was suggested between Factor 1 (early open-field activity) and change in MAP after transfer to the novel chamber ($r=-.45$, $p<.07$).

206.12 A DOUBLE DOSE (150 mg SUSTAINED RELEASE) OF PHENYLPROPANOLAMINE (PPA) CAUSES HYPERTENSION. C.R. Lake, R.E. Clymer*, G. Zaloga*, S.M. Hedges* and B. Chernow*. Dept. of Psychiatry, Uniformed Services Univ. of the Health Sciences, Bethesda, MD 20814.

PPA is a primary ingredient in over 130 medications, including anorectic agents and cough and cold remedies. Over half of these (75) are available without a doctor's prescription or "over the counter" in many drug and grocery stores. Twelve of the 13 diet aids containing PPA on the market are available without prescription. Several billion doses are consumed annually; PPA may be among the top five most frequently used drugs in the United States. Although, to our knowledge, there are no data to suggest the frequency of ingestion of more than the recommended 75 mg, we suspect "double-dosing" occurs often. Whether the recommended dose (75 mg, sustained release) can cause a clinically significant increase in blood pressure (BP), even in some subjects, remains controversial.

In a preliminary study, on 3 separate days, we administered 75 mg PPA, 150 mg PPA and 75 mg PPA plus 400 mg caffeine (all sustained release) to six healthy consenting volunteers, 5 males and 1 female with a mean age of 24 years. We measured supine BP and heart rate (HR) twice before and at 15 minute (min) intervals for 5 hours after single blind,crossover administration of each of the 3 drugs. Once before and at 150 min after drug ingestion, BP and HR also were recorded after a 5 min stand. We observed striking supine BP increases after 150 mg PPA. During the period from 30 to 240 min after drug ingestion, systolic BP (SBP) averaged hypertensive levels of 147 mm Hg after 150 mg PPA versus 125 and 129 for 75 mg PPA and 75 mg PPA plus 400 mg caffeine, respectively ($f=18.95$, $df=2,10$, $p<0.001$). During a broad peak which lasted from 90 to 180 min after drug administration, this difference was even more pronounced: 155 mm Hg versus 125 mm Hg and 132 mm Hg. Increases also were observed in diastolic BP (DBP). Between 30 and 240 min, DBP averaged 81 mm Hg after 150 mg PPA versus 70 after 75 mg PPA and 76 after PPA plus caffeine. This difference was significant with $f=14.2$, $df=2,10$, $p<0.01$. Also interesting were the results of the 5 min stand. Before drug ingestion, the average SBP drop from supine to 5 min of standing was 6 mm Hg (n=18). However, 150 min later, SBP dropped 25 mm Hg after 150 mg PPA, 1 mm Hg with 75 mg PPA and 25 mm Hg with PPA + caffeine. HR was not significantly different across drugs during the 30 to 240 min time frame.
